Many allergens are associated with contact dermatitis (Table 17-2). Among the most common plant-derived sensitizers are urushiol (*Toxicodendron* species), sesquiterpene lactone (ragweed), and tuliposide A (tulip bulbs). Metals, particularly nickel, are commonly implicated in contact dermatitis and should be considered in patients with erythematous, vesicular, or scaly patches or plaques around the umbilicus from nickel buttons on pants, and on the ear lobes from earrings. Several industrial chemicals, such as the thiurams (rubber) and urea formaldehyde resins (plastics), account for the majority of occupational contact dermatitis. Medications, particularly topical

**FIGURE 17-13.** Skin necrosis in a patient after 4 days of warfarin therapy. (Reproduced with permission from Wolff K, Goldsmith LA, Katz SI, et al. *Fitzpatrick's Dermatology in General Medicine, 7th ed.* New York, NY: McGraw-Hill; 2008.)

**FIGURE 17-14.** Contact dermatitis. (1) Causative xenobiotic, typically a hapten of <500 Da, diffuses through stratum corneum and binds to receptor on Langerhans cell (LC). (2) The antigen is processed with major histocompatibility complex II (MHC II) receptor site, presented to T-helper lymphocytes, and carried through the lymphatics to regional lymph nodes. (3) There it undergoes the sensitization phase by producing memory, effector, and suppressor T-lymphocytes. (4) On reexposure to the same, or to a cross-reactive antigen, the LC presents the antigen to T-lymphocytes (--->), which are now sensitized. This initiates an inflammatory process that appears as indurated, scaly patches.

medications such as neomycin, commonly cause contact dermatitis. Another important allergen is paraphenylenediamine, a black dye in permanent and semipermanent hair coloring, leather, fur, textiles, industrial rubber products, and black henna tattoos. According to the North American Contact Dermatitis Group, the frequency of sensitization has been found to be 5%.<sup>69</sup> The management of contact dermatitis varies based on the severity of the reaction, ranging from treatment with topical steroids to oral cyclosporine (Table 17-4). A thorough history in addition to patch testing (the gold standard) will often identify the culprit.

Irritant dermatitis, although clinically indistinguishable from allergic contact dermatitis, results from direct damage to the skin and does not require prior antigen sensitization. Still, the inflammatory response to the initial mild insult is the cause of the majority of the damage. Xenobiotics that cause an irritant dermatitis include acids, bases, solvents, and detergents, many of which, in their concentrated form or after prolonged exposure, can cause direct cellular injury. The specific site of damage varies with the chemical nature of the xenobiotic. Many xenobiotics affect the lipid membrane of the keratinocyte, whereas others diffuse through the membrane, injuring the lysosomes, mitochondria, or nuclear components. When the cell membrane is injured, phospholipases are activated and affect the release of arachidonic acid and the synthesis of eicosanoids. The second-messenger system is then activated, leading to the expression of genes and the synthesis of various cell surface molecules and cytokines. Interleukin-1 is secreted, which can activate T cells directly and indirectly by stimulation of granulocyte-macrophage

colony-stimulating factor production. The treatment is similar to allergic contact dermatitis (Table 17-4).

### Photosensitivity Reactions

Photosensitivity is caused by topical or systemic xenobiotics. Nonionizing radiation, particularly to ultraviolet A (UVA) (320–400 nm) and less often to ultraviolet B (UVB) (280–320 nm), are the wavelengths that commonly cause photosensitivity. There are generally 2 types of xenobiotic-related photosensitivity: phototoxic and photoallergic.<sup>41</sup> Phototoxic reactions occur within 24 hours of the first exposure, usually within hours, and are dose-related. These reactions result from direct tissue injury caused by ultraviolet-induced activation of a phototoxic xenobiotic. The clinical findings include erythema, edema, and vesicles in a light-exposed distribution, and resemble a severe sunburn that lasts days to weeks, with patients complaining of burning and stinging (Fig. 17-15). A subtype of phototoxic reaction is phytophotodermatitis, in which linear streaks of erythema occur due to skin contact with furocoumarins from plants followed by exposure to sunlight (Table 17-2). Photoallergic reactions occur less commonly, occur following even small exposures, and resemble allergic contact dermatitis with lichenoid papules or an eczematous dermatitis on exposed areas and is often pruritic. These are type IV hypersensitivity reactions that develop in response to a xenobiotic that has been altered by absorption of nonionizing radiation, acting as a hapten and eliciting an immune response on first exposure. Only on recurrent exposure do the lesions develop. Studies indicate that benzophenone-3 (oxybenzone), often found in sunscreen, is the most common cause of photoallergic dermatitis.<sup>8,16</sup> Other common photoallergens include xenobiotics such as promethazine, NSAIDs, fragrances, and antibiotics. Photoallergic reactions can be diagnosed by the use of photopatch tests. Both phototoxic and photoallergic reactions are managed with symptomatic treatment, including topical or, if needed, systemic corticosteroids. Identification and avoidance of the triggering xenobiotic are crucial in addition to avoidance of sun exposure and wearing a broad-spectrum sunscreen (SPF 30 or above) that blocks both UVA and UVB preferably without para-aminobenzoic acid (PABA) and oxybenzone. Para-amino benzoic acid is a sensitizer for many patients and is rarely included in current sunscreen products.

**TABLE 17-4** Overview of Treatment of Acute Contact Dermatitis

Identification of contactant and future avoidance (consider patch testing to identify culprit)
Emollients for lichenified lesions
Topical or oral corticosteroids to treat dermatitis (may take 6 weeks of treatment)
Topical calcineurin inhibitors (tacrolimus or pimecrolimus)
Cyclosporine (oral)
Phototherapy: narrow-band UVB

### Scleroderma-Like Reactions

A number of environmental xenobiotics are associated with localized or diffuse scleroderma-like reactions. Scleroderma refers to a tightened indurated surface change of the skin that typically occurs on the face, hands, forearms, and trunk and is 3 times more common in women. This can be accompanied by facial telangiectasias and Raynaud syndrome. Raynaud syndrome consists of skin color changes of white, blue, and red accompanied by intense pain with exposure to cold, and can cause acral ulcerations, if untreated. The fibrotic process usually does not remit with removal of the external stimulus, and specific autoantibodies are absent. The association of scleroderma-like reactions with polyvinyl chloride manufacture is likely related to exposure to vinyl chloride monomers. Similar reports of this syndrome are associated with exposure to trichloroethylene and perchlorethylene, which are structurally similar to vinyl chloride. Epoxy resins, silica, and organic solvents are implicated as environmental causes. Bleomycin, carbidopa, pentazocine, and taxanes are also causative.

In Spain, patients exposed to imported rapeseed oil mixed with an aniline additive and colorant developed widespread cutaneous sclerosis. This became known as the “toxic oil syndrome.” A similar syndrome following ingestion of contaminated L-tryptophan as a dietary supplement used as a sleeping aid resulted in the eosinophilia myalgia syndrome, which is characterized by myalgia, edema, arthralgias, alopecia, urticaria, mucinous yellow papules, and erythematous plaques.<sup>56</sup>

### HAIR LOSS

Xenobiotics have the potential to cause distinctive patterns of hair loss (Table 17-2). Anagen effluvium, or hair loss during the anagen stage of the growth cycle, is caused by interruption of the rapidly dividing cells of the hair matrix, producing rapid hair loss within 2 to 4 weeks. Telogen

effluvium, or toxicity during the resting stage of the cycle, typically produces hair loss 2 to 4 months later and occurs as a side effect of a xenobiotic or in the setting of systemic disease or altered physiologic states (eg, postpartum). Anagen toxicity is commonly associated with xenobiotic exposures such as doxorubicin, cyclophosphamide, vincristine, and thallium.<sup>58</sup> Many chemotherapeutics reduce the mitotic activity of the rapidly dividing hair matrix cells, leading to the formation of a thin, easily breakable shaft. Thallium, classically associated with hair loss, causes alopecia by 2 mechanisms. Thallium distributes intracellularly, like potassium, altering potassium-mediated processes and thereby disrupting protein synthesis. By binding sulfhydryl groups, thallium also inhibits the normal incorporation of cysteine into keratin. Thallium toxicity results in alopecia 1 to 4 weeks after exposure. Within 4 days of exposure, a hair mount observed using light microscopy will demonstrate tapered or bayonet anagen hair with a characteristic bandlike black pigmentation at the base. Seeing this anagen effect can reveal the timing of exposure. Soluble barium salts, such as barium sulfide, are applied topically as a depilatory to produce localized hair loss. The mechanism of hair loss is undefined.

### NAILS

The nail consists of a horny layer: the “nail plate” and 4 specialized epithelia—proximal nail fold, nail matrix, nail bed, and hyponychium. The nail matrix consists of keratinocytes, melanocytes, Langerhans cells, and Merkel cells.

Nail hyperpigmentation occurs for unclear reasons, but can be caused by focal stimulation of melanocytes in the nail matrix leading to melanonychia. The pigment deposition can be longitudinal, diffuse, or perilunar in orientation and typically develops several weeks after chemotherapy.<sup>58</sup> Dark-skinned patients are more commonly affected because of a higher concentration of melanocytes. Cyclophosphamide, doxorubicin, hydroxyurea, zidovudine, and bleomycin are among the most common xenobiotics that cause melanonychia, and the pigmentation generally resolves with cessation of therapy. When approaching a patient with a single streak of longitudinal melanonychia, it is crucial to include nail melanoma in the differential diagnosis, particularly if the band is greater than 3 mm in breadth and/or evolving.

Nail findings serve as important clues to xenobiotic exposures that occurred in the recent past. Matrix keratinization in a programmed and scheduled pattern leads to the formation of the nail plate. Certain changes

**FIGURE 17-16.** Presence of proximal indented Beau line and distal band of leukonychia due to cyclophosphamide 3 months after bone marrow transplantation. (Reproduced with permission from Wolff K, Goldsmith LA, Katz SI, et al. *Fitzpatrick's Dermatology in General Medicine*, 7th ed. New York, NY: McGraw-Hill; 2008.)

in nails, such as Mees lines and Beau lines, result from a temporary arrest of the proximal nail matrix proliferation. These lines can be used to predict the timing of a toxic exposure because of the reliability of rate of growth of the fingernails at approximately 2 to 3 mm per month. Mees lines, first described in 1919 in the setting of arsenic poisoning, can be used to approximate the date of the insult by the position of growth of the Mees line a patterned leukonychia (not indentation) causing transverse white lines.<sup>36</sup> Multiple Mees lines suggests multiple exposures over time. Arsenic, thallium, doxorubicin, vincristine, cyclophosphamide, methotrexate, and 5-fluorouracil cause Mees lines, but Mees lines can develop after any period of critical illness such as sepsis or trauma. Beau lines are transverse grooves or indentations more often in the central portion of the nail plate, most commonly caused by trauma (eg, manicures) or dermatologic disease affecting the proximal nail fold. Beau lines present on multiple digits, especially at the same level on each nail, indicate a systemic illness or xenobiotic exposure (Fig. 17–16).

## SUMMARY

- The integument is constantly exposed to both topical and systemic xenobiotics, and these exposures result in reactive dermatoses.
- Prompt examination of the entire skin, hair, and nails provide invaluable clues about the route and nature of the offending xenobiotic.
- A careful history, clinical examination, and consultation with a dermatologist and biopsy when indicated can aid in identifying the etiology and nature of the reaction and lead to prompt treatment.
- Medication or drug reactions range from ordinary exanthematous reactions to potentially life-threatening drug-induced hypersensitivity reactions and SJS/TEN; these entities can be distinguished with a careful history, physical examination, and precise drug-exposure timeline.

## TRANSDERMAL TOXICOLOGY

Lewis S. Nelson

**HISTORY AND CURRENT USE**

Applying a xenobiotic to the skin to treat a systemic medical condition is not new. Ointments and other salves have been applied topically for thousands of years for the treatment of local and systemic diseases. During World War I, dynamite workers used nitroglycerin applied to their hatbands to prevent angina when they were away from work and no longer exposed to organic nitrates.<sup>36</sup> Mustard seed plaster for chest congestion, releasing allyl isothiocyanate, and topical elemental mercurials for syphilis are other examples of such use in the beginning of the 20th century.<sup>28</sup> Over the past 30 years, an increasing number of medications have been formulated in transdermal delivery systems, or patches, to allow for systemic delivery of a xenobiotic. The first commercially available patch delivered scopolamine for motion sickness (1979), which was followed by nitroglycerin for chronic angina (1981) and then fentanyl for chronic pain management (1990). In the United States, the nicotine patch remains the most widely used transdermal patch, because of both the significant need for smoking cessation and its nonprescription availability. Certain medicinal xenobiotics, such as testosterone, can be administered without a patch, as a spray or gel.<sup>22</sup> Further, xenobiotics are absorbed transdermally, as occurs with nicotine following direct exposure to moist tobacco leaf in patients with “green tobacco sickness” or following direct contact with organic phosphorus compound spraying.<sup>3</sup>

The skin is the largest organ in the body, although it is not widely used as a route for intentional xenobiotic delivery. However, there are several benefits of transdermal delivery of xenobiotics. This route provides a non-invasive means to discretely administer xenobiotics. Patches result in steady plasma concentrations that reduce side effects, particularly for xenobiotics with short half-lives. Although metabolism occurs in the skin, metabolism does not appear to be highly consequential for the majority of currently used transdermal xenobiotics.<sup>18</sup> The patches are designed to be left in place for long periods of time, which improves compliance. Importantly, the avoidance of first-pass metabolism permits an effective means of delivery for poorly orally bioavailable xenobiotics. However, because absorption through the skin following simple application is passive, there is a large degree of variability among both patients and xenobiotics. Newer nanocarriers and minimally invasive technologies, as discussed below, attempt to overcome this limitation.<sup>11,16</sup>

This chapter does not cover xenobiotics applied to the skin to produce an effect locally. These xenobiotics are available in patch formulation (eg, lidocaine and capsaicin) or as a directly applied preparation, such as a variety of antibiotics or acne creams (eg, tretinoin). Locally acting formulations (eg, lidocaine) typically provide only trivial amounts of systemic xenobiotic;<sup>6</sup> for example, with tretinoin, despite devastating fetal complications when taken orally, these same effects do not occur when applied topically.<sup>20</sup> Some xenobiotics, such as capsaicin, have both local (for postherpetic neuralgia) and systemic (for cannabinoid hyperemesis syndrome) effects.<sup>7,31</sup>

**TRANSDERMAL ADMINISTRATION PHARMACOLOGY****Passive Administration**

The same hydrophobic property that allows the skin to prevent water loss hinders the ability to administer a water-soluble xenobiotic transdermally. In order to reach the systemic circulation, a xenobiotic applied to the stratum corneum (horny layer) (Fig. 17-1) must initially pass through about a dozen layers of keratinized epidermal cells and then into the dermis. This

keratinaceous horny layer is highly impervious to water movement because of the presence of ceramides, fatty acids, and other lipids.<sup>5</sup> This property maintains the ability of the skin to lose excess water in dry environments. Burn victims lose the capacity to regulate water loss through injury to the keratinaceous layer. In order for a xenobiotic to partition into the stratum corneum, it must be sufficiently lipid soluble. However, this same xenobiotic must subsequently partition out from the stratum corneum into the aqueous underlying tissue, and this requires sufficient hydrophilicity.<sup>25</sup> The ability to partition into these various phases (lipid and water) is described by the octanol–water partition coefficient. These vary widely among xenobiotics. For example, this coefficient for fentanyl (717) and nicotine (15) suggests sufficient ability to cross the stratum corneum, whereas morphine (0.7) cannot pass through this outer layer.

Fick's first law describes xenobiotic permeation across the stratum corneum. In this model, steady-state flux ( $J$ ) is related to the diffusion coefficient ( $D$ ) of the xenobiotic based on the thickness of the stratum corneum ( $h$ ), the partition coefficient ( $P$ ) between the stratum corneum and the xenobiotic in its vehicle, and the xenobiotic concentration ( $C$ ) that is applied, which is assumed to be constant. This equation demonstrates the influence of solubility and partition coefficient of a xenobiotic on diffusion across the stratum corneum (Equation 9-1). Molecules showing intermediate partition coefficients have adequate solubility within the lipid domains of the stratum corneum to permit diffusion through this domain while still having sufficient hydrophilic nature to allow partitioning into the lower layers (stratum granulosum, stratum spinosum, and the stratum germinativum) of the epidermis.

Permeation enhancers improve absorption by solubilizing the xenobiotic or altering the characteristics of the stratum corneum, effectively increasing the lipid solubility of the xenobiotic.<sup>19,32</sup> Enhancers include solvents such as ethanol, fatty acids, fatty esters, and surfactants that serve as vehicles to improve the solubility of a xenobiotic in the lipids of the stratum corneum layer.<sup>19</sup> An alternative means of enhancing lipophilicity is the addition of organic functional groups to create a prodrug that is cleaved once absorbed.<sup>29</sup> This is similar to the significantly enhanced neurotoxicity of dimethylmercury compared to methylmercury when applied to the skin.<sup>24</sup> Additionally, the use of nanoparticles enhances xenobiotic solubility and surface contact area.<sup>33</sup>

Few xenobiotics have the essential molecular requirements to be systemically delivered by the transdermal route. The upper limit of the molecular weight of an acceptable drug is 500 Da (fentanyl is 337 Da), and the medication must be sufficiently potent to exert the desired effect at concentrations that can reliably be obtained. Although only small quantities, typically less than 2 mg daily are delivered, the largest nicotine patch delivers 21 mg daily.

As suggested by Fick's law, the ability to cross the dermis is related to the concentration gradient provided by the transdermal patch. To allow sufficient delivery, a large amount of xenobiotic is contained in the apparatus to maintain the concentration gradient over time. For example, the 50-mcg/hr fentanyl patch (which delivers 1.2 mg daily) contains 8.4 mg (8,400 mcg) of fentanyl in the patch.<sup>13,36</sup> This excess amount of drug minimizes the fluctuations in delivery over time as the concentration gradient naturally falls during movement of xenobiotic from the patch to the skin. Upon completion of the 3-day use of a fentanyl patch, the amount of fentanyl remaining in a patch ranged from 28% to 85%; at the end of use, 27% to 74% of the contents of a nicotine patch remained.<sup>21,28</sup> Furthermore, in order to prevent rapid

movement into the skin, and also maintain a functional concentration gradient, a rate-controlling membrane is present that allows the passage of a measured amount of drug per area of skin contact surface.

Applying xenobiotic to broken skin or tissue lacking a stratum corneum, such as mucosa, results in a substantial increase in absorption, which is greater than 5- or greater than 30-fold, respectively, for fentanyl.<sup>12,22</sup> For example, application of salicylic acid for a treatment of hyperkeratinization disorders causes salicylate poisoning.<sup>1,32</sup> Because the pharmacokinetics of transmucosal delivery tend to be more predictable than by the transdermal route, certain formulations such as fentanyl citrate (Actiq, Subsys, Fentora) or nicotine (Nicorette gum) are administered transmucosally. However, the greater penetrability accounts for the toxicity associated with improper application to a mucosal surface, which lacks a stratum corneum.<sup>5,26</sup> A small amount of xenobiotic also enters the body by way of the skin appendages, such as the sweat glands or hair follicles.<sup>5,25</sup>

Properties of the skin that account for pharmacokinetic variability include hydration status and temperature. Absorption varies based on the site of application on the body and on both the thickness of the stratum corneum and the blood flow.<sup>2,29,30</sup> Although the average skin thickness of the human body is 40  $\mu\text{m}$ , it ranges between 20 and 80  $\mu\text{m}$  as a result of many factors including body location, race, age, and sex. As an example, in skin samples from 8 individuals, there was more than a 50% difference in the permeability of fentanyl.<sup>17</sup> Because the stratum corneum thickness is most relevant to diffusion rates, those areas that have similar thickness, such as the chest, extremities, and abdomen, provide the most consistent delivery and are generally used as sites for transdermal patch application.<sup>30,33</sup> Intertriginous areas, where skin contacts other skin (axillae, groin, inframammary, and intergluteal) allow greater absorption because of enhanced contact surface, temperature, and moisture.

### Active Administration

As described earlier, passive administration requires the optimization of formulation- or xenobiotic-carrying vehicle to increase skin permeability. However currently used absorption enhancers do not greatly improve the permeation of xenobiotics with molecular weights greater than 500 Da.<sup>27</sup> In contrast, active methods, normally involving physical or mechanical methods of enhancing delivery are generally superior. The delivery of xenobiotics of differing lipophilicity and molecular weight including proteins, peptides, vaccines, and oligonucleotides are improved by active energy-requiring techniques such as electroporation, iontophoresis, and ultrasonography (Tables SC3-1 and SC3-2).<sup>11,37</sup>

### Patch Technology

In most current patches, the drug to be delivered is also incorporated into the adhesive layer to reduce the delay to drug absorption. Multiple layers of

**TABLE SC3-2** Description of Advanced Transdermal Drug Delivery Systems

*Electroporation:* uses high-voltage microsecond duration electrical pulses to create transient pores within the skin (for larger molecules such as peptides).

*Iontophoresis:* uses electrodes to pass a small current through a xenobiotic (pilocarpine for sweat testing for cystic fibrosis and for lidocaine).

*Microneedle based devices:* approximately 10–100  $\mu\text{m}$  in length, and are generally arranged in arrays on patch devices. Each microneedle is coated in the xenobiotic to be delivered, and the small size avoids the production of pain.

*Needleless injection:* compressed air is used to force xenobiotics across the skin surface, and may deliver local anesthetics prior to intravenous line placement.

*Ultrasound:* low frequency ultrasound to promote transcutaneous delivery, also called sonophoresis.

adhesive are often separated by membranes that serve to regulate the release. To allow a longer duration of drug delivery, a reservoir is often added. This compartment contains the medication in solution or suspension, and a rate-regulating membrane ensures that the release follows zero-order kinetics to avoid fluctuations in concentration. Increasing the surface area of contact by enlarging the patch proportionally increases the amount of xenobiotic delivered. The membrane itself is not altered. Removal of the rate-regulating membrane, however, results in rapid absorption of toxic quantities of xenobiotic.<sup>8</sup>

The initial fentanyl patch used a reservoir that contained a large quantity of xenobiotic. This reservoir was at risk for access inadvertently by a child chewing the patch or intentionally by a person seeking to abuse the liquid contents.<sup>23</sup> Cutting the reservoir patch dispersed the fentanyl and would result in either overdose or loss of analgesia. Patch construction defects also occurred that potentially allowed leakage.<sup>14</sup> Alternatively, by incorporating the xenobiotic into a fabric mesh, the matrix patch eliminated the reservoir and reduced the risk for abuse. The matrix patch could be safely cut to change the dosage delivered, based on surface contact area, without risking spillage of any liquid content. The clinical pharmacology of the matrix fentanyl patch is similar to that of the reservoir patch.<sup>9</sup>

### Pharmacokinetics

The initial detection of xenobiotic in the serum following transdermal application is not surprisingly delayed compared to other routes of administration. The delay is dependent on the properties of the xenobiotic, the skin, and the environment. Highly lipophilic xenobiotics form a depot in the subcutaneous tissue as the xenobiotic slowly dissolves in the aqueous tissue for diffusion to allow vascular uptake. Highly hydrophilic xenobiotics slowly penetrate the lipid layers of the epidermis, which is why ionic (salt) forms of drugs are administered by a subcutaneous or intramuscular route. For example, fentanyl concentrations will not be detected in the serum for 1 to 2 hours after placement of a patch, and the peak concentration is typically achieved in a day or longer.<sup>13</sup> For this reason the use of a fentanyl patch is not indicated for the treatment of acute pain, particularly postoperative pain.<sup>23</sup> Because the natural history of acute pain is to rapidly improve over several days, during which time the fentanyl concentrations continue to rise, the risk of toxicity also rises.<sup>34</sup> However, in patients with chronic pain, this pharmacokinetic profile will be beneficial, as long as opioids are indicated and safe use is monitored. Furthermore, as noted, permeation enhancers will commonly alter the xenobiotic or the skin sufficiently to alter the absorption kinetics.<sup>19</sup>

The pharmacokinetic profiles of serial doses of patches is based on removal of the patch after the specified time period, and application of a new patch at a different location.<sup>23</sup> This is important to allow a new subcutaneous depot to form while the existing depot from the initial patch is absorbed. If applied to the same location, rather than initiating absorption from a new site, the dose in the adhesive will combine with the existing depot and alter the clinical pharmacokinetics.

Washing the skin or removing the patch will not result in a rapid fall in serum concentrations or a reduction in clinical effect.<sup>13</sup> Rather, the

Selegiline
Testosterone

concentration and clinical effects will resolve over several hours because of the persistence of the dermal depot, which is not removed by cleansing.<sup>23</sup> For example, the apparent half-life of fentanyl following removal of a fentanyl patch is approximately 18 hours.<sup>13</sup> Therefore, simple removal of a fentanyl patch will not be sufficient treatment of a patient with respiratory depression, and respiratory support or naloxone should be used.

## ADVERSE EFFECTS

Because transdermal administration places the xenobiotic in close contact with the environment, there is substantial risk of variation in absorption as a result of changes in ambient conditions. For example, patches exposed to heat, from heating blankets or saunas, can release drug at a rate greater than expected under conventional ambient conditions.<sup>4</sup> Patches are periodically damaged, either during the manufacturing process or subsequently following application which alters their release profile, resulting in toxicity.<sup>14</sup> Certain patches, such as those with a metal backing, will frequently become exceedingly hot during exposure to magnetic resonance imaging studies and result in burns.

Despite these techniques to enhance xenobiotic delivery, transdermal systems require that large amounts of xenobiotic be present externally to maximize the transcutaneous gradient. Much of the xenobiotic typically remains in the patch when it is removed following its intended course of therapy,<sup>21</sup> raising concerns for safe disposal, especially for children<sup>35</sup> and abuse potential among others.<sup>15</sup>

Perhaps the most insidious adverse effects are related to their complicated pharmacokinetics. Because many prescribers are unfamiliar with the dosing and initiation of therapy with transdermal products, those xenobiotics with consequential adverse effects in overdose, such as fentanyl, are commonly linked to poor outcomes even with intended therapeutic use.<sup>10,23</sup>

## SUMMARY

- A limited number of xenobiotics have the appropriate chemical properties, such as lipophilicity and potency, to permit transdermal absorption.
- Transdermal delivery of a xenobiotic has certain therapeutic advantages over other routes, such as bypassing first-pass hepatic metabolism and providing a discrete administration.
- The pharmacokinetics of transdermal xenobiotic delivery are unique; they are distinctly different than other routes. Absorption is typically slower but more prolonged, which is potentially beneficial in situations in which long-term, round-the-clock dosing is required.
- Because of the atypical pharmacokinetics, both the onset and offset of the clinical effects are slow and relatively unpredictable. The development of toxicity, in particular, is often insidious.

## GASTROINTESTINAL PRINCIPLES

Matthew D. Zuckerman and Richard J. Church

Humans are in constant contact with xenobiotics. In addition to its critical role in absorbing nutrients, the gastrointestinal (GI) tract forms the initial functional barrier between ingested material and the body. An understanding of the structure, physiology, and innervation of the GI tract is critical to the toxicologic concepts of absorption, motility, and toxic insult. This chapter discusses the normal role of the GI tract and its relationship to toxicology. Anatomic, pathologic, and microbiologic principles are discussed, including the role of the GI tract in the metabolism of xenobiotics. Types of GI pathologies and their clinical manifestations are discussed, with examples when appropriate.

### STRUCTURE AND INNERVATION OF THE GASTROINTESTINAL TRACT

The luminal GI tract is divided into 5 distinct structures: oral cavity and hypopharynx, esophagus, stomach, small intestine, and colon (Fig. 18–1). These environments differ in luminal pH, epithelial cell receptor types, and endogenous flora. The transitional areas between these distinct organs have specialized epithelia and muscular sphincters with specific functions and vulnerabilities. Knowing the anatomy of these transition zones is particularly important for the localization and management of foreign bodies. The functions of the pancreas and liver are closely integrated with those of the luminal organs. The pancreas is discussed here; the liver and its metabolic functions are discussed in Chaps. 11 and 21.

The visceral structures of the GI tract are composed of several layers, including the epithelium, lamina propria, submucosa, muscularis layers, and serosa (the last of which is only present in intraperitoneal organs). As the transition is made throughout the GI tract, differences in luminal pH, epithelial cell receptors, muscularity, and endogenous flora are encountered, affecting the absorption and metabolism of individual xenobiotics.

The epithelium, the innermost layer of the GI tract, is the most specialized cell type in the intestine and is composed of epithelial, endocrine, and receptor cells. The basal surface of epithelial cells faces the lamina propria, and the apical surface faces the lumen. They are further specialized for specific functions of secretion or absorption. Additionally, the epithelial cells form part of the mucosal immune defense, where they detect the presence of microbial pathogens and downregulate the immune system in the presence of nonpathogenic or probiotic microbes. The major barrier to penetration of xenobiotics and microbes is the GI epithelium, a single-cell-thick membrane. The cell membrane is a semipermeable lipid bilayer that contains aqueous pores through which certain materials pass, depending on size and molecular structure. The membrane is not continuous because it consists of individual epithelial cells; however, these cells are joined to each other by structures known as tight junctions. The tight junctions have a gap of about 8 Å, which allows passage only of water, ions, and low-molecular-weight substances.

The muscle layer found beneath the lamina propria is made up of the muscularis mucosa, the circular muscles, and the longitudinal muscles. Contraction of the muscularis mucosa causes a change in the surface area of the gut lumen that alters secretion or absorption of nutrients. Whereas depolarization of circular muscle leads to contraction of a ring of smooth muscle and a decrease in the diameter of that segment of the GI tract, depolarization of longitudinal muscle leads to contraction in the longitudinal direction and a decrease in the length of that segment. The function of the muscle layers is integrated with the enteric nervous system to provide for a coordinated movement of luminal contents through the GI tract to maximize absorption and maintain the gastrointestinal microbiota. This

integration facilitates the flow of chyme (undigested food) via a coordinated sequence of muscular contractions and relaxations, leading to segmentation of luminal contents, peristaltic movements, and unidirectional flow through the intestine.

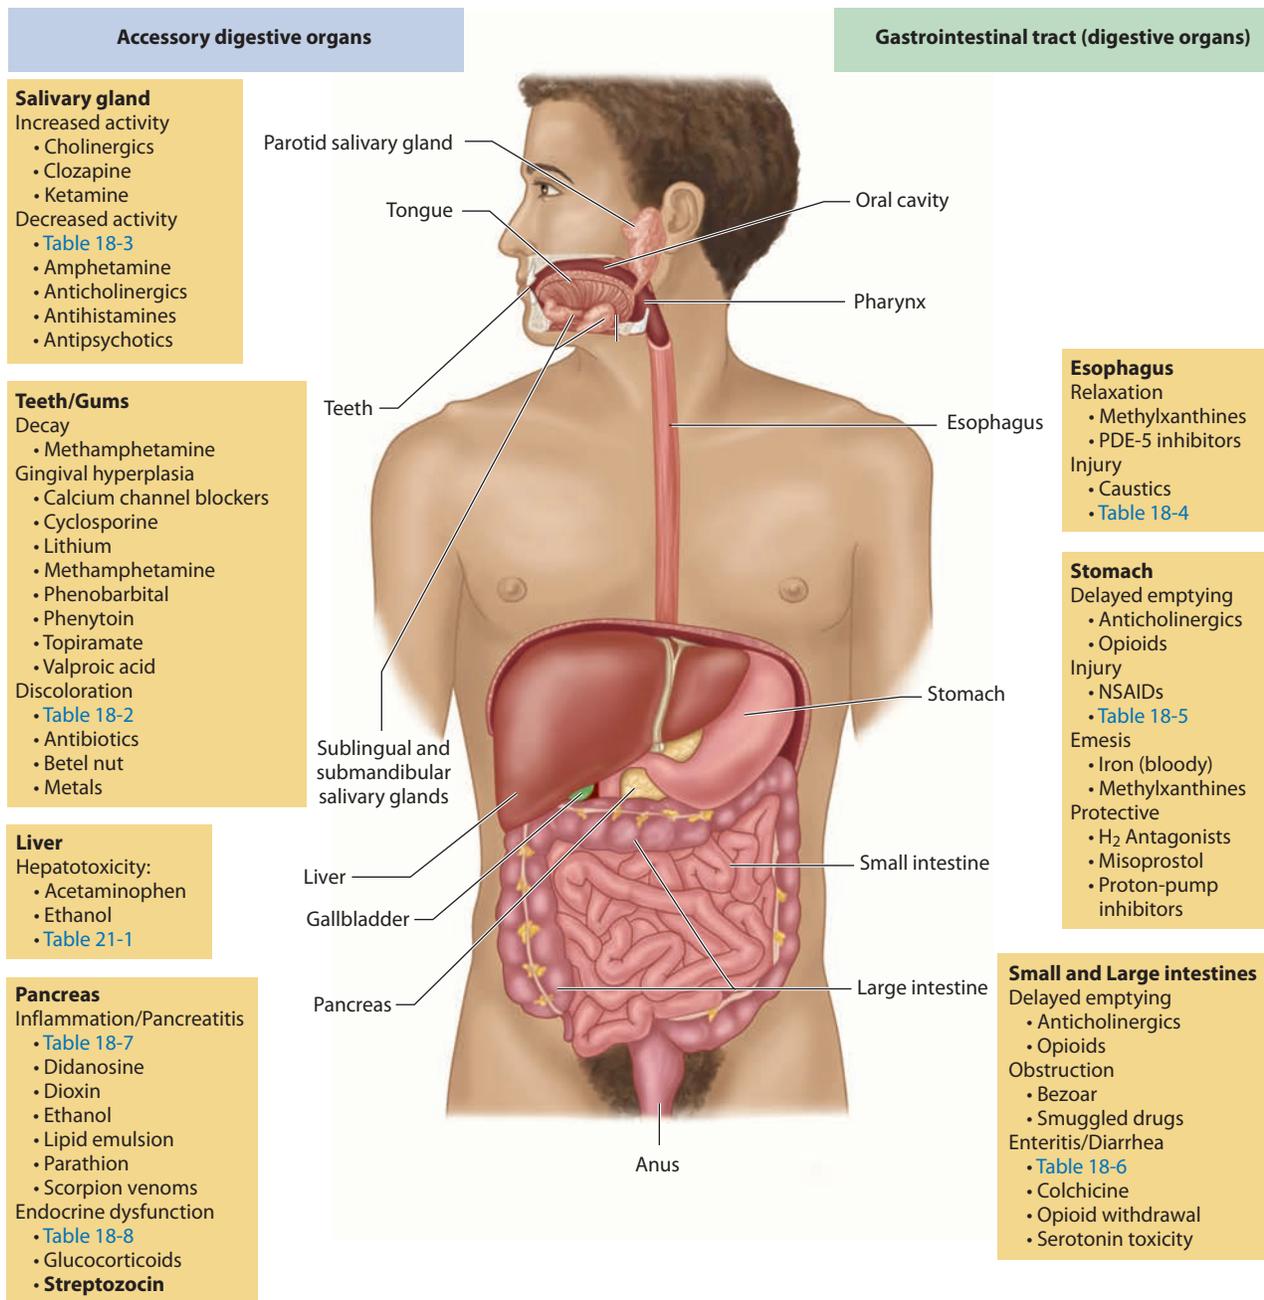

The GI tract is innervated by the autonomic nervous system via both extrinsic and intrinsic pathways (Fig. 18–2). The extrinsic innervation permits communication among the brain, spinal cord, and chemoreceptors and mechanoreceptors located in the gut. Parasympathetic stimulation in the extrinsic pathway tends to be excitatory (“rest and digest”) and is carried via the vagus, splanchnic, and pelvic nerves to the myenteric and submucosal plexuses. In contrast, increased sympathetic tone (“fight or flight”) inhibits digestive and peristaltic activity via fibers that originate in the thoracolumbar cord and terminate in the myenteric and submucosal plexuses. The intrinsic innervation of the GI tract, or enteric nervous system, constitutes a reflex arc that modulates both peristalsis (via the myenteric plexus) and secretion (via the submucosal plexus) in response to parasympathetic and sympathetic tone.

### THE IMMUNE SYSTEM AND MICROBIOLOGY OF THE GASTROINTESTINAL TRACT

An elaborate mucosal immune system has evolved to protect the GI tract from pathogens and modulate functional gastrointestinal diseases.<sup>35,44</sup> Mucosal immunity consists of an afferent limb, which recognizes a pathogen and induces the proliferation and differentiation of immunocompetent cells, and an efferent limb, which coordinates and affects the immune response. The afferent system includes the lymphoid follicles and specialized M-cells found therein that promote transit of antigens to antigen-presenting cells.<sup>37</sup> Once sensitized, immune cells undergo a complicated process of clonal expansion and differentiation, which occurs in mucosal and mesenteric lymphoid follicles, and in extraintestinal sites. Immunocompetent cells then return to the intestine and other mucous membranes and are scattered diffusely within the epithelial and lamina propria compartments.

The normal endogenous flora in the GI tract includes more than 400 species of bacteria along with a small number of fungi and viruses. The intestinal mucosa is normally colonized by large numbers of nonpathogenic anaerobic strains of *Bacteroides* spp, *Eubacterium* spp, *Clostridium* spp, as well as aerobic strains of *Escherichia coli*, *Proteus* spp, *Enterobacter* spp, *Serratia* spp, *Lactobacillus* spp, and *Klebsiella* spp.<sup>19</sup> The concentration of luminal bacteria varies by site, from lowest in the proximal small intestine to highest in the large intestine. En masse, these bacteria are more metabolically active than the liver. Endogenous bacteria occupy unique niches related to host physiology, environmental pressures, and microbial interactions, which result in long-term stability. Following a course of ciprofloxacin, the gut microbiome of healthy volunteers demonstrated a marked shift and loss of biodiversity within days, but began to return to the initial state within a week of cessation.<sup>13</sup> Indeed, the cumulative total of microbial species in the enteric system (or enterotype) is remarkably consistent across countries and continents.<sup>3</sup>

The endogenous flora has multiple metabolic functions. A primary function in the colon is the salvage of malabsorbed carbohydrates by fermentation and production of short-chain fatty acids, a preferred substrate for colonic epithelial cells. This increased metabolic efficiency is best demonstrated when mice grown in germ-free conditions require a higher caloric intake to maintain weight.<sup>48</sup> This has led to some conjecture about the link between human flora and obesity.<sup>16</sup>

**FIGURE 18-1.** Anatomy of the gastrointestinal system. (Modified with permission from Mescher AL: *Junqueira's Basic Histology*, 13th ed. New York, NY: McGraw-Hill; 2013.)

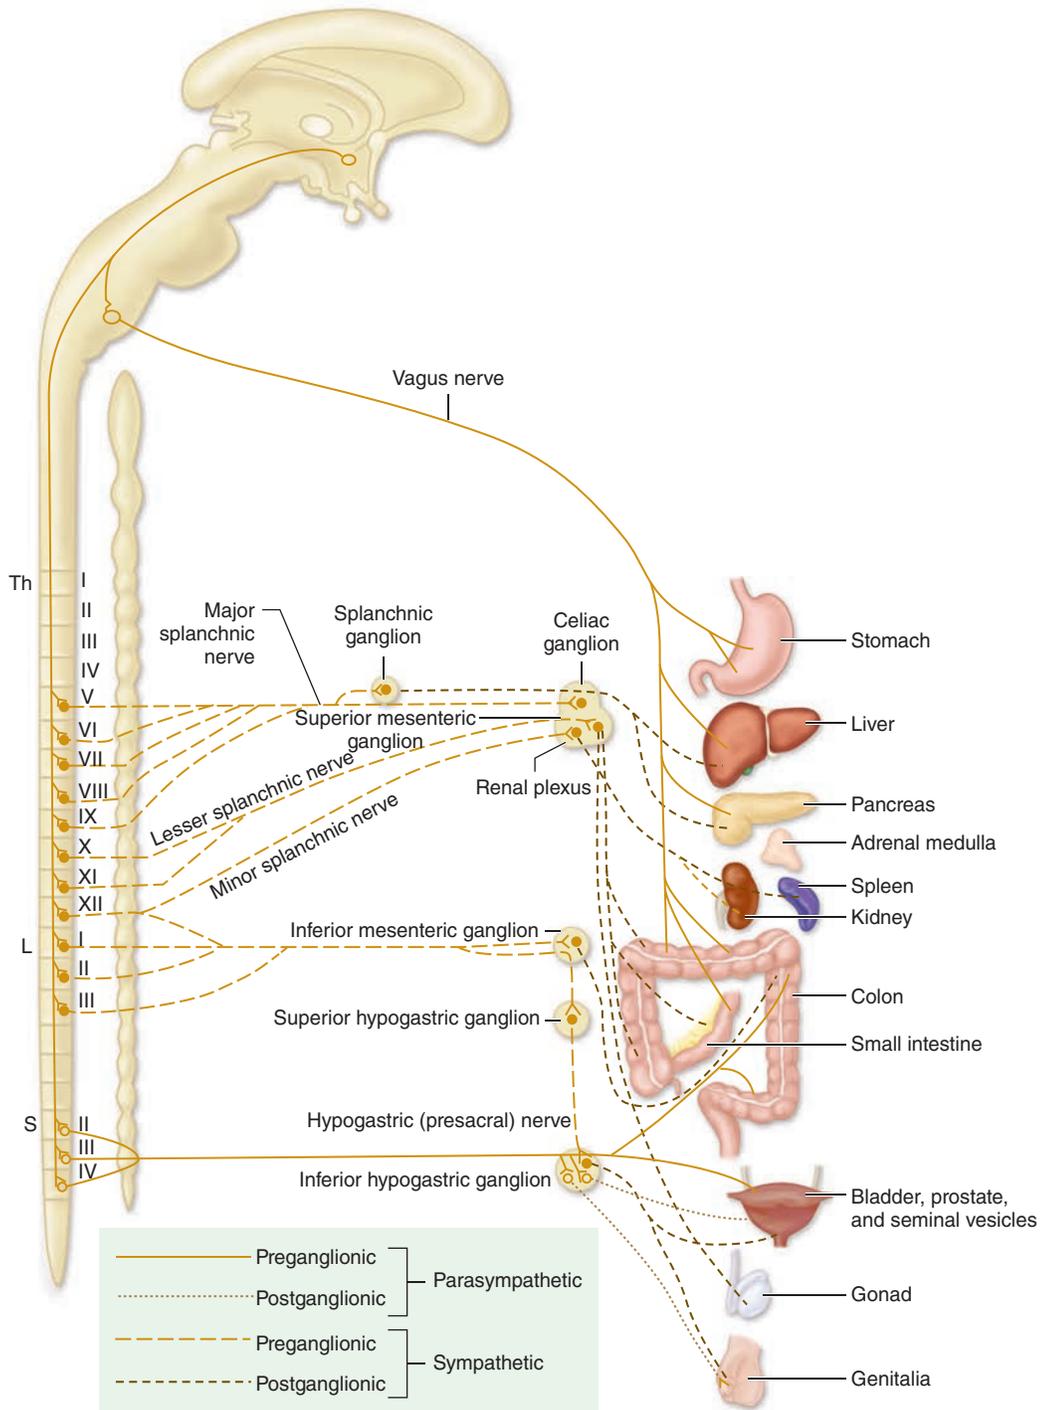

Bacterial metabolism significantly affects the disposition of enteral compounds.<sup>23</sup> For example, the bacterial metabolism of digoxin contributes to its steady-state concentrations, and antibiotic treatment reduces or eradicates the intestinal flora, predisposing to digoxin toxicity.<sup>10</sup> Bacterial contribution to vitamin K metabolism is also demonstrated, necessitating dose adjustments of warfarin during and after antibiotic therapy. The metabolic activity of intraluminal bacteria is exploited in some treatment strategies. For example, sulfasalazine, used in the treatment of ulcerative colitis, is created through the linkage of 5-aminosalicylic acid to sulfapyridine. The azo bonds of the nonabsorbable sulfasalazine are broken by bacterial azoreductases, permitting the absorption of active metabolites in the colon at the site of inflammation.<sup>41</sup>

The normal flora of the gut consists of probiotics—live, nonpathogenic bacteria and fungi that are also used as prophylactic or therapeutic xenobiotics. These bacteria compete for and displace pathogenic bacteria, directly modulate intestinal immune function, and exert a trophic effect on the GI tract. They appear to serve to decrease traveler's diarrhea, suppress

antibiotic-induced diarrhea, and reduce inflammation in ileal pouches after colectomy in patients with ulcerative colitis.<sup>17,20,22</sup>

### REGULATORY SUBSTANCES OF THE GASTROINTESTINAL TRACT

There are 3 groups of regulatory peptide hormones that act on target cells within the GI tract. These are released from endocrine cells in the GI mucosa into the portal circulation and enter the systemic circulation to affect target cells. Gastrin, cholecystokinin (CCK), secretin, and glucose-dependent insulinotropic polypeptide (GIP; formerly gastric inhibitory peptide) are considered the primary GI hormones. Somatostatin and histamine comprise the paracrines, hormones that are released from endocrine cells and diffuse over short distances to act on target cells located in the GI tract. Vasoactive intestinal peptide (VIP), gastrin-releasing peptide (GRP), and enkephalins make up the last group known as neurocrines—substances that are synthesized in neurons of the GI tract, move by axonal transport down the axon, and are then released by action potentials in the nerves. The effects of these regulators are summarized in Table 18-1.<sup>7</sup>

**FIGURE 18-2.** Innervation of the gastrointestinal system. (Adapted with permission from McAninch JW, Lue TF, Smith DR: *Smith and Tanagho's General Urology*, 18th ed. New York, NY: McGraw-Hill Professional; 2013.)

Xenobiotic effects on GI regulation have intended and unintended consequences. Somatostatins reduce splanchnic blood flow and portal blood pressure, leading to their use as therapeutics for bleeding esophageal varices. Erythromycin agonizes motilin receptors, leading to increased GI propulsion, cramping, and diarrhea.

**ANATOMIC AND PHYSIOLOGIC PRINCIPLES**  
**Oropharynx and Hypopharynx**

The main functions of the mouth and oropharynx are chewing, lubrication of food with saliva, and swallowing. Saliva initiates digestion of starch by  $\alpha$ -amylase (ptyalin), triglyceride digestion by lingual lipase, lubrication of

ingested food by mucus, and protection of the mouth and esophagus by dilution and buffering of ingested foods.

Saliva production is unique in that it is increased by both parasympathetic and sympathetic activity. Parasympathetic stimulation, via cranial nerves VII and IX, acts on muscarinic cholinergic receptors on acinar and ductal cells, increasing saliva production via vasodilation and increasing transport processes. Parasympathetic pathways are stimulated by food in the mouth, smells, conditioned reflexes, and nausea, and are inhibited by sleep, dehydration, and fear. Sympathetic stimulation originates from preganglionic nerves in the thoracic segments T1 to T3. When  $\beta$ -adrenergic receptors are triggered by norepinephrine, production of saliva increases but at a rate less than that

TABLE 18–1 Regulatory Substances of the GI Tract			
Substance	Site of Secretion or Release	Stimulus for Secretion/Release	Actions
<i>Endocrines</i>			
Gastrin	G cells of gastric antrum	Small peptides and amino acids Stomach distention Vagal stimulation (via GRP) Inhibited by H <sup>+</sup> in stomach (negative feedback)	↑ Gastric H <sup>+</sup> secretion ↑ Growth of gastric mucosa
Cholecystokinin	I cells of duodenum and jejunum	Small peptides and amino acids Fatty acids and monoglycerides	↑ Contraction of gallbladder and relaxation of sphincter of Oddi ↑ Pancreatic enzyme and HCO <sub>3</sub> <sup>-</sup> secretion ↑ Growth of exocrine pancreas and gallbladder ↓ Gastric emptying (allows more time for digestion and absorption)
Secretin	S cells of duodenum	H <sup>+</sup> in duodenal lumen Fatty acids in duodenal lumen	↓ Small intestinal H <sup>+</sup> ↑ Pancreatic HCO <sub>3</sub> <sup>-</sup> secretion ↑ Biliary HCO <sub>3</sub> <sup>-</sup> secretion ↓ Gastric H <sup>+</sup> secretion ↑ Growth of exocrine pancreas
GIP	K cells of small intestine	Fatty acids, amino acids, oral glucose	↑ Insulin release ↓ H <sup>+</sup> secretion by gastric parietal cells
Motilin	Epithelial cells of duodenum	Periodic (not responsive to food)	↑ Propulsion of smooth muscle
Glucagonlike peptide 1	L cells of small intestine	Meal intake	↑ Insulin secretion ↓ GI motility
Ghrelin	P/D1 cells of stomach	Fasting	↑ Gastric emptying Stimulates feeding
<i>Paracrines</i>			
Somatostatin	D cells throughout GI tract	H <sup>+</sup> in GI tract lumen Inhibited by vagal stimulation	↓ Release of all GI hormones ↓ Gastric H <sup>+</sup> secretion ↓ Pancreatic secretions ↓ Splanchnic blood flow
Histamine	Mast cells of gastric mucosa	Vagal stimulation	↑ Gastric H <sup>+</sup> secretion
Nitric oxide	Enteric nerves	Cellular inflammation	↑ Epithelial secretion Vasodilation Smooth muscle relaxation
<i>Neurocrines</i>			
VIP	GI tract neurons	H <sup>+</sup> in duodenal lumen	Smooth muscle relaxation ↑ Pancreatic HCO <sub>3</sub> <sup>-</sup> secretion ↑ Fluid and electrolyte secretion from intestinal epithelium and bile duct cholangiocytes ↓ Gastric H <sup>+</sup> secretion
Gastrin-releasing peptide	Vagus nerves that innervate G cells	Vagal stimulation	↑ Gastrin release from G cells
Enkephalins (met-enkephalin, leu-enkephalin)	GI tract mucosa and smooth muscle neurons		↑ Contraction of GI smooth muscle ↓ Intestinal secretion of fluid and electrolytes

GIP = glucose-dependent insulintropic polypeptide (formerly gastric inhibitory peptide); GRP = gastrin-releasing peptide; VIP = vasoactive intestinal peptide. G, I, S, K, L D cells are typical cells of a part of the intestine producing an endocrine substance: e.g. G cells of the antrum produce gastrin.

of parasympathetic stimulation.<sup>11</sup> It is theorized that the hypersalivation, or sialorrhea, associated with clozapine is related to agonism of parasympathetic muscarinic receptors or antagonism of adrenergic  $\alpha$  receptors (resulting in unopposed  $\beta$ -adrenergic receptor-mediated vasodilation).<sup>6</sup> Conversely, dysfunction of saliva production, via the anticholinergic side effects of other antipsychotics, leads to dry mouth, or xerostomia.

## Esophagus

The esophagus is a distensible muscular tube that extends from the epiglottis to the gastroesophageal junction. The lumen of the esophagus narrows at several points along its course, first at the cricopharyngeus muscle, then midway down alongside the aortic arch, and then distally where it crosses the diaphragm. The upper esophageal sphincter (UES) and lower

esophageal sphincter (LES) are physiologic high-pressure regions that remain closed except during swallowing. Although the LES is a functional segment without anatomic features, the UES is marked by the presence of striated muscle.

The wall of the esophagus reflects the general structural organization of the GI tract noted previously, consisting of mucosa, submucosa, muscularis propria, and adventitia. The mucosal layer has 3 components. The non-keratinizing stratified squamous epithelial layer faces the lumen; provides protection for underlying tissue; and houses several specialized cell types such as melanocytes, endocrine cells, dendritic cells, and lymphocytes. The lamina propria is the nonepithelialized portion of the mucosa, and the muscularis mucosa, a layer of longitudinally oriented smooth muscle bundles, is the third component.

The submucosa consists of loose connective tissue, and submucosal glands secrete a mucin-containing fluid via squamous epithelium-lined ducts, which facilitates lubrication of the esophageal lumen. The muscularis propria consists of an inner circular and outer longitudinal coat of smooth muscle; this layer also contains striated muscle fibers in the proximal esophagus that are responsible for voluntary swallowing.

The esophagus has no serosal lining. Only small segments of the intra-abdominal esophagus are covered by adventitia, a sheathlike structure that also surrounds the adjacent great vessels, tracheobronchial tree, and other structures of the mediastinum.

The esophagus provides a conduit for food and fluids from the pharynx to the stomach, and the sphincters generally prevent reflux of gastric contents into the esophagus. Normal transit of food involves coordinated motor activity, including a wave of peristaltic contraction, relaxation of the LES (facilitated by nitric oxide and VIP), and subsequent closure of the LES (facilitated by several hormones and neurotransmitters such as gastrin, acetylcholine, serotonin, and motilin). Xenobiotics alter muscle tone in various segments of the esophagus, altering function. Caffeine is associated with relaxation of the LES and decreased peristalsis, increasing incidence of acid reflux.<sup>34</sup> Calcium channel blockers, nitroglycerin,  $\beta$ -adrenergic antagonists and phosphodiesterase inhibitors all relax esophageal smooth muscle, decreasing the pathologically elevated esophageal tone common to patients with achalasia.<sup>9</sup> Because of the rapid transit time of swallowed substances xenobiotics through this portion of the GI tract, digestion does not take place, and passive diffusion of xenobiotics from the food into the bloodstream is prevented.<sup>11,59</sup>

## Stomach

The stomach is a saccular organ covered entirely by peritoneum that has a capacity greater than 3 L. The stomach is divided into 5 anatomic regions: the cardia, fundus, corpus or body, antrum, and pyloric sphincter. The gastric wall consists of mucosa, submucosa, muscularis propria, and serosa. The interior surface of the stomach is marked by coarse rugae, or longitudinal folds. The mucosa is composed of a superficial epithelial cell compartment and a deep glandular compartment. The mucous glands of the cardia, fundus, and body secrete mucus and pepsinogen. Oxyntic, or acid-forming, glands located in the fundus and body contain parietal, chief, and endocrine cells. The parietal cells contain vesicles that house hydrochloric acid-secreting proton pumps and secrete intrinsic factor, a substance necessary for the ileal absorption of vitamin B<sub>12</sub>. Chief cells secrete the proteolytic proenzyme pepsinogen, which is cleaved to its active form, pepsin, upon exposure to the low luminal gastric pH of 3 to 4. Pepsin is subsequently inactivated in the duodenum when the pH increases to 6.0. The endocrine, or enterochromaffinlike (ECL), cells found in the mucosa of the body of the stomach produce histamine, which increases acid production and decreases gastric pH by stimulating H<sub>2</sub> receptors on the parietal cells. Somatostatin and endothelin, both modulators of acid production, are also produced in ECL cells (Fig. 49–4).

Hydrochloric acid is secreted when cephalic, gastric, and intestinal signals converge on the gastric parietal cells to activate proton pumps and release hydrochloric acid in an ATP-dependent process. During the cephalic phase, or the preparatory phase of the brain for eating and digestion,

acetylcholine is released from vagal afferents in response to sight, smell, taste, and chewing. Acetylcholine stimulates the parietal cells via muscarinic receptors, resulting in an increase in cytosolic calcium and activation of the proton pump. Antral G cells of the stomach, produce and release gastrin in response to luminal amino acids and peptides. Gastrin activates receptors within parietal cells, leading to a similar increase in cytosolic calcium. Additionally, gastrin and vagal afferents induce the release of histamine from ECL cells, which stimulates parietal cell H<sub>2</sub> receptors. Lastly, the intestinal phase is initiated when food containing digested protein enters the proximal small intestine and involves gastrin and several other polypeptides in the secretion of hydrochloric acid from the stomach<sup>59</sup> (Fig. 18–3).

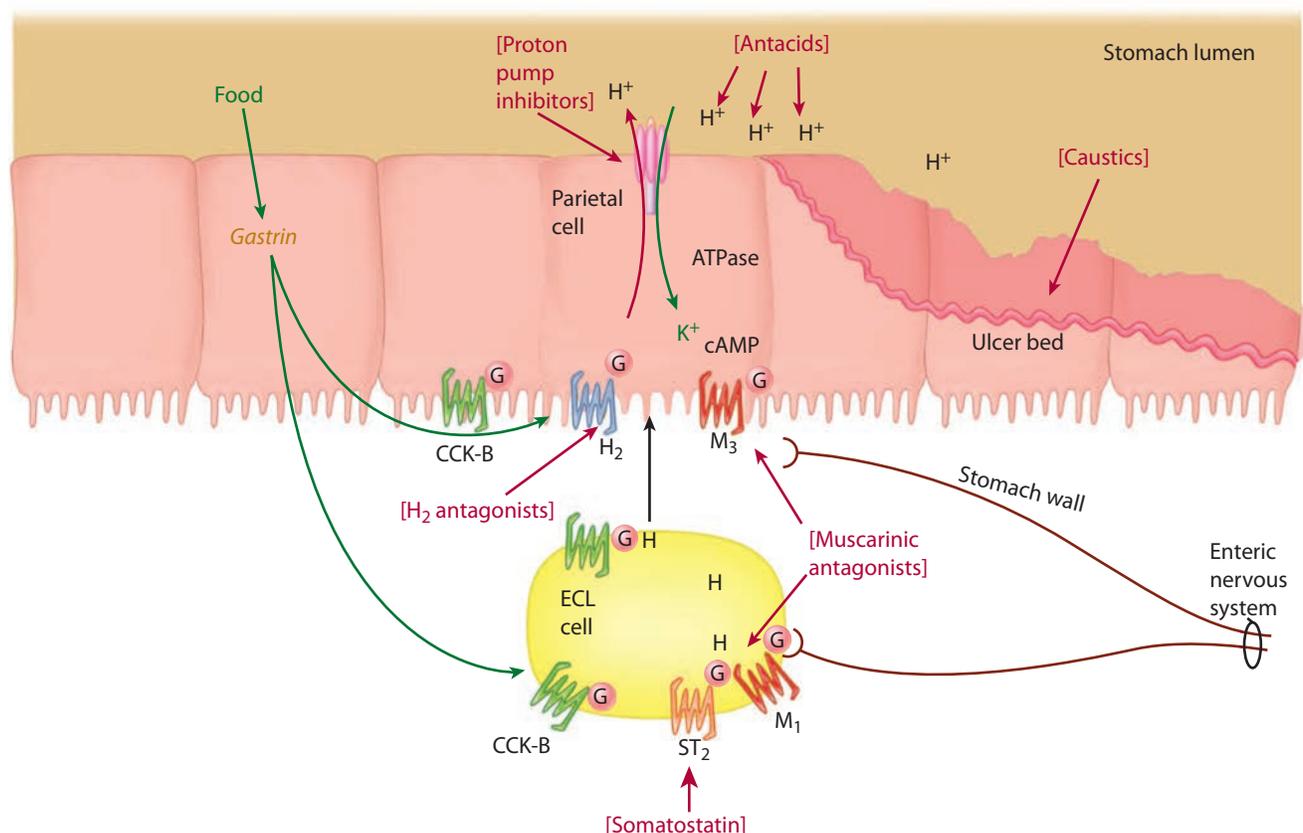

The gastric mucosa is protected from gastric acidic secretions by several mechanisms, including a thin layer of surface mucus and channels that allow acid- and pepsin-containing fluids to exit glands without contact with the surface epithelium. Additionally, surface epithelium secretes bicarbonate, raising the pH at the cell surface. Prostaglandins produced in the mucosal cells stimulate production of bicarbonate and mucus, and inhibit parietal cell production of acid; prostaglandin inhibition by nonsteroidal antiinflammatory drugs (NSAIDs) plays an important role in the pathogenesis of peptic ulcer disease (PUD).<sup>59</sup>

In the stomach, ingested products are ground to particle sizes of less than 0.2 mm, which are then further processed and digested in preparation for absorption of nutrients in the small intestine. Many xenobiotics are weak acids that are no longer ionized in the acidic environment of the stomach, facilitating absorption through the lipid bilayer in the stomach. Other factors that affect xenobiotic absorption include particle size, transit time, and type of drug delivery system. Different drug formulations, such as time release, enteric coating, slowly dissolving matrices, dissolution control via osmotic pumps, ion exchange resins, and pH-sensitive mechanisms, affect bioavailability and the site of maximal release within the GI tract.

The time required for gastric emptying is determined by the complex interplay of innervation, muscle action, underlying illness, and xenobiotic exposure. Digestion and absorption are time-dependent processes, and optimal absorption requires adjustment of the luminal environment through secretion of ions and water, to accommodate meals that vary considerably in nutrient composition, water content, and density. Osmoreceptors and chemoreceptors in the GI tract adjust the digestive and absorptive processes by regulating transit and secretion using a variety of neurocrine, paracrine, and endocrine mechanisms. Interference with this integrated response either leads to stasis and bacterial overgrowth or to rapid transit with decreased absorption and development of diarrhea. Many mediators affect motility, including common neurotransmitters, such as acetylcholine and norepinephrine; hormones; cytokines; and inflammatory compounds. In general, whereas parasympathetic impulses promote motility, sympathetic stimulation inhibits motility. Other neurotransmitters, such as serotonin, promote transit, but dopamine and enkephalins slow motility. Some xenobiotics, such as opioids and diphenhydramine, delay gastric emptying, but other xenobiotics, such as metoclopramide, enhance gastric emptying. Our understanding of the complex neuroendocrine gastric axis continues to evolve in attempts to explain relatively new phenomenon, such as the cannabinoid hyperemesis syndrome, which appears to be caused by cannabinoid receptors in the brain or gut.<sup>52</sup>

## Small and Large Intestines

In an average adult, the small intestine is approximately 6 m in length and begins retroperitoneally as the duodenum, becoming intraperitoneal at the jejunum and ileum. The boundary between the small intestine and large intestine is the ileocecal valve, and the large intestine typically measures 1.5 m in an adult. The large intestine (or colon) is further divided into cecal, ascending, transverse, descending, and sigmoid segments. The sigmoid colon is continuous with the rectum and terminates at the anus. Whereas anterograde and retrograde peristalsis occurs in the small intestine, anterograde peristalsis predominates in the large intestine. This movement allows for mixing of food, maximizes contact with the mucosa, and is mediated by

**FIGURE 18-3.** Effects of various xenobiotics on the gastrointestinal tract. CCK-B = cholecystokinin receptor B; ECL cell = enterochromaffinlike cell; H = histamine;  $H_2$  = histamine-2 ( $H_2$ ) receptor;  $M_1$ ,  $M_3$  = muscarinic receptors;  $ST_2$  = somatostatin-2 receptor.

both the extrinsic and intrinsic nervous systems. The remarkable absorptive capacity of the small intestine is made possible by innumerable villi of the intestinal wall, which extend into the lumen and increase absorptive area. The epithelial border of the small intestine also contains mucin-secreting goblet cells, endocrine cells, and specialized absorptive cells; functionally, these cells create an ideal environment for nutrient absorption. The mucosa of the large intestine is devoid of villi. The large intestine functions primarily to absorb electrolytes and water, secrete potassium, salvage any remaining nutrients, and store and release waste. Intestinal epithelial cells also metabolize xenobiotics, a function typically attributed to the liver (see below).

Regeneration of injured or senescent intestinal epithelial cells begins in the crypts, with differentiation occurring as these cells migrate toward the intestinal lumen. This process occurs rapidly, with turnover of the small intestinal epithelium occurring every 4 to 6 days and large intestinal epithelium turnover occurring every 3 to 8 days. This rapid regeneration leaves the intestinal epithelium vulnerable to processes that interfere with cell replication (eg, radiation, chemotherapy). Sloughing of GI epithelium, typically manifested by hemorrhagic enteritis, is a valuable marker for xenobiotic insults that lead to mitotic arrest.

### Pancreas

The pancreas is a retroperitoneal organ that serves both exocrine and endocrine functions. The exocrine portion of the gland produces digestive enzymes and occupies more than 80% to 85% of the mass of the pancreas. The exocrine pancreas is composed of acinar cells, specialized epithelial cells housing zymogen granules that release digestive enzymes and proenzymes into the duodenum. Columnar epithelial cells produce mucin, and ductal cuboidal epithelial cells secrete a bicarbonate-rich fluid that neutralizes gastric acids. The pancreas secretes 2 to 2.5 L/day of this mixed solution. Typically, the digestive enzymes are released as proenzymes, such as trypsinogen, chymotrypsinogen, and procarboxypeptidase, which are activated on contact with the higher pH of the duodenum; this process

usually helps to prevent autodigestion of the pancreas itself. Enzymes on the brush border of the duodenum, including enteropeptidase, cleave proenzymes to their active forms. Only pancreatic amylase and lipase are secreted in their active forms.

Secretion of pancreatic enzymes is regulated by multiple factors, the most important of which are cholecystokinin and secretin, both produced in the duodenum. Cholecystokinin is released from the duodenum in response to fatty acids and the products of protein catabolism such as peptides and amino acids. Cholecystokinin stimulates acinar cells to release digestive enzymes and proenzymes. Secretin is released by the duodenum in the presence of the decrease in pH caused by gastric acids and luminal fatty acids. Secretin triggers ductal cells to secrete bicarbonate and water. Acetylcholine also plays a role in the regulation of pancreatic exocrine function by stimulating digestive enzyme secretion from the acinus and potentiating the effects of secretin. Vagal reflexes increase acetylcholinergic tone in the setting of decreased pH, protein breakdown products, and fatty acids in the duodenal lumen.

The endocrine portion of the pancreas is composed of approximately one million clusters of cells known as the islets of Langerhans that secrete insulin, glucagon, and somatostatin. Other products of the endocrine pancreas include serotonin and VIP. Injury to the endocrine pancreas or alteration of physiologic functions often results in impaired glucose homeostasis, diabetes, and exocrine insufficiencies.<sup>21,46</sup> Calcium channel blockers interfere with  $Ca^{2+}$ -dependent insulin release, resulting in hyperglycemia. Sulfonylureas close ATP-sensitive  $K^+$ -channels, stimulating insulin release.

### XENOBIOTIC METABOLISM

Although the liver is usually identified as the site of xenobiotic metabolism, a significant amount of CYP and other metabolic enzymes are found in the luminal GI tract, contributing to hydroxylation, sulfation, acetylation, and glucuronidation. In descending order, CYP3A, CYP2C9, and CYP2C19 are the most abundant CYP families in the small intestine.<sup>39</sup> Biotransformation, especially reduction and hydrolysis, is also a property of luminal bacteria.

Gut microbiomes can alter the metabolism of dozens of pharmaceuticals, in many cases changing their efficacy and side effect profiles.<sup>53</sup> First-pass metabolism by the intestine affects the amount of orally administered xenobiotic that enters hepatic portal circulation and, therefore, contributes greatly to the first-pass effect, or presystemic disposition.

One of the most well-described families of export proteins, P-glycoprotein (P-gp), is found in the mucosa of the small and large intestines, hepatocytes, adrenal cortex, renal tubules, and capillary cells lining the blood-brain barrier.<sup>62</sup> The P-gps are susceptible to induction and inhibition in a manner similar to hepatic cytochrome oxidase enzymes. Many of the inhibitors of CYP3A have inhibitory effects on P-gps. Inhibitors of P-gps raise serum concentrations of a xenobiotic, and inducers of P-gps have the potential to prevent therapeutic drug concentrations from ever reaching the target cell. The P-gp system is important in drug interactions and drug resistance (Chap. 9). Novel nanocarrier drug delivery systems containing both substrates and inhibitors of P-gps mitigate some of these effects.<sup>47</sup>

**Postoperative Effects on the Gastrointestinal Tract**

Anatomic and functional changes after bariatric surgery and bowel resection have important effects on drug bioavailability and toxicity. The common Roux-en-Y gastric bypass surgery, which diverts gastric contents into the distal small bowel, increases bioavailability by bypassing intestinal CYP3A and decreases bioavailability by bypassing the proximal jejunum as an area of drug absorption.<sup>15</sup> Alterations in stomach and bowel pH after surgery affect absorption of ionized drugs. Disruption of the enterohepatic recirculation enhances elimination of xenobiotics such as digoxin.<sup>61</sup> Many xenobiotics, such as ethanol, oral morphine, and caffeine, achieve maximum serum concentrations faster because of rapid transit. However, studies evaluating serum concentrations of known CYP substrates (caffeine [CYP1A2], tolbutamide [CYP2C9], omeprazole [CYP219], and midazolam [CYP3A]) in patients with gastric bypass surgery have not found any clinically significant changes in drug metabolism.<sup>55</sup> Because specific data are limited, current recommendations for dosing in postoperative patients are based on extrapolating from a xenobiotic site of absorption and kinetics and a particular patient’s functional GI anatomy.

**PATHOLOGIC CONDITIONS OF THE GASTROINTESTINAL TRACT**

**Oral Pathology**

Discoloration of the teeth is reported with a number of medications, most notably tetracyclines (Table 18–2). Gingival hyperplasia, overgrowth of the gums around the teeth, is an uncommon adverse effect from chronic use of several xenobiotics. Some medications implicated in causing gingival hyperplasia include calcium channel blockers, cyclosporine, lithium, phenobarbital, phenytoin, topiramate, and valproic acid.<sup>1</sup> Xerostomia, or pathologic dryness of the mouth, is an uncomfortable effect of many xenobiotics that lead to increased dental decay. The list of xenobiotics that cause xerostomia

**TABLE 18–2 Xenobiotics Causing Discoloration of the Teeth and Gums**

Betel nut	Red
Cadmium	Yellow
Chlorhexidine oral rinse	Brown
Ciprofloxacin	Green
Doxycycline	Yellow
Fluoride	White flecking
Lead	Blue line
Quinine	Blue-gray or blue-black
Silver	Brown-gray to blue-gray
Tetracycline	Yellow to brown-gray

**TABLE 18–3 Xenobiotics That Commonly Cause Xerostomia**

α <sub>1</sub> -Adrenergic antagonists

Antidepressants (cyclic antidepressants, maprotiline)
Antipsychotics
H <sub>1</sub> antagonists
Protease inhibitors

is extensive, but the most common classes of xenobiotics causing xerostomia are listed in Table 18–3.<sup>1</sup> Chronic methamphetamine use is linked to characteristic oral pathology known as “meth mouth.” This condition, which is common in both inhalational and intravenous users, is characterized by extensive and severe tooth decay and is linked to poor hygiene, bruxism, and xerostomia associated with methamphetamine use.<sup>12</sup> Notably, a case report involved a similar pattern of tooth decay in a heavy user of cocaine, heroin, and marijuana (not methamphetamine), thought to be related to sugary foods, lack of oral hygiene, and xerostomia.<sup>28</sup>

**Esophagitis and Dysphagia**

Xenobiotic-induced esophageal injury includes esophagitis (including pill esophagitis), ulceration, erosion, impacted pill fragments, perforation, and stricture.<sup>27</sup> The most common presenting complaint is a foreign body sensation in the throat.<sup>26</sup> Xenobiotics commonly implicated in esophagitis and esophageal ulcerations are listed in Table 18–4. Patients with preexisting esophageal motility disorders are at higher risk of esophageal pathology. Additionally, xenobiotics with a gelatin matrix, rapid dissolvability, and large size predispose to esophageal injury. Although most symptoms resolve with withdrawal of the offending xenobiotics, patients with persistent or severe odynophagia should be evaluated with endoscopy to identify pathology and prevent perforation caused by retained pills.

**Webs, Strictures, and Esophageal Malignancy**

Caustic injury is one of the most common causes of esophageal strictures and malignancies (Chap. 103). Some authors also postulate the role of pill esophagitis in the evolution of esophageal strictures.<sup>8</sup> As many as 4% of patients with esophageal cancer report a history of caustic injury, and patients with a prior history of caustic ingestion have more than a 1,000-fold higher risk of developing an esophageal malignancy than the general population.<sup>29</sup> Other xenobiotics known to cause esophageal strictures include aluminum phosphate and ionizing radiation.<sup>54</sup>

**Gastritis and Peptic Ulcer Disease**

Gastritis, or inflammation of the gastric mucosa, and PUD are commonly related to xenobiotic exposure (Table 18–5). Symptoms of gastritis and PUD include epigastric pain, nausea, and vomiting as well as hematemesis and melena. The primary distinction between gastritis and PUD is appearance at endoscopy: whereas gastritis is characterized by diffuse inflammation

of the gastric mucosa, an ulcer is a discrete lesion of the mucosa. Nonsteroidal antiinflammatory drugs remain an important part of the pathogenesis of gastritis and PUD by interfering with prostaglandin synthesis and subsequently impairing the integrity of the gastric mucosal barrier to acid. Cyclooxygenase-2 (COX-2) selective inhibitors promised to decrease the incidence of gastric pathology caused by chronic NSAID use; however, unexpected cardiovascular side effects limited their utility. New xenobiotics are focusing on inhibition of other inflammatory mediators that have been previously overlooked, and coadministration of protective xenobiotics. 5-Lipoxygenase (5-LOX) inhibitors reduce production of proinflammatory leukotrienes, and when coadministered with COX inhibitors, they decrease gastric toxicity. Other reformulated NSAIDs are designed to release molecules of NO and H<sub>2</sub>S, which help maintain gastric mucosal integrity. These next generation of drugs may preserve systemic antiinflammatory effects while enhancing the gastric safety profile.<sup>42</sup>

Long-term treatment of PUD with antacids, H<sub>2</sub> antagonists, or proton pump inhibitors leads to hypochlorhydria or achlorhydria, the reduction or absence of gastric acid, respectively. By increasing the pH of the stomach, these conditions increase risk of bacterial overgrowth (*C. difficile*), atrophic gastritis, osteoporosis, hip fracture (via impaired calcium absorption), *Salmonella* and *Vibrio cholerae* infection, gastric carcinoma and impaired magnesium absorption.<sup>60</sup>

### Enteritis and Diarrhea

The symptoms of GI distress are nonspecifically associated with xenobiotic exposure. However, certain xenobiotics that increase peristalsis or impair fluid absorption result in significant diarrhea. Opioid withdrawal, colchicine overdose, and serotonin toxicity are important toxidromes that often feature diarrhea as a prominent symptom. The rapid turnover of the GI mucosa makes it uniquely susceptible to xenobiotics that cause cell death and mitotic arrest. Hemorrhagic enteritis, manifested by hematochezia, is a characteristic finding of certain exposures (Table 18–6).

### Bezoars

The term *bezoar* refers to a concretion formed anywhere in the alimentary system and is a rare complication of overdose. The risk of bezoar formation is increased in cases of massive pill ingestion and varies according to tablet size, adhesiveness, and liquid viscosity.<sup>51</sup> Comorbid illnesses or toxicities that delay gastric emptying and bowel transit time increase the risk of bezoar formation. Effects from bezoars range from mechanical obstruction to severe local irritation (and stricture formation) to continuous delayed absorption of xenobiotics and resulting toxicity. Suspicion for bezoar formation is raised in patients after ingestion who develop signs of obstruction (vomiting, abdominal pain, constipation) and in patients with delayed or prolonged toxicity (eg, rising serum iron concentrations 8 hours following ingestion) after overdose.<sup>51</sup> Depending on the nature of the bezoar, the diagnosis will be achieved by plain radiography; however, in some instances, computed tomography (CT) with oral contrast increases sensitivity. Recent studies have had limited success with ultrasonography as a diagnostic adjuvant, although this requires further study. Ultimately, a high suspicion of bezoar with negative radiographic evaluation findings should prompt consideration of direct visualization with endoscopy and colonoscopy or exploratory surgery. Bezoars frequently require surgical intervention, and several cases report dramatic recovery after removal.

**TABLE 18–6** Xenobiotic-Induced Enteritis

Mechanism	Xenobiotic
Mechanical irritation	Aloe Bacterial food poisoning Laxatives Mushrooms (GI irritant group)
Cholinergic stimulation	Carbamates Neostigmine, physostigmine, pyridostigmine Mushrooms (muscarine containing) Nicotine Organic phosphorus compounds
Inhibitors of mucosal regeneration (hemorrhagic enteritis)	Arsenic Chemotherapeutics Colchicine Iron Mercuric salts Monochloroacetic acid Podophyllin Pokeweed ( <i>Phytolacca americana</i> ) Radiation (ionizing)
Mitochondrial poison	Thallium

### Pancreatitis

Pancreatitis is an acute inflammatory process that results in autolysis of the pancreas from digestive enzymes. Cases range from mild to severe, with an overall mortality rate of 5%.<sup>18</sup> The most common causes of pancreatitis are alcohol abuse and gall bladder disease; however, nonalcoholic xenobiotic-induced pancreatitis accounts for 0.1% to 2% of cases of acute pancreatitis.<sup>5</sup> Populations at higher risk of xenobiotic-induced pancreatitis include children, women, elderly adults, and patients with HIV and inflammatory bowel disease.<sup>5</sup> Acute pancreatitis is defined as having 2 of the following 3 criteria: (1) abdominal pain consistent with acute pancreatitis, (2) serum amylase or lipase greater than 3 times the upper limit of normal (although amylase, which is also released by salivary glands, is less specific and often unnecessary), and (3) characteristic findings of acute pancreatitis on CT scan.<sup>57</sup> The diagnosis of xenobiotic-induced pancreatitis can be impossible to confirm because no diagnostic test or pattern of injury distinguishes xenobiotic-induced pancreatitis from other etiologies. However, the symptoms and laboratory abnormalities associated with xenobiotic-induced pancreatitis tend to resolve shortly after withdrawal of the offending xenobiotic; again, this is often challenging to differentiate from the natural course of mild to moderate disease. It is unclear whether rechallenge with an offending xenobiotic will cause pancreatitis again; however, any xenobiotic suspected of causing pancreatitis should be withheld unless the benefits outweigh this risk. The management of xenobiotic-induced pancreatitis does not differ from other causes and hinges on volume resuscitation, bowel rest, and careful monitoring.

Numerous xenobiotics are associated with pancreatitis, each with varying levels of quality and quantity of evidence; representative xenobiotics are listed in Table 18–7.<sup>4,24</sup> The pathogenic mechanism varies among xenobiotics. The nucleoside reverse transcriptase inhibitor didanosine and dioxin promote pancreatitis as a result of mitochondrial injury.<sup>38,45,49</sup> Cholinergic xenobiotics, such as parathion and certain scorpion venoms, result in pancreatitis caused by overstimulation.<sup>30,43</sup> Vasospasm and ischemia are also a purported mechanism, as in cases of pancreatitis secondary to ergot alkaloids.<sup>14</sup>

The endocrine functions of the pancreas are also susceptible to injury from pancreatitis or toxic insult. Typically, this results from injury to pancreatic  $\beta$  cells leading to impaired glucose homeostasis, similar to diabetes.

**TABLE 18–7 Xenobiotics Commonly Associated with Pancreatitis**

Alcohols: ethanol, methanol
Analgesics: acetaminophen, NSAIDs, codeine
Antibiotics: isoniazid, metronidazole, sulfonamides, tetracycline
Antiepileptics: valproic acid, carbamazepine
Antiretrovirals: didanosine, nelfinavir
Cardiovascular: ACE inhibitors and ARBs, methyl dopa
Dioxin
Diuretics: loop diuretics
HMG-CoA reductase inhibitors
Hormones: corticosteroids, estrogens
Hypoglycemics: DPP-4 inhibitors
Immunosuppressants: azathioprine, corticosteroids, mesalamine
Pesticides: organic phosphorus compounds
Venoms: <i>Buthus quinquestratus</i> , <i>Tityus discrepans</i>

ACE = angiotensin-converting enzyme; ARB = angiotensin II receptor blocker; DPP-4 = dipeptidyl peptidase-4 inhibitors; NSAIDs = nonsteroidal antiinflammatory drugs.

Streptozotocin is notable for its toxicity to pancreatic  $\beta$  cells and ability to induce diabetes in animal models. In one study of patients after episodes of alcoholic pancreatitis, more than one third developed impaired glucose tolerance.<sup>46</sup> There are rare xenobiotics that cause damage to  $\alpha$  cells in animal models; however, they do not consistently cause hypoglycemia (Table 18–8).

### Constipation

Decreased stooling (fewer than 3 bowel movements a week) associated with abdominal pain is a major source of morbidity for patients taking opioids and other drugs that slow gastric emptying and decrease gut motility. In its most extreme form, severe constipation is associated with bowel obstruction and perforation. The bowel function index, a simple 3-item assessment, is useful for assessing opioid induced constipation (OIC).<sup>2</sup> Novel therapeutics for OIC include peripherally acting  $\mu$ -opioid receptor antagonists (PAMORAs) such as prolonged-release naloxone, methylnaltrexone, and naloxegol. Additional therapies aimed at altering fluid secretion include lubiprostone and linaclotide.<sup>36</sup> As OIC affects up to 40% of patients on long-term opioids, this is an active area of drug development.

### FOREIGN BODIES

The esophagus is the most common site of impaction from symptomatic foreign bodies. They tend to be found just proximal to a pathologic esophageal narrowing or in one of 3 anatomic places: at the cervical esophagus near the cricopharyngeus muscle, at the level of the aortic arch, or just above the gastroesophageal junction. The likelihood that a foreign object will lodge in the esophagus is related to its size and shape. The major complications of foreign bodies in the esophagus include pain, bleeding, obstruction, or perforation, which sometimes lead to subsequent mediastinitis or fistula.

**TABLE 18–8 Xenobiotics Associated with Endocrine Pancreatic Dysfunction**

#### $\alpha$ Cells of the pancreas

Cobalt salts	Decamethylene diguanidine
--------------	---------------------------

#### $\beta$ Cells of the pancreas

Alloxan	Glucocorticoids
Androgens	Growth hormone
Cyclizine	Pentamidine
Cyproheptadine	Somatostatin
Diazoxide	Streptozocin
Epinephrine	Sulfonamides
Glucagon	Vacor

They are often managed conservatively up to 12 hours after ingestion of the esophageal foreign body. If serial radiographs demonstrate no movement after 12 hours, endoscopic retrieval or surgery should be considered because the risk of perforation increases after that time; some authors extend this observation period to 24 hours.<sup>25</sup> Ingestion of button batteries proves an important exception to this rule. Esophageal button batteries can cause significant mucosal injury in 2 to 4 hours, with perforation in as little as 6 hours.<sup>33</sup> Proposed mechanisms for the rapid development of esophageal injury include alkaline burn, local current, and pressure necrosis (Chap. 103). Most recently, almost all button battery ingestions associated with serious or fatal outcomes were 20-mm lithium batteries, dangerous for their large size and higher voltage.<sup>32,33,50</sup> Of note, lithium batteries do not contain an alkali solution, lending support to the concept that electrical current results in morbidity rather than leakage of caustic battery contents. All suspected esophageal button batteries should therefore undergo immediate endoscopic removal within 2 hours; success rates with this modality are reported as excellent. Button batteries that are in the stomach or beyond should be allowed to pass spontaneously in asymptomatic patients. Some authors suggest removal of button batteries from the stomach to prevent injury.<sup>40</sup> Early research on specialized battery coatings to reduce mucosal injury during ingestion is promising.<sup>31</sup>

Foreign bodies are also commonly found in the stomach. Many small foreign bodies pass through the stomach and the remainder of the GI tract without difficulty. Objects greater than 5 cm in length or 2 cm in diameter are frequently unable to traverse the duodenum and require endoscopic or surgical removal. Foreign bodies beyond the duodenum usually do not require any intervention except observation; however, some objects become lodged at the ileocecal valve. Serial examinations and radiographs are used for asymptomatic patients; however, increasing abdominal pain or tenderness mandates further imaging and surgical consultation. Recent increase in pediatric ingestion of strong, small magnets present an exception to these recommendations. Multiple magnets attract across bowel walls, preventing transit and leading to intestinal perforation. Ingestion of a single magnet does not increase morbidity and should be managed as a benign foreign body above, but the ingestion of multiple magnets should be managed aggressively with surgical consultation for removal.<sup>56</sup> Body packers represent an unusual exception to these rules. Patients who are discovered to be internally concealing large quantities of illicit drugs frequently require whole-bowel irrigation to facilitate transit of colonic packets and even emergency laparotomy for obstruction or suspected packet rupture in cases of cocaine or methamphetamine smuggling<sup>58</sup> (Special Considerations: SC5).

### SUMMARY

- The GI tract is vulnerable to a wide variety of pathogenic organisms.
- The GI tract modulates absorption and metabolism of xenobiotics.
- Normal GI tract function is dependent on the presence of metabolically active endogenous flora.
- The GI tract involves a complex interplay of regulatory hormones.
- As function follows structure, effects of various xenobiotics are often related to the specific parts of the GI tract that are affected.

## GENITOURINARY PRINCIPLES

Jason Chu

The genitourinary system encompasses 2 major organ systems, the reproductive and the urinary systems. Successful reproduction requires interaction between 2 sexually mature individuals. Xenobiotic exposures to either individual can have an adverse impact on fertility, which is the successful production of children, and fecundity, which is an individual's or a couple's capacity to produce children. The role of occupational and environmental exposures in the development of infertility is difficult to define.<sup>12,42,88</sup> Well-designed and conclusive epidemiologic studies are lacking because of the following factors: laboratory tests used to evaluate fertility are relatively unreliable, clinical endpoints are unclear, xenobiotic exposure is difficult to monitor, and indicators of biologic effects are imprecise. Although the negative impact of xenobiotics on fertility is often ignored, infertility evaluations are incomplete without a thorough xenobiotic exposure and occupational history. Differences in the toxicity of xenobiotics in individuals are sex related, age related, or both. Xenobiotic-related, primary infertility is the result of effects on the hypothalamic–pituitary–gonadal axis or a direct toxic effect on the gonads.<sup>76</sup> Fertility is also affected by exposures that cause abnormal sexual performance. **Table 19–1** lists xenobiotics associated with infertility.

Aphrodisiacs are used to heighten sexual desire and to counteract sexual dysfunction. Humans have long sought the perfect aphrodisiac. However, of those tried, their effectiveness is variable, and toxic consequences occur commonly. Particularly popular are the various treatments for male sexual dysfunction, or erectile dysfunction.

Although many people search for a cure for impotence or infertility, others explore xenobiotics that can be used as abortifacients. Routes of administration used include oral, parenteral, and intravaginal, with an end result of pregnancy termination. However, many of these xenobiotics produce systemic toxic effects on the mother and a nonaborted fetus.

This chapter examines these issues, as well as the impact of xenobiotics on the urinary system, specifically, urinary retention and incontinence, and abnormalities detected in urine specimens. Renal (Chap. 27), reproductive (Chap. 31), and oncologic (Chap. 23) principles are discussed elsewhere in this text.

### MALE FERTILITY

Male fertility is dependent on a normal reproductive system and normal sexual function. The male reproductive system is composed of the central nervous system (CNS) endocrine organs and the male gonads. The hypothalamus and the anterior pituitary gland form the CNS portion of the male reproductive system. Both organs begin low-level hormone secretion as early as in utero gestation. At puberty, the hypothalamus begins pulsatile secretion of gonadotropin-releasing hormone (GnRH). This stimulates the anterior pituitary gland to release follicle-stimulating hormone (FSH) and luteinizing hormone (LH) in a similarly pulsatile fashion. The hormones exert their effects on the male target organs, inducing spermatogenesis and secondary body sexual characteristics.

Disruption of the normal function of any part of the system affects fertility. A number of xenobiotics adversely affect the male reproductive system and sexual function as shown in **Fig. 19–1**.

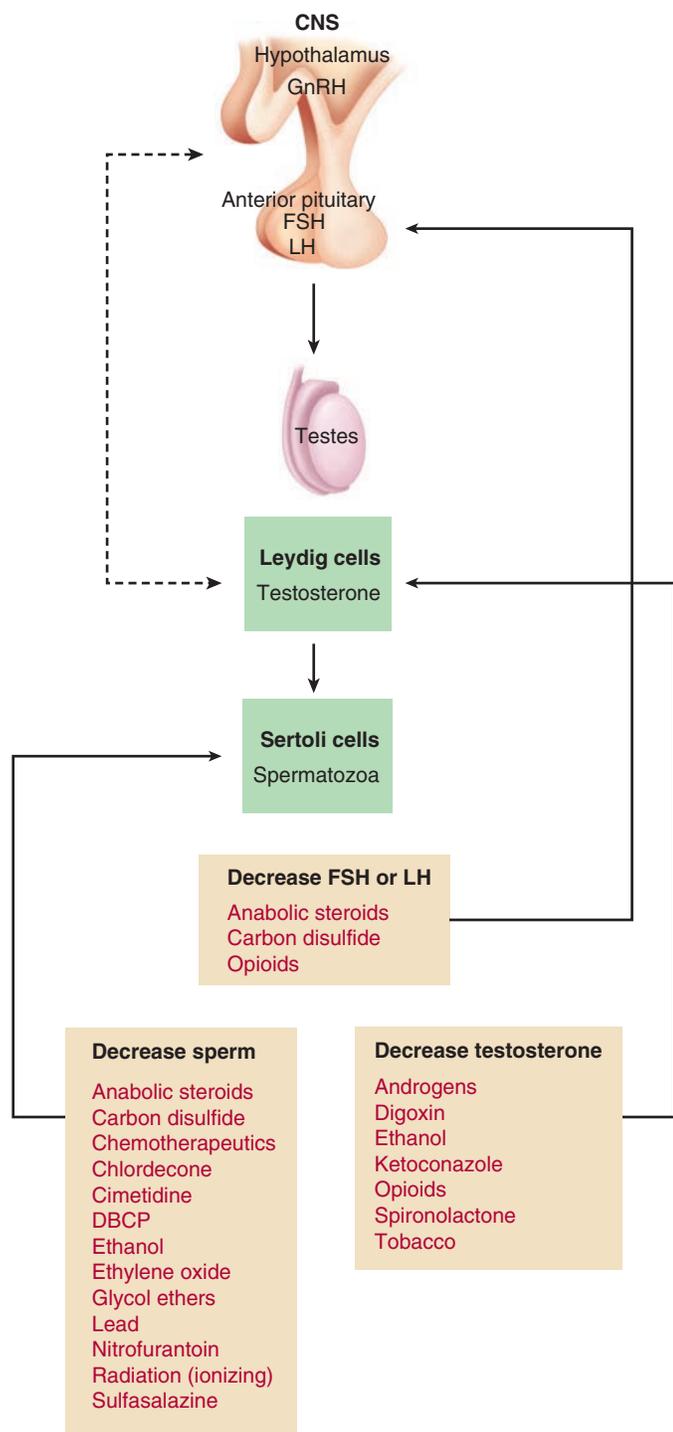

### Spermatogenesis

Central to the male reproductive system is the process of spermatogenesis, which occurs in the testes. The bulk of the testes consist of seminiferous tubules with germinal spermatogonia and Sertoli cells. The remainder of the gonadal tissue is interstitium with blood vessels, lymphatics, supporting

**TABLE 19–1** Xenobiotics Associated with Infertility

<i>Men</i>	
<i>Xenobiotic</i>	<i>Effects</i>
Anabolic steroids	↓ LH, oligospermia
Androgens	↓ Testosterone production
Benzene	Chromosomal aberrations in sperm
Carbon disulfide	↓ FSH, ↓ LH, ↓ spermatogenesis
Chemotherapeutics	Gonadal toxicity
Chlorambucil	Oligospermia
Combination chemotherapy (CVP, MOPP, MVPP)	Oligospermia
Cyclophosphamide	Oligospermia
Methotrexate	Oligospermia
Chlordecone	Asthenospermia, oligospermia
Cimetidine	Oligospermia
Dibromochloropropane	Azoospermia, oligospermia
Diethylstilbestrol	Testicular hypoplasia
Ethanol	↓ Testosterone production, Leydig cell damage, asthenospermia, oligospermia, teratospermia
Ethylene oxide	Asthenospermia (in monkeys), oligospermia
Glycol ethers	Azoospermia, oligospermia, testicular atrophy
2-Ethoxyethanol	
2-Methoxyethanol	
Lead	↓ Spermatogenesis, asthenospermia, teratospermia
Nitrofurantoin	↓ Spermatogenesis
Opioids	↓ LH, ↓ testosterone
PCBs	↓ Sperm motility
Radiation (ionizing)	↓ Spermatogenesis
Styrene	Oligospermia
Sulfasalazine	↓ Spermatogenesis
Tobacco	↓ Testosterone
<i>Women</i>	
<i>Xenobiotic</i>	<i>Effects</i>
Chemotherapeutics	Gonadal toxicity
Cyclophosphamide	Ovarian failure
Busulphan	Amenorrhea
Combination chemotherapy	Amenorrhea
Diethylstilbestrol	Spontaneous abortions
Ethylene oxide	Spontaneous abortions
Lead	Spontaneous abortions, still births
Oral contraceptives	Affect hypothalamic–pituitary axis, end-organ resistance to hormones, amenorrhea
Thyroid hormone	↓ Ovulation

CVP = cyclophosphamide, vincristine, and prednisone; DBCP = dibromochloropropane; FSH = follicle-stimulating hormone; LH = luteinizing hormone; PCB = polychlorinated biphenyl.

**FIGURE 19–1.** Schematic of the male reproductive axis and sites of xenobiotic effects. CNS = central nervous system; DBCP = dibromochloropropane; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone.

cells, and Leydig cells. Spermatogenesis begins with the maturation and differentiation of the germinal spermatogonia. The process is controlled by the secretion of GnRH from the hypothalamus, which in turn stimulates the pituitary to release FSH and LH. Follicle-stimulating hormone stimulates the development of Sertoli cells in the testes, which are responsible for the maturation of spermatids to spermatozoa. Luteinizing hormone promotes production of testosterone by Leydig cells. Testosterone concentrations must be maintained to ensure the formation of spermatids.<sup>21</sup> Both FSH and testosterone are required for initiation of spermatogenesis, but testosterone alone is sufficient to maintain the process.

### Testicular Xenobiotics

Xenobiotics can affect any part of the male reproductive tract, but invariably, the end result is decreased sperm production defined as oligospermia, or absent sperm production, azoospermia. In contrast to oogenesis in women, spermatogenesis is an ongoing process throughout life that is inhibited by decreases in FSH or LH or by Sertoli cell toxicity. Spermatogenic capacity is evaluated by semen analysis, including sperm count, motility, sperm morphology, and penetrating ability. Normal sperm count is greater than 40 million sperm/mL semen, and a count less than 20 million/mL is indicative of infertility.<sup>21</sup> Decreased motility (asthenospermia) less than 40% of normal or abnormal morphology (teratospermia) of greater than 40% of the total number of sperm also indicates infertility.<sup>21,102</sup>

### Physiology of Erection

The penis is composed of 2 corpora cavernosa and a central corpus spongiosum. The internal pudendal arteries supply blood to the penis via 4 branches. Blood outflow is via multiple emissary veins draining into the dorsal vein of the penis and plexus of Santorini. Within the penis, the corpora cavernosa share vascular supply and drainage because of extensive arteriolar, arteriovenous, and sinusoidal anastomoses.<sup>121</sup> Erection occurs when penile blood flow is greater than 20 to 50 mL/min, and tumescence is maintained with flow rates of 12 mL/min. The tunica albuginea limits the absolute size of erection.

In the flaccid state, sympathetic efferent nerves maintain arteriole constriction primarily through norepinephrine-induced  $\alpha$ -adrenergic agonism. Whereas  $\alpha$ -adrenergic receptor agonism in the erectile tissues decreases cyclic adenosine monophosphate (cAMP) to produce flaccidity,  $\alpha$ -adrenergic antagonism can result in pathologic erection (priapism) as a consequence of parasympathetic dominance.<sup>121</sup> Other endogenous vasoconstrictors, such as endothelin, prostaglandin  $F_{2\alpha}$  ( $PGF_{2\alpha}$ ), and thromboxane  $A_2$ , play a role in maintaining corpus cavernosal smooth muscle tone in contraction, which results in a flaccid state.<sup>83</sup>

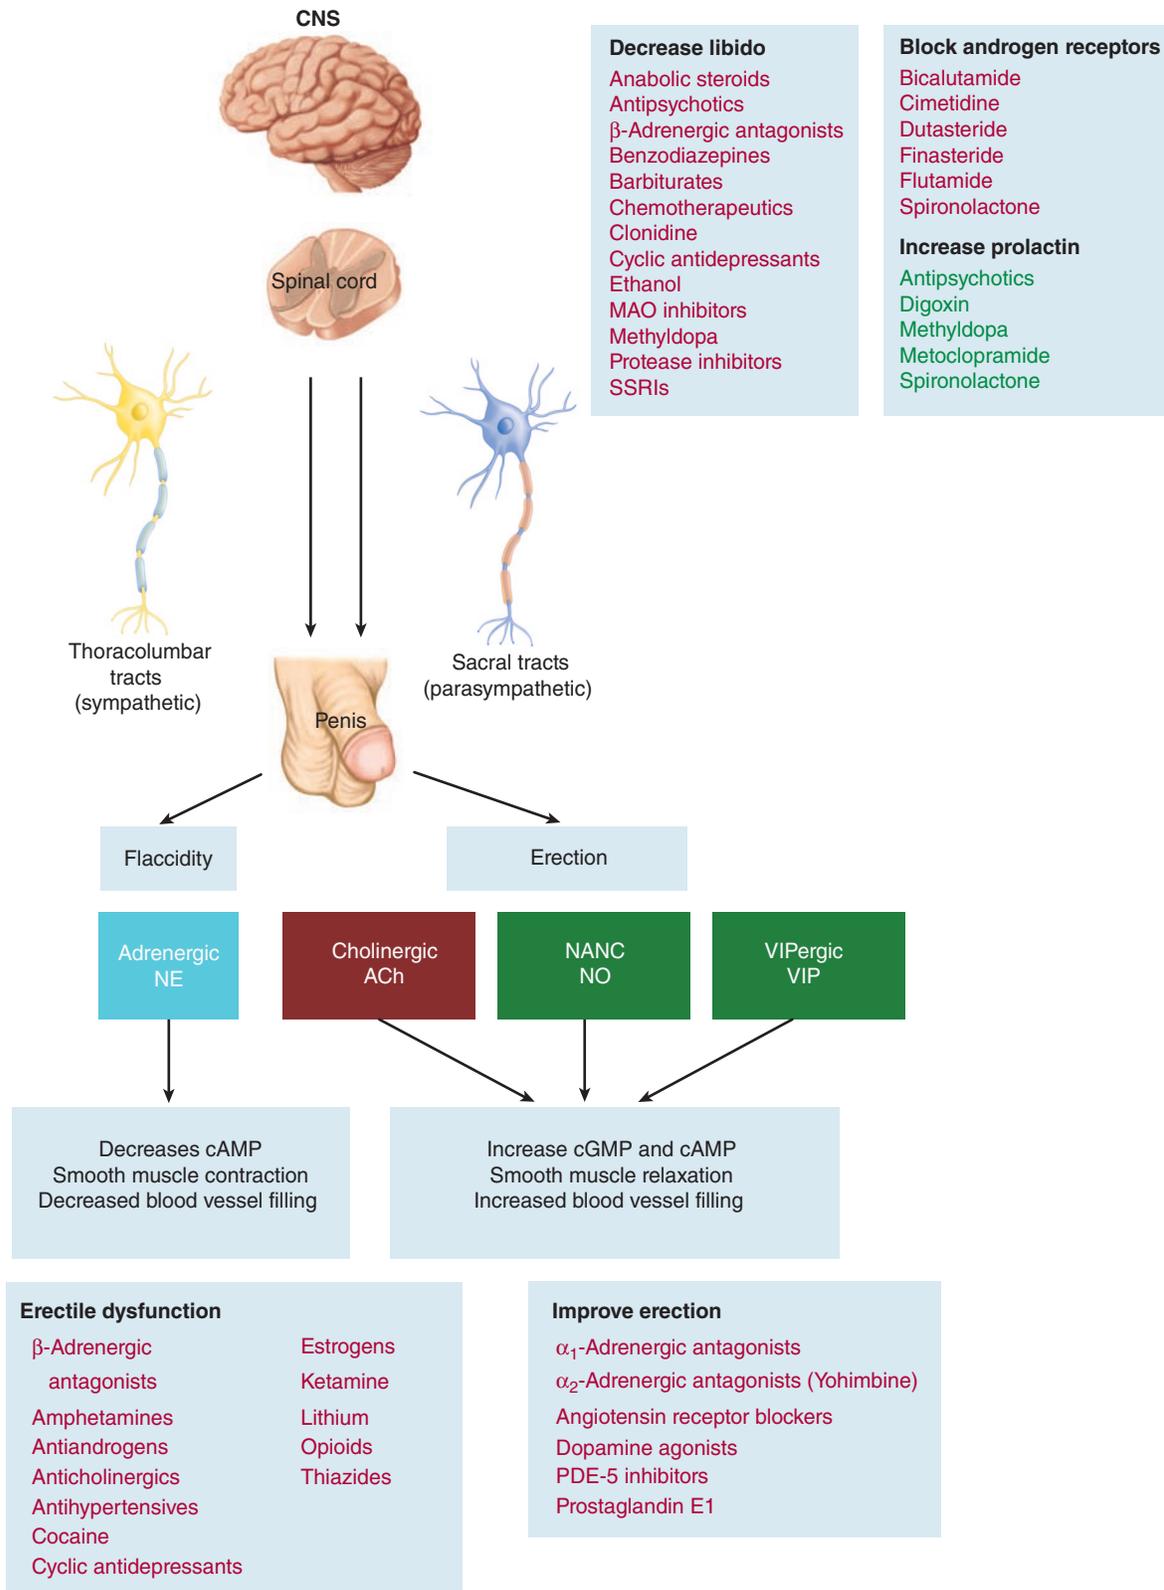

Normal penile erection is a result of both neural and vascular effects. Psychogenic neural stimulation arising from the cerebral cortex inhibits norepinephrine release from thoracolumbar sympathetic pathways, stimulates nitric oxide (NO) and acetylcholine release from sacral parasympathetic tracts, and stimulates acetylcholine release from somatic pathways.<sup>83</sup> Reflex stimulation also occurs from the sacral spinal cord. The pudendal nerves supply the afferent limb and the nervi erigentes (pelvic splanchnic nerves) supply the efferent limb of the reflex arc.

The central impulses stimulate various neurotransmitters to be released by peripheral nerves in the penis. Nonadrenergic–noncholinergic nerves and endothelial cells produce NO, which is the principal neurotransmitter mediating erection.<sup>85</sup> Nitric oxide activates guanylate conversion of guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP). Increasing concentrations of cGMP act as a second messenger, mediating arteriolar and trabecular smooth muscle relaxation to enable increased cavernosal blood flow and penile erection.<sup>83</sup> Both cGMP and cAMP pathways mediate smooth muscle relaxation. Cholinergic nerves release acetylcholine, which stimulates endothelial cells via  $M_3$  receptors to produce NO and prostaglandin  $E_2$  ( $PGE_2$ ). Prostaglandin  $E_2$  and nerves containing vasoactive intestinal peptide (VIP) and calcitonin gene-related peptide (CGRP) increase cellular cAMP to potentiate smooth muscle relaxation.

Penile corpus cavernosal smooth muscle relaxation allows increased blood flow into the corpus cavernosal sinusoids. Expansion of the sinusoids compresses the venous outflow and enables penile erection (Fig. 19–2).

### Male Sexual Dysfunction

The sexual response cycle is divided in 4 stages—sexual desire or libido, sexual arousal of the genitalia, orgasm, and resolution.<sup>99</sup> Dopamine, melatonin, testosterone, and estrogen facilitate libido. Libido is decreased by xenobiotics that either block central dopaminergic or adrenergic pathways while xenobiotics that increase dopamine improve sexual function.

**FIGURE 19-2.** Schematic of erection and xenobiotics that cause sexual dysfunction. ACh = acetylcholine; cAMP = cyclic adenosine monophosphate; cGMP = cyclic guanosine monophosphate; MAOI = monoamine oxidase inhibitor; NANC = nonadrenergic-noncholinergic; NE = norepinephrine; NO = nitric oxide; PDE = phosphodiesterase; VIP = vasoactive intestinal peptide; SSRI = selective serotonin reuptake inhibitor.

Acetylcholine, NO, norepinephrine, melanocortin, testosterone, estrogen and dopamine mediate arousal. Sexual dysfunction is caused by xenobiotics that decrease testosterone production and by xenobiotics that produce dysphoria. Norepinephrine promotes orgasm and male ejaculation. Male sexual dysfunction can result from decreased libido, erectile dysfunction (impotence), and diminished ejaculation. Xenobiotics that increase prolactin decrease libido, and xenobiotics that increase serotonin decrease libido, arousal and orgasm.<sup>64</sup> Xenobiotics that affect spinal reflexes cause diminished ejaculation and erectile dysfunction.<sup>119</sup>

Approximately 30 million men in the United States have erectile dysfunction, with an increased prevalence in older men.<sup>5</sup> Erectile dysfunction is defined as the inability to achieve or maintain an erection for a sufficiently long period of time to permit satisfactory sexual intercourse<sup>5</sup> and is divided into the following classifications: psychogenic, vasculogenic, neurologic, endocrinologic, and xenobiotic-induced. Xenobiotic-induced erectile dysfunction is associated with the following classes of xenobiotics: antidepressants, antipsychotics, centrally and peripherally acting antihypertensives, CNS depressants, anticholinergics, exogenous hormones, antibiotics, and chemotherapeutics.<sup>71,101,119</sup> Treatment of this disorder is varied based on the etiology and includes vacuum-constriction devices, penile prostheses, vascular surgery, and medications that can be administered via the intracavernosal, transdermal, and oral routes.

### Antihypertensives

Erectile dysfunction is reported as an adverse effect with many antihypertensives, and is caused, in part, by a decrease in hypogastric artery pressure, which impairs blood flow to the pelvis.<sup>119</sup> Centrally acting  $\alpha_2$ -adrenergic agonists treat hypertension by inhibiting sympathetic outflow from the brain but this in turn causes male sexual dysfunction.<sup>89</sup> Erectile dysfunction associated with thiazide diuretics are related to decreased vascular resistance, diverting blood from the penis.<sup>22</sup> Spironolactone acts as an antiandrogen by inhibiting the binding of dihydrotestosterone to its receptors. Impotence related to use of  $\beta$ -adrenergic antagonists is caused by unopposed  $\alpha$ -adrenergic-mediated vasoconstriction resulting in reduced penile blood flow and decreased testosterone and FSH concentrations.<sup>30,37</sup> Nebivolol has lower incidences of erectile dysfunction compared to other  $\beta$ -adrenergic antagonists, which is likely due to its ability to increase tissue nitric oxide leading to improved erectile function.<sup>20</sup> Calcium channel blockers, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin receptor blockers have a neutral or beneficial effect on erectile function.<sup>30</sup> Angiotensin II vasoconstriction leads to erectile dysfunction, but ACE inhibitors and angiotensin receptor blockers inhibit angiotensin II production in the corpus cavernosum.<sup>14</sup>

### Ethanol

Ethanol is directly toxic to Leydig cells. Chronic ethanol abuse causes decreased libido and erectile dysfunction and is associated with testicular atrophy. In people with alcoholism, liver disease contributes to sexual dysfunction resulting from decreased testosterone and increased estrogen production or decreased breakdown. People with alcoholism develop autonomic neuropathies affecting penile nerves and subsequent erection. Men who drink heavily have more erectile dysfunction than episodic drinkers.<sup>118</sup>

### Antidepressants and Antipsychotics

Individuals who take psychoactive medications therapeutically have varying degrees of sexual dysfunction related to their underlying disease and their medications. Antidepressant and antipsychotic inhibition of male sexual function is multifactorial and includes serotonin effects on 5HT<sub>2</sub> receptors, anticholinergic, antihistaminergic,  $\alpha$ -adrenergic receptor antagonism, dopamine blockage, and increased prolactin.<sup>63,64</sup> Monoamine oxidase inhibitors (MAOIs), cyclic antidepressants (CAs), antipsychotics, and selective serotonin reuptake inhibitors (SSRIs) are associated with decreased libido and erectile dysfunction in men.<sup>34</sup> Thioridazine is associated with significantly lower LH and testosterone concentrations in men in comparison with other antipsychotics.<sup>21</sup> Antidepressants such as bupropion, nefazodone,

**TABLE 19–2** Xenobiotics Associated with Sexual Dysfunction (Particularly Diminished Libido and Erectile Dysfunction)

$\alpha_1$ -Adrenergic antagonists	Chemotherapeutics
$\alpha_2$ -Adrenergic agonists	Alkylating agents
$\beta$ -Adrenergic antagonists <sup>a</sup>	Cytarabine
Amphetamines	Methotrexate
Anabolic steroids	Vinca alkaloids
Antiandrogens <sup>a</sup>	Cimetidine
Flutamide	Cocaine
Anticholinergics <sup>a</sup>	Digoxin
Antidepressants	Diuretics
Monamine oxidase inhibitors <sup>a</sup>	Loop diuretics
Selective serotonin reuptake inhibitors	Spironolactone
Selective serotonin/norepinephrine reuptake inhibitors	Thiazides
Cyclic antidepressants	Ethanol

Antipsychotics	Ketoconazole
Phenothiazines	Lead
Benzodiazepines	Lithium
	Opioids

<sup>a</sup>Associated with erectile dysfunction.

mirtazapine, and duloxetine have lower incidences of sexual dysfunction in comparison with other antidepressants.<sup>103</sup> Table 19–2 lists xenobiotics associated with sexual dysfunction.

## Xenobiotics Used in the Treatment of Erectile Dysfunction

### Intracavernosal and Intraurethral

Alprostadil (PGE<sub>1</sub>) and papaverine are the most commonly used individual intracavernosal xenobiotics for erectile dysfunction, and combination therapies include alprostadil, papaverine, phentolamine, and atropine. Papaverine is a benzyloisoquinoline alkaloid derived from the poppy plant *Papaver somniferum*. It exerts its effects through nonselective inhibition of phosphodiesterase (PDE), leading to increased cAMP and cGMP concentrations and subsequent cavernosal vasodilation.<sup>55</sup> Papaverine was used for the treatment of cardiac and cerebral ischemia but had limited efficacy. Presently, it is used as intracavernosal therapy for erectile dysfunction alone or in conjunction with phentolamine. Systemic adverse effects include dizziness, nausea, vomiting, hepatotoxicity, metabolic acidosis with elevated lactate concentration with oral administration, and cardiac dysrhythmias with intravenous use. Intracavernosal administration is associated with penile fibrosis, which is related to the frequency and duration of administration, although fibrosis also occurs with limited use.<sup>65</sup> More concerning is the development of priapism with papaverine use.

Alprostadil is a nonspecific agonist of PG receptors resulting in increased concentrations of intracavernosal cAMP, cavernosal smooth muscle relaxation, and penile erection.<sup>55</sup> It is effective via intracavernosal administration as monotherapy. Other preparations include an intraurethral preparation, which is less effective, and a topical gel formulation.<sup>52</sup> Penile fibrosis occurs, but the incidence is lower compared with papaverine. Other adverse effects include penile pain, secondary to its effects as a nonspecific PG receptor agonist, and priapism.

Phentolamine is a competitive  $\alpha$ -adrenergic antagonist at both  $\alpha_1$  and  $\alpha_2$  receptors in cavernosal smooth muscle. Although this increases arterial blood flow and produces erection, it is not effective as a sole therapeutic.<sup>55</sup> It is usually combined with papaverine, alprostadil, or atropine as 2, 3 or 4 xenobiotic mixtures. Penile fibrosis, prolonged erection, and priapism are also more common with these xenobiotic combinations.<sup>55</sup>

**Oral**

Since the development of the PDE-5 inhibitors, oral therapy has replaced intracavernosal injections as the mainstay for treatment of erectile dysfunction. Sildenafil was the first drug developed followed by vardenafil, tadalafil, and avanafil in the United States and lodenafil, mirodenafil, and udenafil in other parts of the world. These medications share a mechanism of action but differ in their pharmacokinetics. Phosphodiesterase-5 inhibitors increase NO-induced cGMP concentrations by preventing PDE breakdown of cGMP, enhancing NO-induced vasodilation to promote penile vascular relaxation and erection.<sup>18</sup>

Sildenafil and vardenafil have similar times to peak concentration, ranging from 30 minutes to 2 hours. Avanafil has a shorter time to peak concentration (30–45 minutes) and tadalafil has a longer time to peak concentration (30 minutes to 6 hours).<sup>62</sup> The PDE-5 inhibitors have large volumes of distribution ranging from 63 L for tadalafil up to 208 L for vardenafil.<sup>62</sup> Elimination half-life is similar for avanafil, sildenafil, and vardenafil (4–5 hours), and tadalafil is longest at 17.5 hours.<sup>62</sup> Serum concentrations of sildenafil and vardenafil are increased in patients older than 65 years, hepatic dysfunction (Child Pugh A and B), severe kidney disease (creatinine clearance <30 mL/min).<sup>28</sup> Age, hepatic dysfunction, and kidney disease do not affect serum concentrations of avanafil or tadalafil.<sup>62</sup> Phosphodiesterase-5 inhibitors are metabolized primarily by the CYP3A4 pathway, with some minor metabolic activity via the CYP2C pathway for sildenafil, tadalafil, and vardenafil.<sup>62</sup> Strong CYP3A4 inhibitors like erythromycin, ketoconazole, cimetidine, protease inhibitors (indinavir, ritonavir, saquinavir), and grapefruit juice will increase PDE-5 inhibitor concentrations.<sup>54</sup> Inducers of CYP3A4 like rifampin, phenobarbital, phenytoin, and carbamazepine can decrease PDE-5 inhibitor concentrations.<sup>79</sup>

The most common adverse effects of the PDE-5 inhibitors are headache, flushing, dyspepsia, and rhinitis, which are related to PDE-1 inhibitory effects in the brain, myocardium, and vascular smooth muscle.<sup>79</sup> Blurred vision, increased light perception, and transient blue-green tinged vision are also reported and are related to the weak PDE-6 inhibition of sildenafil in the retina.<sup>51</sup> Vardenafil and tadalafil are associated with infrequent abnormal vision, including blurred and abnormal color vision.<sup>53</sup> Back pain and myalgia with PDE-5 inhibitor use is postulated to be from PDE-11 inhibition.<sup>79</sup>

More serious adverse effects of PDE-5 inhibitors include myocardial infarction, when used alone or with nitrates; subaortic obstruction; stroke; transient ischemic attack; priapism; and hearing loss.<sup>10,43,58,78,104,110</sup> Phosphodiesterase-5 inhibitors are associated with adverse bleeding events, including epistaxis, variceal bleeding, intracranial hemorrhages, and aortic dissection. The FDA updated the labeling of the PDE-5 inhibitors, warning of possible vision loss after reported cases of nonarteritic ischemic optic neuropathy associated with PDE-5 inhibitor use.<sup>6,16,43</sup>

When taken alone, the vasodilatory effects of PDE-5 inhibitors cause a modest decrease in systemic blood pressure. However, because of their mechanism of action via cGMP inhibition and vascular vasodilation, PDE-5 inhibitors can have synergistic interactions with the vasodilatory effects of nitrates, resulting in profound hypotension.<sup>18,59</sup> A study of healthy male volunteers taking sildenafil demonstrated significantly less tolerance to a nitroglycerin infusion in comparison with those who took placebo.<sup>116</sup> Because of this interaction, patients with acute myocardial ischemic syndromes using PDE-5 inhibitors should avoid taking organic nitrates as well.<sup>28</sup>  $\alpha_1$ -Adrenergic antagonists are also contraindicated with concomitant PDE-5 inhibitor use because of increased hypotensive effects.<sup>59</sup> Hypotension occurred in patients using vardenafil in combination with terazosin and tamsulosin<sup>59</sup> and in patients using tadalafil with doxazosin.<sup>60</sup> However, patients using tadalafil with tamsulosin did not develop hypotension.<sup>60</sup>

Sublingual apomorphine effects erection through activation of central dopaminergic pathways, most likely D<sub>2</sub> receptors in the paraventricular nucleus of the hypothalamus.<sup>56</sup> It reaches maximum serum concentrations within 40 to 60 minutes after sublingual administration and is metabolized hepatically with a half-life of 2 to 3 hours.<sup>9</sup> Common adverse effects

are nausea, vomiting, headache, dizziness, and syncope. Unlike the PDE-5 inhibitors, apomorphine is not associated with hypotension when used with antihypertensives, such as nitrates.

**PRIAPISM**

Priapism is defined as prolonged involuntary erection unassociated with sexual stimulation. Subtypes of priapism are ischemic (characterized by low cavernosal blood flow), nonischemic (characterized by increased arterial flow), and stuttering (recurrent ischemic priapism).<sup>82</sup> It most commonly occurs during the third and fourth decades of life and is caused by inflow of blood to the penis in excess of outflow. The corpora cavernosa become firm and the corpus spongiosum flaccid. Intracavernosal pressures exceed arterial systolic pressure, resulting in cell death. Priapism occurs from an imbalance in neural stimuli, interference with venous outflow or as a result of xenobiotic-induced inhibition of penile detumescence.  $\alpha$ -Adrenergic antagonists prevent constriction of blood vessels supplying erectile tissue, resulting in priapism.<sup>82</sup> One in 10,000 patients taking trazodone develops priapism, which is thought to be related to its  $\alpha$ -adrenergic antagonist effects.<sup>98</sup> Xenobiotics associated with priapism are listed in [Table 19–3](#).

The goal in the treatment of priapism is detumescence with retention of potency. Initial therapy includes sedation with benzodiazepines, analgesia with opioids, ice packs, treatment of underlying systemic diseases such as sickle cell disease, and early urologic consultation. In ischemic priapism, aspiration with or without 9% NaCl solution irrigation of the corpora cavernosa is effective in 24% to 36% of cases, and adding intracavernosal injection of sympathomimetic agents increases priapism resolution to 43% to 81%.<sup>82</sup> The American Urology Association guidelines recommend phenylephrine (100–500 mcg/mL solution) injection into the corpora cavernosa at a dosage of 0.5 to 1 mL every 3 to 5 minutes up to 1 hour.<sup>82</sup> Oral xenobiotics are not recommended for ischemic priapism but oral terbutaline (5–10 mg) was

effective for PGE<sub>1</sub>-induced prolonged erections.<sup>70,82,95</sup> Intracavernosal methylene blue has been used successfully as an alternative to intracavernosal sympathomimetics.<sup>74</sup> If the above measures fail, an operative venous shunt placement is often required.<sup>23</sup>

## FEMALE FERTILITY

The female reproductive system consists of the female gonadal organs and the respective hormonal system (Fig. 19–3). Fertility encompasses the reproductive system, the process of oocyte fertilization, and gestation. Female infertility results from changes in hormone concentrations, direct toxicity to the ovum, interference with the transport of the ovum, or inhibition of implantation of the ovum in the uterus. Women usually notice reproductive abnormalities more quickly than men because menses are affected, although infertility does occur while normal menses persists. Evaluation of female fertility is more difficult because of the complexity of the systems involved and the inaccessibility of the female germ cell. Investigations involve study of the anatomy and hormonal concentrations. The following is a discussion of oogenesis, xenobiotics that disrupt oogenesis, and xenobiotics that affect early embryo gestation.

### Oogenesis

In contrast to men, women have a limited number of reproductive cells (ovarian follicles). Follicles are most numerous while a fetus is in utero, with the number decreasing to approximately 2 million at birth. By the time a woman reaches puberty, the majority of follicles have degenerated, leaving 300,000 to 400,000 ova, of which approximately 400 will eventually produce mature ova during a woman's reproductive years. In contrast, men produce millions of spermatozoa each day. The process of oogenesis requires secretion of GnRH from the hypothalamus, resulting in production of LH and FSH from the pituitary, which are required for ovarian follicle maturation.<sup>21</sup> Follicle-stimulating hormone induces early maturation by stimulating granulosa and thecal cell proliferation and estrogen production. Luteinizing hormone is required for ovulation and for the formation of the corpus luteum. The corpus luteum continues estrogen production and produces progesterone, which stimulates the uterus to develop an endometrium receptive to any

fertilized ovum. Successful ovulation requires not only hormone secretion but also appropriate cyclic secretion.

## Female Sexual Dysfunction

The National Health and Social Life Survey found that 43% of women in the United States (in comparison with 31% of men) reported having sexual dysfunction.<sup>66</sup> In 2013, the *Diagnostic and Statistical Manual of Mental Disorders*, fifth edition, categorized female sexual dysfunction into female orgasmic disorder, female sexual interest/arousal disorder, which includes the previously termed hypoactive sexual desire disorder, and genito-pelvic pain/penetration disorder.<sup>2</sup> The organic etiologies of female sexual dysfunction parallel those of male sexual and erectile dysfunction: vascular, neurologic, muscular, psychogenic, endocrinologic, and xenobiotic-induced causes.<sup>15</sup> Medications implicated in female sexual dysfunction are similar to those associated with male sexual dysfunction, with antihypertensives, antidepressants, especially SSRIs, and antipsychotics as the most frequent causes.<sup>44</sup>

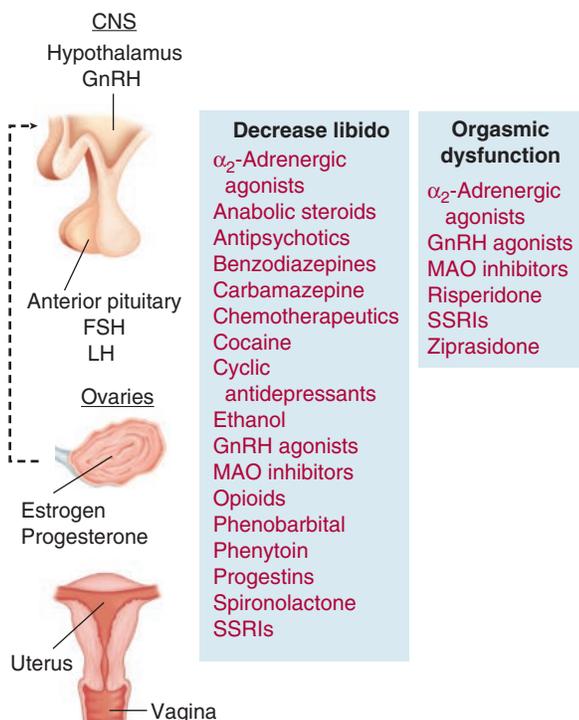

Treatments for xenobiotic-induced female sexual dysfunction include decreasing medication dosages, switching to alternate medications with less adverse effects on sexual function such as bupropion and nefazodone, temporary cessation of the medication (drug holiday), or adding another medication to stimulate sexual function. Bupropion alone was as effective as fluoxetine for the treatment of depression but with less sexual dysfunction,<sup>36</sup> and when used in conjunction with SSRIs, bupropion improved sexual function compared with SSRIs alone.<sup>26,33</sup> Sildenafil was successful for treating spinal cord–induced<sup>108</sup> and antidepressant-induced sexual dysfunction,<sup>87</sup> but larger trials had mixed results with sildenafil for sexual arousal disorder.<sup>13,25</sup> Sublingual apomorphine improved sexual function in women with hypoactive sexual disorder.<sup>24</sup>

Flibanserin is the only FDA-approved medication for generalized hypoactive sexual desire disorder (HSDD) in premenopausal women but the mechanism of action is unknown. It is a 5HT<sub>1A</sub> receptor agonist and 5HT<sub>2A</sub> receptor antagonist with weaker antagonism of 5HT<sub>2B</sub>, 5HT<sub>2C</sub>, and dopamine D4 receptors.<sup>109</sup> Flibanserin has a 33% bioavailability, mean time to maximum concentration of 0.75 hours, 98% protein binding, mean terminal half-life of 11 hours, and is hepatically metabolized by CYP3A4 and CYP2C19.<sup>97</sup> In animal studies, flibanserin decreased CNS serotonin and increased dopamine and norepinephrine concentrations.<sup>40</sup> Common adverse effects are dizziness, somnolence, nausea, fatigue, insomnia, and dry mouth; serious adverse effects are CNS depression, hypotension, and syncope.<sup>97</sup> Flibanserin is contraindicated with concomitant alcohol usage, hepatic dysfunction, and CYP3A4 inhibitors.<sup>97</sup>

Other pharmacotherapies for female sexual dysfunction are estrogen and androgen supplementation. Estrogen replacement therapy is available in oral, dermal, vaginal ring, and topical cream formulations alone or in combination with progesterone.<sup>115</sup> Estrogen therapy is associated with a higher incidence of coronary disease, breast cancer, stroke, and venous thromboembolism. Androgen therapy includes testosterone, formulated as a transdermal patch or spray; methyltestosterone; micronized testosterone; and dehydroepiandrosterone.<sup>7</sup> Adverse effects are hirsutism, acne, weight gain, increased cholesterol concentrations and virilization.<sup>7</sup>

## ABORTIFACIENTS

An abortifacient is defined as a xenobiotic that affects early embryonic gestation to induce abortion. Xenobiotics act by flushing the zygote from the fallopian tube, blocking the uterine horn inhibiting implantation, inducing fetal resorption, or producing oxytocin-like activity that results in uterine irritation and contraction. Abortifacients also indirectly affect pregnancy by altering hormonal concentrations through placental inhibition of human chorionic gonadotropin or progesterone production or through interference with progesterone receptors. Emergency contraceptive medications to prevent pregnancy include levonorgestrel as the most common single hormonal medication, ulipristal, and the combining oral hormonal contraceptive pills.<sup>35</sup> In early pregnancy, medications used for medical termination of pregnancy include mifepristone, methotrexate, prostaglandins (commonly misoprostol), or combinations of mifepristone or methotrexate with prostaglandins.<sup>61</sup>

**FIGURE 19–3.** Schematic of female reproductive axis and sites of xenobiotic action. CNS = central nervous system; FSH = follicle-stimulating hormone; GnRH = gonadotropin-releasing hormone; LH = luteinizing hormone; MAO = monoamine oxidase; SSRI = selective serotonin reuptake inhibitor.

The toxic effects of abortifacients are varied. Many produce GI effects such as abdominal pain, nausea, and vomiting. Abdominal pain is related to the oxytocic uterine effects associated with misoprostol and mifepristone, cytotoxic effects on the GI mucosa associated with methotrexate, leading to stomatitis and ulcers or hepatotoxicity associated with pennyroyal oil.<sup>29</sup> Mifepristone inhibits implantation or has abortive effects that cause severe vaginal bleeding. Other toxic effects are not necessarily

related to their abortive mechanisms but due to the specific xenobiotic. Plant-derived abortifacients such as *Aristolochia* cause nephrotoxicity; dong quai causes photosensitivity; blue cohosh causes seizure; and quinine causes cardiac dysrhythmias.<sup>86</sup> Congenital abnormalities of the scalp and skull defects, cranial nerve palsies, and limb defects such as talipes equinovarus are also reported with misoprostol use that did not terminate pregnancy (Table 19-4).<sup>29</sup>

**TABLE 19-4** Xenobiotics Used as Abortifacients

Source	Common Name	Xenobiotic	Miscellaneous/Toxicity
<i>Inhibit Implantation</i>			
<i>Abrus precatorius</i>	Jequirity pea	Abrin	GI necrosis and multisystem organ failure
<i>Acanthospermum hispidum</i>	Bristly starbur	<i>Acanthospermum hispidum</i>	Impairs implantation
<i>Aristolochia</i> spp	Birthwort	Aristolochic acid	Nephrotoxicity
<i>Momordica charantia</i>	Bitter melon	$\alpha$ -Momorcharin	Inhibits protein synthesis, ↓HCG, ↓progesterone
<i>Cajanus cajan</i>	Pigeon pea	<i>Cajanus cajan</i>	Preimplantation effects
Hormonal therapy	—	Levonorgestrel, Yuzpe regimen: estradiol–levonorgestrel	Nausea, vomiting, abdominal pain, vaginal bleeding
<i>Lagenaria breviflora</i>	Wild colocynth	<i>Lagenaria breviflora</i>	Preimplantation effects
<i>Juniperus sabina</i>	Savin	Oil of savin	Hepatotoxicity in mice
<i>Ricinus communis</i>	Castor	Ricin	GI necrosis and multisystem organ failure
<i>Ruta graveolens</i>	Rue	Chalepesin	Hepatotoxicity, nephrotoxicity, photodermatitis
Selective progesterone receptor modulator	—	Mifepristone, ulipristal	Nausea, vomiting, abdominal pain, vaginal bleeding
<i>Abortive</i>			
<i>Angelica sinensis</i>	Dong quai	Furanocoumarin, phytoestrogen	Anticoagulant effects, gynecomastia, fetal demise
<i>Daphne genkwa</i>	Lilac daphne	Yuanhuacine	
Digoxin (intrafetal)	—		Fetal demise
Lysol disinfectant	—		Death after intrauterine administration
<i>Mentha pulegium</i>	Pennyroyal	Pulegone	Hepatotoxicity
Methotrexate	—		Cytotoxic effects
Mifepristone	—		Nausea, vomiting, abdominal pain, vaginal bleeding
<i>Momordica charantia</i>	Bitter melon	$\alpha$ -Momorcharin	Inhibits protein synthesis ↓HCG, ↓progesterone
<i>Moringa oleifera</i>	Horseradish tree	<i>Moringa oleifera</i>	100% abortifacient in rats
<i>Podophyllum peltatum</i>	Mayapple	Podophyllin	Nausea, vomiting, diarrhea
<i>Ranunculus</i> spp	Buttercup	Devil's claw	Hepatotoxicity
<i>Trichosanthes kirilowii</i>	Snake gourd	Trichosanthin (compound Q)	Inhibits protein synthesis, ↓HCG, ↓progesterone
<i>Oxytocic</i>			
<i>Aristolochia</i> spp	Birthwort	Aristolochic acid	Nephrotoxicity
<i>Caulophyllum thalictroides</i>	Blue cohosh	Methylcytosine	Salivation, nausea, vomiting
<i>Cimicifuga racemosa</i>	Black cohosh	Unknown	Nausea, vomiting, headache, rare hepatotoxicity
<i>Cinchona</i> spp	Quinine bark	Quinine	Nausea, vomiting, tinnitus
<i>Claviceps purpurea</i>	Ergot	Ergotamines	Vasospasm
<i>Lagenaria breviflora</i> Robert	Wild colocynth	<i>Lagenaria breviflora</i> Robert	Inhibits implantation, oxytocic
Misoprostol	—	Prostaglandin E analogue	Teratogenicity, vascular abnormalities
Ulipristal	—	Progesterone agonist/antagonist	Headache, nausea, abdominal pain

HCG = human chorionic gonadotropin; GI = Gastrointestinal.

In a US poison control center study, 5 of 43 pregnant women who intentionally overdosed used known abortifacients, including quinine, misoprostol, methylergonovine, and oral contraceptives. Four of these patients developed vaginal bleeding and cramping, but no short-term (1–3 days) fetal demise was reported.<sup>94</sup> The use of abortifacients is more common in underdeveloped countries and in people without access to safer methods for termination or prevention of pregnancy.

## TOXICITY OF APHRODISIACS

Aphrodisiacs heighten sexual desire, pleasure, or performance and include xenobiotics from the plant, animal, and mineral kingdoms.<sup>38</sup> The search for an effective aphrodisiac has continued for thousands of years. Ancient fertility cults used *Datura*, belladonna, and henbane as aphrodisiacs. Mandrake was used in medieval Europe, and yohimbine was used by African cultures to enhance sexual performance. Yohimbine, an indole alkylamine alkaloid from the West African yohimbe tree (*Corynanthe yohimbe*), is an  $\alpha_2$ -adrenergic antagonist with cholinergic activity and structurally similar to reserpine. It is rapidly absorbed, with peak serum concentrations within 45 to 60 minutes, elimination half-life of 36 minutes, and clearance by hepatic metabolism primarily.<sup>30</sup> Maximum pharmacologic effects occur 1 to 2 hours after ingestion, and effects persist for 3 to 4 hours.<sup>69</sup> Adverse effects include anxiety, headache, confusion, seizures, coma, tachycardia, hypertension, QRS interval widening, and priapism.<sup>49</sup> It is reasonable to administer activated charcoal to symptomatic patients. Clonidine is a reasonable treatment for the central and peripheral effects of yohimbine.<sup>27</sup> Arterial vasodilators and calcium channel blockers are not routinely recommended, and  $\beta$ -adrenergic antagonists are not recommended at this time. Benzodiazepines are reasonable to administer for agitation and seizures related to yohimbine.<sup>27,49</sup>

A small sampling of other xenobiotics used as aphrodisiacs include oysters, live beetles, vitamin E, ginseng, saffron, herba epimedii (horny goat weed), *Lepidium meyenii* (maca) and *Eurycoma longifolia* Jack (tongkat ali).<sup>100,106</sup> Most published studies evaluating aphrodisiacs were conducted in animals, and little information is available in humans. Toxicity occurs from either the aphrodisiac or adulterants<sup>11</sup> (Table 19–5).

**TABLE 19–5** Xenobiotics Used as Aphrodisiacs

Xenobiotic	Toxicity
<i>Oral</i>	
Cantharidin	Vesicant actions—GI mucositis and hemorrhage, hematuria
Cathinone (hagigat)	Hypertension, tachycardia
Dapsone	Methemoglobinemia, hemolysis
Ginseng	GI distress impotence, vaginal bleeding
Lead	Anemia, abdominal pain
<i>Mandragora officinarum</i> (mandrake)	Anticholinergic
<i>Myristica fragrans</i> (nutmeg)	Hallucinogen, GI upset
<i>Tribulus terrestris</i> (Puncturevine)	Gynecomastia, seizures
Yohimbine	Paresthesias, hypertension
<i>Topical</i>	
Cantharidin	Vesicant actions—GI mucositis and hemorrhage, hematuria
Bufotoxin	Nausea, vomiting, dysrhythmias, death
<i>Inhalation</i>	
Alkyl nitrites (amyl, butyl, isobutyl nitrites)	Hemolytic anemia, methemoglobinemia, orthostasis

GI = Gastrointestinal.

Dopamine, NO, oxytocin, and ACTH facilitate sexual behavior. Dopamine stimulates the forebrain and midbrain and leads to an increase in sexual response and arousal. In animals, dopamine agonists, such as apomorphine and quinpirole, have proerectile effects through stimulation of dopamine pathways, increasing NO in the paraventricular nucleus in the hypothalamus, and releasing oxytocin.<sup>83</sup> Other preparations tested for the treatment of impotence include bromocriptine,<sup>1,17</sup> nitroglycerin,<sup>84</sup> zinc,<sup>8</sup> oxytocin,<sup>68</sup> and LH.<sup>67</sup> Endogenous opioids, GABA, and norepinephrine are associated with decreased sexual behavior. Serotonin is generally inhibitory to sexual function, but the effects are dependent on the receptor subclass. Whereas 5-HT<sub>1A</sub> receptor stimulation inhibits erection but facilitates ejaculation in rats, 5-HT<sub>2C</sub> receptors facilitate male sexual behavior.<sup>83</sup> Various serotonergic drugs, including trazodone, nefazodone, bupropion, and clomipramine, are reported to improve sexual dysfunction.<sup>98,120</sup>

## URINARY SYSTEM

The urinary system is composed of the kidneys, ureters, bladder, and urethra (Chap. 27). Many xenobiotics are concentrated by the kidneys and eliminated in the urine. The following discusses the effect of xenobiotics on the bladder and urine.

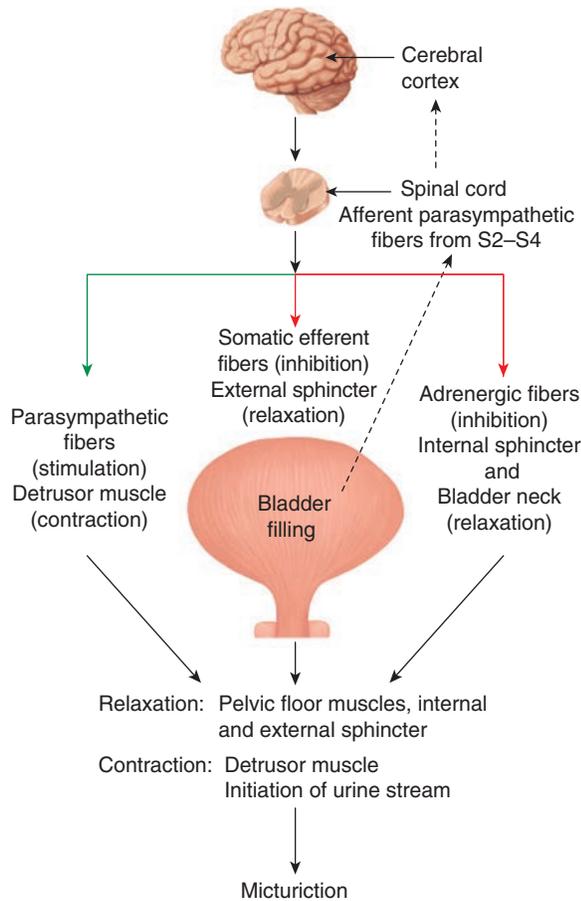

### Bladder Anatomy and Physiology

The bladder is a hollow, muscular reservoir composed of 2 parts—the body and the neck—and normally stores up to 350 to 450 mL of urine in adults. A smooth muscle, the detrusor muscle, makes up the bulk of the body and contracts during urination. Urine from the ureters enters the bladder at the uppermost part of the trigone, an area in the posterior wall of the bladder, and leaves via the neck and the posterior urethra. Surrounding the neck and posterior urethra is smooth muscle interlaced with elastic tissue to form the internal sphincter. Sympathetic innervation from the lumbar spinal cord to the internal sphincter maintains smooth muscle contraction. Distal to the internal sphincter is an area with voluntary skeletal muscle that forms the external sphincter and is innervated by somatic pudendal nerves.

The nerve supply and neurophysiology of urination involve interplay among lumbar sympathetic nerves, sacral parasympathetic nerves, and sacral somatic nerves. Figure 19–4 illustrates the physiology of micturition. With bladder filling, norepinephrine is released by sympathetic postganglionic fibers.  $\alpha$ -Adrenergic receptors predominate in the internal sphincter and the bladder neck, and  $\beta$ -adrenergic receptors supply the detrusor wall of the bladder. Stimulation of  $\alpha$ -adrenergic receptors results in internal sphincter contraction and increased bladder outlet resistance, and stimulation of  $\beta$ -adrenergic receptors leads to detrusor relaxation and bladder filling.<sup>113</sup> In micturition, parasympathetic pre- and postganglionic fibers release acetylcholine to M<sub>2</sub> and M<sub>3</sub> muscarinic receptors in the detrusor muscle. Stimulation of M<sub>3</sub> receptors is responsible for detrusor muscle contraction and bladder emptying.<sup>26</sup> Conversely, anticholinergics prevent bladder emptying and result in urinary retention.<sup>31,46</sup>

### Urinary Abnormalities

Urinary incontinence is common in elderly. As age increases, bladder size decreases, resulting in more frequent emptying. Early detrusor contraction, even with low bladder volumes, occurs more commonly in elderly adults, causing a sense of urgency. There are many etiologies for urinary incontinence, including various xenobiotic exposures (Fig. 19–5). General or regional anesthesia, bladder instrumentation, and medications produce bladder atony, leading to incontinence.<sup>31</sup> Functional incontinence also result from the use of medications, such as sedative-hypnotics and opioids, that causes impaired cognition or decreased mobility.<sup>31</sup> Xenobiotics used in the treatment of urinary incontinence include anticholinergics (darifenacin, fesoterodine, oxybutynin, solifenacin, tolterodine, trospium),  $\alpha_1$ -adrenergic antagonists, PDE<sub>5</sub> inhibitors,  $\beta_3$ -adrenergic antagonists (mirabegron), duloxetine, imipramine, and botulinum toxin A.<sup>3,32</sup> Urinary retention

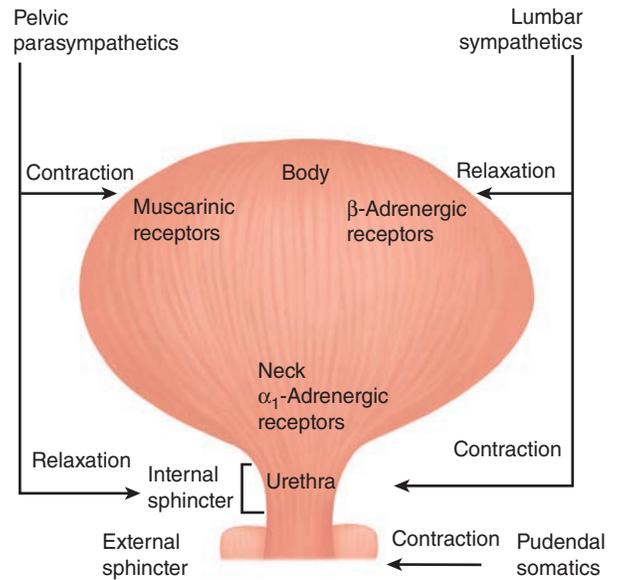

**FIGURE 19-4.** Schematic description of the physiology of micturition. (The dotted lines show the efferent pathway.)

is obstructive, neurogenic, psychogenic, or pharmacologic in origin. Medications associated with urinary retention include sympathomimetics, anticholinergics, antidysrhythmics (quinidine, procainamide, disopyramide), antidepressants, antipsychotics, hormones (progesterone, estrogen, testosterone), and muscle relaxants.<sup>31,46</sup> In men older than 50 years, benign prostatic hyperplasia is the most common cause of bladder outlet obstruction, leading to decreased urinary output and urinary retention. Treatment of benign prostatic hyperplasia consists of 5 $\alpha$ -reductase inhibitors and  $\alpha$ -adrenergic antagonists. 5 $\alpha$ -Reductase inhibitors (finasteride, dutasteride) block the conversion of testosterone to dihydrotestosterone and thereby decrease prostate volume.<sup>77</sup>  $\alpha$ -Adrenergic antagonists (doxazosin, terazosin, alfuzosin, tamsulosin) decrease urethral  $\alpha$ -adrenergic contraction.<sup>47</sup> Table 19-6 lists xenobiotics associated with urinary retention increased urinary frequency and incontinence which may be due to overflow.

**ABNORMALITIES IN URINALYSIS**

Abnormalities of the urinalysis are often useful in identifying xenobiotic exposures. Crystalluria is a common finding and while normal, the presence of crystals may aid in diagnosis. Crystal formation is dependent on supersaturation of the urine and changes in the urine temperature or pH. The most common crystals are calcium oxalate, uric acid, and phosphate. However, crystals of various xenobiotics alone or in combination with other crystals are seen in ingestions.<sup>39</sup> The urinalysis in patients who ingest ethylene glycol reveals calcium oxalate or hippurate crystals in 45% to 63% of cases.<sup>19,57</sup> Calcium oxalate crystals are monohydrates (prism or needlelike) or dihydrates (envelope shaped). Hippurate crystals are needle shaped.<sup>91</sup> Birefringent single or conglomerates of hexagonal crystals are noted after massive primidone

poisoning and result from precipitation of primidone in the urine.<sup>112</sup> Crystalluria occurs with therapeutic doses of salicylate, phenacetin, sulfonamide, and quinolones. Oral sodium phosphate preparations for bowel cleansing have caused calcium phosphate calcifications leading to acute phosphate nephropathy.<sup>72</sup> After large exposures, crystals are also seen with methotrexate, amoxicillin, cephalixin, ampicillin, and indinavir (Table 19-7).

Urine color is dependent on several factors, including pH, concentration, natural pigments, and length of time exposed to air. Normal urine

specimens should be clear and yellow in coloration. Whereas dilute urine secondary to diuretic use, diabetes mellitus, diabetes insipidus, or adequate hydration appears colorless, concentrated urine is usually orange. Fluorescein, present in some antifreeze products, is detected by illumination of the urine with a Wood lamp, although this diagnostic test has poor sensitivity and specificity for antifreeze exposure.<sup>114</sup> One study used urine samples from a group of unpoisoned children and 3 urine samples with

added sodium fluorescein to examine physicians' ability to detect urinary fluorescence with a Wood lamp against a fluorometer. The fluorometer reported fluorescence in 100% of the urine samples, but the physicians reported fluorescence in 70% to 80% of the samples.<sup>92</sup> Urinary fluorescence, even when present, is not recommended as the sole means to establish a diagnosis at this time. **Table 19–8** lists other causes of colored urine (Chap. 106).

There are multiple causes of hematuria<sup>73</sup> (**Table 19–9**). It can occur with xenobiotic-induced interstitial nephritis, a condition distinguished by fever, rash, eosinophilia, eosinophiluria, azotemia, and oliguria.<sup>41</sup> Hemorrhagic cystitis is a more frequent cause of hematuria and is associated with a number of xenobiotics. The clinical presentation of hemorrhagic cystitis includes hematuria, dysuria, and urinary frequency. Criteria for diagnosis of hemorrhagic cystitis include a history of gross hematuria, laboratory findings, of microscopic hematuria (>3 red blood cells/high-power field), platelet count above 50,000/mm<sup>3</sup>, and a negative urine culture result.<sup>96</sup> When in doubt, the diagnosis is confirmed by cystoscopy, which reveals an inflamed, hyperemic, and sometimes ulcerated bladder mucosa.

Cyclophosphamide-related hemorrhagic cystitis was first described in 1959 and is the best-documented type of xenobiotic-induced hemorrhagic cystitis.<sup>81</sup> As many as 40% to 60% of patients receiving cyclophosphamide develop hemorrhagic cystitis.<sup>117</sup> Acrolein, the causative xenobiotic, is a metabolite of cyclophosphamide that damages the urothelium when excreted (Chap. 50).<sup>111</sup> Cyclophosphamide and ifosfamide-induced hemorrhagic cystitis is reduced with mesna therapy.<sup>4</sup>

An outbreak of hemorrhagic cystitis occurred in workers in a packaging plant after exposure to chlordimeform, a formamidine insecticide used to control mites and insects on cotton. Nine workers developed abdominal pain, dysuria, urgency, and hematuria, with biopsy-proven hemorrhagic cystitis.<sup>45</sup> Eight young adults developed painful hematuria after consuming "bootleg" methaqualone. The cause was orthotoluidine, a compound used in the synthesis of methaqualone, and the findings occurred within 6 hours of ingestion.<sup>50</sup> Chronic ketamine and methoxetamine abuse is associated with the development of hemorrhagic ulcerative cystitis<sup>105</sup> (**Fig. 83–2**). Rare cases of hemorrhagic cystitis are also described with ticarcillin, nafcillin, penicillin G, carbenicillin, piperacillin, isoniazid, indomethacin, tiaprofenic acid, and busulphan.<sup>48,75,80,107</sup>

Treatment for hemorrhagic cystitis includes bladder irrigation with saline, alum, prostaglandins, silver nitrate, formalin, and phenol. Systemic therapy include estrogens, vasopressin, aminocaproic acid, and hyperbaric oxygen.<sup>117</sup> These therapies have inherent adverse effects as well. Aluminum toxicity was reported with alum bladder irrigation for hemorrhagic cystitis in patients with kidney failure.<sup>93</sup>

## SUMMARY

- Xenobiotics decrease fertility and fecundity by decreasing FSH and LH centrally or altering sperm production in men and altering ovarian function in women.
- Xenobiotics that increase CNS serotonin or prolactin or decrease CNS urinary frequency dopamine cause sexual dysfunction by decreasing libido in men and women.
- Therapies for erectile dysfunction increase local nitric oxide production via cyclic AMP and cyclic GMP to increase penile blood flow but can result in priapism.
- Abortifacients usually prevent embryo implantation or induce uterine contractions leading to increased vaginal bleeding and abdominal pain.
- Xenobiotics alter bladder function to cause urinary retention or incontinence (at times due to overflow) as well as change the characteristics of urine in terms of color, hematuria, or crystal formation.

# HEMATOLOGIC PRINCIPLES

Marco L. A. Sivilotti

Blood is rightfully considered the vital fluid, because every organ system depends on the normal function of blood. Blood delivers oxygen and other essential substances throughout the body, removes waste products of metabolism, transports hormones from their origin to site of action, signals and defends against threatened infection, promotes healing via the inflammatory response, and maintains the vascular integrity of the circulatory system through the clotting cascade. It also serves as the central compartment in classical pharmacokinetics and thereby comes into direct contact with virtually every systemic xenobiotic that acts on the organism.<sup>92</sup> The ease and frequency with which blood is assayed, its central role in functions vital to the organism, and the ability to analyze its characteristics, at first by light microscopy and more recently with molecular techniques, have enabled a detailed understanding of blood that continues to advance the frontiers of molecular medicine.

In addition to transporting xenobiotics throughout the body, blood and the blood-forming organs can at times be directly affected by these same xenobiotics. For example, decreased blood cell production, increased blood cell destruction, alteration of hemoglobin, and impairment of coagulation can all result from exposure to xenobiotics. The response in many cases depends on the nature and quantity of the xenobiotic as well as the capacity of the system to defend against the insult. In other cases, no clear and predictable dose–response relationship can be determined, especially when the interaction involves the immune system. These latter reactions are often termed idiosyncratic, reflecting an incomplete understanding of their causative mechanism. In general, such reactions can often be reclassified when advancing knowledge identifies the characteristics that render the individual vulnerable.

## HEMATOPOIESIS

Hematopoiesis is the development of the cellular elements of blood. The majority of the cells of the blood system are classified as either lymphoid (B, T, and natural killer lymphocytes) or myeloid (erythrocytes, megakaryocytes, granulocytes, and monocytes). All of these cells originate from a small common pool of totipotent cells called *hematopoietic stem cells*. Indeed, the study of this process and its regulation has provided fundamental insight into embryogenesis, stem cell pluripotency, and complex cell-to-cell signaling and interaction.

### Bone Marrow

Marrow spaces within bone begin to form in humans at about the fifth fetal month and become the sole site of granulocyte and megakaryocyte proliferation. Erythropoiesis moves from the liver to the marrow by the end of the last trimester. At birth, all marrow contributes to blood cell formation and is red, containing very few fat cells. By adulthood, the same volume of hematopoietic marrow is normally restricted to the sternum, ribs, pelvis, upper sacrum, proximal femora and humeri, skull, vertebrae, clavicles, and scapulae. Extramedullary hematopoiesis in the liver and spleen reemerges as a compensatory mechanism only under severe stimulation.

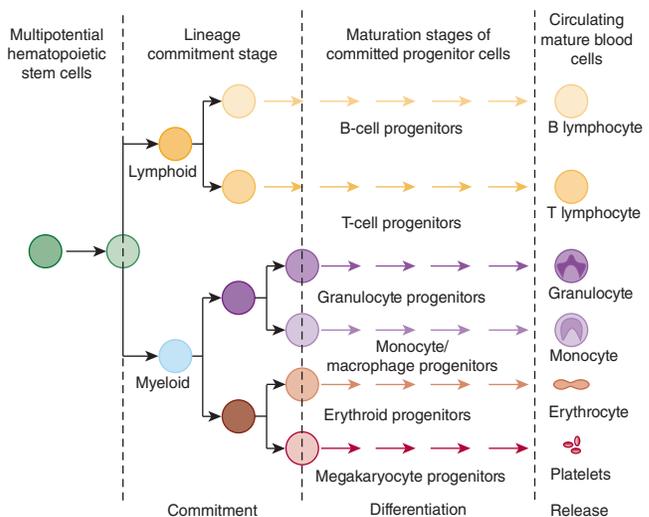

Progenitor cells must interact with a supportive microenvironment to sustain hematopoiesis. The hematopoietic stroma consists of macrophages, fibroblasts, adipocytes, and endothelial cells. The extracellular matrix is produced by the stromal cells and is composed of various fibrous proteins, glycoproteins, and proteoglycans, such as collagen, fibronectin, laminin, hemonectin, and thrombospondin. Hematopoietic progenitor cells have receptors to particular matrix molecules. The extracellular matrix provides a structural network to which the progenitors are anchored. As the

cells approach maturity, they lose their surface receptors, allowing them to leave the hematopoietic space and enter the venous sinuses. Blood cell release depends on a pressure gradient that drives proliferating, mature cells through endothelial cells lining the sinusoidal spaces.<sup>34</sup> This pressure is contained by the surrounding rigid bone cortex and increases under the influence of erythropoietin and granulocyte colony-stimulating factor.

### Stem Cells

A stem cell is capable of self-renewal, as well as differentiation into a specific cell type. The pluripotent hematopoietic stem cells can therefore continuously replicate while awaiting the appropriate signal to differentiate into either a myeloid or a lymphoid stem cell (Fig. 20–1). Stem cells represent only 1 in 100,000 of the nucleated cells of the bone marrow, and most of these stem cells are usually quiescent. Nevertheless, these relatively few cells are directly responsible for the estimated 200 billion red cells, 150 billion platelets, and 100 billion leukocytes produced each day.<sup>34</sup> In response to hemolysis or infection, substantially larger numbers of blood cells are produced.<sup>73</sup> Multiple steps are involved in the commitment of less-differentiated cells to more mature cell lines. The final steps in the maturation of erythrocytes alone, for example, involve extensive remodeling, the restructuring of cellular membranes, the accumulation of hemoglobin, and the loss of nuclei and organelles.

Multipotent mesenchymal stem cells capable of differentiating into other tissue lines, including hepatic, renal, muscle, and perhaps neuronal, are also found in the bone marrow.<sup>41</sup> Furthermore, tissue-specific stem cells capable of self-renewal reside in numerous other organs and to play a fundamental role in repair and regeneration.<sup>21</sup> A variety of strategies have likely evolved to protect the stem cell from injury due to xenobiotics and radiation, and a better understanding of these effects promises to improve our understanding of toxicity and treatment. The hematopoietic stem cell has provided fundamental insights into regenerative biology, and it remains a focus of intense research given the profound implications for organ homeostasis, tissue repair, and gene therapy.<sup>59,62</sup>

**FIGURE 20–1.** Principles of hematopoiesis. Commitment refers to the apparent inability of progenitor cells to generate hematopoietic stem cells. Following differentiation, the various mature blood cells are released into the circulation.

## Cytokines

Cytokines are soluble mediators secreted by cells for cell-to-cell communication. Initially termed growth factors, it is now recognized that not all cytokines are growth factors. Cytokines promote or inhibit the differentiation, proliferation, and trafficking of blood cells and their precursors. Importantly, they can also inhibit apoptosis, and their absence therefore results in the self-destruction of unwanted cells. They include growth factors or colony-stimulating factors (CSFs), interleukins, monokines, interferons, and chemokines. At baseline, these act in concert to maintain normal blood counts. In response to antigens or other stimuli, cytokines are released to combat perceived infection. Recombinant cytokines are being used therapeutically in immunocompromised patients, transplant recipients, and those with hepatitis C, anemia, multiple sclerosis, and cancer. They are also being used in clinical toxicology, for example, for the treatment of leukocytopenia that results from colchicine and podophyllum toxicity.<sup>29,44</sup>

The growth factors are glycoproteins necessary for the differentiation and maturation of individual or multiple cell lines. They fall into 2 families based on their target receptors. The ligands of the cytokine receptor family include growth hormone, interleukin-2 (IL-2), macrophage colony-stimulating factor-1 (CSF-1), granulocyte-macrophage colony-stimulating factor (GM-CSF),  $\gamma$ -interferon, and granulocyte colony-stimulating factor (G-CSF), to name a few. The second group, the tyrosine kinase family, includes Kit ligand and insulinlike growth factor-1 receptor (IGF-1R), a member of the insulin family.

## Cell Surface Antigens

Using monoclonal antibody technology, cell-surface antigens are used to characterize cell types. The cluster designation (CD) nomenclature was introduced by immunologists to ensure a common language when confronted with multiple antibodies to the same leukocyte cell-surface molecule, and hundreds of such unique molecules have been classified.<sup>110</sup> For example, the CD34 antigen is a 115-kilodalton (kDa) highly glycosylated transmembrane protein that is selectively expressed by primitive multipotent hematopoietic stem cells shortly after activation, but is absent from mature T and B lymphocytes.<sup>64</sup> Advances in genomics and proteomics now complement the immunologic designation, but the ability to subtype blood cells phenotypically has transformed the approach to the leukemias, autoimmune disease, transplantation medicine, and thromboembolic disease.

The human leukocyte antigen (HLA) system denotes the major histocompatibility complex in humans, a group of genes involved in antigen presentation to T lymphocytes, the complement system, cancer surveillance, and autoimmune disease. The rich variation in HLA genes, with more than 100 known alleles at 6 loci, may reflect selective evolutionary pressure to deter individuals with similar HLA from mating. Such sexual selection enhancing diversity would protect a population from coevolving pathogens that attempted to mimic a specific human epitope and avoid immune attack. Indeed, humans appear to be able to distinguish and preferentially choose partners with HLA alleles different from their own using smell, promoting heterozygous diversity.<sup>68</sup> Exposure to blood transfusions, pregnancy, and organ grafts can generate antibodies against non-self HLAs.

## APLASTIC ANEMIA

Aplastic anemia is characterized by pancytopenia on peripheral smear, a hypocellular marrow, and delayed plasma iron clearance. Severe aplastic anemia denotes a granulocyte count of less than 500 cells/mm<sup>3</sup>, a platelet count of less than 20,000/mm<sup>3</sup>, and a reticulocyte count of less than 1% after correction for anemia. Following acute insult and depletion of extracirculatory reserves, cell line counts fall at a rate inversely proportional to their life span: granulocytes (circulating half-life 6–12 hours) disappear within days, platelets (life span of 7–10 days) decline by half in about one week, while erythrocytes (normal life span 120 days) decline over weeks in the absence of bleeding or hemolysis. Approximately 1,000 new cases of aplastic anemia are diagnosed yearly in the United States. The incidence is 2 to 3 times higher in Asia, perhaps because of a combination of genetic, environmental, and

**TABLE 20–1** Selected Xenobiotics Associated with Aplastic Anemia

Analgesics	Antirheumatics
Acetaminophen	Gold salts
Diclofenac	Methotrexate
Dipyron	D-Penicillamine
Indomethacin	Antithyroids

Clozapine	

<sup>a</sup>Denotes xenobiotics that predictably result in bone marrow aplasia following a sufficiently large exposure.

infectious factors.<sup>108</sup> Aplastic anemia may be inborn (as in Fanconi anemia) or acquired. A variety of xenobiotics such as benzene, pesticides, and chloramphenicol are associated with acquired aplastic anemia (Table 20–1),<sup>20,109</sup> but causality is uncertain given uncertain case ascertainment and other biases. Epidemiologic studies demonstrate that specific causes are identified in relatively few cases.<sup>52</sup>

Generally speaking, the majority of cases of so-called idiosyncratic aplastic anemia are caused by autoimmune attack on CD34<sup>+</sup> hematopoietic stem cells. Following an exposure to an inciting antigen, cytotoxic T cells secrete interferon- $\gamma$  and tumor necrosis factor  $\alpha$ , which destroy progenitor cells, eventually depleting mature leukocytes, erythrocytes, and platelets in circulation.<sup>109</sup> As with other autoimmune diseases, certain HLA patterns are associated with a genetic predisposition for the condition, namely the HLA DR2. Clozapine-induced agranulocytosis is associated with the HLA B38, DR4, and DQ3 haplotypes.<sup>74</sup> Immunosuppressive therapy or allogeneic stem cell transplantation allows recovery of hematopoiesis, and survival is now expected.<sup>108</sup>

It is important to distinguish immunologic xenobiotic-induced aplastic anemia from the direct myelotoxic effects of radiation and chemotherapy. Following exposure to ionizing radiation, a pancytopenia ensues as a result of injury to stem and progenitor cells. Although atom bomb survivors rarely developed aplastic anemia,<sup>49</sup> fractionated whole body radiation of at least 10 Gy is used to intentionally destroy bone marrow stem cells prior to hematopoietic stem cell transplantation. Cancer chemotherapy is often dosed to the endpoint of reversible hematopoietic toxicity. Vacuolated pronormoblasts are found in the bone marrow when aplasia is due to a myelotoxic drug, and treatment consists primarily of stopping the offending xenobiotic while supporting cell lines and preventing infection and bleeding. Other nonimmunologic mechanisms of aplasia are identified in specific cases. For example, the severe pancytopenia that occasionally occurs following 5-fluorouracil therapy is caused by a deficiency of dihydropyrimidine dehydrogenase present in 3% to 5% of whites.<sup>104</sup>

## THE ERYTHRON

The erythron is often considered to be a single yet dispersed tissue, defined as the entire mass of erythroid cells from the first committed progenitor cell to the mature circulating erythrocyte (red blood cell). This functional definition emphasizes the integrated regulation of the erythron, both in health and disease. The primary function of the erythron is to transport molecular oxygen throughout the organism. To accomplish this, adequate numbers of circulating erythrocytes (nearly half of the blood by volume) must be maintained. These erythrocytes must be able to preserve their structure and flexibility to circuit repeatedly through the microcirculation and to resist oxidant stress accumulated during their life span.<sup>84</sup> The erythrocyte also plays a key role in modulating vascular tone. Interactions between oxyhemoglobin and nitric oxide help match vasomotor tone to local tissue oxygen demands.<sup>30,39,43,67,91</sup>

Homeostasis of erythron proliferation is primarily maintained by the equilibrium between stimulation via the hormone erythropoietin and apoptosis controlled by 2 receptors, Fas and FasL, expressed on the membranes of erythroid precursors. At the other extreme, erythrocytes are culled from the circulation at the end of their life span primarily by the action of the spleen. With age, erythrocytes become less able to negotiate the narrow red pulp passages in the spleen and are phagocytosed by macrophages. By filtering out these senescent cells, the spleen minimizes entrapment in the microvasculature of other organs and prevents spillage of intracellular contents including hemoglobin into the intravascular circulation.

### Erythropoietin

Erythropoietin (EPO) is a glycoprotein hormone of molecular weight 34,000 Da that is produced in the epithelial cells lining the peritubular capillaries of the kidney. Anemia and hypoxemia stimulate its synthesis. Erythropoietin receptors are found in human erythroid cells, megakaryocytes, and fetal liver. Erythropoietin promotes erythroid differentiation, the mobilization of marrow progenitor cells, and the premature release of marrow reticulocytes. The cell most sensitive to EPO is a cell between the erythroid colony-forming unit (CFU-E) and the proerythroblast. The absence of EPO results in DNA cleavage and erythroid cell death.

### The Mature Erythrocyte

The mature erythrocyte is a highly specialized cell, designed primarily for oxygen transport. Accordingly, it is densely packed with hemoglobin, which constitutes approximately 90% of the dry weight of the erythrocyte. During maturation, the erythrocyte loses its nucleus, mitochondria, and other organelles, rendering it incapable of synthesizing new protein, replicating, or using the oxygen being transported for oxidative phosphorylation. Its metabolic repertoire is severely limited and largely restricted to a few pathways (described below under Metabolism). In general, the enzymatic pathways are those required for optimizing oxygen and carbon dioxide exchange, transiting the microcirculation while maintaining cellular integrity and flexibility, and resisting oxidant stress on the iron and protein of the cell. The characteristic biconcave discocyte shape is dynamically maintained, increasing membrane surface-to-cell volume. This shape decreases intracellular diffusion distances to the cell membrane and allows plastic deformation when squeezing through the microcirculation. The shape is the net sum of elastic and electrostatic forces within the membrane, surface tension, and osmotic and hydrostatic pressures. The cell membrane contains globular proteins suspended within the phospholipid bilayer. The major blood group antigens are carried on membrane ceramide glycolipids and proteins, particularly glycophorin A and the Rh proteins. Membrane proteins generally serve to maintain the structure of the cell, to transport ions and other substances across the membrane, or to catalyze a limited number of specific chemical reactions for the cell.

### Structural Proteins

The cell membrane is coupled to, and interacts dynamically with, the cytoskeleton, allowing changes in cell shape such as tank treading or rotation of the membrane relative to the cytoplasm. This cytoskeleton consists of a hexagonal lattice of proteins, especially spectrin, actin, and protein 4.1,

which interact with ankyrin and band 3 in the membrane to provide a strong but flexible structure to the membrane. Other essential structural proteins include tropomyosin, tropomodulin, and adducin. The absence or abnormalities of these proteins results in abnormal erythrocyte shapes such as spherocytes and elliptocytes.

### Transport Proteins

Many specialized transport proteins are embedded in the erythrocyte membrane. These include anion and cation transporters, glucose and urea transporters, and water channels. The erythrocyte membrane is relatively impermeable to ion flux. Band 3 anion-exchange protein plays an important role in the chloride-bicarbonate exchanges that occur as the erythrocyte moves between the lung and tissues. Glucose, the sole source of energy of the erythrocyte, crosses the membrane by facilitated diffusion mediated by a transmembrane glucose transporter. Sodium-potassium adenosine triphosphatase ( $\text{Na}^+, \text{K}^+, \text{ATPase}$ ) maintains the primary cation gradient by pumping sodium out of the erythrocyte in exchange for potassium.

### Membrane-Associated Enzymes

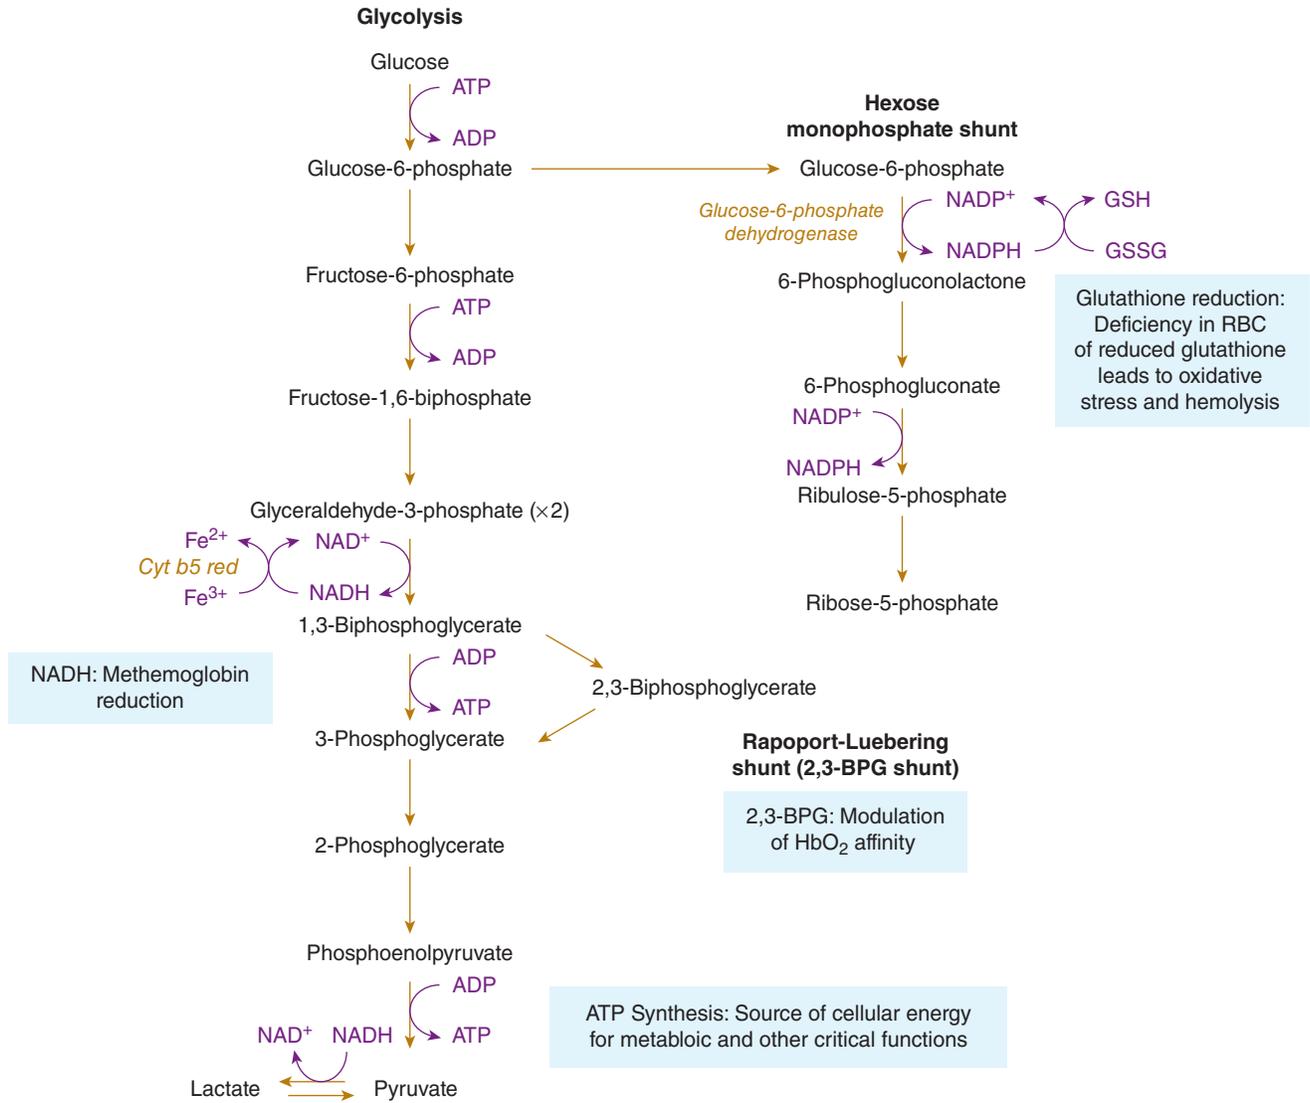

At least 50 membrane-bound or membrane-associated enzymes are known to exist in the human erythrocyte. Acetylcholinesterase is an externally oriented enzyme whose role in the function of the erythrocyte remains obscure. Its function is inhibited by certain xenobiotics, most notably the organic phosphorus compounds, and it is conveniently assayed as a marker for such exposures (Chap. 110).

### Metabolism

Lacking mitochondria and the ability to generate adenosine triphosphate (ATP) using molecular oxygen, the mature erythrocyte has a severely limited repertoire of intermediary metabolism compared to most mammalian cells. Having lost its nucleus, ribosomes, and translational apparatus, new enzymes cannot be synthesized and existing enzymes decline in function over the lifetime of the cell. Fortunately, the metabolic demands of the erythrocyte are usually modest, but under conditions of stress that capacity can be overwhelmed, especially among senescent cells. The greatest expenditure of energy under physiologic conditions is for the maintenance of transmembrane gradients and for the contraction of cytoskeletal elements. However, oxidant stress can put severe strain on the metabolic reserves of the erythrocyte, and lead ultimately to the premature destruction of the cell, a process termed hemolysis.

Figure 20-2 illustrates the main metabolic pathways and their purpose. Embden-Meyerhof glycolysis is the only source of ATP for the erythrocyte and consumes approximately 90% of the glucose imported by the cell. The reduced nicotinamide adenine dinucleotide (NADH) generated during glycolysis, which would ordinarily be used for oxidative phosphorylation in cells containing mitochondria, is directed toward the reduction of either methemoglobin to hemoglobin by cytochrome b5 reductase, or of pyruvate to lactate. Both pyruvate and lactate are exported from the cell. In response to anemia, altitude, or changes in cellular pH, glycolysis is diverted into the Rapoport-Luebering shunt, generating 2,3-bisphosphoglycerate (2,3-BPG, formerly known as 2,3-diphosphoglycerate or 2,3-DPG) in lieu of ATP. 2,3-bisphosphoglycerate binds to deoxyhemoglobin to modulate oxygen affinity and to allow unloading of oxygen at the capillaries, thereby increasing oxygen delivery considerably. Reduced levels of 2,3-BPG in stored blood result in impaired oxygen delivery following massive transfusion.<sup>101</sup>

As an alternative to glycolysis, glucose is diverted to the hexose monophosphate shunt during times of oxidant stress. This pathway results in the generation of reduced nicotinamide adenine dinucleotide phosphate (NADPH), which the erythrocyte uses to maintain reduced glutathione. Reduced glutathione, in turn, inactivates oxidants and protects the sulfhydryl groups of hemoglobin and other proteins. The initial, rate-limiting step of this pathway is controlled by glucose-6-phosphate dehydrogenase (G6PD). Accordingly, cells deficient in this enzyme are less able to maintain reduced glutathione, and are vulnerable to irreversible damage under oxidant stress.

**FIGURE 20–2.** Metabolic pathways of the erythrocyte. The main metabolic pathways available to the mature erythrocyte are shown (rectangles). Glucose is imported into the cell, while pyruvate, lactate, and oxidized glutathione (GSSG) are exported. 2,3-BPG = 2,3-bisphosphoglycerate; ADP = adenosine diphosphate; ATP = adenosine triphosphate; cyt b5 red = cytochrome b5 reductase; G6PD = glucose-6-phosphate dehydrogenase; GSH = reduced glutathione; Hb = hemoglobin; NADH = reduced form of nicotinamide adenine dinucleotide (NAD<sup>+</sup>); NADPH = reduced form of nicotinamide adenine dinucleotide phosphate (NADP<sup>+</sup>); RBC = red blood cell (erythrocyte).

The consequences of this deficiency are discussed in greater detail below under Glucose-6-Phosphate Dehydrogenase Deficiencies.

The erythrocyte also contains enzymes to synthesize glutathione ( $\gamma$ -glutamyl-cysteine synthetase and glutathione synthetase), to convert CO<sub>2</sub> to bicarbonate ion (carbonic anhydrase I), to remove pyrimidines resulting from the degradation of RNA (pyrimidine 5'-nucleotidase), to protect against free radicals (catalase, superoxide dismutase, glutathione peroxidase), and to conjugate glutathione to electrophiles ( $\rho$ -glutathione-S-transferase).

**Hemoglobin**

Hemoglobin, the major constituent of the cytoplasm of the erythrocyte, is a conjugated protein with a molecular weight of 64,500 Da. To put things in perspective, the typical adult man has approximately 75 mL/kg of blood containing 15 g/100 mL of hemoglobin, or nearly 1 kg of hemoglobin. His 0.3-kg heart must pump this entire mass of hemoglobin every minute at rest, which is a substantial work expenditure. One molecule is composed of 4 protein (globin) chains, each attached to a prosthetic group called heme. Heme contains an iron molecule complexed at the center of a porphyrin ring. The globin chains are held together by noncovalent electrostatic attraction into a tetrahedral array. Hemoglobin is so efficient at binding and carrying

oxygen that it enables blood to transport nearly 100 times as much oxygen as could be carried by plasma alone (Chap. 28). In addition, the capacity of hemoglobin to modulate oxygen binding under different conditions allows adaptation to a wide variety of environments and demands. Three complex and integrated pathways are required for the formation of hemoglobin: globin synthesis, protoporphyrin synthesis, and iron metabolism.

**Globin Synthesis**

The protein chains of hemoglobin are produced with information from 2 different genetic loci. The  $\alpha$ -globin gene cluster spans 30 kb on the short arm of chromosome 16, and codes for 2 identical adult  $\alpha$ -chain genes, as well as the  $\zeta$ -chain, an embryonic globulin. The  $\beta$  cluster is 50 kb on chromosome 11, and codes for the 2 adult globins  $\beta$  and  $\delta$ , as well as 2 nearly identical  $\gamma$  chains expressed in the fetus and an embryonic globulin  $\epsilon$ . The expression of genes in each family changes during embryonic, fetal, neonatal, and adult development. Until 8 weeks of intrauterine life,  $\epsilon$ ,  $\zeta$ ,  $\gamma$ , and  $\alpha$  chains are produced and assembled in various combinations in yolk sac-derived erythrocytes. With the shift in erythropoiesis from yolk sac to fetal liver and spleen, embryonic hemoglobin disappears, and the  $\alpha$  and  $\gamma$  globin chains are paired into fetal hemoglobin (HbF =  $\alpha_2\gamma_2$ ). Erythrocytes containing HbF have a higher

O<sub>2</sub> affinity than those containing adult hemoglobin, which is important for oxygen transfer across the placenta into the relatively hypoxic uterine environment. Beginning shortly before birth, expression at the  $\beta$  cluster shifts to the  $\beta$  and  $\delta$  globins. The predominant adult hemoglobin is termed hemoglobin A ( $\alpha_2\beta_2$ ), whereas approximately 2.5% of normal adult hemoglobin is in the form of hemoglobin A<sub>2</sub> ( $\alpha_2\delta_2$ ). The thalassemias, a group of inherited disorders, result from defective synthesis of one or more of the globin chains. Clinically this results in a hypochromic, microcytic anemia.

### Heme Synthesis

Heme is the iron complex of protoporphyrin IX. Protoporphyrin IX is a tetramer composed of 4 porphyrin rings joined in a closed, flat-ring structure. The IX designation refers to the order in which it was first synthesized in Hans Fischer's laboratory. Of the 15 possible isomers, only protoporphyrin IX occurs in living organisms. Technically, only iron complexes with the iron in the Fe<sup>2+</sup> state can be called heme, but the term is commonly used to refer to the prosthetic group of metalloproteins such as peroxidase (ferric) and cytochrome c (both ferric and ferrous), whether the iron is in the Fe<sup>2+</sup> or Fe<sup>3+</sup> state. The terms "hemoglobin" and "ferrihemoglobin" are synonymous with methemoglobin but rarely used. All animal cells can synthesize heme, with the notable exception of mature erythrocytes. Hemoproteins are involved in a multitude of biologic functions, including oxygen binding (hemoglobin, myoglobin), oxygen metabolism (oxidases, peroxidases, catalases, and hydroxylases), and electron transport (cytochromes), as well as metabolism of xenobiotics (cytochrome P450 family). Erythroid cells synthesize 85% of total body heme, with the liver synthesizing most of the balance. Hemoglobin is the most abundant hemoprotein, containing 70% of total body iron.

The first step in the synthesis of heme takes place in the mitochondrion and is the condensation of glycine and succinyl-coenzyme A (CoA) to form 5-aminolevulinic acid (ALA) (Fig. 20-3). The formation of 5-ALA is catalyzed by aminolevulinic acid synthase (ALAS), the rate-limiting step of the pathway. The rate of heme synthesis is closely controlled, given that free intracellular heme is toxic and that this first step is essentially irreversible.

Of the 2 isoforms of ALAS known to exist in mammals, erythroid cells express the ALAS2 isoform, which resides on the X chromosome. Comparatively more is known about ALAS1 (chromosome 3), a housekeeping gene with a short half-life expressed ubiquitously, allowing the synthesis of cellular and mitochondrial hemoproteins. Aminolevulinic acid synthase (ALAS1) activity is induced by many factors, which can increase its expression by 2 orders of magnitude. Moreover, it is strongly inhibited by heme in a classical negative feedback fashion. Aminolevulinic acid synthase (ALAS2) is constitutively expressed at very high concentrations in erythroid precursors, allowing sustained synthesis of heme during erythropoiesis. Pyridoxal phosphate (active vitamin B<sub>6</sub>) serves as a cofactor to both isoforms of ALAS. The clinical consequences of pyridoxine deficiency include a hypochromic, microcytic anemia, iron overload, and neurologic impairment.

The next step in the synthesis of hemoglobin is the formation of the monopyrrole porphobilinogen via the condensation of 2 molecules of ALA.

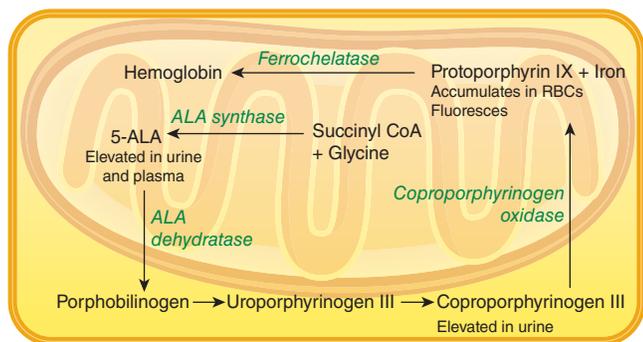

The subsequent steps in heme synthesis involve the condensation of 4 molecules of porphobilinogen into a flat ring, which is transported back into the mitochondrion by an unknown mechanism. The final step is the insertion of iron into protoporphyrin IX, a reaction that is catalyzed by ferrochelatase (also known as heme synthase) to form heme.

Understanding this carefully regulated synthetic pathway is relevant to understanding the laboratory evidence of lead toxicity (Chap. 93), and predicting the response of porphyric patients to a range of xenobiotics. Most steps in the heme biosynthetic pathway are inhibited by lead. ALA dehydratase is the most sensitive, followed by ferrochelatase, coproporphyrinogen oxidase, and porphobilinogen deaminase. As a consequence, ALA is increased in plasma and especially urine. With increasing exposure, ferrochelatase inhibition coupled with iron deficiency causes zinc protoporphyrin to accumulate in erythrocytes, which can easily be detected by fluorescence. Coproporphyrinogen III also appears in the urine. Historically, these effects have served as the basis for a number of tests of lead exposure.

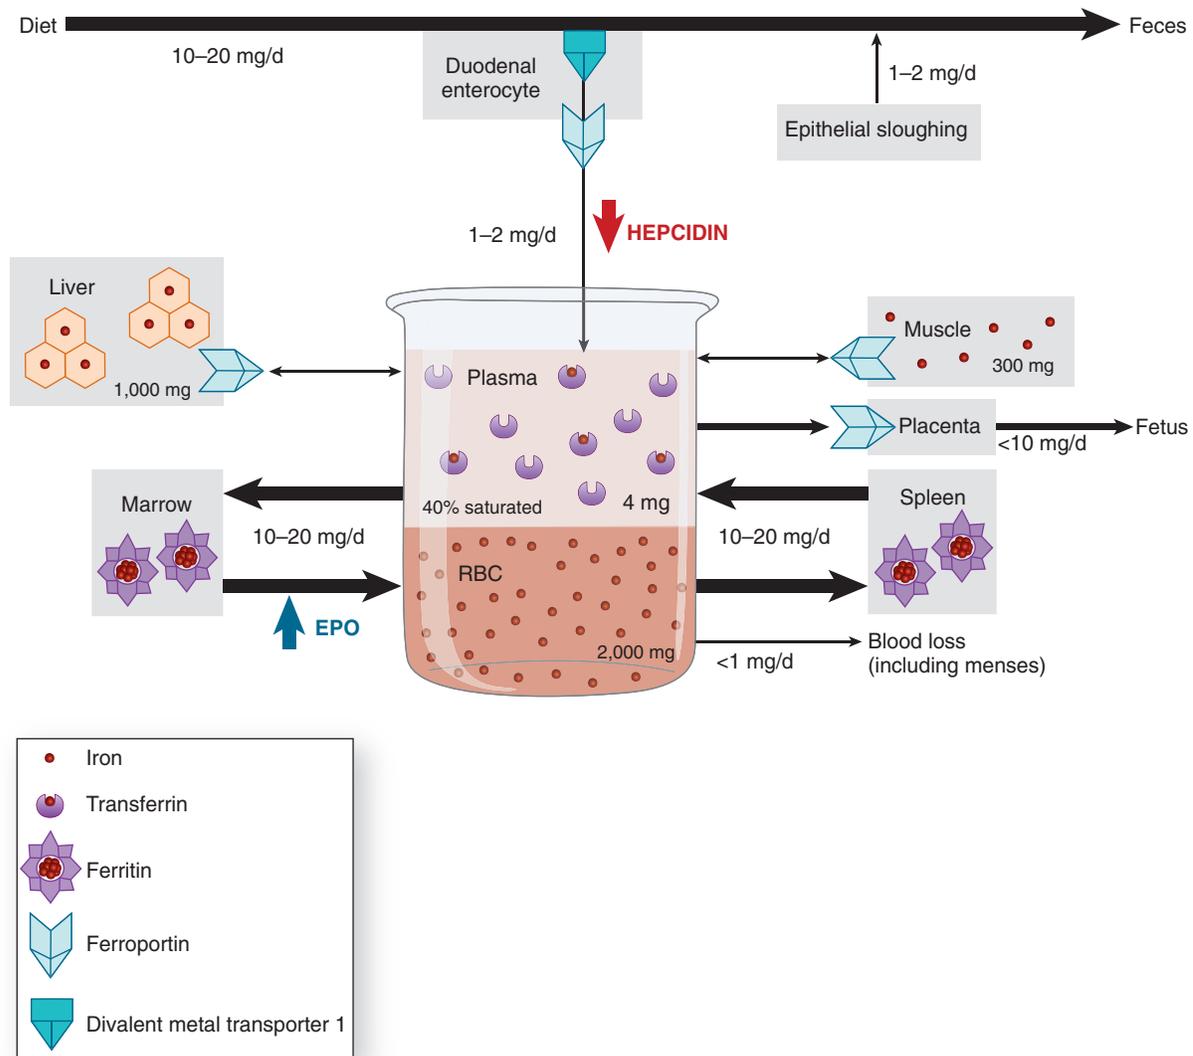

The porphyrias are a group of disorders resulting from an inherited deficiency of any given enzyme that follows ALAS on the heme biosynthetic pathway. As such, when ALAS activity outpaces the activity of the deficient enzyme, the rate-limiting step shifts downstream, and intermediate metabolites accumulate. These metabolites cause characteristic neuropsychiatric symptoms and palsies (caused by ALA and porphobilinogen), and cutaneous reactions, including photosensitivity (due to the fluorescence of the porphyrins). For example, porphobilinogen is excreted in large quantities by patients with acute intermittent porphyria (porphobilinogen deaminase deficiency), and the urine darkens with exposure to air and light due to oxidation to porphobilin and to nonenzymatic assembly into porphyrin rings. A variety of xenobiotics precipitate crises in susceptible individuals, by inducing ALAS1 and overloading the deficient enzyme.<sup>100</sup> The molecular mechanisms that allow xenobiotics to induce the ALAS1 gene closely resemble those accounting for induction of the cytochrome P450 (CYP) genes, which also require heme synthesis. The xenobiotic typically interacts with either the constitutive androstane receptor (CAR) or the pregnane X receptor (PXR), the 2 main so-called orphan nuclear receptors.<sup>107</sup> These transcriptional factors are DNA-binding proteins that induce the expression of a range of drug metabolizing and transporting genes in response to the presence of a xenobiotic and are termed "xenosensors." When activated, they associate with the 9-*cis* retinoic acid xenobiotic receptor (RXR), and then attach to enhancer sequences near the apoCYP or ALAS1 genes to enhance transcription.<sup>81</sup> The multifunctional inducers capable of activating a wide range of hepatic enzymes are therefore extremely porphrogenic and include phenobarbital, phenytoin, carbamazepine, and primidone. Furthermore, because CYP 3A4 and 2C9 represent nearly half of the hepatic CYP pool, inducers of these isoforms also stimulate heme synthesis and induce porphyric crises. Examples include the anticonvulsants; nifedipine; sulfamethoxazole; rifampicin; ketoconazole; and the reproductive steroids progesterone, medroxyprogesterone, and testosterone. Glucocorticoids, on the other hand, despite binding to PXR, suppress ALAS1 induction and translation, and they are not porphrogenic.<sup>100</sup>

### Iron Metabolism

At equilibrium, approximately 1 to 2 mg of iron is absorbed from the diet, and a similar amount is shed from the intestinal epithelium each day. Unless appropriately chelated, free iron not bound by transport or storage proteins can generate harmful oxygen free radicals that damage cellular structures and metabolism (Chaps. 10 and 45). For this reason, serum iron circulates bound to a transfer protein, transferrin, and is stored in the tissues using ferritin (Fig. 20-4). Whereas each molecule of transferrin can bind 2 iron atoms, ferritin has a large internal cavity, approximately 80 Å in diameter, that can hold up to 4500 iron atoms per molecule. The amount of iron transported through plasma depends on total-body iron stores and the rate of erythropoiesis. Only about one-third of the iron-binding sites of circulating transferrin are normally saturated, as demonstrated by the usual serum iron content of 60 to 170 mcg/dL (10–30 μmol/L) as compared to the total iron-binding capacity of 280 to 390 mcg/dL (50–70 μmol/L).

**FIGURE 20-3.** The heme synthesis pathway. The enzymatic steps inhibited by lead are marked in green. 5-ALA = 5-aminolevulinic acid; RBCs = red blood cells.

**FIGURE 20-4.** The iron cycle. The flow of iron is indicated by arrows, and average daily rates of flux are shown for an adult. Absorption at the duodenal enterocyte is tightly controlled, because there are few physiologic processes to regulate losses (other than pregnancy and menstruation). Atomic iron is absorbed via the divalent metal transporter 1, and heme-bound iron via heme carrier protein 1. Heparin is an important circulating peptide inhibitor of ferroportin, thereby limiting absorption when stores are adequate. Iron content (either atomic or heme bound) of specific organs or compartments is shown in milligrams. The largest stores of atomic iron are contained by ferritin, mostly in liver and spleen macrophages, and erythrocyte precursors in the marrow. Only a relatively small amount circulates in the plasma bound to transferrin, which is usually only partially saturated. EPO = erythropoietin; RBC = red blood cell.

Only transferrin can directly supply iron for hemoglobin synthesis. The iron–transferrin complex binds to transferrin receptors on the surface of developing erythroid cells in bone marrow. Iron in the erythroid cell is used for hemoglobin synthesis or is stored in ferritin.

The absorption of nonheme, free ferrous iron from the diet occurs via the divalent metal transporter 1 of the duodenal enterocyte, which then passes it into the circulation via ferroportin. Iron then circulates in the ferric form bound to transferrin.<sup>46</sup> Dietary iron complexed with heme can also be absorbed via the heme carrier protein-1, which transports either iron or zinc protoporphyrin into the enterocyte.<sup>61</sup> The iron may then be freed by microsomal heme oxygenase and follow the transport of atomic iron, or perhaps heme itself can be transferred to the circulation via specific export proteins and circulate bound to its carrier protein, hemopexin.<sup>5</sup>

When the erythrocyte is removed from the circulation by splenic macrophages, heme is degraded by heme oxygenase to carbon monoxide and biliverdin, and the iron extracted. Some iron remains in macrophages in the form of ferritin or hemosiderin. Most is delivered again by ferroportin back to the plasma and bound to transferrin.

Iron homeostasis is largely regulated at the level of absorption, with little physiologic control over its rate of loss. Excess absorption relative to body

stores is the hallmark of hereditary hemochromatosis. The iron regulatory hormone hepcidin produced by the liver plays a central role in iron control, including the anemia of chronic disease caused by inflammatory signals.<sup>46</sup> Heparin is a 25–amino acid peptide that senses iron stores and controls the ferroportin-mediated release of iron from enterocytes, macrophages, and hepatocytes. The liver is an important reservoir of iron because it can store considerable amounts of iron taken from portal blood and release it when needed.

### Oxygen–Carbon Dioxide Exchange

The evolutionary transition of organisms from anaerobic to aerobic life allowed the liberation of 18 times more energy from glucose. Vertebrates developed 2 important systems to overcome the relatively small quantities of oxygen dissolved in aqueous solutions under atmospheric conditions: the circulatory system and hemoglobin. The circulatory system allows delivery of oxygen and removal of carbon dioxide throughout the organism. Hemoglobin plays an essential role in the transport and exchange of both gases. Moreover, the interactions between these gases and hemoglobin are directly linked in a remarkable story of molecular evolution. Understanding this interplay allowed early insight into protein conformation and the importance of allosteric interactions between molecules.

The binding of each oxygen molecule to atomic iron in any of the 4 heme molecules results in conformational changes that affect binding of oxygen at the remaining sites. This phenomenon is known as *cooperativity*, and it is necessary for the transport of relatively large quantities of oxygen and for the unloading of most of this oxygen at tissue sites. Cooperativity results from the intramolecular interactions of the tetrameric hemoglobin, and is expressed in the sigmoidal shape of the oxyhemoglobin dissociation curve (Fig. 28–2). Conversely, the monomeric myoglobin has a hyperbolic oxygen binding curve. The partial pressure of oxygen at which 50% of the oxygen-binding sites of hemoglobin are occupied is about 26 mm Hg, in contrast to about 1 mm Hg for myoglobin. Moreover, hemoglobin is nearly 100% saturated at partial oxygen pressures of about 100 mm Hg in the pulmonary capillaries, transporting 1.34 mL of oxygen per gram of hemoglobin A. About one-third of this oxygen can be unloaded under normal conditions at tissue capillaries with partial oxygen pressures around 35 mm Hg. The proportion unloaded rises during exercise and sepsis, as well as with xenobiotics that uncouple oxidative phosphorylation. Elite athletes can extract up to 80% of the available oxygen under conditions of maximal aerobic effort.

The oxygen reserve, however, is only one of the benefits of the large quantity of hemoglobin in circulation. The ability of hemoglobin to buffer the acid equivalent of CO<sub>2</sub> in solution is equally vital to respiratory physiology, because it allows the removal of large quantities of CO<sub>2</sub> from metabolically active tissues with minimal changes in blood pH. Hemoglobin is by far the largest buffer in circulation, accounting for 7 times the buffering capacity of the serum proteins combined (28 versus 4 mEq H<sup>+</sup>/L of whole blood). For every 1 mole of oxygen unloaded in the tissue, about 0.5 mole of H<sup>+</sup> is loaded onto hemoglobin.

The linked interaction between oxygen and carbon dioxide transport can be first considered from the perspective of oxygen binding to hemoglobin. The affinity of oxygen for hemoglobin is directly affected by pH, which is a function of the CO<sub>2</sub> content of the blood. The oxyhemoglobin dissociation curve shifts to the left in lungs, where the level of carbon dioxide, and thus carbonic acid, are kept relatively low as a result of ventilation, an effect that promotes oxygen binding. The curve shifts to the right in tissues where cellular respiration increases CO<sub>2</sub> concentrations and lowers pH. This phenomenon, known as the *Bohr effect*, promotes the uptake of oxygen in the lungs and the release of oxygen at tissue sites.

From the perspective of carbon dioxide transport, hemoglobin also plays an essential albeit indirect role. Carbon dioxide dissolves into plasma, and is slowly hydrated to carbonic acid, which dissociates to H<sup>+</sup> and HCO<sub>3</sub><sup>-</sup> (pK<sub>a</sub> 6.35). The speed of the hydration reaction is accelerated from about 40 seconds to 10 ms by the abundant enzyme carbonic anhydrase located within the erythrocyte. Most carbon dioxide collected at the tissues diffuses into erythrocytes, where it becomes H<sup>+</sup> and HCO<sub>3</sub><sup>-</sup>. This HCO<sub>3</sub><sup>-</sup> is then rapidly transported back to the serum in exchange for chloride ion via the band 3 anion exchange transporter located in the erythrocyte membrane, thereby shifting serum Cl<sup>-</sup> into the erythrocyte (the *chloride shift*). The hydrogen ion is accepted by hemoglobin, largely at the imidazole ring of histidine residues, which have a pK<sub>a</sub> of about 7.0. A small amount of CO<sub>2</sub> reacts directly with the amino terminal of the globin chains to form carbamino residues (HbNHCOO<sup>-</sup>). Thus, most of the transported carbon dioxide is transformed by the erythrocyte into bicarbonate ion that is returned to the serum and hydrogen ion that is buffered by hemoglobin. Each liter of venous blood typically carries 0.8 mEq dissolved CO<sub>2</sub> + 16 mEq HCO<sub>3</sub><sup>-</sup> in the plasma, and 0.4 mEq dissolved CO<sub>2</sub> + 4.6 mEq HCO<sub>3</sub><sup>-</sup> + 1.2 mEq HbNHCOO<sup>-</sup> in the erythrocyte (a total of 23 mEq CO<sub>2</sub>, equivalent to 510 mL CO<sub>2</sub>/L blood). Although two-thirds of the total CO<sub>2</sub> content is ultimately carried in the plasma, nearly all of the bicarbonate is generated within erythrocytes. In the capillaries of the lungs, the reverse reactions occur to eliminate CO<sub>2</sub>. Because deoxyhemoglobin is better able to buffer hydrogen ions, the release of oxygen from hemoglobin at the tissues facilitates the uptake of carbon dioxide into venous blood. This effect is known as the *Haldane effect*. In fact, 1 L of venous blood at 70% oxygen saturation can transport an additional 20 mL of CO<sub>2</sub> compared to arterial blood, which is nearly 100% saturated. Both the Bohr and Haldane effects

have important consequences at the extremes of acid–base perturbations, as occurs in a number of poisonings that interfere with oxygen metabolism.

Finally, in addition to inactivating nitric oxide, hemoglobin also reversibly binds nitric oxide as S-nitrosohemoglobin, thereby playing an important role in the regulation of microvascular circulation and oxygen delivery. The ability of hemoglobin to vasodilate the surrounding microvasculature in response to oxygen desaturation using nitric oxide provides new insight into oxygen delivery and may be pivotal in such disorders as septic shock, pulmonary hypertension, and senescence of stored red blood cells.<sup>94</sup>

### Abnormal Hemoglobins

Several alterations of the hemoglobin molecule are encountered in clinical toxicology. A detailed understanding of their molecular basis, clinical manifestations, and effects on gas exchange is essential. Unfortunately, the nomenclature can be ambiguous and overlaps with distinct clinical entities such as oxidant injury and hemolysis. Therefore, although a detailed discussion of these abnormal hemoglobins appears elsewhere (Chaps. 122 and 124), an overview of the subject is presented here. It is helpful to recall that the iron atom has 6 binding positions. Four of these positions are attached in a single plane to the protoporphyrin ring to form heme. The remaining 2 binding positions lie on opposite sides of this plane. One site is ordinarily bonded to the F8 proximal histidine residue of the globin chain. The remaining site is available for binding molecular oxygen, but it can also bind carbon monoxide, nitric oxide, cyanide, a hydroxide ion, or water. The E7 distal histidine residue facilitates the binding of oxygen while sterically hindering carbon monoxide binding.

### Methemoglobin

Methemoglobin (ferrihemoglobin or hemoglobin) is the oxidized form of deoxyhemoglobin in which at least one heme iron is in the oxidized (Fe<sup>3+</sup>) valence state. A number of valency hybrids can occur, depending on the number of ferric versus ferrous heme units within the tetramer. Methemoglobin therefore represents oxidation (loss of electrons) of the hemoglobin molecule at the iron atom. It occurs spontaneously as a consequence of interactions between the iron and oxygen. Normally, in deoxygenated hemoglobin, the heme iron is in the ferrous (Fe<sup>2+</sup>) valence state. In this state, there are 6 electrons in the outer shell, 4 of which are unpaired. When oxygen is bound, one of these electrons is partially transferred to it and the iron is reversibly oxidized. When oxygen is released, the electron is usually transferred back to heme iron, yielding the normal reduced state. Sometimes, the electron remains with the oxygen yielding a superoxide anion radical O<sub>2</sub><sup>-</sup> rather than molecular oxygen. In this case, heme iron is left in the Fe<sup>3+</sup>, or oxidized, state and is unable to release another electron to bind oxygen. This oxidation is primarily reversed via the action of cytochrome b5 reductase, also known as NADH methemoglobin reductase, which uses the electron carrier NADH generated by glycolysis (Chap. 11). Minor pathways are also involved in methemoglobin reduction, including NADPH methemoglobin reductase, which normally reduces only approximately 5% of the methemoglobin, and vitamin C, a non-enzymatic reducing agent. The activity of NADPH methemoglobin reductase is significantly accelerated by the presence of the electron donor methylene blue (Antidotes in Depth: A43 and Chap. 124) or riboflavin. Equilibrium is maintained with methemoglobin concentrations of ~1% of total hemoglobin. Many xenobiotics increase the rate of methemoglobin formation by as much as 1,000-fold. Nitrites, nitrates, chlorates, and quinones are capable of directly oxidizing hemoglobin.<sup>19</sup> Certain individuals are especially vulnerable resulting from deficient methemoglobin reduction.<sup>28</sup> The fetus and neonate are more susceptible to methemoglobinemia than the adult, because HbF is more susceptible to oxidation of the heme iron than adult hemoglobin. The newborn also has a limited capacity to reduce methemoglobin, because adult concentrations of cytochrome b5 reductase are only achieved at about 6 months of age.

### Carboxyhemoglobin

Carbon monoxide (CO) can reversibly bind to heme iron in lieu of molecular oxygen. The affinity of CO for hemoglobin is 200–300 times that of oxygen,

despite the steric hindrance of the E7 distal histidine. The presence of CO thereby precludes the binding of oxygen. In addition, CO binding within any one heme subunit degrades the cooperative binding of oxygen at the remaining heme groups of the same hemoglobin molecule. The oxyhemoglobin dissociation curve is therefore shifted to the left, reflecting the fact that oxygen is more tightly bound by hemoglobin and less able to be unloaded to the tissues. In addition, CO binds to the heme group of myoglobin and the cytochromes, interfering with cellular respiration and exacerbating the hypoxia (Chap. 122).<sup>42</sup>

### Sulfhemoglobin

Sulfhemoglobin is a bright green molecule in which the hydrosulfide anion HS<sup>-</sup> irreversibly binds to ferrous hemoglobin. The sulfur atom is probably attached to a β carbon in the porphyrin ring and not at the normal oxygen-binding site.<sup>70</sup> It has a spectrophotometric absorption band at approximately 618 nm,<sup>16</sup> is ineffective in oxygen transport, and clinically produces a condition that resembles cyanosis. The oxygen affinity of sulfhemoglobin is approximately 100 times less than that of oxyhemoglobin, shifting the oxyhemoglobin dissociation curve to the right, in favor of oxygen unbinding. Thus, the symptoms of hypoxia are not as severe with sulfhemoglobinemia as with carboxy- or methemoglobinemia.<sup>77</sup>

### Oxidation of the Globin Chain

Oxidation can also occur at the amino acid side chains of the globin protein. In particular, sulfhydryl groups can oxidize to form disulfide links between cysteine residues, which leads to the unfolding of the protein chain, exposure of other side chains, and further oxidation. When these disulfide links join adjacent hemoglobin molecules, they cause the precipitation of the concentrated hemoglobin molecules out of solution. Covalent links can also form between hemoglobin and other cytoskeletal and membrane proteins.<sup>25</sup> Eventually, aggregates of denatured and insoluble protein are visible on light microscopy as Heinz bodies. The distortion of the cellular architecture and the loss of fluidity in particular signal reticuloendothelial macrophages to excise sections of erythrocyte membrane (“bite cells”) or to remove the entire erythrocyte from the circulation (see below). To guard against these oxidation reactions, the erythrocyte maintains a pool of reduced glutathione via the actions of the NADPH generated in the hexose monophosphate shunt (assuming adequate G6PD activity to initiate this pathway). This glutathione transfers electrons to break open disulfide links and to preserve sulfhydryl groups in their reduced state.

### Hemolysis

Hemolysis is merely the acceleration of the normal process by which senescent or compromised erythrocytes are removed from the circulation.<sup>95</sup> The normal life span of a circulating erythrocyte is approximately 120 days, and any reduction in this life span represents some degree of hemolysis. If sufficiently rapid, hemolysis can overwhelm the regenerative capacity of the erythron, resulting in anemia. Intravascular hemolysis occurs when the rate of hemolysis exceeds the capacity of the reticuloendothelial macrophages to remove damaged erythrocytes, and free hemoglobin and other intracellular contents of the erythrocyte appear in the circulation.

Reticulocytosis, polychromasia, unconjugated (indirect) hyperbilirubinemia, increased serum lactate dehydrogenase, and decreased serum haptoglobin are characteristic of hemolysis. A normal or elevated RBC distribution width (RDW) and thrombocytosis are usually present. The presence of spherocytes on peripheral blood smear suggests an autoimmune or hereditary process and can be pursued with a Coombs' test. Schistocytes suggest thrombotic thrombocytopenic purpura (TTP) or hemolytic uremic syndrome, disseminated intravascular coagulation, or valvular hemolysis. Thrombotic thrombocytopenic purpura and hemolytic uremic syndrome are characterized by a microangiopathic anemia, thrombocytopenia, and normal coagulation parameters (unlike disseminated intravascular coagulation). Thrombotic thrombocytopenic purpura is discussed under platelet disorders below. Hemoglobinemia, hemoglobinuria, and hemosiderinuria occur with intravascular hemolysis. Specialized tests to measure hemolysis

**TABLE 20–2** Representative Xenobiotics Causing Acquired Hemolysis

#### Immune-mediated

Type I: IgG against drug tightly bound to red cell

High-dose penicillin

Type II: Complement activated by antibodies against drug-membrane complex

Cefotaxime, cefotetan, ceftriaxone, quinidine, stibophen

Type III: True autoimmune response to red cell membrane

Chlorpromazine, cladribine, cyclosporine, fludarabine, levodopa, methylodopa, procainamide

#### Nonimmune-mediated

##### Oxidants

Aniline

Benzocaine

Chlorates

Dapsone

Hydrogen peroxide

Hydroxylamine

Methylene blue

Naphthalene

Nitrites

Nitrofurantoin

Oxygen

Phenacetin

Phenazopyridine

Phenol

Platinoids

Sulfonamides

##### Nonoxidants

Arsine (AsH<sub>3</sub>)

Copper

Lead

Pyrogallol acid

Stibine (SbH<sub>3</sub>)

##### Hypophosphatemia

Microangiopathic (eg, ticlopidine, clopidogrel, prasugrel, cyclosporine, tacrolimus, mitomycin, gemcitabine)

Osmotic agents (eg, water)

Venoms (snake, spider)

detect shortened erythrocyte survival, increased endogenous carbon monoxide generation from heme oxygenase, and increased fecal urobilinogen.

Table 20–2 presents a classification of acquired causes of hemolysis relevant to toxicology. Oxidant injury following xenobiotic exposure is one of the triggers of hemolysis, as it causes irreversible changes in the erythrocyte. Erythrocytes deficient in G6PD by virtue of cell age or enzyme mutations are particularly vulnerable to hemolysis following oxidant stress due to limited capacity to generate NADPH and reduced glutathione.<sup>95</sup> The immune-mediated hemolytic anemias occur when ingested xenobiotics trigger an antigen antibody reaction. In general, these molecules are too small to be sensitizing agents, but antigenicity is acquired after binding to carrier proteins in blood. The particulars of the xenobiotic-carrier immune activation sequence form the basis for the classification of this group of hemolytic anemias.<sup>9</sup>

### Nonimmune-Mediated Causes of Xenobiotic-Induced Hemolysis

A number of xenobiotics or their reactive metabolites cause hemolysis via oxidant injury. A Heinz-body hemolytic anemia results, which typically resolves within a few weeks of drug discontinuation. Some xenobiotics cause hemolysis in the absence of overt oxidant injury (Table 20–2). Copper sulfate hemolysis is described in Chap. 92, whereas the delayed hemolysis following exposure to arsine or stibine is described here.

Arsine (AsH<sub>3</sub>) is a colorless, odorless, nonirritating gas that is 2.5 times denser than air (Chap. 86). Clinical signs and symptoms appear after a latent period of up to 24 hours after exposure to concentrations above 30 ppm and may include headache, malaise, dyspnea, abdominal pain with nausea and vomiting, hepatomegaly, hemolysis with hemoglobinuric acute kidney injury, and death.<sup>23,35,54,58,80</sup> The mechanism of hemolysis is believed to involve the fixation of arsine by sulfhydryl groups of hemoglobin and other essential proteins.<sup>40,106</sup> Interestingly, hemolysis is prevented in vitro by conversion to carboxy- or methemoglobin.<sup>45</sup> Impairment of membrane proteins, including Na<sup>+</sup>,K<sup>+</sup>,ATPase, is another potential mechanism for arsine-induced hemolysis.<sup>83</sup> Chronic exposure to low levels of arsine can produce clinically significant disease.<sup>23</sup> Stibine (SbH<sub>3</sub>), an antimony derivative, likely causes hemolysis via similar mechanisms (Chap. 85).

### Glucose-6-Phosphate Dehydrogenase Deficiencies

Glucose-6-phosphate dehydrogenase deficiencies (G6PD) is the enzyme that catalyzes the first step of the hexose monophosphate shunt: the conversion of glucose-6-phosphate to phosphogluconolactone (Fig. 11–8). In the process, NADP<sup>+</sup> is reduced to NADPH, which the erythrocyte uses to maintain a supply of reduced glutathione and to defend against oxidation. It follows that erythrocytes deficient in G6PD activity are less able to resist oxidant attack and, in particular, to maintain sulfhydryl groups of hemoglobin in their reduced state, resulting in hemolysis. It is important to recognize that the term G6PD deficiency encompasses a wide range of differences in enzyme activities among individuals. These differences result from decreased enzyme synthesis, altered catalytic activity, or reduced stability of the enzyme. Approximately 7.5% of the world population is affected to some degree, with more than 400 variants having been identified. Most cases involve relatively mild deficiency and minimal morbidity. Ethnic populations from tropical and subtropical countries (the so-called malaria belt) have a much higher prevalence of G6PD deficiency, possibly because that phenotype protects against malaria.<sup>72</sup>

The gene that encodes for G6PD resides near the end of the long arm of the X-chromosome. Most mutations consist of a single amino acid substitution, as complete absence of this enzyme is lethal. Although men hemizygous for a deficient gene are more severely affected, women randomly inactivate one X-chromosome during cellular differentiation (the Lyon hypothesis). Thus, women carriers heterozygous for a deficient G6PD gene have a mosaic of erythrocytes, some proportion of which expresses the deficient gene during maturation. Accordingly, approximately 10% of carrier women are nearly as severely affected as males hemizygous for the same deficient gene. Because of the high gene frequency in certain ethnic groups, another approximately 10% of women are homozygous for the deficient gene.

Normal G6PD has a half-life of about 60 days. Because the erythrocyte cannot synthesize new protein, the activity of G6PD normally declines by approximately 75% over its 120-day life span. Consequently, even in unaffected individuals, susceptibility to oxidant stress varies based on the age mix of circulating erythrocytes. In all cases, older erythrocytes are less likely to recover following exposure to an oxidant and will hemolyze first. Moreover, after an episode of hemolysis following acute exposure to an oxidant stress, the higher G6PD activity of surviving erythrocytes will confer some resistance against further hemolysis in most individuals with relatively mild deficiency, even if the offending xenobiotic is continued. For this reason, phenotypic testing for G6PD deficiency is best done 2 to 3 months after a hemolytic crisis, which is when the reticulocyte count has usually normalized.

The World Health Organization classification of G6PD is based on the degree of enzyme deficiency and severity of hemolysis.<sup>18</sup> Both class I and class II patients are severely deficient, with less than 10% of normal G6PD activity. Class I individuals are prone to chronic hemolytic anemia, whereas class II patients experience intermittent hemolytic crises. Class III patients have only moderate (10%–60%) enzyme deficiency, and experience self-limiting hemolysis in response to certain xenobiotics and infections.

**TABLE 20–3 Selected Xenobiotics That Cause Hemolysis in Patients with G6PD Deficiency**

Alkyl nitrites	Phenylhydrazine
Doxorubicin	Primaquine
Furazolidone	Sulfacetamide
Methylene blue	Sulfamethoxazole
Nalidixic acid	Sulfanilamide
Naphthalene	Sulfapyridine
Nitrofurantoin	Toluidine blue
Phenazopyridine	Trinitrotoluene

Data from Beutler E: Glucose-6-phosphate dehydrogenase deficiency. *N Engl J Med.* 1991;324:169–174 and Beutler E: G6PD deficiency. *Blood.* 1994;84:3613–3636.

Approximately 11% of African Americans have a class III deficiency, traditionally termed type A<sup>-</sup>, and experience a decline of no more than 30% of the red blood cell mass during any single hemolytic episode. Another 20% of African Americans have type A<sup>+</sup> G6PD enzyme, which is functionally normal, and therefore of no consequence despite a one-base substitution compared to wild-type B. The Mediterranean type found in Sardinia, Corsica, Greece, the Middle East, and India is a class II deficiency, and hemolysis either occurs spontaneously or in response to ingestion of oxidants, such as the β-glycosides found in fava (*Vicia fava*) beans.

The most common clinical presentation of previously unrecognized G6PD deficiency is the acute hemolytic crisis. Typically, hemolysis begins 1 to 4 days following the exposure to an offending xenobiotic or infection (Table 20–3). Jaundice, pallor, and dark urine occur accompanied by abdominal and back pain. A decrease in the concentration of hemoglobin occurs. The peripheral smear demonstrates cell fragments and cells that have had Heinz bodies excised. Bone marrow stimulation results in a reticulocytosis by day 5 and an increased erythrocyte mass. In general, a normal bone marrow can compensate for ongoing hemolysis and can return the hemoglobin concentration to normal. Most crises are self-limiting because of the higher G6PD activity of younger erythrocytes. Historically, the anemia observed when primaquine was administered to type A<sup>-</sup> military recruits for malaria prophylaxis resolved within 3 to 6 weeks in most cases.<sup>17</sup> Some xenobiotics, including APAP, vitamin C, and sulfisoxazole, are safe at therapeutic doses but can cause hemolysis in G6PD-deficient patients following overdose.

Other presentations of more severe variants of G6PD include neonatal jaundice and kernicterus, chronic hemolysis with splenomegaly and black pigment gallstones, megaloblastic crisis caused by folate deficiency, and aplastic crisis after parvovirus B19 infection.

### Megaloblastic Anemia

Vitamin B<sub>12</sub> and folate are essential for one-carbon metabolism in mammals. One-carbon fragments are necessary for the biosynthesis of thymidine, purines, serotonin, and methionine; the methylation of DNA, histones, and other proteins; and the complete catabolism of branched-chain fatty acids and histidine. Unable to synthesize vitamin B<sub>12</sub> or folate, mammals are dependent on dietary sources and microorganisms for these cofactors. The hematologic manifestation of vitamin B<sub>12</sub> or folate deficiency is a characteristic panmyelosis termed *megaloblastic anemia*. The hallmark nuclear-cytoplasmic asynchrony is due to disrupted DNA synthesis, halted interphase and ineffective erythropoiesis.<sup>82</sup> The hyperplastic bone marrow contains precursor cells with abnormal nuclei filled with incompletely condensed chromatin. Among circulating blood cells, macrocytic anemia (macro-ovalocytes) without reticulocytosis is followed by the appearance of granulocytes with an abnormally large, distorted nucleus (hypersegmented neutrophils with 6 or more lobes). Lymphocytes and platelets appear normal but are functionally impaired.

In addition to dietary deficiencies, which have become less common, macrocytic anemia with or without megaloblastosis in adults is usually caused

by chronic ethanol abuse, chemotherapeutics, or antiretrovirals, especially when mean corpuscular volumes are only moderately elevated (100–120 fL).<sup>90</sup> The folate antagonists aminopterin, methotrexate, hydantoins, pyrimethamine, proguanil, sulfasalazine, trimethoprim sulfamethoxazole, and valproate can interfere with DNA synthesis. Ethanol affects folate metabolism and transport. A functional vitamin B<sub>12</sub> deficiency is induced by chronic exposure to nitrous oxide, biguanides, colchicine, neomycin, and the proton pump inhibitors. Purine analogs (eg, azathioprine, 6-mercaptopurine, 6-thioguanine, acyclovir) and pyrimidine analogs (eg, 5-fluorouracil, floxuridine, 5-azacitidine, and zidovudine) also disrupt nucleic acid synthesis. Hydroxyurea and cytarabine, which inhibit ribonucleotide reductase, also delay nuclear maturation and function and frequently cause megaloblastosis.

### Pure Red Cell Aplasia

Pure red cell aplasia is an uncommon condition in which erythrocyte precursors are absent from an otherwise normal bone marrow. It results in a normocytic anemia with inappropriately low reticulocyte count. The other blood cell lines are unaffected, unlike aplastic anemia. Pharmaceuticals cause fewer than 5% of cases of this uncommon condition, having been implicated in fewer than 100 human reports.<sup>99</sup> Only phenytoin, azathioprine, and isoniazid meet criteria for definite causality; chlorpropamide and valproic acid can be considered only as possible causes.<sup>99</sup> Most other xenobiotics are cited only in single case reports, and drug rechallenge was not used, making the association uncertain.

In part because of its rarity, a cluster of 13 cases in France of pure red cell aplasia in hemodialysis patients receiving subcutaneous recombinant EPO ultimately led to an international effort by researchers, regulatory authorities, and industry to identify the etiology.<sup>12,26</sup> To reduce theoretical concerns regarding transmission of variant Creutzfeldt-Jakob disease, human serum albumin was replaced with polysorbate 80 as the stabilizer in a formulation used in Europe and Canada. It is suspected that this change allowed rubber to leach from the uncoated stopper of prefilled syringes, triggering an immune response against both recombinant and endogenous EPO in some patients.<sup>66</sup> This episode not only serves as a recent example of successful pharmacovigilance for rare adverse drug effects but has also influenced safety assessments for an emerging class of biological therapies that include simple peptides, monoclonal antibodies, and recombinant DNA proteins.<sup>14,66</sup>

### Erythrocytosis

Erythrocytosis denotes an increase in the red cell mass, either in absolute terms or relative to a reduced plasma volume. An increasingly recognized cause of drug-induced absolute erythrocytosis is the abuse of recombinant human EPO by athletes to enhance aerobic capacity (Chap. 41). Autologous blood transfusions (doping) are also used in this population, and both can cause dangerous increases in blood viscosity. Cobalt was once considered for the treatment of chronic anemia<sup>32</sup> because of its ability to cause a secondary erythrocytosis (Chap. 91). The mechanism is hypothesized to involve impaired degradation of the transcription factor hypoxia-inducible factor 1 $\alpha$ , thereby prolonging EPO transcription. This effect is more pronounced in high-altitude dwellers, in whom elevated serum EPO concentrations persist despite hematocrits in excess of 75%, and chronic mountain sickness is associated with increased serum cobalt concentrations.<sup>53</sup>

## THE LEUKON

The leukon represents all leukocytes (white blood cells), including precursor cells, cells in the circulation, and the large number of extravascular cells. It includes the granulocytes (neutrophils, eosinophils, and basophils), lymphocytes, and monocytes. Neutrophils (polymorphonuclear leukocytes) are highly specialized mediators of the inflammatory response, and are a primary focus of concern regarding hematologic toxicity of xenobiotics. B and T lymphocytes are involved in antibody production and cell-mediated immunity. Monocytes migrate out of the vascular compartment to become tissue macrophages and to regulate immune system function.

Immunity is generally divided into the *innate* and the *adaptive* responses. *Innate immunity* is an immediate but less specific defense that is highly

conserved in evolutionary terms. It is centered on the neutrophil response, and it involves monocytes and macrophages as well as complement, cytokines, and acute phase proteins. The innate system responds primarily to extracellular pathogens, especially bacteria, by recognizing structures commonly found on pathogens, namely lipopolysaccharide (Gram-negative cell walls), lipoteichoic acid (Gram positive), and mannans (yeast). *Adaptive immunity* is demonstrated only in higher animals and is an antigen-specific response via T and B lymphocytes after antigen presentation and recognition. Although this reaction is more specific, it requires several days to develop, unless that antigen has previously triggered a response (so-called immune memory). This response can also at times be directed against self-antigens, resulting in autoimmune disorders.

The recruitment and activation of neutrophils provide the primary defense against the invasion of bacterial and fungal pathogens. They emerge from the bone marrow with the biochemical and metabolic machinery needed for the efficient killing of microorganisms. Activated macrophages release G-CSF and GM-CSF, which stimulate myeloid differentiation and are recognized on blood testing as the classic neutrophil leukocytosis. Neutrophils are activated when circulating cells detect chemokines released from sites of inflammation. On activation, they undergo conformational and biochemical changes that transform them into powerful host defenders. These changes allow rolling along the endothelial lining of postcapillary venules, migration toward the site of inflammation, adherence to the endothelium, migration through the endothelium to tissue sites, ingestion, killing, and digestion of invading organisms.

Neutrophils migrate to sites of infection along gradients of chemoattractant mediators. An acute inflammatory stimulus leads to the accumulation of neutrophils along the endothelium of postcapillary venules. The major molecules involved in this process are adhesion molecules, chemoattractants, and chemokines. Loose adhesions between neutrophils and endothelium are made and broken, resulting in the slow movement of leukocytes along endothelium and a more intense exposure of neutrophils to activating factors. Chemotaxis requires responses involving actin polymerization–depolymerization adhesion events mediated by integrins and involving microfilament–membrane interactions. All leukocytes including lymphocytes localize infection using these same mediators. Colchicine depolymerizes microfilaments, causing the dissolution of the fibrillar microtubules in granulocytes and other motile cells, impairing this response.

Oposonized particles, immune complexes, and chemotactic factors activate neutrophils in tissues by binding to cell surface receptors. The neutrophil makes tight contact with its target, and the plasma membrane surrounds the organism completely enclosing it. Two mechanisms are then responsible for the destruction of the organism: the oxygen-dependent respiratory burst, and the oxygen-independent response involving cationic enzymes found in cytoplasmic granules. The respiratory burst is caused by an NADPH oxidase complex that assembles at the phagosomal membrane. Electrons are transferred from cytoplasmic NADPH to oxygen on the phagosomal side of the membrane, generating superoxide, hydrogen peroxide, hydroxyl radical, singlet oxygen, hypochlorous acid, chloramines, nitric oxide, and peroxynitrite. Cytoplasmic granules within the neutrophil fuse with the phagosome and empty their contents into it. The components of these granules include myeloperoxidase (MPO), elastase, lipases, metalloproteinases, and a pool of CD11b/CD18 proteins required for adhesion and migration. Finally, the phagocytized organism is digested and eliminated by the neutrophil. Overstimulation of this complex and highly regulated but somewhat nonspecific system can at times become deleterious, as is postulated to occur with reperfusion injury or carbon monoxide poisoning, to cite 2 examples.<sup>98</sup> Vasculitis and the systemic inflammatory response syndrome are further examples of excessive activation of the innate response.

### Neutropenia and Agranulocytosis

Neutropenia is a reduction in circulating neutrophils at least 2 standard deviations below the norm, but the threshold of 1500/mm<sup>3</sup> (1.5 × 10<sup>9</sup>/L) is often used instead.<sup>48</sup> Severe neutropenia is termed *agranulocytosis* and is

generally defined to be an absolute neutrophil count of less than  $500/\text{mm}^3$  ( $0.5 \times 10^9/\text{L}$ ). Neutropenia results from decreased production, increased destruction, or retention of neutrophils in the various storage pools. Their high rate of turnover renders neutrophils vulnerable to any xenobiotic that inhibits cellular reproduction. As such, the various antineoplastics including antimetabolites, alkylating agents, and antimetotics will predictably cause neutropenia. This predictable, dose-dependent reaction represents an important dose-limiting adverse effect of therapy. On the other hand, a number of xenobiotics are implicated in idiosyncratic neutropenia.<sup>3,4</sup> The parent drug or a metabolite usually acts as a hapten to trigger antineutrophil antibodies. Table 20–4 provides an abbreviated list.<sup>2,79,97</sup> Cocaine users are at very high risk for agranulocytosis because of the common contamination of this drug with levamisole (Chaps. 17 and 75).<sup>22</sup>

### Eosinophilia

Eosinophils are primarily responsible for protecting against parasitic infection. Allergic reactions and malignancies such as lymphoma are also common causes of eosinophilia, especially where nematode infection is rare.<sup>88</sup> Eosinophils bind to antigen-specific IgE and discharge their large granules, which contain major basic protein, peroxidase, and eosinophil-derived neurotoxin, onto the surface of the antibody-coated organism. Two unusual toxicologic outbreaks were characterized by eosinophilia, acute cough, fever, and pulmonary infiltrates, followed by severe myalgia, neuropathy, and eosinophilia. The first outbreak, called the toxic oil syndrome, took place in central Spain in 1981, when industrial-use rapeseed oil denatured with 2% aniline was fraudulently sold as olive oil by door-to-door salesmen.<sup>37</sup> The precise causative agent remains uncertain but may include fatty acid esters of 3-(*N*-phenylamino)-1,2-propanediol.<sup>37</sup> The second outbreak, called the eosinophilia-myalgia syndrome, occurred during 1988 and 1989 in users of L-tryptophan supplements traced back to a single wholesaler in Japan.<sup>6</sup> The causative contaminant has not been identified but is believed to have been present in only trace quantities in the L-tryptophan purified from

microbial culture. Both syndromes appear to be mediated by immunologic mechanisms.

### Leukemia

The leukemias represent the malignant, unregulated proliferation of hematopoietic cells. Although monoclonal in origin, they affect all cell lines derived from the progenitor cell. Acute myeloid leukemia (AML) and the myelodysplastic syndromes are the most common leukemias associated with xenobiotics. The long-recognized association between AML and occupational benzene exposure, radiation, or treatment with alkylating antineoplastics has helped to advance understanding of the molecular mechanisms underlying leukemogenesis.<sup>15</sup> The necessary events are believed to involve several sequential genetic and epigenetic alterations, as evidenced by a distinct pattern of chromosomal deletions preceding the development of AML.<sup>50,51</sup> Other recognized xenobiotics that cause leukemia include topoisomerase II inhibitors, 1,3-butanediol, styrol, ethylene oxide, and vinyl chloride.<sup>55,78</sup> In many cases, the latency period between exposure and illness is prolonged. For example, leukemia linked to benzene is preceded by several months of anemia, neutropenia, and thrombocytopenia.

### HEMOSTASIS

In the absence of pathology, blood remains in a fluid form with cells in suspension. Injury triggers coagulation and thrombosis. The resulting clot formation, retraction, and dissolution involve an interaction between the vessel endothelium, soluble constituents of the coagulation system, and proteins located on and within platelets. Platelets respond to signals within their immediate environment and from injured components of the distant microcirculation. A dynamic balance must be maintained between coagulation and fibrinolysis to maintain the integrity of the circulatory system (Fig. 20–5).

### Coagulation

Two basic pathways termed *intrinsic* and *extrinsic* are involved in the initiation of coagulation. The more important extrinsic, or tissue factor, pathway is activated when blood is exposed to tissue factor (also known as thromboplastin) which is normally expressed on subendothelial cells and fibroblasts not in direct contact with blood. Tissue factor activates factor VII and together form the extrinsic tenase complex activating both factors X and IX. The intrinsic, or contact activation, pathway also activates factor IX, which forms the intrinsic tenase (i.e., “ten”-ase) complex with factor VIIIa. Both extrinsic and intrinsic tenase with calcium activate factor X, which binds to factor Va on the surface of activated platelets, forming the prothrombinase complex. The prothrombinase complex activates prothrombin, which results in the generation of thrombin activity. Thrombin activates platelets, promotes its own generation by activation of factors V, VIII, and XI, and converts fibrinogen to fibrin (Chap. 58).<sup>47</sup>

### Laboratory Tests of Coagulation

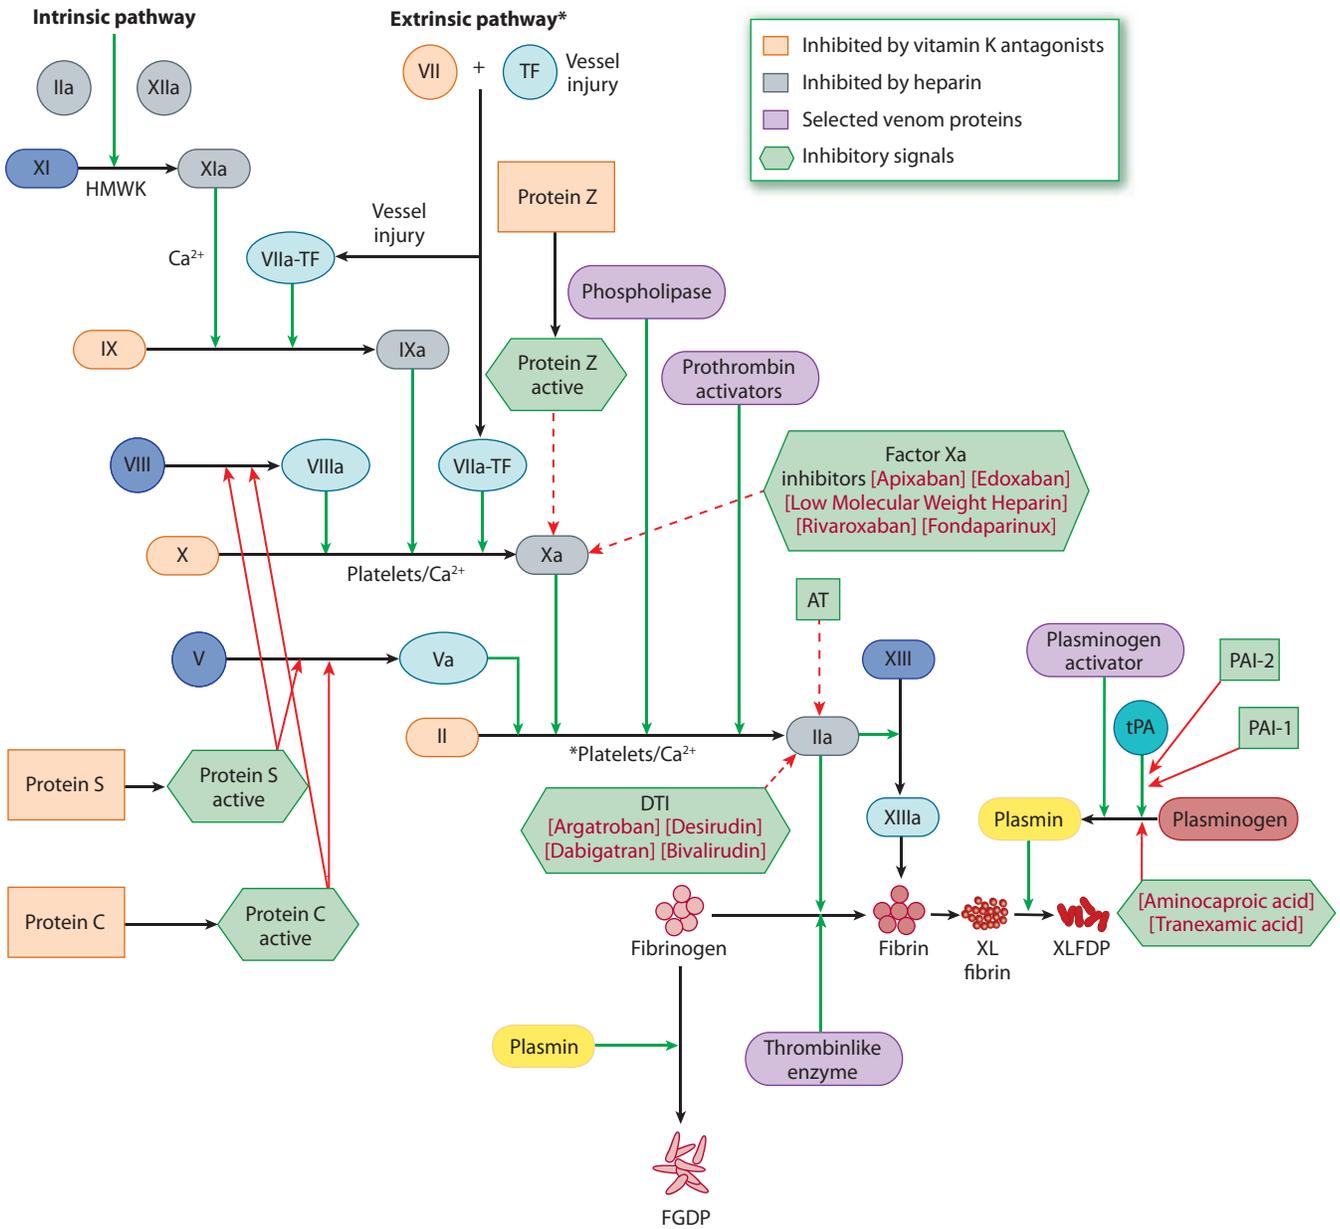

An understanding of several widely available coagulation tests is important to achieve the correct interpretation of the effects of xenobiotics on hemostasis, whether for therapeutic drug monitoring or following overdose. Four studies—prothrombin time (PT, or international normalized ratio<sup>96</sup>), partial thromboplastin time (PTT), thrombin time, and fibrinogen-concentration—are particularly important in the classification of coagulation disorders.

The PT assesses the extrinsic coagulation pathway and is calculated by adding standardized thromboplastin reagent (phospholipid and tissue factor) to a sample of the patient’s citrated plasma (the citrate removes calcium to prevent clotting). Calcium is then introduced, and the time to clotting measured. With the exception of factor X, the PT is unaffected by the presence or absence of factors VIII to XIII, platelets, prekallikrein, and high-molecular-weight kininogen (HMWK). An individual’s PT was formerly expressed as a ratio (PT observed to PT control). Because this ratio is directly affected by both laboratory methodology and the source of the thromboplastin reagent used, the generated results suffered from significant variability between laboratories and countries. Thus, the INR was developed in an attempt to limit this variability. The INR is calculated by

**TABLE 20–4** Selected Causes of Idiosyncratic Drug-Induced Agranulocytosis

Antiepileptics	Antipsychotics
Carbamazepine	Clozapine <sup>a</sup>
Phenytoin	Phenothiazines
Antiinflammatories	Antithyroid agents
Aminopyrine	Methimazole <sup>a</sup>
Ibuprofen	Propylthiouracil <sup>a</sup>
Indomethacin	Cardiovascular
Phenylbutazone	Hydralazine
Antimicrobials	Lidocaine
β-Lactams, including penicillin G <sup>a</sup>	Procainamide <sup>a</sup>

**FIGURE 20-5.** A schematic overview of the coagulation, platelet activation, and fibrinolytic pathways indicating where phospholipids on the platelet surface interact with the coagulation pathway intermediates. Arrows are not shown from platelets to phospholipids involved in the tissue factor VIIa and the factor IX to VIIIa interactions to avoid confusion. Interactions of selected venom proteins are indicated in the purple boxes. The diagram is not complete with reference to the multiple sites of interaction of the serine protease inhibitors (SERPINS) to avoid overcrowding. Solid red lines indicate inhibition of a reaction effect. Black arrows refer to chemical conversion of coagulation factors. Green arrows represent activation of the chemical conversion pathway. Dashed red lines indicate inhibition of a specific clotting factor. \*Refer to Figs. 58-4 and 58-5 for the platelet activation pathway. DTI = direct thrombin inhibitor; FDP = fibrin degradation products; FGDP = fibrinogen degradation product; HMWK = high-molecular-weight kinogen; TF = tissue factor; t-PA = tissue plasminogen activator; XL = cross-linked.

raising the PT ratio to an exponent known as the International Sensitivity Index (ISI), that is,  $(PT \text{ ratio})^{ISI}$ . The ISI is calibrated against an international standard to measure responsiveness of the particular thromboplastin to the effects of warfarin.

Although the use of the INR does not completely eliminate variability, it improves warfarin dosing and comparison with international norms. It should be noted that the ISI, and thus the INR, are designed for greater consistency in measuring coagulation changes due to warfarin, but are often more variable than the PT ratio for patients with other coagulation defects.<sup>87</sup> Specifically, replacing the PT with the INR for prognosis in the setting of fulminant hepatic failure, as occurs following APAP overdose, is controversial.<sup>24</sup> In these patients, the INR is more variable between laboratories, and the use of a substantially different ISI may be warranted.<sup>11</sup>

The PTT tests both the intrinsic and common coagulation pathway. It is measured by adding calcium and an activator (kaolin, silica, or celite)

to citrated plasma and the time to clotting observed. Some tests also use phospholipids in the reagent to activate the remaining coagulation factors, thereby giving rise to the term *activated partial thromboplastin time* (aPTT). Because the PTT and aPTT are essentially interchangeable, the term PTT is used hereafter to represent the concept. The PTT is not affected by alterations in factors VII, XIII, or platelets.

The thrombin time (or thrombin clotting time), determined by adding exogenous thrombin to citrated plasma, evaluates the ability to convert fibrinogen to fibrin, and is thus unaffected by abnormalities of factors II, V, VII to XIII, platelets, prekallikrein, or HMWK. Finally, either a fibrinogen concentration or a determination of fibrin degradation products will help distinguish between problems with clot formation and consumptive coagulopathy (disseminated intravascular coagulation). An evaluation of the combination of normal and abnormal results of these tests usually determines a patient's clotting abnormality (Table 20-5).

**TABLE 20–5** Evaluation of Abnormal Coagulation Times

<b>PT prolonged, PTT normal</b>
Deficiency of factor VII
Warfarin therapy and other vitamin K antagonists (early)
Vitamin K deficiency (mild)
Liver disease (mild)
<b>PT normal, PTT prolonged, bleeding</b>
Deficiencies of factors VIII, IX, XI
von Willebrand disease
<b>PT normal, PTT prolonged, no bleeding</b>
Deficiencies of factor XII, prekallikrein
High-molecular-weight kininogen inhibitor syndrome
<b>PT and PTT prolonged, thrombin time normal, fibrinogen normal</b>
Deficiencies of factors II, V, IX; vitamin K deficiency (severe)
Warfarin therapy (late)
Factor Xa inhibitor therapy (eg, rivaroxaban, apixaban) <sup>a,b</sup>
<b>PT and PTT prolonged, thrombin time abnormal, fibrinogen normal</b>
Heparin therapy <sup>a</sup>
Direct thrombin inhibitor therapy (eg, dabigatran) <sup>c</sup>
Dysfibrinogenemia
<b>PT and PTT prolonged, thrombin time abnormal, fibrinogen abnormal</b>
Crotaline envenomation
Disseminated intravascular coagulation
Fibrinolytic therapy
Liver disease

<sup>a</sup>PTT insensitive to low-molecular-weight heparin effects and less sensitive than PT to factor Xa inhibitor therapy. <sup>b</sup>Normal PT does not exclude effect. <sup>c</sup>Prolongation of PTT is not linearly correlated with dabigatran concentration.

PT = prothrombin time; PTT = partial thromboplastin time.

Inhibitors are diagnosed by “mixing studies,” because only a small percentage of the coagulation factors present in normal plasma are necessary to have normal clotting studies. Factor activity in blood can be as little as 25% of normal without affecting the PT or PTT. Thus, the presence of an abnormal PT or PTT that will not correct despite the addition of an equal volume of normal plasma demonstrates the presence of an inhibitor of coagulation as opposed to a factor deficiency. Heparin-induced anticoagulation results in an elevated PTT that does not correct when mixing studies are performed. More sophisticated studies are used to identify specific coagulation factor deficiencies.

### Xenobiotic-Induced Defects in Coagulation

A rapidly increasing number of xenobiotics are in therapeutic use to antagonize coagulation (Chap. 58). The recognition of a hemorrhagic disease in cattle in the 1920s and the isolation of the causative agent dicoumarol from spoiled sweet clover in the 1940s resulted in the development of the warfarin-type anticoagulants. This group of anticoagulants indirectly inhibits hepatic synthesis of coagulation factors II, VII, IX, X, and proteins C, S, and Z by inhibiting the reductase that is responsible for the regeneration of vitamin K quinone from vitamin K epoxide. Because warfarin is widely prescribed and has a narrow therapeutic index, efforts to improve our understanding of the pharmacology of warfarin are advancing the fields of pharmacogenomics and drug interactions.<sup>105</sup>

Heparin is a highly sulfated glycosaminoglycan that is normally present in tissues. Commercial unfractionated heparin is either bovine or porcine in origin and consists of a mixture of polysaccharides with molecular weights ranging from 4,000 to 30,000 Da. The anticoagulant activity of heparin is through its catalytic activation of antithrombin III, a suicide inhibitor of the serine proteases thrombin and factors IXa, Xa, XIa, and XIIIa.<sup>71</sup>

The low-molecular-weight heparins (LMWHs) have a mean molecular weight of 4,000–6,000 Da.<sup>47</sup> Their subcutaneous bioavailability, more predictable pharmacokinetics, lower protein binding, and longer half-life make them more convenient than unfractionated heparin.<sup>71</sup>

*Heparinoids* are glycosaminoglycans not derived from heparin with anticoagulant effects. This class includes dermatan sulfate and danaparoid sodium. Fondaparinux is a synthetic pentasaccharide that also inhibits factor Xa by binding to antithrombin III and therefore acts upstream of thrombin. Other oral factor Xa inhibitors are approved for human use, including rivaroxaban, apixaban, and edoxaban. Several direct thrombin inhibitors are also in clinical use, including parenterally administered lepirudin, argatroban, bivalirudin, desirudin, and oral dabigatran. These xenobiotics prolong the INR, aPTT, thrombin clotting time, and whole-blood activated clotting time.

### Fibrinolysis

The coagulation system is opposed by 3 major inhibitory systems. Components of the fibrinolytic system circulate as zymogens, activators, inhibitors, and cofactors.<sup>33</sup> Plasminogen can be activated to plasmin by an intrinsic pathway involving factor XII, prekallikrein, and HMWK. This produces the degradation products and fibrin monomers that are found in disseminated intravascular coagulation. The extrinsic pathway involves the release of tissue plasminogen activator (t-PA) from tissues and urokinase plasminogen activator (u-PA) from secretions.<sup>33</sup> Once activated, plasmin degrades fibrinogen, fibrin, and coagulation factors V and VIII. The degradation of cross-linked fibrin strands results in the formation of D-dimers.

Several inhibitors oppose the fibrinolytic system, including  $\alpha_2$ -antiplasmin,  $\alpha_2$ -macroglobulin, both of which oppose plasmin activity, and plasminogen activator inhibitor (PAI) types 1 and 2, which oppose t-PA. Plasminogen activator inhibitor (PAI-1) and PAI-2 are opposed by activated protein C and protein S. Activated protein C is activated by thrombin. Another vitamin K-dependent glycoprotein, protein Z, accelerates the degradation of factor Xa. Congenital deficiencies of proteins C, S, and Z result in pathologic venous thrombosis. Decreased fibrinolytic activity results from decreased synthesis, release of t-PA, or from an elevation of the PAI-1 concentration. Both conditions are observed postoperatively, with the use of oral contraceptives, in the third trimester of pregnancy, and in obesity. The activity of  $\alpha_2$ -antiplasmin and  $\alpha_2$ -macroglobulin are increased in pulmonary fibrosis, malignancy, infection, and myocardial infarction, and in thromboembolic disease.<sup>33</sup>

### Xenobiotic-Induced Defects in Fibrinolysis

Table 20–6 lists xenobiotics associated with an acquired defect of fibrinolysis. The chemotherapeutics result in a reduction in serine-protease inhibitors such as antithrombin. L-Asparaginase is associated with a reduction in

**TABLE 20–6** Selected Xenobiotics and Endogenous Factors, Cytokines, and Hormones That Impair Fibrinolysis

Antifibrinolytics
$\epsilon$ -Aminocaproic acid

Coagulation factors
Cytokines
Erythropoietin
Thrombopoietin
Hormones, including conjugated estrogens

circulating t-PA concentrations. Methotrexate damages vascular endothelium, which triggers thrombosis (Chap. 51).<sup>33</sup> Hemostatic xenobiotics used therapeutically include the synthetic lysine derivatives aminocaproic acid and tranexamic acid, which bind reversibly to plasminogen; the bovine pro-tease inhibitor aprotinin, which inhibits kallikrein; the vasopressin analog desmopressin, which increases plasma concentrations of factor VIII and vWF; and conjugated estrogens, which normalize bleeding times in uremia.<sup>65</sup>

## PLATELETS

In the resting state, platelets maintain a discoid shape. The platelet membrane is a typical trilaminar membrane with glycoproteins, glycolipids, and cholesterol embedded in a phospholipid bilayer. The plasma membrane is in direct continuity with a series of channels, the surface-connected canalicular system (SCCS), which is sometimes referred to as the open canalicular system. The SCCS provides a route of entry and exit for various molecules, a storage pool for platelet glycoproteins, and an internal reservoir of membrane that is recruited to increase platelet surface area. This facilitates platelet spreading and pseudopod formation during the process of cell adhesion.

The glycocalyx, or outer coat, is heavily invested with glycoproteins that serve as receptors for a wide variety of stimuli. The  $\beta_1$ -integrin family includes receptors that mediate interactions between cells and mediators in the extracellular matrix, including collagen, laminin, and fibronectin. The  $\beta_2$ -integrin receptors are present in inflammatory cells and platelets and are important in immune activation. The  $\beta_3$ -integrin receptors (also known as cytoadhesins) include the glycoprotein (GP) IIb-IIIa fibrinogen receptor, as well as vitronectin.<sup>47</sup> Vitronectin has binding sites for other integrins, collagen, heparin, and components of complement. All of the integrins are active in the process of platelet adhesion to surfaces. Platelet aggregation is mediated by the GP IIb-IIIa receptors.<sup>47</sup>

The submembrane region contains actin filaments that stabilize the platelets' discoid shape and are involved in the formation and stabilization of pseudopods. They also generate the force needed for the movement of receptor-ligand complexes from the outer plasma membrane to the SCCS. These mobile receptors are important in the spreading of platelets on surfaces, and for binding fibrin strands and other platelets. Platelet cytoplasm contains 3 types of membrane-bound secretory granules.<sup>47</sup> The  $\alpha$  granules contain  $\beta$ -thromboglobulin, which mediates inflammation, binds and inactivates heparin, and blocks the endothelial release of prostacyclin. In addition, platelet factor-4, which inactivates heparin, and fibrinogen are contained within the  $\alpha$  granules. Dense granules store adenine nucleotides, serotonin, and calcium, which are secreted during the release reaction. Platelet lysosomes contain hydrolytic enzymes. Stimulation by platelet agonists causes the granules to fuse with the channels of the SCCS, driving the contents out of the platelets and into the surrounding media.

### Platelet Adhesion

On the vessel wall, collagen, von Willebrand factor (vWF), and fibronectin are the adhesive proteins that play the most prominent role in the adhesion of platelets to vascular subendothelium. On the exposure of collagen (eg, following a laceration or the rupture of an atherosclerotic plaque), platelet adhesion is triggered. Under conditions of high shear (flowing blood), platelet adhesion is mediated by the binding of GP Ib-V-IX receptors on platelet membranes to vWF in the vascular subendothelium.<sup>47</sup> Following adherence of platelets to subendothelial vWF, a conformational change in GP IIb-IIIa on platelet membrane occurs, activating this receptor complex to ligate vWF and fibrinogen. The result is the amplification of platelet adhesion and aggregation. An important interaction occurs between thrombosis and inflammation. Platelet-activating factor is synthesized and coexpressed with P-selectin on the surface of the endothelium in response to mediators such as histamine or thrombin. Platelet-activating factor interacts with a receptor on the surface of neutrophils that activates the CD11/CD18 adhesion complex, and results in adhesion of neutrophils to endothelium and to platelets. This results in the synthesis of leukotrienes and other mediators of inflammation.

### Platelet Activation

Thrombin, collagen, and epinephrine can activate platelets. In response to thrombin, granules fuse with each other and with elements of the SCCS to form secretory vesicles. These vesicles are believed to fuse with the surface membrane, releasing their contents into the surrounding medium. The membranes of the secretory granules become incorporated into the platelet surface membrane.

### Platelet Aggregation

Following activation, GP IIb-IIIa is expressed in active form on the platelet surface, serving as the final common pathway for platelet aggregation regardless of the inciting stimulus. This receptor binds exogenous calcium and fibrinogen. GP IIb-IIIa ligates fibrinogen along with fibronectin, vitronectin, and vWF, resulting in the binding of platelets to other platelets, and ultimately the formation of the platelet plug. Collagen-induced platelet aggregation is mediated by adenosine diphosphate (ADP) and thromboxane  $A_2$ . Adenosine diphosphate binds to the metabotropic purine receptors P2Y<sub>1</sub> and P2Y<sub>12</sub>, leading to transient and sustained aggregation, respectively.<sup>36</sup> Thromboxane  $A_2$  is formed from arachidonic acid by the action of cyclooxygenase-1. It is a potent vasoconstrictor and inducer of platelet aggregation and release reactions.<sup>47</sup> Platelets participate in triggering the coagulation cascade by binding coagulation factors II, VII, IX, and X to membrane phospholipid, a calcium-dependent process.

### Antiplatelet Xenobiotics

#### Aspirin

Aspirin inhibits prostaglandin H synthase (cyclooxygenase<sup>27</sup>) by irreversibly acetylating a serine residue at the active site of the enzyme. Aspirin inhibition of the COX-1 isoform of this enzyme is 100 to 150 times more potent than its inhibition of the COX-2 isoform. The inhibition of COX-1 results in the irreversible inhibition of thromboxane  $A_2$  formation. Because platelets are activated by other mechanisms including thrombin, thrombosis can develop despite aspirin therapy (Chap. 37).<sup>93</sup>

#### Selective COX-2 Inhibitors

Platelets express primarily COX-1 and use it to produce mostly thromboxane  $A_2$ , which leads to platelet aggregation and vasoconstriction. Endothelial cells express COX-2 and use it to produce prostaglandin  $I_2$ , an inhibitor of platelet aggregation and a vasodilator. Whereas aspirin and traditional (nonselective) nonsteroidal antiinflammatory drugs inhibit the production of thromboxane  $A_2$  and prostaglandin  $I_2$  at both sites, the selective COX-2 inhibitors do not affect platelet-derived thromboxane  $A_2$ , perhaps accounting for the increase in cardiovascular events associated with long-term use of some of these xenobiotics.<sup>27,102</sup>

#### Glycoprotein IIb-IIIa Antagonists

The GP IIb-IIIa antagonist abciximab is a chimeric human-murine monoclonal antibody that binds the GP IIb-IIIa receptor of platelets and megakaryocytes. Two synthetic ligand-mimetic antagonists have also been developed: eptifibatid and tirofiban. These parenteral antagonists are used primarily in patients undergoing percutaneous coronary interventions.<sup>47</sup> By blocking the fibrinogen-binding site of IIb-IIIa, platelet aggregation is reversed regardless of the inciting activation. Reversible thrombocytopenia occurs within hours of initiation of these xenobiotics.<sup>89</sup>

#### ADP Receptor Inhibitors

The thienopyridines clopidogrel, ticlopidine, and prasugrel antagonize platelet aggregation by irreversible inhibition of ADP binding to the P2Y<sub>12</sub> receptor. All 3 prodrugs are associated with TTP, as well as neutropenia and aplastic anemia.<sup>13,75,76</sup> The purine analogs ticagrelor and cangrelor are direct-acting, reversible allosteric antagonists that bind to a different site on the P2Y<sub>12</sub> receptor.

#### Dipyridamole

The pyrimidopyrimidine derivative dipyridamole inhibits cyclic nucleotide phosphodiesterase in platelets, resulting in the accumulation of cyclic

adenosine monophosphate and perhaps cyclic guanine monophosphate. It also inhibits cellular reuptake of adenosine, blocks thromboxane synthase, and inhibits the thromboxane receptor.

### Xenobiotic-Induced Thrombocytopenia

Multiple xenobiotics are reported to cause thrombocytopenia, either via the formation of drug-dependent antiplatelet antibodies or as thrombocytopenic purpura (TTP). Drug-induced platelet antibodies are estimated to occur in 1 in 100,000 drug exposures. Reversible drug binding to platelet epitopes, such as GP Ib-V-IX, GP IIb-IIIa, and platelet-endothelial cell adhesion molecule-1, leads to a structural change that forms or exposes a neoepitope target for antibody formation. The presence of the drug is required for antibody binding and increased platelet destruction, but there is no covalent bond (as occurs in the hapten model of penicillin binding to the erythrocyte membrane).

Thrombocytopenia also occurs as a result of spurious clumping, pregnancy, hypersplenism with cirrhosis, idiopathic thrombocytopenic purpura, heparin-induced thrombocytopenia (Chap. 58), bone marrow toxicity, and TTP. After excluding these conditions and nontherapeutic exposures, a systematic literature search updated annually lists more than 1,000 cases reported in English involving more than 150 xenobiotics. Table 20-7 lists the xenobiotics appearing in multiple cases, satisfying criteria for probable to definite causality including drug rechallenge. Nevertheless, a common clinical problem is to distinguish drug-induced thrombocytopenia from idiopathic thrombocytopenic purpura in a patient on multiple medications who develops thrombocytopenia. In the absence of validated laboratory assays for drug-dependent platelet antibodies other than heparin, diagnosis still depends on the clinical course following drug discontinuation and perhaps rechallenge. Large databases provide some guidance regarding past reported experience.<sup>38,63,85</sup> Severe (<20,000 platelets/mm<sup>3</sup>) or acute transient thrombocytopenia are more likely to be drug-induced.<sup>10</sup>

In patients administered the sensitizing xenobiotic *de novo*, 5 to 7 days are typically required for the development of the immune response. During rechallenge, thrombocytopenia can develop within 12 hours.<sup>10</sup> Interestingly, the unique ability of GP IIb/IIIa inhibitors such as abciximab to cause thrombocytopenia within hours of first use suggests the presence of preformed antibodies directed against platelet epitopes, perhaps accounting for *ex vivo* clumping of platelets observed in approximately one of 500 normal

patients.<sup>86</sup> Clinically, fever, chills, pruritus, and lethargy occur. The onset of life-threatening bleeding may be abrupt. Hemorrhagic vesicles develop in the oral mucosa. Laboratory investigations will demonstrate an absence of platelets on peripheral smear, prolongation of the bleeding time, deficient clot retraction, and an abnormal prothrombin consumption test. Bone marrow aspiration will demonstrate normal or increased numbers of megakaryocytes and immature forms. Treatment includes the transfusion of blood products, glucocorticoids, and the withdrawal of the offending xenobiotic.<sup>10</sup>

### Thrombotic Thrombocytopenic Purpura

Thrombocytopenic purpura is characterized by the triad of microangiopathic hemolytic anemia, severe thrombocytopenia, and fluctuating neurologic abnormalities.<sup>69</sup> Fever and acute kidney injury are also common, although overt kidney failure is rare. The hallmark is the presence of platelet aggregates throughout the microvasculature, without fibrin clot, unlike the fibrin-rich thrombi that occur in disseminated intravascular coagulation or the hemolytic uremic syndrome. In the acquired form, drug-induced autoantibodies inactivate a circulating zinc metalloprotease ADAMTS13, thereby blocking its ability to depolymerize large multimers of vWF and leading to platelet clumping.<sup>7,8,13,60,103</sup> Plasma exchange with fresh-frozen plasma replenishes ADAMTS13 and removes the inhibitory antibodies. Prior to understanding of the molecular mechanism, other causes of microvascular hemolysis with thrombocytopenia were often confused with TTP. These causes included hemolytic uremic syndrome due to shiga toxin, the HELLP syndrome of pregnancy, Rocky Mountain spotted fever, and paroxysmal nocturnal hemoglobinuria. Also included were cases secondary to xenobiotics such as cyclosporine, cocaine, gemcitabine, mitomycin C, and cisplatin, in which ADAMTS13 antibodies are not present.<sup>31,103</sup>

### Heparin-Induced Thrombocytopenia

An immune response to both unfractionated and low-molecular-weight heparin, manifested clinically by the development of thrombocytopenia and, at times, venous thrombosis, is now recognized to result from IgG antibodies against platelet factor-4, a heparin-binding chemokine.<sup>1</sup> The diagnosis is confirmed by testing for these antibodies. The heparin-platelet factor-4 antibody complex results in the release of procoagulant microparticles which release tissue factor, provide an anionic phospholipid membrane surface on which clotting cascade complexes assemble, and can lead to paradoxical thrombosis, which can be limb- or life-threatening (Chap. 58).<sup>56,57</sup>

**TABLE 20-7** Selected Xenobiotics Causing Thrombocytopenia as a Result of Antiplatelet Antibodies<sup>a</sup>

Abciximab	Indinavir
Acetaminophen	Levamisole
Aminoglutethimide	Linezolid
Aminosalicylic acid	Meclofenamic acid
Amiodarone	Nalidixic acid
Amphotericin B	Orbofiban
Carbamazepine	Oxprenolol
Cimetidine	Phenytoin
Danazol	Piperacillin
Diclofenac	Procainamide

Famotidine	Tirofiban
Furosemide	Trimethoprim-sulfamethoxazole
Gold salts	Valproate
Heparin	Vancomycin
Imipenem-cilastatin	

<sup>a</sup>Xenobiotics reported in at least 2 cases to have definitely caused immune thrombocytopenia or in at least 5 cases to have probably caused immune thrombocytopenia following therapeutic use. Data from Li X, Swisher KK, Vesely SK, et al. Drug-induced thrombocytopenia: an updated systematic review. *Drug Safety*. 2007;30:185-186 and <http://www.ouhsc.edu/platelets>.

## SUMMARY

- The mechanisms of toxic injury to the blood are extremely varied, reflecting the complexity of this vital fluid.
- Virtually all xenobiotics come into contact with blood, and have the potential to disrupt its essential functions of oxygen transport, gas exchange, signaling, host defense, and hemostasis.
- Xenobiotics directly injure mature cells, or prohibit their development by injuring the stem cell pool.
- Oxygen transport is disrupted in several distinct ways, including oxidation of the heme iron, protein globin chain disruption, and shift of the oxygen-hemoglobin dissociation curve and hemolysis.
- A common theme in hematologic toxicity is the perturbation of homeostatic equilibria that exist between cell proliferation and apoptosis, between immune activation and suppression, or between thrombophilia and thrombolysis.

# HEPATIC PRINCIPLES

Kathleen A. Delaney and Jakub Furmaga

The liver plays an essential role in metabolic homeostasis. Hepatic functions include the synthesis, storage, and breakdown of glycogen. In addition, the liver is important in the metabolism of lipids; the synthesis of albumin, clotting factors, and other important proteins; the synthesis of the bile acids necessary for absorption of lipids and lipid-soluble vitamins; and the metabolism of cholesterol. Hepatocytes facilitate the excretion of metals, most importantly iron, copper, zinc, manganese, mercury, and aluminum, as well as the detoxification of products of metabolism, such as bilirubin and ammonia.<sup>27,59</sup> Generalized disruption of these important functions results in manifestations of liver failure: hyperbilirubinemia, coagulopathy, hypoalbuminemia, hyperammonemia, and hypoglycemia. Disturbances of more specific functions result in accumulation of lipids, metals, and bilirubin, and the development of lipid-soluble vitamin deficiencies.<sup>125</sup>

The liver is also the primary site of biotransformation and detoxification of xenobiotics. The interposition of the liver between the gastrointestinal tract and systemic circulation makes it the first-pass recipient of ingested xenobiotics. The liver receives blood from the systemic circulation and participates in the detoxification and elimination of xenobiotics that reach the bloodstream through other routes, such as inhalation or cutaneous absorption.<sup>112,125</sup>

Many xenobiotics are lipophilic and inert, requiring chemical modification followed by conjugation to make them sufficiently water-soluble to be eliminated. The liver is the primary organ responsible for this biotransformation, and contains the highest concentration of cytochrome P450 (CYP) enzymes involved in the first stage of detoxification for many lipophilic xenobiotics (Chap. 11). Although many of the xenobiotics that are detoxified in the liver are subsequently excreted in the urine, the biliary tract provides an additional route for their elimination.<sup>43</sup> Although cytochrome P450 phase I activation of xenobiotics usually leads to detoxification, in some cases it can produce xenobiotics with increased toxicity and hepatocyte injury at the site of synthesis.<sup>112</sup>

## MORPHOLOGY AND FUNCTION OF THE LIVER

Two pathologic concepts are used to describe the appearance and function of the liver: a structural one represented by the hepatic lobule, and a functional one represented by the acinus. The basic structural unit of the liver as characterized by light microscopy is the hepatic lobule, a hexagon with the hepatic vein at the center and the portal triads at the angles. The portal triad consists of the portal vein, the common bile duct, and the hepatic artery. Cords of hepatocytes are oriented radially around the central hepatic vein, forming sinusoids. In contrast, the acinus, or “metabolic lobule” is the functional unit of the liver. Located between 2 central hepatic veins, it is bisected by terminal branches of the hepatic artery and portal vein that extend from the bases of the acini toward hepatic venules at the apices. The acinus is subdivided into 3 metabolically distinct zones: Zone 1 lies near the portal triad, zone 3 lies near the central hepatic vein, and zone 2 is the intermediate area.<sup>125</sup> Figure 21–1 illustrates the relationship of the structural and functional concepts of the liver.

Approximately 75% of the blood supply to the liver is derived from the portal vein, which drains the gastrointestinal tract, spleen, and pancreas. This blood is enriched with nutrients and other absorbed xenobiotics and is poor in oxygen. The remainder of the hepatic blood flow comes from the hepatic artery, which delivers well-oxygenated blood from the systemic circulation. Blood from the hepatic artery and portal vein mixes in the sinusoids, coming in close contact with cords of hepatocytes before it exits through small fenestrations in the wall of the vein.<sup>137</sup> Oxygen content diminishes severalfold as blood flows from the portal area to the central hepatic vein.<sup>53</sup>

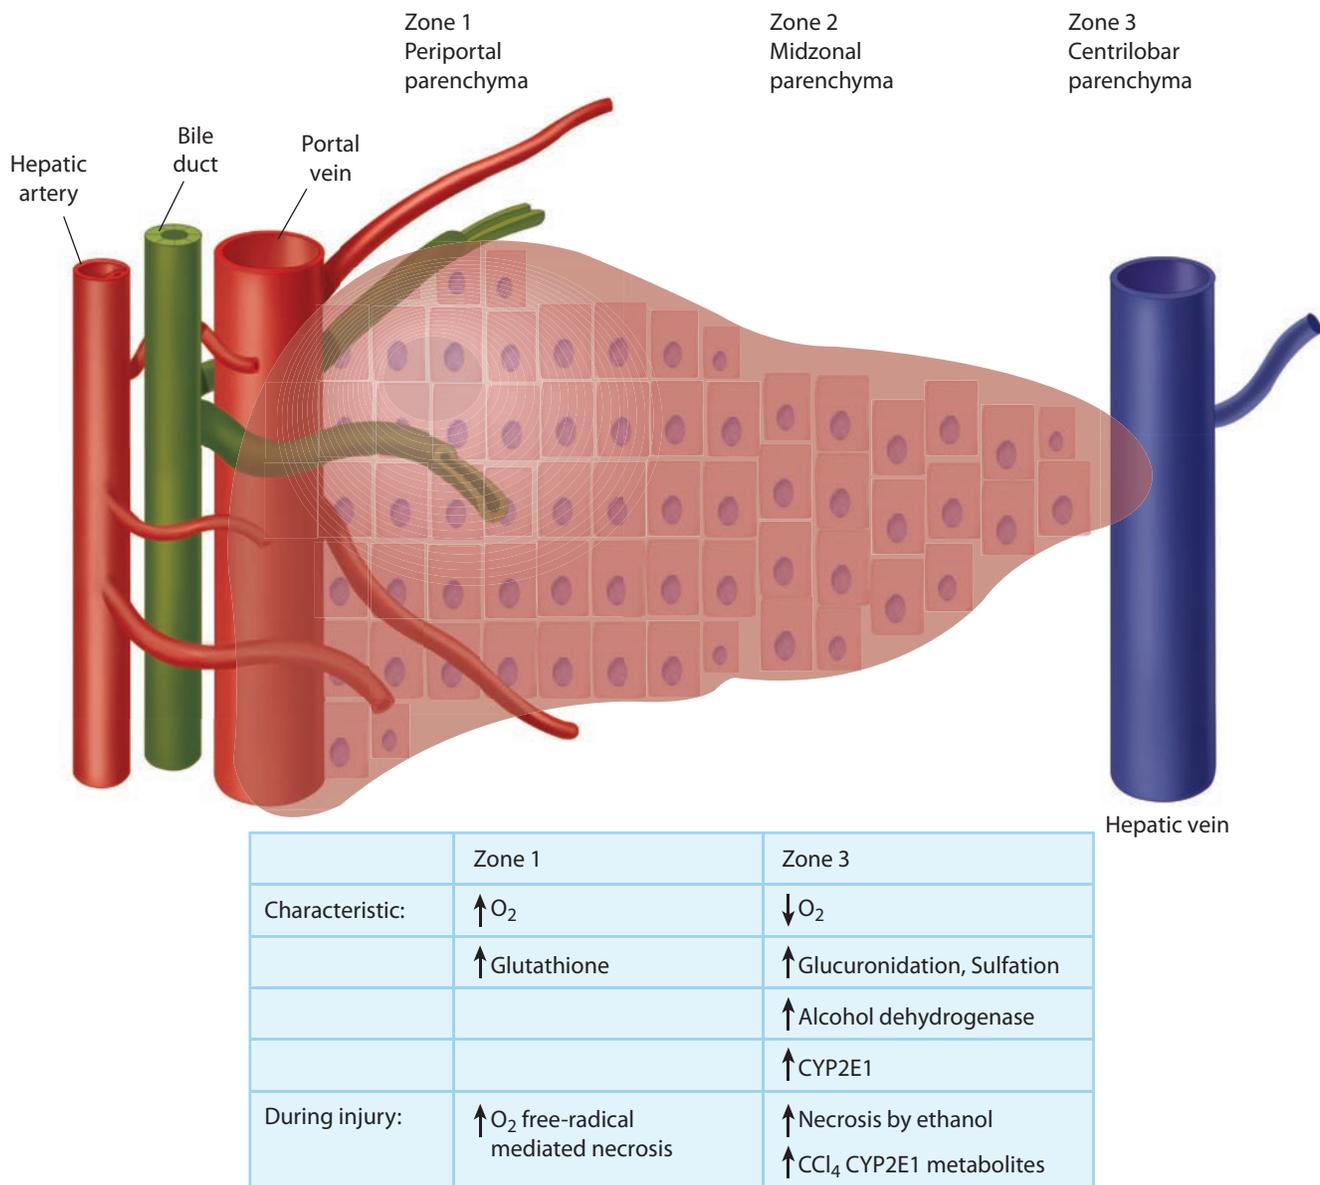

There are 6 types of cells in the liver. Hepatocytes and bile duct epithelia make up the parenchyma. Cells found near the sinusoids include endothelial cells, fixed macrophages (Kupffer cells), hepatic stellate cells (so-called Ito cells), and a large population of lymphocytes that roam the sinusoids. The sinusoidal lining formed by endothelial cells is thin and fenestrated, allowing transfer of fluid, chylomicrons, and proteins across the space of Disse, an extrasinusoidal space filled with microvilli.<sup>137</sup> Kupffer cells remove particles and cell debris that include bacteria and endotoxins from the portal circulation. They also clear many biologically active substances from the systemic circulation.<sup>12</sup> When immunologically activated by xenobiotics, Kupffer cells contribute to the generation of oxygen free radicals<sup>110</sup> and also participate in the production of autoimmune injury to hepatocytes, including activation of hepatic stellate cells.<sup>58,110</sup> Hepatic stellate cells are primary sites for the storage of fat and vitamin A.<sup>36,45</sup> In a quiescent state, they spread out between the sinusoidal endothelium and hepatic parenchymal cells. Filled with microtubules and microfilaments, they project cytoplasmic extensions that contact several cell types.<sup>36,45</sup> Activated stellate cells produce collagen, proteoglycans, and adhesive glycoproteins, which are crucial to the development of hepatic fibrosis.<sup>34</sup> The liver lymphocyte population is enriched with natural killer (NK) or pit cells, which play a key role in host defense by actively lysing tumor cells and virally infected cells<sup>18,35</sup> (Fig. 21–2). Evidence from animal models suggests that NK cells selectively kill activated stellate cells, inhibiting the development of liver fibrosis.<sup>34,35</sup>

Bile acids, organic anions, bilirubin, phospholipids, xenobiotics, and other molecules excreted in bile are actively transported across the hepatocyte plasma membrane into the bile canaliculi at sites that have specificity for acids, bases, and neutral xenobiotics.<sup>94</sup> Tight junctions separate the contents of the bile canaliculi from the sinusoids and hepatocytes, maintaining a rigid and functionally necessary compartmentalization. Bile acids use 3 active transport systems: a sodium-dependent bile salt transporter in the sinusoidal membrane, an adenosine triphosphate (ATP)-dependent bile salt carrier in the canalicular membrane, and a canalicular membrane transport site driven by the membrane proton gradient.<sup>94</sup> Xenobiotics bound to glucuronide are substrates for the bile acid transport systems and are actively secreted into bile. Xenobiotics with molecular weights greater than 500 Da are also preferentially secreted into bile. Like the transport and concentration of constituents from the sinusoids and hepatocytes, the flow of bile through the canaliculi is also an active process facilitated by ATP-dependent contractions of actin filaments that encircle the canaliculi.<sup>94,129</sup>

The enterohepatic recirculation of bile acids and certain vitamins plays a crucial role in their conservation. Unfortunately, this recirculation also impedes the fecal elimination of some xenobiotics by reabsorbing and returning them back into the systemic circulation, prolonging their apparent half-lives and toxicity. Xenobiotics that have low molecular weights and are not ionized at intestinal pH (ie, methylmercury, phencyclidine, and nortriptyline) are most likely to be reabsorbed.<sup>109</sup>

## TYPES OF HEPATIC INJURY

Owing to its location at the end of the portal system and its substantial complement of biotransformation enzymes, the liver is especially vulnerable to toxic injury. The pathologic spectrum of liver injury includes combinations of hepatocellular necrosis with focal or generalized lysis of hepatocytes and elevations of aspartate aminotransferase (AST) and alanine aminotransferase (ALT); hepatitis associated with inflammatory cellular infiltrates and varied elevations of hepatocellular enzymes; cholestasis with pruritus, jaundice, and insignificant elevations of hepatocellular enzymes; steatosis

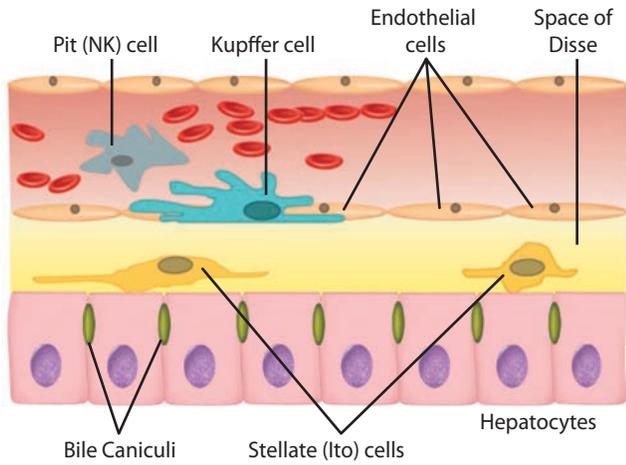

**FIGURE 21-1.** The acinus is defined by 3 functional zones. Specific contributions of each zone to the biotransformation of xenobiotics reflect various metabolic factors that include differences in oxygen content of blood as it flows from the oxygen-rich portal area to the central hepatic vein, differences in glutathione content, different capacities for glucuronidation and sulfation, and variations in content of metabolic enzymes such as CYP2E1. The hepatic lobule (not shown) is a structural concept, a hexagon with the central vein at the center surrounded by six portal areas that contain branches of the hepatic artery, bile duct, and portal vein. Injury to hepatocytes that is confined to zone 3 is called “centrilobular” because in the structure of the lobule, zone 3 encircles the central vein, which is the center of the hepatic lobule.

caused by intracellular deposits of fat; apoptosis, the formation of shrunken, nonfunctioning, eosinophilic bodies; and fibrosis.<sup>125</sup>

### FACTORS THAT AFFECT THE ANATOMIC LOCALIZATION OF HEPATIC INJURY

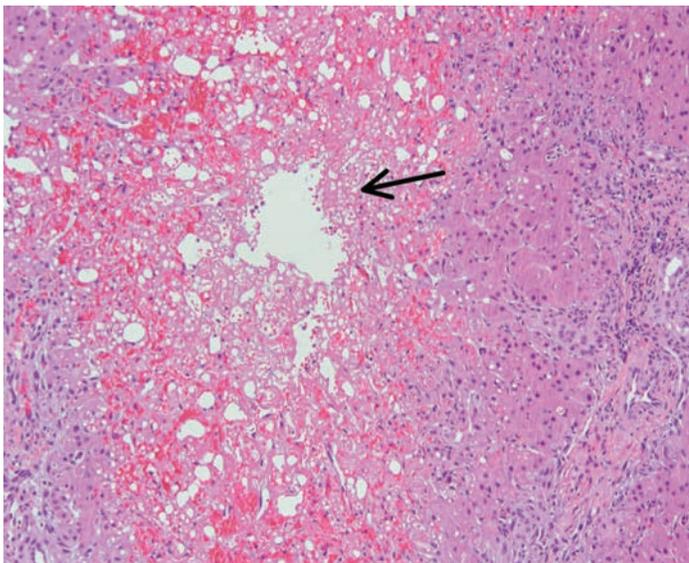

Hepatocellular necrosis that occurs near the portal vein is called *periportal*, or *zone 1* necrosis. The term *centrilobular* or *zone 3* necrosis refers to injury that surrounds the central hepatic vein. Figure 21-3 shows centrilobular necrosis caused by exposure to acetaminophen. Metabolic characteristics of the zones of the acinus have important relevance to the anatomic distribution of toxic liver injury. Because of its location in the periportal area, zone 1 has a 2-fold higher oxygen content than zone 3. Hepatic injury that results from the metabolic production of oxygen free radicals predominates in zone 1. Allyl alcohol, an industrial chemical that is metabolized to a highly reactive aldehyde, is associated with oxygen-dependent lipid peroxidation injury to hepatocytes in zone 1.<sup>3</sup> The tendency for centrilobular or zone 3

accumulation of fat in patients with alcoholic steatosis is attributed to the effect of relative hypoxia in the central vein area on the oxidation potential of the hepatocyte.<sup>6</sup> The availability of substrates for detoxification and the localization of enzymes involved in biotransformation also affect the site of injury. Zone 1 has a higher concentration of glutathione, whereas zone 3 has a greater capacity for glucuronidation and sulfation.<sup>130</sup> Zone 3 has higher concentrations of alcohol dehydrogenase, which leads to increased production of its toxic metabolite acetaldehyde at centrilobular sites.<sup>26,78</sup> Zone 3 also has high concentrations of CYP2E1, which converts many xenobiotics including acetaminophen (APAP), nitrosamines, benzene, and carbon tetrachloride (CCl<sub>4</sub>) to reactive intermediates that cause centrilobular injury. Although CCl<sub>4</sub> is metabolized to a highly reactive oxygen free radical in zone 1, it primarily injures zone 3 for the following reasons: CCl<sub>4</sub> is metabolized by CYP2E1 in zone 3 to a trichloromethyl free radical (-CCl<sub>3</sub>) that forms covalent bonds with cellular proteins, causes lipid peroxidation, or spontaneously reacts with oxygen to form the more highly reactive trichloromethyl peroxy

**FIGURE 21-2.** Blood flowing through the hepatic sinusoids is separated from hepatocytes by fenestrated endothelium that allows passage of many substances across the space of Disse. This figure shows 6 types of cells found in the liver and their localization in relation to the sinusoid. Stellate cells are fat storage cells that promote fibrosis when activated.<sup>34</sup> Kupffer cells are fixed macrophages that participate in immune surveillance and are a source of free radicals when activated. Natural killer (NK) cells are lymphocytes that float freely in the sinusoids, scavenging tumor and virus-infected cells.<sup>18</sup> Hepatocytes and bile epithelial cells form the hepatic parenchyma.

radical ( $\text{CCl}_3\text{OO}\cdot$ ).<sup>9,73</sup> Higher oxygen tension in zone 1 fosters the formation of  $\text{CCl}_3\text{OO}\cdot$ , which is rapidly detoxified by glutathione. Because the less reactive  $\cdot\text{CCl}_3$  that predominates in zone 3 is not readily detoxified by glutathione, zone 3 incurs the greater amount of injury. Hyperbaric oxygen increases the oxygen tension throughout the liver and decreases liver injury caused by  $\text{CCl}_4$ , possibly by increasing the formation of  $\text{CCl}_3\text{OO}\cdot$  in zone 3, which is then efficiently detoxified by glutathione.<sup>14</sup> The observed effects of isoniazid (an inhibitor of CYP2E1) and chronic ethanol intake (an inducer of the CYP2E1) on injury in cell cultures from periportal and centrilobular areas exposed to  $\text{CCl}_4$  support the association of  $\text{CCl}_4$  injury with the localization of CYP2E1 activity. Acute exposure to isoniazid significantly decreases the injury associated with exposure of zone 3 cells to  $\text{CCl}_4$ , whereas chronic treatment with ethanol significantly enhances injury.<sup>73</sup>

**FIGURE 21-3.** Biopsy showing centrilobular necrosis of a liver in a patient with acetaminophen toxicity. The arrow points to the necrotic area with cells without nuclei. There is also the presence of polymorphonuclear leukocyte infiltration in the periphery. (Used with permission from Daniel Mais, MD, Professor of Pathology, University of Texas Health Science Center at San Antonio.)

## FACTORS THAT AFFECT THE DEVELOPMENT OF HEPATOTOXICITY

Xenobiotics that produce liver damage in all humans in a predictable and dose-dependent manner are called *intrinsic* hepatotoxins. They include APAP,  $\text{CCl}_4$ , and yellow phosphorus, to name a few. Those that cause liver damage in a small number of individuals and whose effect is not apparently predictable or dose dependent are called *idiosyncratic* hepatotoxins.<sup>38</sup>

### Prediction of Drug-Induced Liver Injury

Drug-induced liver injury (DILI) refers to the production of liver injury by pharmaceuticals. It is the most common cause of acute liver failure in the United States, and is the most frequent adverse event responsible for the termination of clinical trials of new drugs, as well as postmarketing withdrawals of approved drugs.<sup>98</sup> LiverTox (<https://livertox.nih.gov>) is an up-to-date informational website about the incidence, diagnosis, and management of xenobiotic-associated liver injury.<sup>8</sup>

Prediction of DILI in any individual patient based on clinical trials is difficult because the incidence is rare. Drug-induced liver injury depends largely on factors that affect host susceptibility. These include age, gender, diet, underlying diseases, and concurrent exposure to other xenobiotics.<sup>98</sup> Genetic factors are increasingly elucidated. Many enzymes involved in biotransformation show genetic polymorphism. Inherited variations in CYP enzymes affect susceptibility to DILI.<sup>2</sup> For example, perhexiline, an antianginal marketed in Europe in the 1980s, caused severe liver injury and peripheral neuropathy in persons with an inability to metabolize debrisoquine.<sup>118</sup> The congenital disorder that results in Gilbert syndrome is characterized by decreased glucuronyltransferase. These patients demonstrate decreased glucuronidation and increased bioactivation of APAP during chronic therapeutic dosing, suggesting an increased risk of hepatic injury following ingestion of APAP.<sup>23</sup> Gastrointestinal toxicity due to irinotecan, an antineoplastic used in the treatment of colon cancer, is associated with deficiency of glucuronyltransferase.<sup>87</sup>

Studies that compare the genomes of patients who develop hypersensitivity reactions to various drugs with those who do not show significant associations with human leukocyte antigen (HLA) alleles.<sup>41</sup> Hypersensitivity reactions to abacavir are significantly associated with HLA-B\*5701, such that the Food and Drug Administration now recommends HLA screening prior to the initiation of abacavir.<sup>81</sup> Human leukocyte antigen-B\*5701 is also associated with cholestatic DILI in patients taking flucloxacillin, an antibiotic marketed in Europe.<sup>21</sup> Similarly, HLA-B27 predisposes to the development of agranulocytosis in levamisole-adulterated crack-cocaine exposure.<sup>15</sup> Severe hypersensitivity reactions to carbamazepine are associated with the HLA allele HLA-A\*3101.<sup>82</sup> Specific HLA phenotypes are implicated in the development of cholestatic liver injury in patients exposed to amoxicillin-clavulanate.<sup>76</sup> Drug-induced liver injury in the form of elevation of the ALT occurred in 15% of patients exposed to the first-generation direct thrombin inhibitor ximelagatran, with some developing clinically significant hepatitis. This was associated with 2 specific HLA phenotypes-DRB1\*07 and DQA1\*02.<sup>57</sup>

### Effects of Xenobiotics on Enzyme Function

Some xenobiotic combinations increase the possibility of hepatotoxic reactions because one xenobiotic alters the metabolism of the other, leading to the production of toxic metabolites. This is the case with combinations of rifampin and isoniazid,<sup>132</sup> amoxicillin and clavulanic acid,<sup>24</sup> and trimethoprim and sulfamethoxazole.<sup>19</sup> Changes in the activities of biotransformation enzymes that result in increased formation of hepatotoxic metabolites suggest increased susceptibility to hepatic injury. For example, chronic ethanol exposure causes proliferation of the smooth endoplasmic reticulum in the centrilobular areas resulting in increased CYP2E1 activity.<sup>75</sup> When bromobenzene, a xenobiotic whose metabolism and hepatotoxicity are similar to that of APAP (the toxic metabolite 3,4-epoxide is formed via CYP2E pathway), was administered to rats chronically exposed to ethanol, it caused a more rapid onset of hepatotoxicity compared to the controls. In addition, the dose of bromobenzene required for hepatic injury was not altered by immediate pretreatment with ethanol.<sup>47</sup> This means that hepatic toxicity caused by solvents such as  $\text{CCl}_4$ , dimethylformamide, and bromobenzene is likely exacerbated by chronic exposure to ethanol.<sup>73,102</sup>

### Availability of Substrates

The availability of substrates for detoxification significantly affects both the likelihood and the localization of hepatic injury. The metabolism of APAP illustrates the effect of glutathione concentration on the delicate balance between detoxification and the production of injurious metabolites. In healthy adults taking therapeutic amounts of APAP, approximately 90% of hepatic metabolism results in formation of the glucuronide or sulfate metabolites. Most of the remainder undergoes oxidative metabolism to the toxic electrophile *N*-acetyl-*p*-benzoquinone imine (NAPQI) and is rapidly detoxified by conjugation with glutathione.<sup>111</sup> Glutathione is depleted during the course of metabolism of APAP by otherwise normal livers, but it is also decreased by inadequate nutrition or liver disease.<sup>111</sup> Excessive amounts of APAP result in increased synthesis of NAPQI, which, in the absence of glutathione, reacts avidly with hepatocellular macromolecules. The cellular concentration of glutathione correlates inversely with the demonstrable covalent binding of NAPQI to liver cells.<sup>16</sup> Centrilobular (zone 3) necrosis predominates in APAP-induced hepatic injury, likely related both to the centrilobular localization of CYP2E1 and to the relatively low glutathione concentrations in zone 3 compared to the periportal areas (zone 1).<sup>48</sup>

## MECHANISMS OF HEPATIC INJURY

There are several mechanisms of xenobiotic-induced hepatotoxicity.

### Immune-Mediated Liver Injury

Immune-mediated liver injury is an idiosyncratic and host-dependent hypersensitivity response xenobiotic exposure.<sup>7</sup> Damage to the hepatocytes is mediated by complement- or antibody-directed lysis, by specific cell-mediated cytotoxicity, or by an inflammatory response stimulated by immune complexes and complement.<sup>123</sup> The antibody or cell-mediated response is precipitated by a covalently bound xenobiotic-cell protein adduct that acts as a hapten. The resultant inflammatory response provokes secondary cytokine release that promotes further cell injury by neutrophils.<sup>43</sup> Subsequent apoptosis appears to be partly mediated by tumor necrosis factor (TNF).<sup>123</sup> Immune-mediated toxic hepatitis is differentiated from liver injury caused by other autoimmune disorders by the absence of self-perpetuation; that is, there is a need for continuous exposure to the xenobiotic to perpetuate the injury.<sup>7</sup> It is also less likely to recur following withdrawal of immune suppression therapy.<sup>7</sup>

Hypersensitivity reactions result in hepatitis, cholestasis, and mixed disorders. It is not clear whether all the autoantibodies stimulated by the xenobiotic-protein adducts are the actual mediators of cell injury.<sup>7</sup> In cases where the metabolite is highly unstable, an electrophilic attack is directed against the CYP enzyme at the site of formation of the metabolite.<sup>74</sup> The most severe form of idiosyncratic halothane liver injury is manifested as fulminant hepatic necrosis associated with the formation of adducts of its trifluoroacetyl chloride (TFA) metabolite with numerous hepatoproteins including CYP2E1 and pyruvate dehydrogenase.<sup>28,55</sup> Autoantibodies specifically directed against CYP enzymes are also demonstrated for dihydralazine<sup>10</sup> and phenytoin.<sup>68</sup>

Cell-mediated autoimmune mechanisms are also implicated in the idiosyncratic type of halothane hepatitis, and are now recognized in an increasing number of experimental xenobiotic-mediated liver injury models.<sup>63</sup> Polymorphonucleocyte (PMN) activation and infiltration appear to be an important factor in the production of cholangitis in a rat model of  $\alpha$ -naphthyl-isothiocyanate (ANIT) liver injury.  $\alpha$ -Naphthyl-isothiocyanate stimulates the release of cytotoxic lysosomal enzymes and oxygen free radicals by activated PMNs.<sup>36</sup> Antibodies directed against circulating neutrophils decrease the extent of liver damage caused by ANIT.<sup>20</sup> Natural Killer (NK) T cells are ubiquitous in the liver, and also serve an important role in the cell-mediated autoimmune liver injury.<sup>35</sup>

Drugs most commonly involved in autoimmune injury are nitrofurantoin and minocycline.<sup>7</sup> Drugs with hypersensitivity reactions that typically present with hepatitis include halothane,<sup>63</sup> trimethoprim-sulfamethoxazole,<sup>80</sup> antiepileptics,<sup>139</sup> and allopurinol.<sup>122</sup> Drugs associated with hypersensitivity

that typically present with cholestatic signs include chlorpromazine, erythromycin estolate, penicillins, rifampin, and sulfonamides.<sup>94</sup> Signs of injury typically begin 1 to 8 weeks following the initiation of the medication, although it takes as long as 20 weeks for drugs such as isoniazid or dantrolene. In all cases, the onset is earlier when the patient is rechallenged with the drug. Antinuclear antibodies and smooth muscle antibodies are frequently present, as are eosinophilia, atypical lymphocytosis, fever, and rash. However, their absence does not exclude an autoimmune mechanism of drug-associated liver injury.<sup>7,74</sup> Liver injury characterized by the formation of hepatic granulomas are also a consequence of hypersensitivity reactions.<sup>67</sup>

### Xenobiotics That Target the Biliary Tract

Xenobiotics that undergo biliary excretion are most commonly associated with jaundice in patients with hepatotoxicity. Xenobiotics induce cholestasis by targeting specific mechanisms of bile synthesis and flow or by damaging canalicular cells. Elucidations of various bile transport proteins have led to better understanding of mechanisms of cholestasis in toxic liver injury.<sup>94</sup> Cholestasis occurs with or without associated hepatitis. The development of jaundice following hepatic necrosis is a manifestation of general failure of liver function. More discrete mechanisms that result in intrahepatic cholestasis include (a) impairment of the integrity of tight membrane junctions that functionally isolate the canaliculus from the hepatocyte and sinusoids, (b) failure of transport of bile components across the hepatocytes, (c) blockade of specific membrane active transport sites, (d) decreased membrane fluidity resulting in altered transport, and (e) decreased canalicular contractility resulting in decreased bile flow.<sup>11,61,94,115</sup> Xenobiotics that specifically target bile canaliculi can lead to irreversible injury, the so-called vanishing bile duct syndrome.<sup>127</sup> Estrogens cause intrahepatic cholestasis by altering the composition of the lipid membrane and inhibiting the rate of secretion of bile into the canaliculi.<sup>115</sup> Rifampin impedes the uptake of bilirubin into hepatocytes. Methyltestosterone and C-17 alkylated anabolic steroids impair the secretion of bilirubin into canaliculi.<sup>70</sup> Cyclosporine inhibits sodium-dependent uptake of bile salts across the sinusoidal membrane and blocks ATP-dependent bile salt transport across the canalicular membrane.<sup>11</sup> Floxacillin causes cholestasis with minimal inflammation or evidence of hepatocellular injury.<sup>131</sup> Exposure of rats to ANIT causes a specific injury localized to the tight junctions that separate the hepatocytes from the canaliculi. This results in reflux of bile constituents into the sinusoidal spaces and increased access of sinusoidal molecules to the biliary tree.<sup>138</sup>

### Mitochondrial Injury

Direct mitochondrial injury impairs cellular respiration and is associated with fat accumulation, diminution of ATP production, and metabolic acidosis with elevated lactate.<sup>64</sup> This involves attacks by xenobiotics on structural components of the mitochondria such as DNA, respiratory chain enzymes, and membranes. Nucleoside analogs that inhibit viral reverse transcriptase also inhibit mitochondrial DNA synthesis, leading to depletion of mitochondria.<sup>17</sup>

### Other Targets

Stimulation of Kupffer cells enhances hepatic injury. When immunologically activated by xenobiotics, Kupffer cells contribute to the generation of oxygen free radicals and participate in the production of autoimmune injury to hepatocytes, including activation of hepatic stellate cells.<sup>110</sup> Activated stellate cells produce collagen, proteoglycans, and adhesive glycoproteins, which are crucial to the development of hepatic fibrosis.<sup>34</sup> Hepatic veno-occlusive disease is caused by xenobiotics that injure the endothelium of terminal hepatic venules, resulting in intimal thickening, edema, and non-thrombotic obstruction.<sup>62</sup>

## MORPHOLOGIC MANIFESTATIONS OF TOXIC HEPATIC INJURY

The liver responds to injury in a limited number of ways. Cells may swell and accumulate fat or biliary material. They may necrose and lyse or undergo the slower process of apoptosis, forming shrunken, nonfunctioning, eosinophilic bodies. Necrosis can be focal or bridging, linking the periportal or

centrilobular areas; zonal or panacinar; or it can be massive.<sup>43</sup> An autoimmune type of injury is characterized by hepatitis with a prominent plasma cell infiltrate.<sup>7</sup> Injury to the bile ducts results in cholestasis. Xenobiotics that target canalicular transport proteins can cause cholestasis in the absence of injury to hepatocytes.<sup>94</sup> Direct mitochondrial injury impairs cellular respiration and is associated with fat accumulation, diminution of ATP production, and metabolic acidosis.<sup>95</sup> Injuries to the intima of postsinusoidal veins cause obstruction to venous flow.<sup>140</sup> Table 21–1 lists characteristic morphologies of hepatic injury and associated xenobiotics.

### Acute Hepatocellular Necrosis

Numerous xenobiotics are associated with hepatocellular necrosis (Table 21–1). Acetaminophen is a common cause, as are herbal remedies that contain hepatotoxins, whose risks are increasingly recognized.<sup>29</sup> Many halogenated hydrocarbons including carbon tetrachloride,<sup>14</sup> bromobenzene,<sup>47</sup> hydrochlorofluorocarbons,<sup>49</sup> halothane,<sup>63</sup> and antituberculous medications<sup>113</sup> also produce hepatocellular necrosis. A study of more than 11,000 patients exposed to isoniazid during preventive treatment showed that the risk of hepatocellular necrosis was low, occurring in 0.1% of those starting treatment, and in 0.15% of those completing treatment.<sup>92</sup> Risk factors for the development of hepatotoxicity from isoniazid exposure are female sex, increasing age, coadministration with rifampin, and alcoholism (Chap. 56).<sup>144</sup> The thiazolidinedione antidiabetics pioglitazone, rosiglitazone, and troglitazone are associated with acute hepatocellular necrosis.<sup>33,39</sup> Occupational exposure to solvents including dimethylformamide and CCl<sub>4</sub> causes dose-related hepatocellular necrosis.<sup>102</sup>

Acute necrosis of a hepatocyte disrupts all aspects of its function. Because there is a great deal of functional reserve in the liver, hepatic function is usually preserved despite the development of focal necrosis. However, extensive necrosis results in functional liver failure. The processes that lead to cell necrosis are not well known. Cell lysis is preceded by the formation of blebs in the lipid membrane and leakage of cytosolic enzymes, primarily aminotransferases and lactate dehydrogenase. Coalescence of blebs leads to rupture of the cellular membrane and acute irreversible cell death, with disintegration of the nucleus and termination of all cellular function. Prior to membrane rupture, this injury is reversible by membrane repair processes.<sup>86</sup> The release of intracellular constituents attracts circulating leukocytes and results in an inflammatory response in the hepatic parenchyma. A proposed mechanism of rapid injury to the cell membrane is the initiation of a cascading lipid peroxidation reaction following attack by a free radical. The CYP2E1 enzyme has a significant potential to produce oxygen free radicals, as do activated PMNs and Kupffer cells.<sup>34</sup> Oxidant stress is an important cause of liver injury during the metabolism of ethanol by CYP2E1. This results in cell death and the stimulation of stellate cells, which promotes fibrosis.<sup>26</sup> In addition to peroxidation of membrane lipids, the oxidation of proteins, phospholipid fatty acyl side chains, and nucleosides appear to be widespread. Mitochondrial injury and resultant ATP depletion can also be associated with necrosis.<sup>54</sup> Xenobiotics known to cause mitochondrial injury include antiretroviral drugs that inhibit the replication of mitochondrial DNA,<sup>121</sup> tetracycline,<sup>116</sup> valproic acid,<sup>141</sup> hypoglycin, margosa oil, and cereulide.<sup>114</sup>

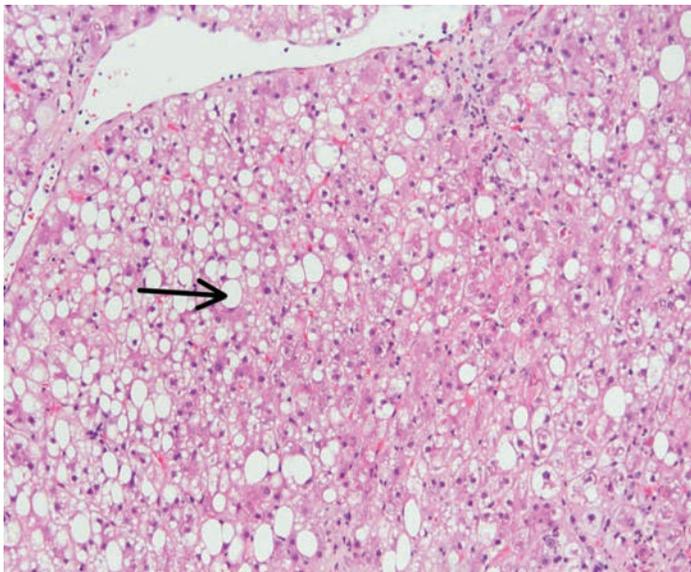

### Steatosis

Steatosis is the abnormal accumulation of fat in hepatocytes. It reflects abnormal cellular metabolism in conditions that include responses to xenobiotics. Cell injury depends on the severity of the underlying metabolic disturbance. Steatosis per se is normally well tolerated and reversible in many cases, although approximately one-third of patients with nonalcoholic steatosis develop steatohepatitis.<sup>30</sup> Nonalcoholic steatosis associated with obesity, insulin resistance, and the metabolic syndrome accounts for many cases of cryptogenic cirrhosis.<sup>30</sup> The  $\beta$ -oxidation of fatty acids depends on a steady synthesis of cellular energy in the form of ATP and takes place in the mitochondria. Mechanisms of impaired  $\beta$ -oxidation of fatty acids include direct inhibition or sequestration of critical cofactors such as coenzyme-A and L-carnitine.<sup>64</sup>

TABLE 21–1 Morphology of Liver Injury by Selected Xenobiotics

<b>Acute Hepatocellular Necrosis</b>	<b>Microvesicular Steatosis</b>	<b>Venoocclusive Disease</b>
Acetaminophen	Aflatoxin	Cyclophosphamide
Allopurinol	Cereulide	Oxaliplatin
Amatoxin	Cocaine	Pyrrrolizidine alkaloids
Arsenic	Dimethylformamide	<b>Peliosis Hepatis</b>
Beryllium	Fialuridine	Androgenic hormones
Carbamazepine	Hypoglycin	Contraceptive steroids
Carbon tetrachloride	Jin bu huan	Thiopurine-derived chemotherapeutics
Chaparral leaf	Margosa oil	Thorium dioxide
Chlordecone (less severe)	Nucleoside analogs (antiretrovirals)	<b>Cholestasis</b>
Clove oil	Tetracycline	Allopurinol
Cocaine	Valproic acid	Amoxicillin/clavulanic acid
Cotrimoxazole	<b>Steatohepatitis</b>	Anabolic steroids
Dimethylformamide	Amiodarone	Androgenic steroids
Ethanol	Dimethylformamide	Chaparral leaf
Ferrous sulfate	Irinotecan	Chlorpromazine
Germander	Perhexiline	Chlorpromazine
Glue thistle	Sodium azide	Clarithromycin
Halothane	<b>Granulomatous Hepatitis</b>	Cyclosporine
Hydralazine	Allopurinol	Erythromycin estolate
Iron	Beryllium	Estrogens
Isoniazid	BCG therapy for cancer	Hydralazine
Ketoconazole	Carbamazepine	Methylenedianiline
Methylenedioxymethamphetamine (MDMA)	Cephalexin	Nimesulide
Methotrexate	Chlorpromazine	Nitrofurantoin
Methyldopa	Chlorpropamide	Oral contraceptives
Monoamine oxidase inhibitors	Copper salts	Piroxicam
Nitrofurantoin	Dapsone	Rifampin
Pennyroyal	Diazepam	Tetracycline
Phenytoin	Diclofenac	Trimethoprim-sulfamethoxazole
Phosphorus (yellow)	Dicloxacillin	<b>Autoimmune Hepatitis</b>
Pioglitazone	Diltiazem	ACEIs
Procainamide	Gold	Clometacin
Propylthiouracil	Halothane	Dantrolene
Quinine	Hydralazine	Diclofenac
Rosiglitazone	Interferon	Methotrexate
Sulfonamides	Isoniazid	Methyldopa
Tetrachloroethane	Mesalamine	Minocycline
Tetrachloroethylene	Methyldopa	Nafcillin
Tetracycline	Metolazone	Nitrofurantoin
Trinitrotoluene	Nitrofurantoin	Propylthiouracil
Troglitazone	Oxacillin	Sulfonamides
Valproic acid	Penicillins	Tamoxifen
Vinyl chloride	Phenylbutazone	Tegafur
<b>Neoplasms</b>	Phenytoin	Trazodone
Anabolic steroids	Procainamide	Uracil
Androgenic hormones	Procarbazine	<b>Fibrosis and Cirrhosis</b>
Arsenic	Quinidine	Ethanol
Copper salts	Quinine	Methotrexate
Contraceptive steroids	Salicylates	Vitamin A
Thorium dioxide	Sulfonamides	
Vinyl chloride	Sulfonyleureas	
<b>Macrovesicular Steatosis</b>	<b>Bile Duct Damage</b>	
Chlorinated hydrocarbons	Amoxicillin	
Ethanol	Carbamazepine	
5-Fluorouracil	$\alpha$ -Naphthyl-isothiocyanate	
Gold	Nitrofurantoin	
Steroids	Oral contraceptives	
Total parenteral nutrition		

ACEIs = angiotensin-converting enzyme inhibitors.

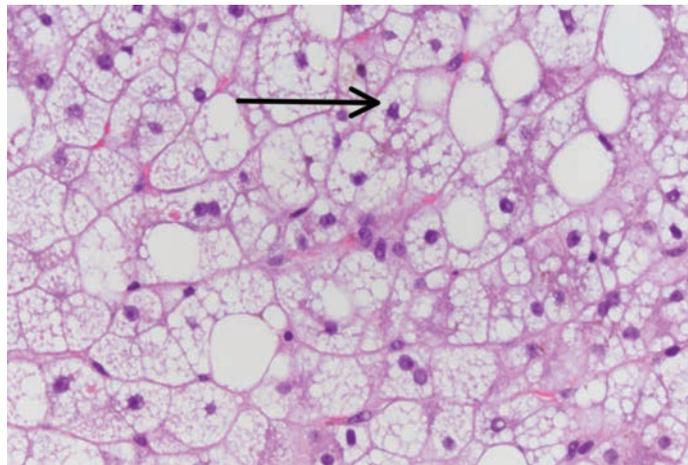

**FIGURE 21-4.** Biopsy showing macrovesicular steatosis in the liver of a patient with methotrexate toxicity. The arrow points to accumulated intracellular fat where the nucleus is pushed to the periphery by the accumulated fat. (Used with permission from Daniel Mais, MD, Professor of Pathology, University of Texas Health Science Center at San Antonio.)

Intracellular fat accumulation occurs as a result of any one or more of the following mechanisms: impaired synthesis of lipoproteins, increased mobilization of peripheral adipose stores, increased uptake of circulating lipids, increased triglyceride production, decreased binding of triglycerides to lipoprotein, and decreased release of very-low-density lipoproteins from the hepatocytes.<sup>64,72</sup> There are 2 light microscopic manifestations of steatosis: *macrovesicular* steatosis, in which the nucleus is displaced by large droplets of intracellular fat, and *microvesicular* steatosis, which is characterized by tiny cytoplasmic fat droplets that do not displace the nucleus. Xenobiotics associated with macrovesicular steatosis include ethanol and amiodarone. Ethanol increases the uptake of fatty acids into hepatocytes and decreases lipoprotein secretion. In addition, the increased ratio of the reduced form of nicotinamide adenine dinucleotide (NADH) to the oxidized form of nicotinamide adenine dinucleotide (NAD<sup>+</sup>), associated with hepatic metabolism of ethanol, decreases oxidation of fatty acids and promotes fatty acid synthesis.<sup>72</sup> An early pathologic lesion that occurs in alcoholic liver disease is reversible macrovesicular steatosis. Steatohepatitis is a more virulent form, characterized by swelling of the hepatocytes and apoptosis that may progress to cirrhosis.<sup>69</sup> Mallory bodies, eosinophilic cytoplasmic deposits of keratin filaments in degenerating hepatocytes, are also common microscopic findings in alcoholic liver disease.<sup>77</sup> Amiodarone hepatic toxicity resembles that of alcoholic hepatitis, with steatosis, Mallory bodies, and potential for progression to cirrhosis.<sup>66</sup> Lamellated intralysosomal phospholipid inclusion bodies are specific for amiodarone toxicity.<sup>105</sup> Figure 21-4 shows macrovesicular steatosis with Mallory bodies caused by methotrexate.

#### Steatosis Associated With Mitochondrial Dysfunction

Microvesicular steatosis is caused by severe impairment of  $\beta$ -oxidation of fatty acids. Valproic acid causes mild elevations of aminotransferases in approximately 11% of patients, usually during the first few months of therapy. The earliest pathologic lesion that signals progression of liver injury is microvesicular steatosis, which occurs in the absence of necrosis. An association between deficiency of carnitine, microsteatosis, and the development of hyperammonemia is observed in children treated with valproic acid.<sup>71</sup> A small percentage of patients progress to fulminant hepatic failure characterized by centrilobular necrosis.<sup>141</sup> The incidence of fatal hepatocellular injury is highest in children, approaching 1 in 800 children younger than 2 years of age.<sup>99</sup>

**FIGURE 21-5.** Biopsy showing microvesicular steatosis in the liver of a patient with valproate toxicity. The arrow demonstrated presence of centrally located nucleus despite fat accumulation. (Used with permission from Daniel Mais, MD, Professor of Pathology, University of Texas Health Science Center at San Antonio.)

Microvesicular steatosis is described in patients taking antiretrovirals such as zidovudine, zalcitabine, and didanosine.<sup>22</sup> In all cases, metabolic acidosis with elevated lactate is a prominent biochemical feature.<sup>22</sup> The nucleoside analog fialuridine caused severe hepatotoxicity during a study of its use in the treatment of chronic hepatitis B infection. Microscopic examinations of liver specimens in these cases showed marked accumulation of fat with minimal necrosis or structural injury. Severe metabolic acidosis and failure of hepatic synthetic function suggested failure of cellular energy production. Mitochondria examined under the electron microscope are demonstrably abnormal.<sup>84</sup> Figure 21-5 demonstrates microvesicular steatosis in a patient with valproate hepatotoxicity. High doses of tetracycline produce microvesicular steatosis associated with moderate elevations of aminotransferases, markedly prolonged prothrombin time (PT), and progression to fulminant hepatic failure.<sup>116</sup> Microvesicular steatosis attributed to failure of mitochondrial energy production was reported in a fatal case of *Bacillus cereus* food poisoning, where high concentration of the bacterial emetic toxin cereulide was found in the bile and liver. In this case, microvesicular steatosis was associated with extensive hepatocellular necrosis.<sup>79</sup> Other xenobiotics that cause mitochondrial failure are hypoglycin, the cause of Jamaican vomiting sickness, aflatoxin, and margosa oil.<sup>114</sup> Steatosis is also observed following exposure to the industrial solvent dimethylformamide. Liver biopsies in patients with acute illness show focal hepatocellular necrosis and microvesicular steatosis. More prolonged, less symptomatic exposures result in significant macrovesicular steatosis with mild aminotransferase elevations.<sup>101</sup>

#### Venoocclusive Disease

Hepatic venoocclusive disease is caused by xenobiotics that injure the endothelium of terminal hepatic venules, resulting in intimal thickening, edema, and nonthrombotic obstruction. Central and sublobular hepatic veins become edematous and fibrosed. There is intense sinusoidal dilation in the centrilobular areas that is associated with liver cell atrophy and necrosis.<sup>136</sup> The gross pathologic appearance is that of a “nutmeg” liver.<sup>62</sup> Massive hepatic congestion and ascites ensue.<sup>104</sup> Hepatic venoocclusive disease is rapidly fatal in 15% to 20% of cases. It is associated with exposure to pyrrolizidine alkaloids found in many plant species including *Symphytum* (comfrey tea),<sup>140</sup> *Heliotrope*, *Senecio*, and *Crotalaria*.<sup>62</sup> It has occurred in epidemic proportions, in South Africa after the ingestion of flour contaminated with ragwort (*Senecio*), in Jamaica after the ingestion of “bush teas” (*Crotalaria* spp), and in India and Afghanistan when food was contaminated with *Heliotropium lasiocarpine* and *Crotalaria*.<sup>13,88</sup> A rapidly progressive form is also reported in bone marrow transplant patients following high-dose treatment with cyclophosphamide.<sup>83</sup>

## Chronic Hepatitis

A form of toxic hepatitis that clinically resembles autoimmune hepatitis occurs with the chronic administration of xenobiotics such as nitrofurantoin, propylthiouracil, and diclofenac.<sup>56,103,117</sup> Many cases are associated with positive antinuclear antibody (ANA), smooth muscle antibody (SMA), and hyperglobulinemia. Jaundice is prominent and hepatocellular enzymes are elevated 5- to 60-fold. Liver biopsy commonly reveals intrahepatic cholestasis, as well as centrilobular inflammation.<sup>7</sup>

Granulomatous hepatitis is characterized by infiltration of the hepatic parenchyma with caseating granulomata. At least 60 xenobiotics are associated with this disorder. Fever and systemic symptoms are common, and 25% of patients have splenomegaly. Liver enzyme abnormalities are mixed, reflecting variable degrees of cholestasis and hepatocellular injury. Eosinophilia occurs in 30% as an extrahepatic manifestation of drug hypersensitivity. Continued exposure results in a more severe form of liver disease. Small vessel vasculitis, which involves the skin, lungs, and kidney, is a disturbing sign associated with increased mortality.<sup>67,85,142</sup> **Table 21–1** lists a number of the xenobiotics that are implicated in this disorder.

## Cirrhosis

Cirrhosis is caused by progressive fibrosis and scarring of the liver, which results in irreversible hepatic dysfunction and portal hypertension. This causes shunting of blood away from hepatocytes and subsequent hepatocellular dysfunction. Activated stellate cells produce collagen, proteoglycans, and adhesive glycoproteins, which are deposited in the space of Disse and are crucial to the development of hepatic fibrosis.<sup>34</sup> The development of fibrosis requires inflammation. Reactive oxygen species derived from lipid peroxidation, reduced NADPH, and apoptotic cells are important inflammatory stimuli that activate stellate cells.<sup>34</sup> In alcoholic cirrhosis, acetaldehyde and tumor necrosis factor provide a cytokine-mediated inflammatory stimulus.<sup>6</sup> Chronic ingestion of excessive amounts of vitamin A (25,000 units/day for 6 years or 100,000 units/day for 2.5 years) results in cirrhosis. An increase in the fat content of the sinusoidal stellate cells with increasing degrees of collagen formation are characteristic lesions that occur early in vitamin A toxicity (Chap. 44). Portal hypertension can be early and striking.<sup>37</sup> Like vitamin A, methyldopa and methotrexate also cause a slow progressive development of cirrhosis, with few clinical symptoms.<sup>65,134</sup> Methotrexate-induced hepatic fibrosis is dose dependent. Risk factors include associated ethanol intake and preexisting liver disease. Reduced dosing has largely eliminated the risk of the development of cirrhosis in patients receiving methotrexate.<sup>134</sup>

## Hepatic Tumors

There is persuasive evidence that the use of oral contraceptive steroids increases the risk of hepatic adenomas.<sup>1</sup> Oral contraceptives also increase the overall risk of hepatocellular carcinoma; however, the number of cases associated with estrogen therapy is low.<sup>51</sup> Anabolic steroids are rarely associated with the development of both benign and malignant hepatic tumors.<sup>120</sup> Angiosarcoma is strongly associated with exposure to vinyl chloride, in addition to arsenic, thorium dioxide, and androgenic hormones.<sup>50,97</sup>

## Hepatic Injury Associated With Plants and Herbs

In addition to the venoocclusive disease associated with pyrrolizidine alkaloids described above, herbal remedies are recognized as a cause of acute hepatocellular injury. Numerous plants or plant products are known or suspected to cause hepatic injury (Chaps. 43 and 118).<sup>29</sup>

## CLINICAL PRESENTATION OF TOXIC LIVER INJURY

Clinical presentations range from indolent, often asymptomatic progression of impairment of hepatic function to rapid development of hepatic failure. Jaundice and pruritus are due to increased concentrations of bile acids and bilirubin in the blood. Failure of hepatocellular synthetic function results in bleeding due to coagulopathy and edema due to hypoalbuminemia. Encephalopathy is due to hypoglycemia, impaired neurotransmission, or accumulation of toxic products of metabolism such as ammonia. Fever occurs with autoimmune-mediated liver injury. Impaired hepatic blood flow results in

familiar manifestations of portal hypertension such as caput medusa, splenomegaly, ascites, and varices. Spider angiomas and gynecomastia also occur as a result of altered estrogen metabolism.<sup>125</sup>

## Acute Liver Failure

Acute liver failure is defined as a rapid onset of liver injury progressing over 2 to 3 weeks that results in altered mental status, vasodilation, kidney and pulmonary failure, frequent infection, and a poor outcome without transplantation.<sup>40</sup> Complications from acute liver failure include encephalopathy, cerebral edema, coagulopathy, acute kidney injury, hypoglycemia, hypotension, acute respiratory distress syndrome, sepsis, and death. The encephalopathy associated with chronic liver disease should be considered separately from the rapidly progressive disorder of acute liver failure.<sup>32</sup> In some cases, patients progress from health to death in as little as 2 to 10 days.<sup>32,67,91,106</sup> **Table 21–2** emphasizes the clinical progression of encephalopathy as acute liver failure develops. The prognosis of acute liver failure is related to the time that passes between the onset of jaundice and the onset of encephalopathy. Perhaps surprisingly, a better prognosis is associated with shorter (2–4 weeks) jaundice-to-encephalopathy intervals.<sup>106,107</sup> Most cases are caused by xenobiotics or viral hepatitis. Acute liver failure is usually associated with extensive necrosis.<sup>46</sup> Some xenobiotics that are associated with acute liver failure are listed in **Table 21–1**.

## Hepatic Encephalopathy

Hepatic encephalopathy (HE) is a complex disorder that affects both cognitive and neuromuscular functions of the central nervous system. Cognitive changes range from barely discernible impairment evident only on psychometric testing to confusion, stupor and coma. Neuromuscular signs include slowed motor responses, asterixis, myoclonus, and rigidity.<sup>108</sup> Hepatic encephalopathy is potentially fully reversible, even in cases of deep coma.<sup>31</sup> **Table 21–2** lists the clinical stages of acute HE. Ammonia concentrations are elevated in 60% to 80% of patients with HE.<sup>108</sup> The finding that ammonia is not elevated in many cases suggests that there are other etiologies and that HE is multifactorial.<sup>107</sup> Disruption of central neurotransmitter regulation including dopamine receptor binding may contribute.<sup>133</sup> There is evidence that liver failure is associated with the accumulation of substances that stimulate central benzodiazepine receptors, leading to enhancement of  $\gamma$ -aminobutyric acid transmission.<sup>135</sup> Other xenobiotics such as mercaptans, phenol, and manganese also play a role.<sup>108</sup> Inflammation and infection is also proposed as an important precipitant. Ammonia is produced in the colon by bacterial breakdown of ingested proteins, and is then transported to the liver via the portal circulation where it is detoxified to glutamine and urea by urea

**TABLE 21–2** Stages of Hepatic Encephalopathy

Clinical Stage	Mental Status	Neuromotor Function
Subclinical	Normal physical examination	Subtle impairment of neuromuscular-function → driving or work injury hazard
I	Euphoric, irritable, depressed, fluctuating mild confusion, poor attention, sleep disturbance	Poor coordination; asterixis alone
II	Impaired memory, cognition, or simple mathematical tasks	Slurred speech, tremor, ataxia
III	Difficult to arouse, persistent confusion, incoherent	Hyperactive reflexes, clonus, nystagmus
IV	Coma; may respond to noxious stimuli	Decerebrate posturing; Cheyne-Stokes respirations; pupils are reactive and the oculocephalic reflex is intact; signs of ↑ intracranial pressure

cycle enzymes.<sup>96</sup> In the presence of liver failure, ammonia accumulates and is shunted into the systemic circulation, where it then crosses the blood–brain barrier. In the brain, the astrocytic glutamine synthetase converts glutamate and ammonia into glutamine, which acts as an osmolyte and increases cerebral volume.<sup>135</sup> Ammonia itself also acts as a neurotoxin, resulting in decreased excitatory neurotransmission.<sup>135</sup> Other processes that raise central nervous system ammonia concentrations include infection, hypokalemia, alkalemia, increased muscle wasting, volume depletion, azotemia, and gastrointestinal bleeding.<sup>108</sup> Alkalemia and hypokalemia facilitate conversion of  $\text{NH}_4^+$  to  $\text{NH}_3$ , which moves more easily across the bowel wall and the blood–brain barrier. Acidification of the bowel by bacterial breakdown of lactulose creates a hostile environment for ammonia-producing bacteria and constructs a gradient that favors entrapment of ammonia in the bowel.<sup>96</sup> In a study of lactulose alone versus placebo, over a 14-month period 19.6% of patients on lactulose had recurrent HE, compared with 48.6% of patients on placebo.<sup>119</sup> A nonabsorbed broad-spectrum antibiotic rifaximin decreases the recurrence of HE in cirrhotic patients, presumably by decreasing the numbers of urease-containing colonic bacteria that produce ammonia.<sup>4</sup>

Flumazenil is proposed by some authors to treat HE. Studies evaluating flumazenil's effectiveness show short-term improvement but no change in patient recovery or survival.<sup>135</sup> Concordantly, benzodiazepines can make HE worse and should be avoided.

## EVALUATION OF THE PATIENT WITH LIVER DISEASE

History is critical in establishing the etiologic diagnosis of the patient with liver disease. Medication history should include careful investigation of non-prescription xenobiotics, especially APAP and any alternative or complementary therapies including herbal and vitamin products. Nearly any chronically used medications should be suspect. An occupational history may indicate exposure to vinyl chloride (plastics industry), dimethylformamide (leather industry), or other industrial solvents. Table 21–3 lists occupational exposures that result in liver injury. Ethanol abuse is a common cause of acute hepatitis and the most common cause of cirrhosis in the United States.<sup>6</sup> A history of male homosexual contacts, health care occupation, or injection drug use indicates the possibility of hepatitis B or C infection. Recent travel

to a developing country suggests the possibility of hepatitis A and other viruses and parasites. In patients with significant pain, a diagnosis of cholelithiasis or cholecystitis should be evaluated.

## Biochemical Patterns of Liver Injury

There are 2 basic biochemical patterns associated with xenobiotic-induced liver injury. The hepatocellular pattern is characterized by elevation of liver aminotransferases due to the destruction of hepatocytes by apoptosis or necrosis.<sup>90</sup> The cholestatic pattern is characterized by elevations of the serum alkaline phosphatase, concentration and conjugated bilirubin, and usually results from injury or functional impairment of the bile ductules.<sup>42</sup> Processes associated with intrahepatic cholestasis in the absence of hepatitis do not always lead to significant aminotransferase elevation.<sup>89</sup>

### Aminotransferases

Laboratory tests are helpful, and certain patterns suggest specific etiologies (Table 21–4). Elevation of hepatocellular enzymes, especially the AST and ALT, indicates hepatocellular injury, and within a given clinical context, has useful diagnostic significance. Aminotransferases often are increased up to 500 times normal when hepatic necrosis is extensive, such as in severe acute viral or toxic hepatitis.<sup>143</sup> The degree of elevation does not always reflect the severity of injury because concentrations decline as liver failure progresses. Only moderately elevated, or occasionally normal, aminotransferase concentrations occur in some patients with hepatic failure caused by mitochondrial failure, cirrhosis, or venoocclusive disease.<sup>84,141</sup> Aminotransferase concentrations can be normal or only slightly elevated in processes associated with intrahepatic cholestasis in the absence of hepatitis.<sup>89</sup> In alcoholic liver disease, in contrast to other forms of hepatitis, the AST concentration is typically 2 to 3 times greater than the ALT. Elevation of either of these enzymes greater than 300 IU/L is inconsistent with injury caused by ethanol.<sup>77</sup> The measurement of  $\gamma$ -glutamyl transpeptidase (GGTP) is not very useful because it is present throughout the liver and its elevation is often nonspecific.<sup>124</sup>

### Alkaline Phosphatase

In patients with cholestasis, bile acids stimulate the synthesis of alkaline phosphatase by hepatocytes and biliary epithelium in response to a number of pathologic processes in the liver. Elevations of the alkaline phosphatase as great as 10-fold can occur with infiltrative liver diseases, but are most commonly associated with extrahepatic obstruction.<sup>124</sup> Although the alkaline phosphatase can be normal or only minimally elevated in hepatocellular injury, it is unusual for obstruction to occur without some elevation of the alkaline phosphatase.

### Bilirubin

Elevation of conjugated (direct) bilirubin implies impairment of secretion into bile, whereas elevation of unconjugated (indirect) bilirubin implies impairment of conjugation. Unconjugated hyperbilirubinemia also occurs during hemolysis and in rare disorders of hepatic conjugation such as Gilbert or Crigler-Najjar syndromes. Except in cases of pure unconjugated hyperbilirubinemia, the fractionation of bilirubin in the case of hepatobiliary disorders does not have any important diagnostic utility, and it will not distinguish patients with parenchymal disorders of the liver from intrinsic or extrinsic cholestasis. The presence of bilirubin in the urine implies elevation of conjugated (direct) bilirubin, which is water soluble and filtered by the glomerulus, obviating the need for laboratory fractionation.<sup>125</sup>

Urobilinogen is produced by the bacterial metabolism of bilirubin in the bowel lumen. It is absorbed and excreted in the urine. Its presence in the urine indicates the normal excretion of bilirubin in bile, while its absence is associated with complete biliary obstruction. As a result of more modern methods of detection of complete obstruction of the biliary tract, this test is mainly of historical interest.

### Serum Albumin

Quantitatively, albumin is the most important protein that is made in the liver. With a half-life as great as 20 days, the albumin is usually normal in the previously healthy patient with acute liver injury. In the absence of disorders

TABLE 21–3 Occupational Exposures Associated With Liver Injury

Xenobiotic	Type of Injury
Arsenic	Cirrhosis, angiosarcoma
Beryllium	Granulomatous hepatitis
Carbon tetrachloride	Acute hepatocellular necrosis
Chlordecone	Minor hepatocellular necrosis
Copper salts	Granulomatous hepatitis, angiosarcoma
Dimethylformamide	Steatohepatitis
Methylenedianiline	Acute hepatocellular cholestasis
Phosphorus	Acute hepatocellular necrosis
Sodium azide	Steatohepatitis
Tetrachloroethane	Acute, subacute hepatocellular necrosis
Tetrachloroethylene	Acute hepatocellular necrosis
Toluene	Hepatocellular steatosis (minor)
Trichloroethane	Hepatocellular steatosis (minor)
Trinitrotoluene	Acute hepatocellular necrosis
Vinyl chloride	Acute hepatocellular necrosis, fibrosis, angiosarcoma
Xylene	Steatosis, hepatocellular vacuolation

TABLE 21–4 Laboratory Used to Evaluate Liver Function

Disorder	Alkaline Phosphatase	AST, ALT	Albumin	Prothrombin Time	Bilirubin	Ammonia	Anion Gap
Cholelithiasis	↑	N or ↑	N	N	N or ↑	N	N
Cholestasis	↑↑	N or ↑	N	N	↑	N	N
Chronic hepatitis	N or ↑	↑	N or ↓	N	N or ↑	N or ↑	N
Cirrhosis	N or ↑	↑	↓	N or ↑	N or ↑	N or ↑	N
Hepatocellular necrosis, acute focal (hepatitis)	N or ↑	↑↑↑	N	N or ↑	↑↑	N	N
Hepatocellular necrosis, acute massive	N or ↑	↑↑↑	N	↑↑	↑↑↑	↑↑	↑
Infiltrative disease, chronic (tumor, fatty liver)	↑↑↑	↑	N	N	N	N	N
Mitochondrial failure (acute)	N or ↑	N or ↑	N	↑↑	↑	↑↑	↑↑↑

↑ = increase; ↓ = decrease; N = normal; AST = aspartate aminotransferase; ALT = alanine aminotransferase.

that affect albumin, such as nephrotic syndrome, protein-losing enteropathy, or starvation, a low serum albumin concentration is a useful marker for the severity of chronic liver disease.<sup>125</sup>

### Serum Prealbumin

Prealbumin is the earliest laboratory indicator of protein malnutrition, and is considered the best way to assess the severity of illness in both the critically ill and the chronically ill. Because albumin has a relatively large body pool, a half-life of 20 days, and its serum concentrations are affected by the patient's hydration status and kidney function, it is not as sensitive as prealbumin in identifying changes in nutrition. Because prealbumin has one of the highest essential-to-nonessential amino acid ratios in the body, it a great marker for protein synthesis.<sup>5</sup>

### Coagulation Factors

Impairment of coagulation is a marker of the severity of hepatic dysfunction in both acute and chronic liver disease. Elevation of the PT in acute hepatitis is associated with a higher risk of hepatic failure.<sup>44</sup> Unlike the case with serum albumin, the onset of coagulopathy as a consequence of impaired synthesis of coagulation factors produced in the liver is rapid. Acute changes in coagulation reflect the concentration of factor VII, which has the shortest half-life.<sup>52</sup> The extrinsic coagulation pathway, as measured by the PT, is affected by reductions in factors VII, IX, and X. In addition to failure of hepatic synthesis, inadequate concentrations of factors II, VII, IX, and X can also result from ingestion of warfarin anticoagulants or malabsorption of vitamin K (Chap. 58).

Because different thromboplastin reagents give different PT values on the same sample, the international normalized ratio (INR) was developed to normalize PT measurements in patients treated with warfarin, allowing comparisons of therapeutic outcomes across different care settings and across the literature. The INR uses the International Sensitivity Index (ISI) that is derived from a cohort of patients on stable anticoagulant therapy. It normalizes the responsiveness of a given thromboplastin reagent in comparison to a WHO reference standard that is assigned a value of 1.0.<sup>60</sup> There is little controversy regarding the value of the INR in comparison with the PT ratio for measuring the extent of warfarin-induced anticoagulation. In patients with liver disease, use of the INR implies a normalized correlation that does not exist and is therefore potentially misleading. Because factor deficiencies in patients with liver disease are different from those in patients on warfarin, there is considerable controversy regarding which measurement is best for patients with liver disease.<sup>25,60</sup> Although comparison of factor concentrations in warfarin-treated patients with those with liver disease showed no difference in factor VII, there are significant differences in factors II, V, X, and fibrinogen. Comparison of the PT with INR in the evaluation of test results with 3 different thromboplastin reagents showed consistency among the control groups of warfarin-treated patients,

but no consistency among PT or INR measurements using the same thromboplastin reagents in patients with liver disease.<sup>60</sup> Because of a failure to demonstrate an advantage, liver specialists have supported the continued use of the PT to describe the degree of liver injury, lacking the availability of a single reliable standard that would help predict operative risk.<sup>25</sup> The implication for toxicologists is that caution should be exercised in relying too heavily on published INR values that purportedly predict the severity of illness in patients with acute liver failure.

A thoughtful review of bleeding risk due to coagulopathy in chronic liver disease discussed the balance of procoagulation forces (elevated factor VIII concentrations, elevated von Willebrand factor, decreased protein C and antithrombin) and anticoagulation forces (decreased fibrinogen and other clotting factors, high tissue plasminogen activator, low platelet count). The balance is simply characterized as a seesaw effect between stimulation of thrombin generation by factor VIII and the suppression of thrombin generation by protein C. This fragile balance between procoagulation and anticoagulation can be tipped by events such as acute kidney injury or infection. It is not effectively characterized by the INR or the PT. The review proposed that the standard belief that patients with liver failure are "auto-anticoagulated" and not at risk of venous or arterial thrombosis is erroneous. Neither the PT nor the INR predict bleeding risk in the cirrhotic patient, and other investigations are proposed to help identify bleeding risk and prevent or manage thrombotic events in cirrhotic patients.<sup>128</sup>

### Ammonia

Severe generalized impairment of hepatic function leads to a rise in the serum ammonia concentration as a result of impairment of hepatic detoxification of ammonia produced during catabolism of proteins.<sup>4</sup> Urease-containing bacteria within the bowel, especially *Klebsiella* and *Proteus* species, are the most prominent producers of ammonia.<sup>107</sup> Some patients treated with valproic acid develop alterations in mental status associated with elevated ammonia concentrations in the absence of other laboratory indicators of hepatic injury.<sup>100</sup> Hyperammonemia in patients on valproic acid is also commonly asymptomatic.<sup>126</sup> This has been attributed to selective impairment of urea cycle enzymes ornithine transcarbamylase or carbamyl phosphate synthetase by pentanoic acid metabolites (Chap. 48).

### Other Laboratory Tests

Serologic studies for the presence of markers of hepatitis A, B, and C should be obtained routinely in patients with hepatitis. In the patient with severe liver injury, hypoglycemia is a major concern because of impairment of glycogen storage and gluconeogenesis. Hyperglycemia also occurs as a result of the inability of the liver to handle a large glucose load. The arterial or venous blood gas commonly shows a respiratory alkalosis. Severe metabolic acidosis with elevated lactate occurs in patients with hepatic failure caused by

mitochondrial injury. Measurement of serum lactate concentration is useful in identifying the cause of acidosis in a patient with suspected toxic liver injury.

Computed tomography and magnetic resonance imaging scans are useful tests for evaluation of parenchymal disease of the liver. An ultrasonographic examination reliably demonstrates dilation of the extrahepatic bile ducts. Liver biopsy is helpful but is not specifically diagnostic of xenobiotic-induced hepatic injury.

## MANAGEMENT

In many patients, toxic liver injury resolves with simple withdrawal of the offending xenobiotic. In patients with severe injury, significant improvement in survival is associated with good supportive care in an intensive care environment. Transplantation is lifesaving for critically ill patients with acute liver failure. Early referral to a transplant center is indicated for patients with evidence of severe or rapidly progressive toxic injury.<sup>93</sup> For discussion of indications for the use of *N*-acetylcysteine and discussion of indications for hepatic transplantation see Chap. 33.

## SUMMARY

- The primary role of the liver in the biotransformation of xenobiotics results in an increased risk of hepatotoxicity. Xenobiotic-induced liver injury is either dose-dependent and predictable or idiosyncratic and unpredictable.
- Predictability is evolving with the science of genome analysis. Injury that is apparently idiosyncratic is affected by host characteristics that include genetic makeup, concomitant or previous exposure to xenobiotics, and the underlying condition of the liver. The ability to predict this susceptibility is increasing.
- The pathologic spectrum of liver injury includes combinations of hepatocellular necrosis, hepatitis, cholestasis, steatosis, apoptosis, and fibrosis.
- Mechanisms of hepatic injury include cell-mediated immune mechanisms that result in inflammation and fibrosis; antibody-mediated immune mechanisms that attack various hepatocyte targets, including critical cellular enzymes; lipid peroxidation initiated by free radicals; and mitochondrial injury.

## CASE STUDY 5

**History** Parents called 911 because they found their 5-year-old girl at home unresponsive. Shortly before emergency medical services (EMS) arrived, the girl had a witnessed self-limited convulsion that the parents described as the sudden onset of unresponsiveness with repetitive shaking and urinary incontinence. When EMS arrived, she was no longer shaking but could not be awoken. The paramedics recorded a respiratory rate of 30 breaths/min with a pulse of 150 beats/min and a point-of-care glucose of 122 mg/dL. They administered oxygen via nasal cannula and transported her to the emergency department (ED).

On arrival at the hospital, the parents reported that the child had no significant past medical history, had a pediatrician, was current with all vaccinations, and was not taking any prescription medications. Although she had a mild cough and nasal congestion, she was able to attend kindergarten the previous day. As further history was being obtained, the child began to shake repetitively once again.

**Physical Examination** The child was attached to continuous cardiac monitoring, and repeat vital signs were as follows: blood pressure, 108/80 mm Hg; pulse, 155 beats/min; respiratory rate, 32 breaths/min; rectal temperature, 99.4°F (37.4°C); oxygen saturation, 100% on a 100% nonre-breather face mask; and glucose, 143 mg/dL. Physical examination revealed a normal head without signs of trauma, pupils that were 4 to 5 mm and reactive, a clear chest, normal heart sounds, a soft abdomen with normal bowel sounds, and skin that was without rashes or other abnormalities. The child was still not verbal but appeared to localize pain and moved all extremities, and she had normal muscle tone.

**Immediate Management** The child was given an intramuscular injection of lorazepam (2 mg; 0.1 mg/kg for an estimated weight of 20 kg) while an intravenous (IV) line was being inserted. Within a few moments, the shaking stopped. Blood samples were sent for a complete blood count and electrolytes and an electrocardiogram (ECG) were ordered. The patient began to seize again, for which IV lorazepam (2 mg) was given with nearly an immediate response. Repeat vital signs and physical examination were essentially unchanged.

**What Is the Differential Diagnosis?** In addition to idiopathic epilepsy, trauma, infections, and structural brain lesions, seizures can result from both exposure to countless xenobiotics as well as withdrawal. In most instances, seizures are usually single and either self-limited or respond easily to an appropriate dose of a benzodiazepine. This child had three seizures in a brief period of time without regaining consciousness, which meets one of the criteria for status epilepticus. Although seizures are common, status epilepticus is rare, thereby narrowing the differential diagnosis to xenobiotics found in [Table CS5-1](#).

Several features distinguish toxic–metabolic seizures from idiopathic epilepsy. With few exceptions, toxic–metabolic seizures often fail to respond to phenytoin. Phenytoin either has no efficacy or is actually detrimental in diverse or toxic–metabolic-induced convulsions associated with alcohol withdrawal, theophylline, cyclic antidepressants, antiepileptics, and cocaine. Conceptually, phenytoin fails because its ability to prevent secondary generalization of a focal seizure in idiopathic epilepsy is lost in toxic–metabolic etiologies where many areas of the brain are likely reaching the convulsive threshold simultaneously. Thus, when a toxic–metabolic cause is suspected, typically a barbiturate or propofol is added when benzodiazepines fail. In some cases, such as isoniazid, a specific antidote may be necessary (*Antidotes in Depth: A15*), and in others, such as theophylline, hemodialysis is often indicated (*Chap. 6*). Finally, it is important to recognize that the cessation of motor activity with toxic–metabolic seizures may be insufficient to prevent serious complications. For example, although it is common that patients with hypoglycemia, hyponatremia, or carbon monoxide poisoning can have their seizures terminated with benzodiazepines, the

failure to correct these underlying issues will likely prevent complete neurologic recovery. The reader is referred to *Antidotes in Depth: A26* for information regarding the choice, dose, and route of commonly used benzodiazepines.

### What Clinical and Laboratory Analyses Can Help Exclude Life-Threatening Causes of This Patient's Presentation?

Many rapidly reversible causes of seizures are assessed by the history and physical examination. Signs and symptoms of trauma, infection, and structural brain injury are often immediately evident. Bedside techniques can assess hypoxia, hypercarbia, and hypoglycemia, and a venous blood gas can confirm or exclude hyponatremia. An ECG provides rapid confirmation of sodium channel blockade, which is frequently associated with the risk of convulsions (*Chaps. 15, 68*). Potassium channel blockade can produce torsade de pointes (*Chaps. 15, 67*), which causes syncope that can be confused with convulsions in unmonitored patients. Vomiting would be commonly expected following overdose, especially with isoniazid (*Chap. 56*) and theophylline (*Chap. 63*). In some patients, computed tomography (CT) of the head, lumbar puncture, and empiric antimicrobials are indicated.

### Further Diagnosis and Treatment

Because of the child's continued depressed mental status, a clinical decision was made to protect her airway. During preparation for intubation, a unique "chemical" odor was noted in the oropharynx. When the parents were questioned, they confirmed that they recently bought camphor (*Chap. 102*) for use in a vaporizer in an attempt to help relieve the symptoms of an upper respiratory tract infection. The child had likely eaten some camphor, based on the odor and the recent purchase by the parents. Intubation was not performed when this history was obtained, because the girl's mental status appeared to be improving. A head CT scan was obtained without contrast and was interpreted as normal. Over the next day, the girl awakened and was neurologically normal. She was discharged after her parents were counseled about the safe storage of chemicals and medications.

## NEUROLOGIC PRINCIPLES

Rama B. Rao

### INTRODUCTION

The central nervous system (CNS) coordinates responses to the fluctuating metabolic requirements of the body and modulates behavior, memory, and higher levels of thinking. These functions require diverse cells: astrocytes, neurons, ependymal cells, and vascular endothelial cells. Disruption or death of any one cell type can cause critical changes in the function or viability of another. This cellular interdependence, along with the high metabolic demands of the CNS, makes neurons especially vulnerable to injury from both endogenous neurotoxins and xenobiotics. Endogenous neurotoxins, such as the metals iron, copper, and manganese, are substances that are critical to CNS function but are harmful when their penetration into the CNS is poorly controlled.

The understanding of the normal chemical and molecular functions of the CNS is limited at best. Interestingly, cellular mechanisms are sometimes revealed by investigating xenobiotic-induced neuronal injuries.<sup>39,69</sup> For example, the pathophysiology of Parkinson disease, which affects movement and motor tone, was elucidated by the inadvertent exposure of individuals to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a by product of synthesis of a meperidine analog. The mechanisms of axonal transport were elucidated by investigations of the effects of acrylamide exposures in human and animal models.<sup>59</sup> The neurodegenerative changes of amyotrophic lateral sclerosis have a promising xenobiotic model in  $\beta$ -methylamino-L-alanine (BMAA), a neurotoxin found in the cyanobacteria associated with cycad plants ingested by the Chamorro people of Guam (Chap. 13).

There are few minimally invasive methods available to investigate xenobiotic-induced CNS injury. Biomarkers are usually nonspecific and not readily available. Xenobiotic concentrations of blood and urine rarely reflect tissue concentrations of the CNS.<sup>61</sup> Cerebrospinal fluid (CSF) is useful in excluding CNS injury from infection, hemorrhage, and inflammatory processes, but is, with few exceptions, poorly reflective of the etiology of neuronal injuries.<sup>93</sup> Similarly, electroencephalograms and electromyograms are useful in only a few types of xenobiotic exposures, and neuroimaging, while progressively evolving,<sup>55</sup> is a poor substitute for neuroanatomical evaluations that are usually available only on autopsy. Much of the current study to elucidate the mechanisms of CNS injury uses animal models, cultured astrocytes, and other tissue, or postmortem investigations. Less commonly, occupational evaluations, such as the enzyme activity of cholinesterases, are used in pesticide-exposed workers.

This chapter reviews some basic anatomic and physiologic principles of the nervous system and the common mechanisms by which xenobiotics exploit the functional and protective components of the CNS, with a few relevant examples. The multiple factors determining the clinical expression of neurotoxicity are reviewed.

### CELLS OF THE NERVOUS SYSTEM: AN OVERVIEW

#### Neurons

Neurons are the major pathway of cellular communication in the CNS. Having one of the highest metabolic rates in the body, these cells are especially sensitive to changes in the microenvironment and are dependent on astrocytes, choroidal epithelium, and capillary endothelium to confer protection and deliver glucose and other sources of energy.

Although each neuron is capable of receiving information through different neurotransmitters and receptor subtypes at the dendrite, neurons typically produce and release a single type of neurotransmitter at the axonal terminal. This specificity allows for cellular classification of neurons based

on the neurotransmitter released, for example, serotonergic, cholinergic, and dopaminergic neurons (Chap. 13). Other substances such as adenosine are produced and released that are less specific to the neuron type.

The anatomic structure of neurons facilitates their function. Dendrites located on the cell body are lined with receptors that bind neurotransmitters and affect cellular changes via several mechanisms. The soma, or cell body, is responsible for coordination and production of multiple proteins required to carry out normal physiological functions. This synthesis occurs at a rate several times greater than that in the liver or kidney. These proteins, organelles, and substrates must then be transported across long distances to the terminal axon. This energy-dependent function is supported by a cytoskeleton composed of neurofilaments, microfilaments, microtubules, and complex transport proteins. Fast anterograde transport of membrane-bound organelles occurs through *kinesin*, a transport protein, at a rate of 200 to 400 mm/d. Channel proteins, synaptic vesicles, mitochondria,  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase, glycolipids, and other substances are transported by kinesin. Slow anterograde transport also occurs, but at a substantially slower rate (0.5–4 mm/d). The retrograde transport protein, *dynein*, is produced in the soma and delivered to the nerve terminal for the movement of larger vesicles and reusable proteins back to the cell body.

In the CNS, groups of neurons are organized into complex functional pathways, with a single class of neurons regulating different functions and clinical effects depending on the brain region. As an example, dopaminergic neurons regulate cravings, movement, and resting muscle tone, each of which is determined not only by dopaminergic neurons and receptor subtype, but the location in the cortex or basal ganglia (Chap. 13).

Neurons must be able to respond to changes in the local environment and alter the expression of different receptors in response to signaling from neurotrophic factors, variations in metabolic requirements, and xenobiotic interactions. This “neuroplasticity” accounts for the diversity of clinical responses to xenobiotics that induce tolerance such as ethanol (Chap. 14).

#### Glial Cells

Glial cells are composed of *astrocytes*, *oligodendrocytes*, *Schwann cells*, and *microglia*. These cells serve to support the neurons both structurally and functionally.

Astrocytes comprise between 25% and 50% of the brain volume.<sup>1,3,4,12</sup> In addition to the anatomic contribution to the blood–brain barrier (BBB), astrocytes play a critical role in maintaining neuronal function.<sup>1,2,96</sup> They contribute to 3 major areas: homeostasis of the extraneuronal environment, provision of energy substrates, and limitation of oxidative stress. In addition, astrocytes contribute to the “plasticity” of cells and receptor expression in the CNS (see later discussion).

In order for cells of all types to function in the CNS, membrane potentials must be adequately maintained. Astrocytes contribute to this by closely regulating the extracellular pH, water, and, like brain capillaries, the extracellular potassium concentration. Metallothioneins, which control the entry of metals necessary for CNS function, are produced by astrocytes.<sup>29,96</sup> Astrocytes also release energy substrates such as lactate, citrate, alanine, glutathione, and  $\alpha$ -ketoglutarate for utilization by neurons.<sup>12</sup>

Astrocytes metabolize glutamate, the main excitatory amino acid (EAA) neurotransmitter in the CNS, as well as ammonia. These cells also produce superoxide dismutase and glutathione peroxidase to reduce free radical propagation. Glutathione, the major antioxidant for the brain, is predominantly located in the astrocytes. It is released into the extracellular space or cleaved for neuronal uptake and intracellular reformulation.<sup>12</sup>

Through the release of complex trophic factors, astrocytes control the expression of endothelial transporters of the BBB and the production of tight junctions in both the blood-CSF barrier and BBB. Angiogenesis is similarly astrocyte regulated, as is detection of neuronal injury, immune mediation, and neurotransmitter production. The growth of neurites, the branches of neuronal cell bodies that eventually become dendrites or axons, is similarly modulated by astrocytes.

Oligodendrocytes are a type of glial cell that provide anatomical support, protective insulation, and facilitate rapid neuronal depolarization by the production of myelin. Myelin is the primary constituent of white matter in the CNS. The production of myelin in the peripheral nervous system (PNS) is performed by the Schwann cells. Although oligodendrocytes support several axons, each Schwann cell is anatomically dedicated to a single axon.

Finally, microglial cells modulate immune response, inflammation, and tissue repair from a variety of CNS injuries. Like neurons, microglia are dependent on signaling from astrocytes.

## MECHANISMS OF NEUROPROTECTION

The nervous system has multiple protective mechanisms. Xenobiotics are prevented from accessing the CNS by the blood-brain and blood-CSF barriers. For xenobiotics that enter the CNS, there are multiple cellular specializations to limit oxidant stress as reviewed below.

### Blood-Brain Barrier

The BBB confers an anatomic and functional barrier to xenobiotic entry into the CNS. Brain capillaries are surrounded by the foot processes of adjacent astrocytes. The potential spaces between endothelial cells are limited by tight junctions, or zonulae occludentes, which are between 50 and 100 times tighter than those found on peripheral capillaries.<sup>1,2,4,53,64</sup> This anatomic barrier prevents movement of substances between cells, also known as the paracellular aqueous pathway, due to osmotic and oncotic forces.<sup>1,2,4,53,64</sup>

Transendothelial movement of critical substrates and, potentially, xenobiotics occurs through 3 major mechanisms: diffusion, transport proteins, and endocytosis.<sup>1,4</sup> These routes allow carefully controlled entry of critical substrates and cofactors while limiting the potential for injury from either endogenous or exogenous neurotoxins.

Lipophilic substances can move directly across the luminal and abluminal endothelial membranes abutting the CNS. Other substances enter the endothelium through bidirectional transport proteins on the luminal surface. Some of these proteins are specific, such as the glucose transporter 1 (GLUT1) protein for uptake of glucose. Other less specific large neutral amino acid transporters can move amino acids and xenobiotics such as baclofen, intracellularly. These transporters also line the abluminal surface of the endothelial cell for movement of substrates and xenobiotics into the CNS. The third line of entry for larger proteins is via endocytosis. This is adsorptive, or mediated through specific receptors such as those for insulin or transferrin.<sup>1,3,4,53,64,96</sup>

Endothelial cells have other protective properties, including intracellular enzymes, to metabolize xenobiotics and efflux proteins to transport certain xenobiotics back into the capillary lumen. These efflux proteins include energy-dependent P-glycoproteins that are ATP-binding cassette transporters and are sometimes referred to as multidrug-resistant (MDR) proteins (Chap. 9). Several hydrophobic xenobiotics are prevented from accumulating in the CNS through these transporters, including vinca alkaloids, digoxin, cyclosporine A, and protease inhibitors. Nonsedating antihistamines and loperamide have limited sedative properties due, in part, to efflux through P-glycoproteins.<sup>26,77</sup> Another type of saturable transporter, known as organic acid transport (OAT) protein, facilitates the efflux of hydrophilic xenobiotics such as valproic acid or baclofen. The expression of each of these transporters is upregulated under certain conditions such as intermittent disruptions in the BBB from seizures. This expression upregulation is theorized to account for the resistance of anticonvulsant medications in patients with epilepsy. Comprehensive lists of xenobiotics that are substrates for these transporters are available elsewhere.<sup>2,53,54</sup>

### Blood-Cerebrospinal Fluid Barrier

The ventricles of the brain are lined by the epithelial cells of the choroid plexus. These cells also have tight junctions but not as extensive as those of the BBB. They are, however, rich in glutathione peroxidase and other xenobiotic-metabolizing enzymes in concentrations approximating those of the liver. Similar to brain capillary cells, the choroid plexus contains efflux transporters for organic anions and cations, as well as MDR efflux proteins (P-glycoproteins) to limit entry of xenobiotics into the CSF.<sup>1,4,53,96</sup>

## NEUROTOXIC PRINCIPLES

### Excitotoxicity

Neuronal function is strictly dependent on aerobic metabolism. When energy expenditure exceeds production, cellular dysfunction and ultimately cell death, or apoptosis, results. The specific cascade of molecular events relating to this process is termed *excitotoxicity*.<sup>11,74</sup>

The initial event is traced to an oxidant stress and excessive stimulation of *N*-methyl-D-aspartate (NMDA) receptors by glutamate, an EAA neurotransmitter. An influx of intracellular calcium changes membrane potentials across the cellular and mitochondrial membranes. The mitochondria become progressively more inefficient at ATP production and handling the resulting reactive oxygen species. As membrane damage is propagated, calcium further depolarizes the mitochondria, activating a permeability transition pore across the mitochondrial membrane. Gradients are further disrupted, precipitating more injury, energy failure, and ultimately cell death.

Excitotoxicity is considered a common mechanism of cell death due to xenobiotic, ischemic, traumatic, infectious, neoplastic, or neurodegenerative injury. It is the subject of study for many therapeutic interventions in CNS injury.

### Determinants of Neurotoxicity

The clinical expression of neurotoxicity is related to many factors. These include the chemical properties of the xenobiotic, the dose and route of administration, xenobiotic interactions, and underlying patient characteristics including age, gender, and comorbid conditions.

### Chemical Properties of Xenobiotics

One of the most important determinants of neurotoxicity is the ability of a xenobiotic to penetrate the BBB. Water-soluble molecules larger than 200 to 400  $M_r$  (molecular weight ratio, or mass of a molecule relative to the mass of an atom) are unable to bypass the tight junctions.<sup>4</sup> Lipid-soluble xenobiotics (those with a high octanol/water partition coefficient) are more likely to passively penetrate the capillary endothelium, and potentially the BBB, whereas those with a low partition coefficient typically require energy-dependent facilitated transport.<sup>64</sup> Xenobiotics that are substrates for capillary endothelial efflux mechanisms will have limited penetration regardless of the coefficient.<sup>1,4,53,64</sup>

### Route of Administration

The route of xenobiotic administration is also consequential. Although most xenobiotics gain access to the nervous system through the circulatory system, aerosolized solvents and heavy metals in industrial and occupational exposures gain CNS access through inhalation, traveling via olfactory and circulatory routes. Alternatively, some substances move from the PNS via retrograde axonal transport to the CNS. Naturally occurring proteins such as tetanospasmin, as well as rabies, polio, and herpes virus use this mechanism to access the PNS and CNS.<sup>14,17,48</sup> The toxalbumins ricin and abrin as well as bismuth salts also use this mechanism to a limited extent.<sup>87,94</sup> This understanding can prove beneficial from a therapeutic perspective. For example, in one small experimental series of patients experiencing severe pain, doxorubicin was injected into the involved peripheral nerves. Therapeutically, a chemical ganglionectomy occurred through retrograde "suicide" transport of doxorubicin, which provided substantial relief for these patients.<sup>51</sup>

Some xenobiotics are delivered directly into the CSF (intrathecally), the consequences of which are variable (Special Considerations: SC7).

## Xenobiotic Interactions

Coadministration of xenobiotics can precipitate neurotoxicity by several mechanisms.<sup>46</sup> Extraaxially (outside of the CNS), xenobiotic interactions that result in an increase of the blood concentration of one or both can overwhelm the protective mechanisms of the BBB.<sup>21</sup> Similar effects can occur in the PNS, where elevated blood concentrations can enhance clinical effects resulting in peripheral neuropathies.<sup>96</sup>

Some xenobiotic interactions are synergistic, acting on the same neuroreceptor. Benzodiazepines and ethanol, for example, both stimulate the  $\gamma$ -aminobutyric acid type A (GABA<sub>A</sub>) receptor. The excessive neuroinhibition results in enhanced sedation and even respiratory depression when these xenobiotics are administered simultaneously.

In some circumstances, xenobiotic interactions result in excessive neurotransmitter availability.<sup>10</sup> This neurotransmitter excess is demonstrated in patients with serotonin toxicity, which results from the coadministration of a monoamine oxidase inhibitor and a serotonin reuptake inhibitor or other serotonergics as an example (Chap. 69).

Access to the CNS can be altered by one of the xenobiotics, allowing the other to bypass the BBB. For example, mannitol causes transient opening of the BBB; as a result, therapeutic use of mannitol is under investigation for the delivery of chemotherapeutics that might otherwise be unable to access the nervous system.<sup>54</sup> Similarly, some xenobiotics, such as verapamil, cyclosporine, and probenecid, are blockers of capillary endothelium efflux.<sup>4,96</sup> These theoretically limit efflux of other substrates of P-glycoprotein or OAT. Loperamide penetration into the CNS is limited by P-glycoprotein. In healthy volunteers the coadministration of quinidine—another P-glycoprotein substrate—with loperamide results in respiratory depression suggestive of increased CNS penetration.<sup>77</sup> The clinical utility of employing such efflux blockers is under investigation as was done in a study in which primates received intrathecal methotrexate. The CSF clearance of methotrexate was reduced in animals administered intrathecal probenecid.<sup>13,78</sup>

## Patient Characteristics

Patient-specific variables also affect the ability of a xenobiotic to penetrate the BBB and/or the clinical effects of a given exposure. For example, age of the patient at the time of exposure is critical, especially in the fetus and neonates.<sup>80</sup> The structural and enzymatic development of the BBB is incomplete, and synaptogenesis, or formation of intercellular relationships, is especially sensitive to impaired protein synthesis or other excitotoxic events. This is demonstrated classically by maternal exposure to methylmercury. The mother can be minimally affected, but the developing fetus suffers profound neurological and developmental consequences (Chaps. 30 and 95).

In neonates, immature liver function can lead to the accumulation of circulating bilirubin. Because of incomplete formation of the BBB, the bilirubin accesses the CNS and produces a form of encephalopathy known as *kernicterus*.

Elderly patients are also susceptible to neurotoxins as a result of relatively impaired circulation or age-related changes in mitochondrial function that predispose to excitotoxicity.<sup>83</sup> Xenobiotic-induced Parkinsonism, or the unmasking of subclinical idiopathic Parkinson disease occurs more readily than in younger patients. Animal models also suggest age-related sensitivity, with one study noting increased manganese toxicity with advanced age.<sup>37</sup>

Gender is contributory to the expression of xenobiotic induced neurologic injury. In animal models, the presence of estrogen-related and progesterone-related compounds are neuroprotective for some xenobiotic injuries.<sup>65,72</sup> In humans, women are more susceptible to some movement disorders such as xenobiotic-induced parkinsonism and tardive dyskinesia, whereas dystonias and bruxism are more prevalent in young men.<sup>75</sup> The etiologies of these gender-related differences are incompletely understood.

## Neurologic Comorbidities

Conditions affecting the integrity of the BBB affect CNS penetration of xenobiotics and endogenous neurotoxins. For example, glutamate concentrations are normally higher in the circulatory system than the CNS.<sup>58</sup> Patients with

trauma, ischemia, or lupus vasculitis<sup>3</sup> can experience neuropsychiatric disorders as a result of increased penetration of glutamate or sensitivity to additional xenobiotics. Similarly, inflammation associated with meningitis and encephalitis causes openings in the BBB, which is exploited therapeutically. Intravenous penicillin achieves a higher CSF concentration in animals with meningitis than in those without meningitis.<sup>79</sup>

In some patients, previously undiagnosed diseases become evident on exposure to xenobiotics. This is especially true in patients with peripheral neuropathies. For example, patients being treated with therapeutic doses of vincristine suffered a severe polyneuropathy due to unmasking of a previously undiagnosed Charcot-Marie-Tooth disease.<sup>10,23</sup> Similarly, patients with diabetes mellitus, the commonest cause of peripheral neuropathy, or human immunodeficiency virus disease have exacerbation of symptoms in the presence of antiretrovirals.<sup>25,73</sup> Patients with myasthenia gravis have exacerbation of weakness with aminoglycoside administration, which affects transmission at the neuromuscular junction (NMJ).<sup>95</sup>

Chronic exposures to some neuroinhibitory xenobiotics such as ethanol alter neuronal receptor expression and upregulate or increase the amount of receptors for EAAs. In addition to receptor augmentation, neurotransmitter concentrations of the excitatory neurotransmitters glutamate and aspartate are increased, as is homocysteine. These changes induce a tolerance to neuroinhibitory xenobiotics acting on the same receptor, and patients require escalating doses to achieve the same clinical effect. In such patients, cessation of ethanol intake results in a relative deficiency of exogenous inhibitory tone. The patient experiences neuroexcitability and the clinical syndrome of withdrawal<sup>18,19</sup> (Chap. 14).

Adequate nutritional status is important for the maintenance of normal neurologic function. The BBB is inadequately maintained in patients with malnutrition. Deficiencies of metal cofactors such as manganese, copper, zinc, and iron affect neurological function. In some cases, the deficiencies enhance absorption of other xenobiotics. For example, iron deficiency enhances lead and manganese absorption in the gastrointestinal tract, which can ultimately overwhelm neuroprotective mechanisms. Vitamins serve as enzymatic cofactors in modulating the production of glutamate, homocysteine, and other amino acids. Specific vitamin deficiencies precipitate neurologic syndromes such as Wernicke encephalopathy in thiamine-depleted patients (Antidotes in Depth: A27 and Chap. 44). The toxicity of xenobiotics is also enhanced. For example, a relative pyridoxine deficiency in patients with acute isoniazid overdose result in seizures as a result of a relative excess of EAAs (Antidotes in Depth: A15 and Chap. 56). Glucose is a critical energy substrate that causes profound neurologic impairment when delivery is inadequate (Antidotes in Depth: A8 and Chap. 47).

Interestingly, certain conditions such as temperature sometimes affect the toxicity of xenobiotics. For example, cooling limits the impedance of acetylcholine neurotransmission caused by botulinum toxin.<sup>42</sup>

## Extraaxial Organ Dysfunction

Kidney failure impairs metabolism or elimination of xenobiotics or endogenous substances such as uremic toxins rendering them more available to the CNS. Hyperglycemia in patients with diabetes mellitus increases formation of CNS reactive oxygen species. Similarly, some patients with liver failure have elevations in CNS manganese resulting in Parkinsonism.<sup>52,81</sup>

Hepatic encephalopathy illustrates the concept of excitotoxicity from endogenous neurotoxins. Hyperammonemia increases oxidative stress and free radical formation in astrocytes. Ammonia potentially decreases critical metabolic enzymes such as catalases, superoxide dismutase, and glutathione peroxidase. Nitric oxide (NO) production is increased as a result of elevations in NO synthetase. Under these conditions, astrocytes upregulate the expression of the peripheral benzodiazepine receptor (PBR) on the outer mitochondrial membrane. The PBR modulates the production of neurosteroids and, in turn, the GABA<sub>A</sub> receptor. Continued CNS exposure to ammonia and other endogenous solutes propagates this oxidative and nitrosative stress to the mitochondrial membrane, potentially opening the mitochondrial permeability transition pore. Osmotic swelling of the mitochondrial

membrane followed by excitotoxicity results in cerebral edema and hepatic encephalopathy.<sup>65–67</sup>

## SPECIFIC MECHANISMS OF NEUROTOXICITY

### Alteration of Endogenous Neurotransmission

Xenobiotics induce neurotoxicity by triggering changes in neurotransmission in either the CNS or PNS. In some cases, xenobiotics enhance neurotransmission through a specific receptor subtype. This enhanced transmission occurs through inhibition of presynaptic metabolism (monoamine oxidase inhibitors), stimulation of neurotransmitter release (amphetamines), impairment of neurotransmitter reuptake (cocaine), or inhibition of synaptic degradation (acetylcholinesterase inhibitors).

Alternatively, synaptic neurotransmission can be impaired.<sup>82</sup> Xenobiotics can inhibit the presynaptic release of neurotransmitters (botulinum toxin), block receptors (antimuscarinics), or alter membrane potentials at the post-synaptic membrane (tetrodotoxin).<sup>33,34</sup> Patients present with a clinical syndrome of toxicity associated with altered neurotransmission of the specific receptor (Chap. 3).

### Direct Receptor Interaction

Some xenobiotics are able to directly stimulate receptors. Both kainate and  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA) are subclasses of the glutamate receptor, which are targeted by some naturally occurring xenobiotics.<sup>43</sup> An example is  $\beta$ -*N*-oxalylamino-L-alanine (BOAA) found in the grass pea, *Lathyrus sativus*.  $\beta$ -*N*-Oxalyl-amino-L-alanine stimulates the AMPA receptor and inhibits specific mitochondrial enzymes, resulting in the spastic paraparesis of lathyrism.<sup>70</sup> Domoic acid stimulates the kainate receptor and causes the neuroexcitation associated with neurotoxic shellfish poisoning (Chap. 39). Direct inhibition is also possible, as exemplified by phencyclidine, an NMDA receptor antagonist.

### Enzyme and Transporter Exploitation

The classic example of xenobiotics that exploit endogenous enzymes and/or transporters is MPTP.<sup>39</sup> Once MPTP crosses the BBB, it is converted by monoamine oxidase to the neurotoxic compound 1-methyl-4-phenylpyridine ion in astrocytes. 1-Methyl-4-phenylpyridine ion (MPP<sup>+</sup>) is taken up by dopamine transporters into the neurons of the substantia nigra pars compacta. It inhibits complex I of the mitochondrial electron transport chain resulting in dopaminergic excitotoxicity and the clinical syndrome similar to Parkinson disease (see below and Chap. 36).

### Altered Conduction Along Membranes: Demyelinating Neurotoxins

Aside from xenobiotics that affect neurotransmission at the postsynaptic membrane, some affect the production or maintenance of myelin by oligodendrocytes and Schwann cells.<sup>24,35,38,49</sup> In the CNS, these are often associated with white matter abnormalities and a leukoencephalopathy.<sup>35</sup> Xenobiotics such as hexachlorophene, arsenic, inhibitors of tumor necrosis factor  $\alpha$ , neural tissue-derived rabies vaccine, and inhaling some forms of volatilized heroin (“chasing the dragon”) are associated with a demyelinating neurotoxicity.<sup>24</sup> In the PNS, suramin and tacrolimus are associated with peripheral demyelination.<sup>47</sup> Nitrous oxide affects the CNS and can also cause axonal degeneration in the PNS.<sup>92</sup>

### Inhibition of Intracellular Functions

Some xenobiotics are nonspecific inhibitors of cellular function.<sup>30</sup> For example, the neurotoxicity of carbon monoxide (CO) or cyanide that can appear as a diffuse impairment of neuropsychiatric dysfunction or, depending on the dose and specific vulnerabilities of an exposed patient, be more focal. Some patients surviving acute CO exposure experience delayed neurologic sequelae that includes a diffuse impairment of neuropsychiatric function, or more focally, present with a xenobiotic-induced Parkinson syndrome (see below and Chap. 122). Patients ingesting inadequately prepared cassava are exposed to excessive linamarins that can result in spastic paralysis, visual disturbances, and somatosensory abnormalities.<sup>88</sup>

Chemotherapeutics affect the production of critical proteins required for cellular maintenance. These can be very specific such as the ability of vincristine and colchicine to impair cytoskeletal transport in the peripheral nervous system (Chap. 34).

## CLINICALLY RELEVANT XENOBIOTIC-MEDIATED CONDITIONS

### Alterations in Consciousness

The toxicologic differential diagnosis of xenobiotics that induce alterations in mental status or consciousness is expansive. These xenobiotics are broadly divided into those that produce some form of neuroexcitation and those that produce neuroinhibition. Although some xenobiotics such as phencyclidine have elements of both depending on dose, this categorization facilitates a general clinical understanding of neurotoxic alterations in mental status.

Xenobiotics resulting in neuroexcitation enhance neurotransmission of EAAs, or diminish inhibitory input from GABAergic neurons. The clinical presentation of the patient varies; some patients are alert and confused, or suffering from an agitated delirium, hallucinations, or a seizure.

Neuroinhibitory xenobiotics typically enhance GABA-mediated neurotransmission. These patients often are somnolent or in deep coma. Benzodiazepines hyperpolarize cells by increasing inward movement of Cl<sup>-</sup> ions through the chloride channel of the GABA<sub>A</sub> receptor. This hyperpolarization limits subsequent neurotransmission (Chap. 13). Less commonly, neuroinhibition is a result of diminution of EAA. Patients presenting the day after bingeing on cocaine are often sleepy but arousable and oriented in what is termed cocaine “washout,” theoretically related to depletion of EAA and dopamine. Xenobiotics that cause diffuse cortical dysfunction through impairment in the delivery or utilization of oxygen or glucose also present with depressed or altered consciousness.

Clinical evaluation of patients with altered consciousness includes obtaining complete history, including medications, comorbid conditions, occupation, and suicidal intent when relevant or available. Patients should have a complete physical examination, with particular attention paid to vital sign abnormalities or findings that indicate a toxic syndrome. Assessment and correction of hypoxia or hypoglycemia should be performed. An electrocardiogram is useful in some circumstances (Chap. 15).

### Xenobiotic-Induced Seizures

Seizures are the most extreme form of neuroexcitation. As with alterations of consciousness, this can be due to enhanced EAA neurotransmission (domoic acid, sympathomimetics) or inhibition of GABAergic tone (isoniazid). Unlike in traumatic or idiopathic seizure disorders with an identifiable seizure focus, the initiation and propagation of xenobiotic-induced seizures is diffuse. It is for this reason that most non-sedative-hypnotic antiepileptics such as phenytoin are ineffective in terminating xenobiotic-induced seizures.

Seizures can be idiosyncratic as described with tramadol and bupropion, or they can be concentration-dependent events as described with theophylline and isoniazid toxicity. Alternatively, seizures can be a result of withdrawal from GABAergic substances.

Status epilepticus is variably defined but involves 2 or more seizures without a lucid interval, or continuous seizure activity for greater than 5 minutes.<sup>60</sup> True xenobiotic induced status epilepticus is rare. Cicutoxin, the toxin in water hemlock, *Cicuta maculata*, is a potent inhibitor of GABA<sub>A</sub> neurotransmission and can cause status epilepticus.

Theophylline toxicity precipitates seizures and status epilepticus through a different mechanism. Normally, endogenous termination of seizures is mediated through presynaptic release of adenosine during the release of the primary neurotransmitter at the terminal axon. Adenosine functions as a feedback inhibitor of the presynaptic neuron, disrupting propagation of excitatory neurotransmission. Theophylline is an adenosine antagonist. Adenosine administration is not a useful therapy for theophylline-induced seizures as adenosine is unable to cross the BBB. Generally high-dose sedative-hypnotics, affecting GABA<sub>A</sub> receptors, are required for seizure control.

TABLE 22-1 Xenobiotics That Commonly Induce Seizures

Concentration Related	Idiosyncratic	Withdrawal Related	Tonic-Clonic Seizurelike
Antihistamines	Bupropion <sup>a</sup>	Baclofen	Strychnine
Baclofen	Carbamazepine	Barbiturates	Tetanospasmin
Camphor <sup>a</sup>	Ergotamines	Benzodiazepines	
Carbon monoxide	GHB	Ethanol	
Chloroquine <sup>a</sup>	Mefenamic acid	GHB	
Cicutoxin <sup>a</sup>	Tramadol		
Cyanide			
Diphenhydramine <sup>a</sup>			
Domoic acid			
Isoniazid <sup>a</sup>			
Hypoglycemics			
Gyromitrin <sup>a</sup>			
Lidocaine			
Meperidine metabolites			
Organic chlorines			
Organic phosphorus compounds			
Propoxyphene metabolites			
Strychnine			
Sympathomimetics			
Tetramethylene disulfotetramine (TETS) <sup>a</sup>			
Thallium			
Theophylline <sup>a</sup>			
Zinc phosphide			

<sup>a</sup>While therapeutic concentrations are associated with seizures idiosyncratically, high concentrations are associated with status epilepticus.

CNS = central nervous system; GHB =  $\gamma$ -hydroxybutyric acid.

Some clinical conditions appear to be centrally mediated tonic-clonic movements but are due to glycine inhibition in the spinal cord. Glycine is the major inhibitory neurotransmitter of motor neurons of the spinal cord. Under normal conditions, glycine contributes to termination of reflex arcs. Glycine inhibition results in myoclonus, hyperreflexia, and opisthotonos, often without alteration in consciousness. Presynaptic glycine release inhibition is caused by tetanospasmin, the major neurotoxin from *Clostridium tetani*. Postsynaptic glycine inhibition is caused by strychnine, the toxin in *Strychnos nux-vomica*. Patients with exposures to tetanospasmin or strychnine are often treated in quiet environments where the stimuli to initiate hyperreflexia are minimized (Chap. 114 and Table 22-1).

### Xenobiotic-Induced Mood Disorders

Certain xenobiotics are inconsistently associated with alterations in mood.<sup>5,20</sup> What predisposes individuals to xenobiotic-induced mood alterations is unclear. In some circumstances, patients with previously undiagnosed bipolar disorder are given a xenobiotic that unmasks their disease. Interestingly, antibiotic-induced mania is found in some patients without a previous psychiatric history. The symptoms of mania are usually evident within the first week of therapy and, unlike the mania of purely psychiatric origin, readily abate within 48 to 72 hours of the last antibiotic dose. Some patients with clarithromycin-induced mania have documented recurrence on rechallenge.<sup>5</sup> In general, xenobiotic-induced manias are idiopathic and very rare. More common are either psychosis from chronic CNS stimulant use or depression from ethanol or the xenobiotics listed in Table 22-2.

### Disorders of Movement and Tone

#### Central Nervous System–Mediated Disorders

Most movement disorders, including akathisia, bradykinesia, tics, chorea, and dystonias, are mediated by the complex dopaminergic pathways of the basal ganglia. Different dopamine receptor subtypes are modulated by serotonergic, GABAergic, glutaminergic, and cholinergic neurons (Chap. 13).

TABLE 22-2 Xenobiotics Commonly Inducing Mood<sup>a</sup> and Neuropsychiatric Disorders

Mania	Depression <sup>a</sup>	Psychosis
Acyclovir	$\beta$ -Adrenergic antagonists	Amantadine
Amantadine	Amiodarone $\alpha$	Glucocorticosteroids
Caffeine	Interferon	Sympathomimetics
Chloroquine	Isoretinoic acid	
Clarithromycin	Ribavirin	
CNS stimulants		
Corticosteroids		
Dextromethorphan		
Dehydroepiandrosterone		
L-Dopa		
Efavirenz		
Fenfluramine		
Fluoroquinolones		
Gabapentin		
Ginseng		
Ifosfamide		
Interferon- $\alpha$		
Isoniazid		
Mefloquine		
Phentermine		
Phenylpropanolamine		
Pseudoephedrine		
Quetiapine		
St. John's wort		
Sympathomimetics		
Testosterone		
Tramadol		

<sup>a</sup>In some patients, antidepressants increase the risk of suicide by converting a vegetative depression to active depression.

CNS = central nervous system.

Chorea rarely occurs in carbamazepine overdose, therapeutic oral contraceptive use,<sup>32</sup> and after cocaine use when the stimulant effects have subsided.<sup>75</sup>

Dopamine receptor antagonists precipitate acute dystonic reactions. The D<sub>2</sub> receptor antagonists, in conjunction with alterations in muscarinic cholinergic tone, are usually implicated. Animal models suggest possible mediation through  $\sigma$  receptors, the craniofacial distribution of which corresponds to the common clinical manifestations of acute dystonias.<sup>50</sup>

Diffusely increased motor tone occurs with glycine antagonists such as tetanospasmin and strychnine, and in adrenergic excess clinical conditions such as acute toxicity with sympathomimetics or withdrawal from sedative-hypnotics. The rare complication of bone fractures associated with severe muscle spasm and myoclonus is reported with chronic bismuth toxicity and inadvertent intrathecal administration of hyperosmolar contrast dye (Chap. 87 and Special Considerations: SC7).

Other centrally mediated disorders of tone include serotonin toxicity and neuroleptic malignant syndrome (NMS). Both of these potentially life-threatening disorders consist of altered consciousness, hyperthermia, rigidity, and autonomic instability. Neuroleptic malignant syndrome occurs in patients taking dopamine receptor antagonists such as antipsychotics or in those with idiopathic Parkinson disease who abruptly stop their dopamine agonist therapy. Dopamine receptor agonists such as bromocriptine or restoration of antiparkinson medications are used therapeutically in these circumstances (Chap. 67). The diagnosis and management of serotonin toxicity is reviewed in Chap. 69.

#### Parkinsonism

Xenobiotic-induced parkinsonism is a syndrome of unstable posture, rigidity, gait disturbance, loss of facial expression, hypokinesia, and variable presence of tremor.<sup>8</sup> The common neuroanatomic target involves the dopaminergic neurons of the basal ganglia, specifically the substantia nigra.<sup>27,89</sup> In some circumstances, the toxicity is transient and the mechanism inadequately understood.

**TABLE 22–3 Xenobiotics Associated with Parkinsonism**

Reversible <sup>a</sup>	Irreversible
Antipsychotics	Carbon disulfide
Calcium channel blockers	Carbon monoxide
Chemotherapeutics	Copper
Cyclosporine	Cyanide
Dopaminergic agonists (withdrawal)	Heroin
<i>Kava kava</i>	Hydrogen sulfide
Progesterone	Manganese
Valproate	MPTP
Trazodone	

<sup>a</sup>Although patients typically improve with removal of xenobiotic, sometimes persistent administration of dopaminergic therapy is required.

MPTP = 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

Some xenobiotics such as carbon monoxide and heroin produce tissue hypoxia and ischemia in the basal ganglia that occasionally results in xenobiotic-induced Parkinson syndrome.

Other xenobiotics such as MPTP, carbon disulfide, manganese, and the endogenous neurotoxin copper in patients with Wilson disease produce predictable mitochondrial impairment of the basal ganglia neurons. Viscose rayon workers exposed to carbon disulfide present with a Parkinson syndrome refractory to L-dopa administration<sup>44,45</sup> (see Enzyme and Transporter Exploitation earlier).

Manganese is a critical substrate for production and metabolism of several neurotransmitters including glutamate. Excessive manganese interferes with normal uptake of glutamate and is critical to the function of superoxide dismutase and glutamine synthetase.<sup>31,36</sup> In patients with liver failure, or who accumulate manganese from occupational exposure, reversal or treatment of liver disease, or removal from exposure can result in resolution of parkinsonism.<sup>37,81</sup>

A review of patients who intravenously injected illicit methcathinone described a Parkinson syndrome thought to be secondary to contamination with manganese from a precursor, potassium permanganate, which is used in methcathinone production. Unlike patients with idiopathic parkinsonism, these patients did not suffer from a resting tremor, and they had a specific gait abnormality in which they walked on the balls of their feet.<sup>86</sup> Like those with occupational manganese exposures and normal liver function, these patients did not respond to L-dopa (Table 22–3).

### Tremors

Tremors are observed with adrenergic excess, with specific xenobiotics such as lithium, or as a result of sedative-hypnotic withdrawal. These are well reviewed elsewhere.<sup>63</sup>

### The Neuromuscular Junction

Flaccid paralysis usually occurs as a result of impaired transmission at the NMJ<sup>15,16,82</sup> or from xenobiotics causing demyelination.<sup>56</sup> Mechanisms of NMJ transmission impairment include impeded propagation of the action potential on the terminal neuron, impaired or excessive release of acetylcholine, depression of motor end-plate potential with failure of depolarization or recovery, or impedance of myofibril excitation<sup>56,82</sup> (Chap. 66).

Xenobiotics can enhance transmission at the NMJ. Latrotoxin, the toxic compound in the black widow spider (*Latrodectus* spp) venom causes enhanced release of acetylcholine at the NMJ with severe, painful muscle contractions. Some types of snake and scorpion venoms act similarly, as do carbamates and organic phosphorus compounds (Chap. 119).

## NEUROPATHIES AND MYOPATHIES

### Cranial Nerves

Xenobiotics are a relatively rare cause of cranial nerve impairment. Some neuropathies are a result of direct delivery of the xenobiotic to the affected cranial nerve. For example, some patients can have optic nerve impairment from intraorbital installation of silicone oil<sup>7</sup> or inadvertent deep space

injection of a local anesthetic during dental anesthesia with a resultant abducens palsy.<sup>62</sup> In some cases, a xenobiotic, methanol, is converted into a toxic substance such as formic acid in the retina.

The NMJ of the cranial nerves (CNs) is sensitive to disruptions in neurotransmission. When xenobiotics affect the oculomotor nerves (CNs III, IV, VI), patients describe diplopia or have gaze palsies on examination. Botulinum toxin, diethylene glycol toxicity, elapid snake venom, and the cranial neuropathy associated with the organic phosphorus compounds–induced intermediate syndrome are some examples.

Absence of glucose or thiamine results in ophthalmoplegia. In most cases, however, the mechanisms underlying the cranial neuropathy are poorly understood, such as is the case with antineoplastics. Some patients who survive ethylene glycol poisoning experience transient ophthalmoplegia days after the initial exposure.<sup>57,84</sup> Transient ataxia and ophthalmoplegia are described in a Nigerian population consuming the larvae of the moth *Anaphe venata* as a source of dietary protein. The larvae contain thiaminase, rendering patients acutely thiamine deficient<sup>6</sup> (Table 22–4 and Chap. 24).

### Peripheral Nerves

Complaints of pain, paresthesias, numbness, or weakness of extremities are clinically termed *neuropathies*. The mechanisms of evolution are variable. Common to most xenobiotic-induced neuropathies is early symmetrical involvement of the lower extremities. This is due in part to the patient's rapid recognition of impairment during an attempt to ambulate. Additionally, the axons serving the lower extremities are longer. Maintenance and transportation of substrates is more energy dependent and sensitive to xenobiotic-induced disruptions.

In some cases, the anatomic structure of the nerve is maintained, but the xenobiotic affects neurotransmission. This can be due to direct impairment of specific enzymes at the NMJ, such as cholinesterase inhibitors.<sup>28</sup> Tri-*ortho*-cresyl phosphate (TOCP) is an inhibitor of neuropathic target esterase. Contamination of food and the alcoholic beverage “Ginger Jake” with TOCP resulted in irreversible lower extremity paralysis in several epidemic exposures during Prohibition.<sup>71,91</sup> Indirectly, the extracellular environment is altered as in the case of hypermagnesemia or hypokalemia, which is induced by multiple xenobiotics (Chap. 12). Ciguatoxin, a sodium channel opener, affects neurotransmission, causing paresthesias and the unusual symptom of temperature reversal in which the perception of temperature is opposite to the stimulus.

Xenobiotics such as amiodarone and tacrolimus induce peripheral demyelination. Patients present with weakness and flaccidity. Nitrous oxide impairs the production of S-adenosyl methionine essential to the production of myelin and is additive to the nitrous oxide disruptions of vitamin B<sub>12</sub>,<sup>92</sup> which further impair axonal function. Patients with chronic nitrous oxide misuse often have proprioceptive loss as a result.<sup>92</sup>

Other xenobiotics affect the structure or intracellular function of the peripheral nerves. Those that induce death of the cell body are termed *neuronopathies* and, at onset, are clinically indistinguishable from those that affect the axon, or *axonopathies*.

Peripheral nerve cell death is usually linked to injury at the spinal cord as was described above by the doxorubicin injection of the peripheral nerves.<sup>51</sup> Pyridoxine overdose is another cause of neuronopathy. However, neuronopathies are an unusual mechanism of peripheral nerve toxicity.

Unlike neuronopathies, axonopathies are potentially reversible and are the most common mechanism of xenobiotic-induced peripheral neuropathy. Xenobiotic-induced axonal injuries to the peripheral nerves are usually diffuse and bilateral, with preservation of the proximal cell body. These often target the cytoskeleton and impair the capacity for the microtubule system to deliver functional substrates.<sup>22,41</sup> Patients with occupational exposure to 2,5-hexanedione, a diketone metabolite of *n*-hexane present in certain glues, suffer from a sensorimotor axonopathy due to cross-linking of neurofilaments and impaired substrate transport.<sup>68</sup> Progressive neuropathy often occurs long after the initial exposure. Vincristine similarly affects axonal transport. Acrylamide impairs fast anterograde and retrograde transport in animal models, suggesting effects on both kinesin and dynein.

TABLE 22–4 Cranial Neuropathies			
Cranial Nerve	Signs	Symptoms/Signs	Xenobiotics <sup>a</sup>
I <sup>b</sup>		Failure to detect odor	Hydrogen sulfide: olfactory fatigue
II	Pupil unresponsive to light	Blindness	Amiodarone, ammonia, cisplatin, cloiquinol, deferoxamine, DEG, dimethyl mercury, holocyclotoxin, interferon $\alpha$ , methanol, methotrexate, methyl iodide, oxaliplatin, quinine, solvents
III	Paralysis: ptosis, mydriasis: unresponsive or sluggish to light, motor impairment extraocular muscles, adduction Stimulation: miosis	Photophobia	Amiodarone, antimuscarinics, botulinum toxin, DEG, holocyclotoxin, hypoglycemics, interferon $\alpha$ , methyl iodide, paralytics, thallium, venoms (Elapidae, scorpion)
		Dim vision	Cholinergic muscarinics
IV	Paralysis of the superior oblique muscle of eye with weakness of downward gaze, slight upward gaze of affected eye	Vertical and torsional diplopia that worsens on adduction and improves with tilt of head	Barbiturates, botulinum toxin, DEG, holocyclotoxin, thallium, venoms
V	Diminished facial sensation, weakness in chewing and swallowing Excessive contraction	Paresthesias face, weakness in chewing	Botulinum toxin, ethylene glycol, holocyclotoxin, oxaliplatin, vincristine
		Trismus	Tetanospasmin and strychnine <sup>c</sup>
VI	Failure to abduct eye on lateral gaze	Diplopia	Botulinum toxin, DEG, holocyclotoxin, intrathecal water-soluble contrast agents, lithium, local anesthetics, MDMA, nitroglycerin, ornithine aminotransferase deficiency, oxaliplatin, thallium, thiamine deficiency, venom (elapid), vitamin A
VII <sup>b</sup>	Weakness of facial muscles, impaired expression	Facial droop, impaired taste	Botulinum toxin, DEG, ethylene glycol, holocyclotoxin
VIII <sup>b</sup>	Impaired hearing on auditory testing, nystagmus	Alterations in hearing, potential alterations in balance	Aminoglycosides, cisplatin, DEG, ethylene glycol, loop diuretics, oxalosis, quinine, salicylates, solvents
IX <sup>d</sup>	Decreased gag reflex	Impaired taste	Anesthetics (oral), botulinum toxin, cholinergic compounds, ethylene glycol, stibantate <sup>d</sup>
X <sup>d,e</sup>	Paralysis: Decreased gag reflex Stimulation: autonomic instability GI stimulation	Choking, change in voice	Botulinum toxin, ethylene glycol, stibantate <sup>d</sup>
		Bradycardia, bronchorrhea bronchospasm, diarrhea, vomiting	Cholinergics
XI <sup>d</sup>	Weakness shoulder shrug	Weakness neck/shoulders	Botulinum toxin, cholinergic compounds, <sup>d</sup> paralytics
XII <sup>d</sup>	Impaired speech, tongue deviation	Dysarthria	Botulinum toxin, cholinergic compounds <sup>d</sup>

<sup>a</sup>Lists are not intended to be exclusive or exhaustive. <sup>b</sup>See also Chap. 25. <sup>c</sup>Tetanus causes indirect effects on masseter muscles; see section on xenobiotic-induced seizures or Chap. 114. <sup>d</sup>Weakness of cranial nerves IX–XII is often referred to as bulbar palsy and can be seen in the intermediate syndrome after acute organic phosphorus compound poisoning. This syndrome is often accompanied by paralysis of extraocular muscles (Chap. 110). <sup>e</sup>See Chap. 3.

DEG = diethylene glycol; MDMA = methylenedioxyamphetamine.

Nucleoside reverse transcriptase inhibitors cause peripheral neuropathy by decreasing the production of mitochondrial DNA.

## Myopathies

Some patients experience local muscle damage as a result of direct injury from extravasation of tissue toxic substances or enzymatic degradation associated with crotalid snake envenomations.

Most xenobiotic-induced muscle injuries or myopathies are more diffuse.<sup>40,76,84,90</sup> 3-Hydroxy-3-methylglutaryl-coenzyme A (HMG Co-A) reductase inhibitors infrequently cause myalgias, cramping, myositis, or rhabdomyolysis. The incidence appears to be higher in patients taking other medications that share the same liver metabolic enzymes. The mechanism underlying the myopathy is likely related to impaired cholesterol synthesis in myocytes or diminished production of regulatory proteins such as ubiquitin and GTP-binding proteins required for mitochondrial function.

Another myopathy that presents predominantly with weakness is the acute quadriplegic myopathy of intensive care patients. This syndrome was originally described in ventilated patients with asthma who received glucocorticoids and nondepolarizing neuromuscular blockers, but is also reported in other critically ill patients<sup>9</sup> (Chap. 66). The mechanisms underlying quadriplegic myopathy, eosinophilia myalgia syndrome, and toxic oil syndrome are poorly described. Xenobiotics associated with muscle injury are found in Table 22–5.

TABLE 22–5 Xenobiotics Associated with Muscle Toxicity\*

$\epsilon$ -Aminocaproic acid	Niacin
Amiodarone	Organic phosphorus compounds
Chloroquine	D-Penicillamine
Cimetidine	Phencyclidine
Clofibrate	Procainamide
<i>Clostridium</i> toxins	Propylthiouracil
Cocaine	Rifampin
Colchicine	Snake venoms
Cyclosporine	Succinylcholine
Doxylamine	Sulfonamides
Ethanol	Syrup of ipecac
Ethchlorvynol	Toxic oil syndrome
Glucocorticosteroids	<i>Tricholoma equestre</i> (mushroom)
Heroin	L-Tryptophan
HMG-CoA reductase inhibitors	Vincristine
Hydroxychloroquine	Zidovudine
<i>Loxosceles</i> spp venom	

\*Toxicity with adrenergics cause indirect rhabdomyolysis due to neurobehavioral muscular exertion and tonic contracture. Similarly xenobiotics which cause status epilepticus, as well as xenobiotics that precipitate NMS or serotonin toxicity also result in indirect rhabdomyolysis.

## SUMMARY

- The central nervous system has unique anatomic and transporter mechanisms to limit xenobiotic penetration.
- Disruption of these protections can result in neurotoxicity.
- The chemical properties of the xenobiotic and the characteristic of the patient exposed affect the clinical expression of neurotoxicity.
- The peripheral nervous system is similarly vulnerable to toxicity and the patterns of injury are reflected in the clinical presentation.

# ONCOLOGIC PRINCIPLES

Richard Y. Wang

In 2012, there were 1.5 million persons with newly diagnosed invasive cancer in the United States.<sup>41</sup> Among patients receiving chemotherapy for their disease, some will seek further care at an emergency department and require inpatient hospitalization for effects related to their treatment.<sup>10,35,38</sup> In a prospective analysis of cancer registry data, 8.7% (179/2068) of patients receiving chemotherapy were admitted to the hospital for chemotherapy-related effects.<sup>14</sup> Fever, neutropenia, and severe gastroenteritis are common reasons for inpatient care among patients receiving chemotherapy.<sup>14,21,35</sup>

The chemotherapeutics employed in curative and palliative regimens in many cases preclude cell division via a variety of mechanisms. Chemotherapeutics have also found expanded use in a variety of rheumatologic, dermatologic, and autoimmune disorders. Clinicians caring for patients affected by chemotherapeutics should understand the expected cellular responses from an initial and long-term exposure perspective. Chemotherapeutics cause damage primarily to deoxyribonucleic acid (DNA). This chapter will provide the reader with a focused review of cellular growth and proliferation, DNA damage from chemotherapeutics, the response of the cell to DNA damage, and the response of the tissues commonly affected by chemotherapeutics. This information will enhance the clinician's management of patients affected by chemotherapeutics. New cancer therapies, such as targeted therapeutics and immunotherapies, are available for clinical use, and these therapies are discussed elsewhere (Chap. 50).<sup>23</sup>

## CELL GROWTH AND PROLIFERATION

### Cell Cycle

Cell activities are growth, metabolism, proliferation, apoptosis, and senescence. The cell cycle is the classic paradigm that depicts cell proliferation in sequential steps that are represented by phases, and it is coordinated by the cell-cycle control system (Fig. 23-1).<sup>47</sup> The phases are  $G_0$  (resting phase),  $G_1$ , S (synthesis),  $G_2$ , and M (mitosis). Stem cells tend to reside at  $G_0$ . When cells are stimulated by a mitotic stimulant, such as a growth factor, they leave the resting phase and enter the cell cycle.  $G_1$ -, S-, and  $G_2$ -phases are known as the *interphase* of the cell cycle, and they encompass cell growth and DNA replication.  $G_1$  and  $G_2$  are growth or *gap* phases, and they allow for growth and regulatory processes that aid in the transition from the S-phase to the M-phase. The  $G_1$ -phase is the most variable in duration among cell types, and it controls or determines the length of the cell cycle. A typical cell cycle takes about 24 hours, and mitosis takes about 20 to 60 minutes.<sup>15</sup> The replication of DNA occurs in the S-phase, and mitosis and cytokinesis occur in the M-phase. The  $G_2$ -phase likely serves to prevent the unintended consequence of a cell undergoing separation with an incomplete copy of the DNA. The fidelity of cellular duplication is ensured by checkpoints located throughout the cell cycle.

### DNA Replication

The process for DNA replication begins in the  $G_1$ -phase, occurs in the S-phase, and ends in the  $G_2$ -phase. There are several steps in the process, including identification of the origins for replication, incorporation of protein complexes at these origins, DNA unwinding, DNA elongation, and DNA termination. The cell enters mitosis at the completion of DNA replication.

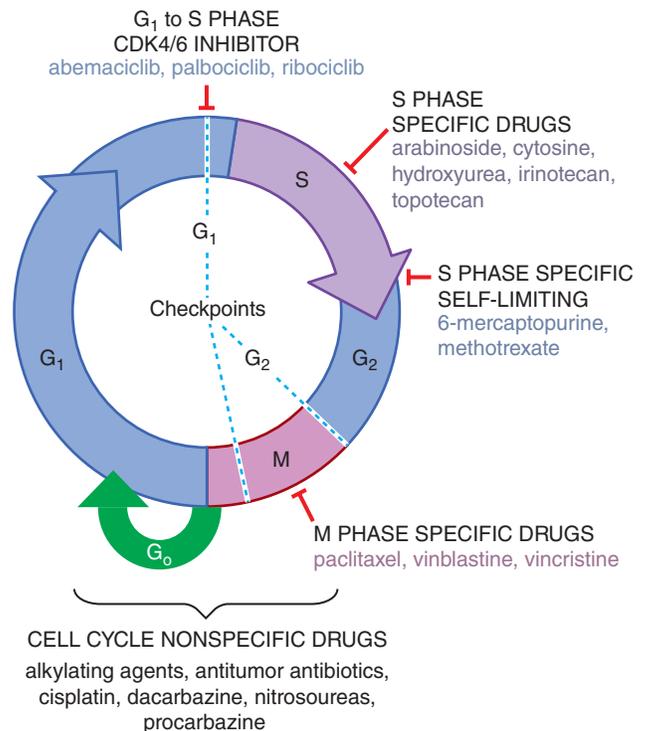

In the  $G_1$ -phase, the replication origins on the DNA are identified and the pre-replication complex (pre-RC) is formed. This complex consists of the origin recognition complex, MCM (mini-microsomal maintenance) (inactive helicase), CDT1, and CDC6, which facilitates the loading of MCM into the pre-RC. In the transition from the  $G_1$ -phase to the S-phase, the pre-RC is

formed and it activates helicase (via the CDC45-MCM-GINS {CMG} helicase complex), which begins DNA replication in the S-phase.

In the S-phase, DNA unwinds using the CMG helicase complex, elongates, and undergoes synthesis. The replisome accomplishes these steps during DNA replication, which includes assembly of supporting proteins, unwinding, polymerization, synthesis of RNA primers, and coordination of the polymerization between the leading and lagging strands of DNA.

The replisome is comprised of DNA polymerase, helicase, single-strand DNA binding protein, trimetric clamp processivity factor (enables DNA polymerase to synthesize a continuous strand of DNA on a template DNA without frequent dissociation), pentameric clamp loader complex, and primase. In addition, the replisome contains a translesion DNA polymerase, which allows the cell to bypass extensively damaged DNA and continue with DNA replication.

In general, the replication process proceeds in the following manner: DNA unwinds, forms replication forks, strands are stabilized by single-strand-binding proteins to prevent coiling, tension on the DNA helix in front of the replication fork is relaxed by topoisomerases I and II, and the ATR-ATRIP complex (ataxia telangiectasia mutated and Rad3-related-ATR-interacting protein) limits excessive firing or activation of origin complexes during the S-phase. Deoxyribonucleic acid elongation uses various DNA polymerases (ie, alpha, delta, and epsilon) in the synthesis of DNA. RNA primase forms a RNA primer

**FIGURE 23-1.** Cell cycle specificity of chemotherapeutics: selected class of cell cycle phase-specific chemotherapeutics and their sites of action in the cell cycle. Arrows represent the progression of the cell cycle by phases,  $G_0$  (resting),  $G_1$  (gap1),  $G_2$  (gap2), M (mitosis), and S (DNA synthesis). The colors of each chemotherapeutic is matched with its cell cycle of activity. (Reproduced with permission from Brunton LL, Hilal-Dandan R, Knollmann BC. Goodman & Gilman's: The Pharmacological Basis of Therapeutics, 13th ed. New York: NY: McGraw Hill Education; 2018.)

that is used by DNA polymerase to synthesize a complementary chain to the template DNA chain in a 5' to 3' direction. In the leading strand, DNA is synthesized in a continuous manner as it follows behind the CMG helicase complex. In contrast to the leading strand, the lagging strand DNA is synthesized in fragments that are later joined to form a continuous strand. Deoxyribonucleic acid polymerase removes RNA primers and replaces the segments with deoxyribonucleotides. Deoxyribonucleic acid ligase joins remaining gaps between fragments. When DNA replication is complete, the cell will enter G<sub>2</sub>/M-phase.

## CELL INJURY AND DNA DAMAGE

Cellular injuries caused by chemotherapeutics are typically from a stress that impairs a DNA function, such as replication. Cells undergoing proliferation that are injured by stress to DNA will halt the cell cycle by activating a checkpoint, and it will attempt to repair the injury. If the repair is unsuccessful or there is a significant injury, the cell will undergo apoptosis or senescence. Stress may also be indirect, such as impairment of the spindle fibers during mitosis. When stress causes a structural change to DNA, such as a break in the strand of DNA or the presence of a bulky adduct, the result is considered a damaged DNA.<sup>43</sup> Structural damage to DNA can be repaired; however, errors in the repair can lead to mutations. Mutation is a heritable change in the encoded nucleotide sequence of the DNA. Cells with mutations and a slow replication tend to accumulate over time, and they will develop into tumors that occur at an increased age of the host organism. Cells with mutations and a fast replication tend to develop into tumors at an early age.

Some chemotherapeutics cause DNA damage by forming bulky adducts, such as by alkylation or intrastrand crosslinks. For example, cisplatin causes DNA crosslinks (approximately 90% intrastrand and <5% interstrand); and nitrogen mustard, nitrosoureas, and triazines cause alkyl-DNA adducts (Fig. 23–2).<sup>6</sup> At very high doses, chemotherapeutics can cause additional

toxicities (Chaps. 50 and 51). Some chemotherapeutics act at specific phases in the cell cycle and they are known as cell cycle phase-specific chemotherapeutics. For example, vincristine acts specifically during the M-phase, and cytarabine acts during the S-phase based on the mechanism of action (Fig. 23–1). These chemotherapeutics will not affect cells in the G<sub>0</sub>-phase. However, cell cycle phase-nonspecific chemotherapeutics, like alkylating agents, affect cells at all phases of the cell cycle.

*Cell senescence* is considered a protective outcome because it arrests DNA-damaged cells, and it is a process of aging. The factors determining cell senescence are the cell type, type of damage, and severity of damage. Although the specific initiators of senescence are unknown, these items likely involve dysfunctional telomeres, damaged DNA, dysfunctional chromatin, oncogenes, and other types of stresses to the cell. The pathways involved with senescence are p53 (primary) and p16-pRB (retinoblastoma protein) (secondary).

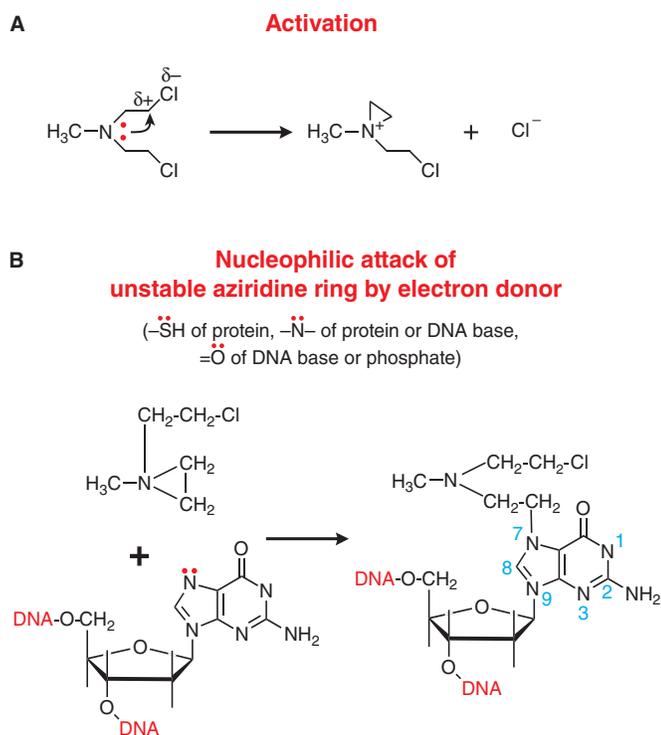

## CHECKPOINTS THAT REGULATE DNA REPLICATION

Checkpoints work with the phases of the cell cycle to regulate cellular duplication so the process is accomplished in a correct manner. For example, cells with damaged DNA will not proceed in the cell cycle because this type of damage will lead to a cell with unstable genetic material during mitosis. Notable checkpoints are located at G<sub>1</sub>/S, the S-phase, the G<sub>2</sub>/M boundary, and the M-phase.<sup>51</sup> The checkpoint at G<sub>1</sub>/S is the major one in humans. In the G-phase, DNA replication checkpoints arrest cell cycle progression and inhibit firing of late replication origins in response to stressors. The checkpoint in the S-phase slows down DNA replication and cell cycle progression when the DNA replication fork stalls. A stalled fork can result from an obstacle such as an adduct, a lack of substrates (eg, nucleotide), or an inactive enzyme.<sup>28</sup> The checkpoint at G<sub>2</sub>/M is considered important for determining cell survival or death because many cells are observed to be halted at the G<sub>2</sub>-phase. In the M-phase, a cell with damaged DNA can undergo apoptosis (initiated by spindle assembly checkpoint {SAC}), undergo endoreplication (ie, DNA replication but no cell division), or return to mitosis.<sup>9</sup> Cells with endoreplication will survive, but they cannot proliferate.

Cyclin-dependent kinases (Cdks) are a family of serine/threonine protein kinases that are responsible for the phosphorylation of specific proteins and the binding of inhibitory proteins in the cell cycle.<sup>7,40</sup> Cyclin-dependent kinases are activated by rising concentrations of specific cyclins and Cdk-activating kinases, and inhibited by other proteins and protein kinases. For example, in the G<sub>1</sub>-phase, mitotic stimulants, such as growth factors, activate the complex cyclin D-Cdk4 by increasing cyclin D by gene expression, which binds to Cdk4. This complex activates the transcription factor E2F, which is important for entering the cell cycle. E2F promotes the expression of genes responsible for DNA synthesis and the production of cyclins E and A, which are needed for the G<sub>1</sub>/S transition and the S-phase, respectively.

Cyclin E complexes with Cdk2, which activates the inhibitory pRb that regulates E2F to ensure the expression of genes specific to G<sub>1</sub>/S at the proper time in the cell cycle. Cyclin A complexes with Cdk2, which is involved with chromosome condensation and the firing of replication origins. In the M-phase, the increased concentration of cyclin A-Cdk complex, decreased concentrations of the protein kinases Wee1 and Myt1, and the increased concentration of the phosphatase Cdc25 activates the cyclin B-Cdk1 complex, which is necessary for the early stages of mitosis leading to metaphase and the activation of the anaphase-promoting complex (APC). The APC is a protease complex that degrades the remaining cyclins in the S- and M-phases, and it signifies the transition from metaphase to anaphase and the beginning of the exit from mitosis. When the cell leaves the M-phase and enters the G<sub>1</sub>-phase, the Cdk concentration is kept low by decreased gene expression of cyclin and increased cyclin degradation. The cell cycle is activated by increasing the concentration of cyclin D at this phase.

A cascading event of inhibitory proteins and protein complexes halt the cell cycle by inhibiting Cdk activity in the G<sub>1</sub>-phase when there is DNA damage. For example, when ATM kinase detects a DNA double-strand break (DSB) it rapidly halts the cell cycle by inhibiting the activation of

**FIGURE 23–2.** Mechanism of action of alkylating agents of mechlorethamine, a prototypic nitrogen mustard. **(A)** Activation reaction. **(B)** Alkylation of N7 of guanine. With bifunctional drugs such as nitrogen mustards, the second 2-chloroethyl side chain can undergo a similar activation crosslink of 2 nucleic acid chains or a nucleic acid to a protein. (Modified with permission from Rollins DE, Blumenthal DK. *Workbook and Casebook for Goodman and Gilman's The Pharmacological Basis of Therapeutics*. New York: NY: McGraw-Hill Education; 2018.)

Cdk2–cyclin through Chk2 and Cdc2. A later process that causes a prolonged cell arrest follows the rapid response and it involves p53. Ataxia telangiectasia mutated kinase activates p53, which causes p21 to bind and inactivate Cdk2–cyclin. When there is a stalled replication fork in the S-phase, ATR can activate p53 and p21 to halt the cell cycle. The cell cycle will restart after the DNA damage is repaired. If the damage cannot be repaired, p53 can remove the cell through apoptosis. The INK4 proteins (p15, p16, 18, and p19) inhibit the binding of Cdk4 and Cdk6 to cyclin D and the activation of cyclin D–Cdk, which halts the cell cycle at the beginning of the G<sub>1</sub>-phase.

The SAC consists of several proteins that monitor the alignment of the spindle at the metaphase plate, the attachment of the chromosomes to the spindles through the kinetochore, and the binding of the kinetochore to spindle fibers at opposite poles.<sup>7</sup> If there is an irregularity in the centromere–kinetochore–microtubule interface or the tension among these structures, the SAC will inhibit the onset of anaphase by blocking the activation of APC, which is needed to activate the protease separase. Separase cleaves the protein complex that holds the sister chromatids together and this step initiates the separation of the sister chromatids during early anaphase. An irregularity in the spindle assembly results in chromosomal instability and abnormal chromosomes, such as aneuploidy. Microtubule inhibitors (eg, vinca alkaloids) prevent the proper assembly of the kinetochore microtubules and will activate the SAC.<sup>48</sup>

## DNA REPAIR MECHANISMS

The DNA damage response (DDR) detects and repairs lesions in the DNA, and coordinates these activities with the cell cycle. The mechanism of the repair for lesions in the DNA depends on the type of the lesion and the location of the lesion in the cell cycle. When there is a lesion to a nucleotide or a single-strand break, the nuclear excision repair (NER) or the base excision repair (BER) mechanism is used to correct the lesion. When there is a double-strand break, the nonhomologous end joining (NHEJ) or the homologous recombination (HR) is used to correct the damage. Interstrand crosslinks in the DNA (caused by nitrogen mustards and cisplatin) are significant to the survival of the cell because these lesions cannot be easily repaired.<sup>6,29</sup> However, intrastrand crosslinks in the DNA can continue on in the cell cycle after the lesion is addressed by the NER.<sup>18</sup>

The DNA repair systems for interstrand crosslinks involve the NER and translesional synthesis (TLS) when the cell is in the G<sub>0</sub>- or G<sub>1</sub>-phase, and HR when the cell is in the S-phase. The TLS allows DNA replication to proceed when there is extensive DNA damage by using a low-fidelity translesion polymerase. The cell's capacity to repair the DNA also determines the repair mechanism. For example, a cell with a damaged DNA and with a mutation at p53 will bypass apoptosis and end up in the M-phase.<sup>13,34</sup>

## DNA Double-Strand Break

When a DNA double-strand break is recognized, the MRN complex (Mre11-Rad50-Nbs1) and Ku proteins secure the ends and initiate a kinase-dependent pathway that halts the cell cycle. The process starts with the ATM (ataxia telangiectasia mutated) kinase, which activates cellular processes responsible for cell cycle arrest. The ATM kinase initially forms the ATR complex (ataxia telangiectasia mutated and Rad3-related), which activates Chk1 and Chk2. The latter items inhibit the activation of Cdks by inhibiting CDC25 phosphatase. The inhibition of Cdk1 and Cdk2 halts the cell cycle, prevents the entry of the cell into the S-phase, arrests progression in the S-phase, and arrests progression in the G<sub>2</sub>/M-phase. When the cyclin concentration is high, such as in the S- or G<sub>2</sub>-phase, the MRN complex reseals the damaged ends, which will allow an ATR-mediated response and repair by using HR. When the cyclin concentration is low, such as in the G<sub>1</sub>-phase, the MRN complex activates the ATM, which will repair the break by using NHEJ.

Nonhomologous end joining is a sequence-independent process, occurs in the G<sub>1</sub>-phase, and is prone to errors because a template is not used in the repair process. The NHEJ process involves binding the DNA strands, processing the adjoining ends, and repairing the break. The proteins involved with the repair are DNA ligase IV, XRCC4 (x-ray repair cross complementing group 4),

DNA-dependent protein kinase catalytic subunit (DNA-PKcs), Ku proteins (Ku70-80), and nucleases (eg, Artemis).<sup>33</sup> The broken strands are initially bound by Ku proteins and DNA-PKcs, the ends are processed by DNA polymerase or Artemis, and finally the ends are joined by XRCC4 /DNA ligase IV complex.<sup>33</sup> X-ray repair cross complementing group 4 is the regulatory unit for DNA ligase IV, and its phosphorylation appears to inhibit the repair of DNA DSBs during mitosis.<sup>44</sup> The NHEJ repair typically results in the loss of a few nucleotides in the sequence and a small mutation. Small mutations accumulate over time from repairs by NHEJ.

Homologous recombination is a process that occurs during the S- or G<sub>2</sub>-phase and it is usually activated by a stalled or broken replication fork. This process requires a template, usually a sister chromatid or a homologous chromosome, to repair the damaged strand, and it is less prone for errors than NHEJ.<sup>15</sup> The typical repair process for a DSB involves the following: resect the ends to form overhanging segments, identify homologous sequence in the complementary strand-by-strand exchange, fill in the gap sequence, and ligate the remaining ends.

When DNA damage is detected by the DDR during mitosis, such as a result of a checkpoint failure or a chromosomal breakage during cytokinesis, the location of the damaged sites are retained, but the ability of DDR to halt the cell cycle is inactivated. The reason for inactivating DNA repair during mitosis appears to be the cell's lack of ability to distinguish damaged DNA strands from undamaged DNA ends containing telomeres. If the repair process were to continue, cells can repair and fuse DNA ends containing telomeres (ie, anaphase bridges), which will form abnormal chromosomes, such as aneuploidy.<sup>32</sup> Thus, when damaged DNA is identified, the broken strands are bound by the MRN complex. The damaged DNA will be repaired when the cell leaves mitosis and enters interphase.<sup>12</sup> Deoxyribonucleic acid with minor damage is repaired in the G<sub>1</sub>-phase, and those with complicated damage are repaired later in the S-phase. However, DNA with significant damage affecting the centromere or defects in chromosomal alignment will activate the SAC and result in mitotic arrest and cell death or mutagenesis through mitotic slippage.<sup>15</sup> The SAC uses cyclin B1 to halt mitosis for a prolonged period that allows for cell death by a caspase-dependent pathway. When cyclin B1 concentrations fall before cell death occurs, there is "mitotic slippage" and a mutagenic cell exits from mitosis.

## DNA Single-Strand Breaks and Nucleotide Lesions

Single-strand breaks and lesions in nucleotides are quickly (in minutes) repaired by using NER, BER, or the mismatch repair system (during replication).<sup>3,22</sup> In addition, there are specialized repair proteins for specific lesions in a nucleotide (eg, methylation by alkylating agents). Some examples of this direct reversal of a lesion in a nucleotide are the methylated adducts of O6-methylguanine, 1-methyladenine, and 3-methylcytosine.

Base excision repair occurs throughout the cell cycle and it removes small non-helix distorting nucleotide lesions from the DNA. Typical lesions amenable to BER are those that result from oxidation, deamination, or alkylation by methylation. The general steps in the repair process are recognition, excision of the base, end processing to remove the sugar phosphate backbone, gap filling, and ligation. Deoxyribonucleic acid polymerases use the other strand as a template to fill in the gap, and the ligation is accomplished by DNA ligases.

Nuclear excision repair removes bulky lesions that distort the helix, such as adducts with a large chemical. The general steps in this process are recognition, incision and end processing, gap filling, and ligation. Nucleases and helicases are used to remove the lesion in NER. The nucleotide is removed by sequential action of 5' and 3' endonucleases followed by polymerase to fill in the remaining gap. The gap filling is accomplished by DNA polymerases and the ligation is accomplished by DNA ligases.

## INJURY TO CELL LINES FROM SELECTED TISSUES

Chemotherapeutics are toxic to cells, and the tissues commonly affected are those with a high turnover of cells. These cells are the hematopoietic cells, intestinal epithelium, epidermis and hair follicles, and sperm.<sup>25</sup> The following

discussion will focus on the cell lines of the hematologic system and intestinal epithelium. The significance of the biology of stem cells for this discussion is it is a site of toxicity for chemotherapeutics, the toxicity to the cell line is typically not immediately apparent, and the effect to the cell line has long-term consequences.<sup>24</sup>

The duration of progression from a stem cell to a mature cell is clinically important because this timeline will contribute to the time of appearance of toxicity from the chemotherapeutic from the time of exposure. For example, tissue toxicity will not be immediately apparent when a chemotherapeutic is administered because mature cells maintain the functioning during their survival. However, toxicity will manifest as the mature cells die and they are not replaced over time because of toxicity to the stem cells. The time between the appearance of toxicity to the cell line and the onset of toxicity to the stem cell is known as the latency period for chemotherapeutics that are toxic to the mitotic cell. The duration of the latency period also depends on the physiological rate of loss (ie, life span) of the mature cells. The duration of recovery from toxicity depends on the dose and rate of administration of a chemotherapeutic because these factors will determine the extent of injury to stem and progenitor cells.

In addition, the chemotherapeutic's site of action in the cell cycle can predict the time of onset and duration of toxicity. For the hematopoietic system, cell cycle phase-specific chemotherapeutics (eg, antimetabolites, vinca alkaloids) cause early onset and recovery of myelosuppression.<sup>16</sup> Cell cycle phase-nonspecific chemotherapeutics result in intermediate to late onset and recovery of myelosuppression. However, nitrogen mustards tend to cause late onset and recovery of myelosuppression because they affect the primitive stem cells.

### Stem Cells

The common features of stem cells are self-renewal and differentiation into specialized cell types, compartmentalization in the body, and existence in a micro-environment known as a niche. The niche consists of many elements, including stem cells, extracellular matrix providing structural support to the cells, and soluble factors, such as growth factors. The niche provides a supportive environment for the survival and self-renewal of the stem cell. In addition, this environment permits the transmission of feedback information that direct behaviors of the stem cell, including entry into the cell cycle, cell fate (resting, self-renewal, differentiation, and apoptosis), and cell motility.<sup>46</sup>

The fate of the stem cells is regulated by extrinsic and intrinsic factors. These factors determine the number of stem cells in the niche by adjusting

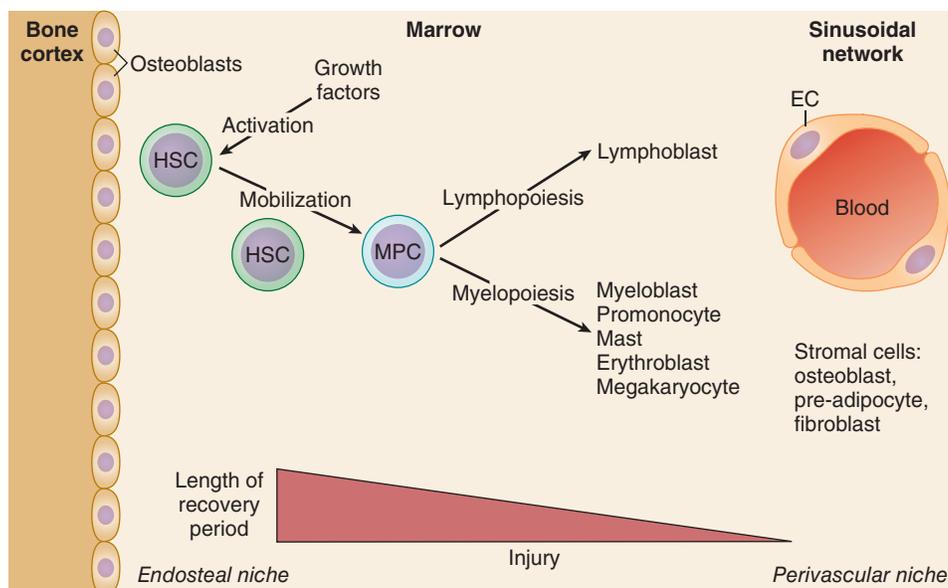

the stem cell's type of cell division (symmetrical versus asymmetrical), cell cycle, fate, and motility.<sup>8</sup> The survival of a stem cell is mostly determined by extrinsic factors. The general order of differentiation by cell type in a cell lineage is stem cell, progenitor cell, and mature or specialized cell. A stem cell tends to stay in the Go-phase and a progenitor cell is continuously active in the cell cycle.

### Hematopoietic Cells

In humans, hematopoiesis predominately occurs in the bone marrow. The majority of cells in the bone marrow transitions from the long bones in the child to the ribs, sternum, and vertebrae in the adult. The hematopoietic system consists of the red blood cells, white blood cells, and platelets. The mature forms of these cells reside in the peripheral compartment and are primarily formed in the central compartment or bone marrow. Stem cells are found in decreasing order at the following locations in the body: the bone marrow, spleen, and the peripheral compartment. A small percentage (10%) of hematopoietic stem cells exists as progenitor or multipotent stem cells in the vasculature.

The progression of the cellular lineage for hematopoietic cells is long-term hematopoietic stem cells (HSC), short-term HSCs (for 8–10 weeks), oligopotent (multi-) progenitor cells (lymphoid and myeloid), committed (limited) progenitor cells for colony forming unit (CFU)–erythroid, CFU–megakaryocyte, and CFU–granulocyte–monocyte, and mature cells (Fig. 23–3). Unlike stem cells, which have high renewal potential and low proliferative rate, committed progenitor cells have a high proliferative rate, which makes them vulnerable to toxicity from chemotherapeutics. The sparing of stem cells from toxicity permits the hematopoietic system to recover from chemotherapy. When stem cells are destroyed, the recovery period for the hematopoietic system is prolonged (ie, several weeks). In addition, age, the cumulative effect of recent chemotherapy, and concurrent infections delay the recovery of the hematopoietic system. Aging alters or decreases the ability of HSCs to respond to stress. The reasons for the former item are an accumulation of damaged DNA, a trend away from self-renewing HSCs, a preference toward myeloid instead of lymphoid lineage, and an increased amount of adipocytes in the niche.<sup>26</sup>

The red blood cell lasts for about 120 days in the peripheral compartment before splenic sequestration. It takes about 7 days before an immature red blood cell is released into the peripheral compartment. Although alkylating agents and antimetabolites can cause aplastic anemia, new-onset anemia occurring post-chemotherapy requires an immediate assessment for acute

**FIGURE 23–3.** A schematic of the hematopoietic stem cell niche in the bone marrow. EC = endothelial cell; HSC = hematopoietic stem cell; MPC = multiprogenitor cell.

blood loss and is not directly attributed to the chemotherapeutic. The longevity of the white blood cell in the peripheral compartment is shorter than it is for the red blood cell, and it varies depending on the maturity and location of the cell. For example, the survival times in the circulation (and other compartments) for mature neutrophils is 12 hours (3 days for those residing in tissues), mature granulocytes is 7 to 24 hours (10–14 days when progenitor cells are committed to mature granulocytes in the bone marrow). The anticipated milestones for white blood cells in response to a chemotherapy schedule of every 3 to 4 weeks is, the nadir will appear at about 10 to 14 days, recovery will begin at 14 days, and full recovery will be at 21 days. Although mature lymphocytes survive for about 6 to 24 hours, lymphopenia is not directly attributed to toxicity from chemotherapy. If lymphopenia occurs soon after chemotherapy, other causes should be initially suspected, such as ionized radiation therapy. Platelets survive for about 10 days in the circulation, and the nadir occurs from 10 to 14 days from the start of chemotherapy. The completion of recovery is expected at about 3 weeks for platelets.

The primary compartment of the HSCs is the bone marrow for the postnatal human. Within the bone marrow, there are 2 niches that are important to HSCs. The endosteal niche (located at the space between the trabecular bone and the bone marrow) consists of quiescent HSCs (long term) (Fig. 23–3). The perivascular niche (located near to the sinusoidal endothelium) consists of actively cycling HSCs (short term). The role of the quiescent HSC is to maintain itself for self-renewal by preventing exhaustion. The roles of the actively cycling HSCs are differentiation and response to stressors, such as ionizing radiation and chemotherapeutics.<sup>39</sup> Hematopoietic stem cells balance the roles of these 2 niches to address the need of the situation.

The niche consists of HSCs, stromal cells, soluble factors, and the extracellular matrix environment. The stromal cells are fibroblasts, preadipocytes, and osteoblasts. The environmental matrix consists of fibronectin, proteoglycan, and hyaluronic acid. Soluble factors are cytokines (eg, IL-3 and IL-6), growth factors, transcription factors, and surface molecules (eg, CD44) produced by the stromal cells.<sup>11</sup> The anaerobic environment of the bone marrow favors glycolysis, which is consistent with the G<sub>0</sub>-phase of the quiescent HSCs. When HSCs undergo differentiation, their metabolism converts to oxidative phosphorylation.<sup>31</sup>

The vascular supplies are arterioles for the endosteum and a sinusoidal network for the perivascular space. Following ionizing radiation injury, HSCs repopulate at the endosteum before the perivascular space because the sinusoid is more sensitive to this type of insult than the arteriole.<sup>2</sup> The HSC niche is regulated by sympathetic innervation, circadian rhythm, hormones, and hypoxia.<sup>4</sup> Hormones that affect HSC directly or indirectly through the niche are parathyroid hormone, estrogen, and prostaglandin E<sub>2</sub>.<sup>17</sup> A disruption of the adrenergic innervation can impair HSC recovery from chemotherapy.<sup>2</sup>

### HSC Response to Stress

Following an injury to the hematopoietic system, the initial response is myelosuppression. Bone marrow failure occurs when actively cycling cells in the marrow are severely injured. Significant injury to HSCs results in long-term consequences to the HSC, including a decrease in the reserve of HSCs or impaired self-renewal. Some potential consequences of a decreased reserve in HSC are hypoplastic anemia, myelodysplastic syndrome, and a diminished response to stress.<sup>39</sup> Hematopoietic stem cells can be injured by a quantitative reduction in HSCs, a qualitative alteration in the replicative function of HSCs, or a damage to the niche, such as the stromal cells.<sup>39</sup> For example, busulfan decreases the reserve of HSCs by inducing senescence.<sup>27</sup> Patients with a decreased reserve in HSCs typically recover with an unremarkable peripheral blood count during nonstressed conditions, but have an inadequate hematopoietic response to a stress that will occur in the future.

The toxicity of a chemotherapeutic on hematopoietic cells is demonstrated by the time of onset of the decline in the cell line, the time to recovery of the cell line, and the occurrence of residual or long-term effects to the cell line. The hematopoietic cells decline in the following order based on survival of the mature cell—granulocytes (48 hours), platelets (10–12 days), and

erythrocytes (120 days). In practice, the decline in granulocytes is usually evident at 1 to 2 weeks after the exposure to a chemotherapeutic because there are residual cells in peripheral tissue compartments.

Prolonged granulocytopenia (ie, neutropenia) results from direct damage to hematopoietic stem or progenitor cells, premature exhaustion of the reserve of HSCs (eg, repeated cycling), premature senescence, and damage to the niche architecture (eg, sinusoidal network by ionizing radiation) or stromal cells. For example, the nitrosourea BCNU (carmustine) damages the CFU-fibroblast, the alkyl sulfonate busulfan induces senescence in the HSC,<sup>27</sup> and cisplatin diminishes the reserve of the stem cell.<sup>24,30</sup> The nitrogen mustard analogue cyclophosphamide causes prolonged granulocytopenia at high and repeated doses.<sup>45</sup> Unlike the previously mentioned cell cycle phase-nonspecific agents, the cell cycle phase-specific agents such as cytosine arabinoside (ara-C, cytarabine) and 5-fluorouracil (5FU) do not cause prolonged myelosuppression.

There are a limited number of options for the medical treatment of hematopoietic injury: transfusion, growth factors, and bone marrow transplantation. The thresholds for the initiation of these therapies are determined by clinical practice.

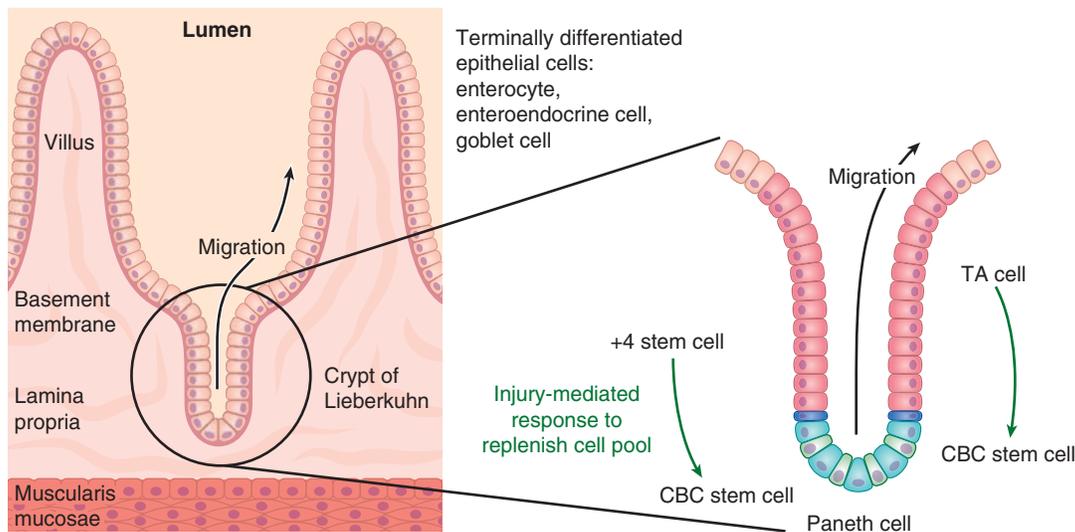

### Intestinal Epithelial Cells

Epithelial cells in the gastrointestinal tract develop from stem cells that are primarily located in the gastric glands and intestinal crypts, which serve as the niche. The cells in the small and large intestines are the predominate stem cells for the gastrointestinal epithelium. The stem cells for the large intestine are located at the ascending and descending portions of the colon. Intestinal stem cells (ISCs) develop from mesenchymal cells in the lamina propria, and they are supported by nutrients and soluble factors in the niche (Fig. 23–4). The hierarchical progression of intestinal epithelial cells is stem cell, progenitor cell (ie, transit-amplifying cell), and differentiated or mature cell. Mature cells are classified by their function (goblet cell, enterocyte, enteroendocrine cell, tuft cell, and Paneth cell) in the intestine. The mature cell is mitotically inactive, not renewed, and eventually sloughed off from the villi and into the gut lumen.

The intestinal epithelial cells are replaced daily because they undergo a high turnover rate. Differentiated epithelial cells migrate up the villi and are sloughed off after 3 to 5 days.<sup>1</sup> In contrast, the Paneth cell is located at the base of the crypt, and they turn over every 3 to 6 weeks. The amount of time it takes for the intestinal epithelium to become denuded following an injury depends on several factors, including the cell cycle time for the cell type (amount of time for one cell division), the number of cell divisions in the transit populations (from stem cell to mature cell), and the transit time for the postmitotic cell to migrate from the crypt to the villi.

The cell cycle times for the intestinal epithelium by section in humans are approximately 30 hours for the ileum, colon and rectum.<sup>37</sup> For comparison, the intestinal cell cycle times by section in mice are small to large bowel (11–26 hours), and in rats are small to large bowel (10–52 hours). The short cell cycle time for the ileum is reflected in the difference in the percentage of cells in mitosis for the total cell population among these sections in the intestine—ileum (53%), colon (25%), and rectum (16%).<sup>36</sup> The progenitor cell divides every 12 to 18 hours, and it undergoes 4 to 6 divisions before becoming a differentiated cell type.<sup>20</sup> An active stem cell (crypt base columnar cell) routinely enters into the cell cycle, but it occurs at a rate slower than the progenitor cell.<sup>20</sup> In a rodent model, it took about 3.2 days for the intestinal epithelium to become denuded following an exposure to ionizing radiation.<sup>37</sup>

Intestinal stem cells exist as 2 populations that function as active stem cells (crypt base columnar, CBC {leucine-rich repeat containing G protein-coupled receptor 5}) and quiescent stem cells (+4 stem cells) in the niche (Fig. 23–4).<sup>1</sup> The +4 stem cells are located at the fourth to fifth cell layer above the base of the crypt,<sup>20</sup> and they will undergo proliferation and differentiation when the active stem cells are damaged from an injury, such as an exposure to ionizing radiation or a chemotherapeutic. The CBC cells are located with the Paneth cells at the base of the crypt.

**FIGURE 23-4.** A schematic of the intestinal stem cell niche in the small intestine. +4 stem cells = quiescent stem cells; CBC = crypt base columnar; TA cell = transit-amplifying cell.

The CBC cells tend to replicate by symmetrical division, producing a pair of stem cells or transit-amplifying (progenitor) cells, to maintain epithelial homeostasis.<sup>1</sup>

There are several signaling pathways involved with the homeostasis of ISCs. One is the Wnt signaling pathway, and it acts on primarily stem cells to produce progenitor cells by activating the cell cycle. In addition, the pathway promotes the regulation of epithelial cell development along the lineage. Wnt appears to accomplish the former activities by stabilizing beta-catenin, which targets genes (CCND1 for cyclin D1 and MYC for c-MYC) that produce proteins involved with the regulation of the cell cycle. The Wnt/beta-catenin pathway appears to be involved with the regeneration of ISC following methotrexate treatment.<sup>42</sup>

There is a decreasing gradient for the Wnt signaling pathway as cells migrate from the crypt to the villi. The BMP signaling pathway serves as a negative regulator of cell proliferation in the crypt, and its gradient increases along the crypt–villi axis. The Notch signaling pathway promotes the maturation of progenitor cells to differentiated secretory cells.

### ISC Response to Stress

Crypt base columnar cells and transit-amplifying cells are sensitive to ionizing radiation and chemotherapeutics and undergo apoptosis when exposed.<sup>19,20,49,50</sup> Although all chemotherapeutics used in a mouse model resulted in death of cells in the crypt, the level of injury in the crypt varied depending on exposure. For example, cell cycle phase–nonspecific chemotherapeutics (nitrosourea, nitrogen mustard analogues, anthracycline) affected cells at position +4 to 11 from the base of the crypt, and cell cycle phase–specific agents (antifolate, Vinca alkaloid, and antipyrimidine) affected cells from +8 to 11 in the crypt.<sup>20</sup> When CBC cells are injured, +4 stem cells and early transit-amplifying cells with regenerative capacity work to replenish the cell pool in the crypt.<sup>1,5</sup>

### SUMMARY

- Chemotherapeutics cause various types of injuries to the cell. These injuries predominantly affect the DNA and they lead to damages of the DNA.
- Deoxyribonucleic acid damages result in cell death or senescence, tissue injury, and toxicity in the patient affected by these chemotherapeutics.
- The understanding of the mechanisms of these injuries and the responses of the cell and tissue to these injuries will enhance the clinician's management of the immediate and long-term consequences in patients affected by these chemotherapeutics.

# OPHTHALMIC PRINCIPLES

Adhi Sharma

Although it is arguable that the eyes are the mirror to the soul, it is certain that the eyes reveal a great deal of information with regard to toxicology. In addition to exhibiting findings of systemic toxicity, they are also subject to the direct effects of xenobiotics and serve as a portal of entry for systemic absorption. An understanding of ophthalmic principles will allow the clinician to make timely and more accurate diagnoses that can be sight-saving or lifesaving and is essential to efficient, organized patient care.

## OPHTHALMIC EXAMINATION

As a matter of convention, the routine eye examination is performed in the following sequence: visual acuity, pupillary response, extraocular muscle function, funduscopy, and, when indicated, a slit-lamp examination. Examination of the pupillary size and response to light can help determine the presence of a toxic syndrome. For example, opioids and cholinergics produce miosis, whereas anticholinergics and sympathomimetics produce mydriasis. Assessment of the extraocular muscles often reveals xenobiotic-induced nystagmus or cranial nerve abnormalities. Funduscopy typically reveals pink discs characteristic of poisoning by methanol or carbon monoxide. The slit-lamp examination allows for evaluation of toxic exposure to the lids, lacrimal systems, conjunctiva, sclera, cornea, and anterior chamber. However, before considering specific xenobiotic exposures in detail, it is important to review the anatomy and physiology of the visual pathways and how alteration of the normal physiology and anatomy correlate with clinical signs and symptoms.

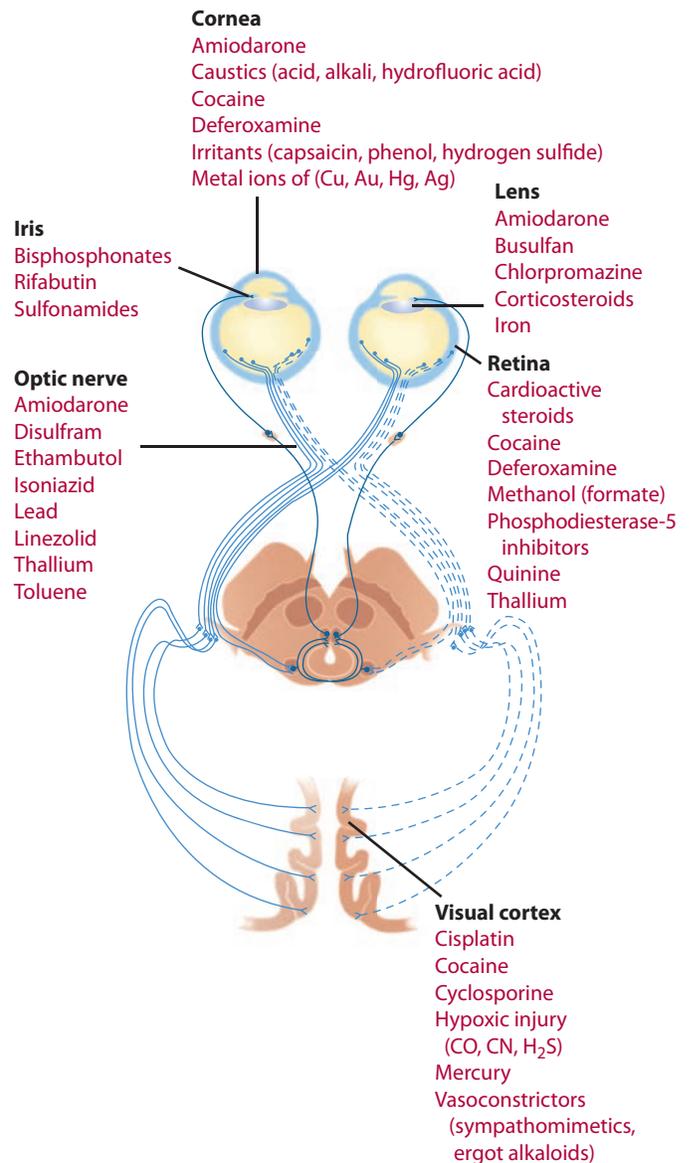

## OPHTHALMIC ANATOMY AND PHYSIOLOGY

The eye is a spherical structure referred to as a globe. The globe is divided into anterior and posterior structures (Fig. 24-1). The most anterior structures are the cornea, conjunctiva, and sclera. Posterior to the cornea are the iris, the lens, and the ciliary body. The space between the cornea and the iris is the anterior chamber, and the space between the iris and the retina is the posterior chamber. The anterior chamber contains *aqueous humor*, which is produced by the ciliary processes; this fluid nourishes the cornea, iris, and lens. The iris, the ciliary processes, and the choroid compose the uvea. The posterior chamber is filled with a transparent gelatinous mass termed the *vitreous humor*. The vitreous humor is an important body fluid in forensic toxicology as it is less susceptible to postmortem redistribution (Chaps. 139 and 140). The fundus is the most posterior structure and includes the retina, retinal vessels, and the head of the optic nerve or disc.

## Visual Acuity and Color Perception

Normal vision is dependent on light transmission through the globe reaching intact posterior neural elements. As such, appropriate light transmission requires a clear cornea, clear aqueous humor, proper pupil size, an unclouded lens, and clear vitreous. The posterior neural elements include the retina, optic nerve, and the optic cortex; in turn, all of these structures require intact blood circulation for proper function. Decreased acuity results from abnormalities anywhere in the visual system that affect either light transmission or the neural elements.<sup>4,12,22</sup> Corneal injury or edema results in blurring of vision, characteristically described as “halos” around lights. Toxicologic causes of corneal abnormalities include direct exposure to chemicals, failure of corneal protective reflexes because of local anesthetic effects or a profoundly decreased level of consciousness, and incomplete eyelid closure during coma. Mydriasis (Table 24-1) interferes with the pupillary constriction necessary for accommodation, thereby resulting in decreased acuity for near objects. Lens clouding or cataract formation causes blurred vision and decreased light perception, as does blood

(hyphema), pus (hypopyon), or other deposits in the aqueous humor or vitreous humor (vitreous hemorrhage). Many xenobiotic-induced lens abnormalities are caused by chronic systemic exposures (Table 24-2).<sup>17,22,30</sup> Even if light reaches the retina without distortion, ischemia or injury to any neural element from the retina to the optic cortex will result in abnormal reception or transmission. Direct, acute, visual neurotoxic injury is rare and is caused almost exclusively by methanol or quinine.<sup>17,43</sup> Indirect injury following xenobiotic-induced central nervous system (CNS) ischemia or hypoxia is far more common. Alterations in color perception generally result from abnormalities in retinal or optic nerve function. Color-vision abnormalities are attributed to numerous xenobiotics, but most are caused by chronic xenobiotic exposure and rarely are features of acute toxicity.<sup>17,22</sup>

**FIGURE 24-1.** The major xenobiotics that cause ophthalmic toxicity and their areas of ophthalmic injury.

**TABLE 24–1** Classic Ophthalmic Findings Caused by Acute Xenobiotic Exposures

<b>Disconjugate gaze</b>
Botulism
Elapid envenomation
Neuromuscular blockers
Paralytic shellfish poisoning
Secondary to decreased level of consciousness
Tetrodotoxin
Thiamine deficiency
<b>Funduscopy abnormalities</b>
Carbon monoxide (red)
Cocaine (vasoconstriction)
Cyanide (retinal vein arterIALIZATION)
Ergot alkaloids (vasoconstriction; disc pallor)
Injection drug use (attenuation or loss of small vessels due to emboli)
Methanol (disc and retinal pallor or hyperemia)
Methemoglobin (cyanosis)
<b>Miosis</b>
Cholinesterase inhibitors (carbamates, organic phosphorus compounds)
Coma from sedative–hypnotics (barbiturates, benzodiazepines, ethanol)
Decreased sympathetic tone (clonidine, opioids, valproic acid)
Increased cholinergic tone (pilocarpine, nicotine)
<b>Mydriasis</b>

### Pupil Size and Reactivity

Generally, pupils are round and symmetric with an average diameter of 3 to 4 mm under typical light conditions. Physiologic anisocoria (unequal pupils) is a normal variant and is defined as a difference in pupil size of 1 mm or less. However, in the absence of a history of physiologic anisocoria, any asymmetry in pupil size should be considered an abnormal finding. Pupils react

<sup>a</sup>This list includes only selected examples and is not intended to be comprehensive. <sup>b</sup>Particularly important example. <sup>c</sup>Reported, but extremely rare from this exposure. <sup>d</sup>Mostly of historical interest; associated with patterns of use that are no longer common.

directly and consensually to light intensity by either constricting or dilating. Constriction is also a component of the near reflex (accommodation) that occurs when the eye focuses on near objects. The iris controls pupil size through a balance of cholinergic innervation of the sphincter (constrictor) muscle by cranial nerve III and sympathetic innervation of the radial (dilator) muscle.<sup>12</sup>

Pupillary dilation (mydriasis) results from increased sympathetic stimulation of the radial muscle by endogenous catecholamines, or from the use

of cocaine, amphetamines, and other sympathomimetics and ophthalmic instillation of sympathomimetics such as phenylephrine. Mydriasis also results from inhibition of muscarinic cholinergic-mediated innervation of the sphincter secondary to systemic or ophthalmic exposure to anticholinergics (Chap. 49). Because pupillary constriction in response to light is a major determinant of normal pupil size, blindness from ocular, retinal, or optic nerve disorders also leads to mydriasis as exemplified by methanol and quinine toxicity. As such, the reactivity of mydriatic pupils to light varies with the etiology of the mydriasis.<sup>22</sup> Although often difficult to appreciate, constriction to light is often elicited after sympathomimetic exposures because constrictor function is preserved, whereas this is often not the case when mydriasis results from anticholinergic excess since constrictor function is potently antagonized. Light reactivity is absent in complete blindness but is preserved if light perception persists.

Miosis results from either increased cholinergic stimulation such as opioids, pilocarpine, and cholinesterase inhibitors, such as organic phosphorus compounds, or inhibition of sympathetic dilation caused by clonidine. Miosis was the most common finding in victims of the Tokyo subway sarin attack of 1995 and was used to distinguish between mild and moderate exposure.<sup>36</sup>

There are conflicting reports regarding the pupillary reactions to many xenobiotics. Depending on the stage and severity of toxicity, the presence of coingestants or coexistent hypoxemia, and numerous other factors, many individual xenobiotics such as clonidine, nicotine, phencyclidine, and barbiturates cause mydriasis, miosis, or hippus, which is defined as a spasmodic and rhythmic, but regular, alteration between miosis and mydriasis.<sup>22,31</sup> For some xenobiotics, the pupillary examination provides consistent information (Table 24–1), but many factors are involved, and the significance of the pupil size and reactivity must always be considered in the context of the remainder of the patient evaluation.

### Extraocular Movement, Diplopia, and Nystagmus

Maintenance of normal eye position and movement requires a coordinated function of a complex circuit involving bilateral frontal and occipital cortices, multiple brain stem nuclei, cranial nerves, and extraocular muscles.<sup>2,12</sup> Because of the many elements necessary for normal function, abnormalities of eye movement result from several causes and are extremely common.<sup>22</sup> Probably the most common abnormality is reversible nystagmus or rhythmic oscillations of the globes (Table 24–1). Nystagmus is divided into 2 types: jerk nystagmus, which has a slow phase and a fast phase, and pendular nystagmus, which has rhythmic oscillation. Either type can be torsional (rotatory) or in a horizontal or vertical direction. Xenobiotic-induced nystagmus takes many forms but is most commonly jerk nystagmus, as opposed to pendular. The nystagmus may be evident at rest but is accentuated by visual pursuit and extreme lateral gaze. Although nystagmus with extreme lateral gaze is a normal finding, it extinguishes within 2 to 5 beats; if nystagmus persists, it is evidence of underlying pathology. Vertical nystagmus in other settings is usually associated with a structural lesion of the CNS. However, xenobiotic-induced vertical nystagmus occurs with phencyclidine, ketamine, dextromethorphan, or phenytoin toxicity. Loss of conjugate gaze commonly results from CNS depression of any etiology, typically after sedative-hypnotic or ethanol poisoning. Except after extremely rare exposures to neurotoxins (Table 24–1), diplopia without a decreased level of consciousness should not be attributed to an acute toxicologic etiology. In addition to the transient effects of some xenobiotics, thallium, carbon disulfide, and carbon monoxide cause sustained gaze disorders as a consequence of residual cranial nerve and CNS injury.<sup>22</sup> Nystagmus and ophthalmoplegia caused by thiamine deficiency (Wernicke encephalopathy) usually improves after therapy, but on occasion the nystagmus completely resolves.<sup>46</sup>

## DIRECT OPHTHALMIC TOXINS

### Chemical Ophthalmic Injury

Chemical injury to the eye from a number of xenobiotics occurs in both residential and industrial settings, and also results from warfare or acts of terrorism. A recent study demonstrated that over a 4-year period there were more

than 144,000 ophthalmic burns recorded in emergency departments in the United States.<sup>23</sup> Although injuries were more common in men than women, children aged 1 to 2 years had the highest incidence of injury. Alkaline injuries resulted in more severe injuries than acids, and were more common.<sup>23</sup> Vision loss is associated with an increased risk for subsequent serious injuries, and will have long-lasting impact on general health.<sup>29</sup>

### Caustics

The initial approach to all patients with ophthalmic caustic exposures should be immediate decontamination by irrigating with copious amounts of fluids.<sup>9,47</sup> Water, 0.9% sodium chloride solution, lactated Ringer solution, and balanced salt solution (BSS) are all appropriate choices. In theory, BSS is ideal, because it is both isotonic and buffered to physiologic pH. Lactated Ringer solution (pH 6–7.5) and 0.9% sodium chloride solution (pH 4.5–7) are also isotonic and therefore theoretically preferable to water.<sup>24</sup> The use of an ophthalmic anesthetic is usually required to perform irrigation properly. Irrigation is intended to accomplish at least 4 objectives: immediate dilution of the offending xenobiotic; removal of the xenobiotic; removal of any foreign body; and, in some cases, normalization of anterior chamber pH. Because delays of even seconds can dramatically affect outcome,<sup>22</sup> there is no justification for waiting for any specific solution if water is the first available therapy or in obtaining visual acuity prior to treatment. Irrigation must include the external and internal palpebral surfaces, as well as the cornea and bulbar conjunctiva and its recesses. Effective irrigation includes lid retraction and eversion or use of a scleral shell or other irrigating device. After irrigation, visual acuity testing, inspection of the eye, and slit-lamp examination should be performed. The immediacy with which an ophthalmologic consultation must be obtained will depend on the degree of injury.

### Sulfur Mustard

This alkylating agent reacts with ophthalmic tissues, resulting in early and late toxic effects. Of note, there is a latency of 30 minutes to 8 hours, during which time victims will be relatively asymptomatic. Initial effects include pain, foreign body sensation (grittiness), lacrimation, photophobia, blepharospasm, corneal ulceration, and blindness.<sup>26</sup> Generally, injury is limited to the anterior chamber. More than 90% of exposed victims will experience late complications associated with conjunctival sensitivity to irritants, with resultant recurrent blepharoconjunctivitis. Fewer than 1% of severely toxic victims will suffer delayed keratopathy, resulting in thinning, neovascularization, and epithelial defects of the cornea.<sup>26</sup>

Management is directed at removal from the exposure and aggressive decontamination of the skin and eyes. Any of the irrigation solutions mentioned above will suffice. The goal is to provide irrigation as soon as possible; to this end, even tap water is an acceptable solution. Animal studies suggest that topical nonsteroidal antiinflammatory drugs (NSAIDs) are helpful; as such, a short course of ophthalmic corticosteroids is reasonable.<sup>5</sup> Ophthalmic corticosteroid treatment should be used in consultation with an ophthalmologist. Late complications are best managed by an ophthalmologist.

### Exposure-Specific Irrigating Solutions

Despite theoretical concern, there is probably no toxic exposure for which standard aqueous solutions are contraindicated. Of greatest concern are xenobiotics such as white or yellow phosphorus, metallic sodium, metallic potassium, and calcium oxide (cement) that typically react in the presence of water, leading to an exothermic or mechanical injury, or resulting in the generation of sodium hydroxide, potassium hydroxide, and calcium hydroxide.<sup>22</sup> Although not well studied, irrigation with large amounts of water probably dissipates the heat of the initial hydration reaction with conjunctival moisture more than it initiates a thermochemical reaction. In addition to removing the offending material, irrigation serves to dilute and remove the alkaline by-products formed by reaction with conjunctival water. Table 24–3 summarizes recommended irrigation solutions for various xenobiotics.

The use of special irrigating solutions for more uncommon exposures, including hydrofluoric acid and phenols, is also debated. Animal models of

**TABLE 24-3** Recommended Irrigation Solutions for Various Xenobiotics

Xenobiotic	Irrigation Solution	Duration of Irrigation <sup>a</sup>
Capsaicin (pepper spray)	NS, LR, BSS	15–20 minutes
Caustics (acids/alkalis)	NS, LR, BSS	1–2 hours
Cyanoacrylate adhesives	Typically none needed	N/A
Hydrofluoric acid	NS	1–2 hours <sup>a</sup>
Phenol	NS, LR, BSS	15–20 minutes

<sup>a</sup>Duration of irrigation should be determined by other endpoints, including symptoms or conjunctival pH. BSS = balanced saline solution (pH ~7.4); LR = lactated Ringer solution (pH 6.0–7.5); NS = 0.9% sodium chloride (pH ~5.5).

alkaline xenobiotics and nitrogen mustard injuries suggest that irrigation with amphoteric or buffered solutions rapidly restores anterior chamber pH.<sup>20,41</sup> Some authors have gone further to conclude that 0.9% sodium chloride solution should be avoided as an irrigation solution.<sup>38</sup> Use of these specialized irrigating solutions is beneficial for cutaneous burns;<sup>14</sup> however, the majority of the published human ophthalmic data are case reports. These solutions are probably best suited for first aid treatment at worksite eyewash stations and are neither practical nor proven for prolonged irrigation.

### Hydrofluoric Acid

For hydrofluoric acid exposures (Chap. 104), experimental irrigation with calcium salt solutions was too irritating to the eye, but isotonic magnesium chloride solutions appear effective and not irritating, and are the preferred irrigant if available.<sup>32,33</sup> However, from a practical standpoint, 0.9% sodium chloride solution remains readily available, well studied, and effective. In one animal model, it was suggested that irrigation beyond the initial liter yielded worse outcomes; however, this was not demonstrated in humans.<sup>32</sup>

### Phenol

For dermal exposure, topical low-molecular-weight polyethylene glycol (PEG) solutions are effective for treatment of experimental skin exposure; for eyes, copious water irrigation appears to be as effective as PEG.<sup>7</sup> There is, however, a report of superior efficacy of PEG-400 over water in treatment of actual phenol eye burns.<sup>28</sup> Although PEG-400 should be readily available at worksites where phenols are used, it is not a realistic option in the emergency department, and there should be no hesitation to use water, 0.9% sodium chloride solution, lactated Ringer solution, or BSS as lavage solutions.

### Cyanoacrylate Adhesives

Ophthalmic exposures to cyanoacrylate adhesives such as Dermabond<sup>®</sup> and Krazy Glue<sup>®</sup> occasionally result in rapid adherence between the upper and lower eyelids that typically persists for days. Classically, such occurrences are associated with corneal abrasions,<sup>13</sup> but are otherwise relatively harmless. In fact, cyanoacrylate is used for the treatment of corneal perforations.<sup>49</sup> Solvents such as acetone or ethanol, which are often effective treatment for dermal-to-dermal adhesions caused by cyanoacrylates, should never be used in or around the eyes because they can result in a severe keratitis. Expectant management is the safest approach, because spontaneous rejection of the glue will occur over time. Application of gauze pads coated with antibiotic ophthalmic ointment will hasten recovery.<sup>27</sup> A thorough eye examination should be performed once the eyelids can be fully opened.

Other xenobiotic-specific treatments have been tried experimentally or clinically,<sup>24</sup> but none should be considered prior to, or instead of, copious irrigation. Most are not advocated, and consideration of such therapies should be vanishingly rare.

### Duration of Irrigation

To accomplish the desired goals of irrigation, the appropriate duration varies with the exposure. Most solvents, for example, do not penetrate deeper than the superficial cornea, and 10–20 minutes of irrigation is generally sufficient.<sup>22</sup> After exposure to acids or alkalis, normalization of the conjunctival

pH is often suggested as a useful endpoint. Testing of pH should be done in every case of acid or alkali exposure, but the limitations of testing must be understood. When measured by sensitive experimental methods, normal pH of the conjunctival surface is 6.5 to 7.6.<sup>1</sup> This is highly method dependent, however, and normal values in the literature range from 5.2 to 8.6.<sup>10</sup> When measured by touching pH-sensitive paper to the moist surface of the conjunctival cul-de-sac, normal pH is most often near 8.<sup>3</sup> Therefore, after irrigation following alkali burns, pH should not be expected to reach 7 and is more likely to stabilize near 8.<sup>22</sup> In this setting, lower pH values likely indicate the pH of the irrigation solution rather than of the ophthalmic surface. Waiting for an interval of several minutes between irrigation and pH testing allows washout of any residual irrigant.<sup>11</sup> Choice of testing paper is important, because some are intended for use at extremes of pH and lack sensitivity in the clinically useful range.

Despite these limitations, a logical role for pH assessment is appropriate. A minimum of 500 to 1,000 mL of irrigant should be used for each affected eye before any assessment of pH, and after a waiting period (7–10 minutes), the pH of the lower fornix conjunctiva should be checked. Thereafter, cycles of 10 to 15 minutes of irrigation followed by rechecks should be continued until the pH is 7.5 to 8. This is certainly adequate for exposures to weak acids, which do not penetrate well, and for alkaline exposures where the pH is less than 12.

For strong or concentrated acid or alkali exposures, normal surface pH is not an adequate endpoint. After these burns, irrigation should be continued for at least 1 to 2 hours, regardless of surface pH, in an attempt to correct anterior chamber pH.<sup>22,39,47</sup> In addition, immediate ophthalmologic consultation is mandatory. Following this lengthy irrigation, it is important to verify that conjunctival pH has normalized. If not, irrigation must be continued, sometimes for 24 to 48 hours.

### Others

Most solvents cause immediate pain and superficial injury because of dissolution of corneal epithelial lipid membranes but do not penetrate or react significantly with deeper tissue.<sup>22</sup> Consequently, even when the epithelial defect is large or complete, the limited depth of injury allows for rapid regeneration of normal epithelium. Detergents and surfactants cause variable injury, ranging from minor irritation from soaps to extensive injury from cationic detergents such as concentrated benzalkonium chloride.<sup>22</sup> Ophthalmic exposure to A-200 Pynrate pediculicide shampoo causes typical detergent-surfactant injury, leading to extensive loss of corneal epithelium but with normal underlying stroma; therefore, complete healing occurs within days. Lacrimators (tear gases), such as chloroacetophenone, stimulate corneal nerve endings and cause pain, burning, and tearing, but produce no structural injury at low concentrations. At high concentrations, these xenobiotics typically produce significant corneal injury.

Pepper spray, often used for self-protection by civilians or to defuse a potentially violent event by law enforcement, contains the active ingredient oleoresin capsicum (OC). Oleoresin capsicum results in rapid depolarization of nociceptors containing substance P, resulting in immediate pain, blepharospasm, tearing, and blurred vision. In general, ophthalmic injury is uncommon, although corneal erosions are reported.<sup>22</sup> The solvent used for the spray is typically more injurious to the eye than the OC itself. Although most sprays use a water-based or oil-based solvent, some use alcohol, which can result in significant corneal damage.<sup>50</sup> Management of pepper spray exposure consists of rapid irrigation and pain control. Corneal erosions (epithelium intact) are often treated with artificial tears and antistaphylococcal antibiotics are recommended for corneal abrasions (epithelial defects). Specific information on numerous other xenobiotics is readily available.<sup>22</sup>

### General Measures

There is a wide array of options for adjunctive therapy of chemical burns of the eye. In all cases in which serious injury is evident, the treatment plan must include consultation with an ophthalmologist. Generally, patients ophthalmic topical antibiotics providing antistaphylococcal and antipseudomonal

coverage are recommended for corneal injuries. Cycloplegics not only reduce pain from ciliary spasm, but also decrease the likelihood of posterior synechiae (scar) formation. Topical nonsteroidal antiinflammatory drugs and systemic analgesics also improve patient comfort. Dispensing topical ophthalmic anesthetics is rarely recommended, because repeated use leads to further corneal disruption both by direct chemical effects and by eliminating corneal protective reflex sensation.

## DISPOSITION

Disposition of patients with chemical burns of the cornea is frequently challenging. Patients with extensive burns to other parts of the body necessitate evaluation for transfer to a burn center. Grading the degree of injury in patients with isolated ophthalmic injury will guide disposition. The most commonly used grading system is the Roper-Hall modification of the Ballen classification system. Injury is graded on a 4-tier scale. Patients with mild conjunctival injection with corneal epithelial loss and minimal corneal haziness are classified as grades 1 and 2 (mild to moderate). These patients can be safely discharged from the emergency department with ophthalmology follow-up within 24 to 48 hours. Patients with severe corneal haziness or opacification with significant limbal ischemia (lack of blood vessels outside the periphery of the cornea) are classified as grade 3 or 4 (moderate to severe) and will benefit from immediate consultation with an ophthalmologist and consultation with a burn unit is advisable.

## SYSTEMIC ABSORPTION AND TOXICITY FROM OPHTHALMIC EXPOSURES

Systemic absorption from ophthalmic exposure causes serious toxicity, morbidity, and even mortality.<sup>15,25</sup> Although the patterns of toxicity are characteristic of the xenobiotics involved, delays in recognition occur as a result of a failure to appreciate the eye as a significant route of absorption. Although transcorneal diffusion of xenobiotics is limited, there is substantial nasal mucosal absorption after nasolacrimal drainage, and absorption via conjunctival capillaries and lymphatics, which is markedly increased during conjunctival inflammation. Unlike the gastrointestinal route of absorption, there is no significant first-pass hepatic removal after ophthalmic absorption; consequently, bioavailability is much greater.<sup>21,25,42</sup> If nasolacrimal outflow is normal, up to 80% of instilled drug is absorbed systemically.<sup>15</sup> Unfortunately, by the time toxicity is apparent, there is no role for ophthalmic decontamination to prevent further absorption. After instillation of eye drops, absorption is generally complete within 7 minutes.

Children are at greatest risk, possibly because of the higher relative drug dose they experience when systemic absorption does occur.<sup>15,37,42</sup> Diligent attempts to comply with prescribed dosing in a struggling, crying infant often results in excessive dosing. As eye drop size (40–50  $\mu\text{L}$ ) exceeds ophthalmic cul-de-sac capacity (30  $\mu\text{L}$ ), overflow often occurs and is assumed to represent a failed instillation, which leads to unnecessary reinstillation. Also, as doses of ophthalmic medications are typically not adjusted based on patient weight, the consequences of equivalent degrees of systemic absorption are much greater for an infant than for an adult. Toxicity from eye drops is also a problem among the immunocompromised, probably because of the combination of greater use of potentially toxic ophthalmic medications and the presence of comorbid conditions.

Prevention of systemic toxicity from topical ophthalmic medications requires recognition of the risk, a careful history, use of the lowest effective concentration and dose, and patient education including proper administration instructions. To minimize inadvertent absorption, no more than one drop of any eye drop solution should be instilled at one time in the superolateral corner of the eye while using gentle finger compression of the medial canthus to limit nasolacrimal drainage.<sup>15,25</sup>

## Mydriatics

Mydriatics are used almost exclusively to dilate the pupils prior to diagnostic evaluation of the eyes. This common practice is not generally considered to be potentially dangerous; however, the risks are substantial if the precautions

outlined are not considered. Anticholinergic poisoning is reported following ophthalmic use of atropine, cyclopentolate, or scopolamine eye drops, especially in infants.

The use of the  $\alpha$ -adrenergic agonist phenylephrine eye drops in a 10% solution led to severe hypertension, subarachnoid hemorrhage, ventricular dysrhythmias, and myocardial infarction.<sup>17</sup> Fortunately, these effects are rare if the 2.5% ophthalmic phenylephrine is used. Mydriatics also risk precipitating acute angle closure glaucoma in susceptible individuals.

## Miotics and Other Antiglaucoma Drugs

Miosis is induced by the cholinesterase inhibitor echothiophate (sometimes used to treat glaucoma or accommodative esotropia; a type of eye-turn related to extraocular muscle weakness). Echothiophate also exacerbates asthma, Parkinsonism, and cardiac disease, and prolongs the metabolism of certain medications such as succinylcholine.<sup>25</sup> Miosis is also produced by use of direct cholinergic agonists, such as pilocarpine. Although absorption is limited, nausea and abdominal cramps are reported at recommended doses. After excessive dosing, salivation, diaphoresis, bradycardia, and hypotension are all described.

$\beta$ -Adrenergic antagonists, such as timolol, levobunolol, metipranolol, carteolol, and betaxolol, are used to lower intraocular pressure but infrequently cause a variety of adverse effects, including bradycardia, hypotension, myocardial infarction, syncope, transient ischemic attacks, congestive heart failure, exacerbation of asthma, and respiratory arrest. Timolol exacerbates weakness in patients with myasthenia gravis and is implicated in both causing and masking the signs and symptoms of hypoglycemia in diabetics.<sup>44,45</sup> Nonspecific complaints of anorexia, anxiety, depression, fatigue, hallucinations, headache, and nausea are also described after the use of timolol eye drops. Despite the cardioselectivity of betaxolol, respiratory effects occur.<sup>15</sup>

Dipivefrin, an esterified epinephrine derivative sometimes used to treat glaucoma, has caused systemic adrenergic effects, although less frequently than those caused by epinephrine. Ophthalmic formulations of highly selective  $\alpha_2$ -adrenergic agonists, brimonidine and apraclonidine, were introduced to treat glaucoma.<sup>15,48</sup> Apraclonidine is expected to have a lower potential for toxicity because of limited CNS penetration. Systemic absorption of brimonidine eye drops in a child led to bradycardia, hypotension, and a decreased level of consciousness, similar to the central effects of other  $\alpha_2$ -adrenoceptor agonists such as clonidine,<sup>6</sup> apparently mediated through both  $\alpha_2$ -adrenoceptors and imidazoline receptors (Chap. 61).<sup>8</sup>

## Antimicrobials

Life-threatening reactions to ophthalmic antimicrobials are unusual. Aplastic anemia occurred after prolonged use of chloramphenicol eye preparations,<sup>16</sup> and Stevens-Johnson syndrome was reported after short-term use of ophthalmic sulfacetamide in a patient with a history of allergy to sulfa drugs.<sup>21</sup>

## TOXICITY TO OPHTHALMIC STRUCTURES FROM NONOPHTHALMIC EXPOSURES

Ophthalmic toxicity from systemic xenobiotics is almost always the result of chronic exposure, and the manifestations develop over a prolonged period of time. Thousands of xenobiotics are implicated, affecting every element of the visual system from the cornea to the optic cortex. Thorough discussion of this topic is beyond the scope of this text, but Table 24–2 lists examples of causative xenobiotics.<sup>17,22</sup> Many topical and systemic medications are associated with inflammation of the eye, such as the development of anterior or posterior uveitis (inflammation of the iris, ciliary process, or choroid membrane).<sup>18</sup> Unlike many other ophthalmic abnormalities caused by xenobiotics, uveitis should prompt immediate ophthalmologic consultation. Because in many cases the etiology is related to commonly prescribed medications, adverse drug effects should always be considered when patients present with visual abnormalities or unusual ophthalmic findings.

In the setting of emergency care, xenobiotic-induced disturbances of normal vision from systemic exposures take many forms. Impaired near-vision

**TABLE 24–4** Common Xenobiotics Reported to Cause Visual Loss After Acute Exposures

Direct Causes	Indirect Causes <sup>b</sup>
Cautics	Cisplatin
Mercuric chloride <sup>a</sup>	Combined endocrine xenobiotics (thyrotropin-releasing hormone with gonadotropin-releasing hormone and glucagon)
Methanol	Embolization of foreign material (intravenous injection)
Lead <sup>a</sup>	Reversible posterior leukoencephalopathy
Quinine	Vasoactive xenobiotics
	Amphetamines
	Cocaine
	Ergot alkaloids
	Hypotension (eg, calcium channel blockers), diazoxide

<sup>a</sup>Distinctly rare with poisoning. <sup>b</sup>Distinctly rare with use of these xenobiotics; visual loss often instantaneous, secondary to sudden hypotension, vascular spasm, or embolization.

from mydriasis, and diplopia or nystagmus from interference with normal control of extraocular movements, are examples of common, usually harmless visual effects. Serious effects generally result from injury or dysfunction of the neural elements from the retina to the cortex. Such toxicity can be either direct (neurotoxic) or indirect (hypoxia, ischemia). Many xenobiotics historically reported to cause acute visual loss directly are no longer available.<sup>22</sup> Methanol and quinine are currently the most important xenobiotics that cause direct visual toxicity after acute oral poisoning. Many xenobiotics capable of causing vasospasm, hypotension, or embolization also cause acute visual loss (Table 24–4).<sup>43</sup> Blindness and other visual defects are described following recovery from severe toxicity with barbiturates and other sedative–hypnotics, opioids, carbon monoxide, and many others.<sup>22</sup>

### OPHTHALMIC COMPLICATIONS OF ILLICIT DRUG USE

In addition to the well-known ophthalmic pupillary signs of opioid, cocaine, amphetamine, and phencyclidine toxicity, a number of complications result from short-term or long-term use of these xenobiotics.<sup>34</sup> Quinine amblyopia (Chap. 55) caused by intravenous use of quinine-adulterated heroin is one of many ophthalmic complications caused by injection of contaminants. Talc contaminants result in talc retinopathy, which was first described after prolonged intravenous use of adulterated methylphenidate,<sup>19</sup> but was also noted after intravenous use of heroin, methadone,<sup>35</sup> codeine, meperidine, and pentazocine. Talc retinopathy develops only after extensive intravenous drug use. In one study of intravenous methadone abusers, only patients who had injected more than 9,000 tablets developed this complication.<sup>35</sup> Infectious complications, such as fungal (*Candida*, *Aspergillus*) or bacterial (*Staphylococcus* spp, *Bacillus cereus*) endophthalmitis, are well known as both direct effects of intravenous drug use and secondary complications of acquired immunodeficiency syndrome (AIDS). In addition to AIDS-related ophthalmic infections such as cytomegalovirus, cryptococcus, toxoplasmosis retinitis, and choroidal *Mycobacterium avium-intracellulare* complex (MAC), other disorders include retinal cotton-wool spots, conjunctival Kaposi sarcoma, and ophthalmic motility disorders caused by infectious or neoplastic meningitis. Corneal defects are reported after smoking cocaine alkaloid (“crack eye”).<sup>40</sup> Cocaine that is either volatilized or inadvertently introduced by direct contact probably results in corneal anesthesia and loss of corneal protective reflex sensation. Minor trauma, such as eye rubbing, then leads to corneal epithelial defects. In addition, there appears to be an increased incidence of infectious keratitis and corneal ulceration in these patients. The ability of local anesthetics to interfere with corneal epithelial adhesion may also play a role.

### SUMMARY

- Systemic and local toxicologic emergencies often have manifestations in the ophthalmic system.

- Although the obvious physical injuries are apparent to the clinician, the subtler clues to toxicologic mechanisms that involve the ophthalmic and neurologic systems are made only by a meticulous examination of the eye.
- Direct ophthalmic toxins should be washed out immediately without delays for determining visual acuity or locating toxin-specific irrigation solutions.
- After initial management it is recommended that patients with moderate–severe injury be promptly referred to an ophthalmologist for further evaluation.

## OTOLARYNGOLOGIC PRINCIPLES

Mai Takematsu and William K. Chiang

Many xenobiotics adversely affect the senses of olfaction, gustation, and cochlear-vestibular functions. Although these toxic effects are not life-threatening they are frequently distressful to patients. Furthermore, because of the dearth of access to standardized diagnostic techniques and normal parameters, such adverse effects are sometimes overlooked or dismissed by health care providers, despite significant patient distress and dysfunction. This is particularly true for disorders of olfaction and gustation. This chapter reviews the anatomy and physiology of these senses, describes the effects of xenobiotics on these senses, and examines the significant diagnostic information these senses contribute to identifying the presence of xenobiotics. Understanding the effects of xenobiotics on these senses allows for early detection, removal, and prevention of future events. In occupational settings, understanding these principles help prevent permanent and life-threatening injuries.

### OLFACTION

#### Anatomy and Physiology

Olfactory receptors are bipolar neurons located in the superior nasal turbinates and the adjacent septum. There are 10 to 20 million receptor cells per nasal chamber, and the receptor portion of the cell undergoes continuous renewal from the olfactory epithelium.<sup>122,127</sup> Renewed olfactory receptors regenerate neural connections to the olfactory bulb. These olfactory receptor neurons are distinctive in their ability to regenerate.<sup>26</sup> The axons of these cells form small bundles that traverse the fenestrations of the cribriform plate of the ethmoid bone to the dura. Within the dura, these bundles form connections with the olfactory bulb from which neural projections then connect to the olfactory cortex. There are extensive interconnections to other parts of the brain, such as the hippocampus, thalamus, hypothalamus, and frontal lobe, suggesting effects on other biologic functions.<sup>122</sup> Although primary odor detection is a function of the olfactory nerve (CN I), some irritant odors, such as ammonia and acetone, are transmitted through the trigeminal nerve (CN V) and its receptors.<sup>48,164</sup>

The actual olfactory receptor sites are guanine nucleotide protein (G protein)-coupled receptors (GPCRs) similar to the taste receptors of the mouth and the photoreceptors of the retina. The receptor is a single-polypeptide chain consisting of approximately 350 amino acids, which folds back and forth onto itself to traverse the cellular membrane 7 times. The outer end of the polypeptide contains an amine group (N-terminal), and the cytosolic end contains a carboxyl group (C-terminal). The transmembranous portions determine the receptor shape and characteristics of the binding site. When a molecule binds to a specific receptor site, the resultant conformational change leads to the activation of the G protein system and calcium and/or sodium channel activation and neurotransmission.<sup>86</sup>

Smelling is an extremely sensitive mechanism of detecting xenobiotics. Olfactory receptors detect the presence of a few molecules of certain xenobiotics with a sensitivity that is superior to some of the most sophisticated laboratory detection instruments, even though human smell is several orders of magnitude less perceptive than other mammals.<sup>78</sup>

#### Clinical Use of Odor Recognition

The sense of smell is extremely useful as a toxicologic warning system. Human olfaction is a variable trait.<sup>5,137,202</sup> For example, 40% to 45% of people have specific anosmia (inability or loss of smell) for the bitter almond odor of cyanide.<sup>49,101,137</sup> There are limited data on the inheritance characteristics or genetic basis of these specific forms of anosmia. Although some studies suggest that the ability to detect the odor of cyanide is a sex-linked

recessive trait,<sup>68</sup> other studies yield conflicting results.<sup>5,20,103</sup> Women have a greater ability to detect androsterone, which is prominent in human underarm secretion.<sup>78</sup> Human olfaction usually can distinguish a mixture of no more than 4 xenobiotics;<sup>107</sup> therefore, specific odors are frequently masked by other stimuli.

Olfactory fatigue is the process of olfactory adaptation following exposure to a stimulus for a variable period of time. This leads to a temporal diminution of the smell. Unfortunately, this adaptation provides a false sense of security during continued exposure to a xenobiotic. For example, hydrogen sulfide, which inhibits cytochrome oxidase, is readily detectable as distinct and offensive at the very low concentration of 0.025 ppm. At a higher and potentially toxic concentration of 50 ppm, the odor is less offensive, and extinguishes recognition after 2 to 15 minutes of exposure.<sup>8,177</sup> At even higher concentrations when toxicity is likely, the onset of olfactory fatigue is even more rapid. The combination of the rapid onset of olfactory fatigue and systemic toxicity at high concentrations of hydrogen sulfide exposure contributes to numerous fatalities (Chap. 123).<sup>1,27,185</sup>

In industrial settings, it is important to be aware of impaired olfactory function in any worker who may be exposed to chemical vapors or gases.<sup>84,177</sup> Such workers are at increased risk for toxic injury. The National Institute for Occupational Safety and Health (NIOSH) requires that an individual using an air-purifying respirator be capable of detecting the odor of a xenobiotic at concentrations below those producing toxicity.<sup>6,177</sup> Sensory perception at this concentration ensures that the individual can detect filter cartridge “breakthrough” or failure at a safe concentration.<sup>177</sup> The odor safety factor refers to the ratio of the time-weighted average (TWA) threshold limit value (TLV) to the odor threshold for a given xenobiotic. A xenobiotic with a high odor safety factor is detectable despite prolonged exposure.<sup>6</sup> Nontoxic xenobiotics with a very high odor safety factor, such as ethyl mercaptan, are added to xenobiotics that are odorless with lower safety factors so that olfactory detection is predictable. This enhanced sensory awareness is the basis for the addition of mercaptans to the odorless natural gases used in the home so as to limit the potential for unrecognized hazardous exposure.

The recognition of odors was traditionally considered an important diagnostic skill in clinical medicine. Some diseases are diagnosed accurately by recognizable associated odors of various affected parts of the body such as the breath, sweat, urine, and wounds: diabetic ketoacidosis as a characteristically fruity odor of the breath; diphtheria as sweet; scurvy as putrid; typhoid fever as fresh-baked brown bread; and scrofula as stale beer.<sup>42</sup> Odors are also described for disorders of amino acid and fatty acid metabolism, such as phenylketonuria, maple syrup urine disease, hypermethioninemia, and isovaleric acidemia.<sup>42</sup>

The recognition of odors continues to be an important diagnostic skill for the rapid detection of some xenobiotics (Table 25–1). To increase awareness of odors of toxic xenobiotics, a “sniffing bar” of commonly available odors may be prepared.<sup>73</sup> Nontoxic xenobiotics that simulate the odors of toxic xenobiotics are placed in test tubes, numbered, and inserted in a test tube rack for circulation among staff. The sniffing bar, brief descriptions of clinical presentations, and a table of diagnostic odors (Table 25–1) is used to teach the recognition of odors in medical toxicology.<sup>73</sup>

#### Classification of Olfactory Impairment

There are different types of olfactory dysfunction. *Anosmia*, the inability to detect odors, and *hyposmia*, a decrease in the perception of certain odors, are the most common forms of olfactory impairment. The etiology of olfactory impairment is classified as conductive, from anatomic obstruction of inspired air, or perceptive, from dysfunction of the olfactory receptors or

TABLE 25–1 Odors Suggestive of a Xenobiotic

Odor	Xenobiotic
Bitter almond	Cyanide
Carrots	Cicutoxin (water hemlock)
Disinfectants	Creosote, phenol
Eggs (rotten)	Carbon disulfide, disulfiram, hydrogen sulfide, mercaptans, <i>N</i> -acetylcysteine
Fish or raw liver (musty)	Aluminum phosphide, zinc phosphide
Fruity	Nitrites (amyl, butyl)
Garlic	Arsenic, dimethyl sulfoxide, organic phosphorus compounds, phosphorus, selenium, tellurium, thallium
Hay	Phosgene
Mothballs	Camphor, naphthalene, <i>p</i> -dichlorobenzene
Pepper	<i>O</i> -Chlorobenzylidene malononitrile
Rope (burnt)	Marijuana, opium
Shoe polish	Nitrobenzene
Sweet fruity	Acetone, chloral hydrate, chloroform, ethanol, isopropanol, lacquer, methylbromide, paraldehyde, trichloroethane
Tobacco	Nicotine
Vinegar	Acetic acid
Violets	Turpentine (metabolites excreted in urine)
Wintergreen	Methyl salicylate

signal transmission. Most conductive olfactory dysfunction results in hyposmia, because the obstruction is usually incomplete.<sup>122,161</sup>

The most common causes of anosmia and hyposmia are viral infections, trauma, xenobiotics, tumors, and congenital and psychiatric disorders (Table 25–2).<sup>48,147,153,161</sup> Viral infections impair olfaction either by obstructing nasal airflow or by causing damage to the olfactory epithelium.<sup>87</sup> Trauma to the head or nose can shear fragile olfactory nerves crossing the cribriform plate.<sup>164,187</sup>

Chronic exposures to numerous xenobiotics are associated with olfactory dysfunction (Table 25–2). The most commonly cited toxic mechanism is perceptive olfactory dysfunction. This is a result of a direct injury, or of a structural alteration of the receptor or its components such as G proteins, adenylate cyclase, or receptor kinase.<sup>85,86</sup> Anosmia or hyposmia from hydrocarbons, formaldehyde, cadmium, and chemotherapeutics such as cytarabine results from direct effects on the receptor sites.<sup>52,86,91</sup> Local effects on the epithelium and the receptors from antibiotic nose drops leads to temporary anosmia and hyposmia.<sup>97,201</sup> Inhaled corticosteroids have local effects on the epithelium, as well as direct effects on both G proteins and adenylate cyclase.<sup>88</sup> Cocaine insufflation causes direct local effects such as nasal septum perforations, as well as effects on receptor functions.<sup>74,76</sup> Because of the limited local effects of most xenobiotics and the regenerative ability of the olfactory receptor neurons, most xenobiotic-induced olfactory dysfunction is reversible.

Many individuals determined to have anosmia actually have congenital anosmia for select molecules, such as hydrogen cyanide, *n*-butyl mercaptan, trimethylamine, and isovaleric acid.<sup>7,48</sup> Some extreme forms of congenital anosmia are associated with other abnormalities, such as Kallmann syndrome, a hereditary form of anosmia associated with hypogonadotropic hypogonadism in which agenesis of the olfactory bulbs and incomplete development of the hypothalamus are responsible for the anosmia.<sup>48,164</sup>

*Dysosmia* or *parosmia* is the distorted perception of smell (Table 25–2). Subclassifications of dysosmia include the perception of foul smell or

TABLE 25–2 Xenobiotics Responsible for Disorders of Smell

<i>Hyposmia/Anosmia</i>	<i>Dysosmia/Cacosmia/Phantosmia</i>
Acrylic acid	β-Adrenergic antagonists
Antihyperlipidemics: cholestyramine, clofibrate, gemfibrozil, HMG-CoA reductase inhibitors	Amebicides/anthelmintics: metronidazole
Cadmium	Anesthetics, local
Chlorhexidine	Anticonvulsants: carbamazepine, phenytoin
Cocaine	Antihistamines
Formaldehyde	Antihypertensives: angiotensin-converting enzyme inhibitors, diazoxide
Gentamicin nose drops	Antimicrobials
Hydrocyanic acid	Antiinflammatory
Hydrocarbons (volatile)	Antirheumatics: allopurinol, colchicine, gold, D-penicillamine
Hydrogen sulfide	Antiparkinsonians: levodopa, bromocriptine
Methylbromide	Antithyroid drugs: methimazole, methylthiouracil, propylthiouracil
Nutritional	Calcium channel blockers
Vitamin B <sub>12</sub> deficiency	Dimethylsulfoxide
Zinc deficiency	Ethacrynic acid
Pentamidine	Insecticides
Sulfur dioxide	Lithium
	Nicotine
	Nonsteroidal antiinflammatory drugs
	Opioids
	Sympathomimetics
	Toothpastes
	Vitamin D

Anosmia = the loss of smell; cacosmia = sensation of a foul smell; dysosmia = a distorted perception of smell; hyposmia = a decreased perception of smell; phantosmia = sensation of smell without stimulus.

*cacosmia*, or *phantosmia* the sensation of smell without a stimulus, or such as the sensation of the smell of a burnt or metallic material, *torquosmia*.<sup>161</sup> The etiologies are classified as peripheral or central. Peripheral etiologies include abnormalities of the nose, sinuses, and upper respiratory tract. Central etiologies are related to disorders such as Addison disease, hypothyroidism, temporal lobe epilepsy, psychosis, or pregnancy.<sup>48,122,162</sup> How these conditions actually alter the perception of smell is unclear. A number of xenobiotics with similar effects are listed in Table 25–2. Bromocriptine alters dopaminergic transmission and inhibits adenylate cyclase. Levodopa affects the dopaminergic transmission and also chelates zinc, which is important in the maintenance of normal receptor functions.<sup>86,88</sup>

### Evaluation of Olfactory Impairment

General evaluation of olfactory function includes a detailed history, focusing on types, duration, and progression of symptoms, recent illnesses, head and nose trauma, sinus diseases, family history, occupational history, exposures hobbies, and xenobiotic exposures.<sup>44,77</sup> A physical examination with a detailed examination of the nasopharynx and sinuses is performed to assess the potential for inflammation or structural abnormality. A simple set of olfactory stimulants, such as ground coffee, almond extract, peppermint extract, and musk, is recommended to test each nostril individually with the patient's eyes closed.<sup>77,164</sup> Standardized smell tests such as the University of Pennsylvania Smell Identification Test (UPSIT) and the Connecticut Chemosensory Clinical Research Center (CCCRC) tests are commercially available, and a composite score based on a panel of tests determines the degree of olfactory dysfunction.<sup>114</sup> Pungent odors or stimulation associated with ammonia, capsaicin, acetone, and menthol are dependent on the trigeminal nerve (CN V) olfactory function, which is mainly responsible for tactile pressure, pain, and temperature sensation in the mouth and nasal cavity. A patient who has olfactory nerve damage should be able to detect these substances; conversely, a person with hysteria

may deny detection of these substances that should physiologically be recognized.<sup>77,164,201</sup> If a xenobiotic-mediated mechanism is suspected, the offending xenobiotic should be discontinued. Coronal computed tomography of the sinuses and nose or magnetic resonance imaging of the brain should be obtained if structural abnormalities are suspected.<sup>164,201</sup> Gas chromatographic analysis of the urine is useful in patients with fish odor syndrome associated with trimethylaminuria.<sup>108,174</sup> Complicated cases and patients with significant impairment should be referred to an otolaryngologist or neurologist.

## GUSTATION

### Anatomy and Physiology

Taste, the sensory interpretation of oral materials, is determined by taste buds on the tongue, palate, throat, and upper third of the esophagus. The cells in the taste buds have a life span of 10 days and are constantly renewed.<sup>11,164</sup> The taste buds on the anterior two-thirds of the tongue and the palate are innervated by the facial nerve (CN VII), those on the posterior one-third of the tongue by the glossopharyngeal nerve (CN IX), and those on the laryngeal and epiglottal regions by the vagus nerve (CN X). The signals are sent to the solitary nucleus in the brain stem, where they are processed and distributed to various regions of the brain. There are at least 14 known chemical taste receptors responsible for the 5 primary taste sensations—sweet, sour, bitter, umami (savory), and salty: 2 sodium receptor types; 2 potassium receptor types; one chloride receptor; one adenosine receptor; 2 inosine receptors; 2 sweet receptor types; 2 bitter receptor types; one glutamate receptor; and one hydrogen ion receptor.<sup>79</sup> One substrate will typically activate multiple taste receptors; the combined effects of these stimulated receptors determine the taste of the substance.<sup>66</sup>

The structure of the taste receptors is similar to that of the olfactory receptors, in that they are coupled to G proteins and sodium and calcium channels permitting neural stimulation. Each receptor is capable of interacting with various classes of xenobiotics, of varying sizes. The pH of the xenobiotic determines sour (acid taste), whereas sodium or potassium concentrations determine salty taste. Many xenobiotics such as sugars, glycols, aldehydes, ketones, amides, amino acids, inorganic salts of lead, and beryllium activate the sweet receptors. Bitter taste results from long-chain organic substances containing nitrogen, or alkaloids, including quinine, strychnine, caffeine, and nicotine.<sup>13,79</sup> The threshold for bitter receptor stimulation is several orders of magnitudes lower than other taste receptors.<sup>13</sup> Umami taste is a more recently accepted primary taste, best defined as a pleasant savory taste. The primary xenobiotic that stimulates umami receptor is glutamate, such as monosodium-L-glutamate. Umami receptor stimulation is enhanced by 5'-ribonucleotide monophosphates such as inosine and guanosine.<sup>205</sup> Salivary proteins, such as zinc containing gustin and ebnerin, are important in the regulation of taste sensation.<sup>86,90,110,172</sup> These molecules serve as binding proteins and growth factors for the regeneration of taste receptors. Taste is also affected significantly by the appreciation of aromas or odors and, to a lesser extent, by visual perception.<sup>162</sup>

### Classification of Gustatory Dysfunction

Types of gustatory dysfunction include *ageusia*, the inability to perceive taste; *hypogeusia*, the diminished sensitivity of taste; and *dysgeusia*, the distortion of normal taste. There are several variations of *dysgeusia*, such as *cacogeusia*, which is a perceived foul, perverted, or metallic taste.<sup>77,119</sup> Taste impairment is commonly related to direct damage to the taste receptors, adverse effects on their regeneration, or effects on receptor mechanisms.<sup>87</sup> These effects result from a xenobiotic, disease, aging, and nutritional disorders (Table 25–3).<sup>72,79,152,183</sup> Any abnormality that interferes with either the direct contact of a xenobiotic with the gustatory cells of the tongue or cranial nerves VII, IX, or X dramatically affects taste.<sup>161</sup> Most common forms of xenobiotic-induced dysgeusia are related to direct effects on the taste receptor site or effects related to receptor mechanisms such as G proteins, adenylate cyclase, and calcium channels.<sup>106</sup> Other forms of dysgeusia result from direct stimulation of chemical receptors by xenobiotics.<sup>79,86</sup>

TABLE 25–3 Xenobiotics Responsible for Alterations of Taste

<i>Hypogeusia/Ageusia</i>	<i>Dysgeusia</i>	<i>Metallic Taste</i>
<b>Local</b>	<b>Local</b>	<b>ACE inhibitors</b>
Chemical and thermal burns	Chemical burn	Acetaldehyde
Radiation therapy	Radiation therapy	Allopurinol
<b>Systemic</b>	<b>Systemic</b>	Arsenicals
ACE inhibitors	ACE inhibitors	Cadmium
Amiloride	Adriamycin	Ciguatoxin
Amrinone	Amphotericin B	Copper
Carbon monoxide	Botulism (in recovery)	<i>Coprinus</i> spp
Cocaine	Carbamazepine	Dipyridamole
Dimethylsulfoxide	Dimethylsulfoxide	Disulfiram
Gasoline	5-Fluorouracil	Ethambutol
Hydrochlorothiazide	Griseofulvin	Ferrous salts
Methylthiouracil	Isotretinoin	Flurazepam
Nitroglycerin	Levodopa	Iodine
NSAIDs	Nicotine	Lead
Penicillamine	Nifedipine	Levamisole
Propranolol	NSAIDs	Lithium
Pyrethrins	Phenylthiourea (hereditary)	Mercury
Smoking	Quinine	Methotrexate
Spironolactone	Zinc deficiency	Metformin
Triazolam		Metoclopramide
		Metronidazole
		Pentamidine
		Pine nuts
		Procaine penicillin
		Propafenone
		Snake venom
		Tetracycline

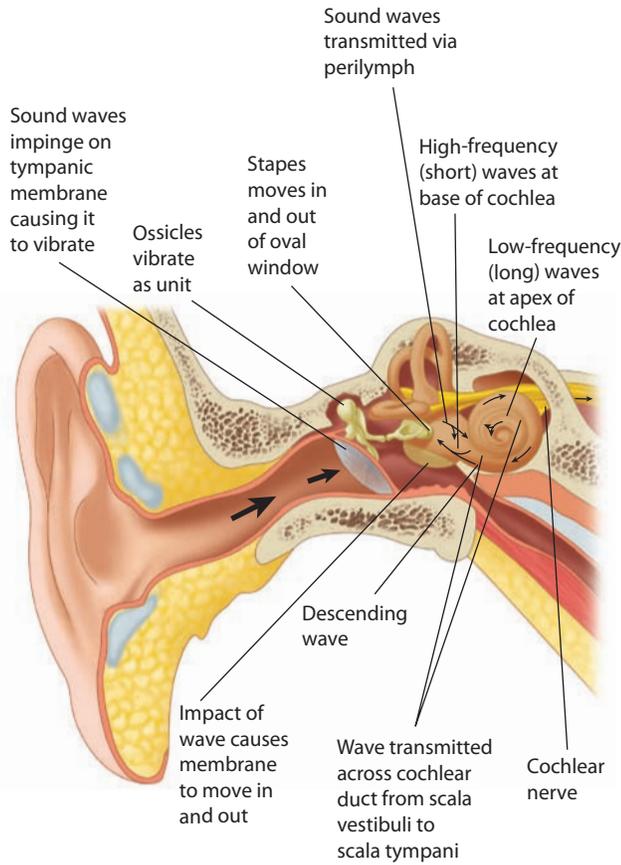

ACE = angiotensin-converting enzyme; NSAID = nonsteroidal antiinflammatory drug.

Angiotensin-converting enzyme (ACE) inhibitors commonly cause gustatory impairment, usually hypogeusia and dysgeusia.<sup>19,74,121,203</sup> Angiotensin-converting enzyme inhibitors work by inhibiting zinc-dependent ACE, and chelating zinc from taste receptors and salivary proteins results in gustatory dysfunction. Calcium channel blockers act by inhibiting calcium channels of the taste receptor mechanisms.<sup>79</sup> Many diuretics cause zinc depletion by enhancing zinc elimination in the urine,<sup>79</sup> whereas furosemide and spironolactone may also chelate zinc. Numerous xenobiotics also cause gustatory dysfunction through variable degrees of zinc chelation: amrinone, ethambutol, hydralazine, methylodopa, the nonsteroidal antiinflammatory drugs (NSAIDs), antithyroid medications, penicillamine, and phenytoin.<sup>79,86,204</sup> Arsenic, mercury, chromium, and lead either lead to chelation of zinc or replace zinc in salivary proteins because of a higher level of affinity. Chemotherapeutics and colchicine inhibit cellular division and taste receptor regeneration. The oral antiseptic chlorhexidine directly alters taste receptor function.<sup>62</sup> Acetazolamide causes cacogeusia when carbonated beverages are consumed. The exact mechanism is unclear, but is postulated to be a result of the inhibition of carbonic anhydrase causing carbon dioxide accumulation and an increased tissue bicarbonate.<sup>86,99,124</sup>

## HEARING

### Anatomy and Physiology

Normal hearing begins when sound waves are captured by the external auricle, traverse the external auditory canal, and are conducted to the tympanic membrane, the 3 auditory ossicles of the middle ear, and move (although dampened) through the oval window to the perilymph in the scala vestibuli

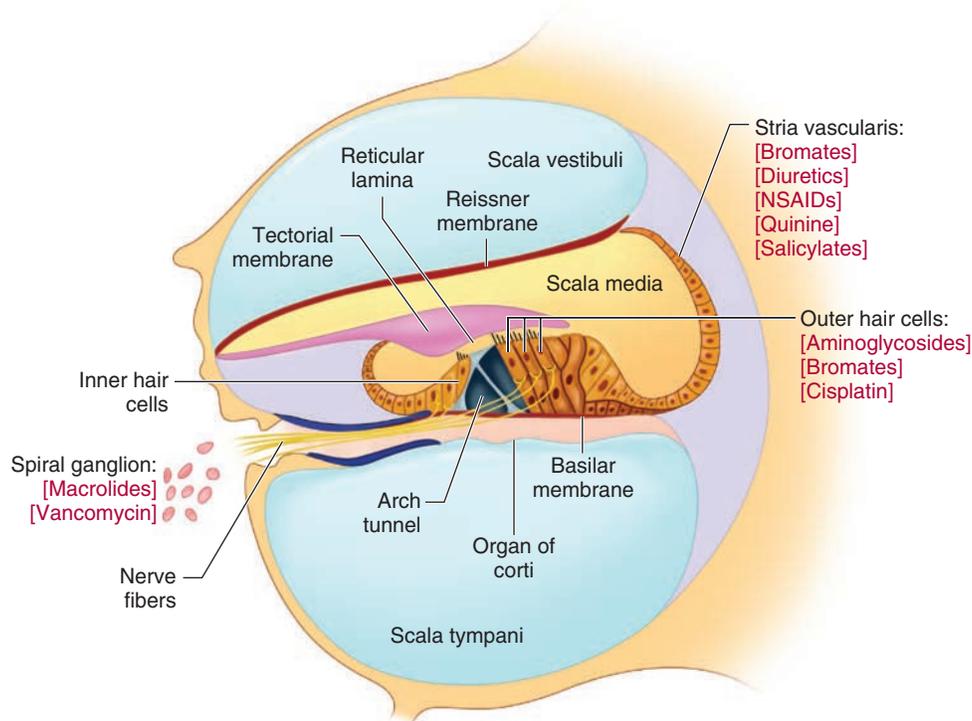

**FIGURE 25-1.** Pathways of sound conduction in the ear.

of the cochlea (Figs. 25-1 and 25-2). The sound wave is then transferred through the Reissner membrane at the roof of the cochlear duct, to the endolymph and the organ of Corti.<sup>58,178</sup> The specialized hair cells of the organ of Corti convert mechanical waves into neurologic signals. The hair cells

contain crosslinked stereocilia projections that detect transmitted shear forces, which lead to the influx of potassium from the endolymph through opened potassium channels.<sup>46,112</sup> Depolarization of the hair cells results in calcium influx and neurotransmitter release to the cochlear nerve. Repetitive movements of the stereocilia will amplify the specific sound signals. Neurologic signals from the cochlear nerve are conducted to the cochlear nucleus of the pons; bilateral projections are then sent to the superior olivary nucleus of the midbrain, nuclei of lateral lemnisci, inferior colliculus, medial geniculate body of the thalamus, and then to the auditory cortex of the temporal lobe.<sup>178</sup> Interruption or damage to any part of the hearing mechanism will lead to auditory impairment.

The anatomy and physiology of the cochlea and its importance in the biomechanics of hearing are reviewed in order to better understand the potential for xenobiotic injury. The word *cochlea* is derived from the Greek word *kochlias*, meaning snail, and describes its general structure—a 2.5-turn, spirally wound tube. The cochlea is further divided into 3 inner tubular structures: the upper tube or scala vestibuli, the middle tube or cochlear duct, and the lower tube or scala tympani. The scala vestibuli and the scala tympani contain the perilymph fluid. The cochlear duct contains endolymph fluid, the Reissner membrane at the roof, and the organ of Corti.<sup>178</sup> The cochlear fluids serve multiple functions: to conduct sound waves to the hair cells; to provide nutrients for and remove waste from the cells lining the cochlear duct; to control pressure distribution in the cochlea; and to maintain an electrochemical gradient for the function of the hair cells. The sodium concentration of the perilymph is similar to that of the extracellular fluid, and the potassium concentration of the endolymph is similar to that of the intracellular fluid.<sup>60</sup> Any significant alterations of the sodium or potassium concentrations will depress the cochlear potential and function. The stria vascularis controls the production of the cochlear fluids and the repolarization of the hair cells, and maintains the electrochemical gradient between the endolymph and the perilymph. The stria vascularis contains a high concentration of the oxidative enzymes, Na<sup>+</sup>,K<sup>+</sup>-ATPase, adenylate cyclase, and carbonic anhydrase, which are all highly susceptible to xenobiotics.<sup>21,92,159</sup>

Although human speech is composed of sounds in the frequency of 250 to 3,000 Hz, humans can normally detect sounds in the frequency range of 20 to 20,000 Hz.<sup>136</sup> The cochlea is a “tuned” structure with varying width and stiffness, such that different regions receive different sound waves. The stiffer

**FIGURE 25-2.** Cross-section of the organ of Corti showing sites of xenobiotic effect.

and wider base of the cochlea serves as a receptacle for higher-frequency sounds, whereas the apex is responsible for receiving the lower-frequency sounds.<sup>58</sup> Because various regions of the cochlea are susceptible to different forms of injury, audiologic testing is tailored specifically to each patient.<sup>29</sup>

**Xenobiotic-Induced Ototoxicity**

Ototoxicity includes effects on the cochlear and vestibular system. This section focuses on cochlear toxicity. Quinine and salicylates were widely recognized in the 1800s and streptomycin in the 1940s as causes of ototoxicity.<sup>92,154</sup> Drugs of abuse such as cocaine and heroin also cause hearing loss.<sup>36,40,133,165,167,173,182</sup> Several hundred xenobiotics are implicated as causes of either reversible or irreversible ototoxicity (Table 25-4).<sup>23,96,104,130</sup> Ototoxic xenobiotics primarily affect 2 different sites in the cochlea: the organ of Corti—specifically the outer hair cells—and the stria vascularis. Because of the limited regenerative capacity of the sensory hair cells and other supporting cells, when significant cellular damage occurs, the loss is often permanent.<sup>50,58,92,176</sup> Although cell death of the outer hair cells from inflammation and necrosis is expected when sufficient insults occur, apoptotic cell death is now postulated to be a major mechanism of ototoxicity from certain xenobiotics such as cisplatin and aminoglycosides.<sup>21,23,47,92,96,151</sup> Inhibition of caspases and calpain associated with apoptosis of the hair cells decreases ototoxicity from cisplatin and aminoglycosides in animals.<sup>151,175</sup> Heat shock proteins are endogenous molecules that respond to cellular stress and inhibit apoptosis. Xenobiotics, such as celestrol, that can up-regulate heat shock proteins prevent cisplatin and aminoglycoside toxicity in animal models.<sup>43,64</sup> Further studies are required to demonstrate clinical utility. Evidence supports the concept that otic injury is potentiated by loud noises. Although the actual cellular mechanisms for many forms of ototoxicity remain unclear,<sup>200</sup> some of the mechanisms are known.<sup>69</sup> Loop diuretics, such as furosemide, bumetanide, and ethacrynic acid, cause physiologic dysfunction and edema at the stria vascularis, resulting in reversible hearing loss.<sup>92,117,194</sup> The underlying mechanisms are the inhibition of potassium pumps and G proteins associated with adenylate cyclase.<sup>9</sup> Studies of loop diuretics demonstrate decreased potassium activity in the endolymph and a decreased endocochlear potential.<sup>156</sup> Permanent hearing loss associated with furosemide and ethacrynic acid is also reported, and appears to be related to direct interference with oxidative metabolism in the outer hair cells.<sup>105,117,166</sup>

Salicylates are a well-known cause of ototoxicity. Aspirin (acetyl-salicylic acid)-induced hearing impairment was first reported in 1877.<sup>100</sup> Salicylate-induced hearing loss is generally a loss of 20 to 40 decibels (dB) and reversible.<sup>18,90</sup> Animal studies demonstrate immediate hearing impairment with the use of high doses of salicylates.<sup>17,118,119,143</sup> The mechanism of salicylate-induced ototoxicity is unclear, although multiple factors are postulated. Salicylates and other NSAIDs inhibit cyclooxygenase, which converts arachidonic acid to prostaglandin G<sub>2</sub> and prostaglandin H<sub>2</sub>. These effects interfere with Na<sup>+</sup>,K<sup>+</sup>-ATPase pump function at the stria vascularis, and also decrease cochlear blood flow.<sup>31,53,100</sup> A reversible decrease in outer hair cell turgor secondary to membrane permeability changes impair otoacoustic emissions.<sup>142,146</sup> In support of these theories, pretreatment of

animals with leukotriene antagonists and α-adrenergic receptor antagonists attenuates or prevents salicylate-induced ototoxicity.<sup>100</sup>

Nonsteroidal antiinflammatory drugs and quinine also cause reversible hearing loss, particularly at the higher frequencies.<sup>33,92</sup> Occasionally, quinine-induced hearing loss is permanent.<sup>92,160</sup> The primary mechanism is related to prostaglandin inhibition.<sup>100</sup> Quinine inhibits the enzyme phospholipase A<sub>2</sub>, which converts phospholipids to arachidonic acid. Quinine also inhibits calcium channels that interact with prostaglandins.<sup>100</sup>

Certain chemotherapeutics, such as cisplatin, vinblastine, and vincristine, cause permanent ototoxicity.<sup>92</sup> Cisplatin is the most ototoxic of the group, with clinically apparent hearing loss noted in 30% to 70% of the patients receiving doses of 50 to 100 mg/m<sup>2</sup>. Other platinum derivatives such as carboplatin and oxaliplatin are less ototoxic than cisplatin. These chemotherapeutics typically damage the outer hair cells and also affect the stria vascularis.<sup>92</sup> The underlying mechanisms are related to the inhibition of adenylate cyclase in the stria vascularis, the inhibition of protein synthesis, and the formation of oxygen free radicals.<sup>9,92,166</sup> The generation of oxygen free radicals and the depletion of antioxidants result in the irreversible damage to the hair cells.<sup>56</sup> Furthermore, cranial radiation will cause synergistic toxicity if radiation precedes cisplatin therapy. Various antioxidants and free radical scavengers prevent cisplatin-induced ototoxicity in animals, perhaps preventing oxidative injury–induced apoptosis to hair cells.<sup>110,125,128,148,151,155,180,198</sup> Amifostine, a precursor to a thiol free radical scavenger, prevents cisplatin-induced nephrotoxicity, does not prevent cisplatin-induced ototoxicity.<sup>158,193</sup>

The aminoglycosides are best known for their association with irreversible ototoxicity,<sup>141</sup> but they are not concentrated in the cochlea. The endolymph concentration of gentamicin is approximately 10% of that in the serum. Neomycin and kanamycin are the most ototoxic, although all aminoglycosides are potentially toxic.<sup>105</sup> With the development of the newer aminoglycosides and therapeutic drug monitoring, the incidence of aminoglycoside-related ototoxicity is decreasing. The reported rates of ototoxicity for the more commonly used aminoglycosides gentamicin and tobramycin are between 5% and 8%.<sup>116</sup> In China, where aminoglycosides are readily available as nonprescription medications, as much as 66% of deafness is directly related to aminoglycoside toxicity.<sup>67,112</sup> Several uncommon genetic mutations that predispose to aminoglycoside-induced ototoxicity are identified, including A1555G and C1494T mutations.<sup>61,81</sup> The genetic transmission appears to be maternal via mitochondrial DNA, and the defects increase aminoglycoside binding to mitochondrial 12S ribosomal RNA.<sup>61</sup> These patients may experience rapid and severe hearing loss compared with normal people with a similar aminoglycoside exposure.<sup>151</sup>

Several mechanisms of aminoglycoside ototoxicity are postulated, including antagonism of calcium channels of the outer hair cells of the cochlea, blocking transduction of the hair cells and resulting in acute, reversible hearing deficits as well as binding to polyphosphoinositides of cell membranes to alter their functions. Polyphosphoinositides are essential for the generation of the second messengers diacylglycerol and inositol triphosphate and their ultimate cellular function, for the maintenance of lipid membrane structure and permeability, and as a source for arachidonic acid.<sup>92,151</sup> However, the most important mechanism is that aminoglycosides interact with transitional metal cations such as iron and copper via the Fenton or Fentonlike reaction to generate free radicals, damaging the hair cells. Aminoglycosides inhibit aconitase in the mitochondria and cause the accumulation of cations including iron that increases free radical generation. Aminoglycosides also inhibit ornithine decarboxylase, which is important for cellular recovery following an injury and makes the cell more susceptible to toxicity.<sup>159</sup> The outer hair cells of the cochlea are increasingly susceptible to aminoglycosides, and damage progresses from the inner row of the outer hair cells to the basal turn of the cochlea and, ultimately, to the apex.<sup>4,7,105,151</sup>

The risks of ototoxicity are increased with a duration of therapy of more than 10 days, concomitant use of other ototoxic xenobiotics, and the development of elevated serum concentrations.<sup>7,59,157</sup> There is no evidence that

**TABLE 25-4 Etiologies of Xenobiotic-Induced Hearing Loss**

Reversible	Irreversible
Antimicrobials: chloroquine, erythromycin, quinine	Aminoglycosides
Carbon monoxide	Bromates
Cocaine	Chemotherapeutics: bleomycin, cisplatin, nitrogen mustard, vincristine, vinblastine
Diuretics: acetazolamide, bumetanide, ethacrynic acid, furosemide, mannitol	Hydrocarbons: styrene, toluene, xylene
Nonsteroidal antiinflammatory drugs	Metals: arsenic, lead, mercury
Opioids (frequently)	Opioids (infrequently)
Salicylates	

single daily dosing of aminoglycosides alters the risk of ototoxicity.<sup>138,191</sup> Loop diuretics increase aminoglycoside toxicity by increasing aminoglycoside penetration into the endolymph. In animal models, certain free radical scavengers, such as glutathione, amifostine, and deferoxamine, decrease aminoglycoside-induced ototoxicity.<sup>70,160,181,188,192</sup> Fosfomycin, a phosphonic antibiotic, has limited efficacy in reducing aminoglycoside-induced ototoxicity.<sup>135</sup> Leupeptin and Z-DEVD-FMK, calpain and caspase inhibitors, respectively, that affect the apoptotic pathway, decrease ototoxicity in animal models.<sup>34,69,170,175</sup> Further studies are required to determine their applicability to humans. Salicylates, which act as free radical scavengers at therapeutic concentrations, prevent gentamicin ototoxicity in animals. Two randomized human trials using concomitant salicylate therapy at 1.5 and 3 g/d significantly attenuated gentamicin-induced ototoxicity.<sup>12,171</sup> Gastric adverse effects, including bleeding, were also more common in the salicylate group. Confirmation of these findings and determining safer alternatives are warranted.

Erythromycin, vancomycin, and their respective analogs are ototoxic. There are a number of reports of hearing loss following erythromycin therapy in humans and an animal study supporting the ototoxic potential. Most deficits in humans are transient, although several cases of permanent hearing loss are reported.<sup>22,25</sup> The mechanisms of toxicity remain unclear, although the proposed effects are on the central auditory pathways. Erythromycin-induced hearing loss occurs at both lower and higher frequencies for speech, allowing for recognition in the early stages of ototoxicity.<sup>25</sup> Similarly, both reversible and irreversible ototoxicities from the newer macrolide antibiotics clarithromycin and azithromycin are reported.<sup>83,123</sup> However, a large retrospective epidemiologic study failed to demonstrate hearing loss with macrolide antibiotics.<sup>54</sup>

The evidence for vancomycin-induced ototoxicity is less convincing. Although numerous cases of presumed vancomycin-related ototoxicity were reported, impurities with initial vancomycin production, and concomitant use of other ototoxic antibiotics and xenobiotics were common, and the lack of audiometric studies lead to complicated conclusions.<sup>25</sup> In limited animal studies, vancomycin alone does not induce ototoxicity, but it increases ototoxicity when administered concomitantly with an aminoglycoside.<sup>24,113,190</sup> A recent retrospective found an increase in hearing loss with vancomycin usage; the study did not find an association with trough vancomycin concentrations and some patients had concomitant ototoxicity xenobiotics.<sup>63</sup> Currently, there are inadequate information on the ototoxicity of other glycopeptide antibiotics similar to vancomycin such as teicoplanin, televancin, and daptomycin.

Bromates are among the most extensively studied ototoxic xenobiotics.<sup>33,39,115,144</sup> Bromates are used in hair “neutralizers,” bread preservatives, and as fuses in explosive devices.<sup>93,144,184</sup> Following bromate administration the stria vascularis and hair cells of the organ of Corti are irreversibly damaged.<sup>144</sup> Substantial exposure to bromates also causes acute kidney injury, which decreases bromate elimination and, in turn, increases its ototoxic potential.<sup>93,144</sup>

It is intriguing that xenobiotics, such as the bromates, loop diuretics, cisplatin, and aminoglycosides, primarily affect both the cochlea and the kidneys. One possible explanation is that the stria vascularis and the renal tubules have similar functions in maintaining electrochemical gradients.<sup>135,136</sup> However, renal tubules regenerate, whereas damage to the hair cells and the stria vascularis of the cochlea is more likely to be permanent. Membrane transporters such as copper-transporter-1 (CTR1) and organic cation transporter 2 (OCT2) are important in the movement of xenobiotics such as cisplatin into cells. Although CTR1 is expressed in many types of cells, OCT2 expression is limited to renal, cochlear, and neural cells and may be critical to cellular toxicity.<sup>37</sup> Targeting the effects of OCT2 has the potential to limit both renal and cochlear toxicity.<sup>199</sup>

Sudden hearing loss is reported with recreational drug use, particularly with cocaine and opioids. For cocaine, the mechanism of injury is presumed to be related to cochlear hemorrhage and hypoxia subsequent to vasoconstriction.<sup>40,133,182</sup> Although other mechanisms such as a direct effect on the potassium channels in the hair cells and sodium channels of the auditory nerve are

postulated, they are not well elucidated in animal models. Concomitant opioid use and adulterants should be evaluated. Various opioids, including heroin, methadone, and hydrocodone, are associated with hearing loss.<sup>36,165,167,173</sup> Neither the route of use nor the presence of adulterants such as quinine can adequately explain the hearing loss. Most cases of opioid-associated hearing loss are reversible, but some are permanent. The mechanisms of opioid-associated hearing loss are unclear. Cases that involved the use of naloxone did not reverse hearing loss, which suggests a different mechanism from the well-known opioid effect that causes respiratory depression.<sup>131,195</sup> Several cases of opioid-acetaminophen-induced hearing loss responded well to cochlear implantation suggesting the site of injury involving the cochlea sparing the auditory nerve.<sup>16,65,134,195</sup> Hypoperfusion of the vestibulocochlear system secondary to opioid-induced vasospasm or vasculitis is postulated to be the cause of injury.<sup>36,134,165,173,195</sup> Another potential mechanism is the stimulation of opioid receptors in the cochlea, which inhibits adenylate cyclase activity, leading to hearing loss.<sup>57</sup> Various opioid receptors are identified in the cochlea, such as in the inner hair cells, outer hair cells, and the spiral ganglion. Others postulate that opioids have potential roles as neurotransmitters or neuromodulators that affect auditory function.<sup>98</sup>

Other xenobiotics implicated as ototoxins are carbon monoxide, lead, arsenic, mercury, toluene, xylene, and styrene.<sup>89,177</sup> However, both human and animal data are quite limited. Carbon disulfide, carbon tetrachloride, and trichloroethylene are also suspected of being ototoxic, but toxicity has not been demonstrated in humans.<sup>89,167</sup> Because exposures to xenobiotics are frequently occupational, they are of great concern as they may potentiate or be additive to other types of occupational hearing impairments.<sup>102,149</sup>

High-frequency hearing is most vulnerable, and early or limited impairment are often not noticeable unless audiometry, especially at 8,000 kHz and above, is performed.<sup>189</sup> These hearing tests are performed in infants using the measurement of auditory brain stem response.<sup>14</sup>

## Noise-Induced Hearing Impairment

Noise-induced hearing impairment was recognized for hundreds of years, but became a great concern and increasingly prevalent with the industrial revolution and the discovery of gunpowder.<sup>54</sup> Some of the anatomic changes in the organ of Corti and the audiometric features of noise-induced hearing impairment were well described by 1900.<sup>2,3,120</sup> Unfortunately, few longitudinal studies on noise-induced hearing impairment are performed.

Although noises of sufficient magnitude cause hearing impairment with limited exposure, most noise-induced hearing losses result from preventable prolonged cumulative occupational exposure. The National Institute for Occupational Safety and Health has estimated that up to 1.7 million workers in the United States between 50 and 59 years of age have significant occupation-related hearing loss.<sup>135</sup> Noise is defined as any unwanted sound, which can be further characterized by duration, time pattern (continuous, intermittent, or impulsive), frequency, and intensity. Although loud sounds from concerts and personal listening devices are not typically classified as noise, they are included as noise for the purpose of this discussion. The intensity is measured in sound pressure levels (SPLs) and expressed in a logarithmic scale in decibels (dB). The intensity of a normal conversation is approximately 65 dB (Table 25–5).<sup>135</sup> The risk of noise-induced hearing loss is related to cumulative duration of exposure, intensity, and individual susceptibility.<sup>132,139,197</sup> Much of the risk assessment of noise-induced hearing loss is inexact. Most authorities agree that sounds with maximal intensity below 75 to 80 dB will not cause hearing impairment, regardless of the duration of exposure.<sup>132</sup> At higher intensity, the risk of hearing impairment increases with increased duration of exposure. Continued occupational exposure at 90 to 94 dB typically causes some high-frequency hearing loss in approximately 10 years.<sup>2,139</sup> Further exposure results in hearing loss in the lower frequency range. The Occupational Safety and Health Administration (OSHA) established guidelines for permissible occupational noise exposure based on an analysis of the average intensity and duration of exposure (Table 25–6).<sup>2,197</sup>

The pathophysiology of noise-induced hearing impairment is related to an excessive energy impact on the cochlea, but the exact biochemical

**TABLE 25–5** Typical Sound Levels on the Decibel Scale

changes are unclear. Apoptotic death of the hair cells is demonstrated and inhibition of apoptotic pathways mitigates noise-induced toxicity in animal models. A limited exposure to excessive noise results in a temporary hearing impairment or temporary threshold shift with a duration of hours to weeks. However, prolonged exposure results in a permanent threshold shift or hearing impairment.<sup>3,58,197</sup> Initially, outer hair cells are lost, but more significant exposures result in damage to both inner and outer hair cells and all supporting structures in the organ of Corti. Cochlear nerve fibers degenerate after hair cell damage.<sup>58,197</sup> The section of the cochlea most at risk from loud noises is at the region of 9 to 13 mm (total length is 32 mm).<sup>120</sup> This region is responsible for hearing at the range of 3,000 to 6,000 kHz, corresponding to the typical noise-induced hearing loss pattern.

Much of the clinical assessment and monitoring of noise-induced hearing loss is based on pure tone hearing loss, demonstrating an audiometric deficit at 3,000 to 6,000 kHz.<sup>136,139,197</sup> Although human speech is composed

mainly of low frequency sounds, the ability to perceive the higher frequency sounds is extremely important in speech recognition. For this reason, the major impairment in patients with noise-induced hearing loss is an inability to discriminate speech, particularly from background noise.<sup>2,45</sup> Currently, the science of the investigation of speech discrimination is limited with extensive areas for research.

Blast injury to the ear results from exposure to sound waves of extremely short duration but very high intensity, usually greater than 140 dB. Military personnel are particularly at risk.<sup>32,140,186,189</sup> Hearing loss from blast injury is related to rupture of the tympanic membrane, disruption of the ossicles, temporary cochlear dysfunction, and permanent cochlear dysfunction from labyrinthine fistulae and basilar membrane rupture.<sup>30</sup> When a large tympanic membrane rupture or disruption of the ossicles occurs, surgical intervention is often required to treat hearing impairment.<sup>30</sup>

Prevention of any type of noise-induced hearing loss remains the best solution. Various hearing protection devices are available if the noise exposure cannot be reduced. Better monitoring and more longitudinal studies are required on noise-induced hearing loss. Exposures to xenobiotics that impair hearing have synergistic effects with noise-induced hearing loss.<sup>102,104</sup> These factors should be addressed when noise exposure is evaluated. Furthermore, noise exposure is not limited to the workplace. Significant noise exposure occurs at home or from leisure activities, such as the use of power tools, loud music, and ambient exposure.<sup>15,41,80,139</sup> The impact of noise exposure outside of the workplace has only recently attracted the attention of investigators.

### Tinnitus

Tinnitus is the sensation of sound not resulting from mechanoacoustic or electric signals. Virtually all humans experience tinnitus during their lives. The exact mechanism or mechanisms resulting in tinnitus are largely unknown.<sup>163</sup> Tinnitus is not necessarily associated with hearing loss. Several theories are proposed, but none is completely satisfactory. Tinnitus may result from spontaneous neurologic discharges when the hair cells or cochlear nerve is injured. Altered sound perception results from local or central effects when feedback mechanisms are interrupted.<sup>48,55,95,119</sup> Severing the cochlear nerve terminates tinnitus in less than half of affected patients, suggesting important central mechanisms.<sup>10</sup> Furthermore, certain etiologies of tinnitus, such as migraine headache and temporal lobe seizures, do not affect hearing directly. *N*-methyl-D-aspartate (NMDA) glutamate receptor activation (and enhanced cochlear signal transmission) is implicated as a mechanism for tinnitus in animal models; NMDA receptor activation results from cyclooxygenase inhibition or neurologic injuries.<sup>82,142</sup> Xenobiotics, including salicylates, cause hair cell dysfunction and modify neurotransmission centrally in both the cochlear nucleus and the inferior colliculus.<sup>71,196</sup> Although the probable sites involved in tinnitus are classified as peripheral (external ear, middle ear, or cochlear {CN VIII}), central, or extra-auditory (vascular, nasopharyngeal), some etiologies affect peripheral and central sites, and many etiologies remain unknown.<sup>38,55,119</sup>

Numerous xenobiotics are associated with tinnitus (Table 25–7), but the incidence is probably low and the implied relationships are usually supported only by case reports.<sup>35,168,169</sup> It is probable that the xenobiotics associated with hearing loss affect cochlear function, whereas those that produce tinnitus without hearing loss probably act on signal transmission at the cochlea and in the central nervous system. Xenobiotics that frequently produce tinnitus include streptomycin, neomycin, indomethacin, doxycycline, ethacrynic acid, furosemide, heavy metals, and high doses of caffeine.<sup>75,168,169</sup> Only a few xenobiotics, such as quinine and salicylates, consistently cause tinnitus at toxic doses.<sup>17,55</sup> These 2 xenobiotics also serve as examples of how the presence of tinnitus may be an indicator of xenobiotic toxicity and useful clinically.

Tinnitus associated with salicylates usually begins when serum concentrations are in the high therapeutic or low toxic range of approximately 20 to 40 mg/dL.<sup>126</sup> Membrane permeability changes cause a loss of outer hair cell turgor in the organ of Corti, which impairs acoustic emissions, explaining tinnitus to some extent.<sup>142,143,146</sup> *N*-Methyl-d-aspartate receptor

TABLE 25–7 Xenobiotics That Cause Tinnitus

β-Adrenergic antagonists
Antidepressants: amoxapine, cyclic antidepressants, lithium, tranylcypromine
Antiepileptics: carbamazepine
Antifungals: amphotericin B
Antihistamines
Antimicrobials: aminoglycosides, clindamycin, dapsone, metronidazole, sulfa derivatives, tetracyclines, thiabendazole, vancomycin
Antiparasitics: chloroquine, hydroxychloroquine
Antipsychotics: haloperidol, molindone
Bromates
Chemotherapeutics: 6-aminonicotinamide, cisplatin, methotrexate, nitrogen mustard, vinblastine
Cinchona alkaloids: quinine, quinidine
Diuretics: bumetanide, ethacrynic acid, furosemide
Hydrocarbons: benzene
Local anesthetics: bupivacaine, lidocaine, mepivacaine
Nonsteroidal antiinflammatory drugs
Oral contraceptives
Salicylates
Sympathomimetics: albuterol, caffeine, metaproterenol, methylphenidate, theophylline

activation from cyclooxygenase inhibition also causes tinnitus.<sup>142</sup> Before the wide availability of serum salicylate measurements, physicians treating gout or rheumatoid arthritis often titrated the salicylate dosage until tinnitus developed.<sup>126</sup> Tinnitus and other signs and symptoms of salicylism (Chap. 37) should be sufficient for physicians to diagnose salicylate toxicity before serum salicylate concentrations are available. However, tinnitus often is not evident in patients with hearing impairment despite significantly elevated salicylate concentrations.<sup>126</sup> The classic constellation of symptoms of quinine and salicylate toxicity, called cinchonism, includes nausea, vomiting, tinnitus, and visual disturbances.<sup>4,28,129</sup> Because serum quinine concentrations are not readily available, symptoms of quinine toxicity define the clinical diagnosis (Chap. 55).<sup>179</sup>

## SUMMARY

- Numerous xenobiotics commonly affect the sense of smell, taste, and hearing, thus causing significant morbidity.
- Some of the events are predictable, whereas others will require monitoring and appropriate testing.
- Current knowledge about the pathophysiology of xenobiotics and these special organs at the molecular level is rapidly expanding.
- Although no definitive antidote is available for the prevention or treatment of xenobiotic-induced ototoxicity in humans, substantial progress has been achieved in both in vitro and in vivo animal models.

# 26

## PSYCHIATRIC PRINCIPLES

Andrea M. Kondracke, Justin M. Lewin, Cathy A. Kondas, and Erin A. Zerbo

Psychiatric symptoms are often the cause of, or the effect of many toxicologic-presentations. Suicide attempts and aggressive behaviors are commonly associated with toxicity and can be uniquely difficult to assess and manage in the emergency department. Patient factors, clinician bias, and a lack of coordination of care exacerbate the difficulties and make evaluating and treating patients with psychiatric symptoms uniquely challenging in the medical setting. Patients are unable or unwilling to communicate adequately. They are frequently disorganized, psychotic, and engaged in self-injurious and/or dangerous behaviors. Mental illness, personality disorders, delirium, intoxication and withdrawal are frequently the underlying etiology of these behaviors and can interfere with treatment. The combative, threatening, and/or violent patient requires special consideration as the safety of the patient and staff is imminently jeopardized. The individual's medical condition and/or behavior can be life threatening, disruptive, and/or destructive. Patient behaviors are viewed dichotomously as deliberate, totally "out of control," and irrational. The truth is more complex, with some aspects occurring within the awareness and control of the patient and other aspects either unknown, out of the patient's control, and/or overwhelming to the patient. Coordination with and availability of psychiatric care is difficult and inaccessible.

Substances of abuse, overdose, and toxicity or adverse effects of psychiatric medications are the most obvious commonalities between the fields of psychiatry and toxicology. However, psychiatric symptoms overshadow other toxic or metabolic conditions and are confused for primary mental illnesses. In addition, the adverse effects or toxicity of xenobiotics mimics various symptoms of mental illness. Given the increased rates of suicide attempts and substance abuse among people with severe mental illness, distinguishing cause and effect is complex.

This chapter will review some of the special considerations that should be recognized when dealing with the overlap between psychiatry and toxicology. The chapter will start with an overview of the capacity assessment and its formal components. Then there is a discussion of the components of the medical evaluation of psychiatric patients for admission to a psychiatric facility. The third section is devoted to suicide and the suicidal or self-injurious patient. And finally substance use disorders are addressed. Principles of workplace violence and the violent patient will be addressed in Special Considerations: SC4.

### CAPACITY ASSESSMENT

"Decision-making capacity is the ability to understand relevant information and to appreciate the reasonably foreseeable consequences of the decision."<sup>3</sup> Every consent form requires documentation of some aspects of a capacity assessment. Physicians are legally and ethically obligated to obtain informed consent for treatment and procedures. The initial presumption when evaluating capacity is that all people have decisional capacity.<sup>2</sup> Depriving a patient of his or her decision-making rights is a serious infringement on his or her liberties that has legal and ethical implications. Yet, only a patient with capacity can legally consent to medical treatment. Allowing a patient without capacity to consent to medical treatment is also problematic and has legal and ethical implications.

Physicians are constantly evaluating capacity, although they are not always cognizant of this fact. Capacity assessments are done quickly and implicitly in every patient encounter. Physicians ask themselves, "Can my patient make a decision?" "Does my patient understand the seriousness of the illness?" "Does the patient understand the treatment being offered and why?" "Does the individual understand the implications of the treatment

and/or the implications of refusing the treatment?" "Does this patient have a problem that is interfering with his or her ability to understand or make a good decision?" If the patient appears to be making a poor decision, the physician may ask, "Why is the patient making this decision?" These are essential questions in patient care, a fundamental part of shared decision making and the basis of the capacity assessment.<sup>27</sup>

It is when there are impasses, ambiguity, or murky ethical situations that a patient's capacity comes into question, such as when a patient refuses a treatment that is clearly beneficial or life-sustaining. Another example occurs when a patient refuses treatment in the setting of a recent suicide attempt, such as refusing a treatment for a potentially lethal ingestion. In these scenarios, having a systematic approach to assessing capacity and good documentation is necessary.

It is important to note that capacity assessments occur at a specific moment in time regarding a specific medical decision. The assessment is not a "global" determination that persists throughout the hospitalization but rather it is a temporary determination that requires reassessment as factors change with time and/or situation. Capacity fluctuates with a change in the patient's mental status, medical or psychiatric condition, the time of day, amount of pain, level of anxiety, perceived support, recent medication administration, or in the context of withdrawal from a xenobiotic.

When assistance from a psychiatry consultant is requested, the primary physician should first perform his or her own capacity assessment. This should be done clearly and in the patient's native language. The physician should take into consideration the patient's health literacy, level of education, and cultural background. The information should be tailored to the patient's ability to understand. For example, it is not productive to refer to percentages to describe outcomes with a patient who has never learned basic math. The physician should be certain to address the medical condition, the procedure, the risks and benefits, and the option of "doing nothing."

The patient must engage in the evaluation. Refusal to engage indicates a lack of capacity by default.

The general legal standard for capacity requires assessment of 4 basic skills. They should be clearly documented.<sup>2</sup>

#### 1. Communicate a Choice

The patient must clearly indicate a preference or choice. This choice should be consistent long enough for the choice to be implemented. The physician could ask the question, "Have you decided what you would like to do?" A patient with capacity can alter their decision over time for a variety of logical reasons such as changes in their medical condition or as additional information becomes available. However, when an individual changes his or her decision repeatedly or is unable to come to a decision despite sufficient time and information, it suggests the individual lacks capacity to make that specific decision. These cases often occur in patients who have a high degree of ambivalence, have poor short-term memory, a thought disorder, or who are delirious.

#### 2. Understand Relevant Information

The patient must comprehend the fundamental information communicated by the care team.<sup>3</sup> The physician could ask, "Can you tell me about your medical problems?" "Can you tell me the procedure that is being offered to you?" "What are the risks and benefits?" This portion is preferably done by the primary physician who best understands the nuances of the procedure.

Often physicians assume that if the patient repeats these factors adequately, that is, the risks, benefits, and alternatives, then the patient has

capacity and the assessment is complete; however, this is not always the case. The patient should be able to understand and manipulate the information independently, which can be demonstrated by asking the patient to paraphrase the physician's explanations rather than repeat verbatim. Difficulties in this domain can arise from deficits in attention, intelligence, or memory.

### 3. Appreciate the Situation and Its Consequences

The patient must be able to incorporate the relevant information. The medical condition in question must be acknowledged, and the individual must demonstrate awareness that the risks and benefits being discussed apply to him or her specifically, and will have implications in the individual's life. The physician can ask, "How will this procedure affect you?" If a patient is unable to answer this question, then he or she does not demonstrate capacity. A statement such as "The doctors say I could die from a heart attack if I do not get this stent placed right now, but I know that's not going to happen to me" would call the patient's capacity into question. Difficulties in this area often arise from denial, mistrust of the physician, cognitive or affective impairment, or delusional/paranoid thought processes.

### 4. Reason About Treatment Options

The patient must be able to demonstrate how, in a logical progression, he or she arrived at the decision. This is a synthesis of all the other requirements. The physician should ask, "How did you come to this decision?" "Why are you willing or unwilling to have the procedure?" The patient should be able to compare treatment options and consequences, and be able to explain how he or she arrived at the decision, including the reasoning involved. Patients can make "unreasonable," "wrong," or "bad" decisions and still have capacity; poor judgment is not equivalent to a lack of capacity. Furthermore, despite the physician's best intentions, every attempt should be made to honor a patient's decision if he or she meets the threshold for capacity. The patient's autonomy should prevail. Difficulties in this domain often occur in patients with delirium, dementia, extreme phobia, panic, anxiety, psychosis, depression, or anger.

If the patient is unable to perform one or more of these steps then he or she lacks capacity. Once a patient has been deemed to lack capacity he or she should be so informed. An assessment of why the patient lacks capacity should follow. Then, every effort to restore capacity and, as such, patient autonomy, should be attempted. For example, a patient with a substance use disorder who is experiencing withdrawal and therefore demands to leave the hospital and unwilling to participate in any discussion would lack capacity. Treatment of an individual's withdrawal will result in significant relief and rapid re-establishment of capacity. A patient experiencing opioid withdrawal feels the need to leave the hospital to use heroin; a dose of methadone to relieve withdrawal symptoms will allow this patient to participate in capacity evaluation and provide a rationally articulate reason for his or her choice, and it often leads to a more reasonable decision to continue the recommended treatment. On the other hand, in a patient who lacks capacity due to an irreversible process such as dementia, capacity cannot be restored.

When a patient is determined to lack capacity in life-threatening situations, physicians need to treat the patient over patient objection. The physician should continue to consider the patient's autonomy.<sup>2</sup> Efforts should always be made to impose the least restrictive measures while still providing appropriate care.

When patients lack capacity, every effort to find an alternative decision maker should be made. When there is no designated health care proxy and family members are not in agreement about what treatment choice the patient would want if he or she had the capacity to make that decision, most states have determined a specific hierarchy to identify which family member should make the decision.<sup>3</sup>

The hierarchy is state dependent. For example, in New York State, the alternative decision maker is determined by the Family Healthcare Decision Act of 2010 which states the hierarchy as: spouse or domestic partner, adult child, parent, adult sibling, friend, or extended family".<sup>19</sup>

**TABLE 26-1** MacArthur Competence Assessment Tool—A Modified Overview<sup>34</sup>

#### Interview Process (15–20 minutes):

- Clinician discloses patient's disorder, recommended treatment, risks, benefits, and alternative treatments
- Patient expresses a treatment choice and explains how the choice was made

Questions embedded in the interview process assess patient's abilities in 3 areas:

#### 1. Understanding

- Ask the patient to paraphrase what has been disclosed about the disorder, the recommended treatment, and the risks/benefits.
- If a patient demonstrates poor understanding, redisclose the information and reassess. (If a patient wasn't paying attention or found the concepts unfamiliar, his or her understanding should improve with redisclosure.)

#### 2. Appreciation

- Does the patient acknowledge that the information applies to him or her? That treatment might have at least some benefit?
- A reasonable difference of opinion is permissible; however, if a patient's opinion is derived from delusional or distorted perceptions, these patients are lacking appreciation.

#### 3. Reasoning

- Has the patient expressed a preference? What are his or her explanations for making that choice? Does he or she mention any consequences of treatment alternatives, how alternatives compare, or any thoughts about consequences besides those offered in the disclosure? Does the patient's final choice follow logically from the explanation?
- If the patient is not able to logically explain how he or she arrived at a choice, or is inconsistent in the choice, this indicates a failure of reasoning.

Although it is important to know what a capacity assessment is, it is equally important to understand its limitations. It does not determine what, if any, treatment should be initiated. It is not a psychiatric evaluation, nor is it a judgment of soundness.

A well-researched scale for determining decisional capacity is the MacArthur Competence Assessment Tool for Treatment (MacCAT-T), which is a semi-structured interview that requires 15 to 20 minutes to administer and is designed for use in a clinical setting (Table 26-1).<sup>34</sup>

### Complexities of Capacity Determination in Clinical Settings

An important concept is the *sliding scale* of capacity, which has been supported by both expert consensus guidelines and the legal system. This "sliding scale" concept indicates that the threshold for deeming a patient to lack capacity changes depending upon the seriousness of the consequences. Refusing life- or limb-saving procedures requires the patient to demonstrate a very high level of understanding and reasoning. On the other hand, even if a patient shows limitations in one of the 4 basic skills during a capacity assessment and the risks of refusal are low, then the patient is thought to have capacity and the patient's autonomy prevails.

Decisional capacity is often part of a larger question about how to proceed with treatment for a particular patient. Once a patient is found to lack capacity, ethical questions arise about the appropriateness and practicality of imposing treatment. For example, should a patient who is refusing a necessary blood draw be sedated for the procedure? Sedating a patient has its own inherent risks, and psychological distress to the patient cannot be discounted. In these situations, it is often helpful to have a discussion involving the psychiatrist, and a general consensus can usually be reached weighing the risks and benefits of proceeding with treatment against a patient's will. In cases of life-threatening refusal of treatment, how to proceed is usually clear, but physicians often encounter situations in which the medical necessity of an intervention is urgent but not emergent. For example, for a patient who needs an amputation for an infected limb that is currently stable but will inevitably proceed to sepsis, the physician has a responsibility to petition the court for treatment over objection. These cases require a team approach involving psychiatry, risk management, legal services, and bioethics.

## MEDICAL EVALUATION OF THE PSYCHIATRIC PATIENT PRIOR TO ADMISSION TO A PSYCHIATRIC FACILITY

Not all patients who present with psychiatric symptoms have mental illness. Intoxication, withdrawal syndromes, medical illness, metabolic abnormalities, organic brain, seizure, and dementia often present with symptoms that mimic mental illness. The psychiatric patient is often unwilling or unable to fully cooperate, creating substantial difficulty in obtaining a comprehensive medical history.

Behavioral disturbances also present unique challenges to diagnostic assessment. Patients are often unwilling or unable to fully cooperate, making it difficult to obtain a comprehensive medical history.

Emergency medicine physicians are often asked to “medically clear” patients for transfer to psychiatric units or psychiatric facilities. These evaluations are challenging because there are no universal standards. In fact, the very term is misleading and can lead to the omission of important details of the patient’s medical history.

The purpose of “medical clearance” requested by evaluating psychiatrist is to:

1. determine if the patient has a serious medical condition that would make admission to a psychiatric hospital unsafe;
2. assess and treat any acute medical issue necessitating urgent or emergent intervention; and
3. help differentiate between an organic illness, a xenobiotic-induced disorder, and a primary mental illness as the cause of psychiatric symptoms.

The presence of either of the first 2 could well obviate the need for psychiatric admission and compromise or invalidate the accuracy of psychiatric assessment.<sup>46</sup> The evaluation should include a history and a thorough physical examination, including neurologic and mental status examination.

Some signs that suggest a medical cause of psychiatric symptoms include new onset of symptoms in a patient older than 40, abnormal vital signs, recent memory loss, or clouded sensorium.<sup>25</sup> Signs and symptoms that require further evaluation include abnormal vital signs, delirium, altered cognition, or an abnormal physical examination. Certain demographics are identified as high risk for medical instability: the elderly or very young, patients with substance abuse, abnormal movements, abrupt onset of symptoms, and patients with no prior psychiatric history. Patients with physical trauma and those with preexisting medical disorders or current medical complaints warrant special attention as well.<sup>33</sup>

Although the psychiatrist often requests routine laboratory testing for medical clearance, a number of studies demonstrate that selective testing based on history and physical examination is the correct and most cost-effective strategy. There is a strong consensus among physicians that routine laboratory testing is unnecessary, and without any clinical suspicion, the probability of false positive laboratory results begins to outweigh true positives.<sup>10,24</sup> The American College of Emergency Physicians provides a level B recommendation that diagnostic evaluation be directed by the history and physical examination, and that routine laboratory testing is low yield and not necessary as part of the emergency department assessment.<sup>46</sup>

The American Psychiatry Association and American Diabetes Association practice guidelines for starting patients on long-term second-generation antipsychotics include obtaining baseline fasting plasma glucose and fasting lipid as these medications are known to cause the metabolic syndrome and/or diabetes. Although these guidelines are not applicable to the emergency department setting, it is helpful to be aware of them.

The American College of Emergency Physicians also provides a level C recommendation against routine urine toxicology testing and blood alcohol concentrations in alert, awake and cooperative patients, and specifies that transfer to psychiatric care should not be delayed to await collection of samples for toxicologic analysis.<sup>46</sup> However, from the psychiatrist’s perspective, this testing is time-sensitive and can change psychiatric management and disposition considerably. If the emergency physician knows the patient will

be transferred for psychiatric care and suspects substance abuse, it is helpful to obtain toxicologic results as early as possible.

Another important and common issue is acute intoxication with ethanol. At what point is it acceptable and appropriate to “medically clear” the patient for psychiatric evaluation? There are no evidence-based data to support that patients regain decision-making capacity at a particular blood alcohol concentration. Depending upon tolerance, cognition varies widely, and patients often develop ethanol withdrawal while significantly elevated blood alcohol concentrations persist.<sup>22</sup> Therefore, The American College of Emergency Physicians provides a level C recommendation that the patient’s cognitive abilities be the basis on which the psychiatric assessment is initiated. A period of observation can be used to see if psychiatric symptoms resolve with resolution of intoxication, at which point the need for a psychiatric assessment can be revisited.<sup>46</sup>

Psychiatric facilities have varying degrees of capacity to care for medical conditions. Some facilities have onsite internal medicine providers and the ability to care for chronic or non-acute medical conditions. However, many do not. A shortcoming of psychiatric facilities is that few have the ability to care for either complicated acute or chronic medical illnesses. They often do not have adequate nursing capabilities or available equipment to care for patients with enhanced nursing need such as tracheostomies, tube feeding, intravenous fluids or medications, or supplemental oxygen. Therefore, emergency physicians are asked to identify a patient’s disabilities. Knowing the limitations of these facilities can enhance the relationship between emergency physicians and psychiatrists, and ultimately help to facilitate transfers. In addition, EMTALA (Emergency Medical Treatment and Labor Act) requires that psychiatric patients with medical problems be transferred to a psychiatric facility that is equipped to handle the patient’s medical problems.

## SUICIDE AND SELF-INJURIOUS BEHAVIOR

### Epidemiology

The term *suicide* refers to self-inflicted death with either explicit or implicit evidence that the person intended to die. Suicide has been the tenth leading cause of death each year in the United States since 2008, and accounted for 44,193 deaths in 2015.<sup>17</sup> It was the second leading cause of death among 10 to 34 year-olds in 2015, and accounts for 15.1% of deaths in this age group annually. Suicide accomplished in a variety of settings and by a variety of means, is associated with psychiatric disorders and/or substance abuse, especially ethanol, and is frequently accomplished using psychoactive xenobiotics alone or in combination. Self-poisoning accounts for more than 70% of all serious suicide attempts.<sup>50</sup>

### Suicidal Ideations

Suicidal thoughts and behaviors are common. The lifetime prevalence of adults having “seriously considered” suicide is 9.2%, whereas 3.1% report having formulated a plan, and 2.7% make a suicide attempt.<sup>32,52</sup> Given less than a third of individuals who have seriously considered suicide in their lifetime ultimately make a suicide attempt, studies have searched for unique risk factors that contribute to the transition from suicidal ideations to attempting suicide.<sup>32,49,54</sup> Given that the act of suicide is a statistically rare event in the overall population, it is difficult to definitively predict who will complete suicide. There are no proven formalized risk assessment tools. However, there are risk factors that are associated with an increase in the likelihood that an individual will attempt suicide, and there are some that are modifiable (Tables 26–2 and 26–3). The identification of modifiable risk factors provides opportunities for interventions. Additionally, there are protective factors that mitigate the risk for suicide, and it is important to assess for the presence or absence of these factors in determining the overall risk for suicide in a patient.

It is worth noting here that not all self-inflicted injuries are suicide attempts. Many of these are suicidal gestures or self-injurious behaviors. It is worth noting the explicit terminology here.

TABLE 26–2 Hierarchy of Factors Associated With an Increased Risk for Suicide

Psychiatric Risk Factors	Neurological and Medical Factors	Sociodemographic Factors	Genetic and Familial Factors
Major depressive disorder	Multiple sclerosis	Access to firearms	Family history of suicide (particularly in first-degree relatives)
Bipolar disorder	Huntington disease	Caucasian race	Family history of mental illness, including substance use disorders
Schizophrenia	Brain and spinal cord injury	Male sex (suicide completion)	
Alcohol use disorder	Seizure disorders	Female sex (suicide attempts)	
Other substance use disorders	Malignant neoplasms	Widowed, divorced, or single marital status, particularly among elderly men	
Alcohol intoxication	HIV/AIDS	Elderly age group	
Personality disorders	Chronic pain syndromes	Adolescent and young adult age groups	
Bulimia or anorexia nervosa	Functional impairment	Gay, lesbian, or bisexual orientation	
Post-traumatic stress disorder	Low concentration of serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) in cerebrospinal fluid—(Research)	Recent lack of social support (including living alone)	
Helplessness		Unemployment	
Hopelessness		Decrease in socioeconomic status	
Impulsivity		Domestic partner violence	
Aggression, including violence against others		Recent stressful life event	
Agitation		Childhood sexual abuse	
Factors related to current or past suicidal behavior:		Childhood physical abuse	
Prior suicide attempts			
Suicidal ideation			
Suicidal plans			
Suicidal intent and lethality			

## Self-Injury and Suicide Attempts

**Self-injurious behavior** refers to the self-infliction of painful, destructive, or injurious acts *without* the intent to die. An example is the superficial cutting that occurs in a patient with a borderline personality disorder, which is actually a coping mechanism that provides psychological relief; one hypothesis is that relief is mediated by the endogenous release of opioids.<sup>62</sup>

**Suicide gesture** refers to an attempt that is not felt to be medically serious, and often implies that the patient is making a “cry for help” rather than an attempt to die; such a *gesture* can still result in death, even if unintentional.

A **suicide attempt** refers to self-inflicted injury with a nonfatal outcome accompanied by either explicit or implicit evidence that the person intended to die. A medically serious suicide attempt is likely to be a more robust marker of successful suicide risk. As defined in the literature, “**serious**” **suicide attempts** meet one of the following criteria:

1. treatment in a specialized unit (such as an intensive care unit),
2. surgery under general anesthesia,
3. medical treatment beyond orogastric lavage, activated charcoal, or routine neurologic observation,
4. method with high risk of fatality (such as hanging or firearm), or
5. hospital admission longer than 24 hours.<sup>6</sup>

Those people who make serious attempts similarly tend to share with completers a higher rate of serious mental illness such as schizophrenia, bipolar disorder, or severe major depressive disorder.<sup>6</sup>

Suicidal or self-injurious patients are often encountered in emergency departments. Approximately 60% to 70% of all nonfatal self-inflicted injuries seen in an emergency department are the result of a suicide attempt, and an

emergency department visit for self-harm is predictive of a completed suicide in the future.<sup>13,61</sup> In fact, based on a review of 90 studies on emergency department presentations for nonfatal self-injury, 16% of individuals will self-harm within the year, and up to 2% will die by suicide.<sup>38,53,61</sup> The average annual number of emergency department visits for attempted suicide and self-injury is increasing; from 2001 to 2014, the age-adjusted annual rates increased by ~35%. Sixty percent of all nonfatal self-injury presentations are by women. Self-poisoning is the most common method of self-injury (51%), followed by cutting or piercing (24%), and will be discussed further in the next section.<sup>18</sup>

## Self-Poisonings

According to the most recent data from the National Electronic Injury Surveillance System (NEISS), there were 469,096 nonfatal self-injury cases treated in the United States emergency departments in 2014. Of these nonfatal self-injuries, self-poisoning was identified as the most common method of self-injury (51% of the cases). However, it should be noted that these data did not distinguish suicide attempts from self-injurious behaviors.

In the 16 states participating in the National Violent Death Reporting System in 2009, self-poisoning was the third leading method of suicide (following firearms and hanging/suffocation).<sup>47</sup> Detailed data from 2005 to 2007 indicates that 75% of individuals poisoned themselves with a substance (either illicit or licit, including alcohol) as opposed to other types of poison such as carbon monoxide. Seventy percent of individuals ingested just one “drug type,” defined as prescription drugs versus nonprescription drugs versus alcohol/illicit drugs. Out of poisoning deaths due to a single “drug type,” 80% were due to prescription drugs such as opioids, benzodiazepines, or antidepressants, and 10% were due to nonprescription drugs such as acetaminophen. When individuals consumed more than one “drug type,” 45% involved alcohol or illicit drugs as part of the combination.<sup>17,47,51</sup>

There is a large body of literature about self-poisoning in the United Kingdom, and their data indicate proportionally higher death rates among poisonings with cyclic antidepressants versus selective serotonin reuptake inhibitors, which is not surprising given the cardiac toxicity of cyclic antidepressants. Venlafaxine, a serotonin-norepinephrine reuptake inhibitor, is more toxic in overdose than selective serotonin reuptake inhibitors. Poisoning deaths with atypical antipsychotics such as clozapine, olanzapine, and quetiapine were increasing, especially as of the early 2000s.<sup>29</sup>

TABLE 26–3 Factors Associated With Protective Effects for Suicide

Children in the home
Effective clinical care for mental, physical, and substance use disorders
Family and community support (connectedness)
Positive social support
Pregnancy
Religious beliefs and cultural practices
Skills in problem solving and conflict resolution

**TABLE 26–4** Case Presentation: Suspected Self-Poisoning

	Case	Evolution		Disposition	
Patient course	Patient found in the community; unresponsive	Patient monitored in the emergency department; vital signs stable; still unresponsive	Patient lethargic but cooperative; answers simple questions	Patient fully awake and alert	Evaluation complete
Treatment course	Prehospital	Triage medical assessment	Observation and monitoring	Formal psychiatric evaluation	Treatment planning
Physician course	Patient identification Search for prescription drugs, drug paraphernalia Assessment of cardiac and respiratory function	Orogastric lavage (?) Activated charcoal (?) Diagnostic testing (blood studies, electrocardiography, urine toxicology) Contact collateral sources for history Prior records	Focused psychiatric assessment: elopement aggressive behavior decisional capacity addressing confidentiality immediate suicide risk	Comprehensive psychiatric assessment: diagnostic interviewing risk factors future risk	Treatments: medication hospitalization substance abuse counseling crisis intervention family therapy

Table 26–4 depicts a case of suspected self-poisoning from the starting point of prehospital care through the completion of a comprehensive assessment and treatment planning.

### Completed Suicide

While the annual rates of completed and attempted suicide continue to rise, there are distinguishing patterns between suicide attempts and completed suicides.<sup>15,16</sup> In 2015, men accounted for approximately 77% of completed suicides in the United States, with a majority by use of firearms (55.6% of male suicides), followed by suffocation (26.9%) then self-poisoning (10%). Men commit suicide at more than 3 times the rate than that of women, 21.76 deaths per 100,000 population versus 6.27 deaths per 100,000 population, respectively. In comparison, women's most common method of completed suicide was self-poisoning (33.4%), followed by firearms (30.5%), then suffocation (26.7%).<sup>18</sup> Given the lethal potential of a firearm and the broad-range of lethality from self-poisoning, one theory to explain the higher rate of suicide by males is their preferential use of firearms when compared to females who use self-poisoning methods more often. This theory is further supported by the fact that females attempt suicide at a higher rate than men.<sup>17,43</sup>

Ninety percent of suicide completers and attempters meet criteria for a diagnosable psychiatric illness, 70% have mood disorders, and 30% have alcohol abuse or dependence.<sup>37</sup> On average, one-third of suicide decedents test positive for alcohol, and 65% of them have a blood alcohol concentration higher than 80 mg/dL.<sup>43</sup>

Many individuals who complete suicide do so with the first attempt. Yet, a prior suicide attempt is still the strongest predictor of a future completed suicide.<sup>36,55</sup>

### Initial Psychiatric Management

In every case of suspected self-poisoning, a thorough psychiatric assessment is warranted. It is helpful to call a psychiatric consult immediately after medical stabilization, even if the patient is unable to communicate, because important information such as pill bottles, ambulance call reports, and the ability to call the patient's family and outside providers are lost if the consult is delayed. It is helpful to the psychiatrist if serum drug concentrations are obtained for medications of which the patient has access. For example, valproic acid and/or lithium concentrations should be obtained if these were prescribed to the patient or a family member. Obtaining concentrations allows to investigate potential medications used in self-poisoning, as well as to determine compliance.

An early, focused assessment by the emergency physician is necessary to ascertain elopement risk and continued dangerous behavior. Subacute residual central nervous system effects of ingestions, such as confusion, disinhibition, fatigue, and fear, predispose patients to wander or elope. The patient should be searched for weapons, pills, and other potentially harmful materials to prevent additional self-harm or ingestion in the hospital. A high level

of supervision should be maintained, and a patient should not be allowed to leave or be left unattended until an adequate assessment of the patient's mental status is completed. Depending on the architecture and organization of the emergency department and its personnel, it may be sufficient to place the patient in an open area in the direct line of sight of the medical staff. If such an arrangement is not possible, or if the patient is agitated and disruptive, it may be necessary to separate the patient from the general population. Under these circumstances, an individual aide should be assigned to observe the patient on a one-to-one basis and remain located within an arm's length of the patient at all times. In extreme cases when all else has failed, physical restraints are necessary to prevent further injury to both the patient and the staff. The need for such measures requires serial reassessment for their necessity.

A more detailed psychiatric assessment should be done as early as possible in the hospital stay as it is critical to address specific clinical concerns. Both history taking and collateral contacts help to establish the patient's baseline and mental status prior to the event. It is often difficult to differentiate a xenobiotic-induced delirium from mental illness. If the patient's cognitive functioning is impaired by xenobiotics, then critical historical details are often unreliable or unattainable.<sup>8,20</sup> Patient reports about intended overdose or self-harm should be documented in the record, because it is particularly important information to consider when patients become guarded and evasive after returning to baseline mental status. It should also be understood that predictable and transient disturbances in mood and perception result from many xenobiotics, and therefore a patient's initial reports while under the influence of the xenobiotic are often ephemeral.<sup>8</sup> The determination that the patient is stable is not solely established on the basis of blood concentrations of xenobiotic and/or ancillary medical tests, but rather when the emergency physician or medical toxicologist deems it appropriate.<sup>39</sup>

The physician cannot solely attribute altered mental status to poisoning or toxicity. Other toxic-metabolic and structural conditions coexist with, and/or masquerade as, toxicity; they must, therefore, be considered and systematically excluded.

### Special Issues of Capacity in Suicide and Self-Poisonings

The emergency exception to the doctrine of informed consent also applies in circumstances where attempted suicide is suspected. The emergency exception permits detention, medication over objection, and necessary medical care until psychiatric assessment can be accomplished. This includes collecting information from collateral sources without the patient's consent. Even after management of the immediate medical emergency and resolution of toxicity, suspected self-injury is sufficient evidence of impaired decisional capacity for the emergency physician to detain a patient for further psychiatric assessment. The emergency physician should document the patient's objections in the medical record and indicate the basis for the determination

of diminished capacity. After the patient is medically stabilized a full psychiatric assessment and formal capacity assessment by a psychiatrist can be initiated.

### Comprehensive Psychiatric Assessment

The goal of comprehensive psychiatric assessment is to

1. characterize the nature of the attempt and any ongoing suicidal ideation that might be present,
2. explore risk factors for another suicide attempt, and
3. formulate a diagnostic impression.

These 3 elements help to determine the level of risk and guide immediate treatment and disposition planning.<sup>68</sup>

The best understanding of suicide at this time is that it results from intrinsic vulnerability factors interacting with external circumstances, which can be termed the “stress vulnerability.” Intrinsic vulnerability is conferred by a variety of traits such as impulsivity or conditions such as depression, anxiety, low self-esteem, low self-efficacy, loneliness, and hopelessness. External factors include stressful life events, access to lethal means, and a host of other factors, positive and negative. Poor interpersonal problem-solving skills and a perceived lack of problem-solving ability also appear to increase risk.<sup>23</sup>

### Assessing Suicide Attempts and Suicidal Ideation

The core of the suicide risk assessment is a detailed discussion of the patient’s suicide attempt and any ongoing suicidal thoughts and urges. It is important to establish rapport and introduce these topics in an appropriate context in order to improve the patient’s candor. This evaluation requires significant time and skillful interviewing, for which there is no substitute. This approach will enhance both the therapeutic quality of the interview and its reliability.

The clinician should explore the exact details of the attempt, including precipitating factors that may have begun days or weeks prior to the actual act. It is critical to determine the level of actual and intended lethality, along with the seriousness of the intent. Why did the patient make an attempt on that day or time? Understanding the patient’s thought process can help to gauge the extent of impulsivity versus planning involved in the attempt. One approach to assess the level of impulsivity involved in a suicide attempt is to determine the time between the patient’s first suicidal thought with a plan and intent, and the actual attempt. Signs of premeditation and planning are concerning, such as extensive researching on methods of suicide, organizing one’s affairs (giving away possessions, ensuring a will is updated), or writing goodbye messages. It is crucial to determine if the patient expected to be found, and if any effort was made to notify someone about the impending attempt such as a phone call, Internet posting, or text message. How was the patient discovered, and by whom? A patient who overdoses alone in a hotel room is very different from someone who overdoses in the bedroom while the family is at home. Current feelings about surviving should also be assessed: Is the patient relieved, indifferent, or upset to be alive? Is there currently active or passive suicidal ideation? How forthcoming does the patient appear to be when discussing this? Other important information includes prior suicide attempts and their lethality and circumstances, the frequency and duration of suicidal ideation in the past, prior psychiatric treatment, prior and current medication trials, and a detailed substance abuse history. Psychological factors such as reactivity to positive and negative external events and subjective distress are also important to explore. The social history should focus on interpersonal conflict, stressors within romantic or family relationships, and employment or financial concerns. Current support systems or lack thereof are important to note, as are feelings of isolation and abandonment, which can all be contributing factors.<sup>40</sup>

The communication of suicidal ideas either directly or indirectly should not be misconstrued as a “cry for help” and hence evidence of lower risk. Communication is probably related to the degree of preoccupation with morbid thoughts and to personality characteristics that predispose individuals to revealing their thoughts to various degrees.<sup>44</sup> In psychological autopsy studies, approximately 50% to 70% of those who completed suicides gave

some warning of their intention, and 30% to 40% disclosed a direct and specific intent to kill themselves.<sup>5,59</sup>

Although every aspect of suicide risk is not fully understood, it is known that an individual is at 50 to 100 times higher risk of suicide within the first 12 months after an episode of self-harm compared with the general population. About one-half of all people who commit suicide have a history of self-harm, and this increases to 60% in the juvenile population.<sup>1</sup> Although assessing the risk of suicide is difficult because there is no “typical” suicidal patient, there is at least one suicide scale that has demonstrated validity: the Columbia-Suicide Severity Rating Scale.<sup>56</sup> However, this scale requires training to administer and is too lengthy to be administered in an emergency department.

### Psychiatric Illness and Suicide

One major consideration in suicide risk assessment is the occurrence of severe mental illness, most commonly affective illnesses (eg, major depressive disorder or bipolar disorder) and psychotic illnesses (eg, schizophrenia or schizoaffective disorder). Suicide risk for individuals with severe mental illness is 20 to 40 times higher than it is for the general population.<sup>45</sup> Psychological autopsy studies, which focus historically on the decedent’s intentions and mental state prior to death, consistently reveal major psychiatric illness to be a factor in suicide and present in 93% of adult suicides.<sup>41,45,57,60</sup> This is also true of those who make medically serious suicide attempts.<sup>7,41</sup> In particular, prospective cohort studies and retrospective case-control investigations reveal clinical depression and bipolar disorder to dramatically increase suicide risk.<sup>35,44,67</sup> For mood disorders, factors correlated with current suicidality include current depression, severe anxiety, anhedonia, panic, insomnia, ambivalence, and active alcohol abuse.<sup>44</sup>

A number of avenues of inquiry suggest that violent suicide attempts are associated with a persistent deficiency in brain serotonin concentrations. Impulsive types of aggression and impulsive suicidal behavior are linked to serotonergic dysfunction in prefrontal cortical regions of the brain.<sup>21</sup> This deficiency is measured in the postmortem brain and cerebrospinal fluid analyses of suicide victims and survivors of violent attempts as compared to nonviolent attempts and to other patients. Hopelessness has also received a significant amount of study as a potential predictor of suicide; unfortunately, it appears to have a high sensitivity but a low specificity.<sup>7</sup> However, identifying hopelessness does provide for an intervention.

After mood disorders, chronic alcoholism is the most commonly reported disorder and is present in approximately 20% of cases. Moreover, alcoholic patients who also experience episodes of depression are at a higher risk for suicide than patients who present with either disorder separately. There are considerable data that other types of substance use such as heroin, cocaine, or polydrug use also increase the risk of suicidality when psychiatric illness is present, and this seems to be especially true in depressive or dysphoric mood disorders (unipolar, bipolar II, and mixed types of bipolar I disorders).<sup>9,66</sup> As a result, any assessment conducted on a patient with a substance use history must include an examination of symptoms of major depression or bipolar illness.<sup>28,70</sup>

Patients with schizophrenia are at risk for suicide at rates comparable to major depression and are 20 times more likely to attempt suicide than the general population.<sup>65</sup> Approximately 50% of patients with schizophrenia will attempt suicide and 13% of schizophrenic patients will successfully complete suicide.<sup>11,65</sup> Additionally, between 5% and 18% of patients with severe borderline personality disorder (especially those patients with comorbid depression) ultimately kill themselves.<sup>30,41,64</sup>

The ability to treat psychiatric disorders such as mood disorders, schizophrenia, borderline personality disorder, and alcoholism suggests that most suicides are preventable. Indeed, a suicide prevention program designed for general practitioners in Sweden demonstrated evidence for prevention based on the detection and treatment of depression.<sup>58</sup> The Centers for Disease Control and Prevention reported that psychiatric problems in US emergency departments represented approximately 3% of visits, which is significantly lower than the national psychiatric rate of 20% to 28%.<sup>14</sup> This suggests that

psychiatric illness is underdiagnosed in the emergency department. Consequently, emergency physicians must enhance the comprehensive nature of their psychiatric screening to identify suicidality and concomitant mental disorders in patients presenting with self-injury.

## Treatment

Following a comprehensive psychiatric assessment, the next step is deciding on treatment alternatives. Any patient who has made a suicide attempt must be considered to be at risk for another attempt, and some further intervention is warranted. The risk of a subsequent lethal attempt is approximately 1% per year over the first 10 years. The risk is highest during the first year. Suicide is most commonly a symptom of an underlying disease process, so the goal is to diagnose and treat the underlying disease in the setting that is the least restrictive while also ensuring safety for the patient. The treatment alternatives available will depend on the psychiatric sophistication of staff available to the emergency department at any given time. This section describes the commonly used interventions in the emergency department; they can be employed singly or in combination.

Psychotropic medications are used acutely in the treatment of severe anxiety or psychosis; however, in the case of antidepressants, several weeks are required for therapeutic effect, so their immediate use is not indicated in the emergency department. However, if the patient is to be discharged to the community with follow-up, it is reasonable for a psychiatrist to start an antidepressant in the emergency department setting. There are concerns about prescribing medications with relatively high potential for lethality in overdose, such as the cyclic antidepressants and nonselective monoamine oxidase inhibitors, to persons who have recently attempted suicide. However, the selective serotonin reuptake inhibitors are first-line treatment for depression and are relatively safe in overdose.

In 2007, the US Food and Drug Administration (FDA) ordered that all antidepressants should include a black box warning stating that there is an increased risk of suicidality in children, adolescents, and adults younger than 24 years of age. This risk was not increased in adults 25 to 64 years of age, and was actually decreased in adults older than 65 years of age. Further studies confirm this age-related difference.<sup>12,63</sup> Proposed explanations include an ascertainment bias, activation and/or akathisia as an adverse event in the first few weeks, or increased energy prior to improvement in mood resulting in increased ability to carry out suicidal plans. Nonetheless, the FDA and other authors emphasize that untreated depression also carries a risk of suicide, and treatment options should be carefully weighed with regard to their risks and benefits. Therefore, we recommend against the initiation of antidepressant therapy by the nonpsychiatric physician unless a tight linkage can be made between discharge and immediate (within days) aftercare by either a community outreach team or a crisis clinic.

Patients with depressive disorders can suffer from significant anxiety, overwhelming situational stressors such as job loss, new financial hardship, bereavement, or divorce. The prescription of a short course (days to weeks) of a benzodiazepine provides significant relief to the patient in crisis. Yet again, close psychiatric follow-up is essential.

After the patient's immediate symptoms have been treated, the next treatment decision is determining the setting in which further treatment may safely be provided. Not all patients with suicidal ideation or even significant attempts necessarily require hospitalization, and there is still a substantial stigma attached to psychiatric hospitalization. In general, hospitalization should be used if less restrictive measures cannot ensure the patient's safety. If significant doubt exists about the safety of outpatient treatment, then the patient should be placed in observation in the emergency department, admitted to a general hospital with close nursing supervision, or admitted to a psychiatric unit. "Holding beds," now available in some larger psychiatric emergency departments, are ideal for this purpose. There are localities with crisis outreach services that follow the patient after emergency department discharge and provide appropriate monitoring and continuity of care.

Patients most likely to respond to interventions in the emergency department are individuals who were stable, but as a result of some external event,

find their way of life threatened. This acute change results in a painful state of anxiety and causes mobilization of some combination of adaptive and maladaptive coping strategies. Finally, a second event, the precipitant, intensifies the anxiety to the point that the patient cannot tolerate the instability and is thrown into crisis. The patient then feels desperate, immobilized or vulnerable to various strong impulses including the impulse to run away, strike out at someone else, or kill him- or herself. Reality testing is preserved, and no major psychiatric syndrome is present. The patient accurately perceives his or her situation, understands that the current reaction is a psychological problem, and is highly motivated to obtain help. The crisis lasts for hours or weeks prior to the emergency department presentation and will ultimately resolve. Such patients respond well to crisis intervention and actually undergo some positive development in the course of treatment.

By contrast, patients whose condition has been deteriorating for some time in the absence of significant stressors, and who appear on examination to be suffering from severe depressive symptoms, are unlikely to benefit rapidly from supportive techniques. If such patients present with suicidal ideation or attempts, it will be difficult, though not impossible, to manage them outside the hospital.

Outpatient settings have the advantage of maintaining the patient's functional status as much as possible. Work and child care responsibilities, financial obligations, and social relationships are not disrupted. Unnecessary regression is halted. The patient assumes more responsibility for his or her outcome, and independence helps preserve self-esteem. These individuals remain closer to and more engaged with the people and situations with whom and with which they must learn to cope. Their morale can rapidly improve by the combination of support, planning, and modest early treatment successes.

However, in some cases, these same factors are disadvantageous. Routine tasks seem overwhelming. High levels of conflict render major relationships at least temporarily unworkable. Inpatient settings offer the advantage of respite, high levels of structure, more intensive professional and peer support, constant supervision, and, usually, more rapid pharmacologic and psychosocial intervention.

The choice of inpatient or outpatient setting will depend on the balance of strengths and weaknesses of the patient, the involvement and competence of family or friends, the availability of a therapist in the community, and the ongoing stresses in the patient's life. This decision is best made by a psychiatrist. Because a psychiatrist is not always present in many facilities, a trained mental health professional should optimally be on call to every emergency department. This may be a psychiatric social worker, nurse clinician, or psychologist. When such services are not available, it is appropriate to detain patients in the emergency department until a practitioner with specific competence is available or to transfer the patient to another facility for evaluation. Every state has laws that provide for the involuntary commitment of the mentally ill under circumstances that vary from state to state (Chap. 138). Any acute, deliberately self-injurious behavior would generally qualify. Chronic, repetitive dangerous behavior that is not deliberate, such as frequent unintentional opioid, alcohol, sedative-hypnotic, or illicit "recreational" psychoactive drug overdoses, warrants careful evaluation. In the absence of psychiatric illness, involuntary treatment is usually not necessary, but should be considered carefully if a patient appears unable to achieve self-care. The practitioner should be familiar with the criteria for commitment and the classes of health care professionals so empowered under state law.

There are other treatment interventions that can be provided in the emergency setting, including crisis intervention, substance abuse counseling, and family therapy. A single session in the emergency department is often sufficient to defuse a crisis or to spur the drug-abusing patient to seek help. Intervention initiated in the emergency department then continued as an outpatient setting.

Crisis intervention is a brief, highly focused therapy that seeks to deconstruct how a crisis occurred, with the intent of examining the patient's role. Often, patients have distorted perceptions of the crisis, and a gentle "correction" of catastrophic thinking is helpful. The crisis is presented to the

patient as an unfortunate and perhaps tragic experience that the patient can overcome. Ideally, the patient should have a relief of symptoms and learn how crises may be avoided in the future. This insight intervention will likely fail for patients with severe depression because of the presence of profound hopelessness. It is most successful for patients who give a history of high functioning just prior to the crisis.

“Contracting for safety” was a popular technique in the past, and consists of patients being asked whether they can remain safe and agree not to engage in self-harm. However, there are no empirical data to show that it is effective, and in court cases it is not protective in terms of liability for the clinician. It is not recognized as part of the standard of care for the suicidal patient, and if anything, it seems to provide the clinician with a false sense of security. Its use is not recommended except as a technique to engage in a larger discussion of a safety plan that delineates scenarios the patient might face after leaving the hospital, and possible coping strategies.<sup>31</sup>

## SUBSTANCE USE DISORDERS

Substance use disorders are characterized by compulsive drug seeking and drug taking in a setting of loss of control, continued use despite negative consequences, and functional impairment in several domains of a person’s life. They are highly comorbid with suicidality, violence, and mental illness as described above in previous sections. Prevalence rates of substance use in the emergency department range from 9% to 47%, depending on the sample.<sup>26</sup> Emergency physicians and medical toxicologists are in a unique

position to identify substance use disorders and refer patients to additional treatment services. There is an extensive array of evidence-based treatment for substance use disorders, but less than 10% of persons with substance use disorders in the United States receive substance abuse treatment. There are increasing efforts to combat this. For example, the American College of Surgeons’ Committee on Trauma (ACS-COT) now requires level I and II trauma centers to identify problem drinkers and level I centers must employ SBIRT (Screening Brief Intervention, and Referral to Treatment).<sup>69</sup>

## DSM-5 Diagnoses

The psychiatrist’s diagnostic handbook, the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), codifies various diagnoses involving the use of substances. The latest version is the fifth edition, DSM-5, which was released in 2013.<sup>4</sup> Although previous versions of the DSM differentiated “substance abuse” and “substance dependence,” the DSM-5 combines these categories into an overarching “substance use disorder” diagnosis with mild, moderate, and severe specifiers. Table 26–5 shows the criteria for an alcohol use disorder, and the reader can use this as a template to substitute other substances of abuse as well.

## Neurobiology of Substance Use Disorders

It is helpful for the emergency physician to be able to recognize the signs and symptoms of a substance use disorder. Although the DSM-5 criteria are straightforward, many patients are not forthcoming and do not share the

TABLE 26–5 DSM-5: Criteria for Alcohol Use Disorder (2013)

### Alcohol Use Disorder

#### Diagnostic Criteria

- A. A problematic pattern of alcohol use leading to clinically significant impairment or distress, as manifested by at least two of the following, occurring within a 12-month period:
1. Alcohol is often taken in larger amounts or over a longer period than was intended.
  2. There is a persistent desire or unsuccessful efforts to cut down or control alcohol use.
  3. A great deal of time is spent in activities necessary to obtain alcohol, use alcohol, or recover from its effects.
  4. Craving, or a strong desire or urge to use alcohol.
  5. Recurrent alcohol use resulting in a failure to fulfill major role obligations at work, school, or home.
  6. Continued alcohol use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of alcohol.
  7. Important social, occupational, or recreational activities are given up or reduced because of alcohol use.
  8. Recurrent alcohol use in situations in which it is physically hazardous.
  9. Alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol.
  10. Tolerance, as defined by either of the following:
    - a. A need for markedly increased amounts of alcohol to achieve intoxication or desired effect.
    - b. A markedly diminished effect with continued use of the same amount of alcohol.
  11. Withdrawal, as manifested by either of the following:
    - a. The characteristic withdrawal syndrome for alcohol (refer to Criteria A and B of the criteria set for alcohol withdrawal).
    - b. Alcohol (or a closely related substance, such as a benzodiazepine) is taken to relieve or avoid withdrawal symptoms.

#### Specify if:

- **In early remission:** After full criteria for alcohol use disorder were previously met, none of the criteria for alcohol use disorder have been met for at least 3 months but for less than 12 months (with the exception that Criterion A4, “Craving, or a strong desire or urge to use alcohol,” may be met).
- **In sustained remission:** After full criteria for alcohol use disorder were previously met, none of the criteria for alcohol use disorder have been met at any time during a period of 12 months or longer (with the exception that Criterion A4, “Craving, or a strong desire or urge to use alcohol,” may be met).

#### Specify if:

- **In a controlled environment:** This additional specifier is used if the individual is in an environment where access to alcohol is restricted.

**Code based on current severity:** Note for ICD-10-CM codes: If an alcohol intoxication, alcohol withdrawal, or another alcohol-induced mental disorder is also present, do not use the codes below for alcohol use disorder. Instead, the comorbid alcohol use disorder is indicated in the 4th character of the alcohol-induced disorder code (see the coding note for alcohol intoxication, alcohol withdrawal, or a specific alcohol-induced mental disorder). For example, if there is comorbid alcohol intoxication and alcohol use disorder, only the alcohol intoxication code is given, with the 4th character indicating whether the comorbid alcohol use disorder is mild, moderate, or severe: F10.129 for mild alcohol use disorder with alcohol intoxication or F10.229 for a moderate or severe alcohol use disorder with alcohol intoxication.

#### Specify current severity:

- **305.00 (F10.10) Mild:** Presence of 2–3 symptoms.
- **303.90 (F10.20) Moderate:** Presence of 4–5 symptoms.
- **303.90 (F10.20) Severe:** Presence of 6 or more symptoms.

extent of their drug use and its effect on their lives. In those cases, one can look for inconsistencies in either the history or the presentation. Denial is often prominent. For example, a patient might present intoxicated with an arm injury, but is unconcerned and dismissive about the incident when no longer intoxicated. One would expect a patient to demonstrate appropriate concern, rather than just “wanting to leave.”

One of the more vexing aspects of substance-dependent patients is the frequency with which they minimize the dangerousness of their actions or the severity of their presentation. This can be interpreted as a sign of prefrontal cortex dysfunction due to the addiction. The patient is incorrectly processing risks and benefits, and is increasingly driven to compulsive drug use at the cost of natural rewards such as food, sex, love, or safety. Initial drug use results in relaxation, euphoria, stress relief, or a variety of other psychological effects, as mediated by the dopaminergic “reward pathway.” It was traditionally taught that dopamine release in this pathway was synonymous with experiencing “pleasure,” but it has become apparent that the function of dopamine is more accurately portrayed as indicating “salience” (or importance). A burst of dopamine in this pathway confers enhanced salience onto a particular stimulus or aspect of the environment, which means that this stimulus now appears more important and there is greater motivation to pay attention to it. One can see how this works well as a survival system, with natural rewards such as food and sex resulting in increased dopamine and subsequently greater salience. Drugs of abuse essentially “hijack” this pathway by directly producing supra-physiologic increases in dopamine that far exceeds the dopaminergic response to natural rewards.<sup>42</sup>

However, activity in the reward pathway only explains the acute effects of drugs and does not explain why someone’s behavior changes so drastically as the individual becomes addicted. The cravings and compulsive behavior that occur in addiction result from glutamate-mediated circuits that develop in the prefrontal cortex and establish aberrant connections to the limbic system. Affected areas include the orbitofrontal cortex, which regulates salience attribution, and the anterior cingulate gyrus, which regulates inhibitory control. Late-stage addiction is characterized by derangements in these areas of the prefrontal cortex, which results in an increased salience for drugs of abuse combined with a reduced ability to inhibit impulsive behavior. It is a resulting “perfect storm”: the person is extremely motivated to find and use drugs, and unable to stop or inhibit this behavior. Environmental “triggers” established by conditioning subsequently act to induce powerful states of craving and increased motivation to find and use a particular drug.<sup>42</sup>

Despite our sophistication in describing the neurobiology of addiction, it can be challenging for an individual clinician to act accordingly when dealing with an addicted patient; we are used to assuming that behavior is voluntary, especially if a person is coherent and oriented. It can be difficult to recall that a patient who is hostile and in denial actually has true neurobiological dysfunction, not unlike a patient with dementia or psychosis. Unfortunately, our current civil commitment laws have not “caught up” with this neurobiological understanding, and we do not hospitalize severely addicted patients against their will even if there are multiple presentations of intoxication or withdrawal and it is clear the patient is suffering substantially. However, some institutions have committed these types of patients and have shown some impressive outcomes.<sup>48</sup>

### Treatment

Substance abuse treatment is ultimately an intermediate (weeks to months) to long-term (months to years) intervention. However, there are powerful initial steps that the emergency physician can take. Central among these is confronting the patient about the medical consequences of substance use. This can take the form of discussion only, or the physician can invite the patient to examine clinical laboratory results or view remarkable clinical diagnostic findings (hepatomegaly, repeated fractures from falls, liver enzyme abnormalities, or evidence of “silent” past myocardial infarction). There is little to be lost from a respectful but blunt confrontation of the patient’s deterioration, and the patient may listen to a physician rather than family or friends. “Physician advice” in this manner is shown to be useful for patients who do

not yet meet criteria for a substance use disorder, and therefore still have sufficient control of their substance use to make a logical decision about the risks versus benefits of continued use.

Patients who are further along the addictive spectrum and who display behavioral or physiologic signs of moderate–severe substance use disorders are much less likely to curb their substance use in the face of adverse medical sequelae. For these patients, more intensive intervention is warranted, often in the form of a consultation. For most hospitals, this type of consultation would be fulfilled by a psychiatrist, but some institutions have a separate substance abuse consult service. Ideally, all patients suspected to have a substance use disorder should be referred to some type of aftercare when possible: inpatient or outpatient detoxification, inpatient or outpatient rehabilitation, or even follow-up with primary care.

In a busy emergency department, this can be quite cumbersome logistically, depending on the demographics of the patient population and the percentage of patients suspected to have a substance use disorder. Regulatory agencies at the state and federal levels are increasingly mandating substance abuse screening, brief interventions, and referrals (SBIRT), much like ACS-COT for trauma surgeons, and it is hoped this will result in increased resources for additional ancillary staff to assist with such tasks.

It is helpful to note that peer counseling is particularly useful in addictive disorders, and community 12-step programs like Narcotics Anonymous (NA) and Alcoholics Anonymous (AA) are ubiquitous worldwide. Alcoholics Anonymous has its own website and specific phone lines in some cities that are staffed by AA members with the express purpose of orienting potential new members and assisting them in attending their first meeting. Even if there is insufficient infrastructure in the emergency department to provide the more intensive intervention that might be needed for a substance-using patient, the physician can at least refer directly to AA. Patients with repeated presentations for substance intoxication/withdrawal should be considered for a higher level of care, since they may be demonstrating the inability to care for themselves. Such a decision would be made in conjunction with the psychiatrist and would have to comply with the local civil commitment laws. Finally, it is important to note that substance abuse treatment is quite effective, and that coerced treatment has been found to be just as effective as voluntary treatment. Given the remarkably high comorbidity of substance use disorders in the emergency department setting, it behooves us to attempt to connect these patients with the appropriate treatment.

### SUMMARY

- Capacity assessment should be approached systematically, and such an approach is helpful in more complex situations. A “sliding scale” is a useful concept; when refusing an intervention would have serious consequences, a patient is held to a higher standard to demonstrate capacity.
- “Medical clearance” does not have a standard protocol, but in general the ED assessment should be guided by the history and physical examination.
- Both violent and suicidal behavior in the emergency department are the cause or the effect of many toxicologic presentations.
- It is incumbent on all emergency physicians to screen patients for psychiatric emergency presentations as part of a comprehensive screening for self-harm.
- Identifying risk factors for suicide and aggression can aid the clinician in employing preventive or early intervention strategies in the ED.
- Important risk factors for both suicidal and violent behavior include history of the behavior, comorbid mental illness, drug and alcohol intoxication, and young age.
- Mental status examination for suicidality should focus on extrinsic factors such as current ideation, intent, lethality of plan, current life stressors, as well as intrinsic vulnerability factors such as comorbid mental illness, feelings of hopelessness, and impulsivity.
- In terms of violence risk assessment, drug and alcohol intoxication, mental illness, and psychiatric medication noncompliance (alone or in

combination) are robust predictors of aggressive behavior in the ED and other inpatient settings.

- Substance use disorders are highly prevalent in patients who present with psychiatric issues in the ED, and there are possibilities for identification and referral even in busy ED settings.

## PATIENT VIOLENCE

Andrea M. Kondracke, Justin M. Lewin, Cathy A. Kondas, and Erin A. Zerbo

The aggressive and/or violent patient presents unique challenges. Like suicidal patients, aggressive individuals are difficult to treat and they tend to elicit strong negative reactions in hospital personnel ranging from anger to fear.<sup>42</sup> Workplace violence is unfortunately commonplace within the health care setting, and is particularly prominent in the inpatient psychiatry ward and emergency department settings.<sup>20</sup> Of the approximately 24,000 annual workplace assaults occurring between the years of 2011 and 2013 in the United States, approximately 75% were within the health care and social service settings.<sup>37</sup> The prevalence of verbal and physical assaults reported by emergency nurses within a 12-month period is as high as 100% and 82%, respectively.<sup>34</sup> Additionally, a survey of emergency physicians within the state of Michigan showed that 25% of emergency physicians reported being a target of physical assault within 12 months.<sup>27</sup> These statistics on workplace violence in health care settings are likely underestimates as events are often underreported to health care supervisors and administrators. Workplace violence occurs so frequently that there is a perception among health care workers that violence is “the norm” and an expected part of their job.<sup>44</sup>

Workplace violence is classified into 4 broad categories that are dependent on the relationship of the perpetrator to the workplace. In type I, which accounts for approximately 80% of workplace homicides, there is not an association between the two. These incidents are generally motivated by theft, with hospitals and pharmacies being susceptible because of their abundance of opioids, equipment, and money. However, this type of violence is no more likely to be experienced in health care settings. Preventive measures include environmental security measures such as metal detectors. In type II, the most common type in the hospital setting, the perpetrator is a patient or customer. In general, these acts of violence occur while workers are performing basic work functions. An example of this would be an intoxicated patient who punches a nurse while obtaining vital signs. In type III, the perpetrator is a current or former employee. In type IV, the perpetrator has a personal relationship with a specific employee but not with the institution.<sup>41</sup> The most common types of hospital violence are incidents of aggression against objects in the hospital (57%), violence directed against the hospital staff (28%), and violence directed against other patients (14%).<sup>43</sup>

In one study of violence in the emergency department, directors of emergency medicine residency programs were surveyed as to the frequency of verbal threats, physical attacks, and the presence of weaponry in the area. Of the 127 institutions surveyed, 74.7% of the residency directors responded; 41 (32%) reported receiving at least one verbal threat each day; 23 (18%) reported that weapons were displayed as a threat at least once each month. Fifty-five program directors (43%) noted that a physical attack on medical staff members occurred at least once a month.<sup>29</sup>

These studies underscore the need for timely identification of the potentially violent patient, as well as appropriate management for this diagnostically heterogeneous group.<sup>13</sup> The assessment and management of the violent patient should include provisions for patient and staff safety as well as a thorough search for the underlying cause of violent behavior.<sup>23,42</sup>

The section below addresses the differential diagnosis of violent behavior, predictions of violence, the pharmacotherapy for the treatment of aggressive and/or agitated behavior, and the use of seclusion and

physical restraint. It also provides an overview of potential risk factors for violent behavior.

### Differential Diagnosis

There are many causes of violent behavior; some are social, medical, or biological in nature. The most common characteristic of the violent patient is alteration in mental status. Factors such as metabolic derangements, exposure to xenobiotics (both licit and illicit), withdrawal syndromes, seizures, head trauma, stroke, psychosis, cognitive impairment, and personality disorder all predispose a patient to aggression and violence. Additionally, patients with severe pain, delirium, or extreme anxiety often respond to the efforts of emergency personnel with resistance, hostility, or overt aggression.

The stress-vulnerability model suggests that violence should be considered as the outcome of a dynamic interaction among numerous factors both intrinsic and extrinsic to the individual. Although education theoretically provides alternatives to violence, xenobiotic-induced delirium will render any education ineffective because delirium prevents patients from reasoning or exercising impulse control. Once confused, the patient often misinterprets health care efforts in a paranoid manner, and becomes violent under circumstances that would not normally be sufficient to provoke a violent outburst in that individual. Some patients, on the other hand, come from cultures in which aggressive behavior is more acceptable and/or expected, and these patients require little stress or provocation before responding in what is often perceived as aggression by Western cultural standards.

### Prediction of Violence

Although there is a high expectation that violence is predictable, there are no proven predictors of violence. Prior history of violence is postulated as a risk factor for future violence. Patients in police custody are involved in 29% of shootings in emergency departments.<sup>37</sup> Predicting violent behavior based on medical diagnosis (eg, patients with HIV) is unfruitful and leads to bias or discrimination. Other factors such as personality disorders, mental illness, dementia, and substance abuse are areas that need further study.<sup>42</sup> Studies of emergency department violence show the following risk factors: the presence of guns, area of gang activity, low socioeconomic status, and interacting with patients who were recently given bad news.<sup>37</sup>

There are several structured approaches to violence risk assessment.<sup>46</sup> Examples are the Psychopathy Checklist-Revised (PCL-R); Historical Clinical Risk Management-20 (HCR-20); Classification of Violence Risk (COVR); Violence Risk Appraisal Guide (VRAG).<sup>46</sup> Structured approaches tend to have better efficacy for predicting violence than an unstructured approach. However, they also have many shortcomings: the sensitivities and specificities tend to hover around 0.7 and they are time consuming and require specific training to administer, rendering them impractical in the emergency department setting.<sup>16</sup>

### Substance Use and Violence

The association between substance use and violence is well established. Alcohol is found in the offender, the victim, or both in one-half to two-thirds of homicides and serious assaults.<sup>9,38</sup> Substance use is seldom the sole cause, but it contributes to violence in a number of ways. Substance use interacts

with other physiologic, cognitive, psychological, situational, and cultural factors including any underlying mental illness. A tripartite model for substance-related violence is described.<sup>18,19</sup>

1. systemic violence related to the sale and distribution of drugs,
2. economic compulsive violence associated with profit-oriented criminal activity to maintain the expenses of an individual's drug habit, and
3. psychopharmacologic violence resulting from the direct effects of the particular xenobiotic.

Toxicity causes disinhibition, impulsivity, perceptual disturbance, paranoia, irritability, misinterpretation, affective instability, and/or confusion. For example, synthetic cannabinoids, synthetic cathinones, and phencyclidine are well known to cause agitation, which is often accompanied by violent and uncontrollable behavior.

Withdrawal syndromes also promote aggressive behavior for a multitude of reasons, including physical discomfort, anticipatory anxiety, irritability as a direct result of withdrawal, and withdrawal-related delirium. Patients experiencing any of these symptoms have the potential to become aggressive, verbally abusive, or threatening. Prompt recognition of these syndromes and immediate treatment will prevent some aggressive outbursts or escalation to assaultive behaviors. Well-known xenobiotics that cause irritability and associated behaviors in withdrawal include ethanol, benzodiazepines, and opioids. Because drug use is often concealed, is difficult to ascertain on clinical grounds, and frequently contributes to violent behavior, urine and blood toxicologic studies are useful in enhancing the understanding and long-term treatment of some patients.<sup>8</sup>

### Mental Illness and Violence

The relationship between mental illness and violence is also complex. The impact of present-day media and the counteracting efforts made to destigmatize mental illness often confound this issue. There are several studies showing an association between mental illness and increased risk for violence.<sup>38</sup> In one large epidemiologic study, the prevalence of violence for those without mental illness was 2%, whereas schizophrenia was associated with an 8% rate of violent behavior. But, of all respondents reporting violent behaviors, 42% had a substance use disorder. In patients with schizophrenia, having a co-occurring substance use disorder more than tripled the rate of violence.<sup>45</sup> However, based on a cohort study from the Netherlands, most of the common mental disorders were associated with violence until adjusting for violent victimization, negative life events, and social supports. Then the association of violence with most mental disorders was negligible, with the exception of substance use disorders, which retain a strong association with violent behavior.<sup>45</sup>

In addition to substance abuse and severe mental illnesses, researchers have consistently found a greater prevalence of personality disorders among individuals who become violent in an inpatient setting as compared to non-violent inpatients.<sup>7</sup> Antisocial personality disorder is the condition most strongly associated with both substance use and aggression. Patients with either borderline or antisocial personality disorders are at risk for violent behavior as a result of chronic poor impulse control and impaired frustration tolerance in the context of poor coping skills.

Although persons with psychotic disorders are not generally aggressive, there are aspects of their psychosis that place them at risk for aggressive behavior. Hallucinations lead to aggression, such as when patients explicitly follow the instructions of a violent command auditory hallucination. Paranoid ideation that leads an individual to believe that she or he is at imminent risk of bodily harm (“They’re trying to kill me”), sexual victimization (“Men and women are raping me”), or humiliation (“Everyone is laughing at me”) or feeling physically trapped are examples of thoughts that lead psychotic patients to be aggressive.

### Alternative Etiologies

Delirium from any underlying condition is a cause of aggression. Patients are often suddenly confused, frightened, or frankly psychotic as a result of

impaired perception. Violence risk is also associated with cognitive dysfunction such as traumatic brain injury and dementia. These patients are unable to engage in a rational manner and verbal de-escalation is often futile.

### Additional Factors in Aggressive Behavior

Many of the factors correlated with aggression are easy to observe and monitor in the hospital, yet some additional factors are not so easy to detect. One study found that most violent incidents in the hospital occur on Mondays and Fridays, and others have postulated that there is a seasonal variation of violence, with violence occurring more often in extreme temperatures.<sup>10</sup> There is an increase in the frequency of assaults by inpatients during the winter months, and it is hypothesized that increased population density, cold temperature, and less sunlight during the day could account for the increased violence. This finding is in contrast to the literature on outpatient violence, which has reported greater incidence of violence during the warmer months.<sup>2</sup> However, this same review conceded that any extreme temperature could evoke aggressive urges and frustration.

Although it is unclear whether cold temperatures provoke aggression to the same extent as hot temperatures, it does seem clear that overcrowding and social stressors, long wait times, and inadequate food supplies can lead to violent behavior.

### Assessment of the Violent Patient

The comprehensive evaluation of the violent patient include a complete physical examination with the intent of revealing the underlying cause of the violent behavior as well as ensuring the discovery of secondary patient injuries. It is important to attempt to differentiate toxicity or withdrawal, cognitive impairment, delirium, and mental illness as treatment differs depending on etiology. Recommended laboratory analyses include blood chemistries (glucose, electrolytes), a complete blood count, liver function tests, renal function tests, thyroid function tests, and urinalysis. The need for lumbar puncture and/or neuroimaging is best guided by clinical history and physical examination.

### Treatment

There are 3 main approaches to controlling aggressive behavior in order of escalation: First and foremost, there is verbal de-escalation. When this has failed, medical anxiolysis and sedation will be the next approach. Finally, under the most extreme circumstances where there is significant risk for harming self or others, the use of physical restraints are indicated.

### Verbal De-escalation

Because of several high-profile deaths involving restraints, there is a continued focus on advancing techniques and training in de-escalation. These are now paramount to the treatment of agitation and violence in the medical setting. These techniques use both verbal and nonverbal communication, and include talking to a patient, building rapport, listening and understanding in a calm and compassionate manner, using a calm voice, making eye contact, and focusing on the person and not the behavior.

Many hospitals have behavioral response teams. At our institution, the creation of a crisis management team has proven to be a very successful way of intervening and avoiding the escalation of a violent situation. The purpose of these teams is to respond, assess, protect, and treat the patient with behavioral disturbances. The teams are generally multidisciplinary in nature and consist of mental health, medical, and security professionals. The members should have specialized training in evaluation, conflict resolution, and de-escalation techniques. Team members should possess good personal control, verbal and nonverbal engagement skills, and learn when and how to intervene while ensuring a safe environment. There is a balance between autonomy and limit-setting.

### Psychopharmacologic Interventions

The goal of acute pharmacologic intervention for agitated or violent behavior is to target the suspected cause of the agitation while regaining behavioral control and ensuring safety. Targeting the underlying cause reduces the

likelihood of recurrent agitation even after the sedating effects of the medications have diminished. Sedation alone may frighten and/or anger the patient and does not address the underlying etiology of the problematic behavior. For example, the patient in ethanol withdrawal presenting with agitation would benefit from a benzodiazepine, whereas, an antipsychotic could be detrimental and lead to unnecessary side effects (Chap. 77).

Given that the goals of treatment are specific to the suspected etiology of agitation, the formerly used term of “chemical restraints” has fallen out of favor. Chemical restraint is defined as “chemical measures for confining a patient’s bodily movements, thereby preventing injury to self or others and reducing agitation.”<sup>12</sup> Given that aggression results from multiple etiologies, there is much debate about the specific sedative and route of administration that should be used. Overall, studies show that both benzodiazepines and antipsychotics result in rapid control of agitation and aggression.<sup>6,14,24,28</sup>

Haloperidol is safely used in the treatment of agitation and aggression in patients with psychoses and delirium.<sup>1,6,14,28</sup> It can be administered orally, intravenously, or intramuscularly. Dosing intervals range from 30 minutes to 2 hours, with a usual regimen of haloperidol 5 mg given every 30 to 60 minutes; most patients respond after one to 3 doses. Older studies indicated that the dose of haloperidol needed to achieve sedation rarely exceeded a total of 50 mg in acute management, but it is unusual that more than 20 mg is needed.<sup>31,32</sup> It is important to take the individual patient into consideration. For example, in elderly and/or medically compromised patients, behavioral control is often achieved at doses as little as 1 to 2 mg. During a behavioral crisis, most psychiatrists would switch to a second-generation antipsychotic such as olanzapine or add a mood stabilizer such as valproic acid rather than continue to titrate haloperidol because of escalating risks of side effects as haloperidol dose is increased (such as extrapyramidal symptoms and QT interval prolongation).

Droperidol is an older antipsychotic used in United States since the 1960s. It is widely used in Europe for treatment of acute and chronic psychoses as it has sedating properties.<sup>25</sup> Droperidol is rarely used as an antipsychotic in the United States. Several studies compared the use of droperidol with alternatives to treat acute agitation, and evidence overall supports its use as a first-line treatment option for acute agitation. When compared to both haloperidol and olanzapine, droperidol had comparable efficacy in sedation on first administration of medication while having a lower risk of participants needing additional sedating medications after 60 minutes.<sup>25</sup> Although midazolam is proven to induce adequate sedation more rapidly than droperidol, 15 versus 30 minutes, respectively, midazolam also has a significantly higher rate of needing rescue medication for sedation, when compared to droperidol, 50% versus 10%, respectively.<sup>33</sup> Droperidol is taken orally at doses from 5 to 20 mg every 4 to 6 hours as needed; given intramuscularly at doses up to 10 mg every 4 to 6 hours as needed; or intravenously at doses of 5 to 15 mg every 4 to 6 hours as needed<sup>25</sup> (Chap. 67).

Various benzodiazepines are quite effective for sedation; their use has been examined in patients with psychoses, stimulant toxicity, sedative-hypnotic and alcohol withdrawal, and postoperative agitation.<sup>17,35</sup> Diazepam is given intravenously (IV) 5 to 10 mg, with rapid repeat dosing titrated to desired effect. Because diazepam is poorly absorbed from intramuscular (IM) sites, its preferred route of administration is either IV or oral. Lorazepam 1 to 2 mg or midazolam 5 to 10 mg is given orally or parenterally and repeated at 15- or 30-minute intervals, respectively, until the patient is calm. Midazolam is frequently used in the emergency department because of its rapid onset of action and short duration of effect of 1 to 4 hours, but it has a significant amnestic effect. Diazepam has a rapid onset of action intravenously and has a prolonged duration of action. The disadvantage of lorazepam is its delay to effect, which limits the rapidity of clinical response.

A 2016 systematic review and meta-analysis aimed to compare the use of benzodiazepines, antipsychotics, and a combination of these 2 classes in the treatment of agitated patients in the emergency department. The investigators’ aim was to determine which of these pharmacologic approaches were more effective, measured by the proportion of individuals who remain sedated at 15 to 20 minutes and the need for repeat sedation,

as well as which approaches were safer, as determined by the proportion of reported adverse events. This systematic review concluded that a larger portion of patients remained sedated with therapeutic combination (use of both benzodiazepine and antipsychotic) compared to benzodiazepines alone. Additionally, antipsychotic monotherapy and combinations both required fewer repeated administrations for sedation than benzodiazepines alone. Benzodiazepine monotherapy was also associated with a higher incidence of adverse events than the antipsychotics alone or combinations.<sup>26</sup> We recommend the use of antipsychotic monotherapy in the presumed agitated psychosis in those primarily calm enough to be cared for by a psychiatrist with limited likelihood of a consequential toxicologic problem, whereas toxicologists treating undifferentiated episodes of toxicity and agitation prefer midazolam, diazepam or lorazepam. When appropriate regimens of monotherapy are initiated in these two scenarios and fail, a combination of benzodiazepines and antipsychotics is reasonable.

There are multiple indications for the use of ketamine within the field of medicine, including a potential treatment for major depressive disorders, as well as use in the emergency department as sedation for procedures and for intubation. Ketamine is an antagonist of the glutamate *N*-methyl-D-aspartate (NMDA) receptor that is a dissociative anesthetic, which provides both analgesia and amnesia.<sup>47</sup> There is some recent interest in the potential use of ketamine for acute agitation in the emergency department setting and in the prehospital setting.<sup>30,40</sup> In a retrospective cohort study, 32 cases of acute agitation in the emergency department were treated with ketamine and monitored for vital sign changes and the need for rescue sedating medications within 3 hours of ketamine administration. This study found that 62.5% of cases required additional sedating medications within 3 hours of initial ketamine administration. The authors hypothesized that the reason that the effects of ketamine on agitation were not sustained were unrelated to the underlying causes of the agitation. However, there were 8 cases where the subject received multiple doses of an antipsychotic or benzodiazepine without resolution of agitation, but on receiving a single dose of ketamine, no further medication for agitation was required for at least another 3 hours. This may indicate a unique role for ketamine as a potential alternative medication for agitation when the agitation is refractory to traditional pharmacologic interventions. In addition to examining the efficacy, this study also investigated the safety of using ketamine for agitation in the emergency department setting. Based on pre- and postadministration vital signs, there were mild increases in systolic blood pressure and heart rate but none of any clinical significance, and there were no cases of oxygen desaturation.<sup>22</sup> In 2017, a single-center, prospective, observational study compared the time to a defined reduction in agitation scores, rate of medication redosing, vital sign changes, and adverse events in agitated individuals in the emergency department receiving ketamine, benzodiazepines, and haloperidol, alone or in combination. This prospective study showed that the ketamine group had more patients who were no longer agitated at 5, 10, and 15 minutes after receiving medication. The ketamine group had similar rates of redosing, changes in vital signs, and adverse events compared to the benzodiazepine and haloperidol groups.<sup>39</sup> The findings in the 2 studies mentioned above are in stark contrast to a few studies on the prehospital administration of ketamine to treat agitation, which reported intubation rates between 39% and 63%.<sup>11,36</sup> In addition, a case series on prehospital use of ketamine for agitation showed that 3 of 13 patients (23%) developed hypoxia and another patient developed laryngospasm.<sup>5</sup> Given the conflicting and limited data on its safety in treating agitation, ketamine is not recommended as a first-line therapy to treat agitation in the emergency department setting, and physicians should use caution when using ketamine given concerns for significant adverse events which means evaluation for airway compromise and resuscitative preparedness (Chap. 83).

If a patient is agitated in the context of alcohol intoxication, we recommend antipsychotics and we suggest that benzodiazepines should be avoided because of the potential to cause additive respiratory depression. In contrast, benzodiazepines have a unique role in the treatment of agitation secondary to cocaine toxicity (Chap. 75 and Antidotes in Depth: A26). Antipsychotics, particularly

low-potency antipsychotics (such as chlorpromazine), lower the seizure threshold in animals, so their use for patients with cocaine/amphetamine toxicity or alcohol/sedative-hypnotic withdrawal is not recommended.

There is special concern about sedation and respiratory depression with IM olanzapine, given that 8 fatalities were reported in the European literature when olanzapine was used in excessive dosages or combined with benzodiazepines and/or other antipsychotics. Although significant comorbidities were present in the patients who died, we now recommended against using IM olanzapine with other CNS depressants.<sup>4</sup> In general, concerns regarding respiratory depression mandate careful observation and monitoring of patients receiving sedation with any xenobiotic (Chap. 67).

**Physical Restraint**

Isolation and mechanical restraints are also used in the treatment of violent behavior. Isolation or seclusion can help to diminish environmental stimuli and thereby reduce hyperreactivity. However, a few aspects are worth mentioning: Because seclusion is defined by a condition of very limited interactive and environmental cues, it is not indicated for patients with unstable medical conditions, delirium, dementia, self-injurious behavior such as cutting or head banging, or those who are experiencing extrapyramidal reactions as a consequence of antipsychotics such as an acute dystonic reaction.<sup>15</sup> Mechanical restraint is used to prevent patient and staff injury, although it does occasionally lead to patient and staff injury itself.<sup>3,21</sup> All facilities should have clear, written policy guidelines for restraint that address monitoring, documentation, and provisions for patient comfort. Frequent reassessment of the patient and documentation of the need for continued restraint are essential and should be performed according to state law. However recommendations are that patients be constantly observed while being physically restrained or in seclusion. Attention is necessary to assess excessive restraint and excessive straining which may lead to sudden cardiac death.

See Tables SC4-1 and SC4-2 for violence warning signs and the S.A.F.E.S.T. Approach.

In conclusion, aggressive and violent behaviors are commonplace in the health care setting, with particularly high incidence of violence toward nursing assistants and nurses, and within the emergency department settings and inpatient psychiatric wards. Some aggressive behavior is attributable to the direct pharmacologic effects of xenobiotics, but probably represents only a modest fraction. Substance use is often implicated in violent behavior in the community, it can occur as a coincidental part of the lifestyle of violent individuals, and both substance use and violence are related to common underlying characteristics such as a personality disorder.

**SUMMARY**

Some ways of mitigating environmental risk factors in the hospital setting include:

- metal detectors and screening patients for weapons,
- ensuring adequate staff to patient ratios,
- early identification of potentially violent patients,
- ensure that staff and patient care are not compromised by overcrowding,
- workplace violence policy and prevention program,
- regular training in preventive measures, and
- violence prevention program and a designated “behavioral crisis response team.”

TABLE SC4-1 Violence Warning Signs
Agitated movements
Body posturing, rapid/shallow breathing
Clenched fists
Loud vocalizations
Pacing
Staring
Striking at inanimate objects
Threatening statements

TABLE SC4-2 S.A.F.E.S.T. Approach	
Spacing	Maintain a safe distance Allow both patient and you to have equal access to the door (but you should be closest) Do not touch the patient
Appearance	Maintain empathetic and professional detachment Use one primary person to build rapport Have security available as a show of strength
Focus	Watch the patient’s hands Look for potential weapons Watch for escalating agitation
Exchange	Attempt to de-escalate by use of calm/continuous talking Avoid punitive or judgmental statements Use good listening skills Elicit patient cooperation by targeting the current problem
Stabilization	By the least restrictive and most appropriate approach(s) possible: Physical restraints Sedation (benzodiazepines) Antipsychotics
Treatment	Treat underlying cause May need to treat involuntarily

# RENAL PRINCIPLES

Marc Ghannoum and David S. Goldfarb

## ANATOMY AND BASIC PHYSIOLOGY

The kidneys lie in the paravertebral grooves at the level of the T12 to L3 vertebrae. The medial margin of each is concave, whereas the lateral margins are convex, giving the organ a bean-shaped appearance. In the adult, each kidney measures 10 to 12 cm in length, 5 to 7.5 cm in width, and 2.5 to 3.0 cm in thickness. In an adult man, each kidney weighs 125 to 170 g; in an adult woman, each kidney weighs 115 to 155 g.

On the medial surface of the kidney is the hilum, through which the renal artery, vein, renal pelvis, a nerve plexus, and lymphatics pass. On the convex surface, the kidney is surrounded by a fibrous capsule, which protects it, and a fatty capsule with a fibroareolar capsule called the *renal fascia*, which offers further protection and serves to anchor it in place.

The arterial supply begins with the renal arteries, which are direct branches of the aorta. On entering the hilum, the arteries subdivide into branches supplying the 5 major segments of each kidney: the apical pole, the anterosuperior segment, the anteroinferior segment, the posterior segment, and the inferior pole. These arteries subsequently divide within each segment to become lobar arteries. In turn, these vessels give rise to arcuate arteries that diverge into the sharply branching interlobular arteries, and then the afferent arterioles that directly supply the glomerular capillary tufts. The capillaries are then drained by the efferent arterioles, and peritubular capillaries, which also supply the vasa recta. Eventually, all are combined into the renal veins, which empty into the inferior vena cava.

The cut surface of the kidney reveals a pale outer rim and a dark inner region corresponding to the cortex and medulla, respectively. The cortex is 1 cm thick and surrounds the base of each medullary pyramid. The medulla consists of between 8 and 18 cone-shaped areas called *medullary pyramids*; the apex of each area forms a papilla containing the ends of the collecting ducts. Urine empties from each papilla into a calyx, and the calyces join together to form the renal pelvis. Urine is drained from the pelvis into the ureters and, subsequently, into the urinary bladder.

The kidneys serve 3 major functions: (1) homeostasis of fluids, acid–base balance, and electrolytes; (2) excretion of nitrogen, as urea, and other waste products; and (3) endocrine production such as 1,25-dihydroxy vitamin D, renin, and erythropoietin.

The kidneys maintain the constancy of the extracellular fluid by creating an ultrafiltrate of the plasma that is virtually free of cells and larger macromolecules, and then processing that filtrate, reclaiming what the body needs and letting the rest escape as urine. Every 24 hours, the adult's glomerular filter nearly 180 L of water (total body water is ~25–60 L) and 25,000 mEq of sodium (total body Na<sup>+</sup> content is 1,200–2,800 mEq). Under normal circumstances, the kidneys regulate salt and water excretion, depending on intake and extrarenal losses. Only approximately 1% of the filtered water and 0.5% to 1% of the filtered Na<sup>+</sup> are excreted.

Renal function begins with filtration of plasma at the glomerulus, a highly permeable capillary network connecting 2 arterioles in series. The relative constriction or dilation of these vessels normally controls the glomerular filtration rate (GFR). The glomerular capillaries are lined with endothelial cells, and encased by specialized epithelial cells called podocytes. The filtration barrier consists of the filtration slits, the connections between adjoining podocytes, and the glomerular basement membrane, the layers between the podocytes and endothelial cells. Under healthy circumstances, the filtration fraction—the proportion of renal plasma that is filtered into the Bowman space, the potential space surrounding the glomerular capillary tuft—is approximately 20%. Plasma water crosses the filter, along with electrolytes, small solutes such as

glucose, amino acids, lactate, and urea; blood cells and most of the larger proteins, including albumin and globulins, do not typically cross the filter, although recent observations suggest that more plasma proteins, including albumin, than previously thought are filtered and reclaimed by the proximal tubule. The filtrate then enters the tubules, the serial segments of which have varying roles to metabolize, reabsorb, and secrete various solutes.

The proximal tubule performs the bulk of reabsorption, isotonicly reclaiming 65% to 70% of the filtrate. It has 3 segments, called S1, S2, and S3. Distal to the proximal tubule is the hairpin turn of the thin limb of the loop of Henle, a segment important in maintaining the corticomedullary concentration gradient, which is important for urinary concentration and dilution. The thick ascending limb of the loop of Henle follows, which also influences concentration and dilution of the urine and plays an important role in the balance of Na<sup>+</sup>, Ca<sup>2+</sup>, and Mg<sup>2+</sup>. The distal convoluted tubules also reabsorb Na<sup>+</sup> and Ca<sup>2+</sup> and are joined by the connecting tubules to form the collecting ducts. These segments are relatively “tight” epithelia, allowing the establishment of gradients of solute concentration from blood to urine or vice versa. These distal segments are where the fine-tuning of excretion and reclamation of water, urea, K<sup>+</sup>, and H<sup>+</sup> occurs.

Given the importance of sodium balance to maintenance of cardiac preload and cardiac output, it is reasonable to consider sodium reabsorption, which occurs to an extent in every segment, as the kidney's most important role. Sodium reabsorption in the proximal tubule occurs both via both paracellular transport and transcellular transport. The former occurs in response to hydrostatic and oncotic pressures between the peritubular capillaries and the tubule, while the latter is mediated by a Na<sup>+</sup>–H<sup>+</sup> exchanger stimulated by angiotensin II. In the distal tubule, hormones such as aldosterone, and a variety of kinases, control sodium transport.

Control of water balance includes urinary dilution or urinary concentration depending on the clinical circumstance. When dilution is appropriate, the ascending limb of the loop of Henle absorbs solute without water. This action produces a dilute tubular fluid and makes the medullary interstitium hypertonic. Suppression of the antidiuretic hormone (ADH; or vasopressin) leads to disappearance of water pores called aquaporins from the collecting duct; electrolyte-free water is then excreted. When urinary concentration is appropriate, ADH stimulates the appearance of aquaporins, allowing water to move from the tubule lumen into the interstitium, to minimize loss of electrolyte-free water.

The kidneys also regulate the balance of K<sup>+</sup> and H<sup>+</sup> (which are secreted by the distal nephron under the influence of aldosterone), and Ca<sup>2+</sup> and phosphate via circulating parathyroid hormone, activated vitamin D, and fibroblast growth factor 23. The tubules also are capable of secretion of many solutes, including drugs such as diuretics, uric acid, and other organic anions.

## XENOBIOTICS AND THE KIDNEYS

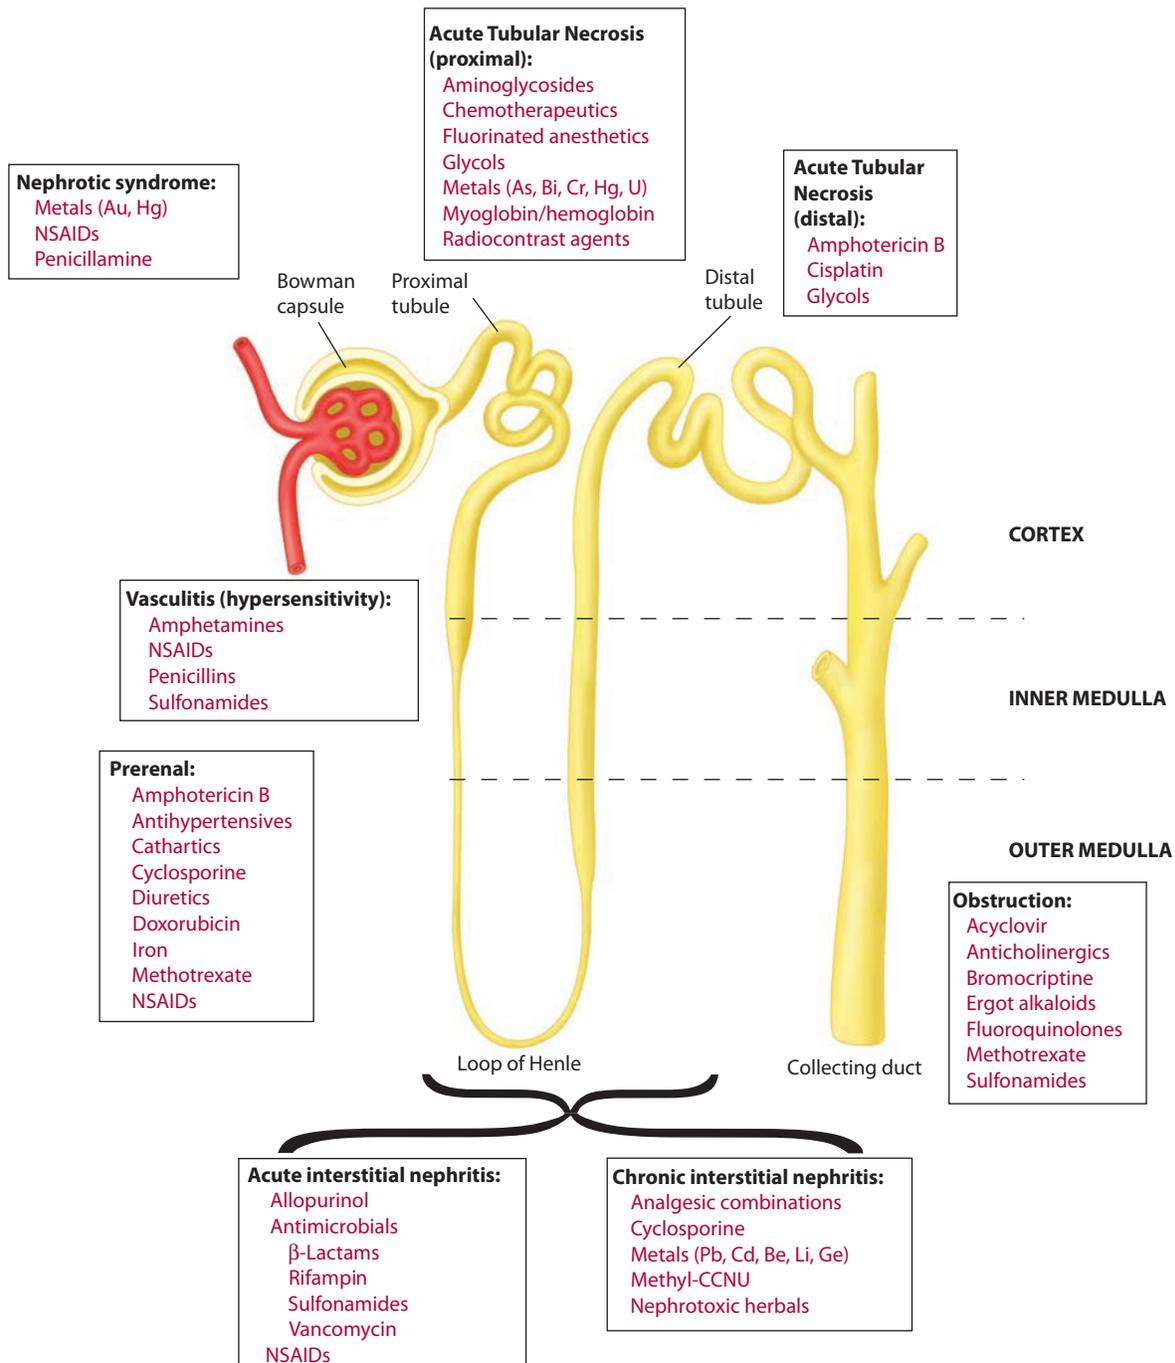

Xenobiotics affect kidney function in various ways and, conversely, renal disease influences their pharmacokinetics, which sometimes leads to dangerous overdosing and potential toxicity. In this case, kidney failure, whether acute or chronic, reduces the clearance of xenobiotics eliminated by the kidneys. The ideal dosing of drugs such as gabapentin, digoxin, baclofen, and vancomycin must be reduced several-fold in patients with advanced kidney failure compared to those with intact kidney function. Some xenobiotics are potentially toxic in patients with kidney impairment while being relatively benign in patients with normal GFR. This is the case for gadolinium-based

contrast used for magnetic resonance imaging, which carries the risk of nephrogenic systemic fibrosis.<sup>55</sup>

Hemodialysis or peritoneal dialysis further complicates pharmacokinetics and drug dosing; in particular, the elimination of many antimicrobials are severely altered in critically ill patients with kidney failure, whether acute or chronic. In this setting, the risk of underdosing with subsequent therapeutic failure and breakthrough resistance acquired by microorganisms occasionally surpasses that of drug accumulation. A notable example is fluconazole: the required dosage in patients undergoing continuous renal replacement therapy even surpasses the drug requirement in patients with intact kidney function.<sup>58</sup> For those drugs of which a substantial fraction is removed by hemodialysis, drug re-dosing after dialysis is often recommended. The use of therapeutic guides is encouraged to ensure proper drug prescription in patients with a history of kidney disease.<sup>16</sup>

Many xenobiotics cause or aggravate renal dysfunction. The kidneys are particularly susceptible to toxic injury for 4 reasons: (1) they receive 20% to 25% of cardiac output, yet make up less than 1% of total body mass (~300 grams in a 70 kg man), implying a relatively large exposure to circulating xenobiotics; (2) they are metabolically active, and thus vulnerable to xenobiotics that disrupt metabolism or are activated by metabolism, such as acetaminophen (APAP); (3) they remove water from the glomerular filtrate, which increases the tubular concentration of xenobiotics; and (4) the glomeruli and interstitium are susceptible to attack by the immune system. Many factors, such as renal perfusion, affect an individual's reaction to a particular nephrotoxin.<sup>3</sup> Clinicians should be aware of these factors so as to minimize the adverse effect of a toxic exposure.

Xenobiotics can affect any part of the nephron (Fig. 27-1), although not every type of toxic renal exposure will result in loss of GFR. The following

**FIGURE 27-1.** Schematic showing the major nephrotoxic processes and the sites on the nephron that xenobiotics chiefly affect. NSAIDs = nonsteroidal antiinflammatory drugs.

will be described: (1) acute kidney injury, (2) chronic kidney disease, and (3) functional kidney disorders.

**Acute Kidney Injury**

Acute kidney injury (AKI; formerly called “acute renal failure”) relates to an abrupt decline in renal function that impairs the capacity of the kidney to maintain metabolic balance. Several definitions of AKI now exist, although they will likely be revised with the advent of newer and more specific biomarkers of kidney injury. The Kidney Disease: Improving Global Outcomes (KDIGO) clinical practice guidelines introduced staging criteria for AKI, based on prior work from the Acute Dialysis Quality Initiative (ADQI) and the Acute Kidney Injury Network (AKIN) (Table 27–1). The 3 traditional, main categories of AKI are prerenal, postrenal, and intrinsic AKI.

**Prerenal AKI**

Prerenal AKI implies impaired renal perfusion, which occurs with volume depletion, systemic vasodilation, heart failure, or preglomerular vasoconstriction. Renal hypoperfusion initiates a sequence of events leading to renal salt and water reabsorption.<sup>3</sup> Renin is released, causing production of angiotensin II, which enhances proximal tubular sodium reabsorption and stimulates adrenal aldosterone release, thus increasing distal sodium reabsorption. Therefore, prerenal AKI is usually accompanied by low urinary sodium excretion. Release of ADH increases water retention, manifested by a high urine osmolality. Histologically, the kidney appears normal.

Any toxic exposure that compromises renal perfusion potentially contributes to prerenal AKI, including bleeding (eg, from overdose of anticoagulants), volume depletion (diuretics, cathartics, or emetics), cardiac dysfunction ( $\beta$ -adrenergic antagonists), or hypotension from any cause.<sup>53</sup> Nonsteroidal antiinflammatory drugs (NSAIDs) lower the filtration rate by inhibiting production of vasodilatory prostaglandins in the afferent arteriole. Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) reduce the vasoconstrictive effect of angiotensin II on the efferent arteriole and can both cause prerenal AKI, especially in the setting of volume contraction. Finally, cardiotoxins, such as doxorubicin, cause severe heart failure (Fig. 27–1). Calcineurin inhibitors (cyclosporine, tacrolimus) also cause prerenal vasoconstriction by their effect on both afferent and efferent arterioles, possibly induced by endothelin. Calcineurin nephrotoxicity is

usually dose-dependent and especially occurs when trough concentrations remain supratherapeutic for an extended period of time. Nephrotoxicity is often reversible after temporary discontinuation or decrease in the calcineurin dose if identified relatively quickly.

Prerenal AKI is also caused by the hepatorenal syndrome, which is characterized by progressive renal hypoperfusion in the context of severe acute or chronic liver failure. In this setting, marked constriction of the renal arterial vasculature coexists with profound systemic and splanchnic hypotension, caused by several circulating mediators, including angiotensin, norepinephrine, vasopressin, endothelin, and isoprostanone F<sub>2</sub>.<sup>50</sup> That the cause of AKI is extrarenal is best illustrated by the fact that the histology of a kidney from a patient with hepatorenal syndrome is completely normal. The prognosis of the hepatorenal syndrome is entirely dependent on the recovery of liver function.

Finally, the entity known as the abdominal compartment syndrome is a potential cause of renal hypoperfusion.<sup>9</sup> Abdominal compartment syndrome is usually defined as new organ dysfunction induced by intraabdominal hypertension and occurs when the intraabdominal pressure exceeds 20 mm Hg, especially if sustained. The abdominal compartment syndrome is caused by several entities, but usually requires some abdominal event, especially with concomitant aggressive fluid resuscitation. Surgical decompression is life-saving in this context.

**Renal AKI**

Renal AKI implies intrinsic damage to the renal parenchyma, which is divided into vascular, glomerular, and tubulointerstitial etiologies.

Vascular etiologies of AKI include vasculitis, malignant hypertension, atheroemboli, scleroderma, and hemolytic-uremic syndrome or thrombotic thrombocytopenic purpura (HUS/TTP), the latter of which is sometimes associated with use of certain xenobiotics (Table 27–2).

Glomerular diseases infrequently cause acute AKI, but more commonly either a chronic or subacute decline in kidney function. Glomerular lesions either present with the nephrotic or nephritic syndrome. A nephritic pattern is associated with histological inflammation, an active urine sediment with proteinuria and hematuria, and impaired kidney function. Hypertension is common. The nephrotic syndrome is characterized by massive proteinuria (>3.5 g/day), hypoalbuminemia, hyperlipidemia, and pitting pedal edema that usually prompts the patient to seek medical attention. Although the relationships between these findings are not completely understood, the underlying event is injury to the glomerular barrier that normally prevents macromolecules from passing from the capillary lumen into the urinary space.

Xenobiotics induce nephrotic syndrome (Table 27–3) in 2 ways. First, they release antigens into the blood, which leads to antigen–antibody complex formation after the immune response is elicited. These complexes such as those of gold salts subsequently deposit in the glomerular basement membrane, thereby changing its properties<sup>19</sup> (Fig. 27–2). Second, they upset the immunoregulatory balance.

Kidney biopsy will permit identification of the characteristic pathologic pattern, which includes but is not limited to minimal glomerular change disease, membranous glomerulopathy, or focal segmental glomerulosclerosis. Hypoalbuminemia usually is worse than urinary excretion of albumin would suggest, as a result of tubular metabolism of filtered protein. The tubules also retain sodium, causing expansion of the extracellular space and edema.

TABLE 27–1 Kidney Disease Improving: Global Outcomes (KDIGO) Staging Criteria of Acute Kidney Injury (AKI)	
Stage 1	Creatinine of 1.5–1.9 times baseline OR $\geq 0.3$ mg/dL ( $\geq 26.5$ $\mu$ mol/L) increase in the serum creatinine OR Urine output $< 0.5$ mL/kg/h for 6–12 hours
Stage 2	Creatinine of 2.0–2.9 times baseline increase in the serum creatinine OR Urine output $< 0.5$ mL/kg/h for $\geq 12$ hours
Stage 3	Creatinine of 3.0 times baseline increase in the serum creatinine OR Increase in serum creatinine to $\geq 4.0$ mg/dL ( $\geq 353.6$ $\mu$ mol/L) OR Urine output of $< 0.3$ mL/kg/h for $\geq 24$ hours OR Anuria for $\geq 12$ hours OR Initiation of renal replacement therapy OR In patients $< 18$ years, decrease in estimated GFR to $< 35$ mL/min per $1.73$ m <sup>2</sup>

TABLE 27–2 Xenobiotics Most Commonly Causing Thrombotic Microangiopathy

Penicillamine
Probenecid
Sirolimus

TABLE 27-4 Xenobiotics Most Commonly Causing Acute Tubular Necrosis

Acetaminophen
Aluminum phosphide
Antibacterials (aminoglycosides, ciprofloxacin, levofloxacin, colistin)
Antifungals (amphotericin B, pentamidine)
Antivirals (acyclovir, foscarnet, ritonavir, tenofovir, cidofovir, adefovir)
Chemotherapeutics (cisplatin, ifosfamide, mithramycin, streptozotocin)
Deferoxamine
Etidronate
Grass carp gallbladder
Halothane
Metals (As, Bi, Cr, Hg, U)
Mushrooms ( <i>Amanita</i> {especially <i>A. smithiana</i> }), <i>Cortarius</i> spp)
Non-protein colloids (mannitol, hydroxyethyl starches, dextran)
Paraquat, diquat
Radiocontrast agents (iodinated contrast, gadolinium)

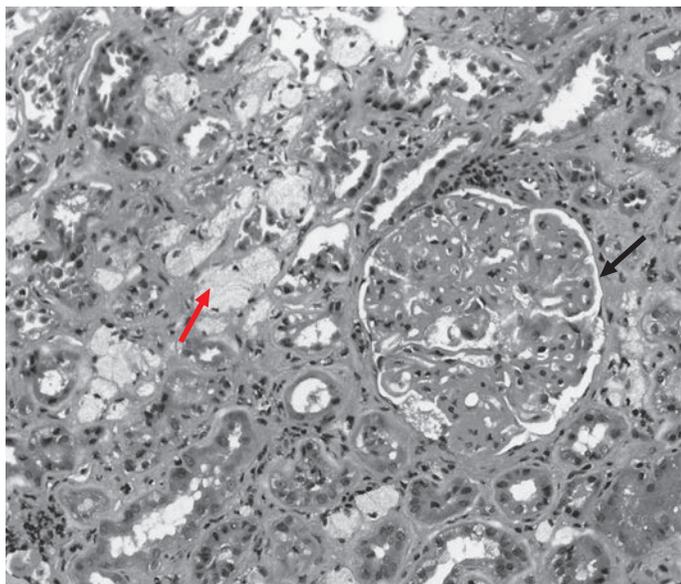

The glomerular lesion will progress to end-stage renal disease (ESRD) if the pathologic process continues.

The major causes of acute tubulointerstitial diseases include acute tubular necrosis (ATN), acute interstitial nephritis (AIN), and tumor lysis syndrome. Although there is controversy about how a tubular lesion leads to glomerular shutdown, it is generally felt that tubular obstruction, back-leak of filtrate across injured epithelium, renal hypoperfusion, and decreased glomerular filtering surface combine to impair glomerular filtration.<sup>5,60</sup> Additionally, filtration pressure is diminished by neutrophil infiltration into the interstitium and vasa recta. Evidence also suggests that prolonged medullary ischemia, perhaps caused by an imbalance in the production of vasoconstrictors such as endothelin and vasodilators such as nitric oxide, is important in prolonging the renal dysfunction after the tubular injury develops.<sup>32</sup>

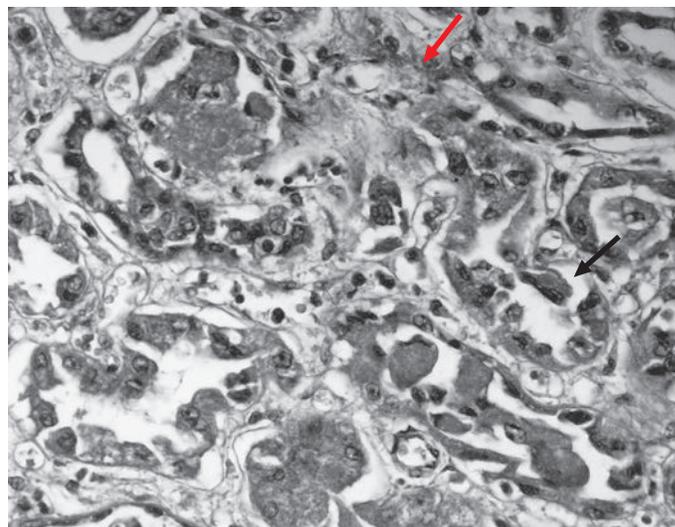

Acute tubular necrosis is the most common cause of AKI in hospitalized patients (Table 27-4). Acute tubular necrosis is manifested pathologically by patchy necrosis of the tubular epithelium and occlusion of the lumen by casts and cellular debris (Fig. 27-3). Clinically, ATN presents as a rapid deterioration of kidney function. Muddy brown casts or renal tubular cells are typically seen in the urinary sediment, but hematuria and leukocyturia are

unusual. Disorders of metabolic balance, such as hyperkalemia and metabolic acidosis, are also common. The abrupt fall in GFR usually leads to positive sodium and water balance.<sup>39</sup>

Acute tubular necrosis occurs following an ischemic or toxic injury.<sup>5,46,60</sup> Direct toxicity accounts for approximately 35% of all cases of ATN. Xenobiotics affect different segments of the renal tubules; for example, uranium and other heavy metals react with the proximal tubule and amphotericin the distal tubule (Fig. 27-1).<sup>49</sup> Certain xenobiotics cause a sudden or progressive decrease in GFR with concomitant prominent tubular wasting for electrolytes, though mechanisms of injury vary; this is the case of ifosfamide,<sup>20</sup> amphotericin B,<sup>49</sup> aminoglycosides,<sup>48</sup> pentamidine,<sup>37</sup> and cisplatin.<sup>11</sup> Poisoning also leads to ischemic tubular necrosis if hypotension or cardiac failure causes prolonged ischemia of nephron segments (proximal straight tubule and inner medullary collecting duct) that are particularly vulnerable to hypoxia. Patients who receive significant amounts of certain colloids (specifically mannitol, dextran, or hydroxyethyl starch)<sup>13</sup> occasionally develop AKI, characterized by tubular vacuolization or “osmotic nephrosis.” Iodinated contrast causes AKI by mediating medullary vasoconstriction and inducing reactive oxygen species in tubules, despite recent studies questioning

**FIGURE 27-2.** Membranous glomerulonephropathy (secondary to gold), a cause of nephrotic syndrome. Selective serotonin reuptake inhibitors
Snake and insect venoms
Xenobiotics causing hypokalemia or hypophosphatemia
Xenobiotics causing prolonged central nervous system depression (immobilization) or seizures
Zidovudine

the existence of this phenomenon. Whatever the clinical pattern of rapidly declining renal function, all forms of ATN usually present with oliguria, aside from toxicity to aminoglycosides that can present as non-oliguric ATN.<sup>7</sup>

Pigmenturia (myoglobinuria following rhabdomyolysis or hemoglobinuria from massive hemolysis) is another cause of tubular injury and necrosis by precipitating in the tubular lumen.<sup>5,59</sup> Myoglobin is normally excreted without causing toxicity. A study of patients with rhabdomyolysis suggests that the concentration of myoglobin in the urine affects the development of AKI.<sup>59</sup> If myoglobin inspissates in the tubular lumen because of renal hypoperfusion and high urinary concentration, it dissociates in the relatively acidic environment as H<sup>+</sup> is secreted, releasing tubulotoxic hematin. This toxicity stems from the iron-catalyzing production of oxygen free radicals.

Rhabdomyolysis is most often caused by direct muscle injury following trauma or prolonged immobilization (Table 27-5). Any poisoning causing extended unconsciousness (eg, opioids and sedative-hypnotics), hyperthermia (neuroleptic malignant syndrome), excessive muscle contraction (cocaine, amphetamines),<sup>14,41</sup> or tonic-clonic seizures (alcohol withdrawal, theophylline, isoniazid) may lead to muscle breakdown.<sup>6</sup> Other xenobiotics are directly myotoxic in some individuals, such as alcohol,<sup>27</sup> β-hydroxy-β-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins),<sup>23</sup> carbon monoxide, copper sulfate, and zinc phosphate.<sup>36,57</sup> Rhabdomyolysis can also occur after extensive bee or wasp stings<sup>26</sup> or fire ant bites.<sup>29</sup> Hypokalemia and hypophosphatemia (eg, following diuretics and laxatives abuse) can also induce rhabdomyolysis. Synthetic cannabinoids are associated with an atypical form of acute kidney injury, sometimes accompanied by rhabdomyolysis.<sup>8,41</sup>

Hemoglobinuria follows hemolysis, which is caused by a number of xenobiotics, including snake and spider venoms, cresol, dapson, phenol, aniline, arsine, stibine, naphthalene, dichromate, and methylene chloride. Sensitivity reactions to drugs (hydralazine, quinine) can also cause hemolysis.<sup>28</sup> The pathophysiology of hemoglobinuric ATN resembles that of myoglobinuria. The pigment deposits in the tubules and dissociates, causing necrosis to occur.<sup>6</sup> Volume depletion and acidosis precipitate the disorder; therefore, volume expansion and alkalinization help prevent kidney injury.

Differentiation of ATN from prerenal AKI is often clinically difficult, especially in critically ill patients; Table 27-6 illustrates empiric criteria to separate them, although there are numerous exceptions to these. These exceptions should always be correlated with clinical status. For example, fractional sodium excretion (the proportion of filtered sodium that appears in the urine, FE<sub>Na</sub>) can be paradoxically high in prerenal AKI associated with metabolic alkalosis, diuretics, or adrenal insufficiency (Table 27-7), and in patients with chronic kidney disease. FE<sub>Na</sub> can also be low in renal AKI secondary to rhabdomyolysis or contrast-induced AKI.<sup>39</sup> Furthermore,

**TABLE 27-6 Differentiation Between Prerenal Acute Kidney Injury and Acute Tubular Necrosis**

	Prerenal Acute Kidney Injury	Acute Tubular Necrosis
Fractional excretion of sodium (FE <sub>Na</sub> )	<1%	>2%
Fractional excretion of urea (FE <sub>Urea</sub> )	<35%	>50%
Serum urea/creatinine	>20	10–15
Urine osmolality	>400 mOsm/kg H <sub>2</sub> O	Equivalent to plasma (isosthenuric)
Urine sodium	<20 mEq/L	>40 mEq/L
Urine sediment	Bland	Muddy “dirty” brown casts

distinction between both entities is difficult when there is exposure to xenobiotics capable of affecting the kidneys in various ways. Nonsteroidal antiinflammatory drugs, for example, can cause prerenal AKI, ATN, acute interstitial nephritis, analgesic nephropathy, or membranous nephropathy.

The other major tubulointerstitial cause of AKI is AIN (Table 27-8), which is characteristically distinguished from ATN by a dense cellular infiltrate separating tubular structures on renal biopsy (Fig. 27-4). Nearly all cases of acute interstitial nephritis are caused by hypersensitivity.<sup>38,47</sup> Commonly implicated xenobiotics are antibiotics, proton-pump inhibitors, and NSAIDs. The diagnosis may be clear and kidney biopsy not necessary if kidney failure follows exposure to culpable xenobiotics and is accompanied by classic manifestations of systemic allergy such as fever, rash, or eosinophilia, although only 10% of patients typically present with this classic triad.<sup>43</sup> Flank pain or arthralgia may also be present. Unlike those with ATN, many patients with AIN have hematuria and

**TABLE 27-7 Calculations**

$$\text{Fractional Na}^+ \text{ excretion (FE}_{\text{Na}}) = \frac{([\text{Na}^+]_{\text{urine}} / [\text{Na}^+]_{\text{plasma}}) \times 100}{([\text{Creat}]_{\text{urine}} / [\text{Creat}]_{\text{plasma}})}$$

$$\text{Fractional Urea excretion (FE}_{\text{Urea}}) = \frac{([\text{Urea}]_{\text{urine}} / [\text{Urea}]_{\text{plasma}}) \times 100}{([\text{Creat}]_{\text{urine}} / [\text{Creat}]_{\text{plasma}})}$$

$$\text{Creatinine clearance (by urine collection)} = \frac{([\text{Creat}]_{\text{urine}} \times \text{urine flow})}{([\text{Creat}]_{\text{plasma}})}$$

Cockcroft-Gault formula

$$\text{Estimated creatinine clearance} = \frac{(140 - \text{age}) \times \text{ideal body weight}}{(72 \times [\text{Creat}]_{\text{plasma}}) (\times 0.85 \text{ if female})}$$

MDRD formula

$$\text{Estimated glomerular filtration rate} = \frac{186 \times [\text{Creat}]_{\text{plasma}}^{-1.154} \times \text{Age}^{-0.203}}{(\times 0.74 \text{ if female}) (\times 1.21 \text{ if African American})}$$

CKD-EPI formula:

$$\text{Estimated glomerular filtration rate} = 141 \times \text{min}(\text{Scr}/\kappa, 1)^{\alpha} \times \text{max}(\text{Scr}/\kappa, 1)^{-1.209} \times 0.993^{\text{Age}} \times 1.018 \text{ [if female]}, 1.159 \text{ [if black]}, \text{ where Scr} \text{ is serum creatinine, } \kappa \text{ is } 0.7 \text{ for females and } 0.9 \text{ for males, } \alpha \text{ is } -0.329 \text{ for females and } -0.411 \text{ for males, min indicates the minimum of } \text{Scr}/\kappa \text{ or } 1, \text{ and max indicates the maximum of } \text{Scr}/\kappa \text{ or } 1. \text{ In this table, the multiplication factors for race and sex are incorporated into the intercept, which results in different intercepts for age and sex combinations.}^{33}$$

Units: urine flow (mL/min), creatinine concentration (mg/dL), weight (kg), age (years). N.B. these formulae are only applicable in a steady state (ie, if renal function is stable). MDRD = Modification of Diet in Renal Disease.

**TABLE 27–8** Xenobiotics Most Commonly Causing Acute Interstitial Nephritis

Allopurinol
Antiepileptics (carbamazepine, phenobarbital, phenytoin)
Antimicrobials ( $\beta$ -lactams, especially methicillin and cloxacillin, fluoroquinolones, sulfonamides, vancomycin, rifampin, nitrofurantoin, aminoglycosides, tetracyclines, colistin)
Azathioprine
Chinese herbs ( <i>Stephania tetrandra</i> , <i>Magnolia officinalis</i> )
Diuretics (furosemide, thiazides)
H <sub>2</sub> -antagonists (cimetidine, ranitidine)
Nonsteroidal antiinflammatory drugs (including selective cyclooxygenase-2 inhibitors)
Proton-pump inhibitors
Sulfinpyrazone
Zoledronate

**TABLE 27–9** Xenobiotics Most Commonly Causing Postrenal Acute Kidney Injury

Bladder Dysfunction	Crystals	Retroperitoneal Fibrosis
Anticholinergics (antihistamines, atropine, cyclic antidepressants, scopolamine)	Acyclovir	$\beta$ -Adrenergic antagonists
Antipsychotics (butyrophenones, phenothiazines)	Antiretroviral (indinavir, nelfinavir, saquinavir, atazanavir)	Bromocriptine
Bromocriptine	Ciprofloxacin	Herbals ( <i>Stephania</i> spp, <i>Aristolochia</i> spp)
Central nervous system depressants	Diethylene glycol	Hydralazine
	Ethylene glycol	Methyldopa
	Fluorinated anesthetics	Methysergide
	Fluoroquinolones	Pergolide
	Hemoglobin, myoglobin	
	Melamine	
	Methotrexate	
	Phenylbutazone	
	Sulfonamides	
	Vitamin C	

leukocyturia,<sup>45</sup> and sometimes eosinophiluria; however these tests have limited diagnostic utility.<sup>43</sup> The development of AIN is not dose-dependent and usually improves after cessation of the offending xenobiotic, although corticosteroids hasten recovery in severe cases.<sup>15</sup>

Tumor lysis syndrome also affects the tubulointerstitium and usually occurs following chemotherapy for large bulky lymphoproliferative, but not solid, tumors.<sup>40</sup> The incidence of tumor lysis has decreased with better pretherapeutic hydration and premedication with allopurinol or rasburicase.

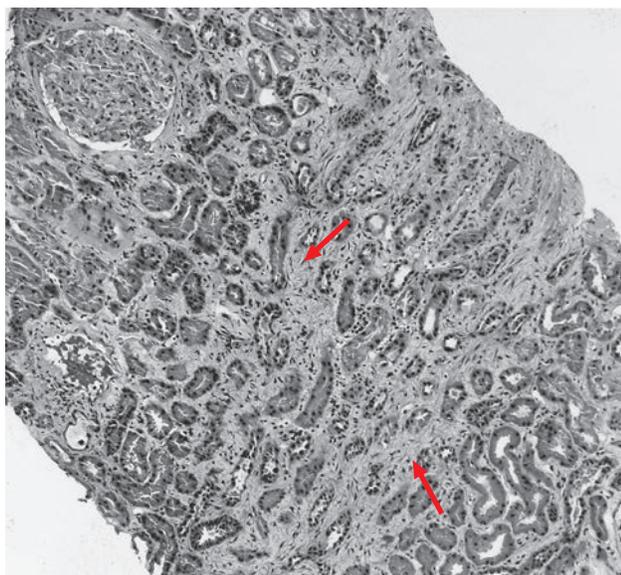

### Postrenal AKI

Postrenal AKI implies obstruction of urine flow anywhere from the renal pelvis to the urethra. An inclusive definition could classify obstruction of tubules due to crystals as postrenal AKI as well. Regardless of the cause of urinary tract obstruction, there are characteristic histologic and pathophysiologic alterations in the kidney: tubular dilation, predominantly in the distal tubule and collecting ducts, occurs initially and glomerular structure is preserved; subsequently dilation of the Bowman space occurs, and finally periglomerular fibrosis develops. Tubular function is impaired such that concentrating ability, potassium secretory function, and urinary acidification mechanisms are all altered.<sup>56</sup>

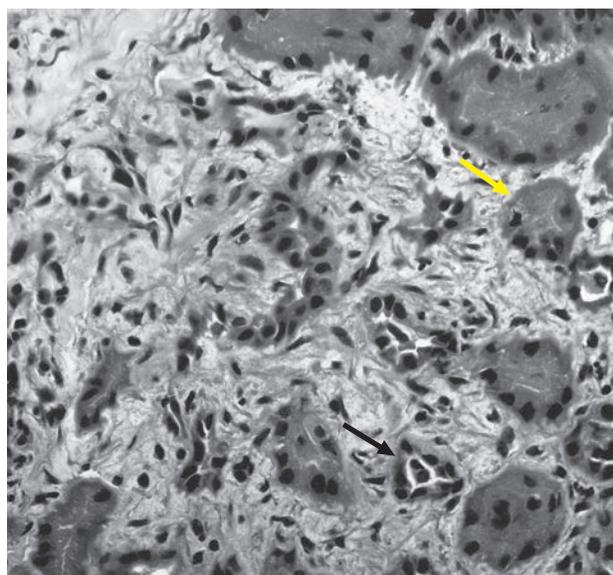

Urinary tract obstruction should always be considered when the kidneys fail rapidly. Acute kidney injury due to obstruction is divided into lower tract obstruction, which occurs at the bladder outlet, or upper tract obstruction,

occurring above the ureterovesical junctions. Lower tract obstruction occurs most frequently in men due to prostatic hypertrophy or prostate cancer, and in women due to cervical or endometrial cancer. Upper tract obstruction causing AKI is less frequent as it requires obstruction of both kidneys or ureters, unless the patient has a solitary kidney. Usually there is a history of abdominal or genitourinary cancer, or of kidney stones. Sudden anuria is a classical but rare feature of obstructive nephropathy; alternating phases of oliguria and polyuria are more common. Continued production of urine in the presence of obstruction leads to distension of the urinary tract above the blockage, manifesting as hydronephrosis or hydronephrosis. Calyceal dilation is common. Likewise, obstruction of the bladder outlet or urethra distends the bladder.

Xenobiotics are a common cause of obstruction (Table 27–9). Most such xenobiotics do so by impairing contraction of the bladder through anticholinergic action (atropine, antidepressants). Rarely, certain xenobiotics, particularly methysergide,<sup>54</sup> cause retroperitoneal fibrosis and ureteral constriction. Finally, a few xenobiotics lead to crystalluria and intratubular obstruction

(eg, oxalosis in ethylene glycol poisoning<sup>35</sup>). Sometimes the xenobiotic itself forms precipitates (sulfonamides, protease inhibitors such as atazanavir, or methotrexate).<sup>22,44,51</sup>

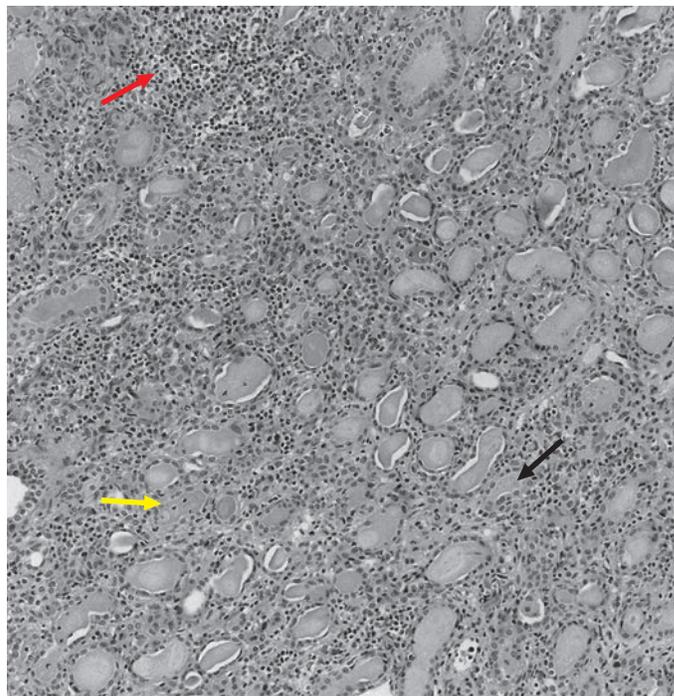

Patients who present with acutely deteriorating kidney function often represent a difficult diagnostic challenge. Not only are there 3 major etiologic categories, each category has several subdivisions; and more than one factor may be present. For example, a patient with an opioid overdose may have neurogenic hypotension (prerenal), together with muscle necrosis causing myoglobinuric AKI (intrinsic renal), and opioid-induced urinary retention (postrenal). Because renal, prerenal, and postrenal processes are not mutually exclusive and require different interventions, all 3 should always be considered, even when one appears to be the most obvious cause of the kidney failure.

### Chronic Kidney Disease

Chronic kidney disease (CKD) refers to a disease process of a minimum duration of 3 months that causes a progressive decline of renal function. There is usually a gradual rise in blood urea nitrogen (BUN) and serum creatinine concentration as the GFR falls; unless advanced, there are often no clinical manifestations other than hypertension and nocturia (indicating loss of urinary concentrating ability). Classification of various stages of CKD, presently endorsed by KDIGO, is presented in [Table 27–10](#).

Throughout the world, most cases of CKD are caused by diabetes, hypertension, or glomerulonephritis. Nevertheless, many xenobiotics are implicated as nephrotoxins in long-term exposures. The most common lesion of nephrotoxic CKD is chronic interstitial nephritis ([Fig. 27–5](#)), which involves destruction of tubules over a prolonged period,<sup>12</sup> with tubular atrophy, fibrosis, and a variable cellular infiltrate ([Fig. 27–5](#)), sometimes accompanied by papillary necrosis. This process then leads to ureteral colic via papillary sloughing. Acute interstitial nephritis progresses to chronic interstitial nephritis, if exposure is prolonged.<sup>41</sup> Analgesic nephropathy was a common etiology of CKD until certain analgesics (such as phenacetin) were discontinued.<sup>36</sup> Chronic interstitial nephritis presents with mild to moderate proteinuria that remains well under the nephrotic range. Unlike other chronic renal disorders, it is characterized by failure of the diseased tubules to adapt to the renal impairment, resulting in metabolic imbalances such as hyperchloremic metabolic acidosis, sodium wasting, and hyperkalemia early in the disease course.<sup>10</sup> Anemia is frequently observed.

Tenofovir, used in the treatment of HIV and hepatitis B, is associated with AKI with a risk of progressive CKD, attributed to mitochondrial DNA depletion and dysfunction of oxidative phosphorylation dysfunction.<sup>42</sup> The development of a tenofovir prodrug, tenofovir alafenamide, or TAF, achieves a higher intracellular concentration of the active metabolite tenofovir-diphosphate in the relevant immune cells. A much lower dose and lower plasma concentrations are required, and the prodrug fails to enter proximal

**FIGURE 27–5.** Chronic interstitial nephritis (secondary to NSAIDs). Interstitial fibrosis (→), lymphocytic infiltration (↗), and tubular atrophy (↘). Hematoxylin and eosin stain,  $\times 225$ . (Used with permission from Dr. Rabia Mir.)

tubule cells. These properties of the prodrug offer the potential for important renal sparing benefit.<sup>1</sup>

### Functional Toxic Renal Disorders

Although most toxic renal injury results in decreased renal function, certain functional disorders upset systemic balance despite normal GFR in anatomically normal kidneys. Three examples are presented here: renal tubular acidosis (RTA), syndrome of inappropriate secretion of ADH (SIADH), and diabetes insipidus (DI).

Renal tubular acidosis is a loss of ability to reclaim the filtered bicarbonate (proximal type 2 RTA) or a decreased ability to secrete protons and generate new bicarbonate to replace that lost in buffering the daily acid load (distal type 1 RTA). In either case, there is a non-anion gap hyperchloremic metabolic acidosis ([Chap. 12](#)).<sup>31</sup>

The primary defect in distal RTA (also called type 1 RTA) involves the decreased secretion of protons ( $H^+$ ) from the intercalated cells of the distal tubule. This results most frequently from a defect in the  $H^+$ -translocating adenosine triphosphatase (ATPase) on the luminal surface of these cells. Less frequently occurring mechanisms include abnormalities of the chloride-bicarbonate exchanger, which is responsible for returning bicarbonate generated within the cell to the systemic circulation.<sup>31</sup> Amphotericin B and some analgesics cause a distal RTA by allowing secreted  $H^+$  to leak back into the tubular cells.<sup>49</sup>

The primary defect in proximal type 2 RTA is variable and impairs reabsorption of sodium bicarbonate. Normally, the  $Na^+-H^+$  exchanger in the luminal membrane (NHE3), the  $Na^+,K^+-ATPase$  in the basolateral membrane, and the enzyme carbonic anhydrase are the key systems necessary for proximal tubular bicarbonate reabsorption. Exit of sodium bicarbonate at the basolateral membrane requires the sodium-bicarbonate cotransporter NBC. If one or more of these mechanisms becomes disordered, then the resorptive capacity of the proximal tubule is diminished. Proximal RTA often occurs as part of the Fanconi syndrome, a generalized failure of proximal tubular transport (proximal RTA plus amino-aciduria, glycosuria, and hyperphosphaturia). Xenobiotics associated with type 2 RTA include aminoglycosides, lead, ifosfamide, mercury, and carbonic anhydrase inhibitors such as acetazolamide.<sup>21</sup>

**TABLE 27–10** Classification of Chronic Kidney Disease as Defined by the Kidney Disease Outcomes Quality Initiative and Modified and Endorsed by the Kidney Disease: Improving Global Outcomes

Stage	GFR	Description
1	$\geq 90$	Any kidney damage with normal or $\uparrow$ in GFR
2	60–89	Kidney damage with mild $\downarrow$ in GFR
3a	45–59	Mild to moderate $\downarrow$ in GFR
3b	30–44	Moderate to severe $\downarrow$ in GFR
4	15–29	Severe $\downarrow$ in GFR
5	<15 or on dialysis	Kidney failure

GFR = glomerular filtration rate, determined by the 2009 CKD-EPI creatinine equation.

Reproduced with permission from Eckardt KU, Berns JS, Rocco MV, Kasiske BL. Definition and classification of CKD: the debate should be about patient prognosis—a position statement from KDOQI and KDIGO. *Am J Kidney Dis.* 2009;June;53(6):915–920.

What was once known as type 3 RTA is recognized to be a combination of features of both distal and proximal RTA and affects infants as part of an autosomal recessive syndrome. Carbonic anhydrase inhibitors affect the enzyme in both the proximal and distal tubules. Type 4 RTA is caused by a deficiency of aldosterone or by tubular resistance to its action. It most often occurs in adult patients with both diabetes and CKD who have hyporeninemic hypoaldosteronism. Hyperkalemia is the most prominent electrolyte disturbance while the metabolic acidosis, attributed to the ability of  $K^+$  to inhibit glutaminase, the rate-limiting step of ammoniogenesis, is usually mild. The findings of Type 4 RTA most often occur as the result of treatment of hypertension and chronic kidney disease with angiotensin converting enzyme inhibitors, angiotensin receptor blockers, and mineralocorticoid receptor antagonists.<sup>18</sup> Nonsteroidal antiinflammatory drugs often cause hyperkalemia with or without metabolic acidosis through similar mechanisms.<sup>25</sup>

The syndrome of inappropriate secretion of ADH occurs when the posterior pituitary gland or abnormal, unregulated sources such as malignancies secrete ADH despite the absence of physiological conditions that normally stimulate ADH secretion.<sup>17</sup> The usual stimulus for ADH release in normal, daily physiology is elevated plasma osmolality as the result of a temporary decreased availability of electrolyte-free water. The ADH release occurs as well despite normal serum osmolality when pathologic contraction of the effective arterial blood volume occurs (eg, volume depletion, congestive heart failure, cirrhosis). Antidiuretic hormone primarily affects the collecting tubule and causes increased water reabsorption by increasing the water permeability of the collecting duct by causing movement of aquaporins from intracellular lysosomes to the apical membranes. This effect of ADH leads to the main clinical manifestations of SIADH, namely, hyponatremia in the setting of euolemia, accompanied by inappropriately concentrated urine (as reflected in a failure to decrease urine osmolality to 50–100 mOsm/kg). Although this manifestation most often occurs as a complication of intracranial lesions or from ectopic ADH production by a tumor or a diseased lung, many xenobiotics (eg, carbamazepine, chlorpropamide, antidepressants, vincristine, opioids, methylenedioxymethamphetamine {MDMA}) can also cause inappropriate ADH release (Chap. 12).

Diabetes insipidus (DI) is the inability of the kidneys to maximally concentrate the urine and retain water leading to inappropriate loss of urine. Its 2 causes are the absence of pituitary ADH secretion (central DI) or the absence of an appropriate renal response to ADH stimulation (nephrogenic DI).<sup>4</sup> Diabetes insipidus typically presents with polyuria or hypernatremia if water intake is limited in the presence of inappropriately dilute urine. Central DI can be due to autoimmune destruction of the pituitary or trauma but often is the result of a space-occupying lesion affecting the posterior pituitary. Nephrogenic diabetes insipidus (NDI) is caused by a variety of factors, including genetic disorders, kidney failure, disease states, or electrolyte perturbations, but xenobiotics are often implicated. Lithium, demeclocycline, foscarnet, and clozapine are drugs that can cause this syndrome (Chap. 12). Nephrogenic DI from lithium exposure is thought to result from impaired aquaporin-2 synthesis and transport despite normal ADH binding to vasopressin type 2 receptors at the basolateral membranes of the collecting ducts.<sup>4</sup>

## PATIENT EVALUATION

Evaluation of a patient with suspected toxic renal injury should include consideration of extrarenal as well as renal factors. The response of the kidney to xenobiotics is affected by baseline renal function, renal blood flow, and the presence of urinary tract obstruction, all of which must be evaluated.

### History

A history of kidney disease or conditions that affect the kidney (eg, diabetes, hypertension, cardiovascular disease, kidney stones, urinary tract infection, prior chemotherapy) should be noted. Pertinent family history of kidney disease, glomerulopathy, kidney stones, and polycystic kidney disease needs to be recorded. Flank pain, hematuria, urine discoloration, or an abnormal pattern of urine output are important findings. Acute loss of kidney function

is often suspected if urine output decreases, although this is a late sign and not universal. The patient's intravascular volume status affects renal perfusion. Thus, a recent history of heart disease, vomiting, or diarrhea is important. Symptoms of kidney failure are usually only present when severe but include anorexia, nausea and vomiting, tachypnea, chest pain (from uremic pericarditis), leg cramps, fatigue, edema, bleeding (from uremic platelet dysfunction), and mental status changes. Systemic symptoms such as arthralgias, weight loss, and fever suggest vasculitis.

All current xenobiotics should be evaluated for potential renal effects.<sup>32</sup> The patient's intake of ethanol and drugs of abuse, as well as intake of natural products and medicinal herbs, should be explored. A careful occupational history and assessment of hobbies and lifestyle are crucial, with emphasis on exposure to nephrotoxic xenobiotics.

### Physical Examination

The patient's hemodynamic status should be carefully assessed. Postural changes in pulse and blood pressure, and either engorgement or decreased filling of the neck veins, may provide useful information about the intravascular volume, but seldom are they sensitive or specific. The skin should be examined for lesions. Funduscopy may reveal evidence of chronic hypertension or diabetes. All aspects of cardiac function should be noted, including presence or absence of a pericardial rub and edema. New-onset bluish lesions of toes suggest recent cholesterol emboli. Injuries or scars in the suprapubic area or evidence of past urologic or retroperitoneal surgery suggest obstruction, as does a palpable or percussible bladder. Asterixis and cognitive impairment is often present in late stages of uremic encephalopathy.

### Laboratory Evaluation

Although history and physical examination are essential to identify nephrotoxic injury, laboratory testing is indispensable to confirm the degree of renal dysfunction. The initial approach to a patient with renal disease usually combines both assessment of GFR and urinalysis. Both are noninvasive, inexpensive, and have considerable predictive value for patients with renal disease.

Because creatinine is freely filtered by the glomerulus and not significantly reabsorbed or metabolized in the tubule, serum creatinine concentration is used as the preeminent marker of overall kidney function; because a small proportion of total excreted creatinine in urine appears as the result of tubular secretion, creatinine clearance always overestimates GFR. As the kidneys fail, creatinine concentration increases. However, the relationship between its concentration and GFR is hyperbolic, not linear; therefore, a small initial elevation in serum concentration denotes a large decrease in kidney function. By the time the serum creatinine concentration exceeds the upper limit of normal, GFR is reduced by up to 50%. Furthermore, creatinine secretion becomes a significantly greater proportion of creatinine excretion as GFR fails. Renal hypoperfusion and prerenal states are associated with a disproportionate rise in urea in comparison with the rise in creatinine, because urea is partially reabsorbed in the proximal tubule along with salt and water.<sup>39</sup> However, this often-cited increase in the BUN-creatinine ratio may fail to occur in patients with chronic kidney disease, including the elderly. There are other limitations of their use as markers of renal injury; decreased production of urea (starvation or liver failure) or creatinine (amputation, muscle wasting) may result in a normal BUN or creatinine in the presence of significant renal impairment. Certain xenobiotics alter measured concentrations of urea and creatinine in the absence of any change in renal function.<sup>12</sup> The most obvious is exogenous creatine taken to build muscle mass. Drugs that block renal creatinine secretion, such as cimetidine and trimethoprim, also increase serum creatinine. The BUN is raised independently of renal function by corticosteroids (increased protein catabolism), and tetracycline.

Recently, more sensitive serum or urine markers of early AKI have been proposed, such as serum cystatin C, urinary kidney injury molecule-1, neutrophil gelatinase-associated lipocalin (NGAL), and *N*-acetyl- $\beta$ -glucosaminidase. Early studies suggest they help discriminate between ATN and prerenal AKI although they are costly and unavailable in most centers.<sup>2,10</sup>

Renal function is best evaluated by nuclear medicine (DTPA or MAG3 nuclear scan) and inulin clearance but these tests are impractical and expensive.

In patients with stable chronic kidney disease, a more precise estimation of the glomerular filtration rate is available. All laboratories today report an estimated GFR (eGFR), which has been validated in several populations of people with chronic kidney disease (Table 27–10). Most laboratories still report an estimate derived from the Modification of Diet in Renal Disease study (MDRD), while most research reports estimates derived from the CKD-EPI formula.<sup>33,34</sup> Twenty-four-hour urine collections to calculate creatinine clearance are occasionally done when low or high muscle mass are suspected to cause inaccuracies in estimates of GFR. Using any of these measurements in AKI is not helpful, as the accuracy of the measurement of clearance implies a steady state. Changing GFR during a clearance time period distorts the resulting estimation. There is also a lag period between changes in kidney function and changes in BUN or creatinine concentrations. An extreme example would be a patient undergoing bilateral nephrectomy: although GFR immediately postoperatively equals 0 mL/min, the increase in serum creatinine will only be evident after a few hours. Any clearance calculation would yield an estimated GFR very different from true GFR. In general, a patient with AKI and rapidly increasing creatinine concentration should be managed as if GFR were less than 10 mL/min until serum creatinine concentration stabilizes and GFR can more accurately be estimated. Estimation of GFR is most important in prescribing drugs. Because much of the relevant pharmacology literature pre-dates the current equations used to estimate GFR, many recommendations for drug dosing are still based on the Cockcroft–Gault formula, which estimates creatinine clearance.

Most patients presenting with AKI should have their urine examined. Standard automated dipsticks will detect albumin and glucose. The presence of a positive dipstick for blood when the urine contains no or few RBCs suggests either rhabdomyolysis or hemolysis. A simple urine spot test may help discriminate prerenal azotemia from ATN (Table 27–6); this is suggested by a fractional sodium excretion below 1% and urine osmolality above 400 mOsm/kg. Direct microscopic examination of the urine sediment also provides useful clues.<sup>24</sup> Dysmorphic red cells suggest glomerular hematuria but are neither sensitive nor specific. If acute interstitial nephritis is a consideration, a fresh urine sample should be stained for eosinophils, though frequently these cells are absent.<sup>43</sup> Calcium oxalate crystalluria is suggestive of exposure to xenobiotics such as ethylene glycol and vitamin C.<sup>30</sup>

Measurement of postvoiding residual urine volume, preferably by suprapubic ultrasonography or by passage of a urinary catheter with complete bladder emptying, can demonstrate lower urinary tract obstruction; if the volume is in excess of 75 to 100 mL, then bladder dysfunction or obstruction should be suspected. Among the many radiologic studies used in patients with kidney diseases, renal ultrasonography is the most useful and is indicated in all patients with AKI or CKD of unknown etiology; postrenal AKI is suggested by obstruction of the urinary tree, characteristically by swelling of one or 2 kidneys (hydronephrosis).<sup>56</sup> Asymmetry between kidney diameters is suggestive of renal artery stenosis. Cortex thinning and a poorly differentiated corticomedullary junction are consistent with long-standing kidney failure of any etiology. When the etiology of kidney disease remains elusive, a percutaneous renal biopsy will establish the final diagnosis. Table 27–11 summarizes the diverse nephrotoxic effects of various metals.

**TABLE 27–11** Nephrotoxic Effects of Metals

	<i>Toxic ATN</i>	<i>Shock ATN</i>	<i>Hemolysis</i>	<i>Acute Interstitial Nephritis</i>	<i>Chronic Interstitial Nephritis</i>	<i>Tubular Dysfunction</i>	<i>Nephrotic Syndrome</i>

+++ = common; + = uncommon. ATN = acute tubular necrosis.

The absence of a +, ++ or +++ indicates no evidence of this effect.

## SUMMARY

- The kidneys act as primary defenders against harmful xenobiotics entering the bloodstream.
- The environment, the workplace, and, especially, the administration of medications represent potential sources of nephrotoxicity. Consequently, it is important to determine, by history and observation, to which xenobiotics a patient was exposed and to be aware of their potential to harm the kidneys.
- It is equally crucial to work the other way when a patient presents with renal dysfunction: review all xenobiotics, both conventional and complementary, all xenobiotic exposures, and any conditions that can adversely affect the kidneys.

# RESPIRATORY PRINCIPLES

Andrew Stolbach and Robert S. Hoffman

The primary function of the lungs is gas exchange. Specifically, this involves the transport of oxygen (O<sub>2</sub>) into the blood, and the elimination of carbon dioxide (CO<sub>2</sub>) from the blood. In addition, the lungs serve as minor organs of metabolism and elimination for a number of xenobiotics, a source of insensible water loss, and a means of temperature regulation. Air is conducted through proximal airways, made up of columnar epithelium and mucin-secreting goblet cells. Oxygen exchange occurs in distal airways, through type I pneumocytes, which make up most of alveolar surface area. Type II pneumocytes, which secrete surfactant, take up less pulmonary surface area.

Cellular oxygen use is dependent on many factors, including respiratory drive; percentage of oxygen in inspired air; airway patency; chest wall and pulmonary compliance; diffusing capacity; ventilation-perfusion mismatch; hemoglobin content; hemoglobin oxygen loading and unloading; cellular oxygen uptake; and cardiac output. Xenobiotics have the unique ability to impair each of these factors necessary for oxygen use and result in respiratory dysfunction (Table 28–1). This chapter illustrates how xenobiotics interact with the mechanisms of gas exchange and oxygen use. Discussion of chronic occupational lung injury is beyond the scope of this text; the reader is referred to a number of reviews for further information.<sup>5</sup>

## PULMONARY MANIFESTATIONS OF XENOBIOTIC EXPOSURES

### Respiratory Drive

Respiratory rate and depth are regulated by the need to maintain a normal partial pressure of carbon dioxide (PCO<sub>2</sub>) and pH. Most of the control for ventilation occurs at the level of the medulla, although it is modulated both by involuntary input from the pons and voluntary input from the higher cortices. Changes in PCO<sub>2</sub> are measured primarily by a central chemoreceptor, which measures cerebrospinal fluid pH, and secondarily by peripheral chemoreceptors in the carotid and aortic bodies, which measure PCO<sub>2</sub>. Input with regard to partial pressure of oxygen (PO<sub>2</sub>) is obtained from carotid and aortic chemoreceptors. Stretch receptors in the chest relay information about pulmonary dynamics, such as the volume and pressure.

Xenobiotics affect respiratory drive in one of several ways: direct suppression of the respiratory center; alteration in the response of chemoreceptors to changes in PCO<sub>2</sub>; direct stimulation of the respiratory center; increase in metabolic demands such as those resulting from agitation or fever, which, in turn, increases total body oxygen consumption; or indirectly, as a result of the creation of acid-base disorders. For example, opioids (Chap. 36) depress respiration by decreasing the responsiveness of chemoreceptors to CO<sub>2</sub> and by direct suppression of the pontine and medullary respiratory centers.<sup>36,87,113</sup> Any xenobiotic that causes a decreased respiratory drive or a decreased level of consciousness can produce bradypnea (a decreased respiratory rate), hypopnea (a decreased tidal volume), or both, resulting in absolute or relative hypoventilation (Chap. 3).

Methylxanthines and sympathomimetics increase both respiratory drive and oxygen consumption. Salicylates produce hyperventilation by both central and peripheral effects via respiratory alkalosis and metabolic acidosis. The net consequence of increased respiratory drive, increased oxygen consumption, or metabolic acidosis is the generation of tachypnea (an elevated respiratory rate), hyperpnea (an increased tidal volume), or both. Either alone or in combination, tachypnea and hyperpnea produce hyperventilation. Tables 28–2 and 28–3 both list xenobiotics that commonly produce hypoventilation and hyperventilation.

### Decreased FiO<sub>2</sub>

Barometric pressure at sea level ranges near 760 mm Hg. At this pressure, 21% of ambient air is composed of oxygen (the fraction of inspired oxygen {FiO<sub>2</sub>} = 21%), and, after subtracting for the water vapor normally present in the lungs, the alveolar partial pressure of oxygen (PAO<sub>2</sub>) is about 150 mm Hg. Any reduction in FiO<sub>2</sub> decreases the PAO<sub>2</sub>, thereby producing signs and symptoms of hypoxemia (a low arterial partial pressure of oxygen {PaO<sub>2</sub>}). At an FiO<sub>2</sub> of 12% to 16%, patients experience tachypnea, tachycardia, headache, mild confusion, and impaired coordination. A further decrease to an FiO<sub>2</sub> of 10% to 14% produces severe fatigue and cognitive impairment and when the FiO<sub>2</sub> decreases to between 6% and 10%, nausea, vomiting, and lethargy develop. An FiO<sub>2</sub> less than 6% is incompatible with life.<sup>66</sup>

**TABLE 28–1** Respiration as a Target of Common Xenobiotics

Location	Mechanism of Effect	Common Xenobiotics
Oxygen displacement	Simple asphyxiation	Carbon dioxide

Xenobiotic induced electrolyte abnormalities

This effect on  $PAO_2$  is typically observed as elevation increases above sea level, because while  $FiO_2$  remains 21%, barometric pressure falls. At 18,000 feet, barometric pressure is only 380 mm Hg, and the  $PAO_2$  falls to below 70 mm Hg. At 63,000 feet, the barometric pressure falls to 47 mm Hg, a level where the  $PAO_2$  equals 0 mm Hg. Although it is important to remember this relationship, altitude-induced decreases in  $PAO_2$  are rarely important in clinical medicine, even in commercial airline flights, in which the cabins are pressurized to a maximum of several thousand feet above sea level. However, in closed or low-lying spaces, oxygen is replaced or displaced by other gases that have no intrinsic toxicity. Common examples of these gases, referred to as simple asphyxiants (Table 28–4), are found alone or in combination with more toxic gases. Because they have little or no toxicity other than their ability to replace oxygen, removal of the victim from exposure and administration of supplemental oxygen are curative if permanent injury as a consequence of hypoxia has not already developed (Chap. 121).

Carbon dioxide	Methane
Ethane	Nitrogen
Helium	Propane

The potential magnitude of toxicity from simple asphyxiants is best exemplified by disasters in Cameroon near Lake Mounoun and Lake Nyos, in 1984 and 1986, respectively. Following an earthquake, Lake Nyos, a volcanic lake, released a cloud of  $CO_2$  gas of approximately one-quarter million tons. Because  $CO_2$  is 1.5 times heavier than air, the gas cloud flowed into the surrounding low-lying valleys, killing by asphyxia more than 1700 people, and affecting countless more people because of hypoxia. Most survivors recovered without complications.<sup>11,40</sup> Smaller-scale, but equally serious, toxicity from  $CO_2$  results from improper handling of dry ice or release into a closed space.<sup>42,47</sup>

### Chest Wall

Hypoventilation can result from a decrease in either respiratory rate or tidal volume. Thus, even when the stimulus to breathe is normal, adequate ventilation is dependent on the coordination and function of the muscles of the diaphragm and chest wall. Changes in this function can result in hypoventilation by 2 separate mechanisms; both muscle weakness and muscle rigidity impair the patient's ability to expand the chest wall. Some examples of toxicologic causes of muscle weakness include botulinum toxin,<sup>97</sup> electrolyte abnormalities, such as hypokalemia,<sup>59,114</sup> or hypermagnesemia,<sup>2,33</sup> organic phosphorus compounds,<sup>77,98</sup> and neuromuscular blockers.<sup>15,52</sup> Patients with hypoventilation caused by muscle weakness respond well to assisted ventilation and correction of the underlying problem (Chaps. 12, 38, 66, and 111). Chest-wall rigidity impairing ventilation can occur in strychnine poisoning,<sup>17,57,64</sup> tetanus,<sup>24,57,103</sup> and fentanyl use<sup>23,25</sup> (Chaps. 36 and 114). Often these patients are difficult to ventilate despite endotracheal intubation and therefore require muscle relaxants, neuromuscular blockers, or naloxone (for fentanyl).

### Airway Patency

The airway can be compromised in several ways. As a patient's mental status becomes impaired, the airway is often obstructed by the tongue.<sup>44</sup> Alternatively, the presence of vomitus, or aspiration of activated charcoal or a foreign body, directly obstructs the trachea or major bronchi with resultant hypoxia.<sup>54,72,90</sup> Obstruction also results from increased secretions produced during organic phosphorus compound poisoning. Laryngospasm occurs either as a manifestation of systemic reactions, such as anaphylaxis, as a result of edema from thermal or caustic injury (Chaps. 103 and 120), or as a direct response to an irritant gas (Chap. 121). Similarly, if the tongue becomes swollen in response to thermal or caustic injury or toxic exposure to plants such as *Dieffenbachia* spp, or as a result of angioedema from drugs such as angiotensin-converting enzyme inhibitors, airway obstruction results (Chaps. 61, 103, 118, and 120).<sup>36</sup> Regardless of the mechanism, upper airway obstruction produces hypoventilation, hypoxemia, and hypercapnia (hypercarbia) with the persistence of a normal alveolar–arterial (A–a) gradient (see discussion of A–a gradients). Upper airway obstruction is often acute and severe and requires immediate therapy to prevent further clinical compromise. Bronchospasm, a common manifestation of anaphylaxis, also results from exposure to pyrolyzed cocaine,<sup>96</sup> smoke, irritant gases<sup>46</sup> (Table 28–5), dust (eg, cotton in byssinosis), or as a result of work-related asthma<sup>63</sup> and hypersensitivity pneumonitis<sup>120</sup> (Chaps. 120 and 121).

### Pressure Phenomenon

Pneumothorax is an example of airway collapse caused by barotrauma, which more commonly results from the manner of administration of illicit

TABLE 28–5 Examples of Irritant Gases

Ammonia	Isocyanates

Chloroacetophenone	Phosgene
Chlorobenzylidene-malononitrile	Phosphine
Fluorine	Sulfur dioxide
Hydrogen chloride	

xenobiotics than from actual drug overdose. Barotrauma also results from nasal insufflation or inhalation of drugs. This form of barotrauma occurs most often in cocaine (particularly in the form of “crack”) and marijuana users, who either smoke or insufflate these xenobiotics and then perform prolonged Valsalva or Mueller maneuvers in an attempt to enhance the effects of these xenobiotics (Chaps. 74 and 75).<sup>13,100,116</sup> The increased airway pressure leads to rupture of an alveolar bleb, and free air dissects along the peribronchial paths into the mediastinum and pleural cavities. Nitrous oxide abuse also causes barotrauma.<sup>55</sup> Siphoning of nitrous oxide from low-pressure tanks meant for inhalation is not typically associated with barotrauma. By contrast, inhalation of nitrous oxide, used as a propellant in whipped cream cans, generates tremendous pressure that sometimes results in severe barotrauma (Chaps. 65 and 81).

### Ventilation–Perfusion Mismatch

Ventilation–perfusion (V/Q) mismatch is manifested at the extremes by aeration of the lung without arterial blood supply (as in pulmonary embolism from injected contaminants) and by a normal blood supply to the lung without any ventilation. Impaired blood supply to a normal lung and normal blood supply to an inadequately ventilated lung constitute an infinite number of gradations that exist between the extremes. The normal response to regional variations in ventilation is to shunt blood away from an area of lung poorly ventilated, thereby preferentially delivering blood to an area of the lung where gas exchange is more efficient. A hypoxia-induced reduction in local nitric oxide production appears to be responsible for the regional vasoconstriction that occurs.<sup>1</sup> This effect, commonly known as hypoxic pulmonary vasoconstriction, is best described in patients with chronic obstructive lung disease and facilitates compensation for the V/Q mismatch associated with that disorder. It is unclear whether xenobiotic-induced alterations in pulmonary nitric oxide production are significant determinants in the V/Q mismatch that occurs in poisoning.

In toxicology, V/Q mismatch most commonly results from perfusion of an abnormally ventilated lung that results from aspiration of gastric contents, a frequent complication of many types of poisoning.<sup>54,78</sup> Although alterations in consciousness and loss of protective airway reflexes are predisposing factors, certain xenobiotics, such as hydrocarbons, directly result in aspiration pneumonia because of their specific characteristics of high volatility, low viscosity, and low surface tension (Chap. 105).

The diagnosis of aspiration pneumonia often relies on chest radiography for confirmation. The location of the infiltrate depends on the patient's position when the aspiration occurred. Most commonly, aspiration occurs in the right mainstem bronchus, because the angle with the carina is not as acute as it is for entry into the left mainstem bronchus. When aspiration occurs in the supine position, the subsequent infiltrate is usually manifest in the posterior segments of the upper lobe and superior segments of the lower lobe. Aspiration typically involves vomitus; however, secretions, activated charcoal, teeth, dentures, food, and other foreign bodies are also frequently aspirated.

### Diffusing Capacity Abnormalities

Severe impairment in diffusing capacity commonly results from local injury to the lungs in disorders such as interstitial pneumonia, aspiration, toxic

inhalations, and near drowning, and from systemic effects of sepsis, trauma, and various other medical disorders.<sup>10</sup> When this process is acute and associated with clinical criteria, including crackles, hypoxemia, and bilateral infiltrates on a chest radiograph demonstrating a normal heart size, it has been historically referred to as *noncardiogenic pulmonary edema* or *acute lung injury* (ALI).<sup>10</sup> The most severe manifestation of these processes was described as acute respiratory distress syndrome (ARDS). However, a task force of pulmonary specialists determined that all of these conditions are best classified as gradations of ARDS. According to the 2012 Berlin definition, ARDS consists of bilateral pulmonary infiltrates (by radiography or computed tomography), which occur within 7 days of an inciting event and are not explained by heart failure or fluid overload. Severity of ARDS is determined by the PaO<sub>2</sub>/FiO<sub>2</sub> ratio. Acute respiratory distress syndrome is classified as mild (200 mm Hg < PaO<sub>2</sub>/FiO<sub>2</sub> ≤ 300 mm Hg), moderate (100 mm Hg < PaO<sub>2</sub>/FiO<sub>2</sub> ≤ 200 mm Hg), and severe (PaO<sub>2</sub>/FiO<sub>2</sub> ≤ 100 mm Hg). Cases that once were described as ALI now fit under the mild ARDS classification.

Throughout this chapter and text, this newer nomenclature will be used. Using the older definition, it was estimated that 150,000 Americans developed ARDS annually, many as a result of xenobiotics; severe ARDS has a fatality rate approximating 50%.<sup>4,35</sup>

Commonly, patients are chronically exposed to xenobiotics associated with reduced diffusing capacity by smoking tobacco and other xenobiotics or working with asbestos, silica, and coal, which slowly causes pulmonary fibrosis or promotes emphysema. Chronically smoked cocaine is also recognized to alter pulmonary function.<sup>104</sup> Acutely, ARDS from opioids, salicylates, or phosgene and delayed severe fibrosis from paraquat causes profound alterations in diffusion (Chaps. 36, 37, 109, and 126).<sup>82,91,121</sup> Associated parenchymal damage is almost always present and causes both reduction in lung volumes and V/Q mismatch. Intravenous injection of talc, a common contaminant found in drugs of abuse,<sup>85</sup> and septic emboli from right-sided endocarditis<sup>83,102</sup> result in isolated vascular defects with reduction in diffusion capacity. Similarly, cocaine-induced pulmonary artery spasm obstructs vascular channels and alters pulmonary function, creating V/Q mismatch.<sup>29</sup>

Acute respiratory distress syndrome commonly occurs in cases of poisoning. The edema fluid (and the resulting hypoxia, pulmonary crackles, and radiographic abnormalities) develops in part because of increased permeability of the alveolar and capillary basement membrane.<sup>22,26,67,91</sup> Proteinaceous fluid leaks from the capillaries into the alveoli and interstitium of the lung. Several mechanisms are proposed as the cause of ARDS, although no single unifying mechanism exists for all of the xenobiotics implicated. Acute respiratory distress syndrome results from exposure to xenobiotics that produce hypoventilation by at least 3 different mechanisms: (1) hypoxia injures the vascular endothelial cells, (2) autoregulatory vascular redistribution causes localized capillary hypertension, or (3) alveolar microtrauma occurs as alveolar units collapse, only to be reopened suddenly during reventilation.<sup>91</sup> These and other events activate neutrophils and release inflammatory cytokines.<sup>3,112</sup> Other xenobiotics are directly toxic to the capillary epithelial cells or are at least partly responsible for the release of vasoactive substances.<sup>3</sup> The effects of salicylates and other nonsteroidal antiinflammatory drugs are most likely mediated via effects on prostaglandin synthesis. Finally, sympathomimetic stimulants occasionally cause “neurogenic” pulmonary edema, which is likely mediated by massive catecholamine discharge. Elevated catecholamine concentrations are also noted in experimental opioid overdose, possibly representing support for a link between hypoxia, hypercarbia, and the catecholamine hypothesis of ARDS.<sup>76</sup>

In the 1880s, William Osler described “oedema of left lung” in a morphine user. The opioids are still among the most common causes of ARDS (Chap. 36), but it is now recognized that there are many types of xenobiotics that can cause or are associated with ARDS, such as the sedative–hypnotics, salicylates, cocaine, carbon monoxide, diuretics, and calcium channel blockers (Table 28–6).<sup>30,32,34,38,39,45,48,51,58,86,88,101,102,121</sup> The route of xenobiotic administration is not usually the determining factor; ARDS results from oral, intravenous, and inhalational exposures. Because the source of the problem is increased pulmonary capillary permeability, patients with ARDS have a

**TABLE 28–6** Common Xenobiotic Causes of Acute Respiratory Distress Syndrome

normal pulmonary-capillary wedge pressure, unlike patients with cardiogenic pulmonary edema.

True cardiogenic pulmonary edema also occurs as the result of poisoning. Etiologies for this phenomenon include the ingestion of xenobiotics with negative inotropy (eg,  $\beta$ -adrenergic antagonists, type IA antidysrhythmics), myocardial ischemia, dysrhythmia, or infarction (cocaine). Because many overdoses are mixed overdoses, the distinction between cardiogenic pulmonary edema and ARDS is often difficult to establish by physical examination and requires invasive monitoring techniques.

Although the treatments for cardiogenic pulmonary edema and ARDS have many similarities, critical aspects of the therapy differ; therefore, an accurate diagnosis must be established. Most diagnostic tests are not helpful in differentiating between the 2 diseases. Physical examination reveals the presence of crackles with both entities. An S3 gallop, if present, suggests a cardiac cause, but its absence does not establish the diagnosis of ARDS. In both entities, the arterial blood–gas analysis demonstrates hypoxia and chest radiography shows perihilar, basilar, or diffuse alveolar infiltrates. However, the presence of “vascular redistribution” on chest radiography is suggestive of a cardiogenic etiology; a normal-sized heart is more commonly associated with ARDS, whereas an enlarged heart is more typical of cardiogenic pulmonary edema. The diagnostic tests that are useful in establishing the correct diagnosis include echocardiography, transcutaneous bioimpedance, pulmonary artery catheter pressure measurements, and radionuclide ventriculography (“gated-pool” scan). Although the radionuclide scan accurately measures cardiac output, it is not routinely available in the emergency department or intensive care unit and usually requires the transport of a critically ill patient to the nuclear medicine suite. Although echocardiography is easily performed as a portable “bedside” technique, it is less sensitive and less specific for determinations of cardiac output. Therefore, the most definitive diagnostic procedure in the emergency setting is the insertion of a pulmonary artery catheter for hemodynamic monitoring. Cardiogenic pulmonary edema results from an elevated left-atrial filling pressure (elevated pulmonary-capillary wedge pressure) and a decreased cardiac output. In patients with ARDS, the pulmonary artery wedge pressure and the cardiac output are normal. Although not specifically well investigated in poisoning, experiences with transcutaneous bioimpedance measurements of cardiac output show promise for this portable noninvasive technique.<sup>10,27,75,79</sup>

The basic treatment for ARDS is supportive care while the xenobiotic is eliminated and healing occurs in the pulmonary capillaries.<sup>3,61</sup> The most important specific therapeutic intervention in patients with ARDS requiring mechanical ventilation involves the use of low tidal-volume ventilation ( $\leq 6$  mL/kg predicted body weight).<sup>1,43,112</sup>

This results in reduced airway pressures, which seem to decrease the chance for alveolar distension and subsequent injury. The efficacy of jet ventilators or membrane oxygenators is inadequately studied. Some studies suggest a potential role for extracorporeal membrane oxygenation in the

treatment of ARDS.<sup>56</sup> Positive end-expiratory pressure (PEEP), which likely derives its benefit from keeping alveoli open, is considered an essential component in the management of ARDS.<sup>31,43</sup>

Positive end-expiratory pressure should be maintained in the range of 5 to 12 cm H<sub>2</sub>O, to maintain a PO<sub>2</sub> of at least 55 mm Hg, or an oxygen saturation of 88%, with an inspired oxygen concentration of  $\leq 40\%$ . Although in cases of grave lung injury, higher PEEP settings are often required, they come with an increased incidence of pneumothorax or hypotension. Also, while an increase in PEEP typically results in a modest increase in PO<sub>2</sub>, it causes a larger decrease in venous return and decreased cardiac output. Therefore, with each change in PEEP, the resulting increase (or perhaps decrease) in oxygen delivery to the body should be determined.<sup>4</sup>

A conservative fluid strategy improves oxygenation and decreases length of stay in the intensive care unit without increasing the incidence of shock or the need for hemodialysis. A conservative fluid management strategy is recommended for patients with ARDS who are not in shock, have not been in shock for at least 12 hours, and do not have other reasons to require liberal fluid administration.<sup>115</sup>

### Hemoglobin and Chemical Asphyxiants

Disorders of hemoglobin oxygen content, and of hemoglobin loading and unloading, result in cellular hypoxia, which, in turn, results in hyperventilation. Anemia is a common complication of the infectious diseases associated with injection drug use. In addition, many xenobiotics result in hemolysis or direct bone marrow suppression. Among the latter group are the metals, lead, benzene, and ethanol. Hemolysis also occurs in individuals exposed to lead, copper, or arsine gas, and in patients with glucose-6-phosphate dehydrogenase deficiency exposed to oxidants (Chap. 20).

The oxygen-carrying capacity of blood declines in almost direct proportion to hemoglobin content,<sup>106</sup> as seen in Fig. 28–1. As shown in Fig. 28–1A, under most normal conditions the dissolved oxygen content of the blood contributes little; thus, the last portion of the equation can be eliminated. Anemia resulting in a decrease of the hemoglobin content to 7.5 g/dL (a hematocrit of  $\sim 22\%$ ) decreases the oxygen content of the blood to about 10.2 mL O<sub>2</sub>/dL (Fig. 28–1B). Because central cyanosis is only visible with a concentration of reduced deoxyhemoglobin of at least 5 g/dL, unless an

#### Oxygen content (O<sub>2</sub> content) = hemoglobin bound oxygen + dissolved oxygen

**A. Normal conditions:** hemoglobin (Hb) = 15 g/dL; PO<sub>2</sub> = 100 mm Hg,

$$\begin{aligned} \text{oxygen saturation (O}_2 \text{ sat)} &= 95\% \\ \text{O}_2 \text{ (content)} &= (\text{Hb})(\text{O}_2 \text{ sat}) (\text{constant}) + (\text{another constant})(\text{PO}_2) \\ &= (\text{Hb})(\text{O}_2 \text{ sat})(1.39 \text{ mL O}_2/\text{g}) \\ &\quad + (0.003 \text{ mL O}_2/\text{dL}/\text{mm Hg})(\text{PO}_2) \\ &= (15 \text{ g/dL})(95\%)(1.39 \text{ mL O}_2/\text{g}) \\ &\quad + (0.003 \text{ mL O}_2/\text{dL}/\text{mm Hg})(100 \text{ mm Hg}) \\ &= (19.8 \text{ mL O}_2/\text{dL}) + (0.3 \text{ mL O}_2/\text{dL}) \\ &= \mathbf{20.1 \text{ mL O}_2/\text{dL} = \mathbf{20.1 \text{ vol}\%}} \end{aligned}$$

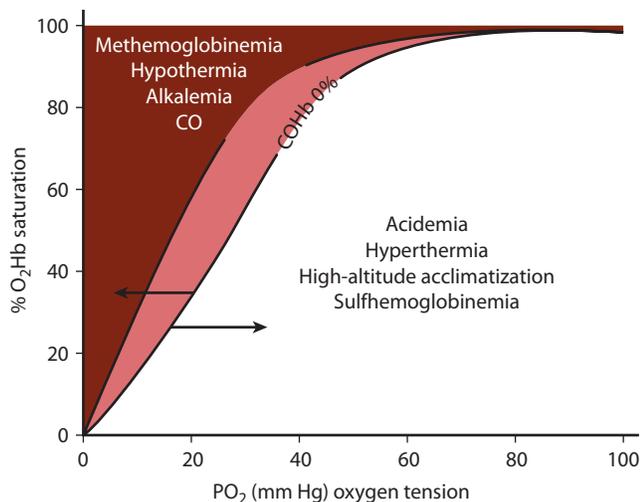

**B. Anemia:** Hb = 7.5 g/dL; PO<sub>2</sub> = 100 mm Hg, O<sub>2</sub> Sat = 95%

$$\begin{aligned} \text{O}_2 \text{ content} &= (\text{Hb})(\text{O}_2 \text{ sat})(1.39 \text{ mL O}_2/\text{g}) \\ &\quad + (0.003 \text{ mL O}_2/\text{dL}/\text{mm Hg})(\text{PO}_2) \\ &= (7.5 \text{ g/dL})(95\%)(1.39 \text{ mL O}_2/\text{g}) \\ &\quad + (0.003 \text{ mL O}_2/\text{dL}/\text{mm Hg})(100 \text{ mm Hg}) \\ &= (9.9 \text{ mL O}_2/\text{dL}) + (0.3 \text{ mL O}_2/\text{dL}) \\ &= \mathbf{10.2 \text{ mL O}_2/\text{dL} = \mathbf{10.2 \text{ vol}\%}} \end{aligned}$$

**C. Hyperbaric oxygen:** Hb = 15 g/dL; PO<sub>2</sub> = 1500 mm Hg, O<sub>2</sub> Sat = 100%

$$\begin{aligned} \text{O}_2 \text{ content} &= (\text{Hb})(\text{O}_2 \text{ sat})(1.39 \text{ mL O}_2/\text{g}) \\ &\quad + (0.003 \text{ mL O}_2/\text{dL}/\text{mm Hg})(\text{PO}_2) \\ &= (15 \text{ g/dL})(100\%)(1.39 \text{ mL O}_2/\text{g}) \\ &\quad + (0.003 \text{ mL O}_2/\text{dL}/\text{mm Hg})(1500 \text{ mm Hg}) \\ &= (20.9 \text{ mL O}_2/\text{dL}) + (4.5 \text{ mL O}_2/\text{dL}) \\ &= \mathbf{25.4 \text{ mL O}_2/\text{dL} = \mathbf{25.4 \text{ vol}\%}} \end{aligned}$$

**FIGURE 28–1.** Examples of calculations of the oxygen content of the blood under various conditions.

**FIGURE 28-2.** Oxyhemoglobin dissociation curve at 98.6°F (37°C) and pH 7.40. Hematocrit does not alter this relationship.

abnormal hemoglobin concentration is present, anemia significantly impairs oxygen-carrying capacity without the development of this common physical manifestation (Chap. 124).

By contrast, as the  $PO_2$  reaches higher values (as in hyperbaric oxygen chambers), the dissolved oxygen content becomes significant and of therapeutic value, particularly when the oxygen-carrying content of hemoglobin is compromised. The  $PO_2$  corresponding to an  $FiO_2$  of 100% at 1 atm is approximately 575 mm Hg. By contrast, with hyperbaric oxygen at 3 atm and 100% oxygen,  $PO_2$  values in excess of 1500 mm Hg can be achieved.<sup>66</sup> Under these conditions, the dissolved oxygen content of the blood rises dramatically (to as much as 4.5 mL  $O_2$ /dL) and becomes adequate to sustain life, even in the absence of any contribution from hemoglobin (Fig. 28-1C).

The chemical asphyxiants that produce methemoglobin, carboxyhemoglobin, and sulfhemoglobin interfere with oxygen loading and/or unloading to various degrees. Methemoglobin inhibits oxygen loading, producing cyanosis unresponsive to supplemental oxygen (Chap. 124). In addition, the oxyhemoglobin dissociation curve is shifted to the left, interfering with unloading (Fig. 28-2). Carboxyhemoglobin has similar effects on oxygen loading and unloading, but carboxyhemoglobin is not associated with cyanosis (Chap. 122). Although sulfhemoglobin also impairs oxygen loading, it shifts the oxyhemoglobin saturation curve to the right, favoring unloading of the remaining normal hemoglobin. Cyanide, hydrogen sulfide, and sodium azide primarily affect oxygen use by interfering with the cytochrome oxidase system (Chap. 123).

### Cardiac Output

Any xenobiotic that causes a decreased cardiac output or hypotension has the potential to result in tissue hypoxia and tachypnea. This occurs most frequently with overdoses of  $\beta$ -adrenergic antagonists and calcium channel blockers, anti-dysrhythmics, cyclic antidepressants, and phenothiazines (Chap. 16).

### Asthma and Occupational Exposures

Usually considered a cause of morbidity more than mortality, work-related asthma is frequently encountered by the practitioner. The pathophysiology of these illnesses is still being elucidated, and likely results from both immunoglobulin (Ig) E and non-IgE-related mechanisms.<sup>16</sup>

Work-related asthma is typically divided into 3 distinct clinical entities:

1. Work-aggravated asthma: Preexisting asthma worsened by allergens in the workplace.
2. Occupational asthma: Asthma caused by workplace exposure and not factors outside the workplace. There is a latency period between the symptoms and the first exposure, possibly as long as several years.

3. Reactive airway dysfunction syndrome (RADS): Asthma caused by nonimmunogenic stimuli in the workplace, occurring for the first time within 24 hours of exposure to an inhaled irritant xenobiotic.<sup>6,21,111</sup>

Occupational exposures are thought to be responsible for a substantial proportion of adult-onset asthma, estimated at 10% to 25% in one international prospective study.<sup>20</sup>

A large number of xenobiotics and occupations are associated with the development of work-aggravated and work-related asthma. Because researchers rely on surveys and interviews, the latency period between exposure and symptoms makes identification of these associations a challenge.

Many high-molecular-weight xenobiotics, usually plant or animal derived, are known etiologies, such as arthropod- and mite-related materials, latex, flour, molds, endotoxins, and biological enzymes. Lower-molecular-weight xenobiotics associated with work-related asthma include isocyanates (used in spray paints and foam manufacturing), cleaning agents, anhydrides, amines, dyes, and glues. For more information on specific xenobiotics, see Chap. 121.

In one study, the following occupations were found, in decreasing order, to be associated with the development of occupational asthma: printing, woodworking, nursing, agriculture and forestry, cleaning and caretaking, and electrical processors.<sup>60</sup>

By contrast to occupational asthma and work-aggravated asthma, the latency period between exposure and symptoms in RADS is short or absent, so it is typically easier for the health care professional to identify the precipitant from history. Xenobiotics frequently associated with RADS include cleaning agents (including chlorine, hypochlorite, ammonia, and chloramines), solvents, toluene diisocyanate, acids, alkali, nitrogen oxides, smoke, and diesel exhaust.<sup>49,99</sup>

## APPROACH TO RESPIRATORY DYSFUNCTION IN THE POISONED PATIENT

The initial assessment of each patient must involve the evaluation of upper airway patency. Adequacy of ventilation should then be determined. If concomitant injury is suspected, then care must be taken to protect the cervical spine. When airway patency is in question, maneuvers to establish and protect the airway are of prime importance. Often this simply involves repositioning the chin, jaw, or head, or suctioning secretions or vomitus from the airway. However, insertion of an oral or nasopharyngeal airway, or nasopharyngeal or endotracheal intubation, or surgical cricothyroidotomy should be performed as clinically indicated. After the airway is secured, high-flow supplemental oxygen should be provided if needed and the depth, rate, and rhythm of respirations evaluated. An acceptable tidal breath is one that transports 10 to 15 mL of air/kg of body weight.<sup>4</sup>

Hypoventilation that results from an inadequate respiratory rate or tidal volume is arbitrarily defined as an arterial  $PCO_2$  higher than 44 mm Hg and leads to hypoxia and ventilatory failure if uncorrected.<sup>117</sup> The symptoms of hypoxia and/or hypercarbia are nonspecific and resemble toxicity from many xenobiotics. Initially, patients appear restless and confused. Signs of sympathetic discharge, such as tachycardia and diaphoresis, are commonly noted. Later, patients complain of headache, only to become sedated and subsequently comatose, as further deterioration occurs. These signs and symptoms are often nonspecific. We recommend early determination of oxygenation and ventilation when there is concern for respiratory failure in patients following xenobiotic overdose. Arterial blood gas and pulse oximetry are used to identify hypoxia, whereas capnography and blood gas (venous or arterial) are usually reasonable surrogates for determining ventilation.

A trial of naloxone, hypertonic dextrose, and thiamine is indicated for the patient with an altered mental status and/or respiratory compromise when these etiologies are not otherwise easily clinically excluded (Chap. 4). Because opioid overdose and hypoglycemia are rapidly reversible, potential causes of respiratory failure, these diagnoses should be addressed before

most other interventions are considered. Failure to identify and reverse these conditions will result in unnecessary diagnostic and therapeutic interventions in addition to irreversible neurologic sequelae.

Once an acceptable airway is established the remainder of the evaluation can proceed. A rapid assessment of the remainder of the vital signs (Chap. 3) should then occur. Obtaining a history and physical examination, measured oxygen saturation, measured ventilation, and chest radiography are sufficient to determine the diagnosis of pulmonary pathology in most cases. However, adjuncts, such as measurement of negative inspiratory force (NIF), invasive hemodynamic monitoring, evaluation of the arterial-venous oxygen difference, xenon ventilation and technetium scanning, and computed tomographic scanning are frequently required.

### History

A directed history must include questions on the nature, onset, and duration of symptoms; substance use and abuse; home and occupational exposures; and underlying pulmonary pathology. If the patient has a significant degree of respiratory compromise, most or all of the history will have to be obtained from friends, relatives, paramedics, coworkers, or others.

### Physical Examination

The physical evaluation must include a detailed assessment of depth, rate, and rhythm of respirations, use of accessory muscles, direct evaluation of the oropharynx, position of the trachea, and presence and quality of breathing sounds. Skin, nail bed, and conjunctival color must be observed for pallor or cyanosis. Funduscopic examination is a useful adjunct to the examination. Papilledema occurs in the presence of acute hypercapnia, but is neither sensitive nor specific for that diagnosis. Additionally, because cyanide poisoning interferes with oxygen delivery to tissue, the venous oxygen saturation remains high. During the funduscopic examination, this classically appears as arterialization of the retinal veins, in which the veins take on a color more characteristic of arteries (Chap. 123). A general assessment of muscle tone, with a specific emphasis on ocular and neck muscles, will give clues to weakness or rigidity syndromes that interfere with respiration. When in doubt, a determination of the negative inspiratory force will provide a rapid, objective, quantifiable bedside assessment of respiratory strength.

### Pulse Oximetry

Pulse oximeters widely accepted as rapid, noninvasive indicators of hemoglobin oxygen saturation. As defined, hemoglobin-oxygen saturation is the ratio of oxyhemoglobin to total hemoglobin. By using 2 light-emitting diodes, the pulse oximeter is able to measure absorbance at the peak wavelengths for oxyhemoglobin and deoxyhemoglobin (typically at 940 and 660 nm). Thus, the ratio of oxyhemoglobin to oxyhemoglobin plus deoxyhemoglobin (total hemoglobin) is calculated. The clinician then estimates the  $PO_2$  from the oxygen saturation.

Limitations of this approach require elaboration. Because the oxyhemoglobin dissociation curve becomes quite flat above 90% saturation (Fig. 28-2), small changes in saturation greater than 90% represent very large changes in  $PO_2$ . Thus, a decrease from 97% saturation to 95% saturation represents a substantial decrease in  $PO_2$ . Although a low saturation is an early indicator of hypoxic hypoxia, this is only one of many causes of tissue hypoxia. If total hemoglobin is low, then the oxygen-carrying capacity is inadequate even with excellent saturation (Fig. 28-1). Dyshemoglobinemias, such as carboxyhemoglobin, methemoglobin, and possibly sulfhemoglobin, interfere with the accuracy of pulse oximeter determinations and are of particular concern in the poisoned patient. Specifically, using a standard pulse oximeter, the presence of elevated levels of methemoglobin will tend to make the saturation determined by pulse oximetry approach 84% to 86% (Chap. 124).<sup>8,83</sup> Carboxyhemoglobin is falsely interpreted by the pulse oximeter as mostly oxyhemoglobin; thus, readings tend to appear normal even with significant carbon monoxide poisoning (Table 28-7).<sup>107</sup> Accurate response by the pulse oximeter also requires adequate blood pressure, lack of strong venous pulsations (as might occur in a patient with tricuspid regurgitation),

**TABLE 28-7** Sample Interpretations of Oxygen Saturations Reported by Various Sources of Measurement

Condition	Percent Oxygen Saturation			
	$PO_2$ (mm Hg)	Arterial Blood Gas	Pulse Oximeter	Cooximeter
Normal	95	95	95	95
Anemia	95	95	95	95*
Methemoglobinemia (30%)	95	95	85	70
Carboxyhemoglobinemia (30%)	95	95	95	70
Hypoxemia	60	90	90	90

The table demonstrates limitations of the various methods for determining oxygen saturation ( $O_2$  saturation). The arterial blood gas calculates the  $O_2$  saturation from the dissolved oxygen content ( $PO_2$ ) and becomes abnormal only when the  $PO_2$  falls. The pulse oximeter uses only 2 wavelengths of light and produces substantial errors in the presence of a dyshemoglobinemia. Because the cooximeter uses more wavelengths of light than the pulse oximeter, it can correctly identify the presence of carboxyhemoglobin and methemoglobin. The cooximeter has the additional advantage (\*) of measuring the total hemoglobin and oxygen content, so that it is useful in the setting of anemia. All techniques are acceptable for the assessment of hypoxemia.

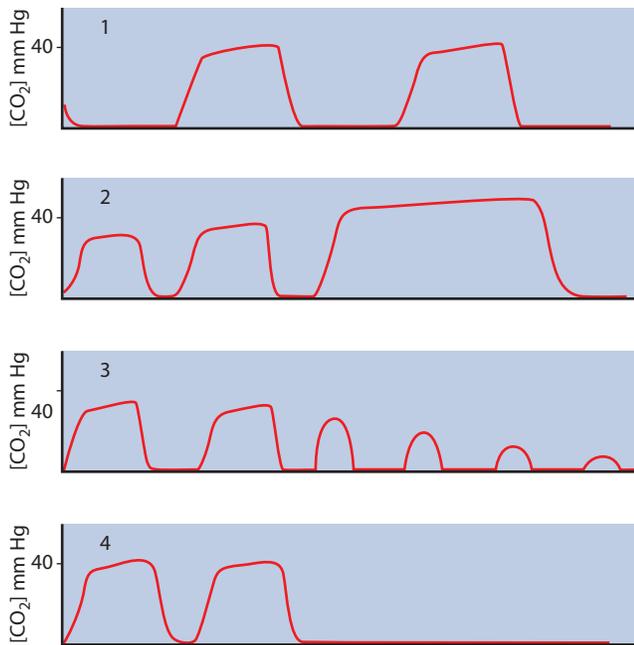

translucent nails (some shades of nail polish interfere), absence of circulating dyes (methylene blue), and a near-normal temperature. If the pulse oximeter does not produce an accurate reading, then an arterial blood gas should be obtained to assess oxygenation. Finally, we are often more interested in  $PCO_2$  than  $PO_2$ , which is not a direct measure of ventilation. The pulse oximeter gives no information with regard to  $PCO_2$ . Although the pulse oximeter gives early clues to the presence of hypoxic hypoxia, extrapolation of oxygen saturation to standard arterial blood-gas values is problematic because of the many possible sources of error.

Pulse cooximeters (noninvasive spectral analysis cooximeter), designed to measure carboxyhemoglobin and methemoglobin, in addition to hemoglobin oxygen saturation, are now part of many clinical practices. Although these devices held promise to facilitate early, noninvasive diagnosis of carbon monoxide poisoning and methemoglobinemia, their utility is limited at best. A volunteer study, sponsored by the manufacturer of the device, demonstrated the ability to measure carboxyhemoglobin with an uncertainty of  $\pm 2\%$  within the range of 0% to 15% and methemoglobin with an uncertainty of 0.5% within the range of 0% to 12%.<sup>7</sup> In a large study of screening for carboxyhemoglobin, the noninvasive cooximeter was 94% sensitive (95% confidence interval {CI}: 71%–100%) and 77% specific (95% CI: 75%–79%) for identification of a carboxyhemoglobin rate above 6.6%.<sup>95</sup> Other authors found high rates of false negatives when using the noninvasive cooximeter to screen for carbon monoxide poisoning.<sup>105</sup> A recent consensus group concluded that based on available data, these devices should not be used.<sup>119</sup>

Because of these limitations, the best role for this device is as a rapid screening tool perhaps best used in the prehospital setting. Positive results should be confirmed with a blood carboxyhemoglobin concentration, as should normal results whenever carbon monoxide poisoning is highly suspected, or when the result from the device is not consistent with the clinical appearance of the patient.

### Capnography

Capnography is the noninvasive measurement of  $PCO_2$  from the airway. Both the numerical value of  $CO_2$  and the shape of the tracing, the capnogram, provide information to the clinician (Fig. 28-3). Measurements are obtained constantly during inhalation and exhalation. End-tidal  $CO_2$  ( $EtCO_2$ ) is the maximum partial pressure of  $CO_2$  at the end of exhalation. End-tidal  $CO_2$  underestimates  $PaCO_2$  because exhaled air consists mostly of  $CO_2$ -poor air from dead space, in addition to air expired from alveoli. Anatomic dead space, always present, is from the nonventilated upper airways, whereas

**FIGURE 28-3.** Capnograms. (1) Normal capnogram. (2) Bradypnea and hypoventilation. The tidal volumes are the same as (1) but the rate is slowing down. (3) Hypopnea and hypoventilation. The amplitude of the waveforms is decreasing. (4) Complete laryngospasm or apnea. After initial waveforms, there is no expired  $\text{CO}_2$ .

physiologic dead space results from underperfused areas of the lung. Therefore, a high  $\text{EtCO}_2$  always correlates with an elevated  $\text{PaCO}_2$ , whereas a low value is potentially spurious. In patients without pulmonary disease,  $\text{EtCO}_2$  is 2 to 5 mm Hg less than  $\text{PaCO}_2$ .<sup>80</sup> In nonintubated emergency department patients with metabolic acidosis, the mean difference was 6 mm Hg.<sup>9</sup> End-tidal  $\text{CO}_2$  can be used to confirm endotracheal intubation, monitor endotracheal tube placement, monitor patients during procedural sedation, and assess patients with pulmonary illness. End-tidal  $\text{CO}_2$  is also used as a tool to assess ventilation in patients obtunded from a xenobiotic (Fig. 28-3).<sup>28</sup> Although not considered as accurate a reflection of  $\text{PCO}_2$  as endotracheal  $\text{EtCO}_2$ , noninvasive  $\text{EtCO}_2$  would theoretically be the modality best used in nonintubated sedative-poisoned patients who are at risk for hypoventilation. Unfortunately, in a prospective cohort of patients poisoned with respiratory depressants, noninvasive  $\text{EtCO}_2 \geq 50$  mm Hg predicted complications of hypoventilation with only 46% sensitivity and 86% specificity.<sup>108</sup> Therefore, elevated noninvasive  $\text{EtCO}_2$  predicts complications when elevated but cannot exclude complications when nonelevated.

## Analytical Adjuncts

### Blood Gas Analysis

Arterial blood gas analysis is an easy and rapid means of evaluating both acid–base status and gas exchange. Attention must be paid to the method for determining oxygen saturation, specifically whether it is measured or calculated from the  $\text{PO}_2$ . If the measured  $\text{O}_2$  saturation is lower than would be predicted from the  $\text{PO}_2$  (the calculated  $\text{O}_2$  saturation), then the presence of an abnormal hemoglobin concentration (such as carboxyhemoglobin or methemoglobin) must be suspected. A normal calculated  $\text{O}_2$  saturation does not exclude these disorders (see Use of the Cooximeter).

Because it is easier to obtain, venous blood gas analysis is often used as a substitute for arterial blood gas analysis.<sup>18</sup> In comparison with arterial values, venous pH and  $\text{PO}_2$  are lower, whereas  $\text{PCO}_2$  is higher. Errors can be introduced by increased muscle activity of the extremity being tested (seizures). In most cases, a venous blood gas can be used to evaluate  $\text{PCO}_2$  and pH, but not  $\text{PO}_2$ . However, mixed venous blood (defined as right-heart blood) is required for accurate determination of the arterial–venous

oxygen extraction and is an excellent indicator of acid–base status, cardiovascular function, and oxygen use. Unfortunately, a central venous catheter is required for sampling. When performing a peripheral venous blood gas analysis, it is usually assumed that this is only an approximation of mixed venous blood.

The arterial  $\text{PO}_2$  is generally considered adequate only if it lies within the flat portion at the upper right of the sigmoidal-shaped oxyhemoglobin dissociation curve (Fig. 28-2). That portion of the curve includes the  $\text{PO}_2$  range from 60 to 100 mm Hg, which corresponds to oxygen saturations higher than 90%. As mentioned earlier, within this flat portion, there can be discernible changes in  $\text{PO}_2$  with little change in oxygen saturation. For instance, an arterial  $\text{PO}_2$  of 80 mm Hg corresponds roughly to an oxygen saturation of 95%. If the  $\text{PO}_2$  falls to 60 mm Hg, then the oxygen saturation falls to 90%. This insignificant decrease in the oxygen-carrying capacity of the blood is of minimal clinical concern. However, if the  $\text{PO}_2$  falls another 20 mm Hg, then there is a more significant reduction in oxygen saturation, to approximately 70%. Thus, changes in  $\text{PO}_2$  higher than 60 mm Hg are usually not of acute therapeutic significance, because the  $\text{O}_2$  saturation is higher than 90%. However, these changes are frequently of diagnostic significance.

An exception to this concept applies to the patient who is under metabolic stress, as might result from low cardiac output, impaired vascular flow, anemia, or dyshemoglobinemia. Under these circumstances, even the modest gain achieved by increasing both dissolved oxygen content and hemoglobin saturation higher than 90% is desirable, as discussed earlier (see Hemoglobin and Chemical Asphyxiants). Also, even if a  $\text{PO}_2$  higher than 60 mm Hg or an  $\text{O}_2$  saturation higher than 90% is considered acceptable in most acute settings, it is rarely desirable to achieve greater values over concerns for oxygen toxicity.

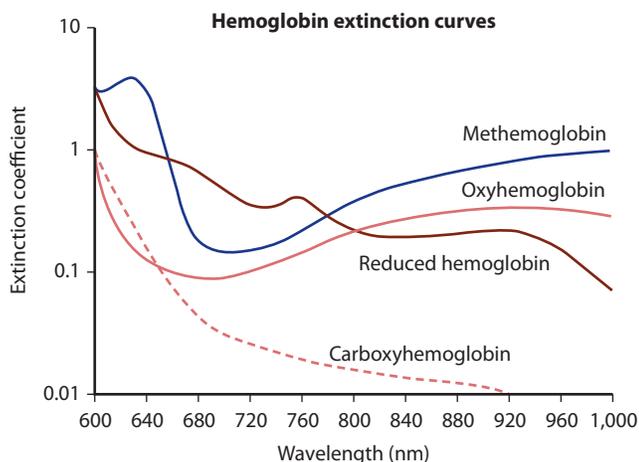

### Significance of a Decreased $\text{PO}_2$

In a patient with a diminished  $\text{PO}_2$ , 5 clinically relevant mechanisms for the hypoxemia should be considered: (1) alveolar hypoventilation, (2) V/Q mismatch, (3) shunting, (4) diffusion abnormality, and, rarely, (5) a decrease in  $\text{FiO}_2$ . In most clinical circumstances, diffusion defects cannot be distinguished from V/Q mismatch. Usually the responsible mechanism can be identified by calculating the A–a oxygen gradient. In patients with alveolar hypoventilation, the A–a gradient is completely normal ( $\leq 15$  mm Hg when breathing room air). Patients with V/Q mismatch have an A–a gradient that is increased but that normalizes when 100% oxygen is administered for at least 20 minutes. A normal A–a gradient is defined as less than 100 mm Hg on 100% oxygen. The arterial  $\text{PO}_2$  on 100% oxygen reaches approximately 575 mm Hg. By contrast, a patient with a shunt will also have an increased A–a gradient while breathing room air, but when 100% oxygen is administered, the arterial  $\text{PO}_2$  falls to substantially less than 575 mm Hg and the A–a gradient does not normalize. Finally, in the case of a patient with hypoxia resulting from breathing in an environment in which the  $\text{FiO}_2$  is less than 21%, the  $\text{PO}_2$  should correct rapidly when the patient is removed from the environment or supplemental oxygen is delivered.

In general, a low  $\text{PO}_2$  can be improved by supplying supplemental oxygen. Although in this instance the patient's laboratory values are improved, the underlying process persists. It is important to remember that the laboratory correlate of hypoventilation is hypercapnia on the arterial blood–gas analysis. If hypercapnia is associated with acidemia, then assisted ventilation is recommended, regardless of whether the  $\text{PO}_2$  corrects with supplemental oxygen.

### Use of the Cooximeter

Routine analysis of an arterial blood gas yields a measured pH, a measured  $\text{PO}_2$ , and a measured  $\text{PCO}_2$ . Ordinarily, the serum bicarbonate, base excess, and percent oxygen saturation of hemoglobin are all calculated values. The oxygen saturation is of clinical significance because it usually correlates with the oxygen content of the blood; thus, the oxygen available to the tissues. However, implied in this relationship is a normal amount of functional hemoglobin. Because the oxygen saturation is calculated from the measured

**FIGURE 28-4.** Cooximetry curves for normal and abnormal hemoglobin variants. Transmitted light absorbance spectra are shown for 4 hemoglobin species: oxyhemoglobin, reduced (deoxy) hemoglobin, carboxyhemoglobin, and methemoglobin.

PO<sub>2</sub> using the oxyhemoglobin dissociation curve, it represents only the saturation of normal hemoglobin. Thus, in the presence of even a small percentage of abnormal hemoglobin, the calculated oxygen saturation overestimates the total oxygen content of the blood. For example, a patient with a PO<sub>2</sub> of 95 mm Hg has a calculated oxygen saturation of 95%. If the patient also has a 30% methemoglobinemia, only 70% of the total hemoglobin is saturated to 95% and the actual saturation is only 67%. This gap is clinically important because hemoglobin saturations of less than 90% do not provide adequate oxygen delivery to the tissues.

As discussed above, despite the development of bedside noninvasive pulse-cooximetry, most clinicians still depend on laboratory cooximeters for measurement of carboxyhemoglobin and methemoglobin. Most cooximeters spectrophotometrically measure total hemoglobin, oxyhemoglobin, deoxyhemoglobin, carboxyhemoglobin, and methemoglobin. Newer models also measure fetal hemoglobin and sulfhemoglobin (Fig. 28-4). The resultant saturation is a measured oxygen saturation of the total hemoglobin by including all measured hemoglobin variants, and thus correlates with the total oxygen content of the blood.

The difference between measured and calculated oxygen saturation represents the percentage of abnormal hemoglobin present. This gap is helpful in the diagnosis of methemoglobin and carboxyhemoglobin, and is useful in assessing the adequacy of therapy for these disorders. Common indications for cooximetry include cyanosis that is unresponsive to oxygen (methemoglobin and sulfhemoglobin), known use of methemoglobin-forming xenobiotics (benzocaine, dapsone), smoke inhalation (carboxyhemoglobin and possibly methemoglobin), and evaluation of therapy for cyanide toxicity (methemoglobin).

Like so many other tools, the cooximeter is not perfect. Its biggest limitation occurs when dealing with uncommon hemoglobins. Older cooximeters use 4 wavelengths of light and have the ability to define only 4 hemoglobin variants. Consequently, rare dyshemoglobinemias, such as sulfhemoglobin, are misinterpreted as one or a combination of the 4 common hemoglobin variants, giving erroneous results. This phenomenon is commonly noted in neonates in whom fetal hemoglobin was interpreted as carboxyhemoglobin.<sup>110,118</sup> Although this error rarely adds greater than 10% to the true carboxyhemoglobin value, this amount is significant because of the difficulties in assessing the cognitive status of infants possibly exposed to carbon monoxide. Newer cooximeters use at least 6 wavelengths of light and are designed to measure fetal hemoglobin and sulfhemoglobin directly, avoiding these interference problems.<sup>53</sup> Another source of interference with cooximetry is the use of hydroxocobalamin, which has a deep red color. Hydroxocobalamin

administration resulted in falsely low carboxyhemoglobin by laboratory cooximetry.<sup>73,84,120</sup> Clinicians should use caution in interpreting carboxyhemoglobin concentrations in patients who have received hydroxocobalamin. When available, a sample obtained before hydroxocobalamin administration should be sent for cooximeter analysis. Additionally, cooximeters tend to inconsistently interpret low levels (<2.5%) of carboxyhemoglobin.<sup>74</sup> Fortunately, this rarely has clinical implications.

## Imaging Adjuncts

### Bedside Ultrasound

Bedside ultrasound is frequently used in lieu of or as an adjunct to chest radiography to help establish diagnoses of pulmonary edema, pleural effusion, compromised cardiac function, and pneumothorax. Ultrasound requires operator training and is more technically challenging in obese patients or those with subcutaneous emphysema. The diagnostic performance of ultrasound is discussed below. For a review of specific sonographic techniques and signs, we recommend a resource-focused ultrasound review.<sup>41</sup> In one observational study of patients in ICU, the presence of anterior diffuse B lines with lung sliding indicated pulmonary edema with 97% sensitivity and 95% specificity.<sup>70</sup> When combined with echocardiography, the presence of decreased left ventricular ejection fraction can help determine whether lung edema is cardiogenic or the result of ARDS. Ultrasound can reliably diagnose pneumothorax, as well. The combination of abolished lung sliding (extremely sensitive) with anterior A-lines strongly suggests pneumothorax. The presence of a “lung point” is pathognomonic for the condition. When these 3 signs were observed together, ultrasound had 88% sensitivity and 100% specificity in identifying pneumothorax in ICU patients.<sup>71</sup> In a prospective study of healthy volunteers and ARDS patients, ultrasound was 92% sensitive and 93% specific for identification of pleural effusion, compared to 42% sensitivity and 90% specificity for auscultation.<sup>69</sup>

### Chest Radiography

Radiographic detection of a pneumothorax or pneumomediastinum, cardiogenic pulmonary edema, ARDS, aspiration pneumonitis, or the presence of a foreign body is crucial, but can usually be delayed until the initial evaluation is completed. Confirmation of endotracheal tube placement is necessary but initially can be ascertained by auscultating bilateral breath sounds following compression of a bag-valve-mask, or using a variety of marketed devices such as EtCO<sub>2</sub> detectors designed to help confirm tube placement. For patients with occupational disorders, chest radiography is essential to confirm and stage exposures to asbestos, silica, coal, and other causes of pneumoconiosis (Chap. 8).

### Pulmonary Function Tests

Formal pulmonary function tests are seldom indicated in acute poisoning. However, bedside tests are helpful to predict respiratory failure in patients with suspected respiratory muscle weakness, such as that occurring from botulinum toxin, elapid venom, inhibitors of acetylcholinesterase, nicotine, and others. The determination of the maximum inspiratory pressure (MIP; sometimes referred to as “negative inspiratory force” {NIF}) identifies subclinical diaphragmatic weakness. In patients with primary neurologic conditions, a MIP of worse (closer to zero) than negative 30 cm H<sub>2</sub>O is predictive of respiratory failure.<sup>65</sup> Although poor effort also results in an abnormal value, a normal value excludes respiratory muscle weakness. The test should be performed serially, at least every 2 to 4 hours following initial presentation, to identify changes in patient condition.

## THERAPEUTIC OPTIONS

### Supplemental Oxygen

Supplemental oxygen is indicated for all patients with suspected or confirmed respiratory insufficiency. Although it is generally advisable to begin

with high flow (12 L/min) via a nonrebreather mask, administering lower concentrations of oxygen is reasonable in more stable patients. Supplemental oxygen should be titrated to the minimum flow rate required to achieve adequate oxygen saturation. High-flow nasal oxygen (HFNO) systems deliver heated, humidified oxygen at flow rates up to 60 L/min.<sup>68</sup> These devices reduce dead space and increase oxygen delivery compared to conventional nasal cannulae. They are associated with improved user comfort and reduced minute ventilation requirement. High-flow nasal oxygen likely has its greatest benefit in patients who are hypoxic but not hypercapnic.

Pulse oximetry is a good modality for monitoring oxygenation, especially if used in conjunction with EtCO<sub>2</sub>, recognizing the limitations of both modalities. An arterial blood gas should be obtained if there is concern that pulse oximetry saturation and the EtCO<sub>2</sub> are not reflective of the true saturation. Hyperbaric oxygen is indicated for carbon monoxide poisoning and rarely other exposures (Antidotes in Depth: A40).

Initially, there should be limited concern over worsening hypercapnia in patients with chronic obstructive pulmonary disease and respiratory failure. This concern should not deter clinicians from providing needed oxygen, because many of these patients will require intubation for their hypoventilation. It is important to appreciate that supplemental oxygen will improve hypoxia but not hypercarbia.

Additional respiratory support can be offered from bilevel positive airway pressure (BiPAP). Some experimental evidence supports the use of BiPAP for patients with acute respiratory dysfunction in the emergency department.<sup>89</sup> Although this technique is useful in overdosed patients, it should be considered only as a temporizing measure for patients who are expected to recover rapidly, or while preparing for intubation.

## Intubation

Most sedative-hypnotic-poisoned patients are managed without intubation. However, in a large retrospective review of poisoned patients, sedative-hypnotics and opioids were still the first and second largest categories of exposures treated with endotracheal intubation.<sup>12</sup> After the decision for mechanical ventilation is made, the route needs to be selected. We recommend oral intubation because it permits the use of a larger endotracheal tube—usually 8 mm or even larger in adults—than does nasal intubation. If the patient later needs bronchoscopy, then it can be performed through the endotracheal tube. Some data suggest that bronchoscopy with bronchoalveolar lavage is of both diagnostic<sup>109</sup> and therapeutic<sup>62</sup> benefit for selected poisoned patients. Fiberoptic devices facilitate oral intubation in difficult cases, making nasotracheal intubation almost obsolete. However, an advantage of nasotracheal intubation over oral intubation is that orogastric lavage is performed more easily when the oral cavity is unimpeded. After the trachea is intubated, the tube should be checked to ensure that it is correctly positioned.

All patients who overdose and show signs or symptoms of respiratory insufficiency should have chest radiography performed. Unfortunately, intubated patients usually have portable radiography performed and the carina is frequently difficult to visualize because of the poor quality of the study. When seen, the carina is visualized between T5 and T7 in most patients. Thus, the tip of the endotracheal tube should be above T5 for proper (safe) placement. When portable chest radiography is obtained, the patient's neck is often either extended or flexed, altering the location of the endotracheal tube tip. For this reason, it is essential to note the position of the neck during radiography, because the tip of the endotracheal tube will move up (with flexion) or down (with extension) by almost 2 cm.<sup>14</sup>

## Mechanical Ventilation

After a patient is intubated for ventilatory support, the respirator mode is selected. Patients with pure hypoventilation usually require a controlled fixed rate that is easily adjusted based on pulse oximetry, EtCO<sub>2</sub>, and/or serial venous or arterial blood-gas analyses. Patients with pulmonary

parenchymal processes, such as ARDS or pneumonia, usually do best when placed on either assist control (AC) or intermittent mechanical ventilation (IMV) mode. Both of these modes are volume-controlled, meaning the clinicians set a volume and a minimal rate. In each of these modes, the patient is able to take additional breaths. In AC, the additional patient breaths trigger a ventilator-delivered breath at the preset tidal volume. With the IMV mode, the tidal volume of extra patient-initiated breaths is determined by the patient. This lowers mean airway pressure, which theoretically reduces the risk of barotrauma and hemodynamic compromise. Although the lower airway pressures associated with IMV are desirable, many authorities recommend the use of the assist mode because it eliminates the patient's work of breathing.<sup>61</sup>

The next step is to determine the appropriate FiO<sub>2</sub> to be delivered to the patient. A number of approaches are available to assist with this decision. One simple approach is to intubate a patient, control breathing, administer 100% oxygen, and decrease to an FiO<sub>2</sub> of less than 50% as quickly as possible in an attempt to prevent oxygen toxicity.<sup>3</sup> Although the toxic effects of oxygen are well known for paraquat (Chap. 109), evidence suggests that oxygen is an important mediator of other xenobiotic-induced pulmonary injuries such as with iron.<sup>50</sup> A PO<sub>2</sub> of at least 55 mm Hg or a measured oxygen saturation greater than 88% is generally acceptable, although many clinicians feel more comfortable establishing a "buffer" against deterioration by increasing the PO<sub>2</sub> to greater than 60 mm Hg.<sup>112</sup> In most patients, tidal volumes should be set on the order of 6 mL/kg/breath. These lower, "protective" tidal volumes cause less barotrauma, lung injury, and cytokine release. Lower tidal volumes decrease mortality and ventilator days for patients with ARDS and to improve clinical outcomes in patients without ARDS.<sup>1,81</sup> If oxygenation cannot be maintained with FiO<sub>2</sub> at or less than 50%, PEEP should be used, with careful reassessment of serial arterial blood-gas analyses, changes in effective compliance, and hemodynamic data with each increment in PEEP.

## Pharmacologic Interventions: Antidotes

Only a few antidotes have a significant role in reversing xenobiotic-induced respiratory dysfunction. Naloxone has the greatest role. Respiratory stimulants were historically used to treat sedative poisoning, but this practice lost favor because of limited efficacy and the occurrence of adverse effects, such as seizures.<sup>94</sup> Recent authors reported the use of doxapram to stimulate ventilation in alcohol and GHB-poisoned patients.<sup>92,93</sup> However, because these poisonings can be managed almost universally safely by conservative non-pharmacologic means, the use of stimulants cannot be recommended at this time. Atropine and pralidoxime are useful for respiratory dysfunction from cholinesterase inhibitors (Antidotes in Depth: A35 and A36, and Chap. 111). Elapid antivenom (A39) and botulinum antitoxin (A6) are rarely used but may be lifesaving in the appropriate clinical scenario. Neostigmine and sugammadex reverse muscle weakness from nondepolarizing neuromuscular blockers (Chap. 66). More commonly, clinicians are required to treat bronchospasm from exposure to pulmonary irritants. The use of β<sub>2</sub>-selective adrenergic-agonist bronchodilators are effective in these patients.<sup>37</sup> Although the role of corticosteroids remains controversial, they are reasonable adjuncts.<sup>3</sup>

When treating patients with bronchospasm from one of the work-related asthma syndromes, it is reasonable that management should be similar to that of any patient with pulmonary bronchospasm, such as emphasizing inhaled bronchodilators and corticosteroids (Fig. 28-5).

An inhaled solution of 2% sodium bicarbonate often provides symptomatic relief for patients with pulmonary exposure to hydrogen chloride or to chlorine (Antidotes in Depth: A5).

Exogenous nitric oxide was evaluated for a variety of pulmonary conditions. Specifically, indications investigated for nitric oxide include as a bronchodilator,<sup>19</sup> a means to reverse hypoxic pulmonary vasoconstriction,<sup>3</sup> and as treatment for ARDS.<sup>2</sup> Unfortunately, controlled studies fail to demonstrate a benefit for nitric oxide in patients with ARDS.<sup>3,112</sup> Similarly, the

Two 30-year-old patients who overdosed were brought to the ED. Each had ingested substantial amounts of barbiturates and diazepam. An arterial blood gas drawn from patient 1 while he was breathing room air revealed a pH of 7.18, PCO<sub>2</sub> of 70 mm Hg, PO<sub>2</sub> of 50 mm Hg, and a calculated bicarbonate of 24 mEq/L. An arterial blood gas drawn from patient 2, also breathing room air, revealed a pH of 7.31, PCO<sub>2</sub> of 50 mm Hg, PO<sub>2</sub> of 50 mm Hg, and a calculated bicarbonate of 25 mEq/L. Quick analysis showed that patient 1 was hypercapnic with a significant respiratory acidosis. Patient 2 did not appear as ill; his PCO<sub>2</sub> was not very elevated and his pH was not significantly reduced. The A–a gradients were calculated to be 12.5 mm Hg for patient 1 and 37.5 mm Hg for patient 2.

**A.** Arterial PCO<sub>2</sub> approximates alveolar PCO<sub>2</sub> and is substituted as:

$$PAO_2 = PiO_2 - \frac{PCO_2}{R}$$

$$PiO_2 = (FiO_2)(PB - PH_2O)$$

where PAO<sub>2</sub> is alveolar PO<sub>2</sub>, PiO<sub>2</sub> is partial pressure of inspired O<sub>2</sub>, PaCO<sub>2</sub> is arterial PCO<sub>2</sub>, and R is the respiratory exchange ratio. Therefore:

$$PAO_2 = [(FiO_2)(PB - PH_2O)] - \frac{PCO_2}{R}$$

where FiO<sub>2</sub> is the inspired O<sub>2</sub> fraction, PH<sub>2</sub>O is water vapor pressure, and PB is barometric pressure. On room air at sea level, FiO<sub>2</sub> = 21%. At steady state, R = 0.8. At sea level, PB = 760 mm Hg, and PH<sub>2</sub>O = 47 mm Hg. Therefore:

$$PAO_2 = [(FiO_2)(PB - PH_2O)] - \frac{PCO_2}{R}$$

$$= [(0.21)(760 - 47)] - \frac{PCO_2}{R}$$

$$= 150 - [(1.25)(PCO_2)]$$

**Because the A–a gradient is equal to PAO<sub>2</sub> – PaO<sub>2</sub> it can be expressed as:**

$$150 - [(1.25)(PCO_2)] - PaO_2 \text{ or } 150 - [(1.25)(PCO_2) + PaO_2]$$

A normal A–a gradient on room air is 10–15 mm Hg, but this increases with age. A rough estimate of the normal A–a gradient is one-third the patient's age.

**B.** Referring to the two overdosed patients above, the A–a gradient for patient 1 is:

$$150 - [(1.25)(70) + 50] = 12.5 \text{ mm Hg}$$

This calculation reveals a normal gradient, indicating that the etiology for hypoxemia and hypoventilation is extrinsic to the lung itself. In patient 2, the A–a gradient is:

$$150 - [(1.25)(50) + 50] = 37.5 \text{ mm Hg}$$

This abnormally high A–a gradient is consistent with the aspiration which was pneumonia seen on the patient's chest radiograph.

**FIGURE 28–5.** (A) Derivation of the definition of alveolar–arterial (A–a) oxygen gradients. (B) Applying the A–a gradients.

results are disappointing for corticosteroids, surfactants, and a variety of antiinflammatory drugs.<sup>4,112</sup>

## SUMMARY

- Xenobiotics adversely affect tissue oxygenation at every step required for ventilation, oxygen delivery, and cellular respiration.
- Hypoxia and hypercarbia should be addressed as soon as they are suspected clinically. The use of supplemental oxygen or assisted ventilation should not be delayed.
- Although the clinical manifestations of hypoxia are constant regardless of etiology, the history, physical examination, and diagnostic testing often help to identify the specific mechanism of hypoxia.
- Invasive and noninvasive measures of oxygenation and ventilation should be used to assess response to therapy and need for further therapy. Clinicians should familiarize themselves with the strengths and

limitations of pulse oximetry, end-tidal carbon dioxide capnography, venous and arterial blood–gas analyses, and cooximetry.

- In most cases of xenobiotic-induced respiratory depression, general supportive measures are favored over specific antidotal therapy.

## THERMOREGULATORY PRINCIPLES

Susi U. Vassallo and Kathleen A. Delaney

Despite exposure to wide fluctuations of environmental temperatures, human body temperature is maintained within a narrow range.<sup>16,120</sup> Elevation or depression of body temperature occurs when (1) thermoregulatory mechanisms are overwhelmed by exposure to extremes of environmental heat or cold; (2) endogenous heat production is either inadequate, resulting in hypothermia, or exceeds the physiologic capacity for dissipation, resulting in hyperthermia; or (3) disease processes or xenobiotic effects interfere with normal thermoregulatory responses to heat or cold exposure.

### METHODS OF HEAT TRANSFER

Heat is transferred to or away from the body through radiation, conduction, convection, and evaporation. *Radiation* involves the transfer of heat from an object to the environment and from warm objects in the environment to another object, for example, from the sun to a body. *Conduction* involves the transfer of heat to solid or liquid media in direct contact with the body. Water immersion conducts significant amounts of heat away from the body. This effect facilitates cooling in a swimming pool on a hot summer day and hypothermia despite moderate ambient temperatures when an individual is wet on a rainy day. The amount of heat lost through conduction and radiation depends on the temperature gradient between the skin and its surroundings; cutaneous blood flow; and insulation such as subcutaneous fat, hair, clothing.<sup>134</sup> In the respiratory tract, heat is lost by conduction to water vapor or gas. In animals unable to sweat, this represents the primary method of heat loss. The amount of heat lost through the respiratory tract depends on the temperature gradient between inspired air and the environment and the rate and depth of breathing.<sup>134</sup> *Convection* is the transfer of heat to the air surrounding the body. Wind velocity and ambient air temperature are the major determinants of convective heat loss. *Evaporation* is the process of vaporization of water, such as that in sweat. Large amounts of heat are dissipated from the skin during this process, resulting in cooling. Ambient temperature, rate of sweating, air velocity, and relative humidity are important factors in determining how much heat is lost through evaporation. On a very hot and humid day, sweat pours off an exercising person, rather than evaporating and initiating heat loss. In very warm environments, thermal gradients are reversed, leading to transfer of heat to the body by radiation, conduction, or convection.<sup>143</sup>

### PHYSIOLOGY OF THERMOREGULATION

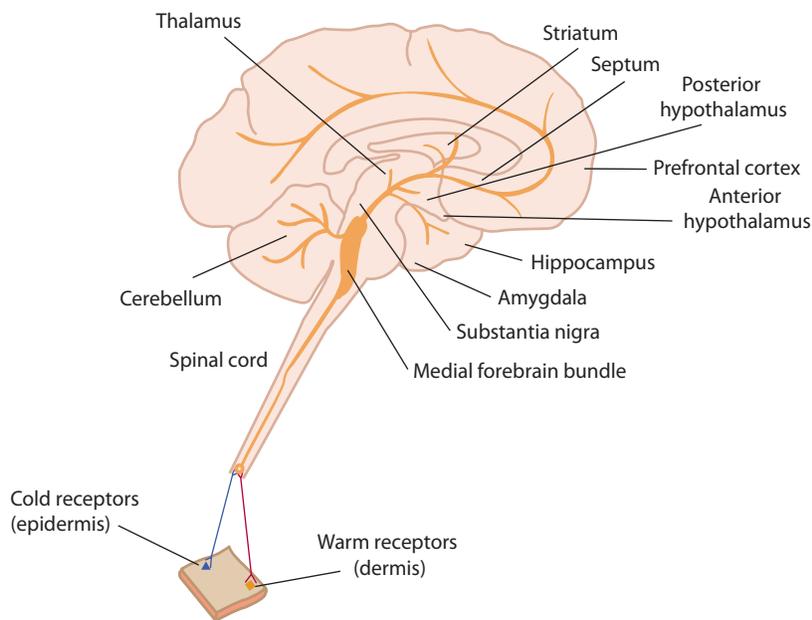

In a human not affected by xenobiotics or disease, stimulation of peripheral and hypothalamic temperature-sensitive neurons results in autonomic, somatic, and behavioral responses that lead to the dissipation or conservation of heat. Thermoregulation is the complex physiologic process that serves to maintain hypothalamic temperature within a narrow range of  $98.6 \pm 0.8^\circ\text{F}$  ( $37 \pm 0.4^\circ\text{C}$ ), known as the *set point*.<sup>120</sup> This hypothalamic set point is influenced by factors such as diurnal variation, the menstrual cycle, and others. Maintaining, raising, or lowering the set point results in many outwardly visible physiologic manifestations of thermoregulation such as sweating, shivering, flushing, or panting. In the central nervous system (CNS), thermosensitive neurons are located predominantly in the preoptic area of the anterior hypothalamus, but to a lesser extent in the posterior hypothalamus. These neurons are divided into those that are hot, cold sensitive, or temperature insensitive. Approximately 30% of preoptic neurons are warm sensitive. These increase their firing rate during warming and decrease their firing rate during cooling.<sup>28</sup> Warming of the hypothalamus in conscious animals results in vasodilation, hyperventilation, salivation, and increases in evaporative water loss, as well as a reduction of cold-induced shivering

and vasoconstriction.<sup>120</sup> Cooling of the hypothalamus in conscious animals causes shivering, vasoconstriction, and increased metabolic rate even if the environment is hot.<sup>113</sup> How these temperature-sensitive neurons of the hypothalamus detect temperature changes and affect neuronal transmission is unclear. Altered action potential initiation and propagation caused by temperature-dependent membrane potential changes are associated with the ratios of  $\text{Na}^+$  to  $\text{Ca}^{2+}$  that alter neuronal excitability and neurotransmitter release, or effect on the  $\text{Na}^+, \text{K}^+$ -ATPase (adenosine triphosphatase) pump.<sup>134</sup> Xenobiotics that increase intracellular cyclic adenosine monophosphate (cAMP) concentrations increase the thermosensitivity of warm-sensitive neurons.<sup>28</sup> In the brain stem, warm- and cold-sensitive neurons are located in the medullary reticular formation, where information from cutaneous receptors, spinal cord, and preoptic area of the anterior hypothalamus is integrated.<sup>125</sup>

The spinal cord is thermosensitive. Heat- and cold-sensitive ascending spinal impulses are conducted in the spinothalamic tract. As in the hypothalamus, local heating or cooling of the spinal cord results in thermoregulatory responses.<sup>120</sup> In addition to the hypothalamus, brain stem, and spinal cord, there is evidence of thermosensitivity in the deep abdominal viscera.<sup>110,120,209</sup> Intraabdominal heating or cooling results in thermoregulatory responses. Cold- and warm-sensitive afferent impulses are recorded from the splanchnic nerves in animals.<sup>110,211</sup> Finally, the skin also contains heat and cold thermosensitive neurons. Whereas cold receptors are free nerve endings that protrude into the basal epidermis, warm-sensitive receptors protrude into the dermis.<sup>119,121</sup> Cutaneous thermoreceptor output is affected by the absolute temperature of the skin, rate of temperature change, and area of stimulation.<sup>120</sup> Cutaneous cold receptors are A- $\delta$  and C nociceptor afferent fibers. A- $\delta$  fibers are small-diameter, thinly myelinated fibers that conduct at 5 to 30 m/sec, and C fibers are small-diameter, unmyelinated fibers that conduct at 0.5 to 2 m/sec.<sup>115</sup> Afferents from heat receptors are primarily C fibers. Cutaneous thermoreceptive neurons respond to external temperature change as well as rate of temperature change, sending early warning to the CNS via afferent impulses, allowing rapid and transient thermoregulatory responses before brain temperature changes (Fig. 29–1). It is important to emphasize that thermoregulatory responses as described above are affected by xenobiotics and disease processes.

### Vasomotor and Sweat Gland Function

Vasomotor responses to thermoregulatory input differ according to location. The normal thermoregulatory response to heat stress is mediated primarily by heat-sensitive neurons in the hypothalamus. In healthy individuals without impairment of vasodilatory mechanisms by xenobiotics, active vasodilation in the extremities occurs under noradrenergic control; increasing sympathetic stimulation results in vasoconstriction, and decreasing sympathetic stimulation results in vasodilation. Vasodilation in the head, trunk, and proximal limbs is not a result of decreased sympathetic tone; instead, it is a result of an active process involving the central nervous system and the peripheral cholinergic sudomotor nerves and the local effects of temperature on venomotor tone. Sweat glands release local transmitters, such as vasoactive intestinal polypeptide (VIP) or bradykinins, and vasodilation results. Areas of the body such as the forehead, where sweating is most prominent during heat stress, correspond to areas where active vasodilation is greatest. The neurotransmitters involved in the regulation of relationships between vasodilation and sweating as a response to heat stress are not fully elucidated in humans, but animal evidence suggests the presence of specific vasodilator nerves.<sup>120</sup>

**FIGURE 29-1.** A representation of the response of cutaneous thermoreceptive neurons to external temperature change as an early warning to the central nervous system.

Sweat glands are controlled by postganglionic nerve fibers, which are cholinergic, and large amounts of acetylcholinesterase as well as other peptides modulate neural transmission.<sup>125,126</sup>

### Neurotransmitters and Thermoregulation

The neurotransmitters involved in thermoregulation include serotonin, norepinephrine, acetylcholine, dopamine, prostaglandins,  $\beta$ -endorphins, and intrinsic hypothalamic peptides such as arginine vasopressin, adrenocorticotropic hormone (ACTH) thyrotropin-releasing hormone (TRH), and melanocyte-stimulating hormone (MSH).<sup>50,199</sup> Studies on the effects of individual neurotransmitters in thermoregulation yield contradictory results, depending on the animal species and the route of administration of the exogenous neurotransmitter. However, epidemiologic studies demonstrate that patients taking xenobiotics affecting these neurotransmitters are at greater risk for heat illness. In the laboratory, refinements in techniques of microinjection of neurotransmitters into the hypothalamus of animals, rather than intraventricular instillation, have elucidated microanatomic sites where neurotransmitters are active. More research is needed, however, because interspecies variations and theoretical differences in response to exogenous versus endogenous peptides make this area of study complex. There is ample clinical and epidemiologic evidence that xenobiotics that affect the neurotransmitters listed above influence the ability to thermoregulate.

Apomorphine is a mixed dopamine agonist that causes hypothermia in animals; studies using selective  $D_1$ - and  $D_2$ -receptor agonists and antagonists demonstrate the hypothermic effect of apomorphine as a result of its effects on  $D_2$  receptors, with some modulation by  $D_1$  receptors in the hypothalamus.<sup>179</sup> Stimulation of  $D_2$  receptors mediate the hypothermia induced by the peptide sauvagine.<sup>30</sup> Stimulation of  $D_3$  by specific agonists caused hypothermia in an animal model.<sup>180,181</sup> The link between dopamine  $D_2$  receptors and norepinephrine receptors in the hypothalamus leads to vasodilation and hypothermia. The effect of clozapine in producing hypothermia in rats is caused by  $D_1$  and  $D_3$  stimulation.<sup>180,220</sup> Lesser-known peptides are also involved in thermoregulation. For example, neuropeptide Y is an amino acid neurotransmitter that occurs in high concentrations in the preoptic area of the anterior hypothalamus. Administration of neuropeptide Y caused a reduction in core temperature when administered with adrenergic receptor antagonists such as prazosin, an  $\alpha_1$ -adrenergic antagonist; propranolol, a  $\beta$ -adrenergic antagonist; and clonidine, a central  $\alpha_2$ -adrenergic agonist.<sup>84,218</sup> Temperature regulation is complicated as both central and peripheral mechanisms are involved. The results of studies of temperature changes

induced in animal models by the administration of xenobiotics frequently vary depending on the ambient temperature at which the experiment is performed, and on the species of animal. The  $\alpha_2$ -adrenergic agonist clonidine induced a dose-dependent significant increase in temperature of rats kept at high ambient temperature. This effect was mediated by the  $\alpha_2$ -adrenergic postsynaptic receptors. The administration of an  $\alpha_1$ -adrenergic antagonist and a central  $\alpha_2$ -adrenergic agonist reduced the rise in temperature. The  $\beta_2$ -adrenergic agonist clenbuterol-induced hyperthermia is mediated by  $\beta$ -adrenergic receptors. However, the hyperthermic effect of clenbuterol may result from secondary  $\alpha_2$ -adrenergic agonist stimulation centrally, perhaps from the norepinephrine release that results from  $\beta$ -adrenergic stimulation. In support of this is that the  $\alpha_2$ -adrenergic antagonists block the increase in temperature caused by clenbuterol.<sup>184</sup>

Studies on muscarinic receptors demonstrate involvement of muscarinic  $M_2$  and  $M_3$  receptors in the production of hypothermia when agonists to these receptors are administered centrally.<sup>221</sup> Blockers of ATP-sensitive  $K^+$  channels can reverse the effect of cholinomimetic drugs in producing hypothermia.<sup>206</sup>

### XENOBIOTIC EFFECTS ON THERMOREGULATION

Many xenobiotics have pharmacologic effects that interfere with thermoregulatory responses (Tables 29-1 and 29-2).<sup>168,170,252</sup>  $\alpha$ -Adrenergic agonists prevent vasodilation in response to heat stress. Increased endogenous heat production in the setting of increased motor activity occurs during exercise and also occurs in patients manifesting cocaine or amphetamine toxicity. Life-threatening hyperthermia is associated with the use of these xenobiotics. Whereas adrenergic antagonists and calcium channel blockers diminish the cardiac reserve available to compensate for heat-induced vasodilation, diuretics decrease cardiac reserve through their effects on intravascular volume.<sup>63</sup>  $\beta$ -Adrenergic antagonists also interfere with the capacity to maintain normothermia under conditions of cold stress, possibly related to their interference with the mobilization of substrates required for thermogenesis.<sup>170</sup> Opioids and diverse sedative-hypnotics depress hypothalamic function and predispose to hypothermia.<sup>85</sup> Carbon monoxide poisoning must also be considered in hypothermic patients. Organic phosphorus compounds and other xenobiotics that cause cholinergic stimulation cause hypothermia by stimulation of inappropriate sweating and possibly through depression of the endogenous use of calorogenic substrates.<sup>170</sup> Xenobiotics with anticholinergic effects decrease sweating and predispose to hyperthermia, which is of particular concern during environmental heat exposure or exercise.

TABLE 29–1 Effects of Xenobiotics That Predispose to Hyperthermia

<b>I. Impaired cutaneous heat loss</b>
A. Vasoconstriction through $\alpha$ -adrenergic stimulation

Phencyclidine
Serotonin toxicity
Strychnine
Thyroid hormone excess
<b>VII. Dystonia</b>
Antipsychotics
Neuroleptic Malignant Syndrome (NMS)
<b>VIII. Withdrawal</b>
Dopamine agonists
Ethanol
Sedative–hypnotics

Phenothiazines appear to interfere with normal response to both heat and cold. Severe hyperthermia associated with the absence of sweating is frequently described in patients using phenothiazines and is a consequence of their anticholinergic effects.<sup>222,264</sup> In addition, phenothiazines have central effects interfering with the hypothalamus, commonly although incompletely attributed

to the antidopamine effect. Effects on cold tolerance are attributed to their  $\alpha$ -adrenergic antagonist effects, which prevent vasoconstriction in response to cold stress.<sup>169</sup> In addition, hyperthermia associated with severe extrapyramidal rigidity occurs in patients taking antipsychotics.<sup>161</sup> This rigidity is attributed to the dopamine-blocking effects of this class of drugs.

### The Effects of Ethanol

Ethanol is the xenobiotic most commonly related to the occurrence of hypothermia by virtue of its effects on CNS depression, vasodilation, and blunting of behavioral responses to cold. However, thermoregulatory dysfunction associated with ethanol intoxication is undoubtedly more complex.

In animal models, ethanol leads to hypothermia, the extent of which is partly dependent on ambient temperature.<sup>194,212,213</sup> In mice, as the dose of ethanol increased, body temperature decreased, and the rate of this decline in body temperature was faster at higher ethanol doses.<sup>190</sup> The decline in body temperature could be reversed by increasing ambient temperature; increasing ambient temperature to 96.8°F (36°C) caused an immediate rise in the body temperature.<sup>190</sup> The poikilothermic effect of ethanol was not a result of hypoglycemia. Poikilothermia is the variation in body temperature greater than  $\pm 3.6^\circ\text{F}$  ( $\pm 2^\circ\text{C}$ ) on exposure to environmental temperature changes. Rats treated with equipotent amounts of pentobarbital showed the same effects on body temperature as rats treated with ethanol, suggesting a similar central mechanism of CNS depression resulting in altered thermoregulation.<sup>190</sup>

Numerous mechanisms are involved in the ethanol-induced depression of CNS function.<sup>215</sup> Genetic factors influence the role of ethanol in the production of hypothermia. Mice are selectively bred for genetic sensitivity or insensitivity to acute ethanol-induced hypothermia, and the differences appear to be mediated by the serotonergic systems.<sup>86,100,185,190</sup> Cyclo His-Pro DKP, another neurotransmitter that is found in many animal species, acts at the preoptic-anterior hypothalamus to modulate body temperature. Exogenous administration of this neuropeptide produced a dose-dependent decrease in ethanol-induced hypothermia. Attenuation of hypothermia resulted from passive immunization with Cyclo His-Pro DKP antibody.<sup>37,130</sup> Ethanol effects appears to be mediated through modulation of endogenous opioid peptides because high-dose (10 mg/kg) naloxone reverses ethanol-induced hypothermia in animals.<sup>202</sup>

Pharmacokinetic characteristics of ethanol metabolism change in the presence of hypothermia. Hypothermic piglets infused with ethanol showed slower ethanol metabolism and a smaller volume of distribution ( $V_d$ ) and, as

a result, higher ethanol concentrations than normothermic control piglets. Ethanol elimination and metabolism decreased as temperature fell.<sup>148</sup>

Tolerance develops to the effect of ethanol-induced hypothermia in all species.<sup>88,194</sup> The degree of tolerance is proportional to the dose and duration of treatment with ethanol and is not explained by the increased rate of metabolism with chronic exposure.<sup>134</sup> Age is a factor in the development of tolerance; older animals do not display the same degree of tolerance to the hypothermic effects of chronic ethanol administration as do younger animals.<sup>187,202,262</sup> The development of tolerance to ethanol-induced hypothermia is affected by genetic factors. Experimentally, tolerance to ethanol-induced hypothermia increases the incorporation of certain amino acids into proteins in the rat brain. The formation of new proteins in ethanol-tolerant rats suggests stimulation of gene expression associated with ethanol tolerance.<sup>134,255</sup> Upregulation of the *N*-methyl-D-aspartate (NMDA) receptors are also implicated in the development of ethanol tolerance. In addition, altered nicotinamide adenine dinucleotide (NADH) oxidation to NAD<sup>+</sup>, diminishes blood flow to the liver, or slows metabolism through the microsomal enzyme system.<sup>215</sup>

Hypothermia alters the breath-ethanol partition in the alveolus, and the temperature of expired breath alters breath-ethanol analysis results. In patients with mild hypothermia, breath-ethanol analysis results in lower values by 7.3% per degree centigrade (or 1.8°F) decrease in body temperature.<sup>91</sup> Whether breath-ethanol analysis is also affected by hyperthermia remains to be studied.<sup>91</sup>

## DISEASE PROCESSES AND THERMOREGULATION

Many disease processes interfere with normal thermoregulation, limiting an individual's capacity to prevent hypothermia or hyperthermia. Extensive dermatologic disease or cutaneous burns impair sweating and vasomotor responses to heat stress.<sup>34</sup> Patients with autonomic disturbances secondary to diabetes mellitus or peripheral vascular disease also have altered vasomotor responses that impair vasodilation and sweating.<sup>236</sup> Extensive surgical dressings preclude the evaporation of sweat in an otherwise normal patient. Heat-stressed persons with poor cardiac reserve and lower cardiac output are not able to sustain skin blood flow rates high enough to maintain normothermia.<sup>77,240</sup> Intense motor activity leads to excessive heat production in all patients, particularly those with Parkinson disease or hyperthyroidism. Patients with agitated delirium or seizures also have significantly elevated rates of endogenous heat production. Hypothalamic injury caused by cerebrovascular accidents, trauma, or infection disturb thermoregulation.<sup>76,165</sup> Hypothalamic dysfunction leads to high, unremitting fevers and insufficient stimulation of heat loss mechanisms such as sweating. Hypothalamic damage predisposes to hypothermia by interference with centrally mediated heat conservation.<sup>76,165,223,224</sup> Fever, the normal response to stimulation of the hypothalamus by pyrogens, results in an elevated physiologic temperature set point and is a disadvantage in the heat-stressed individual<sup>120</sup> (Table 29–3).

## HYPOTHERMIA

### Epidemiology

Hypothermia is defined as a lowering of the core body temperature to below 95°F (<35°C). Between 2003 and 2013, there were 13,419 hypothermia-related deaths for the United States overall. The Centers for Disease Control and Prevention defines these deaths as those with an underlying or contributing cause of death from exposure to excessive natural cold<sup>45</sup> (Table 29–3).

Alaska, Montana, Wyoming, and New Mexico had the greatest overall death rates from hypothermia. States with milder climates and rapid fluctuations in temperature, such as North and South Carolina, and western states, such as Arizona, with high elevations and cold nighttime temperatures also report hypothermia-related deaths.<sup>44</sup>

### Response to Cold

The normal physiologic response to cold is initiated by stimulation of cold-sensitive neurons in the skin, so that the onset of the body response to cold occurs before cooling of central blood. Cold-sensitive neurons in the skin send afferent impulses to the hypothalamus, resulting in shivering and

TABLE 29–3 Factors Predisposing to Hypothermia

<b>Advanced age</b>	<b>Immobilization</b>
Decreased ability to shiver	Central nervous system dysfunction illness
Decreased metabolic rate	Spinal cord injury
Decreased temperature discrimination	Trauma
Reduced peripheral blood flow	<b>Medical Diseases</b>
<b>Central nervous system depression</b>	Hepatic failure

Unintentional exposure to ....	

piloerection. Shivering is the main thermoregulatory response to cold in humans, except in neonates, in whom nonshivering thermogenesis prevails. Shivering is initiated in the posterior hypothalamus when impulses from cold-sensitive thermoreceptors are integrated in the anterior hypothalamus and communicated to the posterior hypothalamus or when cold-sensitive neurons in the posterior hypothalamus are activated directly. Efferent stimuli from the posterior hypothalamus travel through the midbrain tegmentum, pons, and lateral medullary reticular formation to the motor pathways of the tectospinal and rubrospinal tracts, resulting in shivering.<sup>19</sup> A mechanism of stimulation of shivering that usually occurs later when core temperature drops is the local cooling of the spinal cord, which leads to shivering by increasing excitability of motor neurons.

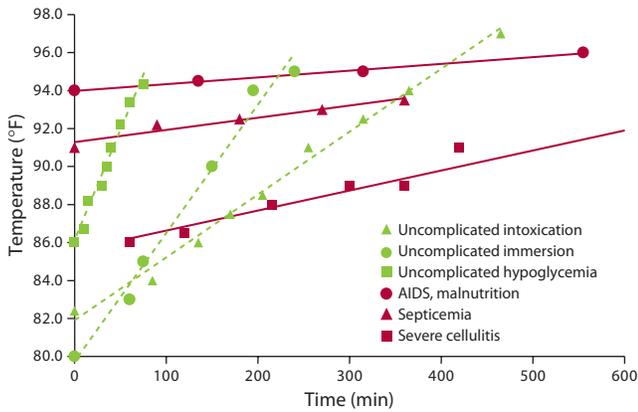

Heat produced without muscle contraction is known as nonshivering thermogenesis.<sup>32,120</sup> Nonshivering thermogenesis is mediated by the sympathetic nervous system.<sup>54</sup> Catecholamines activate adenylyl cyclase, increasing cAMP, resulting in mobilization of fat and glucose stores ( $\beta$ -adrenergic receptors).<sup>171,217</sup> Nonshivering thermogenesis is blocked by  $\alpha$ -adrenergic receptor antagonism and increased by administration of norepinephrine. Brown adipose tissue is the most important site of nonshivering thermogenesis. In humans, brown fat is found primarily in neonates, although in cold-acclimatized people, small amounts are found on autopsy.<sup>32</sup> Brown adipose tissue functions as a thermoregulatory effector organ, producing heat by the oxidation of fatty acids when the tissue is stimulated by norepinephrine.<sup>36</sup>

In addition to shivering and nonshivering thermogenesis, efferent sympathetic fibers from the hypothalamus stimulate peripheral vasoconstriction ( $\alpha$ -adrenergic receptors). Piloerection and vasoconstriction result in decreased heat loss from the body. Intense vasoconstriction shunts blood away from the periphery to the core and antidiuretic hormone antagonism results in increased urine output and hemoconcentration.

Several disease processes commonly result in an inability to maintain a normal body temperature in a cool environment (Table 29–3).<sup>65,163</sup>

### Underlying Illness in Hypothermia

Evaluations to determine the presence of underlying diseases are often difficult in a patient with hypothermia.<sup>67,89,163</sup> The mental status is not usually significantly abnormal until the temperature falls below 90°F (32.2°C). If normal mental status is not regained when the temperature reaches 90°F (32.2°C) during rewarming, underlying CNS structural, toxic, or metabolic problems

**FIGURE 29-2.** Relation of rewarming rate to underlying illness. (Reproduced with permission from Delaney KA, Vassallo SU, Larkin GL, et al. Rewarming rates in urban patients with hypothermia: prediction of underlying infection. *Acad Emerg Med*, 2006 Sep;13(9):913-921.)

are probable.<sup>67,89,163,207</sup> Failure of the patient to rewarm quickly suggests the presence of underlying disease<sup>67</sup> (Fig. 29-2). In one study, whereas hypothermic patients without underlying disease are reported to rewarm at a rate of 1.0°F/h to 3.7°F/h (0.6°C/h–2.1°C/h) (average, 2.1°F/h; 1.2°C/h), patients with significant underlying disease (sepsis, gastrointestinal hemorrhage, diabetic ketoacidosis, pulmonary embolus, myocardial infarction) warmed at a rate of 0.25°F/h to 1.8°F/h (0.1°C/h–1.0°C/h) (average, 1°F/h; 0.6°C/h).<sup>67,258</sup>

### Alteration of Pharmacology in Hypothermia

The pharmacology of certain xenobiotics is altered in the setting of hypothermia. In hypothermic piglets, the  $V_d$  and the clearance of fentanyl are decreased.<sup>149</sup> Similarly, in piglets given gentamicin, the  $V_d$  and clearance rate decreased in direct proportion to the decrease in cardiac output and glomerular filtration rate (GFR).<sup>147</sup> Hypothermic puppies given intravenous (IV) lidocaine showed slower rates of disappearance of the drug than when normothermic.<sup>186</sup> Humans and animals given propranolol showed a reduced  $V_d$  and decreased total body clearance, resulting in higher than expected propranolol concentrations.<sup>175,176,192</sup> Decreased hepatic metabolism of propranolol during hypothermia is demonstrated in vitro.<sup>176</sup> Hypothermia prolongs neuromuscular blockade with *d*-tubocurarine<sup>111</sup> and increases neuromuscular blockade with suxamethonium.<sup>262</sup> Phenobarbital metabolism and  $V_d$  decreased with hypothermia in children.<sup>133</sup> The lethal dose of digoxin was doubled in hypothermic dogs.<sup>17</sup> Digoxinlike substances are present during hypothermia.<sup>124</sup>

Reasons for altered metabolism in hypothermia include delayed distribution of the drug and altered enzyme function with temperature and pH changes. Cardiac output decreases, leading to decreased liver perfusion and decreased delivery of drug to hepatic microsomal enzymes.<sup>111,136-138,200</sup> Plasma volume decreases as free water moves intracellularly, causing hemoconcentration and further decreasing organ perfusion.<sup>112</sup> Biliary excretion of atropine, procaine, and sulfanilamide decreases in vitro.<sup>136-138</sup> In vitro, the activity of metabolic pathways, including acetylation and hydrolysis, decrease with cooling.<sup>136,137</sup>

These same metabolic changes occur in therapeutic hypothermia. Hypothermia is induced for its neuroprotective effects but requires attention to alterations in pharmacokinetics and pharmacodynamics of xenobiotics administered during hypothermia. Physiological changes during induced hypothermia are similar to those of unintentional hypothermia and include slowed enzymatic reactions, vasoconstriction, decreased-cardiac output, and hemoconcentration. Studies support a decrease in the  $V_d$  of pancuronium, midazolam, morphine, and gentamicin.<sup>64</sup> Clearance of xenobiotics is affected by organ perfusion, enzyme activity, and xenobiotic characteristics such as the degree of protein binding and the  $pK_a$ . Hepatic and renal clearance is affected by regional blood flow, which is decreased during hypothermia. In general, the decrease in the  $V_d$  and the decrease in clearance

result in increased serum xenobiotic concentrations.<sup>64</sup> Experimental studies in animals demonstrate a 25% increase in fentanyl concentrations at a core temperature of 32°C.<sup>92</sup> Concurrent-supportive modalities during hypothermia such as cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO) further alter the kinetics of xenobiotics during hypothermia.<sup>260</sup> In neonates, asphyxia treated with induced hypothermia presents the additional complication of rapidly changing neonatal physiology and the effects of supportive measures such as ECMO.<sup>64</sup>

### Clinical Findings

The clinical effects of hypothermia are related to the membrane depressant effects of cold, which result in ionic and electrical conduction disturbances in the brain, heart, peripheral nerves, and other major organs<sup>123</sup> (Table 29-4). Cold tissues are protected by decreases in tissue oxygen requirements. As body temperature decreases, metabolic activity declines at a rate of approximately 7% per 1.8°F (1°C).<sup>263</sup> This effect provides significant protection to vital organs despite the potentially deleterious effects of membrane suppression.

Effects on the CNS are temperature dependent. However, predicting the temperature of the patient based on the clinical presentation is unreliable.<sup>31,33,71</sup> The patient with mild hypothermia (90°F–95°F; 32.2°C–35°C) may have a relatively normal clinical appearance. Ataxia, clumsiness, slowed response to stimuli, and dysarthria are common.<sup>89</sup> As cooling continues, the mental status

**TABLE 29-4** Physiologic and Clinical Manifestations of Hypothermia

#### Cardiovascular

- Normal, decreased, or increased cardiac output
- Normal heart rate or tachycardia 20 to shivering, then bradycardia as severity of hypothermia increases
- Vasoconstriction and central shunting of blood

#### Electrocardiogram

- Prolongation of intervals (PR, QRS and QT)
- Atrial fibrillation
- Increased ventricular irritability
- J-point elevation (“Osborn waves”)

#### Central nervous system

- Mild: 90°F–95°F (32°C–35°C)
  - Normal mental status or slightly slowed
- Moderate: 80°F–90°F (27°C–32°C)
  - Lethargic but verbally responsive
- Severe: 68°F–80°F (20°C–27°C)
  - Unlikely to respond verbally or purposefully to noxious stimuli
- Profound: <68°F (<20°C)
  - Unresponsive; appears dead

#### Gastrointestinal tract

- Decreased motility
- Depressed hepatic metabolism

#### Hematologic

- Hemoconcentration
- Left shift of oxyhemoglobin dissociation curve

#### Kidneys

- Cold-induced diuresis (antidiuretic hormone antagonism)

#### Lungs

- Hyperventilation to hypoventilation with increasing hypothermia
- Bronchorrhhea

#### Metabolic

- Metabolic acidosis
- Increased glycogenolysis
- Increased serum free fatty acids
- Normal thyroid and adrenal function

slowly deteriorates. In moderate hypothermia (80°F–90°F; 27°C–32.2°C), the patient is usually lethargic but still likely to respond verbally. In severe hypothermia (68°F–80°F; 20°C–26.6°C), the patient is unlikely to respond verbally but will react purposefully to noxious stimuli.<sup>89,116</sup> With profound hypothermia (<68°F; <20°C), the patient is unresponsive to stimuli. The patient “appears dead.”<sup>116</sup> However, standard criteria for brain death do not apply to hypothermic patients. The hypothermia itself protects against cerebral hypoxic damage.<sup>123</sup> Temperature drop inhibits the release of the excitatory neurotransmitter glutamate and attenuates the release of dopamine in animal models of brain ischemia, suggesting a protective effect of hypothermia in brain injury.<sup>39</sup> Cerebrospinal fluid (CSF) glutamate concentrations were lower in patients showing benefit from mild induced hypothermia after brain injury compared with brain-injured patients kept normothermic.<sup>173</sup>

Patients have survived with body temperatures as low as 48.2°F (9°C).<sup>93</sup> Vigorous resuscitation is required for these patients. This approach leads to hours of cardiopulmonary resuscitation (CPR) of hypothermic patients with ventricular fibrillation, ventricular tachycardia, or asystole but is sometimes successful in resuscitating patients initially presumed to be dead.<sup>238</sup>

For field rescue work, the Swiss distinguish between 5 stages of hypothermia and provide guidelines for rescue in dangerous environmental conditions. These stages are based on the degree of consciousness, the presence or absence of shivering, cardiac activity, and core temperature.<sup>33,75</sup> The adage that a patient cannot be considered dead until the patient is warm and dead is further refined by the Swiss guidelines for field rescue attempts under avalanche conditions.

The cardiac and hemodynamic effects of cold correlate closely with body temperature. As cooling begins, there is a transient increase in cardiac output. Tachycardia develops secondary to shivering and sympathetic stimulation. At about 81°F (27.2°C), shivering ceases. Bradycardia develops with maintenance of a normal cardiac stroke volume.<sup>35,67</sup> This bradycardia is responsible for the decreased myocardial oxygen demand, which is protective in the setting of hypothermia.<sup>35</sup> In profound hypothermia, bradycardia may progress to asystole and death.

Unlike cerebral circulation, where autoregulation is preserved during cooling, coronary autoregulation is disturbed during hypothermia, and the myocardium is at risk of compromise.<sup>142</sup> Attempts to maximize myocardial oxygenation through administration of oxygen and volume replacement to increase diastolic filling pressures are recommended.

The initial response to cold is hyperventilation; however, as temperature continues to decrease, hypoventilation develops, which infrequently progresses to apnea and death. In animal models, this is attributed to cold-induced failure of phrenic nerve conduction.<sup>142</sup>

### The Cardiac Rhythm Disturbances

The most common electrocardiographic (ECG) abnormality in hypothermia is generalized, progressive depression of myocardial conduction. The PR, QRS, and QT intervals all prolong, and increasingly profound hypothermia

leads to gradual progression to asystole.<sup>74,251</sup> Ventricular fibrillation occurs in an irritable myocardium most commonly at temperatures less than 86°F (30°C), resulting in a high O<sub>2</sub> consumption dysrhythmia. Atrial fibrillation is the most common dysrhythmia occurring in the presence of hypothermia.<sup>90,201,253</sup> Shivering is not always clinically evident, but the characteristic fine muscular tremor frequently produces a mechanical artifact in the baseline of the ECG.<sup>78</sup> A deflection occurring at the junction of the QRS and ST segment is invariably present in patients with temperatures <86°F (<30°C) (Fig. 29–3). First described in a single patient in 1938, the J-point deflection is commonly known as the *Osborn wave*.<sup>79,203,247</sup> The J-point deflection, thought to be a “current of injury” associated with CO<sub>2</sub> retention under hypothermic conditions, was believed to be a poor prognostic sign.<sup>203</sup> Subsequent study does not support any prognostic significance because the J-point deflection is invariably found in hypothermic patients when multiple ECG leads are obtained.<sup>78,79,201,249,253</sup> The size of the J-point deflection increases as body temperature decreases.<sup>219,282</sup> Atrial dysrhythmias that occur in the absence of underlying heart disease invariably disappear solely with rewarming.

### Management

After blood specimens are drawn, the hypothermic patient in whom hypoglycemia is present should be given 0.5 to 1.0 g of dextrose/kg of body weight as D<sub>50</sub>W (50% dextrose in water in adults or D<sub>20</sub>W or D<sub>10</sub>W as appropriate for children) and at least 100 mg of IV thiamine. If hypoglycemia is the cause of the hypothermia, the response to dextrose is usually dramatic, heralded by the onset of shivering and rapid return to normal body temperature. Wernicke encephalopathy is uncommon but is associated with mild hypothermia; thermoregulation and normal ocular motion typically returns after the initiation of thiamine therapy.<sup>57</sup>

Hypothermia shifts the oxygen dissociation curve to the left (Chap. 28), resulting in decreased oxygen unloading to tissues; therefore, oxygen administration is reasonable.<sup>66</sup> If clinically indicated, endotracheal intubation should be performed for airway protection or inadequate ventilation or oxygenation.<sup>60</sup> However, there are rare case reports of ventricular fibrillation occurring during endotracheal intubation.<sup>14,99,116,204</sup> Every effort should be made to limit patient activity and stimulation during the acute rewarming period because activity increases myocardial oxygen demand or alters myocardial temperature gradients, increasing the risk of iatrogenic ventricular fibrillation. Although pulmonary artery catheters and central venous lines are typically inserted in clinically unstable patients they should be avoided unless absolutely essential so as not to precipitate ventricular dysrhythmias.<sup>114,157,248</sup> If a central venous catheter is considered necessary, it should not be allowed to touch the endocardium.<sup>250</sup> Patients who develop ventricular fibrillation or asystole are difficult to manage because of the many supportive therapies required at once and the often lengthy resuscitation efforts. In these instances, CPR should be initiated and the patient intubated and ventilated to maintain a pH of 7.40, uncorrected for temperature.<sup>66</sup> Active internal rewarming (see later discussion) should be instituted in the

**FIGURE 29–3.** A characteristic electrocardiographic finding in a patient with profound hypothermia. The terminal phase of the QRS complex shows a typical elevation of the J-point Osborn wave (↑). (Adapted from the research performed by Susi Vassallo, MD and Kathleen A. Delaney, MD.)

patient in cardiac arrest because standard therapy for ventricular fibrillation or asystole are often unsuccessful until rewarming is achieved. There is a risk of toxicity if multiple doses of drugs are administered in the hypothermic patient in whom drug metabolism is altered and circulation is arrested. However, based on current research discussed later, it is reasonable to incorporate pharmacotherapy into the management of hypothermic cardiac arrest. A vasopressor, either epinephrine or vasopressin, is reasonable to increase the coronary perfusion pressure. Amiodarone or lidocaine should be administered if ventricular fibrillation is present. Defibrillation in humans is often not successful until the temperature exceeds 86°F (30°C); however, defibrillation can be successfully accomplished in animals and patients with temperatures of less than 86°F (30°C).<sup>6,14,61,261</sup> A reasonable approach is that if defibrillation is unsuccessful below 86°F (30°C), defibrillation should not be attempted again until the patient is warmed several degrees centigrade. Pneumatically powered devices capable of mechanical chest compression and cardiopulmonary bypass are appropriate and safe during prolonged hypothermic cardiopulmonary arrests.<sup>14,53,239,248</sup>

### Arterial Blood Gas Physiochemistry in Hypothermia

Assessment of the adequacy of ventilation and oxygenation in the hypothermic patient often poses a dilemma to clinicians because the chemical effects of cold on arterial pH and blood gases lead to confusion in the interpretation of arterial blood gas values. Cold inhibits the dissociation of water molecules, causing pH to increase as cooling occurs. In vitro, the pH change of blood as it is cooled increases parallel to the pH change of neutral water. The partial pressures of CO<sub>2</sub> and O<sub>2</sub> decrease as cooling occurs even as the blood content of those gases remains unchanged. Blood in a syringe taken from a patient whose body temperature is 98.6°F (37°C) yields a pH of 7.40 and a PCO<sub>2</sub> of 40 mm Hg in the blood gas machine at 98.6°F (37°C) but yields a pH of 7.72 and a PCO<sub>2</sub> of 14 mm Hg if the blood is cooled to 61°F (16°C) and the values are measured at that temperature. Specially calibrated laboratory equipment, not routinely available, is required to measure blood gas values directly at other than normal body temperature. A patient whose body temperature is 61°F (16°C) and whose actual in vivo blood gas values are a pH of 7.72 and PCO<sub>2</sub> of 14 mm Hg will have a pH of 7.40 and PCO<sub>2</sub> of 40 mm Hg when the blood is warmed to 98.6°F (37°C) and measured in the standard laboratory blood gas machine. Because the machine measures pH and blood gas pressures only in blood warmed to 98.6°F (37°C) (the uncorrected values), the actual in vivo values in hypothermic patients can be approximated using mathematically derived corrected values. Because the pH of neutrality has also increased, it is unclear what clinical meanings these corrected values have. The uncorrected values indicate what the pH and PCO<sub>2</sub> would be if the patient were normothermic. At first glance, the clinician might be content to learn that a hypothermic patient at 61°F (16°C) has a corrected pH of 7.47 and PCO<sub>2</sub> of 40 mm Hg. However, the uncorrected values in the blood gas machine at 98.6°F (37°C) of pH of 7.18 and PCO<sub>2</sub> of 111 mm Hg indicate that the patient has a significant respiratory acidosis. Attempts to maintain a corrected pH of 7.40 will lead to hypoventilation and risk alveolar collapse and impairment of oxygenation. The preponderance of evidence in the anesthesia and cardiovascular surgery literature suggests that maintenance of ventilation is associated with a decreased incidence of myocardial injury and a decreased incidence of ventricular fibrillation.<sup>66</sup> Thus, the pH and PCO<sub>2</sub> blood gas values should be left uncorrected after the blood sample is warmed in the blood gas machine and interpreted in the same way as in a normothermic patient.<sup>66</sup>

### Hypotension

When hypotension occurs in a patient with hypothermia, it is possibly a result of the presence of bradycardia and volume depletion. However, hypotension is a predictor of infection, particularly when associated with a slow rewarming rate.<sup>67</sup> In hypothermia, salt and water depletion occurs as a result of a variety of mechanisms, including central shunting of blood by vasoconstriction and cold-induced diuresis. Cold diuresis occurs when increases in central blood volume result in inhibition of the release of antidiuretic

hormone. Impairment of renal enzyme activity and decreased renal tubular reabsorption contribute to the large quantities of dilute urine known as cold diuresis.<sup>112,116,157,263</sup> An infusion of 0.9% NaCl should be given to expand intravascular volume. Urine output is an important indicator of organ perfusion and the adequacy of intravascular volume in hypothermic patients, although the initial cold diuresis leads to underestimation of fluid needs.<sup>263</sup>

The best means to effect resuscitation of a hypothermic victim in ventricular fibrillation is controversial. The most recent recommendations of the American Heart Association (AHA) for the treatment of cardiac arrest when the core body temperature is below 86°F (<30°C) states that the administration of a vasopressor or antidysrhythmic according to standard Advanced Cardiac Life Support algorithm concurrent with rewarming is reasonable.<sup>7,156</sup> A meta-analysis of animal studies of antidysrhythmic and vasopressor therapy for ventricular fibrillation in the setting of hypothermia found that there was significant improvement in the return of spontaneous circulation (ROSC) in animals that received epinephrine or vasopressin.<sup>261</sup> In this report, the authors could not identify a benefit to the use of amiodarone administered without a vasopressor. They postulated that this is most likely due to the improvement in coronary perfusion pressure caused by vasopressors during cardiac arrest.<sup>261</sup> The benefit of amiodarone in profound hypothermia is probably limited but is reasonable and as there are no other options indicated.

### Epinephrine and Vasopressin

The administration of vasopressin to pigs in hypothermic cardiac arrest increased coronary perfusion pressure and improved defibrillation success.<sup>228</sup> In a pig model, when warmed thoracic lavage was used, vasopressin increased coronary perfusion pressure and increased the 1-hour survival.<sup>229</sup> In this study, the administration of 0.9% NaCl resulted in zero episodes of successful defibrillation, but all 8 vasopressin-treated pigs had restoration of spontaneous circulation after electrical defibrillation and had improved short-term survival. The whole-body temperature was not increased, but the authors postulated that myocardial warming occurred.<sup>228</sup> In another study in which epinephrine was given to one group of pigs and vasopressin to another, increased coronary perfusion pressure and ROSC resulted in both groups.<sup>152,153</sup> In contrast, body temperature significantly increased during CPR with thoracic lavage, and epinephrine increased coronary perfusion pressure, but no improvement in ROSC occurred.<sup>150</sup> The length of time of cardiac arrest, the doses of drug, and the efforts to rewarm differed in these studies. A 19-year-old patient who had a prolonged hypothermic cardiopulmonary arrest showed no improvement after 2 mg of epinephrine but had immediate restoration of spontaneous circulation after the administration of vasopressin.<sup>244</sup> Interactions with epinephrine, vasopressin, and ischemia during CPR are complex and incompletely understood.<sup>153,261</sup>

### Amiodarone

Amiodarone is recommended in the current AHA algorithm for ventricular fibrillation in normothermia.<sup>7</sup> In one study comparing the use of amiodarone, bretylium, and placebo in a hypothermic dog model, amiodarone showed no statistical improvement in causing ROSC.<sup>242</sup> There was no significant difference among the groups; only one of 10 amiodarone-treated dogs demonstrated ROSC versus 3 of 10 in the placebo group and 4 of 10 in the bretylium-treated dogs.<sup>267</sup> However, in a study in which hypothermic dogs in ventricular fibrillation were treated with epinephrine before administration of 10 mg/kg of amiodarone, there was a significantly higher rate of ROSC.<sup>261</sup> It is therefore reasonable to administer amiodarone with epinephrine for ventricular fibrillation in patients with hypothermia.

### Dopamine

Dopamine increases cardiac output, mean arterial pressure, heart rate, and stroke volume in dogs cooled to 77°F (25°C) and stabilizes pulmonary arterial wedge pressure.<sup>191</sup> In a canine hypothermia model, dopamine infusions provided some protection from ventricular fibrillation. Dopamine lowered the temperature at which ventricular fibrillation occurred and reduced the incidence of ventricular fibrillation, as did infusion of norepinephrine.<sup>9</sup> The added benefit of dopamine in hypothermia results from its renal and

splanchnic vasodilating properties, increasing renal perfusion and supporting urine output.<sup>102</sup> Dopamine increases myocardial oxygen demand and decreases peripheral perfusion, potentially detrimental effects in hypothermic patients.<sup>9</sup> For this reason, dopamine is not indicated in profoundly compromised patients with hypothermia.

## Rewarming

Three types of rewarming modalities are used in the management of hypothermic patients.<sup>56,79</sup>

*Passive external rewarming* involves covering the patient with blankets and protecting the patient from further heat loss. Passive external rewarming uses the patient's own endogenous heat production for rewarming and is most successful in healthy patients with mild to moderate hypothermia whose capacity for endogenous heat production is intact.<sup>115</sup> Passive external rewarming is reported to be successful in hypothermic patients with temperatures as low as 69°F (20.6°C).<sup>246,253,259</sup> Advocates of passive external rewarming argue that it allows vasoconstriction to persist and decreases the afterdrop and shock from vasodilation associated with active skin rewarming.<sup>115,182,246</sup>

*Active external rewarming* involves the external application of heat to the patient. There is disagreement about the possible detrimental effects of active external rewarming. For example, skin warming leads to a physiologically detrimental suppression of shivering.<sup>115</sup> Acute vasodilation of peripheral vessels could cause hypotension and an increased peripheral demand on the persistently cold myocardium. The return of cold blood from the extremities to the heart is suggested to exacerbate intramyocardial temperature gradients, which could cause ventricular irritability during hypothermia. However, in pigs, blood returning to the heart was found to be warm before warming of central organs occurred.<sup>103</sup>

Afterdrop is the continuing decrease in temperature after rewarming begins. There is no evidence that it actually occurs in humans.<sup>243</sup> In one study of 33 patients with core temperature below 82.4°F (<28°C), no patient experienced afterdrop during peripheral rewarming.<sup>214</sup>

There is no evidence of pooling of blood in the periphery nor of increased flow during surface rewarming.<sup>167,225,257</sup> Flow studies in the hand, arm, calf, and foot demonstrate that afterdrop has already occurred and is completed before any increase in blood flow occurs in the limbs.<sup>179,286</sup> Initial experiments demonstrating afterdrop reflected continued cooling of central structures before heat from external sources reached the core and are no longer considered relevant to the human resuscitation.<sup>103,167,257</sup>

Mortality rates for active external rewarming are frequently reported to be higher than for passive external rewarming,<sup>210</sup> but case selection is not controlled in these series. Sicker patients with stable cardiac rhythms who fail to rewarm passively and are then actively rewarmed have a higher mortality rate directly correlated with their underlying disease rather than by the method of therapy.<sup>67</sup> Selection of either passive or active external rewarming in treatment of mild to moderate hypothermic patients with perfusing cardiac rhythms does not appear to influence the prognosis as much as the presence or absence of underlying disease.<sup>67,128,182,258</sup> In our experience, active external rewarming has not resulted in death except in patients with severe underlying disease.<sup>67</sup>

*Active internal rewarming* involves attempts to increase central core temperature directly by warming the heart before the extremities or periphery. Minimally invasive modalities of active internal rewarming include the administration of heated, humidified oxygen delivered by face mask or endotracheal tube<sup>117</sup> and gastric lavage with warmed fluids. More invasive modalities, procedures that are fundamental to the rewarming controversy, include peritoneal lavage with warmed dialysate<sup>132,195</sup> and the rerouting of blood through external blood-rewarming equipment via cardiopulmonary or femoral–femoral bypass and hemodialysis.<sup>38,122,188</sup> Heparin-coated bypass systems are available that avoid systemic anticoagulation, thus decreasing the risk of bleeding complications. It is suggested that extracorporeal venovenous rewarming and continuous arteriovenous rewarming show improved rewarming rates compared with standard techniques such as saline lavage of the bladder, stomach, or peritoneal cavity.<sup>96</sup> Extracorporeal methods of active

internal rewarming should be reserved for severely hypothermic patients (<80°F or <27°C) or those with unstable cardiac rhythms (ventricular fibrillation, ventricular tachycardia, or asystole) attributed to hypothermia.<sup>6,65,113</sup> In patients with stable rhythms, studies are essential to resolve the debate over the merits of passive or active external rewarming versus active internal rewarming. Transcutaneous pacing was successful in improving hemodynamic parameters and speeding rewarming in an animal model.<sup>76</sup>

Many patients with temperatures below 86°F (30°C) were successfully treated with passive external rewarming with, at most, the addition of warm, humidified oxygen.<sup>67,235,259</sup> Patient temperature correlates poorly with outcome.<sup>6,61,155,251</sup> Treatment recommendations should never be based solely on temperature as the stability of the vital signs, the cardiac rhythm, and the underlying cause of hypothermia are much more critical considerations in management.

Hyperkalemia is not described as a consequence of rewarming.<sup>60</sup> In all of the evidence collected with regard to hyperkalemia, this abnormality was present as a consequence of the hypothermia and not the rewarming.<sup>116,171,226</sup>

## Prognosis in Hypothermia

Except in cases of profound hypothermia,<sup>116</sup> the prognosis is most closely correlated with the presence or absence of underlying disease.<sup>128,182,198,258,259</sup> In patients with hypothermia alone, in the absence of underlying disease, the mortality rate is 0% to 10%. In the presence of a severe underlying disease such as sepsis, the mortality rate is much greater.<sup>67</sup> Morbidity results from associated frostbite and trauma.

Prolonged cardiopulmonary arrest and absolute temperature are not predictive of poor outcome.<sup>6,61,155,248,251</sup> In severely hypothermic patients, profound hyperkalemia ( $[K^+] > 10$  mEq/L) is associated with unsuccessful resuscitation.<sup>116,171,226</sup>

## Frostbite

Hypothermia is sometimes accompanied by frostbite when patients are exposed to environmental temperatures that are lower than 20°F (6.7°C).<sup>183</sup> Frostbite should be managed by rapid rewarming of the frozen part of the affected person. The extremity involved is placed in warm water (100°F–108°F; 38°C–43°C) for 30 minutes. The water temperature must be maintained and corrected because the frozen extremity will cool the water in the basin.

The amputation rate is decreased with the use of iloprost, a prostacyclin. The dose is 2 ng/mL per minute for 6 hours each day for 5 days.<sup>40</sup> Parenteral analgesics are frequently necessary because the rewarming process is often painful. Frostbitten areas should never be rubbed because the tissue is particularly sensitive to trauma.

## HYPERTHERMIA

### Definition of Heatstroke

Heatstroke is defined by a rectal temperature greater than 105.5°F (40.8°C) in the setting of a neurologic disturbance manifested by mental status changes, including confusion, delirium, stupor, coma, or convulsions.<sup>143</sup> However, temperature measurements typically occur post cooling efforts and the site of the temperature measurement does not adequately reflect core temperature. Another definition of heatstroke is "a form of hyperthermia associated with systemic inflammatory response syndrome leading to multiorgan dysfunction in which encephalopathy predominates."<sup>26,160</sup>

Although the absence of sweating was once thought to be an essential component of the definition of heatstroke,<sup>51,196</sup> many patients with heatstroke maintain the ability to sweat.<sup>59,172,232,254</sup> The presence or absence of sweating at the time of collapse is not a part of the clinical diagnosis of heatstroke.<sup>172</sup> If maximal heat loss mechanisms are in play, the patient will be sweating but the heat loss mechanisms are simply inadequate to keep up with heat stress. Temperature criteria cannot be absolute because information regarding the patient's temperature is rarely available at the time of onset of heatstroke. In some instances, the temperature will not be measured for several hours, during which time cooling will commonly have been instituted or occurred spontaneously.<sup>140,141</sup> When appropriate environmental conditions prevail, the diagnosis of heatstroke should be made liberally. Autopsy findings

demonstrate extensive diffuse tissue injury.<sup>73</sup> In the establishment of the cause of death, the forensic literature emphasizes the need to consider the circumstances of death, environmental temperatures and the victim's coexisting medical conditions and medications that predispose to heatstroke.<sup>73</sup>

### Epidemiology of Heatstroke

Hundreds of people die annually of heatstroke in the United States, 80% of whom are older than age 50 years.<sup>41</sup> Heat waves or extended periods of high temperatures kill more people than any other weather-related event in the United States.<sup>62</sup> Midwestern and southern states experience the highest temperatures and the highest numbers of heat stress hospitalizations. When counting heat-related fatalities, the number is underestimated if only death certificates are included in which hyperthermia is listed as the underlying cause of death. Including hyperthermia as a contributing factor to death increased the total number of heat-related deaths by 54% from 1993 to 2003; several studies show mortality rates from heatstroke to be 5.6% to 80%.<sup>13,42,43</sup> Thousands of other victims survive with significant heat-related morbidity. The high morbidity and mortality of heatstroke markedly contrast with those of profound hypothermia, in which the prognosis is related not to the temperature itself but to the underlying etiology. The overall prognosis in heatstroke depends primarily on how long the body temperature is elevated before cooling, the maximum temperature reached, and the affected individual's premorbid health.<sup>25</sup>

### Thermoregulation and Heat Stress

The normal thermoregulatory response to heat stress is mediated primarily by heat-sensitive neurons in the hypothalamus. Increased body core temperature results in active dilation of cutaneous vessels, and skin blood flow increases.<sup>120,217</sup> Because increased skin blood flow is attained primarily by an increase in heart rate and stroke volume, the capacity to increase cardiac output is critical to cooling. Compensatory shifting of blood flow from the splanchnic and renal vessels to the skin further increases skin blood flow.<sup>127</sup> The combination of vasodilation, increased skin blood flow, and increased sweating results in heat loss through convection and evaporation. Salt and water depletion that occurs after profuse sweating increases plasma osmolarity. Heat-sensitive neurons in the preoptic anterior hypothalamus are inhibited by locally increased osmolarity and by input from distal hepatoportal osmoreceptors. The inhibition of heat sensitive neurons results in decreased heat dissipation response.<sup>50,199</sup>

### Types of Heatstroke

Heatstroke is commonly divided into 2 types, exertional and nonexertional. Nonexertional, or classic, heatstroke describes heatstroke occurring in the absence of extreme exercise. Nonexertional heatstroke is most commonly described during heat waves to excess wearing clothing that causes heat retention (lower evaporation), and the victims are predominantly those persons least able to tolerate heat: infants,<sup>12</sup> older adults,<sup>55,232</sup> individuals with psychiatric disorders, and chronically ill individuals.

Exertional heatstroke occurs as a result of increased motor activity. It occurs in young, healthy individuals who are exercising or in individuals whose increased motor activity results from other causes, such as seizures or agitation. Often a period of significant heat stress in exercising individuals precedes the development of heatstroke. Military recruits who develop heatstroke sometimes present to the camp infirmary with vague complaints before collapse.<sup>232</sup> Published studies of heatstroke in miners, athletes, and military recruits describe several precipitating factors in heatstroke, including fatigue associated with a recent deficit in sleep, poor physical conditioning, a recent febrile illness, recent heat-related symptoms such as thirst or weakness, relative volume depletion, failure to allow for acclimatization or inability to acclimatize, and obesity. Symptoms of nausea, weakness, headache, diarrhea, or irritability often precede the development of heatstroke. A rapid onset of symptoms and acute loss of consciousness are frequently reported as the heatstroke, the preceding period of heat stress, and insidious symptoms often go unrecognized. Although exertional heatstroke is more likely to occur during intense exertion in a hot, humid

environment, it also occurs with moderately intense exercise early in the morning, when environmental conditions are not recognized as a thermoregulatory stress.<sup>10</sup>

### Differential Diagnosis of Hyperthermia

In addition to exposure and exertion, conditions that predispose to severe hyperthermia include primary hypothalamic lesions, intracranial hemorrhage, agitation, alcohol and sedative-hypnotic withdrawal, seizures, and the use of therapeutic and illicit xenobiotics (Table 29-5).<sup>101,105,107,151,174,245</sup> Heatstroke occurs with the medical use of amphetamines to treat attention-deficit hyperactivity disorder, and the use of amphetamines as a party drug at dance events called raves. Mortality from cocaine overdose

**TABLE 29-5** Differential Diagnosis of Hyperthermia

#### I. Increased heat production

- Increased muscle activity
  - Agitation
  - Catatonias
  - Ethanol withdrawal
  - Exercise
  - Infectious diseases
  - Malignant hyperthermia
  - Monoamine oxidase inhibitor drug interactions
  - Neuroleptic malignant syndrome
  - Parkinson disease
  - Sedative-hypnotic withdrawal
  - Seizures
  - Serotonin toxicity
  - Xenobiotics
- Increased metabolic rate
  - Hyperthyroidism
  - Pheochromocytoma
  - Sympathomimetics

#### II. Impaired heat loss

- Environmental
  - Heat
  - Humidity
  - Lack of acclimatization
- Social disadvantage
  - Confinement to bed
  - Top floor apartments
  - Isolation
  - Lack of air conditioning
  - Closed windows
  - Poverty
- Medical illness
  - Cardiac insufficiency
  - Central nervous system dysfunction
  - Diabetes
  - Hypertension
  - Pulmonary
- Salt and water depletion
- Fatigue
- Limited behavioral response
  - Extremes of age
  - Intellectual disability
  - Psychiatric impairment
  - Xenobiotics

increases in high ambient temperature. The mean daily number of deaths from cocaine overdose was 33% higher when the ambient temperature exceeded 88°F (31°C).<sup>186</sup>

### Serotonin Toxicity

Serotonin toxicity, results from excess stimulation of the serotonin receptors, primarily the 5-HT<sub>1A</sub> subtype.<sup>103</sup> Treatment focuses on control of hyperthermia by using aggressive cooling; muscle relaxation, primarily by using benzodiazepines; or, in severe cases, endotracheal intubation and paralysis (Chap. 69).

### Malignant Hyperthermia

Malignant hyperthermia is a very rare disorder, that is associated with a congenital disturbance of calcium regulation in striated muscle. Malignant hyperthermia was first reported in 1960. Ten deaths occurred in a single family after general anesthesia.<sup>72</sup> Exposure to anesthetics, depolarizing muscle relaxants, or rarely, severe exertion precipitates uncontrolled calcium efflux from the sarcoplasmic reticulum, leading to severe muscle rigidity and hyperthermia.<sup>108</sup> The clinical setting of severe muscle rigidity and hyperthermia after general anesthesia usually is adequate to define the syndrome (Chap. 66).

### Neuroleptic Malignant Syndrome

Neuroleptic malignant syndrome, a severe extrapyramidal syndrome associated with muscle rigidity, autonomic dysfunction, and altered mental status, was first described in 1968.<sup>68</sup> This disorder develops during the administration of antipsychotics or the withdrawal of dopaminergic xenobiotics. Increased muscle tone because of dopaminergic blockade of the striatum as well as central altered hypothalamic thermoregulation leads to hyperthermia.<sup>118</sup> Neuroleptic malignant syndrome must be distinguished from the much more common cases of classical or exertional heatstroke (Chap. 67).

These medical conditions, serotonin toxicity, malignant hyperthermia, and neuroleptic malignant syndrome are distinguished by the patient's history of present illness, physical examination, clinical presentation including the time course of illness, and the environmental conditions.

### Inflammatory Mediators in Heatstroke

The response to heat stress is a coordinated interplay between the mediators of inflammation, including endothelial cells, leukocytes, inflammatory cytokines, and endotoxins.<sup>160</sup> These are important mediators of the systemic immune response. However, in heatstroke, they are responsible for systemic inflammation and activation of the coagulation cascade, similar to the systemic inflammatory response syndrome (SIRS). Many proinflammatory cytokines are identified in heatstroke, including tumor necrosis factor (TNF); interleukins-2, -6, -8, -10, and -12; interferon- $\alpha$  and - $\beta$ ; and granulocyte colony-stimulating factors.<sup>24</sup> In one study of 18 heatstroke patients, circulating cytokine concentrations correlated with clinical indices of heatstroke severity.<sup>129,160</sup> Cooling delays the release of interleukin-1 $\beta$ , interleukin-6, and TNF in vitro. Studies in hyperthermic animals focus on the modulation of the mediators of inflammation as possible future adjuncts to cooling. In another study, recombinant human activated protein C provided cytoprotection by decreasing release of inflammatory cytokines but did not improve survival.<sup>27</sup> Whole-body cooling restored appropriate concentrations of cardiac tissue protein associated with loss of structural integrity of the cardiac myocytes and reversed cardiac dysfunction.<sup>47</sup>

Heat stress causes increased gene transcription of heat shock proteins, which render the organism more resistant to heat injury, protecting cells from injury and increasing cell survival. Heat shock protein 72 is protective against injury from heat stress,<sup>97</sup> and the extent of protection correlates with the concentration of heat shock protein.<sup>126,168</sup>

During exercise, splanchnic hypoperfusion increases the translocation of bacteria from the gut into the bloodstream, establishing the cascade of inflammation and injury that perpetuates tissue injury after normothermia is established.<sup>83</sup>

### Pathophysiologic Characteristics of Heatstroke

In heatstroke, hypotension and tachycardia are caused by a number of factors. Patients with heatstroke often have a reduced plasma volume secondary to salt and water depletion. Peripheral pooling of blood is associated with an increase in cutaneous blood flow from 0.5 to 7 or 8 L/min.<sup>127,217</sup> In addition, patients often manifest primary myocardial insufficiency.<sup>144</sup> Clinically, patients exhibit either a hypo- or hyperdynamic circulatory response. The observed circulatory response to heat stress is a function of the patient's cardiac reserve, volume status, and degree of myocardial heat injury. The hyperdynamic condition is characterized by increased cardiac index and decreased systemic vascular resistance.<sup>197</sup> These hemodynamic characteristics occur in patients who are able to maintain a significantly increased cardiac output in response to the circulatory demand of heat stress.

Volume-depleted patients and those patients with primary myocardial insufficiency exhibit a hypodynamic response. These patients have a decreased cardiac index and increased systemic vascular resistance.<sup>197,241</sup> Whether pulmonary vascular resistance is affected is unclear. High central venous pressures (CVPs) were found in some patients, with evidence of right heart failure and right heart dilation on autopsy.<sup>172</sup> These findings led to the suggestion that pulmonary vascular resistance was elevated.<sup>197</sup> In 22 of 34 patients with heatstroke, CVPs were greater than 3 cm H<sub>2</sub>O. Twelve patients had a CVP of 0 cm H<sub>2</sub>O, and 10 had a CVP that exceeded 10 cm H<sub>2</sub>O. The authors cautioned against injudicious infusion of large quantities of IV fluids that result in complications of congestive heart failure and fluid overload. In the study, only 3 patients required more than 2 L of 0.9% sodium chloride solution during cooling. Crystalloid infusion ranged from 500 to 2500 mL, and none of the patients developed problems associated with fluid overload.<sup>230</sup>

A study of compromised elderly patients with heatstroke using pulmonary artery catheters showed that pulmonary vascular resistance was low or normal. Pulmonary capillary wedge pressures were not elevated.<sup>240</sup> A study of 13 cases of heatstroke in pilgrims to Mecca, Saudi Arabia, monitored with pulmonary artery catheters demonstrated a good correlation of CVP with pulmonary capillary wedge pressures.<sup>3</sup> Serial ECGs in 51 of these pilgrims with heatstroke showed normal sinus rhythm in 25%, sinus tachycardia in 52%, atrial fibrillation in 16%, and sinus bradycardia in 6%. ST-segment depression and other ST segment and T wave changes were reported. The QT interval showed no abnormality.<sup>3</sup> Electrocardiographic changes suggestive of acute coronary syndrome occur, yet normal coronary arteries are noted on coronary catheterization.<sup>1</sup> In some patients, echocardiography showed pericardial effusions and regional wall motion abnormalities, asymmetric septal hypertrophy, right ventricular dilation, and left ventricular dilation with impaired function.<sup>4</sup>

Autopsy studies of the heart demonstrate right heart dilation, pericardial effusions, interstitial edema, degeneration and necrosis of myocardial fibers, and subendocardial hemorrhages. Postmortem examination of the lungs revealed vascular congestion, pleural effusions, and parenchymal hemorrhages.<sup>172,197</sup>

Gastrointestinal hemorrhage, vomiting, and diarrhea occur frequently.<sup>232</sup> At autopsy, edema and hemorrhage of the bowel wall occur.<sup>46</sup> These changes are partly a result of the regional ischemia of splanchnic blood vessels and resultant hypoperfusion and hypoxia. Increased bowel wall edema and bleeding predispose to the release of bacteria into the bloodstream from the gut, causing focal microvascular changes in the intestinal villi, leading to bowel wall anoxia and further injury.<sup>26</sup> Liver injury occurs commonly and is not clinically manifest until the second or third day after the temperature increase.<sup>140,232</sup> Centrilobular changes, such as widening of central veins and adjacent sinusoids and pooling of blood, and varying degrees of hepatocellular degeneration are demonstrated on liver biopsy. Repeat biopsies demonstrated that these changes resolve as the patient recovers.<sup>140</sup> In other cases, only congestion and fatty infiltration are reported (Chap. 21).<sup>46</sup>

Neuropsychiatric impairment is, by definition, present in all cases of heatstroke, and the duration of altered consciousness correlates significantly with mortality.<sup>11,232</sup> Autopsy studies demonstrate a variety of structural and microscopic CNS injuries. Edema and venous congestion are evident. The number of cortical neurons is reduced, with concomitant glial proliferation.

Cerebellar Purkinje cell deterioration is marked. The hypothalamus appears to be relatively spared, with limited edema of the neuronal nuclei. Hemorrhages occur throughout the brain.<sup>46,172,232</sup> Carotid artery vasoconstriction occurs in response to heating in an *in vitro* model using the carotid arteries of rabbits to elucidate the mechanism of ischemia and injury in heatstroke.<sup>189</sup> Heatstroke-induced cerebral ischemia is associated with increased glutamate release, activation of cerebral dopaminergic neurons causing dopamine overload, and gliosis. These changes are attenuated by induction of hypothermia in an animal model.<sup>49</sup>

Reports of magnetic resonance imaging (MRI) of brains of patients recovering from heatstroke describe radiographic findings, including hemorrhagic and ischemic abnormalities of the cerebrum and cerebellum, delayed cerebellar atrophy, central pontine myelinolysis, vascular infarcts, and medial thalamic lesions, which correspond anatomically to the paraventricular nucleus. The paraventricular nucleus is involved with core temperature regulation via the hypothalamic–pituitary–adrenal axis.<sup>18</sup> The clinical symptoms of dysphagia, quadriplegia, wasting, extrapyramidal syndrome, and pancerebellar syndrome have corresponding MRI findings.<sup>5</sup> Persistent cerebellar dysfunction occurs, as does lower motor neuron damage, manifested by areflexia and muscle wasting.<sup>69,158</sup> Abnormal nerve conduction studies are documented.<sup>135</sup> Higher cortical functions are spared in survivors or are reversible when they occur.<sup>82,162,178</sup> Permanent neurologic sequelae are correlated with the degree and duration of hyperthermia.

Acute kidney injury (AKI) was a major cause of death in heatstroke victims before the advent of hemodialysis.<sup>227,254</sup> In addition to the direct effects of heat, volume depletion, and hypotension, myoglobinuria secondary to rhabdomyolysis results in further renal tubular injury. This is especially common in an agitated or exercising patient.<sup>52,101,205</sup> The mechanism by which myoglobin contributes to AKI remains controversial. At autopsy, the kidneys are enlarged, with extensive petechial hemorrhage.<sup>205</sup> Acute tubular necrosis is demonstrated on biopsy. In exertional heatstroke with AKI, renal hemodynamics are compromised because of increased vasoconstrictive hormones, such as catecholamines, renin, aldosterone, and endothelin-1, and decreased vasodilatory hormones, such as prostaglandin E<sub>2</sub>.<sup>164</sup>

Bleeding is associated with significant morbidity and mortality in many cases of heatstroke. The etiology of coagulation disturbances in patients with heatstroke appear to be multifactorial. Elevation of the prothrombin time occurs within 30 minutes of temperature elevation and is attributed to direct heat injury of clotting factors.<sup>15</sup> Liver damage significantly contributes to the coagulation disturbances, although this does not manifest as rapidly.<sup>15,190,208</sup> Two patients with severe liver failure secondary to heatstroke received liver transplantation; both died after chronic rejection.<sup>219</sup> A third patient with extensive liver cell necrosis as a consequence of heatstroke was referred for liver transplantation but recovered completely with supportive therapy.<sup>98</sup> Evidence of diffuse capillary basement membrane injury is demonstrable by electron microscopy and is thought to precipitate consumptive coagulopathy in severe cases of heatstroke.<sup>46,237</sup> Thrombocytopenia is very common and occurs within 30 minutes of onset of heatstroke, frequently in the absence of other evidence of disseminated intravascular coagulation. Direct thermal injury leading to decreased platelet survival and megakaryocyte damage plays a role (Table 29–6).<sup>172,190</sup>

### Clinical Findings in Heatstroke

Clinical evaluation of a hyperthermic patient begins with careful assessment of the vital signs. Vital sign abnormalities commonly include tachycardia with heart rates greater than 130 beats/min, hypotension, and tachypnea with the respiratory rates often above 30 breaths/min. Most importantly, temperature is elevated. After cooling, there is often a secondary rise in temperature that suggests persistent disturbances central hypothalamic dysregulation.<sup>172</sup>

Neurologic examination reveals a confused, delirious, comatose, or seizing patient. Pupils are normal, fixed and dilated, or pinpoint. Decerebrate or decorticate posturing is sometimes present. Muscle tone is increased, normal, or flaccid. The skin is often hot and dry, or diaphoretic. Nasal and oropharyngeal bleeding presents as a consequence of the acute coagulopathy.

**TABLE 29–6** Physiologic and Clinical Manifestations of Heatstroke

#### Cardiovascular

- Hypodynamic in elderly adults
- Hyperdynamic in young, healthy individuals
- Electrocardiogram
  - Nonspecific
  - Widening of QRS because of an underlying abnormality (cocaine toxicity, hyperkalemia associated with rhabdomyolysis)

#### Central nervous system

- Altered mental status
  - Irritability, confusion, ataxia, seizures, coma
  - Weakness, dizziness, headache
  - Plantar extension, pupillary abnormalities, decorticate posturing
- Electroencephalogram
  - Normal or diffuse slowing
- Cerebrospinal fluid
  - Normal or increased protein
  - Lymphocytosis

#### Gastrointestinal

- Vomiting, diarrhea, hematemesis

#### Hematologic

- Bleeding diathesis
  - Prolonged PT and PTT
  - Disseminated intravascular coagulation
  - Thrombocytopenia
  - Petechiae
  - Purpura
- Leukocytosis

#### Hepatic

- Hepatic insufficiency at 12–36 hours
- Elevated AST, ALT, LDH

#### Metabolic

- Metabolic acidosis and respiratory alkalosis
- Electrolyte disturbance
  - Hypernatremia
  - Hypokalemia
  - Hypocalcemia
  - Hypophosphatemia

#### Muscle

- Rhabdomyolysis
- Elevated CPK

#### Renal

- Decreased renal perfusion
- Myoglobinuria
- Proteinuria
- Oliguria
- Acute tubular necrosis
- Interstitial necrosis

ALT = alanine aminotransferase; AST = aspartate aminotransferase; CPK = creatine phosphokinase; LDH = lactate dehydrogenase; PT = prothrombin time; PTT = partial thromboplastin time.

Examination of the lungs is often nonspecific, although heatstroke victims are at risk of acute respiratory distress syndrome (ARDS) as a primary event associated with capillary endothelial damage or after overly aggressive fluid resuscitation. Aspiration secondary to seizures occurs. Cardiac auscultation reveals a flow murmur secondary to high cardiac output or a right ventricular gallop. Neck vein distension indicates increased central venous pressure. Jaundice suggests hepatic injury and occurs on the second or third

day after the onset of heatstroke.<sup>48</sup> Gross gastrointestinal bleeding is sometimes present. A petechial rash develops, probably secondary to capillary endothelial damage.

Laboratory findings of severe hyperthermia include lactate dehydrogenase (LDH) elevation as a consequence of diffuse tissue injury. Early rises in alanine aminotransferase (ALT) and aspartate aminotransferase (AST), which peak at 48 hours, are indicators of the liver damage that occurs during heatstroke.<sup>140</sup> Muscle enzymes were elevated in all patients in a study of exertional heatstroke<sup>232</sup> and in 86% of patients in one study of nonexertional heatstroke.<sup>106</sup> Nonspecific ST- and T-wave changes on ECG are common. Myocardial enzyme elevation occurs and correlates with ECG changes.<sup>141</sup> Results of lumbar puncture are nonspecific, are often normal, and often demonstrate elevated CSF protein and a lymphocytosis.<sup>232</sup>

Other laboratory parameters are affected by heatstroke. Salt and water depletion leads to hemoconcentration in patients exposed to elevated temperatures for a period of time. Hypokalemia is common, with potassium deficits as great as 500 mEq occurring during the early period of heat exposure. Arterial blood gas analysis typically shows a respiratory alkalosis secondary to direct stimulation of the respiratory center by heat or a metabolic acidosis with an elevated lactate concentration.<sup>59,232</sup> Metabolic acidosis is the most frequent acid–base disturbance, either alone or part of a mixed picture. The prevalence of metabolic acidosis correlates with the degree of hyperthermia; 95% of patients demonstrated metabolic acidosis when the body temperature exceeded 107.6°F (42°C).<sup>24</sup>

Hypophosphatemia is common and is attributed to respiratory alkalosis, which causes intracellular shifts of phosphate. However, 8 of 10 heatstroke patients developed hypophosphatemia, and none was alkalemic.<sup>23</sup> The hypophosphatemia in these patients was associated with increased phosphaturia and decreased tubular reabsorption of phosphorus, a finding that reversed after cooling.<sup>145</sup> Renal tubular damage leads to phosphate depletion.<sup>109</sup> In contrast, phosphate and potassium are elevated when significant muscle injury occurs. Calcium is normal or low, the latter secondary to binding to damaged muscle tissue. Later, hypercalcemia occurs, possibly as a result of release of this bound calcium.<sup>94,166</sup>

Significant alterations occur in lymphocyte subsets in heatstroke victims. One study reported an increased ratio of T-suppressor to T-cytotoxic cells, as well as increased natural killer cells. There was a significant decrease in the percentages of T and B cells and T-helper cells. These changes correlate with the degree of hyperthermia.<sup>21,159</sup> Catecholamines are increased in heatstroke<sup>2</sup> and affect the distribution of the lymphocyte subsets.<sup>25</sup> It is possible that the increased susceptibility to infection described in heatstroke and the alterations in lymphocyte populations are related.<sup>21</sup>

### Effects of Xenobiotics in Heatstroke

Xenobiotics predispose the individual to heatstroke by 2 primary mechanisms: increased production of heat as a result of xenobiotic action and interference with the body's ability to dissipate heat because of pharmacologic or toxicologic effects on thermoregulation (Table 29–5). Xenobiotic interactions also cause life-threatening increases in temperature, such as the combination of monoamine oxidase inhibitors with meperidine or dextromethorphan resulting in serotonin toxicity.

During heat stress, vasodilation leads to increased cutaneous blood flow requiring an increased cardiac output to maintain blood pressure. Parasympathetic stimulation results in increased sudomotor activation. Xenobiotics that impair these physiologic mechanisms for heat dissipation predispose the individual to heatstroke. Xenobiotics with anticholinergic effects, such as antihistamines, cyclic antidepressants, and antipsychotics, interfere with sweating. Heatstroke as a result of oligohydrosis is reported for zonisamide and topiramate.<sup>146–193</sup> The mechanism is postulated to concern the inhibition of carbonic anhydrase, an enzyme associated with eccrine sweat gland function. Sympathomimetics stimulate  $\alpha$ -adrenergic receptors, impairing vasodilation. Antihypertensives and antianginals (most notably calcium channel antagonists and  $\beta$ -adrenergic antagonists) with negative inotropic

and chronotropic effects impair the ability of the heart to meet the output requirements of increased skin blood flow. Diuretic-induced salt and water depletion also limits cardiac output. Antipsychotics cause hypothalamic depression and are anticholinergic, altering the normal CNS response to heat stress. Finally, xenobiotics such as ethanol, opioids, and sedative–hypnotics impair normal behavioral responses, and heat-related discomfort may go unnoticed.

### Heatstroke and Subsequent Heat Intolerance

Whether heatstroke victims are subsequently unable to adapt to exercise in a hot environment remains unclear. Is the heatstroke victim genetically predisposed to heat intolerance, or does heatstroke occur as a result of environmental and host factors? Several studies suggest that heatstroke leads to persistent heat intolerance. These studies often use a single heat intolerance test.<sup>81,231,233,234</sup> A study of 10 previous heatstroke victims showed no difference in acclimatization responses, thermoregulation, whole-body sodium and potassium balance, sweat gland function, and blood values when compared with control participants.<sup>10</sup> The rate of recovery from exertional heatstroke probably differs among individuals. In this study, one of 10 patients was found to have recurrent heat intolerance 12 months after the study.<sup>10</sup> Resolution of heat intolerance was delayed for 5 months in an individual who had experienced heatstroke twice.<sup>139</sup>

The effects of xenobiotics on acclimatization requires a sound understanding of the physiology of heat loss mechanisms in humans. Xenobiotics and medical conditions affect the ability to acclimatize. The physiological effectiveness of heat loss is critical to maintenance of normal body temperature. There are reports of the effects of drugs on the ability to acclimatize to heat.<sup>104</sup> Hyoscine produced a 43% depression in sweat rate in this report, retarding the development of acclimatization. Salicylates do not affect the hyperthermia of exercise. Acclimatization studies in humans most often use young and healthy exercising subjects.

### Treatment of Heatstroke

Management must focus on the early recognition of hyperthermia. Rapid cooling is the first priority and is associated with improved outcomes. Cooling that is delayed allowing body temperatures to remain above 102.2°F (38.9°C) for more than 30 minutes is associated with a high morbidity and mortality. In one report of the Chicago heat wave of 1995, only one patient of 58 victims was cooled within 30 minutes, resulting in an in-hospital mortality rate of 21% and an additional 28% mortality rate within 1 year.<sup>70</sup> Cooling by covering in ice water was twice as rapid in lowering the core temperature as was cooling by using an evaporative spray.<sup>10</sup> Ice water immersion results in faster cooling compared with all of the evaporative cooling methods in some studies.<sup>39,58,87,95,154</sup> A report of endovascular cooling using a heat exchange balloon catheter demonstrated dangerously lengthy cooling times and inadequate cooling measures.<sup>177</sup>

Successful treatment requires adequate preparation. Equipment needed for rapid cooling should always be readily available in the emergency department and includes fans, ice, and tubs for immersion. En route to the hospital, the patient should be soaked in water and ice to begin rapid and aggressive cooling. Respiration and cardiovascular status should be stabilized and monitored. The cause of the heatstroke should be determined and appropriate measures initiated immediately. Xenobiotics, such as antihistamines, butyrophenones, and phenothiazines, and physical restraints that interfere with heat dissipation, such as straitjackets, are contraindicated.<sup>107</sup> A patient who is hyperthermic in the setting of ethanol or sedative–hypnotic withdrawal should be treated with a benzodiazepine.<sup>106</sup> The patient should never be confined to a small, unventilated seclusion room. Adequate cooling, hydration, sedation, and electrolytes and substrate repletion should be ensured.<sup>105</sup>

In the emergency department, appropriate laboratory studies should be performed and an IV line inserted. A rectal probe should be placed for continuous temperature monitoring. The patient should be immersed in an ice bath with a fan blowing over the patient if possible.

Agitation, seizures, and cardiac dysrhythmias must be managed while cooling is accomplished. Benzodiazepines are the treatment of choice for agitation and seizures. Hypotension should be treated with fluids and cooling. Volume repletion should be monitored carefully by parameters such as blood pressure, pulse, and urine output. As the temperature returns to normal, the hypotension will resolve if significant volume deficits are not present.<sup>51,143,144</sup> In patients with myoglobinuria, an attempt should be made to increase renal blood flow and urine output. The use of sodium bicarbonate and mannitol in the prevention of acute tubular necrosis in these cases is not routinely recommended.<sup>80,94,216</sup>

Phenothiazines and butyrophenones should not be used because they depress an already altered mental status, produce hepatotoxicity in a compromised liver, lower the seizure threshold,<sup>20</sup> cause acute dystonic reactions, exacerbate hypotension, and interfere with thermoregulation and cooling by affecting the hypothalamus. When shivering occurs during cooling, we recommend the judicious use of a benzodiazepine. In addition, benzodiazepines treat ethanol and sedative-hypnotic withdrawal and cocaine toxicity, common causes of hyperthermia.

There is no role for antipyretics in the management of heatstroke. Aspirin and acetaminophen lower temperature by reducing the hypothalamic set point, which is only altered in a patient febrile from inflammation or endogenous pyrogens.<sup>72,120</sup> Heatstroke occurs when cooling mechanisms are overwhelmed. The hypothalamic thermoregulatory set point is not disturbed.<sup>16</sup>

Dantrolene is the preferred drug in the treatment of malignant hyperthermia (Antidotes in Depth: A24).<sup>131,256</sup> It acts directly on skeletal muscle and either inhibits the release of calcium or increases calcium uptake through the sarcoplasmic reticulum.<sup>29</sup> Its usefulness has not been demonstrated in other conditions associated with hyperthermia, and there is no evidence to support its administration for other conditions.<sup>8</sup> In a prospective, randomized, double-blind, placebo-controlled study of 52 patients with heatstroke, IV dantrolene at 2 mg/kg of body weight did not alter cooling time.<sup>22</sup> There was no significant difference in the mean number of hospital days necessitated by heatstroke victims who received dantrolene and cooling versus those who received cooling alone. The dopamine agonists bromocriptine and amantadine sometimes administered as part of the treatment of neuroleptic malignant syndrome are not indicated in the management of classical or exertional heatstroke (Table 29–7).

**TABLE 29–7 Management of Heatstroke**

**Preparation**

- Ice and cooling fans available in emergency department
- Monitor weather reports
- Alert media

**On arrival**

- Rapid cooling—monitor with rectal probe
  - Clear airway and administer oxygen
  - Cover with ice and water-soaked sheets
  - Stabilize respiratory and cardiovascular status
  - Cool as rapidly as possible

**Intravenous access**

- Dextrose (0.5–1.0 g/kg) and 100 mg of thiamine as clinically indicated
- Benzodiazepines for agitation, shivering, seizures

**Continuous monitoring**

- Remove from ice bath at 101–102°F (38.3–38.8°C)
- Watch for rebound hyperthermia

**Cautions**

- Antipsychotics contraindicated because of serious adverse effects
- Antipyretics do not work
- Dantrolene is not indicated
- Cooling blankets alone are inadequate

**SUMMARY**

- Xenobiotics disturb normal thermoregulation, and it leads to the abnormal conditions of hyperthermia or hypothermia. These disturbances of homeostasis present significant clinical management challenges.
- Hypothermia and heatstroke are preventable conditions.
- Immediate and aggressive cooling is imperative in heatstroke. Near-normal body temperature should be achieved within 30 minutes from onset of heatstroke.
- Rewarming of the patient with hypothermia and a stable cardiac rhythm can often be successfully accomplished with patience and without extracorporeal methods.
- Many xenobiotics increase the risk to patients when the heat index is excessive and the very medications used to treat their chronic diseases increase their risks of heat-related morbidity and mortality.
- Climate change causing increasingly hot weather demands systemic national preventive health efforts municipal preparedness and public education efforts to prevent deaths during increasingly hot conditions.

# REPRODUCTIVE AND PERINATAL PRINCIPLES

Jeffrey S. Fine

Reproductive and perinatal principles in toxicology are often derived from basic science studies and are applied cautiously to clinical practice. This chapter reviews several principles of reproductive medicine that have implications for toxicology, including the physiology of pregnancy and placental xenobiotic transfer, the effects of xenobiotics on the developing fetus and the neonate, and the management of poisoning or overdose in pregnant women.

One of the most dramatic effects of exposure to a xenobiotic during pregnancy is the birth of a child with congenital malformations. Teratology, the study of birth defects, has principally been concerned with the study of physical malformations. A broader view of teratology includes “developmental” teratogens—xenobiotics that induce structural malformations, metabolic or physiologic dysfunction, or psychological or behavioral alterations or deficits in the offspring, either at or after birth.<sup>291</sup> Only 4% to 6% of birth defects are attributable to known pharmaceuticals or occupational and environmental exposures.<sup>291,302</sup>

Some reproductive effects of xenobiotics occur before conception. Female germ cells are formed in utero; adverse effects from xenobiotic exposure theoretically occur from the time of a woman’s own intrauterine development to the end of her reproductive years. An example of a xenobiotic that had both teratogenic and reproductive effects is diethylstilbestrol (DES), which was most notable for causing vaginal or cervical adenocarcinoma (or both) in some women who were exposed to DES in utero and which also had adverse effects on fertility and pregnancy outcome in the same cohort of women exposed in utero.<sup>239,263</sup>

Men generally receive less attention with respect to reproductive risks. Male gametes are formed after puberty; only from that time on are they susceptible to xenobiotic injury. An example of a xenobiotic affecting male reproduction is dibromochloropropane, which reduces spermatogenesis and, consequently, fertility. In general, much less is known about the paternal contribution to teratogenesis.<sup>63,130,152</sup>

Occupational exposures to xenobiotics are potentially important but are often poorly defined. In 2015, there were approximately 43 million women of reproductive age in the workforce.<sup>331</sup> Although approximately 90,000 chemicals are used commercially in the United States, only a few thousand of them have been specifically evaluated for reproductive toxicity. Many xenobiotics have teratogenic effects when tested in animal models, but there are relatively few well-defined human teratogens (Table 30-1).<sup>302</sup> Thus, most tested xenobiotics do not appear to present a human teratogenic risk, but most xenobiotics have not been tested. Some of the presumed safe xenobiotics have other reproductive, nonteratogenic toxicities. Several excellent reviews and online resources are available.<sup>39,106,266,302,325</sup>

Another type of xenobiotic exposure for a pregnant woman is intentional overdose. Although a xenobiotic taken in overdose can have direct toxicity to the fetus, fetal toxicity frequently results from maternal pulmonary or hemodynamic compromise, further emphasizing the critical interdependency of the maternal–fetal dyad.

Xenobiotic exposures before and during pregnancy can have effects throughout gestation and also extend into and beyond the newborn period. In addition, the effects of xenobiotic administration in the perinatal period and the special case of delivering xenobiotics to an infant via breast milk deserve particular consideration.

## PHYSIOLOGIC CHANGES DURING PREGNANCY THAT AFFECT DRUG PHARMACOKINETICS

Many physical and physiologic changes that occur during pregnancy affect both the absorption and distribution of xenobiotics in the pregnant woman and consequently potentially affect the amount of xenobiotics delivered to the fetus.<sup>21</sup>

Delayed gastric emptying, decreased gastrointestinal (GI) motility, and increased transit time through the GI tract occur during pregnancy. These changes result in delayed but more complete GI absorption of xenobiotics and, consequently, lower peak plasma concentrations which may be consequential in an adverse manner. Because blood flow to the skin and mucous membranes is increased, absorption from dermal exposure is increased. Similarly, absorption of inhaled xenobiotics is increased because of increased tidal volume and decreased residual lung volume.

An increased free xenobiotic concentration in the pregnant woman can be caused by several factors during the later stages of pregnancy a decreased plasma albumin, increased binding competition, and decreased hepatic biotransformation. Fat stores increase throughout pregnancy and are maximal at about 30 weeks; near term, free fatty acids are released, and along with them the lipophilic xenobiotics that have accumulated in the lipid compartment are released. The increased concentration of circulating free fatty acids leads to competition with circulating free xenobiotics for binding sites on albumin.

Other factors leading to decreased free xenobiotic concentrations, early in pregnancy, are increased fat stores, as well as the increased plasma and extracellular fluid volume, which lead to a greater volume of distribution. Increased renal blood flow and glomerular filtration may or can result in increased renal elimination.

Cardiac output increases throughout pregnancy, with the placenta receiving a gradually increasing proportion of total blood volume. Xenobiotic delivery to the placenta therefore increases over the course of pregnancy.

These processes interact dynamically, and it is difficult to predict their net effect. The concentrations of many xenobiotics, such as lithium, gentamicin, and carbamazepine, decrease during pregnancy even if the dose administered is unchanged.<sup>110</sup>

Although not specifically related to the physiologic changes occurring during pregnancy, the fetus can also be exposed to xenobiotics that had accumulated in adipose tissue before pregnancy. For example, typical retinoid malformations occurred in a baby born to a woman whose pregnancy began one year after she discontinued the use of etretinate (retinoic acid), a medication that is used to treat severe psoriasis, congenital ichthyosis acne, and several other disorders of keratinization which may have clinical implications.<sup>179</sup>

## XENOBIOTIC EXPOSURE IN PREGNANT WOMEN

Exposure to xenobiotics during pregnancy is common. At some time during pregnancy, as many as 90% of pregnant women take prescription or nonprescription medications other than vitamins, mineral supplements, and iron. The most commonly used are analgesics, antipyretics, antimicrobials, antihistamines, vitamin B<sub>6</sub> and antiemetics.<sup>73,74,198,250,310,328</sup> In addition, use of caffeine, tobacco, and alcohol is common. Some pregnant women use xenobiotics to treat a preexisting chronic disease such as epilepsy or a newly diagnosed

**TABLE 30–1** Known and Possible Human Teratogens

<i>Xenobiotic</i>	<i>Reported Effects</i>	<i>Comments</i>
Alkylating agents (eg, busulfan, chlorambucil, cyclophosphamide, mechlorethamine, nitrogen mustard)	Growth retardation, cleft palate, microphthalmia, hypoplastic ovaries, cloudy corneas, renal agenesis, malformations of digits, cardiac defects, other anomalies	10%–50% malformation rate, depending on the agent. Cyclophosphamide-induced damage requires cytochrome P450 oxidation.
Aminopterin, methotrexate (amethopterin)	Hydro- or microcephaly; meningoencephalocele; anencephaly; abnormal cranial ossification; cerebral hypoplasia; growth retardation; eye, ear, and nose malformations; cleft palate; malformed extremities or fingers; reduction in derivatives of first branchial arch; developmental delay	Folate antagonists inhibit dihydrofolate reductase. High rate of malformations.
Amiodarone	Transient neonatal hypothyroidism, with or without goiter; hyperthyroidism	Amiodarone contains 39% iodine by weight. Small to moderate risk from 10 weeks to term for thyroid dysfunction.
Androgens	Virilization of the female external genitalia: clitoromegaly, labioscrotal fusion	Dose dependent. Stimulates growth of sex steroid receptor–containing tissue.
Angiotensin-converting enzyme inhibitors and angiotensin II type 1 receptors blockers	Fetal or neonatal death, prematurity, oligohydramnios, neonatal anuria, IUGR, secondary skull hypoplasia, limb contractures, pulmonary hypoplasia	Significant risk of effects related to chronic fetal hypotension during second or third trimester. If used during early pregnancy, can be switched during first trimester.
Carbamazepine	Upslanting palpebral fissures, epicanthal folds, short nose with long philtrum, fingernail hypoplasia, developmental delay, NTD	1% risk for NTD. Risk of other malformations is unquantified. Risk is increased in setting of therapy with multiple antiepileptics, particularly valproic acid. Mechanism involves an epoxide intermediate. High-dose folate is recommended to prevent NTDs.
Carbon monoxide	Cerebral atrophy, intellectual disability, microcephaly, convulsions, spastic disorders, intrauterine death	With severe maternal poisoning, high risk for neurologic sequelae.
Cocaine	IUGR, microcephaly, neurobehavioral abnormalities, vascular disruptive phenomenon (limb amputation, cerebral infarction, visceral or urinary tract abnormalities)	Vascular disruptive effects because of decreased uterine blood flow and fetal vascular effects from first trimester through the end of pregnancy.
Diazepam	Cleft palate	Controversial association, probably low risk.
Diethylstilbestrol (DES)	<i>Female offspring:</i> vaginal adenosis, clear cell adenocarcinoma of the vagina, irregular menses, reduced pregnancy rates, increased rate of preterm deliveries, increased perinatal mortality and spontaneous abortion <i>Male offspring:</i> epididymal cysts, cryptorchidism, hypogonadism, diminished spermatogenesis	A synthetic nonsteroidal estrogen that stimulates estrogen receptor–containing tissue. 40%–70% risk of morphologic changes in vaginal epithelium. Risk of carcinoma is approximately one in 1,000 for exposure before the 18th gestational week. Most patients exposed to DES in utero can conceive and deliver normal children.
Ethanol	FAS: pre- or postnatal growth retardation, intellectual disability, fine motor dysfunction, hyperactivity, microcephaly, maxillary hypoplasia, short palpebral fissures, hypoplastic philtrum, thinned upper lips, joint, digit anomalies	Neither a threshold for effects nor a safe dose has been identified. Partial expression or other congenital anomalies. Increased incidence of spontaneous abortion, premature delivery, and stillbirth; neonatal withdrawal.
Fluconazole	Craniosynostosis, orbital hypoplasia, humeral radial synostosis, femoral bowing	Risk related to high-dose (400–800 mg/d), chronic, parenteral use. Single 150-mg oral dose probably safe.
Iodine and iodine-containing products	Thyroid hypoplasia after the eighth week of development	High doses of radioiodine isotopes can additionally produce cell death and mitotic delay. Tissue- and organ-specific damage depends on the specific radioisotope, dose, distribution, metabolism, and localization.
Lead	Lower scores on developmental tests	Higher risk when maternal lead is >10 mcg/dL.
Lithium carbonate	Ebstein anomaly	Controversial association. Low risk.
Methimazole	Aplasia cutis, skull hypoplasia, dystrophic nails, nipple abnormalities, hypo- or hyperthyroidism	Small risk of anomalies or goiter with first trimester exposure. Hypothyroidism risk after 10 weeks of gestation.
Methyl mercury, mercuric sulfide	Normal appearance at birth; cerebral palsylike syndrome after several months; microcephaly, intellectual disability, cerebellar symptoms, eye or dental anomalies	Inhibits enzymes, particularly those with sulfhydryl groups. In acute poisoning, the fetus is 4–10 times more sensitive than an adult.
Methylene blue (intraamniotic injection)	Hemolytic anemia, neonatal jaundice, possible intestinal atresia,	Used to identify twin amniotic sacs during amniocentesis.
Misoprostol	Vascular disruptive phenomena (eg, limb reduction defects); Moebius syndrome (paralysis of sixth and seventh facial nerves)	Synthetic prostaglandin E <sub>1</sub> analog. Effects observed in women after unsuccessful attempts to terminate pregnancy.

(Continued)

TABLE 30-1 Known and Possible Human Teratogens (Continued)

Xenobiotic	Reported Effects	Comments
Mycophenolate mofetil	Microtia, orofacial cleft, coloboma, hypertelorism, micrognathia, conotruncal CHD, agenesis of the corpus callosum, esophageal atresia, digital hypoplasia	Immunosuppressive xenobiotic used in transplant recipients, inhibits inosine monophosphate dehydrogenase and blocks de novo purine synthesis in T and B lymphocytes.
Oxazolidinone-2,4-diones (trimethadione, paramethadione)	Fetal trimethadione syndrome: V-shaped eyebrows; low-set ears with anteriorly folded helix; high-arched palate; irregular teeth; CNS anomalies; severe developmental delay; cardiovascular, genitourinary, and other anomalies	An 83% risk of at least one major malformation with any exposure; 32% die. Characteristic facial features are associated with chronic exposure.
Paroxetine	Cardiovascular malformations, mostly VSD and ASD	Possible small (1%) increased risk. Possible risk with other SSRIs has not been quantified.
Penicillamine	Cutis laxa, hyperflexibility of joints	Copper chelator—copper deficiency inhibits collagen synthesis or maturation. Few case reports; low risk.
Phenytoin	Fetal hydantoin syndrome: microcephaly, intellectual disability, cleft lip or palate, hypoplastic nails or phalanges, characteristic facies—low nasal bridge, inner epicanthal folds, ptosis, strabismus, hypertelorism, low-set ears, wide mouth	Effects seen with chronic exposure. A 5%–10% risk of typical syndrome, 30% risk of partial syndrome. Risks confounded by those associated with epilepsy itself and use of other antiepileptics.
Polychlorinated biphenyls	Cola-colored children; pigmentation of gums, nails, and groin; hypoplastic, deformed nails; IUGR; abnormal skull calcifications	Cytotoxic xenobiotic. Body residue can affect subsequent offspring for up to 4 years after exposure. Most cases followed high consumption of PCB-contaminated rice oil; 4%–20% of offspring were affected.
Progestins (eg, ethisterone, norethindrone)	Masculinization of female external genitalia	Progestogens are converted into androgens or have weak androgenic activity. Stimulate or interfere with sex steroid receptors. Effects occur only after exposure to high doses of some testosterone-derived progestins in <1% of those exposed. Oral contraceptives containing these agents are not thought to present teratogenic risk.
Quinine	Hypoplasia of eighth nerve, deafness, abortion	Effects related to high doses used as abortifacients.
Radiation, ionizing	Microcephaly, intellectual disability, eye anomalies, growth retardation, visceral malformations	Significant doses of radiation from diagnostic or therapeutic sources produce cell death and mitotic delay. There is no measurable risk with x-ray exposures of 5 rads or less at any stage of pregnancy.
Retinoids (isotretinoin, etretinate, high-dose vitamin A)	Spontaneous abortions; micro- or hydrocephalus; deformities of cranium, ears, face, heart, limbs, liver	Retinoids can cause direct cytotoxicity, alter apoptosis, and inhibit migration of neural crest cells. For isotretinoin, 38% risk of malformations; 80% are CNS malformations. Effects are associated with vitamin A doses of 25,000–100,000 units/day. Exposures below 10,000 IU/day present no risk to fetuses. Topical retinoids are not considered a reproductive risk.
Smoking	Placental lesions, IUGR, increased perinatal mortality, increased risk of SIDS, neurobehavioral effects such as learning deficits and hyperactivity.	Possible mechanisms include vasoconstriction (nicotine effect); hypoxia secondary to hypoperfusion, CO, and CN; and altered development of neurons and neural pathways via stimulation of nicotinic acetylcholine receptors.
Streptomycin	Hearing loss	Rare reports.
Tetracycline	Yellow, gray-brown, or brown staining of deciduous teeth, hypoplastic tooth enamel	Effects seen after 4 months of gestation because tetracyclines must interact with calcified tissue.
Thalidomide	Limb phocomelia, amelia, hypoplasia, congenital heart defects, renal malformations, cryptorchidism, abducens paralysis, deafness, microtia, anotia	~20% risk for exposure during days 34–50 of gestation.
Trimethoprim	NTD, oral clefts, hypospadias, and cardiovascular defects	~1% risk of NTD for first trimester exposure. Mechanism is folic acid inhibition.
Valproic acid	Spina bifida, ASD, cleft palate, hypospadias, polydactyly, craniosynostosis, cognitive deficits	Risk for spina bifida is ~1%, but the risk for dysmorphic facies is greater. Risk is confounded by risks associated with epilepsy itself or use of other anticonvulsants.
Vitamin D	Possible association with supraaortic stenosis, elfin facies, and intellectual disability	Large doses of vitamin D disrupt cellular calcium regulation. Genetic susceptibility plays a role.
Warfarin	Fetal warfarin syndrome: nasal hypoplasia, chondrodysplasia punctata, brachydactyly, skull defects, abnormal ears, malformed eyes, CNS malformations, microcephaly, hydrocephalus, skeletal deformities, intellectual disability, spasticity	10%–25% risk of malformation for first trimester exposure, 3% risk of hemorrhage, 8% risk of stillbirth. Bleeding is an unlikely explanation for effects produced in the first trimester. CNS defects occur during the second or third trimesters and are related to bleeding.

ASD = atrial septal defect; CHD = congestive heart disease; CN = cyanide; CNS = central nervous system; CO = carbon monoxide; FAS = fetal alcohol syndrome; IUGR = intrauterine growth restriction; NSAID = nonsteroidal antiinflammatory drug; NTD = neural tube defect; PCB = polychlorinated biphenyl; SIDS = sudden infant death syndrome; SSRI = selective serotonin reuptake inhibitor; VSD = ventricular septal defect. Data from Brent RL. Environmental causes of human congenital malformations: The pediatrician's role in dealing with these complex clinical problems caused by a multiplicity of environmental and genetic factors. *Pediatrics*. 2004;113:957-968; Nulman I, et al. Teratogenic drugs and chemicals in humans. In: Koren G, ed. *Medication Safety in Pregnancy and Breastfeeding*. New York: McGraw-Hill; 2007:21-30; and Polifka JE, Friedman JM. Medical genetics: 1. disease such as deep vein thrombosis. Many women use various prescription and nonprescription xenobiotics before recognizing that they are pregnant.

Following the international experience with thalidomide in the 1960s that identified a high frequency of congenital malformations associated with its use, the US Food and Drug Administration (FDA) decided there was a need for guidance to prescribers regarding the use of medications during pregnancy. In 1979, the FDA began to require pharmaceutical manufacturers to label their products with respect to use in pregnancy and introduced the ABCDX classification scheme familiar to most practitioners in the United States.<sup>332</sup> Classification systems similar to the former FDA system were developed in Sweden and Australia.<sup>272,289</sup>

The intent of those classification systems was to inform practitioners about the nature of the available evidence regarding risk in pregnancy. However, the ABCDX system was criticized for a number of reasons—the manufacturer assigned the risk category, there was no requirement for additional research, and there was no requirement to update the label when new information became available.<sup>6</sup>

One of the most significant problems with the ABCDX system is the general impression among health care practitioners that the letter categories indicated teratogenic risk with a hierarchy of harmful effects and an equivalence of risk within each category.<sup>82,296,297</sup> For example, a category C medication was generally considered riskier than a category B medication in pregnancy even though category C was the default category for medications about which there was little or no specific human information available and for which the risk was unknown. Approximately 90% of medications were classified as category C.<sup>193</sup>

In addition, there was significant discordance between the use-in-pregnancy labeling and the teratogenic risk as determined by clinical teratologists.<sup>5,193</sup> Manufacturers labeled certain medications as category X (contraindicated in pregnancy) even when there was only limited information associating the medication with any adverse fetal or neonatal effects. For example, oral contraceptives carried a category X classification even though they are not considered teratogenic; the category X was assigned because there was no indication for use of oral contraceptives in pregnancy.<sup>176</sup> Certain medications that carried a category D (high-risk) classification might have caused problems only at certain times during pregnancy or in particular circumstances. In several reports, approximately 6% of pregnant women were prescribed medications that were categorized as D or X and 1% were prescribed medications that are considered teratogenic.<sup>5,13,193</sup> Even medications that have been classified as category D or X sometimes had only a very low risk of teratogenicity or other adverse effects, and exposure to these xenobiotics, even during the first trimester, would not necessarily have been an indication to terminate a pregnancy.<sup>86</sup>

The difficulty regarding appropriate drug labeling reflects many complex questions regarding the use of medications during pregnancy. How should animal data in general be evaluated? How should animal data be extrapolated to humans? How should the teratogenic risk be defined and quantified for any particular xenobiotic? How should the risk of not treating a particular disease be compared with the risk of using a particular medication to treat that disease? Finally, how should the answers to these questions be communicated to practitioners and the public?<sup>297</sup>

In an attempt to address many of these problems, the FDA organized a taskforce in 1998 to propose changes to the labeling of medications for use in pregnancy and lactation.<sup>142,176</sup> The changes, referred to as the “Pregnancy and Lactation Labeling Rule” (PLLR), were initially published in 2008, finalized in 2014, and took effect in 2015 with full implementation expected by 2020.<sup>334</sup> The new PLLR requires “the removal of pregnancy categories A, B, C, D, and X from all human and prescription drug and product labeling” and specifies the content and format for new labels. This content requires (1) a concise description and estimate of the risk of structural teratogenesis, fetal or infant mortality, and impaired growth or physiologic function; (2) details of animal and human data, in particular information from registries, cohort studies, and case-control studies; and (3) clinical considerations such as risk of the disease (treated or untreated) versus risk of the medication, need for

dose adjustment in pregnancy, adverse drug reactions specific to pregnancy, monitoring of drug use and effect, effects on labor and delivery, and neonatal complications. The PLLR also requires detailed information with regard to medication use during lactation (previously referred to as the “nursing mothers” section) as well as a new section that describes medication effects on both female and male fertility. There is also a requirement to update the label as new information becomes available that could make the label “inaccurate, false, or misleading.”

The new labels will be completely phased in by 2020. Drugs approved after 2015 must use the new labeling format. Drugs released after 2001 will have the newly formatted labels phased in over several years. Drugs approved and released prior to 2001 will not be required to use the new format but will be required to eliminate any reference to a previously assigned letter from the ABCDX system. Considering that the new FDA labels are being phased in over several years, the editors have decided to retain the ABCDX designation in other chapters for this edition.

Specific current information on individual xenobiotics can be obtained from local and regional teratogen information services and published books,<sup>39,302</sup> some of which also have online versions.<sup>228,266,325</sup> *Motherisk* is a Canadian program that uses accumulated evidence and experience to advise women about their actual risk of using a particular medication or being exposed to a particular xenobiotic in a current or planned pregnancy.<sup>227,228</sup>

Although most women are primarily concerned about the teratogenic effects of medications, in utero exposure to therapeutic medications has other pharmacologic effects on newborn infants, such as hyperbilirubinemia or withdrawal syndromes.<sup>39,78</sup>

Estimates of substance use in pregnancy vary tremendously, depending on the geographic location, practice environment, patient population, and screening method. In the National Survey on Drug Use and Health, approximately 16% of pregnant women smoked cigarettes, 11% drank ethanol, 5% used marijuana, 0.25% used cocaine, and 0.1% used heroin.<sup>285</sup> Women tend to decrease their exposure to xenobiotics after they know they are pregnant.<sup>33,150,153</sup>

## PLACENTAL REGULATION OF XENOBOTIC TRANSFER TO FETUSES

With respect to the transfer of xenobiotics from mother to fetus, the placenta functions in a manner similar to other lipoprotein membranes. Most xenobiotics enter the fetal circulation by passive diffusion down a concentration gradient across the placental membranes. The characteristics of a substance that favor this passive diffusion are low molecular weight (LMW), lipid solubility, neutral polarity, and low protein binding.<sup>9</sup> Polar molecules and ions are transported through interstitial pores.<sup>9</sup>

Xenobiotics with a MW greater than 1,000 Da do not diffuse passively across the placenta, and this characteristic is used to therapeutic advantage. For example, warfarin (MW, 1,000 Da) easily crosses the placenta and causes specific fetal malformations.<sup>342</sup> However, heparin (MW, 15,000 Da), which is too large to cross the placenta, is not teratogenic and, consequently, is the preferred anticoagulant during pregnancy. Most medications have MWs between 250 and 400 Da and easily cross the placenta. For example, thiopental is highly lipid soluble and crosses the placenta rapidly. Fetal plasma concentrations reach maternal concentrations within a few minutes. Neuromuscular blockers such as vecuronium are more polar and cross the placenta slowly.<sup>9</sup>

Although ionization is a limiting factor for diffusion, some highly charged molecules will diffuse across the placenta. Valproic acid ( $pK_a$  of 4.7) is nearly completely ionized at physiologic pH, yet there is rapid equilibration across the placental membrane. The small amount of xenobiotic that exists in the nonionized form rapidly crosses the placenta, and as the equilibrium is reestablished, an additional, small amount of nonionized xenobiotic becomes available for diffusion.<sup>9</sup>

Fetal blood pH changes during gestation. Embryonic intracellular pH is high relative to the intracellular pH of the pregnant woman. During this developmental stage, weak acids diffuse across the placenta to the embryo and remain there because of “ion trapping.” Many teratogens, such as valproic acid, trimethadione, phenytoin, thalidomide, warfarin, and isotretinoin, are

weak acids. Although ion trapping does not explain the mechanism of teratogenesis, it explains how xenobiotics accumulate in an embryo. Late in gestation, the fetal blood is 0.10 to 0.15 pH units more acidic than the maternal blood; this pH differential permits weakly basic xenobiotics to concentrate in the fetus during this period.<sup>9</sup>

The relative concentrations of protein-binding sites in the pregnant woman and fetus also have an impact on the extent of xenobiotic transfer to the fetus. As maternal free fatty acid concentrations increase near term, these fatty acids displace xenobiotics such as valproic acid or diazepam from maternal protein-binding sites and make more free xenobiotic available for transfer to the fetus.<sup>9</sup> Fetal albumin concentrations increase during gestation and exceed maternal albumin concentrations by term. Because the fetus does not have high concentrations of free fatty acids to compete for protein-binding sites, these sites are available for binding the xenobiotics. At birth, when neonatal free fatty acid concentrations increase 2- to 3-fold, they displace stored xenobiotic from the binding protein. In the cases of valproic acid and diazepam, the elevated concentrations of free xenobiotic have adverse effects on the newborn infant.<sup>114,151,236,265</sup>

The placenta also affects xenobiotic presentation to the fetus by ion trapping and xenobiotic metabolism. The placenta blocks the transfer of some positively charged ions such as cadmium and mercury<sup>125</sup> and actually accumulates them. This barrier does not necessarily protect the fetus, however, because these metal ions interfere with normal placental function and lead to placental necrosis and subsequent fetal death.

Beyond diffusion, specific transporters are found on both the fetal and maternal sides of the placenta. Transporters from the ATP-binding class (ABC) and the solute carrier class (SLC) have been identified.<sup>46</sup> These transporters help to deliver maternal solutes to the fetus and help the fetus to eliminate metabolic byproducts. They are also involved in the delivery of xenobiotics to the fetus.

The placenta contains xenobiotic-metabolizing enzymes capable of performing both phase I and phase II reactions (Chaps. 11 and 21). CYP1A1 is the primary CYP enzyme found in the placenta.<sup>46</sup> However, the concentration of biotransforming enzymes in the placenta is significantly lower than that in the liver, and it is unlikely that the level of enzymatic activity is protective

for the fetus.<sup>230</sup> Moreover, the fetus is exposed to reactive intermediates that form during these processes.

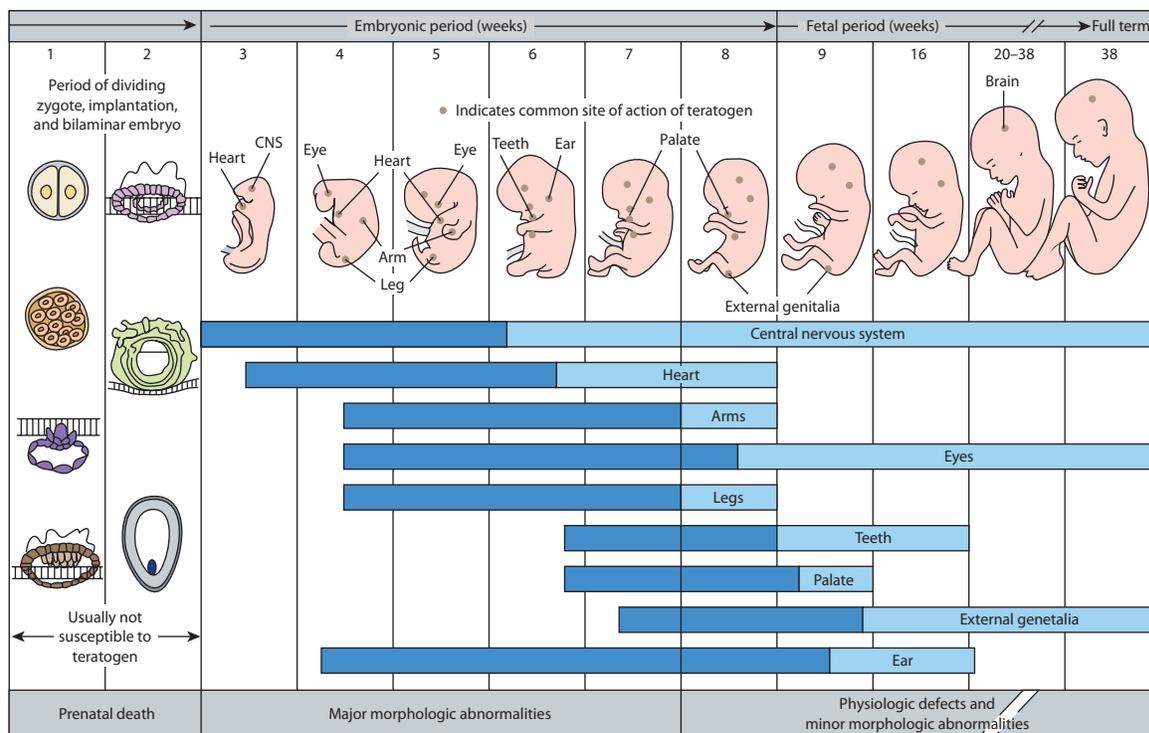

Placental transfer of xenobiotics has a positive effect as it permits delivery of desired therapies to the fetus. For example, if a fetus is found to have a supraventricular tachycardia or atrial flutter, digoxin given to the mother treats the tachydysrhythmia in the fetus.<sup>145,231-234</sup>

## EFFECTS OF XENOBIOTICS ON THE DEVELOPING ORGANISM

A basic premise of teratogenicity is that the particular toxic effects of a xenobiotic are determined by the stage of development of the embryo or fetus.<sup>38</sup> Although the fertilized ovum is generally thought to be resistant to toxic insult before implantation,<sup>37</sup> xenobiotics in the fallopian or uterine secretions prevent implantation of the embryo. Xenobiotic exposure leading to cell loss or chromosomal abnormalities also leads to loss of the embryo, possibly even before pregnancy is detected. If the preimplantation embryo survives a xenobiotic exposure, the functional cells usually proceed to normal development.<sup>298</sup> Teratogens that act in such a manner elicit an “all-or-none response”; that is, the exposed embryo will either die or go on to normal development.

The dose–response curve of an environmental xenobiotic demonstrates *deterministic* (threshold) or *stochastic* (no threshold) effects.<sup>38</sup> Mutagenic and carcinogenic events are stochastic phenomena. Teratogenesis is a deterministic phenomenon with a threshold dose below which no effects occur. As the dose of the teratogen increases above the threshold, the magnitude of the effect increases. The effects might be the number of offspring that die or develop malformations or the extent or severity of malformations. Radiation has both deterministic effects (eg, microcephaly and growth retardation) and stochastic effects (induction of leukemia). Strictly speaking, teratogenic effects are those that occur at doses that do not cause maternal toxicity because maternal toxicity itself might be responsible for an observed adverse or teratogenic effect on the developing organism.<sup>37</sup>

Organogenesis occurs during the embryonic stage of development between days 18 and 60 of gestation. Most gross malformations are determined before day 36, although genitourinary and craniofacial anomalies occur later.<sup>37</sup> The period of susceptibility to teratogenic effects varies for each organ system (Fig. 30-1). For instance, the palate has a very short

**FIGURE 30-1.** Critical periods of human prenatal development. (Modified with permission from Moore KL, Persaud TVN, Torchia MG. *Before We Are Born: Essentials of Embryology and Birth Defects*, 8th ed. Philadelphia, PA: Saunders; 2013.)

period of sensitivity, lasting approximately 3 weeks, whereas the complete development of the central nervous system (CNS), including neurogenesis and differentiation, arborization, synaptogenesis and synaptic organization, and myelination and gliogenesis, remains susceptible throughout the fetal period and into the neonatal period and infancy.

Theoretically, knowing the exact time of teratogen exposure during gestation would allow prediction of a teratogenic effect; this is true in animal models, where the dose and time of exposure can be strictly controlled. It is also true for thalidomide in which different limb anomalies are specifically related to exposures on particular days of gestation.<sup>337</sup> In many clinical situations, for xenobiotics administered either for a short course or chronically, relating teratogenicity to a particular xenobiotic exposure is difficult because the exact time of conception and the exact time of exposure are unknown. This is particularly true when the primary exposure precedes the identification of pregnancy but there is secondary or ongoing exposure during pregnancy as xenobiotics are redistributed from tissue storage sites.<sup>179</sup>

During the fetal period, formed organs continue their cellular differentiation and grow to functional maturity. Exposure to xenobiotics such as cigarettes and their toxic constituents during this period generally leads to growth retardation. Teratogenic malformations or death occur as a result of disruption or destruction of growing organs, as has resulted from exposure to angiotensin-converting enzyme inhibitors and angiotensin II, type I receptor blockers during the second and third trimesters.<sup>45</sup>

Another concern during the fetal period is the initiation of carcinogenesis. Significant cellular replication and proliferation lead to a dramatic growth in size of the organism. At the same time, when the fetus is exposed to xenobiotics, development of biotransformation systems expose the organism to reactive metabolites that also initiate tumor formation. Some tumors, such as neuroblastoma, appear so early in postnatal life that their prenatal origin is likely. In pregnant rats given ethylnitrosourea during the embryonic period, lethal or teratogenic effects occur.<sup>267</sup> If ethylnitrosourea is administered during the fetal period, there is an increased incidence of tumors in the offspring. Clear cell vaginal and cervical adenocarcinomas occur in the female offspring of women exposed to diethylstilbestrol (DES) during pregnancy.<sup>263</sup>

## MECHANISMS OF TERATOGENESIS

Cytotoxicity is one mechanism of teratogenesis and is the characteristic result of exposure to alkylating or chemotherapeutic agents. Aminopterin, for example, inhibits dihydrofolate reductase activity and leads to suppression of mitosis and cell death. If exposure to a cytotoxic xenobiotic occurs very early in development, the conceptus can die, but sublethal exposure during organogenesis can result in maldevelopment of particular structures. There is evidence that after cell death, the remaining cells in an affected region try to repair the damage caused by the missing cellular elements. This “restorative growth” can lead to uncoordinated growth and exacerbate the original malformation.

In the case of cytotoxic agents, the mechanism of action is understood, although it is not always clear why particular xenobiotics affect particular structures. With other xenobiotics, the structural effects have a clearer relationship to the site of action. For instance, when corticosteroids are administered in large doses to some experimental animals during the period of organogenesis, malformations of the palate occur. Glucocorticoid receptors are found in high concentrations in the palate of the developing mouse embryo.<sup>259</sup> Corticosteroid exposure had previously been thought to cause cleft palate in humans at a low frequency,<sup>251,301</sup> but recent work suggests there is no association between corticosteroid exposure and cleft palate.<sup>25,307</sup>

Caloric deficiency is not considered teratogenic during the period of organogenesis; however, specific nutritional or vitamin deficiencies are. In particular, there is an increased incidence of neural tube defects (anencephaly and spina bifida) associated with dietary folate deficiency, although the specific mechanism of teratogenesis is unknown. To ensure that all women of childbearing age have adequate folate stores by the time they become pregnant and during their pregnancy and to reduce the number of severe

birth defects, it is important for women of childbearing age to have folate supplementation either as vitamin or dietary supplements even before they become pregnant. Because fortification of grain products is considered critical to help accomplish this goal, the FDA requires US manufacturers to add folic acid to enriched breads, cereals, flours, corn meals, pastas, rice, and other grain products.<sup>244</sup>

Ethanol affects fetuses both directly and indirectly. The craniofacial malformations that occur in fetal alcohol syndrome (FAS) probably result from the effects of ethanol during the period of organogenesis. Growth retardation results from direct effects of ethanol on fetal growth or from indirect effects resulting from ethanol-induced maternal nutritional deficiencies.

## MANAGEMENT OF ACUTE POISONING IN PREGNANT WOMEN

For most women, pregnancy and the postpartum period are a period of emotional happiness. However, women have a lifetime prevalence of depression that is 2 to 3 times higher than men, and for some women, psychiatric illness during pregnancy, particularly depression and anxiety, represents a significant comorbidity. A new first episode or recurrence of major depression occurs in approximately 3% to 5% of pregnant women and 1% to 6% of women in the postpartum period; an additional 5% to 6% of women during pregnancy and the postpartum period will have minor symptoms of depression.<sup>188</sup> Overall, these rates of depression are about the same in pregnant and nonpregnant women; however, during the postpartum period, the onset of new episodes of depression are higher than for nonpregnant women. Pregnant teenagers are also at higher risk of depression during pregnancy.<sup>191</sup>

Postpartum “baby blues” are common, typically involve relatively mild symptoms including mood swings, irritability, anxiety, and crying spells, and generally resolve by 2 weeks after delivery.<sup>199</sup> Postpartum blues do not include suicidal ideation. True depression is manifested by feelings of hopelessness or helplessness and include suicidal ideation. Postpartum psychosis, typically associated with bipolar disorder, is uncommon, but it represents a true psychiatric emergency because there is a high risk of suicide, infanticide, or both.<sup>28</sup>

Risk factors for perinatal depression include an unplanned pregnancy, ambivalence about the pregnancy, poor social support, marital difficulties, adverse life events, and chronic stressors such as financial problems.<sup>61,181,338</sup> Of substantial importance is a personal or family history of depression, particularly previous perinatal depression. Discontinuation of antidepressant therapy represents a significant risk for relapse of disease, although relapse is possible even while a woman is receiving an antidepressant. Additional risk factors for depression include miscarriage, stillbirth, and preterm delivery.<sup>293</sup>

Depression in pregnancy has adverse effects on both the mother and the fetus.<sup>32,216</sup> For the pregnant woman, adverse effects include noncompliance with prenatal care; self-medication with tobacco, ethanol, and both licit and illicit xenobiotics drugs; poor sleep; poor appetite; and poor weight gain. In addition, there is an increased risk of spontaneous abortion, preeclampsia, preterm delivery, and fetal growth retardation. For many of these outcomes, it is difficult to differentiate the contributions from multiple confounding and interacting factors, including psychopathology, socioeconomic status, acute and chronic stressors, smoking, and the use of ethanol and other drugs of abuse.

One of the most extreme outcomes of depression is suicide. Suicidal ideation occurs in about 5% of pregnant women in community samples and up to 20% in women with underlying psychiatric illness.<sup>111,191,240</sup> Even so, suicide and suicide attempts during pregnancy are uncommon. Each year a small number of women die during pregnancy or the postpartum period; 1% to 5% of these pregnancy-related deaths are the result of suicide.<sup>51,72,245</sup> Between 2% and 12% of women who attempt or commit suicide are pregnant.<sup>161,164,257</sup> Overall, completed suicide occurs less frequently during pregnancy.<sup>14,191,212</sup> Psychiatric illness, including previous suicide attempts, predisposes to suicide attempts in pregnancy. Acute stressors leading to impulsive acts account for most of the uncompleted suicide attempts; these reasons include loss of a lover, economic crisis, prior loss of children, an unwanted pregnancy, and desire for an abortion.<sup>68,187,350</sup>

Women who complete suicide typically have more severe psychiatric illness. In particular, these women are likely to use more violent means of suicide such as hanging or self-inflicted gunshot wounds, although poisonings are a significant contributor to these deaths.<sup>90,245</sup> In addition, substance and ethanol use are significant contributing factors in many cases; additionally, some pregnancy-related deaths are secondary to complications of substance use, such as overdose.<sup>245</sup> Initiation of child protection proceedings, particularly in the setting of maternal substance use, is an additional risk factor for postpartum suicide.<sup>245</sup> Some suicides follow pregnancy-related or neonatal complications.<sup>90</sup>

Ingestion of xenobiotics is the most common method of attempted suicide during pregnancy and the postpartum period.<sup>61,109,257,261</sup> There are approximately 7,000 xenobiotic exposures in pregnant women reported to the AAPCC annually, which account for approximately 2% of the exposures in adolescent and adult females of childbearing age (Chap. 130). The patterns of xenobiotic exposure are similar to those of adolescent and adult exposures in general with analgesics being the most common exposure. A similar pattern has also been reported for a California sample.<sup>218</sup> Some of these xenobiotic exposures are attempts to terminate pregnancy (Chap. 19).<sup>257</sup> As with most poisonings overall, the severity of poisoning in pregnant women is typically minor.<sup>240,245</sup>

In one US national sample, 1,659 pregnant women had poisoning-related hospitalizations, representing 0.04% of all hospitalized pregnant women and approximately 10% of injury-related admissions of pregnant women. A total of 244 of these women (15%) delivered their babies during these poisoning-related hospitalizations.<sup>173</sup> In a Swedish cohort, there was a higher rate of miscarriage than expected.<sup>102</sup>

In national samples from both the United States and England, approximately 2% to 3% of deaths in pregnancy and the immediate postpartum period follow suicidal poisoning.<sup>51,245</sup> The AAPCC reports approximately 2 deaths per year in pregnant women, which represents approximately 2 per 1,000 AAPCC-reported adolescent and adult deaths overall, 4 per 1,000 deaths in adolescent and adult women, and approximately 3 deaths per 10,000 (0.03%) xenobiotic exposures in pregnancy (Chap. 130). In a combined Hungarian series of pregnant women who had suicidal poisonings, 19 of 1,044 (1.8%) died.<sup>69</sup>

Any woman who attempts suicide during pregnancy or the postpartum period should have a psychiatric evaluation after she is medically stabilized. In particular, a growing number of specialized units or teams focus on pregnant and postpartum women and attempt to keep women and infants together in the postpartum period.<sup>199,245</sup>

Managing any acute overdose during pregnancy provokes discussion of several questions. Is the general management different? Do altered metabolism and pharmacokinetics increase or decrease the woman's risk of morbidity or mortality from a xenobiotic overdose? Is the fetus at risk of poisoning from a maternal overdose? Is there a teratogenic risk to the fetus from an acute overdose or poisoning? Is the use of an antidote contraindicated or should use be modified? When should a potentially viable fetus be emergently delivered to prevent toxicity? When should termination of a pregnancy be recommended?

As described earlier, physiologic changes during pregnancy affect pharmacokinetics; xenobiotics taken in overdose also have unpredictable toxicokinetics. In any significant overdose during pregnancy, pregnancy-related alterations in pharmacokinetics are unlikely to protect the woman from significant morbidity or mortality.

Although a single high-dose exposure to a xenobiotic during the period of organogenesis might seem analogous to an experimental model to induce teratogenesis, most xenobiotics ingested as a single, acute overdose do not induce physical deformities.<sup>70</sup> Antiepileptics are teratogenic and sometime are ingested in suicide gestures or attempts, but their teratogenicity is probably more directly related to chronic exposure. Acute acetaminophen (APAP) toxicity in the first trimester leads to an increased risk of spontaneous abortion,<sup>270</sup> suggesting a teratogenic effect similar to the all-or-none response described earlier. In general, however, it is extremely difficult to

ascribe teratogenicity to a particular xenobiotic exposure based on a single case report. There is, for example, a report of multiple severe congenital malformations in the stillborn fetus of a woman who overdosed on isoniazid during the 12th week of pregnancy.<sup>185</sup> However, because the background incidence of congenital malformations is 3% to 6%, it is almost impossible to determine for a single individual whether a particular exposure is the etiology of observed malformations.<sup>71</sup> The Budapest Registry of Self-Poisoned Patients uses this construct to screen for possible teratogenic effects of xenobiotics in overdose.<sup>69,70</sup> Considering the successful outcome of most pregnancies that progress to term after an acute overdose, it is very unlikely that the small risk of teratogenesis would lead to a recommendation for termination of pregnancy after an acute overdose of most xenobiotics.<sup>86</sup>

In general, any condition that leads to a severe metabolic derangement in a pregnant woman is likely to have an adverse impact on her developing fetus. Therefore, the management of overdose in a pregnant woman usually follows the principles outlined in Chap. 4, with close attention paid to the airway, oxygenation, and hemodynamic stability. The use of naloxone or dextrose has not been specifically assessed in pregnancy, but clinicians should be guided by the same considerations raised in managing the nonpregnant patient with alterations in respiratory or neurologic function. Opioid-induced respiratory failure in a pregnant patient will lead to fetal hypoxia and adverse effects; opioid withdrawal in a pregnant woman, whether induced by abstinence or the use of naloxone, can adversely affect the fetus or the pregnancy. Consideration of the benefits and risks of the use of naloxone for an opioid-poisoned woman in respiratory distress or coma suggests that reduced morbidity, for both the mother and fetus, is achieved by the use of carefully titrated doses of naloxone to minimize the likelihood of maternal withdrawal (Chap. 36 and Antidotes in Depth: A4).

Gastrointestinal decontamination is frequently a part of the early management of acute poisoning in nonpregnant patients. Gastric lavage is not specifically contraindicated for pregnant patients, and the usual concerns about airway management apply.

There is no specific contraindication to the use of activated charcoal in a pregnant woman. There is limited evidence for a role for whole-bowel irrigation (WBI) in the management of pregnant patients with certain xenobiotic exposures, for example, in the treatment of iron overdose in pregnancy.<sup>335</sup> The use of oral polyethylene glycol-electrolyte solution (PEG) is safe in pregnant women.<sup>237</sup>

There have been no clinical trials on the use of antidotes in pregnant women in the context of acute poisoning. Deferoxamine is studied to treat chronic iron overload in pregnant women, and there is supportive data for this medication. Because there are no reports of adverse fetal effects from antidotal treatment of a poisoned pregnant woman, the benefit of antidotal therapy will almost invariably outweighs the risk of use in pregnancy. Conversely, in at least one case, withholding deferoxamine therapy contributed to the death of both a woman and her fetus.<sup>207,320</sup>

## ACETAMINOPHEN

Acetaminophen is the most common analgesic and antipyretic used during pregnancy and is also one of the most common xenobiotic overdoses during pregnancy. There are 3 published series of acute APAP overdose during all trimesters of pregnancy<sup>220,221,270</sup> in addition to multiple case reports. Overall, most pregnant women who continue their pregnancies recover from an APAP ingestion without adverse effects to themselves or their babies.

Twenty-eight women with first trimester exposures who continued their pregnancies are reported.<sup>221,270</sup> Nineteen women, 5 of whom had toxic serum APAP concentrations, delivered full-term infants. One woman with severe hepatotoxicity died along with the fetus. Eight women had spontaneous abortions; 5 of these 8 had toxic serum concentrations and received NAC (one within 8 hours and 4 between 12 and 17 hours after ingestion).

Thirty-two women with second-trimester exposures who continued their pregnancies are reported.<sup>105,197,221,270,275,317</sup> Twenty-seven women, 7 of whom had toxic serum APAP concentrations, delivered full-term infants. One woman developed fulminant hepatic failure and underwent liver transplant

at 20 weeks' gestation; the infant developed severe complications in utero, and the woman terminated the pregnancy at 23 weeks. Two women, one with a nontoxic serum concentration and one who developed hepatotoxicity, delivered premature infants. Two women with nontoxic serum APAP concentrations had spontaneous abortions probably unrelated to the overdose.

Fifty-five women with third trimester exposures who continued their pregnancies are reported.<sup>20,47,66,107,126,141,172,184,221,256,270,274,279,281,287,322,340</sup> Forty-two women, 15 of whom had toxic serum APAP concentrations, delivered full-term infants. Eleven women delivered premature infants. Five of them had toxic serum APAP concentrations and hepatotoxicity, 4 had toxic serum APAP concentrations without hepatotoxicity, and 2 had nontoxic serum APAP concentrations. Two women with severe hepatotoxicity delivered still-born infants who also showed signs of hepatotoxicity and one woman with severe hepatotoxicity delivered an infant who died at 34 hours of life.

There are also several case reports of adverse pregnancy outcome in the setting of chronic use of APAP or acute overdose associated with chronic substance use.<sup>52,141,174,200,270,327</sup> It is difficult to interpret these reports with respect to specific APAP effect because of the confounders of chronic disease, chronic APAP use, and the use of additional medications and substances.

Although APAP at recommended doses is considered safe in pregnancy,<sup>189</sup> in overdose, it puts the developing fetus at risk. As the cases demonstrate, APAP crosses the placenta to reach the fetus. The cases suggest an increased risk of spontaneous abortion after overdose during the first trimester, particularly in the setting of toxic serum APAP concentrations and delayed NAC therapy.<sup>270</sup> The cases also suggest that overdose during the first trimester can lead to late sequelae, for instance, premature labor.

Some experimental work might explain early pregnancy loss after overdose. Acetaminophen prevented the development of preimplantation (2-cell stage) mouse embryos in culture, an effect that was not associated with alterations in glutathione concentrations,<sup>182</sup> and led to abnormal neuropore development in cultured rat embryos.<sup>315</sup> These data suggest that APAP is directly toxic to the immature organism. However, other work reported that similar embryotoxic effects were associated with reductions in glutathione concentrations<sup>346</sup> and that *N*-acetyl-*p*-benzoquinoneimine (NAPQI) produced nonspecific toxicity when added to the rat embryo culture medium.<sup>315</sup>

The fetal liver has some ability to metabolize APAP to a reactive intermediate in vitro. Cytochrome P450 (CYP) activity was detected in intact hepatocytes, as well as in microsomal fractions isolated from the livers of fetuses aborted between 18 and 23 weeks of gestation. This fetal hepatic CYP activity increased between 18 and 23 weeks (the only period studied) but was maximally only 10% of the activity of hepatocytes isolated from adults after brain death.<sup>277</sup> In 2 clinical cases, cysteine and mercapturate conjugates were identified in newborns exposed to APAP in utero, suggesting that the fetus and neonate metabolize APAP through the CYP system.<sup>184</sup> These data suggest that the fetus in utero and the neonate generate a toxic metabolite. The clinical cases suggest that the fetal liver is susceptible to injury, although whether this fetal hepatotoxicity is related to fetal APAP toxicity, maternal toxicity, or postmortem changes is unclear.

This CYP activity has not been further characterized. However, CYP2E1, one of the cytochromes responsible for APAP metabolism, is present in human fetal tissues as early as 16 weeks of gestation.<sup>225</sup> CYP3A4 and CYP1A2 are also involved in APAP metabolism but are not present in fetal liver. CYP3A7 is a functional fetal form of the CYP3 family, but its metabolic activity with respect to APAP is unstudied.<sup>127</sup>

The clinical cases help address several questions regarding management of overdose during the third trimester (Table 30-2). Eight women whose pregnancies were all at less than 36 weeks of gestation developed hepatotoxicity. Two infants died in utero and one infant died on the second day of life with evidence of hepatotoxicity. The other 5 infants experienced problems associated with prematurity but did not develop obvious hepatotoxicity. One of these 5 infants had 4 exchange transfusions to treat a cord acetaminophen concentration of 76 mcg/mL and had an unexplained death at 3 months of age. Five women whose pregnancies were all at 36 or more weeks of gestation

did not develop hepatotoxicity. One infant had 2 exchange transfusions to treat a cord acetaminophen concentration of 217 mcg/mL and did not develop hepatotoxicity but died of sudden infant death syndrome (SIDS) at 5 months of age. One infant received intravenous (IV) NAC and had a transient elevation of aspartate aminotransferase (AST) and prothrombin time. Two infants were not treated, and both did well, although one had a transient elevation of AST. One infant was born 6 weeks after the overdose and was normal.

Taken together these cases suggest that when there is maternal hepatotoxicity there is a moderate risk of fetal hepatotoxicity and fetal morbidity. There is also a moderate risk of prematurity delivery.

Urgent delivery is often recommended in the setting of severe maternal hepatotoxicity that is associated with fetal distress. Although a fetus with prolonged exposure to APAP in utero is at risk of developing severe hepatotoxicity, not all at-risk infants have been affected. The contribution of gestational age, maternal disease state, or other maternal factors to fetal or neonatal toxicity is unknown. Although there are insufficient case data to suggest that APAP overdose per se is an indication for urgent delivery, some authorities recommend urgent delivery when the maternal serum APAP concentration is in the toxic range but hepatotoxicity has not yet developed.<sup>324</sup> The clinical cases also suggest that significant APAP overdose with or without associated hepatotoxicity can precipitate premature labor and that even women with nontoxic serum concentrations are at an increased risk.

In 2 cases, exchange transfusion was used to treat the exposed neonate. In both cases, the APAP half-life was prolonged, and in neither case was this affected by the transfusion. Disturbingly, these 2 infants had unexplained deaths at several months of age. There are currently no data to support the use of exchange transfusion as therapy for elevated serum APAP concentrations in a neonate.

A pregnant woman with acute toxic APAP ingestion should be treated with NAC (Chap. 33 and Antidotes in Depth: A3). This therapy is intended to treat the mother. Maternal hepatotoxicity and delayed NAC therapy are associated with fetal toxicity;<sup>270</sup> whether NAC therapy can prevent later sequelae such as premature delivery is unclear. Although NAC did not cross the sheep placenta in vivo<sup>299</sup> and the perfused human placenta in vitro, NAC was found in cord blood after it was administered to 4 mothers before delivery.<sup>141</sup> Even if NAC does cross the placenta, whether it can prevent fetal hepatotoxicity is unknown because not all exposed fetuses develop hepatotoxicity.

Use of APAP during pregnancy may be associated with other risks. One area of concern is the association of prenatal exposure to APAP with the development of childhood asthma. Several meta-analyses have reviewed many of the published studies.<sup>57,91,93</sup> Many of those studies were criticized for lack of control of potential confounders such as the stage of pregnancy, dose and frequency of use, variable definitions of asthma, and the different childhood age groups considered. One of the biggest concerns is the possible confounding by indication because why a pregnant woman took acetaminophen, whether for a respiratory tract infection or for back pain for example, may be important as a predictor. Notwithstanding these concerns, the meta-analyses report a positive association between prenatal exposure to APAP and childhood wheezing and/or asthma with an OR of approximately 1.28-1.5.

## IRON

Intentional iron exposures during pregnancy are reported; maternal toxicity is generally greater than fetal toxicity. In 2 cases, normal babies were delivered, although the mothers died.<sup>247,268</sup> In another case, the mother had severe iron toxicity with metabolic acidosis, shock, kidney failure, and disseminated intravascular coagulation but was not treated with deferoxamine because of concerns about its teratogenic risks. Instead, the mother received an exchange transfusion followed 45 minutes later by a spontaneous abortion of the 16-week fetus.<sup>207,320</sup> Neonatal and cord blood iron concentrations were not elevated. In several cases, pregnant women who had signs and symptoms of iron poisoning and elevated serum iron concentrations were treated with deferoxamine and subsequently delivered normal babies.<sup>30,162,177,262,292,330</sup>

TABLE 30–2 Reported Cases of Third Trimester APAP Overdose

Gestational Age (wk)	Maternal		Infant		Comment	Reference
	APAP Concentration (mcg/mL)(time <sup>a</sup> )	AST Peak (IU/L)(time <sup>a</sup> )	APAP Concentration (mcg/mL)(time <sup>a</sup> )	Hepatotoxicity (Yes/No)		
27	0 (36 hours)	1,226 (36 hours)	ND	No	C/S for fetal distress. Infant: mild respiratory distress syndrome.	107
27–28	56 (16 hours)	6,226 (96 hours)	ND	Yes	Ingestion over 24 hours. No fetal movements at presentation. PO NAC started at 20 hours. Induced labor at 4 days. Infant: stillborn with diffuse hepatic necrosis. Hepatic APAP 250 mcg/g.	126
29	160 (10 hours)	4,300 (50 hours)	76 (16 hours, cord)	No	Ingestion of aspirin, caffeine, and quinine followed 17 hours later by APAP. Presented in labor. Treated with oral methionine. Spontaneous delivery at 16 hours. Infant: moderate hyaline membrane disease. Peak AST of 86 IU/L (cord). Four whole-blood exchange transfusions. Discharged home at 54 days of life. Died at 106 days; no apparent cause.	184, 322
30	55 (18 hours)	4,000 (48 hours)	ND	ND	Maternal chorioamnionitis with delivery at 31 weeks. Respiratory distress syndrome and hyperbilirubinemia.	256
31	40 (26 hours)	13,320 (60 hours)	41 (27)	Yes	APAP only, C/S for fetal distress one hour after initial maternal evaluation. Infant's birth weight was 1,620 g. Apgar scores 0, 0, 1. <sup>b</sup> Infant died at 34 hours of life. Mother died at 34 hours postingestion. No autopsy of mother or child.	340
32	448 (12 hours)	5,269 (48 hours)	0 (84 hours, cord)	No	IV NAC started at 12 hours. Induced delivery at 84 hours. Infant: transient hypoglycemia, mild respiratory distress, mild jaundice. Peak AST of 56 IU/L (day 1 of life).	221, 279
32	166 (4 hours)	"Normal"	ND	ND	Vaginal delivery at term without complications.	66
33	135 (28 hours)	6,237 (66 hours)	330 (3 days, cord)	Yes	Oral NAC at 12 hours. Fetal death at 2 days; spontaneous delivery at 3 days. Infant: stillborn with diffuse hepatic necrosis.	270
36	280 (3–4 hours)	"Normal"	217 (6–7 hours, cord)	No	Ingestion of APAP, ethanol, barbiturates. Elective C/S at 6–7 hours. Infant: double-volume exchange transfusion at 18 hours. Discharge at 40 days, "cot death" at 157 days.	274
36	200 (5 hours)	25 (24 hours)	ND	No	Oral NAC (? time). Infant: spontaneous delivery 6 weeks after ingestion. Normal neonatal course.	47
38	216 (4 hours)	"Normal"	13 (17 hours, cord)	No	NAC (? route). Infant: normal neonatal course.	172, 281
"Term"	147 (9 hours)	28 (9 hours)	133 (9 hours, 4 hours of life)	No	Infant PT of 44 at 4 hours of life. IV NAC. No problems. AST of 86 IU/L at 4 hours of life.	20
Term?	89 (11 hours)	326 (35 hours)	144 (11 hours, 4 hours of life)	No	Mother presented in labor at 6 hours. Infant received IV NAC at 4 hours of life. AST of 55 IU/L at 4 hours of life.	287

<sup>a</sup>Time after maternal ingestion. <sup>b</sup>Apgar scores are at 1, 5, and 10 minutes.

APAP = acetaminophen; AST = aspartate aminotransferase; C/S = cesarean section; IV = intravenous; NAC = *N*-acetylcysteine; ND = not done or not reported; PO = oral; PT = prothrombin time.

Although the placenta transports iron to the fetus efficiently,<sup>19</sup> it also blocks the transfer of large quantities of iron. In a sheep model of iron poisoning, only a small amount of iron was transferred across the placenta despite significantly elevated serum iron concentrations.<sup>67</sup>

Deferoxamine is an effective antidote for iron poisoning (Chap. 45 and Antidotes in Depth: A7), but it is reported to be a teratogen that causes skeletal deformities and abnormalities of ossification when given to pregnant rabbits at high doses. A rat model observed similar effects but only with doses of deferoxamine that caused maternal toxicity.<sup>34</sup> Experimentally, in sheep, deferoxamine was minimally transported across the placenta;<sup>67</sup> therefore, the reported fetal effects could be secondary to chelation of essential nutrients (eg, trace metals) on the maternal side of the placenta.<sup>324</sup>

In clinical case reports of iron overdose for which deferoxamine was used, there have been no adverse effects on the fetus, although most have been either second or third trimester poisonings.<sup>30,162,177,247,262,292,330</sup> In a case series of 49 patients with iron poisoning during pregnancy, few of the patients exhibited any clinical toxicity other than vomiting and diarrhea; 25 received

deferoxamine, most by the oral route.<sup>219</sup> One woman with a first trimester overdose, 8 women with second trimester overdoses, and 12 women with third trimester overdoses were treated with deferoxamine and subsequently delivered full-term infants. One infant whose mother overdosed at 30 weeks of gestation had webbed fingers on one hand. One woman who overdosed at 20 weeks had minimal clinical toxicity, received deferoxamine, and delivered a 2.5-kg male infant at 34 weeks of gestation. One woman with a first trimester overdose and 2 women with second trimester overdoses elected to terminate their pregnancies.

Further support for the safe use of deferoxamine in pregnancy is the experience with its use for pregnant women with thalassemia major. For many years, deferoxamine has been administered as part of the therapy for posttransfusion iron overload without adverse effects.<sup>305</sup> Considering the potentially fatal nature of severe iron poisoning, deferoxamine should be administered when signs and symptoms indicate significant poisoning.

Iron overdose is one of the few specific indications for WBI, because iron is not adsorbed to activated charcoal (Antidotes in Depth: A1 and A2). A case

report demonstrated elimination of pill fragments after treatment of a pregnant woman with WBI.<sup>335</sup>

## CARBON MONOXIDE

Carbon monoxide is the leading cause of unintentional poisoning fatalities in the United States. In contrast to iron and most other xenobiotics, when pregnant women are exposed to carbon monoxide, the fetus is at greater risk of toxicity than the mother. There are reports of both the mother and fetus dying; the mother surviving but the fetus dying; and both the mother and fetus surviving but with an adverse neonatal outcome, primarily brain damage resembling that seen after severe cerebral ischemia.<sup>48,65,169,194,208,242,335,353</sup> Similar clinical effects are also observed in animal models.<sup>83,115,195</sup>

The case literature suggests an increased risk of poor fetal outcome with clinically severe maternal poisoning or significantly elevated carboxyhemoglobin concentrations.<sup>169,242</sup> Women with minimal symptoms or low concentrations of carboxyhemoglobin have a low risk of fetal toxicity, but a lower limit of exposure without effect has not been specifically defined.<sup>169</sup>

In animal models, under experimental conditions, the fetus has a carboxyhemoglobin concentration 10% to 15% higher than the mother.<sup>135,195</sup> After exposure to carbon monoxide, the fetus achieves peak carboxyhemoglobin concentrations 58% higher than those achieved by the mother at steady state, and the time to peak concentration is also delayed compared with that of the mother. Similarly, the elimination of carbon monoxide occurs more slowly in the fetus than in the mother.<sup>135,194,195</sup> One case report describes such a phenomenon: after one hour of supplemental oxygen, the maternal carboxyhemoglobin concentration was 7% and the fetal carboxyhemoglobin concentration was 61% at the time of death in utero.<sup>88</sup>

Carbon monoxide leads to fetal hypoxia by several mechanisms: (1) maternal carboxyhemoglobin leads to a decrease in the oxygen content of maternal blood, and therefore less oxygen is delivered across the placenta to the fetus, which normally has an arterial  $PO_2$  of only 20 to 30 mm Hg; (2) fetal carboxyhemoglobin causes a decrease in fetal  $PO_2$ ; (3) carbon monoxide shifts the oxyhemoglobin dissociation curve to the left and decreases the release of oxygen to the fetal tissues (an exacerbation of the physiologic left shift found with normal fetal hemoglobin); and (4) carbon monoxide inhibits cytochrome oxidase or other mitochondrial functions.

The treatment for severe carbon monoxide poisoning is hyperbaric oxygen therapy (HBO) (Chap. 122 and Antidotes in Depth: A40). There are questions about the use of HBO in pregnant women because animal models suggest HBO adversely affects the embryo or fetus.<sup>98,226,290,323</sup> The applicability of these animal models to humans is difficult to assess; many of the animal models used hyperbaric conditions of greater pressures and duration than those clinically used for humans.

Hyperbaric oxygen therapy has been used therapeutically for carbon monoxide poisoning in pregnancy with good results reported, although there are limited data on the long-term follow-up of the children.<sup>41,97,108,120,136,169,336</sup> One large series reported 44 women who were exposed to carbon monoxide during pregnancy and were treated with HBO, regardless of clinical severity or gestational age: 33 had term births, one had a premature delivery 22 weeks after HBO during an episode of maternal fever, 2 had spontaneous miscarriages (one 12 hours after severe poisoning and one 15 days after mild poisoning), one delivered a child with Down syndrome, one had an elective abortion, and 6 were lost to follow-up.<sup>88</sup> Details regarding trimester of exposure, maternal carboxyhemoglobin concentration, and severity of symptoms are not available, making it difficult to interpret the reported adverse outcomes. Although HBO appears to be safe for pregnant women and seems to present little risk to the fetus, it is not clear whether HBO can prevent carbon monoxide-related fetal toxicity.

Hyperbaric oxygen is appropriate therapy for any pregnant woman exposed to carbon monoxide with an elevated serum carboxyhemoglobin concentration or evidence of fetal distress. To allow the fetal carboxyhemoglobin to be eliminated, if HBO therapy is not available, 100% oxygen is recommended for all pregnant women for 5 times as long as the time needed for her carboxyhemoglobin concentration to return to the normal range.<sup>194</sup>

Thus, if a pregnant woman's carboxyhemoglobin concentration returns to normal in one hour, she should continue to receive 100% oxygen for at least 5 hours.

## SUBSTANCE USE DURING PREGNANCY

Substance use during pregnancy leads to complex medical and psychosocial effects for the pregnant woman as well as the fetus and newborn infant. With the increased use of cocaine during the latter half of the 1980s and 1990s, there was great interest in determining the effects of cocaine use during pregnancy. As research in this area progressed, many of the critical methodologic issues related to substance use research were highlighted.<sup>99,149,186,238,354</sup>

Substance-using women often have multiple risk factors for adverse pregnancy outcomes, such as low socioeconomic status, polysubstance use, ethanol and cigarette use, sexually transmitted infections, AIDS, malnutrition, and lack of prenatal care. Lack of prenatal care is highly correlated with premature birth, and smoking is associated with spontaneous abortion, growth retardation, and SIDS.<sup>158,348</sup> Other factors not specifically related to substance use such as age, race, gravidity, and prior pregnancies also affect pregnancy outcome. Each of these factors represents a significant potential confounding variable when the effects of a particular xenobiotic such as ethanol or opioids are evaluated during pregnancy and must be controlled for in research design. Many of these factors are also significant confounders in evaluation of postnatal growth and development.

Bias can occur in the selection of study subjects. For example, if all the patients are selected from an inner-city public hospital obstetrics service, minorities may be over-represented. On the other hand, if all the patients are selected from substance-using populations of rural Vermont or West Virginia, minorities may be under-represented. There may be significant differences in socioeconomic status or genetics. If cohorts are followed over a long time, study subjects are frequently lost to follow-up. The ones who continue may be more motivated or may have more problems that need attention?

Categorizing patients into substance-use groups is difficult. Self-reporting of substance use is frequently unreliable or inaccurate and making determinations about the nature, frequency, quantity (dose), or timing (with respect to gestation) of xenobiotic exposure is difficult. Because substance users frequently use multiple xenobiotics, it is difficult to categorize subjects into particular xenobiotic-use groups, and patients using different xenobiotics can be inadvertently grouped together. In fact, there probably are no actual xenobiotic-free control groups.

When urine drug screens are used to identify substance users, there is a high probability of false negatives because drug screens reflect only recent use. This factor is particularly important because substance use tends to decrease later in pregnancy and a negative urine drug screen in the third trimester or at delivery will fail to identify a woman who was using xenobiotics early in pregnancy. Testing for xenobiotics in hair or meconium can improve the accuracy of the analysis with regard to the entire pregnancy.<sup>35,167</sup>

Another bias involves selection of infants who are exposed to xenobiotics. Evaluating newborns who are "at risk," show signs of substance withdrawal, or have positive urine drug screens will miss some exposed infants. When research concerns the neurobehavioral development of children exposed in utero to substances, it is important that the examiners performing the evaluation be blinded to the infants' xenobiotic exposure category. Finally, there is bias against publishing research that shows a negative or nonsignificant effect.<sup>168</sup>

### Ethanol

Approximately 9% of pregnant women (200,000) 15 to 44 years of age report consuming ethanol during the previous month, 4.6% (100,000) report binge drinking, and 0.8% (20,000) report heavy drinking. Of nonpregnant women 15 to 44 years of age, about 55% report consuming ethanol during the previous month, 30% report binge drinking, and 6% report heavy drinking.<sup>286</sup> The highest prevalence of drinking is during the first trimester and decreases in the second and third trimesters. These numbers are consistent with the CDC estimate of a 7.3% risk of an ethanol-exposed pregnancy.<sup>119</sup>

Chronic ethanol use during pregnancy produces a constellation of fetal effects. *Fetal alcohol spectrum disorders* (FASD) is an umbrella term describing the range of effects that can occur in an individual whose mother drank ethanol during pregnancy.<sup>29,311</sup>

The most severe effects occur in the FAS which is characterized by (1) intrauterine or postnatal growth retardation; (2) intellectual disability or behavioral abnormalities; and (3) facial dysmorphism, particularly microcephaly, short palpebral fissures, epicanthal folds, maxillary hypoplasia, cleft palate, a hypoplastic philtrum, and micrognathia.<sup>29,206</sup> A child can be diagnosed with FAS even when a history of regular gestational ethanol use cannot be confirmed.

In an attempt to formalize diagnostic criteria for FAS and other gestational ethanol-related effects, the Institute of Medicine proposed some additional descriptors that are in common use and which have been refined.<sup>143,318</sup> *Partial FAS* is applied to a child with some of the characteristic facial features and with growth retardation, neurodevelopmental abnormalities, or other behavioral problems. *Alcohol-related birth defects* (ARBD) are congenital anomalies other than the characteristic facial features described earlier, for example, cleft palate, which sometimes occurs with regular gestational ethanol use. *Alcohol-related neurodevelopmental disorder* (ARND) describes neurodevelopmental abnormalities or other behavioral problems, which sometimes occur with regular gestational alcohol use.

Differential expression of the syndrome reflects the effects of varying quantities of ethanol ingested at critical periods specific for particular effects. The craniofacial anomalies probably represent teratogenic effects during organogenesis but some CNS abnormalities and growth retardation result from adverse effects later in gestation.

There is considerable controversy about what amount of ethanol consumption causes FASD.<sup>235,243</sup> Some researchers believe that FASD is a result of alcoholism—chronic regular use or frequent bingeing—rather than to low concentrations of gestational ethanol exposure, no matter how little or how infrequent.<sup>218</sup> A high level of consumption would be in the range of 50 to 100 mL of 100% ethanol (4–6 “standard” drinks of hard liquor) regularly throughout pregnancy<sup>318</sup> or binge drinking (at least 5 standard drinks per occasion), with a significantly elevated peak blood ethanol concentration.<sup>101,215</sup> However there are reports of behavioral abnormalities associated with the consumption of as little as one drink per week.<sup>312</sup> In this regard, neither a no-effect amount nor a safe amount of ethanol use in pregnancy has been determined,<sup>156</sup> and therefore the US Surgeon General recommends no ethanol consumption during pregnancy.<sup>246</sup>

The incidence of FAS in the United States is reported as 0.3 to 0.8 per 1,000 children when measured by passive surveillance and record review.<sup>103</sup> In-person expert assessment of a community-based school-age sample reported an incidence of 6 to 9 per 1,000 children.<sup>214</sup> This means that several hundred children with FAS and several thousand with fetal ethanol effects will be born each year; thus, ethanol use is considered the leading preventable cause of intellectual disability in this country.<sup>318</sup> Although the primary determinant of FAS and its effects is the amount of maternal ethanol consumption, there is some evidence that paternal ethanol exposure plays a contributing role.<sup>1</sup>

Ethanol use during pregnancy leads to an increased incidence of spontaneous abortion, premature deliveries, stillbirths,<sup>205</sup> neonatal ethanol withdrawal,<sup>26,241</sup> and possibly carcinogenesis.<sup>163</sup> Infants can be irritable or hypertonic and can have problems with habituation and arousal. Long-term behavioral and intellectual effects include decreased IQ, learning disabilities, memory deficits, speech and language disorders, hyperactivity, and dysfunctional behavior in school.<sup>213,312,319</sup>

Autopsies of children with FAS demonstrate malformations of gray and white matter, a failure of certain regions such as the corpus callosum to develop, a failure of certain cells such as the cerebellar astrocytes to migrate, and a tendency for tissue in certain regions to die.<sup>96</sup> The mechanisms of ethanol-induced teratogenesis are not fully elucidated.<sup>27,128</sup> Much of the work in animals has focused on the developing nervous system, where ethanol adversely affects nerve cell growth, differentiation, and migration, particularly in areas of the neocortex, hippocampus, sensory nucleus, and cerebellum.<sup>123,321</sup>

Several mechanisms are potential contributors to the effects of ethanol.<sup>117,222</sup> Ethanol interferes with a number of different growth factors that affect neuronal migration and development.<sup>349</sup> In addition, ethanol interferes with the development and function of both serotonin and *N*-methyl-D-aspartate (NMDA) receptors. Ethanol, or possibly its metabolite acetaldehyde, also causes cell necrosis directly or through the generation of free radicals and excessive apoptosis.<sup>60,96,132</sup> In particular, craniofacial abnormalities could be related to apoptosis of neural crest cells through the formation of free radicals, a deficiency of retinoic acid, or the altered expression of homeobox genes that regulate growth and development.<sup>321</sup>

One integrative model of ethanol-induced teratogenesis proposes that sociobehavioral risk factors, such as drinking behavior, smoking behavior, low socioeconomic status, and cultural or ethnic influences, create provocative biologic conditions, such as high peak blood ethanol concentrations, circulating tobacco constituents, and undernutrition. These provocative factors exacerbate fetal vulnerability to potential teratogenic mechanisms, such as ethanol-related hypoxia or free radical-induced cell damage.<sup>3</sup>

## Opioids

Opioid use in pregnancy remains a significant cause of both maternal and neonatal morbidity. Over the past 2 decades, use and misuse of opioids, particularly prescription opioids, has been spiraling upward in the United States. Of women 15 to 44 years of age, 25% to 40% are prescribed opioids, in particular hydrocodone, codeine, and oxycodone.<sup>7</sup> These prescription rates are higher for women insured by Medicaid compared to private insurance and for women living in the south compared to the northeast. Similarly, opioid prescription rates for pregnant women are also high, ranging from 10% in a Veterans Administration sample, to 14% in a commercial insurance sample, to 29% in a Medicaid sample.<sup>23,76,89,171</sup> Again there are significant regional (state to state) variations as well as urban versus rural differences in these prescribing patterns during pregnancy that reflect general trends in opioid prescribing.<sup>76,339</sup> Hydrocodone, codeine, and oxycodone are also the primary opioids prescribed during pregnancy.

Past month surveys provide a different perspective. Approximately 21,000 pregnant women 15 to 44 years of age report illicit and prescription opioid misuse and abuse (approximately 0.2% of pregnant women report heroin use, 0.8% report the illicit use of prescription analgesics, and approximately 0.1% report the use of oxycodone).<sup>284,286,309</sup>

Pregnant opioid users are at increased risk for many medical complications of pregnancy, such as hepatitis, sepsis, endocarditis, sexually transmitted infections, and AIDS, and at increased risk for obstetric complications, such as miscarriage, premature delivery, or stillbirth.<sup>99,116</sup> Some of the obstetric complications are related to associated risk factors in addition to the opioid use. Maternal opioid use most commonly affects fetal growth.<sup>99,116,354</sup> There is an increased incidence of low birth weight in babies born to opioid-using mothers compared with control participants, and the effect is greater for heroin than for methadone.

There is extensive clinical experience with Medication Assisted Therapy (MAT) with methadone maintenance during pregnancy. Compared with untreated heroin use, methadone maintenance during pregnancy is associated with better obstetric care, decreased risk of maternal withdrawal, increased fetal growth, decreased fetal mortality, decreased risk of HIV infection, and increased likelihood that a child will be discharged home with his or her parents.<sup>154</sup> Women who receive low-dose methadone and good prenatal care are at increased risk for pregnancy-related complications but have birth outcomes similar to nonusers.<sup>99</sup>

Just as alternative opioid replacement strategies with buprenorphine were introduced for opioid users in general, buprenorphine is more frequently being used during pregnancy especially for women maintained on buprenorphine before becoming pregnant. In one large trial, obstetric outcomes were similar after buprenorphine treatment compared with methadone although more women in the buprenorphine arm dropped out of the study because they did not feel well during the induction of therapy.<sup>154,155</sup> Similar results regarding obstetric outcomes were reported in one study primarily looking

at neonatal abstinence syndrome (NAS).<sup>42</sup> In another large cohort of women on MAT, a small number of women switched from buprenorphine to methadone for a variety of reasons, but some birth outcomes such as gestational age and birth weight were a little better in the buprenorphine group.<sup>224</sup> One group in Australia reported the use of implantable naltrexone in pregnant patients after opioid detoxification.<sup>146,147</sup>

The most significant acute neonatal complication of opioid use during pregnancy is the NAS, which is characterized by hyperirritability; GI dysfunction; respiratory distress; and vague autonomic effects, including yawning, sneezing, mottling, and fever.<sup>144</sup> Myoclonic jerks or seizures also signify neurologic irritability. Withdrawing infants are recognizable by their extreme jitteriness despite efforts at consolation. Approximately 50% to 90% of chronic opioid-exposed newborns show some signs of NAS.<sup>99,154</sup>

Just as opioid use and misuse has increased among the general population overall and pregnant women in particular, so has the frequency of NAS increased in the United States and abroad. In the United States, between 2000 and 2012 the rate of NAS increased from 1.2 per 1,000 to 5.8 per 1,000 live births.<sup>253,255</sup> Again there is significant regional variation. The rate of NAS varied from a low of 0.7 per 1,000 births in Hawaii to 33.4 per 1,000 in West Virginia<sup>165</sup> and is more prevalent in rural compared to urban areas.<sup>339</sup> In 2012, the average cost of hospitalization was \$66,700 for a baby with NAS and \$93,400 for a baby with NAS treated pharmacologically as compared to \$3500 for an uncomplicated term newborn. Considering that approximately 4% of neonatal ICU days overall and in some centers as much as 40% to 50% of neonatal ICU days are attributed to babies with NAS, much of this cost is related to an increased number of infants admitted to NICUs for therapy and to prolonged lengths of stay for treatment.<sup>329</sup> Approximately 80% of the 2012 aggregate cost of 1.5 billion dollars was covered by Medicaid.

The Neonatal alcohol abstinence syndrome typically occurs within one week of birth. Heroin withdrawal usually occurs within the first 24 hours whereas methadone and buprenorphine withdrawal usually occur within 2 to 3 days of delivery. The onset of methadone withdrawal is delayed compared to heroin because methadone has a larger volume of distribution and slower metabolism in the neonate and therefore an increased half-life. The onset and severity of methadone withdrawal may be related to the absolute neonatal serum concentration or possibly to the rate of decline in concentration.<sup>80,175</sup> In one study, methadone withdrawal occurred when the plasma concentration fell below 0.06 mg/mL.<sup>278</sup>

As mentioned previously, the onset and severity of withdrawal is related to which opioids were used; which other prescription medications or substances were used; how much of these prescription medications or other substances was used long-term; how much was used near the time of delivery; the character of the labor; whether analgesics or anesthetics were used; and the maturity, nutrition, and medical condition of the neonate.<sup>77</sup> Acute NAS generally last from days to weeks but as many as 80% of infants were reported to have recurrence of some symptoms such as restlessness, agitation, tremors, wakefulness, hyperphagia, colic, or vomiting for 3 to 6 months.<sup>54</sup> In general, the incidence and severity of withdrawal are greater from methadone than from either heroin or buprenorphine.<sup>144</sup>

In general, babies who are extremely irritable; have feeding difficulties, diarrhea, or significant tremors; or cry continuously should receive pharmacological therapy.<sup>144</sup> The severity of withdrawal as measured by a standardized scoring scale is typically used to determine the need for therapy; several scales are in use although none has been validated.<sup>99,192</sup> Although most hospitals have treatment protocols for NAS, there is significant variation in their use.<sup>31,254</sup> Reducing this variation by training staff to apply these scores in a consistent manner leads to reductions in length of treatment, length of hospital stay, and total dose of opioid administered.<sup>18</sup>

Severe NAS often require pharmacologic therapy, and the typical approach was to provide care in a NICU. However, considering that treatment of withdrawal is recommended to begin with swaddling or tightly wrapping the infant, minimal handling or stimulation, and demand feeding, all in a quiet and comforting environment, the NICU is increasingly being seen as a less-than-ideal environment to provide care. In fact, this phase of

treatment is generally neither standardized nor controlled in clinical trials of pharmacologic therapy.<sup>122</sup>

In one center where a standardized approach to treatment based on a rooming-in model with increased family involvement was implemented on an inpatient non-NICU ward, the proportion of infants treated with morphine decreased from 46% to 27% and the morphine dose decreased from 13.7 mg to 6.6 mg per infant.<sup>137</sup> In addition, the length of stay (LOS) decreased from 16.9 to 12.3 days and the average cost decreased from \$19,737 to \$8,755 per treated infant. This center also used a standardized treatment and weaning protocol. In another center using a similar approach, the proportion of infants treated decreased from 98% to 14%, the average LOS decreased from 22.4 days to 5.9 days, and the average cost decreased from \$44,824 to \$10,259 per infant.<sup>121</sup> In contrast to almost every other study that uses the original or modified version of the Finnegan neonatal abstinence scoring system to determine the need for pharmacologic therapy, this group developed a score focused only on what might be considered an infant's primary needs—the ability to eat, sleep, and be consoled. Pharmacologic therapy was instituted only if maximal nonpharmacologic intervention was unsuccessful and these primary needs could not be fulfilled.

Opioid agonists such as morphine, methadone, buprenorphine, tincture of opium, and paregoric; sedative-hypnotics such as diazepam and phenobarbital; and clonidine have all been used both individually and in various combinations to treat withdrawal. Most centers primarily use oral morphine to treat withdrawal because it is a short-acting pure opioid agonist and the formulation has no additives.<sup>260</sup> Buprenorphine is being increasingly explored as a primary treatment option. Clonidine and phenobarbital are typically used as adjunctive therapies. Few well-controlled trials have evaluated the relative efficacy of various approaches or examined long-term effects of therapy.<sup>248,249</sup>

At one center, sublingual buprenorphine was compared to oral morphine.<sup>154,155</sup> In these trials, buprenorphine was associated with a 5- to 15-day (18%–46%) decreased length of opioid treatment (LOT) and an 11- to 19-day (29%–36%) decreased length of stay (LOS). In one trial comparing buprenorphine to methadone, both the average LOT and the average LOS were both approximately 4.5 days less in the buprenorphine group. In this study, the LOT for buprenorphine was shorter than the LOT in 2 of the 3 buprenorphine versus morphine studies. It is hard to know exactly how to compare these findings, considering that the studies have different patient populations and different treatment algorithms, and that regardless of the opioid chosen the LOT and LOS can decrease in association with standardized opioid treatment and weaning protocols as well as with a standardized and intensified approach to nonpharmacologic intervention. Nonetheless, the evidence suggests that the LOT and LOS are both shorter after buprenorphine compared to either morphine or methadone.

Five percent to 7% of babies showing signs of withdrawal experience seizures, generally by 10 days after birth.<sup>134</sup> Seizures occur more frequently after methadone withdrawal than after heroin withdrawal. These seizures do not necessarily predispose to idiopathic epilepsy; in one small study, children who had withdrawal seizures were without seizures and had normal neurologic examination findings and psychometric testing at one-year follow-up.<sup>81</sup>

Opioid agonists are more effective at preventing withdrawal seizures from heroin or methadone than phenobarbital or diazepam are.<sup>134,157</sup> However, sedative-hypnotics are commonly abused by pregnant heroin users or pregnant women maintained on methadone. Therefore sedative-hypnotic withdrawal seizures can contribute to the overall neonatal abstinence symptomatology, and for this reason, many treatment protocols include the use phenobarbital as a treatment adjunct.

Infants of opioid-using mothers have a 2 to 3 times increased risk for SIDS compared with control participants.<sup>158,159</sup> Proposed mechanisms include a decreased medullary responsiveness to CO<sub>2</sub> or some condition related to the postnatal environment.<sup>99</sup>

Although young children born to opioid users do not seem to have significant differences in behavior compared to control participants, older

children have increased learning problems and school dysfunction particularly related to behavior difficulties.<sup>354</sup>

## Cocaine

Approximately 0.1% of pregnant women in the United States between the ages of 15 and 44 years report previous-month use of cocaine; for 2016, this represented only 1,000 women.<sup>286</sup> This is in contrast to approximately 431,000 female cocaine users between the ages of 15 and 44 years who reported previous-month use for the same period. Compared to the numbers reported during the cocaine epidemic of the 1990s, this is a significant reduction in exposure. Nonetheless, the number of children exposed to cocaine in utero over the past 30 years has been estimated at 7.5 million.<sup>50</sup> The consequences of cocaine use during pregnancy have been extensively reviewed.<sup>139,178,210,258</sup>

The incidence of abruptio placentae may be significant when related to acute cocaine use.<sup>303</sup> Some uncommon perinatal problems include seizures, cerebral infarctions, and intraventricular hemorrhage.<sup>58,258</sup>

Cocaine use is significantly related to decreases in gestational age, birth weight, length, and head circumference, although these growth parameters generally correct by several years of age.<sup>178,210</sup> In addition, these growth effects are exacerbated by concomitant ethanol, tobacco, and opioid use.<sup>178,210</sup> Good prenatal care can mitigate many of these adverse effects of cocaine.<sup>201,269,354</sup>

Significant congenital malformations were reported among some infants who were exposed to cocaine in utero, specifically genitourinary malformations, cardiovascular malformations, and limb-reduction defects.<sup>44,106</sup> However, in one large population-based study, there was no increase in the incidence of malformations.<sup>209</sup>

Teratogenic effects are observed in animal models of in utero cocaine exposure. Decreased maternal and fetal weight gain and an increased frequency of fetal resorption were demonstrated in rats<sup>95</sup>; sporadic physical anomalies are also observed.<sup>59</sup> Teratogenic effects similar to those observed in humans were reported in mice, including bony defects of the skull, cryptorchidism, hydronephrosis, ileal atresia, cardiac defects, limb deformities, and eye abnormalities.<sup>100,202,203,223</sup> Cocaine caused hemorrhage and edema of the extremities and, subsequently, limb-reduction defects in rats when administered during midgestation in the postorganogenic period.<sup>343</sup>

The perinatal effects of cocaine are probably mediated through a vascular mechanism. Cocaine administration in the pregnant ovine model causes increased uterine vascular resistance, decreased uterine blood flow, increased fetal heart rate and arterial blood pressure, and decreased fetal  $PO_2$  and  $O_2$  content.<sup>17,351</sup> Similar effects are reported in rats.<sup>252</sup> Fetal hypoxia causes rupture of fetal blood vessels and infarction in developing organ systems such as the genitourinary system<sup>56,223,308</sup> or the CNS.<sup>53,79,344</sup> Hyperthermia or direct effects of cocaine in the fetus could exacerbate these effects.<sup>36</sup> Limb-reduction defects similar to those attributed to cocaine are produced after mechanical clamping of the uterine vessels.<sup>36,345</sup> A developing concept is that after vasospasm and ischemia, reperfusion occurs with the generation of oxygen free radicals and subsequent injury.<sup>351,352</sup>

Despite the reported malformations and a possible mechanism neither the human epidemiology nor the effects observed in animal models suggest a specific teratogenic syndrome. The risk of a significant malformation from prenatal cocaine exposure is low, but the effect, if one occurs, could be severe.<sup>37,84,106</sup>

One of the greatest concerns about prenatal cocaine exposure is the potential adverse effect on the developing child, and this is an intensive area of epidemiologic research. The most common findings in early infancy are lability of behavior and autonomic regulation; decreased alertness and orientation; and abnormal reflexes, tone, and motor maturity. However, many studies show no effect, especially after controlling for confounding variables.<sup>94,178,210</sup> For some children, effects manifest in later infancy as difficulty with information processing and learning. For school-age children, observed cognitive deficits are often related to the home environment even for children who showed some of the typical neonatal behaviors.<sup>104,178,210</sup> Nonetheless, there is evidence of impairment in modulating attention and impulsivity, which makes handling unfamiliar, complex, and stressful tasks

more difficult,<sup>178,210,216</sup> and these effects are also observed in animal models of prenatal cocaine exposure.<sup>84,129,190,313</sup>

The mechanism of neurotoxicity is not specifically elucidated. As described earlier, for many of the maternal and fetal physical defects, cocaine has direct toxicity, or alternatively, effects could be mediated through hypoxia or oxygen free radicals. Because cocaine interferes with neurotransmitter reuptake, it is likely that cocaine also disrupts normal neural ontogeny by interfering with the trophic functions of neurotransmitters on the developing brain, in particular dysfunction of signal transduction via the dopamine  $D_1$  receptor.<sup>129,190,217</sup> These mechanisms are important in the etiology of neurobehavioral effects.

## BREASTFEEDING

In the United States, breastfeeding is the recommended method of infant nutrition because it offers nutritional, immunologic, and psychological benefits without additional costs. Many women use prescription and non-prescription xenobiotics while breastfeeding and are concerned about the possible ill effects on their infants of these xenobiotics in the breast milk. This concern extends to the possible exposure of infants to occupational and environmental xenobiotics via breast milk.<sup>276,295</sup> The response to many of these concerns can be determined by the answer to the following question: Does the risk to an infant from a xenobiotic exposure via breast milk exceed the benefit of being breastfed?<sup>183</sup>

Pharmacokinetic factors determine the amount of xenobiotic available for transfer from maternal plasma into breast milk; only free xenobiotic can traverse the mammary alveolar membrane. Most xenobiotics are transported by passive diffusion. A few xenobiotics, such as ethanol and lithium, are transported through aqueous-filled pores. The factors that determine how well a xenobiotic diffuses across the membrane are similar to those for other biologic membranes such as the placenta: MW, lipid solubility, and degree of ionization.

Large-molecular-weight xenobiotics, such as heparin and insulin, do not pass into breast milk. Lipid solubility is important not only for diffusion but also for xenobiotic accumulation in breast milk because breast milk is rich in fat, especially breast milk that is produced in the postcolostrual period (~3–4 days postpartum). With a pH near 7.0, breast milk is slightly more acidic than plasma. Consequently, xenobiotics that are weak acids in plasma exist largely as ionized molecules and cannot be easily transported into milk. Conversely, xenobiotics that are weak bases exist in plasma largely as non-ionized molecules and are available for transport into breast milk. In breast milk, ionization of the weak base xenobiotics occurs, and the xenobiotics are concentrated as a result of ion trapping. In other words, xenobiotics that are weak bases could concentrate in breast milk. Whereas sulfacetamide ( $pK_a$  of 5.4, a weak acid) has a concentration in plasma 10 times its concentration in breast milk, sulfanilamide ( $pK_a$  of 10.4, a weak base) is found in equal concentrations in both plasma and breast milk.<sup>183</sup>

The net effect of these physiologic processes is expressed in the milk-to-plasma (M/P) ratio. Xenobiotics with higher M/P ratios have relatively greater concentrations in breast milk. The M/P ratio does not, however, reflect the absolute concentration of a xenobiotic in the breast milk, and a xenobiotic with a high M/P ratio is not necessarily found at a high concentration in the breast milk. For example, morphine has an M/P ratio of 2.46 (is concentrated in breast milk), but only 0.4% of a maternal dose is excreted into the breast milk.<sup>16</sup> In general, for most xenobiotics, approximately 1% to 2% of the maternally administered dose is presented to the infant in breast milk.<sup>183</sup>

The M/P ratio has several limitations. It does not account for differences in xenobiotic concentration that result from (1) repeat or chronic dosing, (2) breastfeeding at different times relative to maternal xenobiotic dosing, (3) differences in milk production during the day or even during a particular breastfeeding session, (4) the time postpartum (days, weeks, or months) when the measurement is made, and (5) maternal disease.

While being cognizant of the limitations, a spot breast milk xenobiotic concentration or a concentration estimate based on the M/P ratio allows

a simplistic estimation of the quantity of xenobiotic to which an infant is exposed, assuming a constant breast milk concentration:

$$\text{Infant dose} = \text{Breast milk concentration} \times \text{Amount consumed}$$

The effect of this dose on the infant depends on the bioavailability of the xenobiotic in breast milk, the pharmacokinetic parameters that determine xenobiotic concentrations in the infant, and the infant's receptor sensitivity to the xenobiotic. These parameters are often different in neonates than in adults and could lead to xenobiotic accumulation; generally, absorption is greater, but metabolism and clearance are reduced.<sup>15</sup> These effects are exaggerated in premature infants.<sup>264,273</sup> The amount of most xenobiotics delivered to infants in breast milk is usually adequately metabolized and eliminated.<sup>183</sup>

Many of the above considerations are theoretical, and the number of specifically contraindicated xenobiotics is quite small.<sup>283</sup> Published guidelines on the advisability of breastfeeding during periods of maternal therapy are generally based on the expected effects of full doses in the infant or on case reports of adverse occurrences. Interestingly, when the reports of adverse effects were reviewed, 37% of cases were in infants younger than 2 weeks, 63% were in infants younger than 1 month, and 78% were in infants younger than 2 months; 18% were in infants 2 to 6 months old; and only 4% were in infants older than 6 months.<sup>12</sup> It seems, therefore, that adverse effects are most likely to be observed in the first few weeks of life, when an infant's metabolic capacity is significantly less than that of an older infant, child, or adult.<sup>8,75</sup>

For most xenobiotics, a risk-to-benefit analysis must be made. For example, lithium is transferred in breast milk and leads to measurable, although subtherapeutic, serum concentrations in a breastfed infant. Although the effects of such exposure to lithium are unknown, many practitioners believe that the benefit of treating a mother's bipolar illness outweighs the potential risk to the infant.<sup>183,294</sup> There is also a small increased risk of carcinogenicity associated with exposure to some environmental xenobiotics through breast milk.<sup>276</sup>

Similarly, the breastfed infant of a woman who smokes is exposed to nicotine and other tobacco constituents, both by inhalation and via breast milk. Although such a child is at increased risk for respiratory illness as a result of exposure to tobacco smoke, some of the risk may be mitigated by breastfeeding.<sup>271,283</sup>

In most cases, women do not need to stop breastfeeding while using pharmaceuticals, such as most common antibiotics. However, "compatibility" with breastfeeding is generally based on a lack of reported adverse effects, which reflects limited clinical experience with a particular xenobiotic in breastfeeding patients. Therefore, in the setting of limited information, exposure to a xenobiotic through breast milk should be regarded as a small potential risk, and the infant should receive appropriate medical follow-up. Not all "compatible" medications are safe in all situations. For instance, phenobarbital can produce CNS depression in an infant if the mother's serum concentration is in the high therapeutic or supratherapeutic range, which often occurs while dosage adjustments are being made. Such a concentration may or may not produce CNS depression in the mother. Nalidixic acid, nitrofurantoin, sulfapyridine, and sulfisoxazole, although generally safe, can cause hemolysis in a breastfed infant with glucose-6-phosphate dehydrogenase deficiency.

When women use substances postpartum, there is delivery of some xenobiotic to the infant via breast milk, and there are rare case reports of infants experiencing adverse effects.<sup>55</sup> Because of these possible direct effects on the baby, as well as the detrimental effects on the physical and emotional health of the mother and on the caregiving environment, the use of substances such as cocaine, methamphetamine, and heroin during the breastfeeding period is discouraged, and women actively using substances are discouraged from breastfeeding.<sup>283</sup> However, women who are or have been abstinent from substance use and are participating in a treatment program are generally encouraged to breastfeed their infants.<sup>4,183</sup>

Although ethanol is not specifically contraindicated for breastfeeding mothers, decreased milk production and adverse effects in infants are noted with maternal consumption of large amounts of ethanol.

Questions sometimes arise regarding possible lead exposure during breastfeeding. Lead crosses into breast milk from blood and is the most likely source of lead exposure for most breastfeeding infants.<sup>196</sup> Approximately 1% of US women between the ages of 15 and 49 years have blood lead concentrations greater than 5 mcg/dL.<sup>92</sup> Some estimates suggest that breast milk concentrations are less than 3% of the maternal blood lead; therefore, if the maternal lead concentration is 5 mcg/dL, then the amount of lead delivered to the infant could be 1.5 mcg/L of breast milk.<sup>124,170</sup> This represents a relatively small exposure. In a sample of breastfed babies from one US city, the mean infant lead concentration was less than 3 mcg/dL, the highest concentration was 8 mcg/dL, and only 7.8% of values were greater than 5 mcg/dL.<sup>196</sup> The current consensus is that the benefits of breastfeeding outweigh the relatively small exposure to lead in breast milk.<sup>347</sup> Blood lead screening for most women is not recommended.

There are, however, some subpopulations of pregnant women at increased risk of elevated environmental lead exposure for whom blood lead screening is recommended. Risk factors for significant lead exposure in pregnant women include recent immigration, pica practices, occupational exposure, poor nutritional status, culturally specific practices such as the use of traditional remedies or imported cosmetics, and the use of traditional lead-glazed pottery for cooking and storing as well as those involved with renovation or remodeling in older homes.<sup>92</sup>

All women should have an assessment of risk for environmental lead exposure. Women at increased risk should have blood lead screening. When possible, pregnant and postpartum women with blood lead concentrations of 5 mcg/dL or higher should be removed from occupational or environmental lead sources and discouraged from practices or activities that result in increased exposure.<sup>92</sup> In addition, some evidence suggests that dietary supplementation of calcium can reduce the mobilization of lead in postpartum women.<sup>133</sup> In cases of elevated maternal lead concentrations, decisions regarding breastfeeding should be made on an individual basis.

In 2007, after the death of a breastfeeding 13-day-old infant whose mother was using codeine, the US FDA issued a public health advisory regarding the use of codeine by breastfeeding women.<sup>333</sup> In the initial case, the mother was found to be compound heterozygous for a *CYP2D6*\*2A allele and a *CYP2D6*\*2x2 gene duplication and therefore an "ultrametabolizer" of codeine.<sup>166</sup> In other words, codeine was metabolized to morphine at an exaggerated rate, and the infant ingested a high dose of morphine via the breast milk. The ultrametabolizer phenotype is present in up to 10% of whites and up to 30% of Ethiopians, North Africans, and Saudi Arabians.<sup>333</sup> In addition, both the mother and the infant were homozygous for the *UGT2B7*\*2 allele, which leads to elevated concentrations of morphine-6-glucuronide, an active metabolite.

Another decreased-function gene variant of *ABCB1* has a role in this codeine toxicity. *ABCB1* codes for a P-glycoprotein involved in transporting morphine out of the CNS. Decreased gene function would lead to increased accumulation of morphine in the CNS and potentially increased toxicity.<sup>306</sup>

Decisions on breastfeeding should be made with the informed involvement of the woman; her physicians; and when necessary, a consultant with special expertise in this field. Guidelines are available from several sources.<sup>39,183</sup>

## TOXICOLOGIC PROBLEMS IN NEONATES

Physiologic differences between adults and newborn infants affect xenobiotic absorption, distribution, and metabolism.<sup>15,160,341</sup> Appropriate administration of xenobiotics to newborn infants therefore requires an understanding of the appropriate developmental state for medication dosing and pharmacokinetics. Even so, approximately 8% of all medication doses administered in NICUs are up to 10 times greater or lesser than the dose ordered,<sup>64</sup> and as many as 30% of newborns in NICUs sustain adverse drug effects, some of which are life threatening or fatal.<sup>16</sup> Pharmacokinetic differences between adults and newborns account for some cases of unanticipated xenobiotic toxicity that occur in newborn infants.

Gastrointestinal absorption of xenobiotics in neonates is generally slower than in adults.<sup>15,160,341</sup> This delay is related to decreased gastric acid secretion, decreased gastric emptying and transit time, and decreased pancreatic enzyme activity. The GI environment of newborns and young infants allows the growth of *Clostridium botulinum* and the subsequent development of infant botulism (Chap. 38). Infantile botulism is reported in infants several weeks of age.<sup>148,326</sup>

Although it is uncommon, cutaneous absorption of xenobiotics is sometimes a route of toxic exposure in a newborn.<sup>87,282</sup> Aniline dyes used for marking diapers are absorbed, causing methemoglobinemia,<sup>282</sup> and contaminated diapers were responsible for one epidemic of mercury poisoning.<sup>22</sup> The absorption of hexachlorophene antiseptic wash has led to neurotoxicity with marked vacuolization of myelin seen microscopically.<sup>180,211,304</sup> The dermal application of antiseptic ethanol has caused hemorrhagic necrosis of the skin of some premature infants. Iodine antiseptics have led to hypothyroidism in mature newborns.<sup>49</sup> An increased potential for absorption and toxicity has followed the application of corticosteroids<sup>112,280</sup> and boric acid<sup>85</sup> to the skin of children with cutaneous disorders.

Other routes of exposure have led to clinical poisoning. Several children inhaled talcum powder and died from acute respiratory distress syndrome.<sup>40,229</sup> Inhalation of mercury from incubator thermometers is a potential risk.<sup>11</sup> One child died after the ophthalmic instillation of cyclopentolate hydrochloride.<sup>24</sup>

Because of differences in total body water and fat compared with adults, the distribution of absorbed xenobiotics differs in neonates.<sup>15,160,341</sup> Water represents 80% of body weight in a full-term baby compared with 60% in an adult. Approximately 20% of a term baby's body weight is fat compared with only 3% in a premature baby. The increased volume of water means that the volume of distribution for some water-soluble xenobiotics, such as theophylline and phenobarbital, is increased.

Protein binding of xenobiotics is lower in newborns compared with adults: the serum concentration of proteins is lower, there are fewer receptor sites that become saturated at lower xenobiotic concentrations, and binding sites have decreased binding affinity.<sup>15,160,341</sup> Protein binding has potential relevance with respect to bilirubin, an endogenous metabolite that at very high concentrations causes kernicterus; bilirubin competes with exogenously administered xenobiotics for protein binding sites. In vitro, certain xenobiotics, such as sulfonamides and ceftriaxone, displace bilirubin from protein receptor sites, which might increase the risk of kernicterus, although this has not been clinically demonstrated. Conversely, bilirubin itself displaces other xenobiotics, such as phenobarbital or phenytoin, leading to increased plasma xenobiotic concentrations.

Newborn infants have decreased hepatic metabolic capacity compared with adults, which can lead to xenobiotic toxicity.<sup>15,160</sup> For example, caffeine, used in the treatment of neonatal apnea, has an extremely prolonged half-life in newborns because CYP1A2 has only 5% of the normal adult activity.<sup>15</sup> Except for CYP1A2, most of the CYP isoenzymes reach approximately 25% of adult activity in newborns by about 1 month of age.

Two disease clusters related to immature metabolic function are described. The "gasping baby syndrome," characterized by gasping respirations, metabolic acidosis, hypotension, CNS depression, convulsions, kidney failure, and occasionally death, is attributed to high concentrations of benzyl alcohol and benzoic acid in the plasma of affected infants.<sup>10,43,113</sup> Benzyl alcohol, a bacteriostatic, was added to IV flush solutions and accumulated in newborns after repetitive doses. The high concentrations of benzoic acid could not be further metabolized to hippuric acid by the immature liver. Immature glucuronidation in neonates is responsible for the "gray-baby syndrome" after high doses of chloramphenicol (Chaps. 31, 46 and 54).<sup>138</sup>

The umbilical vessels are a common site of vascular access in sick neonates. Because blood drains into the portal vein, it is possible that IV medications experience a "first-pass" effect, although whether this route of xenobiotic administration affects metabolism or clearance has not been well studied. Most functions of the kidney, including glomerular filtration rate (GFR) and tubular secretion, are relatively immature at birth;<sup>15</sup> the GFR

of a newborn is approximately 30% of that of an adult. Xenobiotics such as aminoglycosides and digoxin are excreted unchanged by the kidney and therefore depend on glomerular filtration for clearance. Dosing of these xenobiotics in a newborn must account for these differences.

An interesting association has been made periodically over the years between the use of erythromycin, particularly in the first 2 weeks of life, and idiopathic hypertrophic pyloric stenosis.<sup>62,140,204,288,314</sup> Although erythromycin is known to interact with motilin receptors in the antrum of the stomach, no specific etiology has been defined.<sup>131</sup>

Very little specific information is available to guide clinicians in the management of xenobiotic poisoning in newborn infants. In the case of cutaneous exposure to a xenobiotic, absorption is probably already complete by the time toxicity is noted. Nonetheless, the xenobiotic should be discontinued and the skin surface should be decontaminated. In the case of oral exposure, gastrointestinal decontamination is not generally performed in neonates, and neonates are at increased risk of fluid, electrolyte, and thermoregulatory problems after gastric lavage or the use of cathartics. Multiple-dose activated charcoal was used in a 1.4-kg, 2-week-old premature infant to treat iatrogenic theophylline toxicity.<sup>300</sup> Hemodialysis, hemoperfusion, and exchange transfusion can be used in neonates to treat xenobiotic toxicity but require care in specialized units that experience with these extra-corporeal modalities (Chaps. 6 and 31).

## SUMMARY

- Human embryos and fetuses are exposed to xenobiotics through the placenta of the pregnant woman; the neonates are exposed to xenobiotics via breast milk.
- Xenobiotic effects on developing humans include both congenital malformations as well as neurobehavioral abnormalities that manifest later in life.
- The use of xenobiotics in a pregnant or breastfeeding woman is a complex area of medical practice and presents clinicians with potentially difficult management decisions regarding the benefit of therapy to the mother and the risk to the mother or fetus of xenobiotic exposure.
- The goal is to optimize benefit for both the mother and the child but at least to minimize the risk to the fetus. In almost all cases, the primary approach is to fully and appropriately treat the mother.
- Appropriate management of many of the potential problems is facilitated by the coordinated efforts of obstetricians, perinatologists, neonatologists, pediatricians, and toxicologists.

# PEDIATRIC PRINCIPLES

Elizabeth Q. Hines and Jeffrey S. Fine

Poisoning remains a significant but preventable cause of pediatric injury. Phone calls to poison control centers regarding pediatric exposures are more frequent than those regarding any other age group. Pediatricians have been leaders for 60 years in helping to establish and promote the study of medical toxicology, supporting the use of regional poison control centers and promoting the principles of poison prevention. Although the basic approaches to the medical management of toxicologic problems outlined in Chaps. 3 and 4 are generally applicable to both children and adults, some issues such as child abuse by poisoning are of particular concern. This chapter provides a perspective on the application of generally accepted toxicologic principles to children.

## EPIDEMIOLOGY

To understand the magnitude of pediatric poisoning and its impact, epidemiologists examine multiple parameters, such as exposure, morbidity, mortality, and cost; however, these parameters are often difficult to measure accurately. An important source of information on the extent and effects of poisoning exposures in the United States is the American Association of Poison Control Centers' (AAPCC's) National Poison Data System. Every year, the AAPCC compiles standardized data collected from poison control centers throughout the United States; the 2015 annual review includes information submitted by 55 regional poison control centers. In the following discussion, comments on AAPCC data refer to cumulative information from the previous 5 published reports covering the years 2011 to 2015 (Chap. 130).

Each year, the AAPCC reports approximately 1.1 million potentially toxic exposures in young children from birth to 6 years of age that account for almost half (48%) of all reported exposures in the AAPCC database. Pediatric exposures involving all children and adolescents younger than 19 years account for 61% of all reported exposures. Of the reported pediatric exposures in children and adolescents, young children (younger than 6 years) account for 78%, school-age children (between 6 and 12 years) account for 10%, and adolescents (between 13 and 19 years of age) account for 12%. Females represent 43% of the reported poisoning exposures in young children and 58% of the reported exposures among adolescents.

Among the AAPCC-reported xenobiotic exposures in young children, 99% are coded as unintentional. There is some controversy regarding the use of the term *unintentional* with respect to childhood poisoning. A toddler quite purposefully *intends* to ingest a substance but does *not intend* to injure or harm him- or herself. *Unsupervised* is a term preferred by some epidemiologists to better describe the etiology of these exposures.<sup>110</sup> In contrast, 39% of reported adolescent exposures are coded as unintentional, and 56% of adolescent exposures are coded as intentional. This shift in intentionality is due to an increased frequency of adolescent intentional substance use, abuse, and suicidal exposures. This high frequency of intentional poisoning in adolescents has been reported by others.<sup>36,141,183</sup>

Table 31-1 shows the leading causes of AAPCC-reported exposures in children under 6 years. Exposures in this age group include xenobiotics that are commonly found around the house, such as cleaning products, cosmetics, plants, hydrocarbons, and insecticides as well as pharmaceuticals. It is important to understand that Table 31-1 lists the most commonly reported exposures, but that not all of these reported exposures are confirmed exposures and not even all confirmed exposures lead to serious morbidity or mortality. For example, children are most frequently exposed to cosmetic products; however, the amount ingested is typically small and most cosmetics manufactured in the United States are nontoxic, making the outcome of exposure minor.

Clinically significant exposures are unusual in children younger than 6 months. When they do occur, they most commonly result from the inadvertent administration of an incorrect drug or drug dose by a parent,<sup>23,62,110,126</sup> intentional administration of a drug by a parent or sibling,<sup>45,78</sup> or passive exposure (eg, to the smoke of "crack" cocaine or phencyclidine).<sup>17,77,128,158,191</sup> Any poisoning in a child younger than one year of age should be carefully evaluated for possible child abuse or neglect (see later discussion).<sup>78</sup>

Several characteristics typically associated with ingestions by young children differentiate them from ingestions by adolescents or adults: (a) they are without suicidal intent; (b) there is usually only one xenobiotic involved; (c) the xenobiotics are usually nontoxic; (d) the amount is usually small; and (e) toddlers usually present for evaluation relatively soon after the ingestion is discovered, generally within 1 to 2 hours. The peak age for childhood poisoning is between 1 and 3 years.<sup>23,31,110,155</sup> Unintentional ingestion is unusual after age 5 years although when it occurs it is sometimes the result of mistakenly consuming a xenobiotic from a mislabeled container.<sup>26</sup> Some intentional ingestions between the ages of 5 and 9 years result from intrafamilial stress or suicidal intent. After age 9 years and through adolescence, overdose or poisoning frequently results from either suicidal gestures or suicidal attempts or from the adverse effects of alcohol or substance use. This previously discussed age-dependent shift in intentionality toward substance use and abuse and suicide is associated with a significant change in outcome. Only 1% of exposed children under 6 years have a recorded outcome as moderate, major, or death compared to 17% of adolescents (Table 31-2).

The peak age for hospitalizing young children exposed to xenobiotics is between 1 and 3 years, reflecting the peak age of exposure. Whereas hospitalization of children younger than age 2 years typically results from exposure to nonpharmaceutical xenobiotics, children older than 2 years as well as adolescents are more commonly exposed to pharmaceuticals.<sup>55,63,183</sup> Adolescents are also thought to be more frequently hospitalized than children after exposure to xenobiotics but this is a subject of debate.<sup>63</sup> This is a result of the need for medical management and, often, psychiatric hospitalization. As many as 30% of children who experience one ingestion will experience a repeat ingestion; adolescents are particularly prone to recidivism.<sup>63,86</sup> Children who ingest poisons are also at a greater risk for other types of injuries.<sup>15,53</sup>

Another source of data related to poisoning morbidity is the National Electronic Injury Surveillance System (NEISS) online database maintained by the US Centers for Disease Control and Prevention (CDC), which provides information on emergency department (ED) visits and hospitalizations.<sup>32</sup> For the period 2005 to 2014, the CDC estimates approximately 45,000 ED visits and 3,400 hospitalizations (8%) per year for young children 0 to 5 years who are exposed to a xenobiotic. Children 6 to 12 years old account for approximately 10,000 ED visits and 1,000 hospitalizations (10%) per year and adolescents 13 to 19 years old account for approximately 109,000 ED visits and 21,000 hospitalizations (19%) per year.

In a published review of NEISS data related to medication exposures in young children, approximately one-half of the ED visits were the result of unsupervised medication exposures and one-half were the result of adverse drug events after caregiver medication administration.<sup>110</sup> Approximately one-half of the medications were prescription pharmaceuticals and the other half were over-the-counter products. The most commonly involved prescription medication categories were opioids, benzodiazepines, antidepressants, beta adrenergic antagonists, and amphetamines. Ninety-two percent of all over-the-counter exposures involved acetaminophen (APAP), cough and cold products, ibuprofen, and diphenhydramine. The admission

**TABLE 31–1** Average Annual Totals for the Most Common Pediatric Xenobiotic Exposures Reported to the American Association of Poison Control Centers (2011–2015)<sup>a,b</sup>

Age Younger Than 6 Years	
Category	Number of Exposures
Cosmetics and personal care products	154,459
Cleaning substances	116,366
Analgesics	104,870
Topical preparations	67,231
Vitamins	49,005
Antihistamines	45,323
Insecticides, pesticides, and rodenticides	36,353
Plants	29,603
Gastrointestinal preparations	29,377
Antimicrobials	28,836
Ages 6–12 Years	
Category	Number of Exposures
Cosmetics and personal care products	9,342
Analgesics	8,657
Antihistamines	7,160
Vitamins	6,504
Cleaning substances	5,867
Bites and envenomations	5,759
Plants	5,051
Stimulants and street drugs	4,968
Cough and cold preparations	4,743
Cardiovascular pharmaceuticals	4,045
Ages 13–19 Years	
Category	Number of Exposures
Analgesics	23,064
Antidepressants	9,225
Sedative–hypnotics	7,286
Stimulants and street drugs	7,267
Cough and cold preparations	6,478
Cleaning substances	6,394
Antihistamines	6,130
Cosmetics and personal care products	6,051
Bites and envenomations	4,743
Anticonvulsants	2,554

<sup>a</sup>See Chap. 130 for references and discussion. <sup>b</sup>Does not include the American Association of Poison Control Centers' category "foreign bodies."

**TABLE 31–2** Outcome of Reported Pediatric Xenobiotic Exposures (2011–2015)<sup>a</sup>

Age (years)	Effects (% of Reported Exposures) <sup>b,c</sup>			
	Minor or None	Moderate	Major	Death
0–5	99	0.97	0.08	0.003
6–12	97	3	0.18	0.007
13–19	83	15	1.5	0.04
All children and adolescents 0–19	97	2.8	0.26	0.008

<sup>a</sup>See Chap. 130 for references and discussion. <sup>b</sup>Approximate percentage. <sup>c</sup>Minor is minimal signs and symptoms, often not requiring therapy or had no follow-up; moderate is more pronounced, prolonged, or systemic signs and symptoms, often requiring therapy; and major is life-threatening signs and symptoms.

rate in this population was 18.5% for unsupervised ingestions and 6.0% for caregiver-administered medication events.

Although the AAPCC reports overall outcome related to age, it does not specifically stratify outcome of exposure to individual xenobiotics by age. In a multiyear review published in 1992, the AAPCC did report the xenobiotics that caused the greatest number of major and fatal effects in young children. The categories associated with the greatest number of major effects included cleaning substances, cardiovascular drugs, hydrocarbons, sedative/hypnotics, and antidepressants.<sup>107</sup> A more recent study reported a shift in the substances with highest morbidity requiring pediatric intensive care unit (PICU) admissions. PICU admissions following unintentional ingestions were more frequently due to buprenorphine/naloxone, cardiac medications, and alpha-2-agonists. However, PICU admissions following intentional ingestions were due to medications from 43 different drug classes; patients frequently took their own medications, over-the-counter medications, or substances they obtained from a friend often with suicidal intent.<sup>54</sup>

Other national and international reports of hospitalized patients include a similar distribution of xenobiotic exposures that cause significant morbidity and hospitalizations.<sup>4,10,33,197</sup> However, in rural areas of many developing countries, kerosene and pesticides are the leading causes of xenobiotic-related hospitalizations, and the spectrum of pharmaceutical exposures is often different (Chap. 136).<sup>2,72,74,127,134,136</sup>

Poisoning accounts for approximately 2% of young childhood and 7% of adolescent injury-related deaths in the United States.<sup>32</sup> Based on information from death certificates filed in state vital statistics offices as well as demographic information provided by funeral directors, the CDC reports 1023 poisoning deaths in children younger than 6 years of age from 2005 to 2014 for an average of about 102 per year. These deaths represent a 78% decrease from the 456 deaths reported by the CDC in 1959.<sup>31</sup> There are several factors responsible for this decrease, including improved poisoning prevention strategies such as child-resistant closures and improved medical care. In addition, some industrial or pharmaceutical products previously found around the home have been replaced with less toxic products or were reformulated to safer concentrations.<sup>28</sup> It is also possible that there has been a decrease in reporting (Chap. 130).

Although the AAPCC data provide a remarkable amount of epidemiologic information, there are questions about the accuracy of the data.<sup>75,76,190</sup> For example, as mentioned earlier, the CDC reported 1023 poisoning-related deaths in children younger than 6 years of age from 2005 to 2014. During the same period, the AAPCC reported 253 deaths in young children. A primary weakness of the AAPCC data is due to its voluntary reporting method of ascertainment and it must be recognized that many significant poisonings go unreported to poison control centers. In Rhode Island, only 45 of 369 poisoning deaths were reported to the regional poison control center<sup>105</sup> (Chap. 130).

According to the 2013 AAPCC National Poison Database System pediatric fatality review, 47% of the reported pediatric fatalities resulted from

unintentional exposures. Of these 47% were environmental exposures, mostly carbon monoxide poisoning, 40% were xenobiotic ingestions, and 10% were therapeutic errors.<sup>111</sup> Fifty-three percent of AAPCC-reported pediatric fatalities were the result of intentional exposures primarily related to substance use, abuse, and suicidal intent.

There are some significant etiologic differences between children and adolescents, particularly with regard to the lethality of xenobiotics. According to the 2013 NPDS pediatric fatality review, the xenobiotics causing the greatest number of childhood deaths were carbon monoxide, household products (gasoline, batteries, cleaners, laundry detergent, lamp oils), and pharmaceuticals, with opiates (buprenorphine and methadone) accounting for 10% of the unintentional childhood deaths. In contrast, the xenobiotics causing the greatest number of adolescent deaths were “designer drugs” (psychogenic phenylethylamines and synthetic cannabinoids), prescription opioids (methadone, oxycodone, hydrocodone, buprenorphine), and antidepressants. Unfortunately, there is an increasing trend in exposures of adolescents to these substances, and although the overall number of actual deaths from use, abuse, and suicide remain too small to comment on statistically, they are of concern.

The most notable difference between the xenobiotics causing pediatric morbidity and mortality today and studies from the 1960s and 1970s is that salicylates are no longer a leading cause of reported poisoning morbidity and mortality.<sup>40,44</sup> This change is likely related to a combination of factors, including federal regulations requiring child-resistant closures, the 81-mg dose form replacing higher doses as the most common formulation of aspirin prescribed, as well as the overall decreased use of aspirin in children (Chap. 37).<sup>18,38,84,129,147</sup>

Poisoning also has an economic cost. An ED visit for a poisoned child costs \$1,077, on average, while the mean charge for hospitalization is \$11,792, which can vary significantly based on the length of stay and outcome. Based on the estimated number of poisoned children seen in the ED each year, the total US health care cost for emergency care would be estimated as \$162.3 million dollars.<sup>131</sup> According to the CDC in 2010, for fatal poisonings of children and adolescents, the average medical cost was approximately \$6,000, but the average work loss cost was \$1.9 million for a total cost of \$1.9 billion.<sup>32</sup>

## BEHAVIORAL, ENVIRONMENTAL, AND PHYSICAL ISSUES

An oversimplification of the etiology of childhood poisonings would be the formulation that unsupervised toddlers exploring their environment inadvertently ingest xenobiotics. However, this approach ignores the complex interplay of factors that contribute to most ingestions in children.

One approach to understanding injury causation uses the Haddon Matrix.<sup>73</sup> Applying this model to poisoning, there are 3 interacting factors: the patient (host), the xenobiotic (agent), and the environment. These factors interact during 3 phases: preinjury, injury, and postinjury. The factors themselves contribute to the likelihood, nature, magnitude of, and host response to an injury. Modification of these factors helps reduce the frequency or severity of an injury.

For example, if a 2-year-old child finds a tablet there is a risk of ingestion. Storing the tablets in a child-resistant container (CRC) or storing the container out of reach can help to reduce the risk of ingestion. In this case, both the agent and the environment are modified in the preinjury phase. However, both of these strategies are considered active prevention strategies, as they require the caregiver to actively replace the top back on the container or actively place the container back on a high shelf. Another method of preinjury prevention involves passive prevention. For example, if the tablet is an iron-containing multivitamin, limiting the amount of iron in each tablet would make the formulation of the product safer overall. In this regard, the availability of a safer product is passive for the user but active for the manufacturer or for regulators.<sup>29</sup>

The injury phase covers both the ingestion and the initial pathophysiologic host response. Again, particular factors determine the nature and extent of injury. Continuing the example above, if the tablet is a 325-mg APAP

tablet, the ingestion will not lead to injury. However, if the tablet is a 0.2-mg clonidine tablet, there is a higher likelihood of toxicity.

The postinjury phase is concerned with both the ongoing host response and the medical management of the patient who is poisoned. In this phase, it would be determined whether the 2-year-old child with a clonidine ingestion is manifesting signs of toxicity, such as coma or hypotension; whether the child requires treatment with activated charcoal (AC), intravenous (IV) fluid, or naloxone; and whether the child requires hospital admission.

This paradigm is only a model. In reality, it is often difficult to examine any individual factor independently, and the relative contributions of these factors are not well defined. Nonetheless, consideration of the individual factors of host, agent, and environment allows us to focus on several relevant aspects of poisoning in children.

Childhood and adolescence are times of tremendous growth and development.<sup>205</sup> Some of these physical and social changes place children and teenagers at increased risk for poisonings. By 7 months of age, an infant can sit up and can pivot to grab an object; by 9 to 10 months of age, most infants can creep and crawl; by 15 months of age, most toddlers are walking quite competently and eagerly exploring. Between 9 and 12 months of age, a skillful pincer grasp with the thumb and forefinger develops that allows the child to pick up small objects. Throughout this period, one of the child's primary sensory experiences is sucking on or gumming objects that are placed in the mouth. Thus, the combination of 3 developmental skills—the ability to move around the home and depart the immediate view of a guardian, the ability to pick up and manipulate small objects, and the tendency of children to put things in their mouths—places them at risk for poisoning.

As children develop socially, they desire to become more like their parents and they tend to imitate behaviors such as taking medicine or using mouthwash. Children are typically taught that medicine is good for them when they are sick. Many children's medicines are sweetened and flavored to make them more palatable, and many parents inappropriately encourage their children to take medicines by telling them “it tastes like candy.” Children are observed “making tea” from plants or “making pizza” with mushrooms from the yard.<sup>26</sup>

As children become more mobile, agile, and curious, xenobiotics that were previously outside their reach become accessible even when stored in difficult-to-reach places. Evidence suggests that some parents underestimate the developmental skills of their children.<sup>53</sup> Although 87% of parents believe unintentional injuries and poisonings are preventable, only 68% actually take action such as using safety belts or car seats. These parents also consider “being careful” as an effective preventive action and only 10% take any action toward removing or securing poisons.<sup>52</sup> Unfortunately, a primary motivator to shift parental perception of risk and precipitate action occurs only after a child poisoning event or a near miss when it is too late. Additionally, there is often the risk of perceived safety if an event is not associated with any morbidity.<sup>66,130</sup>

As previously discussed, some of the reasons why a child ingests a pill are that it is there, it looks and maybe tastes like candy or food, or the child is mimicking the behavior of a parent who ingests medicines or vitamins to cure illness and improve health. However, these reasons may not be sufficient to explain why xenobiotic exposures occur. Another aspect of poisoning that must be considered is the interaction between the child's temperament and the social environment.

Many authors have tried to identify psychosocial predictors for childhood poisoning in general and for repeat poisoning in particular.<sup>21,56,87,90,173</sup> As many as 30% of children repeatedly ingest xenobiotics, frequently the same xenobiotic. Factors associated with single and repeat episodes of childhood poisoning include hyperactivity, impulsive risk-taking behavior, rebelliousness, and negativistic attitude. Other factors seem to be associated more with the quality of supervision by parents or guardians, who themselves are experiencing medical illnesses, depression, or social isolation.<sup>90</sup> Finally, a stressful environment or a major social problem also contributes.<sup>167,174</sup>

With regard to the xenobiotic, a number of issues affect the preinjury and injury phases, and modification of any one of the interacting factors of

host, xenobiotic, or environment potentially prevents or reduces the severity of injury. By decreasing the inherent toxicity of household products available around the house, the likelihood of injury is reduced after exposure to one of these products. For example, less toxic rodenticides such as warfarin replaced more toxic ones such as thallium or sodium monofluoroacetate and relatively nontoxic paradichlorobenzene mothballs have largely replaced the relatively more toxic camphor-containing mothballs.

It is also possible to reduce the likelihood of ingestion by making a xenobiotic unpalatable. Denatonium benzoate is an aversive bitter xenobiotic that is added to some liquids such as windshield washer fluid and antifreeze to prevent unintentional poisoning.<sup>85</sup> However, some trials show that whereas older children respond negatively to these xenobiotics with the first taste, younger children have already ingested 1 to 2 teaspoonfuls before being deterred by the bitter flavor.<sup>20,166</sup> This is an important consideration because even a small amount of a xenobiotic such as methanol can be toxic (see later discussion). The actual efficacy of denatonium benzoate in poison prevention is largely unstudied.<sup>148</sup>

The problem of unintentional ingestions is compounded by poison “look-alikes,” xenobiotics that resemble candy or food products.<sup>57</sup> Some common examples are ferrous sulfate tablets and vitamins that look like common candies and fuel oils that come in cans resembling soft drink containers. Many shampoos and dishwashing detergents are given lemon or strawberry scents and have pictures of fruits on the labels. More recently changes in marijuana legalization across the country have led to more edible marijuana products coming to the market. Children easily confuse marijuana cookies and candies with their traditional counterparts. In states where these products are legally sold, the number of poisoned children is climbing.<sup>19,188</sup> Children are not always able to distinguish poison “look-alikes” from real candies, fruits, and sodas, and they may be attracted to bright colors, pleasant smells, and appealing packages. Eliminating these “look-alikes” might prevent some unintentional ingestions.

Probably the most significant changes to xenobiotics themselves have occurred in the physical characteristics with regard to packaging and dispensing of pharmaceuticals and some other xenobiotics with child-resistant closures mandated by the Poison Prevention Packaging Act of 1970 (Chap. 1).<sup>29,39</sup> According to the act, “child-resistant” means that the packaging must be effective at preventing 85% of children from opening the package and yet allow 90% of adults to open the package. This legislation is credited with causing a significant reduction in morbidity and mortality caused by poisoning from aspirin and other regulated products, although this analysis was challenged.<sup>38,146,186</sup> Child-resistant closures are also credited with reducing the number of toxic exposures to kerosene.<sup>101</sup>

Although child-resistant containers are a significant deterrent to unintentional ingestions in toddlers, they are not completely effective; by definition, they allow 15% of children to gain access. Problems include the dispensing of pharmaceuticals in nonresistant containers, not properly closing child-resistant containers, leaving pharmaceuticals out of the child-resistant container, and transferring products to a different nonresistant container.<sup>30,172</sup> Up to 70% of potentially toxic pharmaceuticals are stored in non-child-resistant or in improperly functioning child-resistant containers. Several studies identified poor functioning of the closures when there is sticky liquid or pill residue around the top or in the screw threads of the child-resistant container.<sup>86,94,195</sup> A false sense of security associated with these closures leads some parents to be less compulsive regarding safe storage of the containers.<sup>66,130</sup> A double barrier, such as a unit-dose dispenser within a child-resistant container or a blister pack, is recommended for a few pharmaceuticals associated with significant poisonings such as iron and antidepressants.<sup>94</sup> Recently, flow restrictor valves were voluntarily added to some over-the-counter analgesic liquid products to help decrease the volume of liquid dispensed when the child-resistant closure is not fully secured or the child is able to breach the closure mechanism.<sup>109</sup>

In 1997, the Food and Drug Administration (FDA) issued a regulation to package products with 30 mg or more of elemental iron per tablet in unit-dose packages such as blister packs.<sup>59</sup> The intent of this regulation was to

reduce the likelihood of iron poisoning in children. Even before this regulation was instituted, the number of fatal childhood iron ingestions declined significantly; therefore, it is not known how much if any of the decrease was related to the mandated packaging changes. In any case, the rule was overturned in 2003, when it was determined that the FDA did not have the statutory authority to regulate a drug for the purpose of poison prevention.<sup>60</sup> As yet there is no evidence of a resurgence of iron-related fatalities.

A discussion of containers and storage naturally leads to a consideration of the third factor in the injury-causation model discussed earlier, the environment, which is particularly important in the preinjury and the injury phases. Approximately 80% of childhood pharmaceutical ingestions occur at home; most of the remainder occurs at the homes of grandparents, other relatives, and friends. At home, the medicine usually belongs either to the child or to a parent, although a significant number of medications, both at home and away from home, belong to a grandparent.<sup>86,106</sup> Grandparents, other relatives, and family friends without children at home often do not obtain or retain medications in child-resistant containers and are not as attentive to safe storage practices. Poison prevention education directed to these groups is particularly helpful.<sup>119</sup>

Medications are frequently kept in the kitchen or bedroom while they are being used.<sup>86,195</sup> In the kitchen, medications are stored in the refrigerator, on the table, or on the counter; in the bedroom, medications are left on a dresser or bedside table. A parent’s or grandparent’s belongings are another location where medications are commonly found. Interestingly, there are no significant differences in the storage practices in the homes of children who ingest and those who do not ingest medicines, so storage practices alone cannot predict the likelihood of childhood poisoning.<sup>173,195</sup>

One important caveat relates to the storage of nonpharmaceutical xenobiotics, particularly those in liquid form. These types of xenobiotics should never be transferred for storage to familiar household containers, such as food jars or wine or soda bottles; stored in areas low to the ground such as beneath sinks; or kept in cabinets that do not have child-resistant locks. Both children and adults have been unintentionally exposed to xenobiotics, such as sodium hydroxide, pesticides, hydrocarbons, and potassium cyanide, that were stored in bottles in the refrigerator.<sup>182</sup> Many of the kerosene exposures reported from developing countries occur because the kerosene is stored in water bottles, jugs, or other containers in easily accessible locations. When the weather is hot, children mistake the clear liquid kerosene for water.<sup>1,2,165</sup>

## HISTORY OF THE INGESTION

The appropriate management of any poisoned patient is influenced by the history of the exposure. Except in rare cases of child abuse, parents or guardians generally provide information to the fullest extent possible. As a rule, in the case of children, the xenobiotic and time of ingestion are known. However, the reported number of pills or volume of liquid ingested is rarely accurate.<sup>80,150</sup> Clues to the amount ingested are the number of pills or volume of liquid in a bottle before and after an ingestion, the number of pills set out on the night table, or the area of a spot of liquid after a spill. When symptoms are suggestive of poisoning but the history is inadequate, information about possible exposure outside of the home, such as with a babysitter, grandparent, friend, or other relative, should be obtained because approximately 15% of childhood poisonings occur outside the home.<sup>86,138</sup>

In contrast, many adolescents are not forthcoming when relating the history of an intentional ingestion, especially when they are depressed, suicidal, or concerned about the response of their guardian or parent. When caring for these patients, the clinician must use the history provided but should remain skeptical about the reported type and number of xenobiotics ingested, as well as the time of ingestion.

When a child is suspected of being the victim of abuse or intentionally poisoned by a parent or guardian, the health care provider must ensure that (a) the history of the poisoning remains consistent over time and among people providing the details of the event, (b) the child’s clinical presentation is consistent with the history of the poisoning, and (c) the reported actions are consistent with the child’s developmental level.

## GASTROINTESTINAL DECONTAMINATION

Chapter 5 is devoted to a complete discussion of gastrointestinal (GI) decontamination. This section reiterates and emphasizes only a few important points.

As described earlier, children generally ingest small quantities of a single xenobiotic. For most of these ingestions, gastric emptying is unnecessary. Some examples of nontoxic ingestions are eating a crayon or the leaf of a jade plant, licking the cap of a household bleach container, or swallowing 2 adult-strength APAP tablets.

Orogastric lavage is a method of gastric emptying occasionally indicated for the most serious ingestions. Orogastric lavage typically requires a very large bore 40-French tube in order to guarantee that the interior diameter and side-port holes are large enough to allow pill fragments to effectively pass back out through the tube. Small children, however, cannot generally tolerate such a large orogastric lavage tube, and a smaller tube is unlikely to be effective for removing large pills or fragments from the stomach of a small child. Additionally, placement of an orogastric tube is an unpleasant and frightening procedure for an infant or child. There is a risk of local trauma from tube placement, and there is the potential for more serious injury such as esophageal perforation. Also, many children vomit during placement of an orogastric tube, increasing the risk for aspiration. Therefore, the use of orogastric lavage is practically limited to adolescents with large potentially fatal ingestions. Orogastric lavage should never be used as a form of punishment or as a form of education. The patient should be intubated to protect the airway before orogastric lavage if the patient has a diminished gag reflex or a depressed level of consciousness.

Historically, administration of syrup of ipecac to poisoned patients was considered a primary emergency intervention and the availability of syrup of ipecac in the home was a primary tenet of pediatric anticipatory guidance. Since 2004 the American Academy of Pediatrics, the American Academy of Clinical Toxicology, and the European Association of Poison Control Centers and Clinical Toxicologists have all recommended against the use because of its unproven benefit, its adverse effects, and its abuse potential.<sup>6,8</sup>

Activated charcoal (AC) is a current mainstay of poison treatment in EDs.<sup>5,37</sup> Children will generally drink AC when coaxed to do so if the AC is disguised in a baby bottle or soft drink container or sweetened with juice or sorbitol.<sup>192</sup> A nasogastric or orogastric tube should rarely ever be inserted to administer AC in an awake patient. Placement of the tube, the presence of AC in the stomach, the effects of the xenobiotic, all may make the child vomit, making aspiration of AC or stomach contents a risk. For AC to be used safely in a patient who is comatose and who does not have a gag reflex, the patient should be intubated and the airway protected first, prior to insertion of an orogastric tube. Because of these risks, AC alone is unnecessary for a nontoxic or minimally toxic ingestion.

## METHODS OF ENHANCED ELIMINATION

For consequential poisoning with xenobiotics such as methanol, ethylene glycol, salicylates, lithium, and theophylline, hemodialysis is the optimal technique to enhance elimination. It is feasible to perform these extracorporeal techniques on newborns or small infants in appropriately equipped centers with dedicated personnel. The primary limiting factor is the ability to obtain vascular access.<sup>124,177,178</sup> However, even large centers that routinely do hemodialysis in children will periodically not be able to manage very small infants. Peritoneal dialysis was used for the treatment of ethanol intoxication in a child,<sup>71</sup> but this technique is not recommended.

Exchange transfusion is occasionally used to enhance xenobiotic elimination. This technique is potentially useful for a xenobiotic with a small volume of distribution when multiple-dose AC cannot be administered, the xenobiotic is poorly adsorbed to AC, and when access to specialized hemodialysis or hemoperfusion is not readily available. Exchange transfusion was used successfully for poisoning by salicylates<sup>50,117</sup> and theophylline.<sup>16,135,161</sup> Another xenobiotic for which exchange transfusion is a potential therapeutic alternative is chloral hydrate.<sup>11</sup>

**TABLE 31–3** Xenobiotics That Cause Severe Toxicity to an Infant After a Small Adult Dose, a Single Pill, or a Small Volume

β-Adrenergic antagonists (sustained release)
Benzocaine
Bupropion
Caffeine (Powdered)
Calcium channel blockers (sustained release)
Camphor
Caustics (sodium hydroxide)
Chloroquine
Clonidine
Cyclic antidepressants
Cycloplegics (ophthalmic)
Diphenoxylate and atropine (Lomotil)
Ethylene glycol
Imidazolines (nasal spray)
Methanol
Methyl salicylate (oil of wintergreen)
Nicotine (liquid)
Opioids
Pesticides (organophosphates and carbamates, phosphides, and tetramine)
Phenothiazines
Quinine
Sulfonylureas
Theophylline

## XENOBIOTICS THAT ARE TOXIC IN SMALL QUANTITIES

When children ingest even small quantities of toxic xenobiotics, they are potentially ingesting relatively large doses because of their small size. There are a number of xenobiotics that cause significant toxicity or rarely death with as little as one pill or one teaspoonful.<sup>14,104</sup> Table 31–3 lists these xenobiotics.

## XENOBIOTICS THAT CAUSE DELAYED TOXICITY IN CHILDREN

Several xenobiotics warrant particular concern because their effects are frequently significantly delayed. Classic examples are atropine–diphenoxylate (Lomotil)<sup>22,42,118</sup> and sulfonylurea antidiabetics such as glipizide.<sup>69,139,180</sup> Both of these xenobiotics have the potential to cause serious morbidity with initial symptoms or recurrence of symptoms delayed by as many as 24 hours after ingestion.

Children with real or possible ingestions of Lomotil or a sulfonylurea should be admitted for observation and monitoring even if they are initially asymptomatic (Chaps. 36 and 47). With the advent of new modified-release formulations of calcium channel blockers and β-adrenergic antagonists, concern for delayed toxicity and possibly death has become even greater.<sup>126</sup>

## XENOBIOTICS THAT CAUSE UNUSUAL OR IDIOSYNCRATIC REACTIONS IN NEONATES OR CHILDREN

### Benzyl Alcohol: Gaspng Syndrome

Benzyl alcohol is a preservative added to some liquid pharmaceutical preparations (Chap. 46). IV flush solutions containing benzyl alcohol were implicated as the cause of the “gaspng syndrome” in sick newborns; the syndrome includes severe metabolic acidosis, encephalopathy, respiratory depression, and gasping.<sup>7</sup> The association was made when elevated concentrations of benzoic acid and hippuric acid—metabolites of benzyl alcohol—were found in infants with this syndrome.<sup>27,65</sup>

### Chloramphenicol: Gray Baby Syndrome

Chloramphenicol is a broad-spectrum antibiotic that was used in children because of its activity against *Haemophilus influenzae*. It was largely replaced by other antibiotics in the United States because of its association with

aplastic anemia. When administered at high doses, chloramphenicol is associated with the “gray baby syndrome,” which includes abdominal distension, vomiting, metabolic acidosis, progressive pallid cyanosis, irregular respirations, hypothermia, hypotension, and vasomotor collapse. Although these effects occur primarily in premature newborn infants, they also occur in older children and adults (Chap. 54).

Gray baby syndrome is associated with serum chloramphenicol concentrations greater than 100 mg/L. Increased chloramphenicol concentrations result from (a) inadequate conjugation of chloramphenicol with glucuronic acid because of inadequate activity of glucuronyl transferase in the newborn liver and (b) decreased renal elimination of unconjugated chloramphenicol. The exact mechanism of toxicity is unknown; there is speculation that free radicals produced during the metabolism of chloramphenicol may interfere with mitochondrial function.<sup>82</sup>

### Ethanol: Hypoglycemia

Ethanol is a major constituent of many liquid preparations, such as mouthwash, vanilla flavoring, perfume, and hand sanitizers. Besides its well-known sedative-hypnotic effects, ethanol poisoning in children is associated with hypoglycemia. Typical ethanol metabolism to acetic acid results in a shift to higher NADH:NAD<sup>+</sup> ratio. This redox state favors the conversion of pyruvate to lactate, diverting pyruvate away from the Krebs cycle and gluconeogenesis. This decreased source of energy and glucose is poorly tolerated in children, especially because of reduced hepatic glycogen stores. Ethanol-induced hypoglycemia increases the risk for seizure and exacerbation of other CNS effects induced by ethanol poisoning. There does not seem to be a definite blood alcohol concentration threshold for the development of hypoglycemia, which has been reported with blood alcohol concentrations as low as 20 mg/dL<sup>41</sup> (Chap. 76).

### Imidazolines and Clonidine: Central Nervous System Effects

Imidazolines such as tetrahydrozoline, oxymetazoline, xylometazoline, and naphazoline are nonprescription sympathomimetics used as nasal decongestants and conjunctival vasoconstrictors (Chap. 49). Clonidine is an imidazoline derivative used as an antihypertensive (Chap. 61). In small children, these xenobiotics cause severe central nervous system (CNS) depression, respiratory depression, bradycardia, miosis, and hypotension.<sup>13,116,193</sup> The presumed mechanism of action is by stimulation of central  $\alpha_2$ -adrenergic and imidazole receptors. Although naloxone has been reported to reverse some of the CNS effects of clonidine, there are no reports of its successful use with the other imidazolines (Chap. 61).

## HISTORICAL POISONINGS

There have been numerous times throughout history that children have been disproportionately affected by a toxicologic mass casualty incident.

### Aniline Dye

In 1886, Rayner first described a series of newborn children on his maternity ward appearing dusky in color and somewhat limp. Six months later when a second series of newborns presented, he linked the symptoms to a delivery of diapers that were freshly stamped with aniline dye.<sup>89</sup> The dye was absorbed through the newborn skin causing symptoms of what is now known as methemoglobinemia. Despite reports and warnings, aniline continued to be used as a diaper marking dye for decades.<sup>83,89,137</sup> Today, we continue to see pediatric aniline-dye-induced methemoglobinemia from contaminated Indian Holi festival dyes and shoe dyes as well.<sup>132,170</sup>

### Sulfanilamide Elixir

In the late 1930s, the antibiotic medication sulfanilamide was used to treat infections such as streptococcal pharyngitis. Because of a demand for a liquid preparation, an elixir was rushed to market without adequate testing. Sulfanilamide itself is poorly soluble and many of the typical diluents were inadequate; however diethylene glycol functioned well as a solvent and was sweet tasting. Unfortunately diethylene glycol is severely toxic and causes acute kidney injury.<sup>64</sup> The use of diethylene glycol as a diluent for sulfanilamide caused more than 100 deaths including many children.<sup>12,187</sup> As a result and to avoid similar tragedies, the Food,

Drug, and Cosmetic Act was passed in 1938 that requires animal testing of new drugs and data submission to the FDA before marketing to the public.

Unfortunately diethylene glycol continues to be used sporadically around the world with the same tragic effects. In 1996, in Haiti, there were 85 deaths of 109 children treated for acute kidney injury associated with the use of diethylene glycol-contaminated APAP syrup.<sup>133</sup> Again in 1998, in India, 33 out of 36 children who presented with acute kidney injury died after ingesting diethylene glycol-containing cough expectorant.<sup>169</sup> Whether use of diethylene glycol in these cases despite available information regarding its toxicity was out of ignorance or related to unethical financial corruption has not been resolved.

### Melamine

Melamine has widespread uses, most commonly in the plastic dinnerware industry. In the trace quantities that may leach from dinnerware into food to be eaten, melamine is generally considered not toxic. However, in 2008, in China, an outbreak of infantile urolithiasis was associated with melamine-containing powdered infant formula.

The protein content of food is measured based on its nitrogen content. Melamine is more than 60% nitrogen by weight, and by adding melamine to a dry powdered formula the apparent protein content is falsely elevated. Unfortunately, some Chinese formulas were measuring more than 6,000 ppm melamine compared to less than 1 ppm in a comparable US product.<sup>171</sup> More than 294,000 Chinese children were affected, leading to 51,900 hospitalizations and 6 deaths.

## MEDICATION ERRORS

Ever since the publication of the Institute of Medicine’s report titled *To Err Is Human* in 1999, increasing attention is being paid to the issue of medical errors in medicine.<sup>95</sup> Although most of the research regarding medication errors has focused on adults (Chap. 134), this problem also affects children. Remarks in this section are generally limited to the pediatric literature.

Approximately 276,600 exposures each year are classified by the AAPCC as therapeutic errors. For 2011 to 2015, there were a total of 7 deaths attributed to therapeutic errors. Of children younger than the age of 6 years, approximately 40% of the errors resulting in severe injury or death occurred in children younger than the age of 1 year.<sup>184</sup>

Medication errors occur at any phase of a process that includes ordering, order transcription, pharmacy dispensing, preparation and administration of the medication, and monitoring of medication effects. In fact, the same types of errors occur at multiple points in the process. [Table 31–4](#) provides some examples of errors.

**TABLE 31–4** Examples of Medication Errors

- Wrong drug.** In one nursery, an epidemic mimicking neonatal sepsis was caused when racemic epinephrine was inadvertently administered instead of vitamin E because both drugs were manufactured by the same company, distributed in nearly identical bottles, and stored near each other inside the nursery refrigerator.<sup>176</sup>
- Wrong drug formulation.** Acetaminophen suppositories (120 mg) were ordered for a toddler, but adult-strength suppositories (650 mg) were distributed and administered every 4 hours. The child developed hepatotoxicity requiring hospitalization and therapy (Chap. 33).
- Wrong dose.** A 1-kg premature infant required sedation for a diagnostic study. A high dose of chloral hydrate, 100 mg/kg, was miscalculated to be 1 g (1,000 mg) instead of 100 mg. The child had a cardiopulmonary arrest and died. When drugs require milligram per kilogram dosing, it is easy to make decimal mistakes in the calculation or in the transcription.
- Wrong route.** A 17-month-old girl with a central venous line (CVL) and a gastrostomy tube required an upper gastrointestinal series. Barium sulfate was inadvertently injected into the CVL instead of the gastrostomy tube. The patient had several episodes of vomiting and developed fever and rigors but ultimately recovered.<sup>175</sup>
- Wrong dose.** A patient had the dose of cyclosporine changed from 10 mg to 7 mg twice daily. The child received 70 mg (0.7 mL of solution) instead of 7 mg (0.07 mL). When the prescription was refilled, the parents received a 5-mL syringe to use instead of a 1-mL syringe they had used previously.<sup>46</sup>

Most of the analyses of medication errors have occurred in inpatient settings. The reported frequencies of medication errors vary widely—from 0.47% to 5.7% of written orders and from 0.51 to 157 per 1,000 patient-days.<sup>58,81,88,91,153</sup>

The variance largely depends on whether the definition of “error” does or does not include prescribing errors, regardless of whether or not they are corrected, and whether potential, or only actual, adverse drug events are included. The reported frequencies also vary depending on whether there is active case finding or whether there is only voluntary reporting.

In a 2001 study of pediatric inpatients in which orders were actively monitored for a 6-week period, 5.7% of 10,778 prescriptions had errors in the order for the medication, transcription of the order, dispensing or administration of the medication, or monitoring of medication effects (56 per 100 admissions, 157 per 1,000 patient-days).<sup>91</sup> Overall, 1.1% of these errors could have *potentially* caused an adverse effect (10 per 100 admissions, 29 per 1,000 patient-days). Eighty-four percent of the errors occurred during the ordering or transcription phase, so most of the errors were intercepted and corrected before drug administration. There were 26 true adverse drug events, but only 5 were considered preventable errors (0.05%, 0.52 per 100 admissions, 1.8 per 1,000 patient-days). Although the overall error rate was similar to that reported by the same group in a study of adults, the rate of errors that could *potentially* have caused harm was 3 times greater; 41% of the potentially harmful errors were not intercepted. However, one review suggests that the prescription error rate is higher in adults than in children.<sup>103</sup>

Generally, error rates are higher in intensive care units, where the sickest patients are cared for; such patients often receive multiple medications with complex administration regimens.<sup>58,81,91,140,153,185,194</sup> Results similar to those from inpatient settings are reported in pediatric EDs.<sup>99,159</sup>

Children are at increased risk of a medication error for several reasons: (a) someone other than the child administers the medication, so there is little opportunity to prevent or limit drug administration; (b) a young child cannot warn practitioners about possible problems such as allergies; (c) a young child cannot inform practitioners when he or she is experiencing an adverse event; (d) medication ordering and administration in children frequently requires dose calculations; (e) inexperienced practitioners are uncomfortable with pediatric dosing or related calculations; and (f) incorrect measurement or dilution of concentrated stock solutions may yield a small volume, which is not perceived as containing a relatively large dose of medication.<sup>34,46,67</sup>

One of the most common errors is prescription, preparation, or administration of an incorrect dose, particularly in children, for whom almost every prescription requires knowledge of the patient’s weight and a calculation of a weight-based dose.<sup>91,100,102</sup> In addition, even the milligram per kilogram dose varies depending on the age of the patient or the diagnosis. Although pediatric doses are generally determined on a milligram per kilogram basis, if the weight is recorded in pounds and this weight is used in the calculation, there will be a built-in 2-fold error. Calculation errors also occur when drug preparation requires dilution of a concentrated stock solution or special compounding.<sup>184</sup> Further confusion arises when *mg* is written as or misinterpreted as *mcg* or  $\mu\text{g}$  in a calculation or vice versa.<sup>43</sup>

When an extra zero is added or a required zero is omitted from calculations, written or verbal prescriptions, or in dispensed and administered medications, a 10-fold error occurs. These large errors are common and result in significant under- or overdosing; 10-fold errors are reported in testing scenarios, case series, and case reports.<sup>46,49,96,97,100,140,144,149,153</sup> These errors are of particular concern because the risk of toxicity generally increases with significant overdose.

Because the causes of medication error are numerous and complex, the solutions must be multifaceted and interdisciplinary. The approach to the problem is contained within the field of human factors research and potentially requires changes in individual factors such as knowledge; environmental factors such as interruptions; and system problems such as how medications are ordered, stocked, and dispensed (Chap. 134).<sup>95,179,189</sup>

Pediatric critical care areas, including the ED, benefit from having precalculated weight-based dosing charts available for resuscitation medications

and for other commonly prescribed medications; this is a recommendation of the American Heart Association.<sup>9</sup> Many clinical units have developed their own dosing schemes. Commercial products, such as the Broselow–Luten system, are also available and reduce the number of medication errors in simulated<sup>13,112,113,160</sup> and actual resuscitations.<sup>152</sup> There is some controversy related to the ability of these length-based commercial products to accurately predict the weights of American children because of the growing obesity epidemic. However, most resuscitation medications should be dosed on ideal body weight as estimated by these length-based tools when a patient’s clinical status precludes obtaining an accurate weight.<sup>114</sup> Additionally, international populations, depending on their development status, also vary from the length-based weight predictions set forth by the Broselow–Luten system.<sup>125</sup>

The previous discussion was almost exclusively related to hospital-based medication use, but significant errors also occur in outpatient settings. Antipyretics are among the most frequently recommended medications for children. Although significant toxicity after unintentional ingestions in toddlers is now rare, administration of multiple supratherapeutic doses of APAP is common and can cause significant hepatotoxicity.<sup>98</sup>

In fact, many parents have difficulty calculating the appropriate dose of APAP and measuring out the appropriate amount after it is calculated despite having received instructions and graduated cups or oral-dosing syringes.<sup>70,115,121,168</sup> In a simulated encounter, only 11% of medical students were able to identify a pediatric APAP dosing error even when provided with appropriate history, actual product used, and dosing instructions.<sup>51</sup> Relevant factors related to these errors include the characteristics of the instructions regarding medication measurement and administration, the health literacy and health numeracy of caregivers, and the accuracy of different measuring devices (Chap. 129).

Two of the most commonly used measuring devices are also the most inaccurate—the teaspoon and the graduated cup.<sup>154,200</sup> The household teaspoon is not standardized for volume and can easily be confused with a household tablespoon.<sup>115</sup> Acetaminophen and ibuprofen elixirs are typically packaged with a graduated cup for administration even though graduated syringes are considered the most accurate of the measuring instruments available and are recommended by the AAP for young children. In addition, over-the-counter products are sold with inconsistencies between the dosing instructions and the measuring device.<sup>202</sup> In other words, the instructions may describe mL measurement when the measuring device has teaspoon graduations or vice versa.

Health literacy and health numeracy are becoming increasingly understood factors with regard to the safe and effective delivery of health care in general and the reduction of the rate of medical errors in particular. Health literacy plays a key role in a caregiver’s ability to read and understand instructions about and labels on prescriptions and nonprescription medications.<sup>164</sup> The labels on medication containers are not standardized with respect to the layout and placement of information or the use of abbreviations or units of measure, may be printed in small fonts that are physically difficult to read, and difficult to understand by people with lower health literacy or limited English proficiency.<sup>108,201,202</sup> Instructions for medication administration have the same problems. Visual cues using pictograms in the instructions or color-coded or premarked syringes are practical ways to improve the accuracy of parental medication dosing (Chap. 129).<sup>61,198,199</sup>

## INTENTIONAL POISONING AND CHILD ABUSE

Intentional poisoning of children is a rare, but significant, form of child abuse. As previously discussed, the majority of unintentional childhood poisonings have no or only mild effects. However, the risk of morbidity or mortality from “malicious” intentional poisoning is as high as 20% to 30%.<sup>47,78,181</sup> In 1967, Kempe described the “battered child” as a syndrome of classic physical injuries, including long bone fractures, subdural hematomas, and nutritional wasting, that placed the young child at risk for death.<sup>92</sup> This early description also defined child abuse by poisoning as the intentional administration of a drug or the exposure of a child to a natural gas or toxic substance.

Today, there are 4 primary scenarios of child abuse by poisoning: (a) medical child abuse (previously *Munchausen syndrome by proxy*); (b) disciplinary/behavioral modification; (c) drug-assisted sexual assault; and (d) attempted homicide.<sup>48</sup>

In 1977, the term *Munchausen syndrome by proxy* was first used to describe a condition in which a parent or guardian falsifies medical evidence of nonexistent disease(s) or creates the signs and symptoms of disease in a child (factitious illness).<sup>122,123,151</sup> For example, the first 2 published cases involved (a) a case of adulterated urine used to simulate disease and (b) a case of repetitive salt poisoning used to produce symptoms of hypernatremic disease, which ultimately proved fatal. This intentional poisoning of a child, although typically a manifestation of the parent's complex psychiatric illness, is today considered medical child abuse regardless of underlying intent.<sup>24,68,156</sup>

These children suffer both from the symptoms related to the poisoning itself as well as from multiple medical evaluations, frequent hospitalizations, invasive medical procedures, diagnostic testing, and unneeded therapy. Rarely these children die. Since the parent is the caregiver and historian as well as the perpetrator, a prerequisite for this challenging diagnosis is a low index of suspicion.<sup>78</sup> Several warning signals help suggest a diagnosis of medical child abuse (Table 31–5).

Typically, patients present with 4 main categories of illness: (a) metabolic derangements (eg, salt or water ingestion), (b) gastrointestinal symptoms (eg, laxative or syrup of ipecac poisoning), (c) hemorrhagic disease (eg, warfarins), or (d) neurologic symptoms (central nervous system depression or excitation). Despite the historic prevalence of these types of poisonings, this is a partial list because any xenobiotic could be used to poison a child as was seen in 2 recent studies, where the National Poison Data System (NPDS) if not already used in this chapter was queried for childhood cases coded as “malicious” intent. There were approximately 160 cases per year of malicious administration involving pharmaceuticals and 450 cases per year involving the malicious administration of nonpharmaceuticals. The median age of exposure was 1.5 years (pharmaceuticals) and 3 years (nonpharmaceuticals). The most commonly reported pharmaceutical categories included analgesics, stimulants/street drugs, sedatives/hypnotics, cough and cold products, and ethanol. The most commonly reported nonpharmaceutical categories included cleaning products, cosmetic products, and pesticides.<sup>203,204</sup>

Intentional poisoning is associated with other forms of abuse; approximately 20% of poisoned children have evidence of physical abuse.<sup>47,78</sup> Of children presenting to EDs after presumed unintentional poisoning, 36% had previous ED visits for trauma, 7% for poisoning, 6% for both trauma and poisoning, and 1.4% for failure to thrive. At the time of the visit, only 7% were

evaluated for possible abuse, and 2.7% were considered neglected.<sup>78</sup> These data do not prove an association between poisoning and physical trauma; however, in some children, repeat episodes of trauma or poisoning could signal a significant intrafamilial stress or neglect. As previously discussed, almost all of the reported young childhood poison exposures are recorded as unintentional ingestions typical of exploratory behavior; however, some of these exposures are likely due to neglect. Although medical neglect is difficult to define, it should be considered every time a caregiver has failed to provide adequate supervision to prevent a xenobiotic exposure,<sup>78,196</sup> with particular attention paid to cases involving repeated exposures, endangerment, or exposure to illicit substances and drugs of abuse.<sup>48</sup>

In households where legal and illegal substances are present and used, a chaotic environment leads to poor supervision and increased risk of exposure to these substances. Exposure occurs via side-stream/secondhand exposure,<sup>17,77,128,157,191</sup> unintentional ingestion,<sup>93,145</sup> and rectal administration,<sup>142</sup> as well as through breast milk.<sup>35</sup> Children have been given doses of alcohol, methadone, and other xenobiotics to quiet them or to prevent withdrawal.<sup>44,79,143</sup> There are reports of babysitters blowing marijuana smoke into babies' faces to “get them high” or to quiet them.<sup>158</sup>

Siblings of children evaluated and treated for poisoning also suffer from medical child abuse. In addition, significant psychiatric problems are manifested by the victim, parents, and siblings.<sup>25,120,156,162</sup>

Child abuse or neglect must be part of the differential diagnosis of any case of childhood poisoning. Intentional poisoning should be considered and evaluated for.<sup>78,79</sup>

- An “ingestion” in a child younger than one year
- A case with a confusing history or presentation
- A child with signs and symptoms inconsistent with the history (lacks biologic/chronologic plausibility)
- A child with a previous poisoning or a child whose siblings were previously evaluated for poisoning
- A child with a previous presentation for a rare or unexplained medical condition
- A child with apnea, unexplained seizures, currently defined as brief resolved unexplained events (BRUE) previously called an apparent life-threatening events (ALTE)
- A massive ingestion by a small child
- An ingestion of multiple xenobiotics by a small child
- An exposure to substances of abuse
- An intoxication with a xenobiotic to which a child could or would not typically have access
- “Accidental ingestions” in a school-age child
- A history of previous trauma, child abuse, or neglect
- Sudden infant death syndrome or an unexplained death

These considerations of child abuse notwithstanding, rare diseases do occur. One child's rare inherited metabolic disorder, methyl malonic acidemia, was misdiagnosed as ethylene glycol poisoning because the chromatographic appearance of the metabolite propionic acid was similar to that of ethylene glycol.<sup>163</sup>

## SUMMARY

- Young children and adolescents are frequently exposed to potentially toxic xenobiotics; fortunately, most childhood exposures are ingestions of nonpoisonous xenobiotics or small nontoxic quantities of potentially toxic xenobiotics.
- When a child sustains a significant toxic exposure, management follows general toxicologic principles.
- Although most childhood exposures are unintentional, the clinician should be alert to the possibility of intentional poisoning of a child with pharmaceutical or household products.
- The normal development of children places them at risk for unintentional ingestions. A chaotic home environment or a disorganized social structure augments these risks.

**TABLE 31–5** Medical Child Abuse: Suggestive Characteristics in Clinical Situations

1. The child has a persistent or recurrent illness that cannot be explained.
2. The history of disease or results of diagnostic tests are inconsistent with the general health and appearance of the child.
3. The signs and symptoms cause the mature clinician to remark, “I’ve never seen anything like this before!”
4. The signs and symptoms do not occur when the child is separated from the parent.
5. The parent is particularly attentive and refuses to leave the child's bedside even for a few minutes.
6. The parent develops particularly close relations with hospital staff.
7. The parent seems less worried than the physician about the child's condition.
8. Treatments are not tolerated (eg, intravenous lines fall out frequently, prescribed medications lead to vomiting).
9. The proposed diagnosis is a rare disease.
10. “Seizures” are unwitnessed by medical staff and reportedly do not respond to any treatment.
11. The parent has a complicated medical or psychiatric history.
12. The parent is or was associated with the health care field.

Data from Meadow R. Munchausen syndrome by proxy. *Arch Dis Child.* 1982 Feb;57(2):92–98.

- Small size puts children at increased risks for medication dosing and dispensing errors, and their immature metabolic processes leads to unexpected toxicity from pharmaceuticals.
- Toxicologists should encourage parents to provide as safe a home environment as possible to prevent unintentional ingestions and must encourage practitioners to exercise special vigilance when administering medications to children.

## CASE STUDY 6

**History** A 78-year-old man presents to the emergency department after his family found him to be acutely confused. The family states that he was in his usual state of health until one day prior to presentation. The patient had not complained of nausea, vomiting, diarrhea, or abdominal pain. The family is unaware of any new medications that the patient might have been prescribed or any new exposures.

**Physical Examination** On presentation to the emergency department, the patient appeared confused and disoriented. Blood pressure, 140/70 mmHg, pulse, 115 beats/min, respiratory rate, 26 breaths/min; oxygen saturation, 94% on room air, and tympanic temperature 38.2°C (100.8°F). The physical examination demonstrated dry mucous membranes and clear lung sounds with crackles at the bases; his neurologic examination was nonfocal. He was not following commands, but appeared to be moving all extremities with equal strength.

**Initial Management** Given the elevated temperature and the confusion, the medical team was concerned that the patient's delirium had an infectious etiology the point of care glucose was normal, and they ordered a noncontrast head CT, chest radiograph, venous blood gas with a lactate concentration, basic metabolic panel, hepatic function tests, a complete blood count, urinalysis, and blood and urine cultures. The patient was empirically started on broad-spectrum antibiotics; and 1 L of 0.9% sodium chloride solution was administered intravenously over 30 minutes. Pertinent laboratory results included a urinalysis with 1+ leukocyte esterase and trace ketones and basic metabolic panel with an anion gap of 18 mEq/L. The blood gas analysis revealed a pH 7.46, PCO<sub>2</sub> 22 mm Hg, HCO<sub>3</sub><sup>-</sup> 14 mEq/L, and lactate 3.5 mmol/L.

**What Is the Differential Diagnosis?** Confusion and delirium are common reasons for elderly patients to present to the emergency department. Often, an

infection is the etiology for the acute onset of delirium. However, older patients often suffer from several chronic conditions, and are taking multiple medications, enhancing the risk of drug-induced adverse effects, including drug-induced delirium. Furthermore, some patients have underlying dementia and can inadvertently take too much of their own medication (Chap. 32).

In recent years, there has been an increase in the prevalence of illicit substance abuse and prescription drug misuse in the older population, which, along with alcohol misuse, may be clinically unrecognized. In patients who present with confusion, elevated temperature, tachycardia, and hypertension, it is important consider ethanol withdrawal in the differential diagnosis (Chap. 77). A full drug history should include prescription and nonprescription items, and non-oral drugs, including drug-releasing patches. Numerous drugs are available as transdermal patches, and incorrect use, such as application of multiple patches, can lead to toxicity. Therefore, the patient must fully undress and be placed in a gown for a thorough physical evaluation. Anticholinergic patches are common as a treatment for vertigo and motion sickness (Chap. 49). Patients who have signs of anticholinergic toxicity can present with an altered sensorium and an elevated temperature, which can initially be mistaken for sepsis.

**What Clinical and Laboratory Analyses Help Explain the Causes of This Patient's Presentation?** A geriatric patient who presents with confusion should be evaluated for medical causes of delirium. A thorough patient history and physical examination can frequently reveal the cause of the patient's altered mental status and, therefore, should direct the laboratory evaluation. In general, the physician should order serum electrolytes and glucose urinalysis, blood and urine cultures, and a chest radiograph in patients with fever, as well as an electrocardiogram. In patients who have an unexplained altered mental status, a

lumbar puncture is indicated to evaluate for meningitis and encephalitis. If no obvious infection is found to explain delirium, and there is inadequate reason to diagnose anticholinergic toxicity, a salicylate concentration should be ordered (Chap. 37).

Chronic salicylate toxicity is much more frequently missed than acute toxicity. Often, elderly patients with chronic salicylism are misdiagnosed with a delirium that is undifferentiated or of unclear etiology and admitted with a diagnosis such as delirium of unclear etiology, resulting in a significant delay in initiating the appropriate therapy. The mortality associated with chronic salicylate toxicity is higher than acute salicylate toxicity. Therefore, in elderly patients who present with a new delirium of unclear etiology, the physician should closely review of the anion gap and blood gas; for example, this patient's mixed picture of metabolic acidosis and respiratory alkalosis might point to potential salicylate toxicity (Chap. 7).

**Further Diagnosis and Treatment** In this patient, a presumptive diagnosis of urosepsis was initially made. The patient was admitted to the hospital and was continued on antibiotics. After being in the hospital for 2 days, the patient was persistently agitated and delirious, at which point a neurology consult was obtained. At that time, the family revealed that the patient had been complaining of worsening arthritis pain and had been taking aspirin to treat the pain. A salicylate concentration was ordered, and it was found to be significantly elevated at 58 mg/dL. The patient received a sodium bicarbonate bolus and was started on a sodium bicarbonate infusion was begun (Antidotes in depth: A5). In view of the patient's altered mental status, a nephrology consult was also obtained and the patient underwent dialysis (Chap. 6). The patient improved, his mental status cleared, and he was discharged home. The family and the patient were counseled regarding safe practices for storage and administration of medication.

# GERIATRIC PRINCIPLES

Michael E. Stern, Judith C. Ahronheim, and Mary Ann Howland

## PREVALENCE, LETHALITY, AND UNDERRECOGNITION OF TOXIC EXPOSURE

The population is aging steadily across the world. In the United States, people older than 65 years of age comprise an increasing proportion of the population at large (14.5%), and those 85 years and older represent the fastest growing segment of the population.<sup>3</sup> The elderly also comprise an increasing proportion of patients cared for in multiple medical settings, not the least of which is the emergency department (ED) setting. As a result of continuing advances in health education, technology, and pharmacotherapy, many people are living longer. Long life is associated with an increased disease burden. The aging of the “baby boomer” generation (people born between 1946 and 1964) is rapidly changing the medical landscape. Compared with all other age groups, patients 65 years of age and older account for 16% of the total population of patients who visit an ED, one-third of ED ambulance arrivals, and the highest proportion of patients in EDs triaged as emergent.<sup>32</sup> Moreover, this population represents the highest number of hospital and intensive care unit admissions.<sup>159</sup>

Although the elderly account for only a small minority of toxicologic exposures, when exposed, they have a high overall mortality rate. Among exposures reported to the American Association of Poison Control Centers (AAPCC), the fatality ratio for adults (ie, number of cases divided by number of deaths) exhibits a bimodal pattern, declining after age 30 until age 60, when it again rises (Chap. 130).

The factors associated with the increased fatality ratio after age 60 are complex, but are likely due in part to physiologic vulnerability. The geriatric population is physiologically heterogeneous, encumbering research that seeks to differentiate “normal” senescence from changes that occur as a result of disease. This heterogeneity is pertinent to clinical response to xenobiotics, variability of pharmacokinetics, and recovery from exogenous insults, such as adverse drug effects and toxicologic emergencies.

Exposures reported to the AAPCC underestimate the serious consequences for elderly people exposed to xenobiotics that are toxic or potentially toxic. Data from the National Electronic Injury Surveillance System–Cooperative Adverse Drug Event Surveillance Project (NEISS-CADES) indicate that patients aged 65 years and older accounted for 25% of estimated visits related to adverse drug events (ADEs), with almost 50% of such visits requiring hospitalization or prolonged monitoring in the ED during 2004–2005.<sup>20</sup> Furthermore, the incidence of ADEs increases steeply from age 65 years through the tenth decade of life.<sup>20</sup> More recent NEISS-CADES data indicate that almost 50% of elders who required emergency hospitalization as a result of ADEs are 80 years of age or older.<sup>19</sup> Finally, the problem is likely even greater than the NEISS-CADES study suggests, because their data did not capture ADEs in patients treated or dying outside of EDs, ADEs that could only have been recognized after admission, or that were erroneously diagnosed as non-drug-related problems. A better understanding of the specific contributions of overall disease burden in elderly patients and, in particular, the role of high-risk medications to ED presentations of geriatric syndromes, will also produce data that more accurately reflect the scope of the problem.<sup>86</sup>

In one study, 7 specific pharmaceuticals were selected from the AAPCC database for analysis based on their prevalent use and potential toxicity from 1995 through 2002. These pharmaceuticals were theophylline, digoxin, benzodiazepines, cyclic antidepressants (CAs), calcium channel blockers, acetaminophen (APAP), and salicylates.<sup>154</sup> The death rate from intentional or unintentional exposure to these 7 pharmaceuticals increased by 35% for each decade of life after age 19 years. Although prescribing patterns change over

time, most of these drugs, as well as many others, continue to pose problems for patients in the latest decades of life.<sup>20,82</sup> Problems such as these have been accompanied by continuous and longstanding input from geriatric organizations and professionals,<sup>162</sup> and a series of published guidelines with regard to prescribing, namely the “Beers Criteria” governing potentially inappropriate medications (PIMs)<sup>8,15</sup> and “STOPP/START.”<sup>64,139</sup> Still, there remains a limited understanding of PIMs across all provider types, that continues to result in increased morbidity and mortality in geriatric patients. For example, despite cautionary guidelines, benzodiazepine prescribing for older adults in both ambulatory clinics and EDs did not change from 2001 to 2010, and in the oldest individuals, aged 85 and older, who are at highest risk of adverse events, there was an increase in benzodiazepine use.<sup>126</sup> Providers other than geriatricians, by whom and toward whom these guidelines were developed and directed, often lack knowledge of their existence. To that end, several organizations have made efforts to promulgate the published criteria for a broader number of practitioners.<sup>4,56,156</sup>

Toxic exposures in the elderly are underrecognized in the clinical setting for a number of reasons. First, because of pharmacokinetic and pharmacodynamic changes that occur with aging,<sup>11,44</sup> a standard adult dose, even when associated with a “therapeutic” serum concentration, can produce an unexpected, serious effect that goes unrecognized by the clinician. Second, the presentation of disease, including xenobiotic toxicity, is often deemed “atypical” in the elderly,<sup>94</sup> although in geriatric practice, many “atypical” presentations constitute classic geriatric syndromes. Geriatric syndromes include, among others, falls<sup>123</sup> and delirium,<sup>91</sup> which have a multiplicity of causes, but in the elderly are common presenting signs of xenobiotic toxicity. In the case of falls, sedative–hypnotics, opioids, antipsychotics, antidepressants, and certain cardiovascular medications are among the most often implicated.<sup>60,145,155,179</sup> Even the antidementia cholinesterase inhibitors are implicated (though less commonly) because of their potential to cause bradycardia in patients at risk.<sup>144</sup> If the patient is cognitively impaired and the fall is unwitnessed, when the immediate consequences of the fall are addressed (eg, fracture or rhabdomyolysis), the xenobiotic or other primary etiology causing it is often neglected.<sup>109</sup> Delirium, likewise, is a common presentation of xenobiotic toxicity.<sup>78,91</sup> A large variety of xenobiotics cause mental status changes that are mistakenly attributed to non-xenobiotic-related causes in the elderly.<sup>173</sup> Conversely, altered mental status as a manifestation of delirium frequently goes unrecognized<sup>88,120</sup> or misdiagnosed, for example, as Alzheimer disease or psychiatric illness.<sup>151</sup> A striking case of drug-induced mental status changes is represented by a previously normal 66-year-old man who developed psychosis and attempted suicide after taking increasing doses of dextromethorphan-containing cough syrup for a respiratory infection. The patient was treated with psychiatric medications, and several months elapsed before providers realized that his behavior was xenobiotic-induced rather than due to a primary psychiatric condition.<sup>128</sup>

Finally, in some circumstances, the presentation of drug toxicity is delayed in elderly individuals. Drugs with long half-lives often take days to reach a steady state and hence do not achieve peak effects until days after the drug therapy is initiated. In some older patients, the active metabolite of flurazepam, desalkylflurazepam, has a half-life of up to 100 hours or longer, which requires weeks to achieve a steady state.<sup>72</sup> When peak effects are delayed in this manner, xenobiotic toxicities are easily mistaken for non-xenobiotic-related illnesses.

Table 32–1 lists xenobiotics commonly responsible for toxicity in the elderly.

**TABLE 32–1 Xenobiotics That Pose an Increased Risk of Toxicity in the Elderly<sup>a</sup>**

Anticholinergics and antispasmodics
Anticoagulants and platelet inhibitors
Antidepressants
Antidiabetics
Antipsychotics
Antiparkinsons
Benzodiazepines and other sedative–hypnotics
Cardiovascular medications
β-Adrenergic antagonists
Calcium channel blockers
Digoxin
Peripheral α <sub>1</sub> -adrenergic receptor antagonists
Ethanol
Magnesium- and phosphate-containing laxatives
Metoclopramide
Nonsteroidal antiinflammatory drugs
Opioids
Proton-pump inhibitors (chronic use)
Salicylates
Skeletal muscle relaxants

<sup>a</sup>List is consistent with “Beers” Criteria for which recommendations regarding caution are “strong,” as supported by “moderate” quality of evidence or greater.<sup>8</sup>

## PHARMACOKINETICS

Age-related pharmacokinetic changes have important clinical implications for elderly patients, with certain processes having greater or more consistent impact (eg, renal elimination) than others.

### Absorption

In general, absorption of xenobiotics does not decline significantly with age, but specific examples serve to highlight some age-associated impact. For example, a decline in gastric alcohol dehydrogenase activity increases the bioavailability of ingested ethanol in the elderly.<sup>147</sup> The decline in this enzyme is attributed to an increased incidence of gastric atrophy that occurs with age, and which is associated with underlying *Helicobacter pylori* infection, an increase in antiparietal cell antibodies, and age-associated decline in gastric blood flow and overall mucosal function.<sup>50,169,205</sup> Whether age-related changes occur in metabolic enzymes that are present in the intestines, brain, kidneys, and other organ systems and what impact such changes have on drug disposition and drug interactions remain open questions. The precise

contributions of age-related changes in the gastric and intestinal tract (eg, alteration in gastric pH and a decrease in small bowel surface area) to xenobiotic absorption are not adequately determined. Delayed gastric emptying leads to delayed intestinal absorption of certain xenobiotics, but changes in direct absorption of pharmaceuticals are not substantial enough to have an important clinical impact on overall bioavailability. Xenobiotic-to-xenobiotic interactions likely play the main role in decreased bioavailability in the elderly.

P-glycoprotein (P-gp), a transmembrane transport protein involved in xenobiotic interactions and movement in the kidneys, intestines, and other organs, has been widely studied. Limited research on the impact of aging suggests a decline in P-gp activity, but this has not been a consistent finding.<sup>18,191</sup> Studies more consistently demonstrate an age-associated diminished P-gp expression at the blood–brain barrier,<sup>13,33,186,192,193</sup> a decrease that is inversely related to the degree of amyloid in the brain.<sup>33,192,193</sup> This suggests that diminished P-gp activity is associated with reduced efflux of beta-amyloid protein, leading to its accumulation in the brain, arguably playing a role in the pathogenesis of Alzheimer disease. Positron emission tomography (PET) studies of normal humans and those with Alzheimer disease, using radiolabeled verapamil, a P-gp substrate, demonstrate decreased P-gp activity as represented by increased volume of distribution of verapamil in the brain.<sup>13,185,186</sup> Noting that the altered pharmacokinetics in such studies resembles that of P-gp inhibition of xenobiotics explored in therapeutic drug research (eg, to enhance CNS penetration of antiepileptics in refractory seizures), researchers raise the possibility that an age-associated reduction in P-gp activity could also be responsible for enhanced CNS effects of various xenobiotics in the elderly.<sup>185</sup> More research is needed to explore the neurotoxic implications of chronic P-gp deficiency,<sup>33,109</sup> as well as its role in enhanced sensitivity that elderly patients exhibit to numerous xenobiotics, an enduring problem accounting for a very high proportion of ADEs in that population, with serious clinical ramifications.

### Distribution

Age-related alterations in body composition affects xenobiotic disposition in later life (Table 32–2). For example, lean muscle mass and total body water decline, and the fat-to-lean ratio increases with advancing age.<sup>108,137</sup> Thus, highly lipid-soluble xenobiotics tend to have an increased volume of distribution ( $V_d$ ). As a result, there is often a delay before steady state is reached, and peak effect and toxicity typically occur later than expected, as demonstrated with amiodarone and certain benzodiazepines. In contrast, xenobiotics that distribute in water, such as ethanol, have a smaller  $V_d$ , leading to higher peak concentrations and potential toxicity. This accounts, at least in part, for the more pronounced peak effect of ethanol in the elderly and for the increased blood alcohol concentration (BAC) attained in an older adult who drinks an equivalent amount of ethanol compared to a younger person.<sup>180,189</sup>

**TABLE 32–2 Pharmacokinetic Considerations in the Elderly**

	Young	Elderly	Effect on Kinetics
Fat (% of body weight)	15	↑30	↑ $V_d$ for xenobiotics distributing to fat (amitriptyline, diazepam)
Intracellular water (% of body weight)	42	↓30	↓ $V_d$ for water soluble xenobiotics
Muscle (% of body weight)	17	↓12	↓ $V_d$ for xenobiotics distributing into lean tissue (APAP, caffeine, digoxin, ethanol)
Albumin (g/dL)	≥4	↓With acute or chronic illness	↑Free concentrations of xenobiotics if >90% bound to albumin, especially in overdose; interpretation of serum concentration altered
Liver	Normal	↓Size ↓Hepatic blood flow	Liver enzymes not predictive of compromise; concentrations of xenobiotics with high extraction (propranolol, triazolam) may increase; ↓hepatic oxidation (diazepam, chlordiazepoxide)
Kidney	Normal	↓Renal blood flow ↓GFR ↓Tubular secretion	↑Accumulation (lithium, aminoglycosides, <i>N</i> -acetyl procainamide, ACE inhibitors, cimetidine, digoxin, opioid metabolites)

ACE = angiotensin-converting enzyme; APAP = acetaminophen; GFR = glomerular filtration rate;  $V_d$  = volume of distribution.

Protein reserve diminishes with age as a consequence of decreased muscle mass and decreased protein synthesis.<sup>150</sup> Although serum albumin concentration remains in the normal range in healthy elderly individuals,<sup>26</sup> elderly people are more likely to experience a rapid decrease in albumin concentrations when experiencing acute or chronic illness or when their protein intake diminishes.<sup>45,203</sup> A decline in serum protein concentration increases the free or active fraction of xenobiotics that are otherwise highly protein bound. Free xenobiotic is able to travel more readily to the liver and kidney for metabolism or excretion, so a gradual change in the serum protein concentration is unlikely to lead to a change in the patient's overall response to the xenobiotic. However, these changes are clinically important for interpreting serum concentrations of highly protein-bound xenobiotics. Clinical laboratories typically measure total xenobiotic concentrations, which include both free and bound xenobiotic. Because most xenobiotic is bound, the reported value reflects mostly bound xenobiotic; therefore, the total xenobiotic concentration often is in the therapeutic range even though the active unbound fraction is actually elevated. Phenytoin, which is highly bound to albumin, serves as an illustrative example. If the serum concentration of phenytoin is reported as subtherapeutic, the physician might order a dose increase even though the free fraction of phenytoin actually is in the therapeutic range. With a dose increase, the free or active fraction increases to toxic concentrations. Basic xenobiotics are not bound to albumin but to  $\alpha$ 1-acid glycoprotein, an acute-phase reactant that tends to increase, rather than decrease, with age.<sup>1</sup> However, the increase attributed to age is most likely related to underlying disease. These unpredictable changes would be expected to have the reverse effect on the ratio of bound to unbound xenobiotic in any laboratory report. However, the correlation between clinical effect and free xenobiotic concentrations requires further study because of the complex factors involved—for example, alterations in  $V_d$ , tissue-specific xenobiotic concentrations, changes to the number of protein-binding sites, and the contribution of other serum proteins to xenobiotic binding.

### Hepatic Metabolism

The nature of age-associated changes in hepatic metabolism and their impact on xenobiotic elimination is controversial. A decline in functional hepatocyte number occurs with age. This reduction in liver mass is accompanied by a decrease in hepatic blood flow,<sup>200</sup> which results in decreased efficiency of hepatic extraction. Drugs with a high extraction ratio are dependent on liver blood flow and are most affected (eg, lidocaine; propranolol). This diminished hepatic extraction results in delayed clearance of xenobiotics, particularly those that undergo extensive first-pass hepatic metabolism when orally administered, thus increasing their potential toxicity (eg, calcium channel blockers, certain beta adrenergic antagonists, morphine). Enzymatic processes themselves are less predictable.<sup>104</sup> Aging appears to affect the synthetic enzymatic phase 2 reactions (conjugation) less than the nonsynthetic hepatic biotransformation phase 1 reactions (eg, oxidative, others) (Chap. 11). There is substantial genetic variability among cytochrome P450 enzymes, making it difficult to interpret studies of age-related alterations in phase 1. Studies that account for confounding factors that could affect those enzymes, such as concurrent xenobiotics or cigarette smoking, or that account for isoenzyme genotype, fail to fully demonstrate an age-related change in hepatic oxidative enzyme function.<sup>17</sup>

Hepatic conjugation does not decline significantly with age, so xenobiotics such as lorazepam and temazepam that are metabolized by these processes do not have prolonged elimination half-lives. In contrast, xenobiotics such as diazepam and flurazepam, which are metabolized by hepatic oxidative enzymes, are eliminated more slowly with age.<sup>72</sup> Similar to many oxidized xenobiotics, metabolites of diazepam and flurazepam are active, undergo further metabolism, and remain in circulation after the parent xenobiotic has been metabolized. The active metabolites of some xenobiotics, such as opioids, are renally eliminated, and excretion is prolonged because of an age-related decline in kidney function (Table 32–3).

Regardless of duration of action, however, benzodiazepines, opioids, and various other xenobiotics must be used with caution in the elderly because

**TABLE 32–3** Xenobiotics with Narrow Therapeutic-to-Toxic Ratios and Potential for Accumulation in the Presence of Diminished Kidney Function

Anticoagulants

Meperidine (normeperidine: neuroexcitation, seizures)
Procainamide ( <i>N</i> -acetyl procainamide metabolites)
Salicylates

of their enhanced effect even at low doses and even at onset of action (see Pharmacodynamics, below).

### Renal Function and Occult Reduction in Glomerular Filtration Rate

The most consistent age-associated pharmacokinetic change is a decline in glomerular filtration rate (GFR). Glomerular filtration rate declines, on the average, by 50% between the ages of 30 and 80 years,<sup>48,157</sup> with an accelerated decline in the last decades of life.<sup>124,157</sup> However, serum creatinine does not rise in parallel with the reduction of GFR, because lean body muscle mass, the source of serum creatinine, declines with age.<sup>108,137</sup> Therefore, serum creatinine is an unreliable marker of renal function in older adults and cannot be expected to accurately predict the renal elimination of xenobiotics or their metabolites in the elderly.

Numerous authors have reviewed the large body of existing research regarding age-related renal changes, and the limitations of cross-sectional and longitudinal data of healthy and nonhealthy subjects.<sup>11,49,69</sup> Studies focus on measured or estimated glomerular filtration rate,<sup>48,124,157</sup> microanatomy of cadaver kidneys,<sup>69</sup> biopsy of kidneys from healthy older organ donors,<sup>158</sup> and anti-aging gene expression.<sup>52</sup> Still, because of the heterogeneity of the aging population, research has not yet identified a precise “senescent” change separate from changes due to disease. For example, despite a virtual universality of “nephrosclerosis”<sup>69</sup> among those older than 85 years, this complex of anatomic and histologic findings does not correlate with declines in GFR.<sup>158</sup>

Because it is impractical, often difficult, and arguably of questionable value to measure GFR before instituting therapy with a renally excreted xenobiotic, clinicians commonly (eGFR) using age-adjusted formulas based on serum creatinine, or on cystatin C, a nonmuscle-based protein.<sup>36,118</sup> However, age-related declines in GFR are not universal, and limited data from longitudinal studies suggest that as many as 33% of elderly individuals do not experience this age-related decline.<sup>122,157</sup> Modifications of predictive formulas to correct for body surface area<sup>89,165</sup> and obesity<sup>198</sup> are offered to better reflect kidney function, but

anthropomorphic measurements are unreliable in the elderly,<sup>105,170</sup> and physiologic variability is great. Conversely, predictive formulas could significantly overestimate actual GFR in chronically ill, debilitated elderly people, including those with chronic kidney disease (CKD),<sup>112</sup> or inappropriately label robust older adults as having a potentially progressive form of CKD when they do not.<sup>68</sup> Current consensus guidelines for estimating GFR play a large role in research studies and in predicting outcomes in adults with chronic kidney disease,<sup>90,118</sup> but their accuracy in the oldest subjects has been criticized, given the paucity of studies involving or focusing on elderly subjects,<sup>68,146</sup> and remains controversial.<sup>68,119</sup> To overcome the limitations inherent in using an age-heterogeneous cohort, alternate methods of estimating GFR have been offered, based on a cohort of apparently healthy subjects 70 years of age and older (mean age 78).<sup>146,160</sup> An estimate using such a cohort would arguably incorporate age-appropriate normative values for serum creatinine and cystatin C, both of which exhibit non-GFR alterations that would be more prevalent in an elderly population.

The pertinent question here, however, is how to make decisions about “renal” dosing for elderly patients, whether they are apparently healthy or appear ill and debilitated. To this end, a practical approach is called for.

We suggest that the clinician:

1. Recognize that mild to moderate reduced kidney function in the elderly is typically occult, masked by a normal or even low serum creatinine. This problem is enhanced in older adults who are frail or chronically ill.
2. Exercise great caution when prescribing maintenance doses of renally eliminated medications that have a narrow therapeutic index (Table 32–3).
3. Follow therapeutic concentrations of renally excreted xenobiotics when appropriate and available, recognizing that “trough” concentrations are only accurate once steady state is reached, and a steady state will be unexpectedly delayed in an elderly patient whose reduced kidney function is occult.

Failure to exercise caution in these cases is an important iatrogenic cause of toxicity.<sup>117</sup>

## PHARMACODYNAMICS

Pharmacodynamic factors also affect a patient’s response to a particular xenobiotic. In general, age-related physiologic changes in target or nontarget organs lead to increased sensitivity to most xenobiotics, although sensitivity to some xenobiotics is also decreased. For example, experimental evidence demonstrates that the sensitivity of the  $\beta$ -adrenergic receptor declines with aging, leading to a diminished response to both  $\beta$ -adrenergic agonists and antagonists.<sup>39,58,190</sup> However, these experimental findings are not necessarily demonstrated clinically.<sup>9,10</sup> Observed enhanced sensitivity to xenobiotics is probably due to altered pharmacokinetics in many, if not most, cases.<sup>75</sup> Proving that enhanced sensitivity is related to altered pharmacodynamics would require demonstrating that the concentration of xenobiotic at the tissue site was not increased as the result of diminished elimination. Nonetheless, the clinical response to many xenobiotics is altered in diverse ways among the elderly, because of age-related changes and the presence of disease in the target or a nontarget organ.<sup>35,75</sup> Table 32–4 provides examples of pathologic or physiologic changes that frequently occur in the elderly and disorders that are worsened or unmasked by xenobiotics.

## UNINTENTIONAL POISONING, ADVERSE DRUG EVENTS, AND THERAPEUTIC ERRORS

Although the elderly account for numerically far fewer reported poisonings overall, the exposure rate per 100,000 population remains substantial (Chap. 130). The contribution of adverse drug events (ADEs) and therapeutic errors pose a particular problem for older patients and are an important part of poisoning analysis.<sup>154</sup>

The incidence of ADEs among adults increases steadily with age; it is at least twice as high among those aged 65 years and older compared to younger patients,<sup>20</sup> and is highest of all in those aged 80 years and older.<sup>20,84</sup> An ADE refers to “an unwanted event that occurs with normal, prescribed, labeled or

**TABLE 32–4 Pathophysiologic Disorders Exacerbated or Unmasked by Xenobiotics in the Elderly<sup>a</sup>**

Disorder or Alteration	Drug	Possible Outcome
ADH secretion (increased)	Antipsychotics, SSRIs	Hyponatremia
Androgenic hormones (decreased in men)	Digoxin, spironolactone	Gynecomastia
Baroreceptor dysfunction, venous insufficiency	Antipsychotics, diuretics, TCAs, $\alpha_1$ -adrenergic antagonists	Orthostatic hypotension
Bladder dysfunction	Diuretics, $\alpha_1$ -adrenergic antagonists	Incontinence
Cardiac disease	Thiazolidinediones	Congestive heart failure
Dementia	Sedatives, anticholinergics, many others	Confusion
Gastritis (atrophic)	NSAIDs, salicylates	Gastric hemorrhage
Immobility, cathartic bowel	Anticholinergics, cholinesterase inhibitors, opioids, CCBs	Constipation; fecal impaction
Nodal disease (sinus or AV)	$\beta$ -Adrenergic antagonists, CCBs, digoxin	Bradycardia
Parkinson disease; Lewy body dementia	Antipsychotics, metoclopramide	Parkinsonism
Prostatic hyperplasia	Anticholinergics, CAs, disopyramide	Urinary retention
Thermoregulation, disordered	Antipsychotics	Hypo- or hyperthermia
Venous insufficiency	CCBs, gabapentin	Edema

<sup>a</sup>Disorder often preclinical before drug started.

ADH = antidiuretic hormone; AV = atrioventricular; CCB = calcium channel blocker; DPP-4 = dipeptidyl peptidase-4; NSAID = nonsteroidal antiinflammatory drug; SSRI = selective serotonin reuptake inhibitor; CA = cyclic antidepressants.

recommended use of the drug” (Chap. 134). Adverse drug events are more likely to be serious in the elderly than in younger adults. Serious ADEs, that is, those resulting in death, hospitalization, life-threatening outcome, disability, or other serious outcomes, are most prevalent among people 85 years of age and older.<sup>23</sup> Adverse drug events in persons older than 60 years are often the result of therapeutic errors.<sup>37,47,82</sup> A therapeutic error is defined as “an unintentional deviation from a proper therapeutic regimen that results in the wrong dose, incorrect route of administration, administration to the wrong person, or administration of the wrong substance”; therapeutic errors also include “unintentional administration of drugs or foods that are known to interact” (Chap. 134). In the NEISS-CADES study, unintentional overdoses (defined as “excessive doses or supratherapeutic drug effects”) accounted for 65.7% of ADE-related hospitalizations in older adults.<sup>19</sup>

Many serious ADEs reported in elderly patients are potentially preventable.<sup>76,77,100</sup> The NEISS-CADES data reveal that drugs requiring careful outpatient monitoring are disproportionately represented among ED visits attributed to unintentional drug overdose.<sup>19,21</sup> Data from 2007 to 2009 indicate that warfarin, insulins, antiplatelet drugs, and antidiabetics accounted for an estimated 67% of ADE-related hospitalizations in people 65 years of age and older, with digoxin and anticonvulsants contributing another 5.2%.<sup>21</sup> Furthermore, ADEs, many of which are preventable, are common shortly after hospital discharge.<sup>100</sup>

For certain medications, ADEs are often best prevented by not prescribing them to vulnerable patients (or if essential, prescribing with great caution

and careful monitoring), and by cautioning against their use if they are available without prescription. Criteria that guide clinicians regarding PIMs in elderly patients are periodically updated, and serve to enable the prescribing clinician to appraise the regimen in the context of the patient's concurrent diagnoses and then alert the prescriber to more appropriate treatment choices. Although PIMs cause numerically fewer ADEs than more frequently prescribed xenobiotics,<sup>19,21</sup> consensus as well as evidence exist that they are still strongly associated with adverse outcomes in elderly patients, including hospitalization and mortality.<sup>61,99,114</sup> Potentially inappropriate medications are also linked to enhanced risk of specific ADEs. For example, the elderly are at enhanced risk of severe upper gastrointestinal (GI) bleeding<sup>199</sup> and adverse cardiovascular outcomes due to NSAIDs.<sup>187</sup> Although this could be explained partly by increased exposure to and regular use of these drugs for chronic conditions, older adults are particularly vulnerable because of underlying atrophic gastritis, and silent or overt cardiovascular disease, respectively, which can be unmasked by exposure to the NSAID. Similarly, elderly diabetics are at enhanced risk of developing heart failure from certain antidiabetics. For example, thiazolidinediones, which promote fluid retention by enhancing renal sodium absorption, are contraindicated in advanced heart failure but can unmask abnormal cardiac function in elderly patients with apparently silent disease.<sup>136,167</sup> The elderly are also at greater risk of prolonged hypoglycemia from certain sulfonylureas, particularly glyburide.<sup>166</sup> Age-related mechanisms to explain this vulnerability to glyburide include a decreased counterregulatory hormonal response to xenobiotic-induced hypoglycemia,<sup>131</sup> inappropriate stimulation of insulin if hypoglycemia is present,<sup>174</sup> or reduced excretion of a renally eliminated active metabolite of glyburide.<sup>97</sup> Last, but not least, anticholinergics are also problematic, causing confusion in patients with preclinical or overt dementia, and, particularly in men, causing urinary retention due to underlying BPH.<sup>99</sup> Other age-related factors involved in enhanced susceptibility to ADEs are given in [Tables 32–2](#) and [32–4](#).

Precautionary admonitions notwithstanding, guidelines are meant to enhance physician prescribing choices and in no way replace rigorous clinical judgement in any individual patient.

In contrast to serious consequences of therapeutic errors or unintentional overdoses, serious reactions occur even with appropriate doses of certain medications. An important example is the neuroleptic malignant syndrome (NMS), which is potentially life threatening. Although the risk of developing NMS has not been linked to advanced age per se,<sup>29</sup> antipsychotics are often prescribed to frail elderly, such as those with dementia, and NMS can be overlooked in a patient with comorbidities that could obscure a precise diagnosis, such as cerebrovascular events, heat stroke, or antipsychotic sensitivity syndrome,<sup>29</sup> or be diagnosed as akinetic crisis, which it closely resembles.<sup>141</sup> However, the clinical distinction is less important than the need for the prescriber to exercise extreme caution before using antipsychotics in patients at high risk such as those with Parkinson disease or Lewy body dementia.<sup>65,164</sup>

## ADVERSE DRUG EVENTS: RECOGNIZING RISK AND AVOIDING PITFALLS

In addition to physiologic changes that influence xenobiotic disposition or effect, multiple factors contribute to the high risk of ADEs in older adults. Importantly, many of these factors can be foreseen and prevented, and are reviewed in detail here.

### Complicated Medication Regimens and Polypharmacy

A complicated medication regimen reduces adherence, increases errors, and increases the risk of potentially important xenobiotic interactions.<sup>24,133</sup> Older adults take more prescription and nonprescription xenobiotics than any other patient group,<sup>73,101</sup> and the likelihood of experiencing an ADE increases with the increasing number of xenobiotics taken.<sup>86</sup> The problem is amplified by the common practice of pharmacies to fill an ongoing prescription of a particular medication with different brands over time; this diversity is expected but often problematic, and it is not necessarily accompanied by an adequate discussion with the patient or caregiver, or in the case of a mail

order pharmacy, by highlighting the change. The new drug will differ in size, shape, or color from the medication previously dispensed, sometimes also appearing similar or identical to a different medication of the patient's regimen, and medication errors can occur. The same problem occurs when a generic version of the prescribed medication is replaced with the proprietary name. These complexities are compounded by involvement of multiple providers,<sup>178</sup> complex medication scheduling, long-term use, underlying cognitive dysfunction, poor vision, and lack of assistance or monitoring in medication administration.

### Comorbidity—Overt and Subclinical

Concurrent disease in target or nontarget organs alters the patient's sensitivity to a xenobiotic, resulting in a serious ADE, which is possible even when the patient is given a standard or previously used dose. Coexistent disease is often subclinical, and the patient's enhanced sensitivity will not be anticipated. For example, a patient with subclinical Alzheimer disease whose cognitive function is overtly normal can often acutely develop delirium or symptoms of dementia when given standard doses of such drugs as sedative-hypnotics or cyclic antidepressants. Adverse drug events commonly manifest as delirium.<sup>63</sup> Delirium is a medical emergency and an important cause of ED visits by the elderly.<sup>88</sup> Unfortunately, ED physicians often fail to correctly diagnose delirium,<sup>70,78</sup> despite the fact that the one-year mortality rate is similar to that observed with acute myocardial infarction and sepsis. Furthermore, the delirium often remains undiagnosed by the hospital physician, perhaps because many if not most elderly with delirium have a "hypoactive" presentation, characterized by sedation and reduced psychomotor activity.<sup>79</sup>

A large variety of symptoms occur when unrecognized disease is worsened or unmasked by xenobiotics ([Table 32-4](#)).

### Prescriber Lack of Knowledge

Another factor contributing to ADEs is the physician's lack of knowledge with regard to the principles of geriatric prescribing.<sup>55,80,93,115,142</sup> In addition to prescribing inappropriate doses or increasing the dose too rapidly, clinicians often prescribe drugs considered potentially inappropriate for the elderly at any dose, such as cyclic antidepressants, anticholinergics, and long-acting benzodiazepines.<sup>8</sup> Although such medications are useful in certain circumstances, appropriate caution and monitoring is essential. At a minimum, and particularly in the case of PIMs, it is reasonable to attend to specific risk factors outlined here and elsewhere in an effort to prevent ADEs.

### Prescribing New Medications Too Soon: Learning From History

Very often, clinicians are unduly ready to prescribe medications newly on the market, despite available alternatives. Pharmaceuticals recently approved by the Food and Drug Administration (FDA) are sometimes promoted as being safer than older ones, but problems often become apparent only after marketing and use by large numbers of patients. Many examples are illustrative. Gatifloxacin, a renally eliminated fluoroquinolone, was removed from the market only after several years of use when it was finally linked to both hypoglycemia and hyperglycemia in large numbers of elderly subjects.<sup>74,143</sup> The hypnotic zolpidem was marketed as a safe alternative to benzodiazepines for the elderly, but was soon reported to cause comparable problems, including confusion, global amnesia, memory loss, and falls.<sup>194,196</sup> Benzodiazepines themselves represented an apparent improvement over earlier sedative hypnotics, such as barbiturates, chloral hydrate, and meprobamate, which have narrow therapeutic indices as well as important pharmacokinetic interactions. Fundamentally, however, the intrinsic properties of any new sedating medication should be anticipated to create significant problems in those at risk. Analogously, newly approved anticoagulants, despite apparent theoretical advantages, predictably confer an enhanced bleeding risk in elderly patients due to high-risk occult pathologies, risk of falling, problems inherent in the renal route of elimination, and pharmacodynamic, and in some cases, pharmacokinetic interactions. For example, low-molecular-weight heparins were expected to be safer than unfractionated heparin but therapeutic monitoring requires measurement of antifactor Xa activity, which is not as readily available as standard tests that guided dosing of older anticoagulants;

hence, therapeutic monitoring is usually not performed.<sup>84</sup> Low-molecular-weight heparins are eliminated by the kidneys, and repeated doses lead to progressive anticoagulation when GFR is below the level needed for adequate clearance,<sup>34,121</sup> a degree of CKD that is often overlooked in elderly patients.<sup>87</sup> Reported cases of serious, unexpected enoxaparin-induced bleeding occur in elderly patients who are receiving “standard,” not age-appropriate, dosing.<sup>183,188</sup> Similarly, the release of dabigatran, a renally eliminated direct thrombin inhibitor approved in 2010, was soon followed by many reports of severe GI bleeding and hemorrhagic stroke in the United States,<sup>171,181</sup> and internationally.<sup>83</sup> The latter source specifically noted the preponderance of elderly patients in the reports. This finding is consistent with its use in atrial fibrillation, which is most prevalent among the elderly and for which dabigatran was approved. It is premature to conclude that the lack of monitoring or failure to adjust for occult CKD is a cause; however, the clinical trial supporting approval of dabigatran, which randomized subjects with mean age of 71 years, specifically excluded those with estimated GFR less than or equal to 30 mL/min.<sup>40</sup> Similar pharmacokinetics apply to the new class of anticoagulants, the direct factor Xa inhibitors (eg, apixaban, rivaroxaban), and bleeding that was identified in a largely elderly population<sup>41</sup> should surprise no one. Importantly, anticoagulants in general remain among the most important causes of ADEs, therapeutic errors, and hospitalizations.<sup>19,82</sup> In order to reduce untoward bleeding in the elderly, who are at highest risk, it is essential for clinicians to be mindful of the possible presence of occult CKD when elimination is via the renal route, the presence of lesions with the potential to bleed, and the possibility of pharmacodynamic and pharmacokinetic interactions, and should be prepared to perform therapeutic monitoring if appropriate and available.

### Inadequate Research on Geriatric Subjects in Premarketing Studies

It is not surprising that ADEs are first noted following FDA approval in the postmarketing period when actual patients (as opposed to carefully selected research subjects) are exposed to the new medication, because their effects are often inadequately studied in the elderly, generally comprising low numbers in clinical trials.<sup>14,22,116</sup> The nature of research itself is also relevant. When subjects are young adults and disease free, pharmacokinetic profiles do not reflect patterns of medication disposition characteristic of geriatric patients. Pharmacokinetic testing is sometimes limited to a one-time dose, and frequently the evaluation takes place over a short period of time. On average, approximately 5 half-lives of a xenobiotic are necessary to achieve steady-state concentrations (Chap. 9). Thus, a xenobiotic with a half-life of 24 hours will not reach a steady state for 5 days, and in the presence of prolonged elimination associated with age-related factors, a steady state will not be reached for substantially longer. As a result, even if elderly subjects are included in a drug trial, the ultimate effect might not be appreciated during testing intervals designed for younger patients. Even when a substantial number of subjects older than 60 years are enrolled in a clinical trial, a much smaller proportion of patients older than 70 years is included.<sup>14,116,161</sup> Furthermore, the heterogeneity of elderly subjects themselves makes it even more difficult to draw conclusions and make clinical assumptions across the entire group of “elderly” reported in studies. At a minimum, research should endeavor to identify subgroup age cohorts when conceptualizing care approaches and applying research design and analysis to geriatric patients.

Adverse events from xenobiotics that are studied in the elderly or others with chronic illness are typically less obvious in the presence of a comorbidity in the population at risk. The cyclooxygenase-2 (COX-2) inhibitor rofecoxib (Vioxx) was withdrawn from the market in 2004 after it was shown to increase the risk of myocardial infarction and stroke, especially in older adults.<sup>51</sup> Based on the complex actions of COX-1 and COX-2 in many tissues, the possibility existed that COX-2 inhibition increased cardiovascular morbidity, for example, by leaving COX-1-mediated platelet aggregation unopposed while inhibiting prostacyclin-induced vasodilation or by leading to fluid retention and increased blood pressure via renal mechanisms.<sup>81,148</sup> Because the elderly typically have one or more chronic illnesses<sup>35</sup> as well as occult disease, extra vigilance is required when new xenobiotics are given,

and clinicians and clinical investigators must be very mindful of the theoretical possibilities of adverse outcomes.

In view of the vulnerability of older patients to many medications, the FDA requires that sponsors of new drug applications present effectiveness and safety data for important demographic subgroups, including the elderly, in their FDA submission data.<sup>30</sup> However, exceptions to the rule are allowed. For example, when studies include insufficient numbers of subjects older than 65 years to determine whether the elderly respond differently to the medication, the labeling must state this, but the statement is a poor substitute for providing actual efficacy and safety data.<sup>38</sup> Unfortunately, geriatric recommendations in the package insert are often insufficiently specific to provide guidance for medications commonly used in this population.<sup>172</sup> International guidelines, likewise, have had limited adherence and impact on the proportion of older adults in clinical trials, even for diseases most common in the elderly.<sup>14</sup>

### Medication/Xenobiotic Interactions—Provider Factors

Drugs, such as anticoagulants, digoxin, diuretics, and many others commonly prescribed in the elderly, are frequently involved in serious drug interactions.<sup>86</sup> This situation is complicated by the frequency with which elderly patients, who often have multisystem disease, visit multiple physicians, who prescribe medications without specific knowledge of, or attention to, the remainder of the patient’s medication regimen, thereby increasing the risk of inappropriate combinations.<sup>71,177</sup> In addition to lack of communication among providers, one physician often prescribes a medication to treat the side effect of a different one that was previously prescribed by another provider without ever making the connection as to the cause. This usually unnecessary and potentially dangerous practice is tantamount to a “prescribing cascade” that results in iatrogenic polypharmacy. Problems also arise when patients obtain prescriptions from more than one pharmacy.<sup>125</sup> Warfarin is a particular problem, owing to its narrow therapeutic index and numerous xenobiotic interactions, the potential for which is often ignored at the point of care.<sup>66</sup> Examples of such prescribing oversights, include, among others, antibiotics such as ciprofloxacin, clarithromycin, and trimethoprim/sulfamethoxazole.

Herbal preparations also interact with prescription pharmaceuticals.<sup>92</sup> The use of herbal preparations has increased substantially in recent years, but few patients voluntarily report use of these or other nonprescribed therapies to their physicians, and too often physicians fail to inquire specifically about such “alternative” or “complementary” therapies. These xenobiotics are commonly used by elderly patients,<sup>149</sup> in whom targeted symptoms or illness often occur. For example, ginkgo is promoted for memory, hawthorn leaf for cardiovascular disease, saw palmetto for benign prostatic hyperplasia (BPH), and St John’s wort for depression; all of these can interact with prescription medications or cause adverse reactions on their own. Poisonings, herb–drug interactions, and other problems related to herbal preparations are discussed further in Chap. 43.

Nonprescription pharmaceuticals also cause serious adverse effects and participate in also drug food interactions.<sup>134</sup> Approximately 40% of older adults take one or more nonprescription in addition to prescription medications and dietary supplements,<sup>149</sup> and some lead to problems. For example, excessive use of magnesium-containing preparations frequently causes severe toxicity in older individuals.<sup>62,140</sup> Impaired GFR, decreased GI motility, and other medical comorbidities are just 3 risk factors that potentiate magnesium toxicity in the elderly. The source of magnesium in these cases include the cathartics that contain magnesium hydroxide (Milk of Magnesia) and magnesium citrate, antacid preparations, and magnesium sulfate (Epsom salts).<sup>62</sup> Likewise, sodium phosphate formulations harm kidney function in certain elderly patients despite normal baseline creatinine,<sup>103</sup> leading the FDA to issue warnings about dosage for patients at risk, including those 55 years of age and older.<sup>183</sup> Virtually all of the most popular nonprescription medications are more likely to produce problems in the elderly than in younger patients, including GI bleeding (aspirin and other NSAIDs), enhanced warfarin sensitivity (cimetidine), confusion and urinary retention (anticholinergic

antihistamines/sleep aids), and cardiovascular symptoms (pseudoephedrine). Furthermore, increasing numbers of prescription medications have switched to nonprescription status, compounding the problem.<sup>42,138</sup>

Outdated and discontinued medications are an additional problem for the elderly, who often retain unused or partially used products in their homes for decades or continue to request prescription renewals when safer or more effective alternatives are available. Patients often are unwilling to change or physicians continue to renew the prescription without sufficiently reevaluating the patient or to consider safer new alternatives. Potential examples include digoxin and theophylline, which were responsible for large numbers of adverse events diagnosed in EDs,<sup>19,20</sup> as well as sedating antihistamines, other anticholinergics, and diazepam.

### Other Patient Factors

Other age-related factors increase the risk of unintentional poisonings in geriatric patients; impaired vision, hearing, and memory lead to misunderstanding or an inability to follow directions concerning the use of prescription and nonprescription medications. Dementia is another important risk factor in unintentional poisonings. These patients are reported to have twice the incidence of unintentional poisonings compared to those without dementia.<sup>132</sup> In addition to cognitive impairment, patients with dementia sometimes exhibit abnormal feeding behaviors leading to toxic ingestions.<sup>197</sup>

## SUICIDE AND INTENTIONAL POISONINGS

The risk of suicide in men increases with age in a bimodal distribution, rising steadily after age 70 years. By age 85 years, the age-adjusted rate among men was 48 suicides per 100,000 in 2015.<sup>31</sup> White men have a substantially higher risk of suicide than age-matched cohorts among the African American population. Native American and Alaskan Native men comprise another high-risk group; however, after age 55 years, the numbers in those groups are too small to make meaningful comparisons.<sup>31</sup> In women, the suicide rate peaks in midlife and then declines. Notably, however, among adults of all races and age groups combined, women have a much lower rate of suicide than men, a gender difference that exists in virtually all regions of the world.<sup>201</sup> In the United States, among those 65 and older, the suicide rate in women was 5.1 per 100,000 in 2015, as compared to 31.0 for men.<sup>31</sup>

Methods of suicides differ by gender, however.<sup>25</sup> In the United States, the proportion of suicides by poisoning is much lower among men than women at all ages.<sup>31</sup> Firearms account for far more suicide-related deaths than do poisonings or other methods, particularly among men, in whom the proportion of deaths due to firearms increases steadily after age 60 years. Among men 70 years and older in 2015, more than 80% of suicides were due to firearms, compared to 7% attributed to poisons.<sup>31</sup> Among the few women 70 years and older who commit suicide, 35% of suicides were attributed to firearms, and 35% to poisons.<sup>31</sup> Geographic and cultural factors also determine the method of suicide. In countries other than the United States, firearms are much less frequently used to commit suicide at any age, with suicide by oral overdose, toxic inhalation, or hanging comprising a much greater proportion.<sup>5,175</sup> Among the elderly, limited data suggest that the pattern of xenobiotics responsible for suicidal deaths is changing because selective serotonin reuptake inhibitors are increasingly prescribed for depression instead of older antidepressants.<sup>27</sup> In the United States, higher suicide rates are associated with greater use of cyclic antidepressants than SSRIs or other, newer antidepressants,<sup>67</sup> which could be related to the greater lethality of cyclic antidepressants in overdose, or poorer tolerability leading to nonadherence and enhanced suicide risk. In a Swedish study examining autopsy-confirmed suicides that included analysis of legal xenobiotics, the incidence of suicidal fatalities attributed to benzodiazepines was reported to be increasing despite a marked decrease in benzodiazepine prescriptions.<sup>28</sup> Overdose of benzodiazepines is rarely fatal unless it is accompanied by alcohol or another xenobiotic or a serious medical condition.<sup>53</sup> However, the likelihood of fatality from an overdose of benzodiazepine taken alone increases markedly with each decade of life,<sup>154</sup> perhaps because benzodiazepines in frail elderly people commonly lead to secondary morbidity and mortality from

aspiration pneumonia, falls including hip fracture and traumatic intracranial hemorrhage, and other medical complications that are the proximate cause of death in the case of overdose.

Notably, flunitrazepam and nitrazepam, the 2 most frequently implicated in single benzodiazepine suicides in Sweden,<sup>28</sup> are not available in the United States. However, single-drug suicides are reported with other benzodiazepines that are available, such as flurazepam, triazolam, diazepam, and oxazepam.<sup>28,127,130</sup>

## SUBSTANCE ABUSE IN THE ELDERLY

Substance abuse declines with age<sup>57</sup> but is important to consider in older adults under relevant clinical circumstances. Abuse of alcohol or other xenobiotics frequently is the continuation of long-term habits, or in some individuals begins later in life.<sup>102</sup> Alcohol is the most common substance of abuse in people older than 65 years, but surveys demonstrate an increase in illicit xenobiotic use and prescription drug misuse among older adults in recent years.<sup>12,129,202</sup> As increasing numbers of people enter the later decades of life (including those with past history of abuse disorders), illicit and nonmedical use is expected to increase still further. Unfortunately, a strong case can be made that middle-aged substance abusers have an “accelerated rate of biological aging” than their nonabusing peers<sup>98</sup> and are less likely to survive into old age, or will be frailer than their same-age peers.

One could argue that frailty could hamper a person’s acquisition of illicit substances, but analgesics are among the most commonly prescribed group of medications among elderly people, second only to cardiovascular medications. In a 2003 survey of community residing elderly, 23%, 21%, and 52% of those aged 65 to 74, 75 to 84, and 85 and older, respectively, had some exposure to opioids.<sup>135</sup> More recently, the Office of Inspector General (OIG) reported that 32% of Medicare part D beneficiaries received at least one prescription schedule II or III medications in 2014.<sup>129</sup> The OIG report, which does not state how many beneficiaries were older than 65 years, also noted an increase in fraud complaints involving incidents of “questionable” billing and prescribing, raising a concern that patients were receiving unnecessary opioids or that diversion of these controlled substances was occurring.<sup>129</sup>

Although only a small proportion of people who take opioids are likely to abuse them, concern exists that long-term use could ensue once a prescription is written, even for procedures such as low-risk surgery.<sup>6</sup> In a recent study of Medicare Part D insurance claims, 14.9% of 92,882 hospitalized beneficiaries with no recent opioid use had a new opioid claim within 7 days after hospitalization; of these, 72.3% were aged 65 years or older, and one-third of the older beneficiaries had a claim 90 days postdischarge.<sup>95</sup> In a separate study of 1,808,355 Medicare Part D beneficiaries prescribed opioids, 34.6%, 14.2%, and 11.9% filled prescriptions from 2, 3, and 4 or more separate providers, respectively.<sup>96</sup>

Another recent misused medication among older adults is the antidiarrheal loperamide, a poorly absorbed, nonprescription synthetic opioid, and a popular alternative to prescription opioids. A study of trends in intentional loperamide abuse and misuse between 2010 and 2015 revealed that 14.8% (257) of 1,736 exposures were in patients older than 60 years, of which 62 were suspected suicide attempts, with 2 resulting in fatalities.<sup>184</sup>

Substance abuse in late life is probably underrecognized and underreported.<sup>152,204</sup> In a 5-year study of patients admitted to a level I trauma unit, among those 65 years of age or older (average age approximately 75 years) who underwent toxicologic screening, a positive BAC was present in 11% (mean concentration 163 mg/dL) and a positive urine drug screen in 48.3%.<sup>54</sup> Sixty-nine percent had a BAC greater than 80 mg/dL, which is consistent with other studies of elderly patients presenting to trauma facilities, in which a large majority have a BAC of 80 mg/dL or above.<sup>163,204</sup> Such results, although similarly found in nonelderly trauma patients,<sup>54,204</sup> have different implications in the older adult. As a result of physiologic and pharmacologic changes discussed earlier, the elderly have greater risks on cognitive and motor function, despite a smaller amount of ethanol ingested,<sup>180,189</sup> Also, while many are injured as drivers in motor vehicle crashes, the majority have serious trauma due to falling.<sup>54</sup>

Among elderly trauma patients who are screened for and have positive urine toxicology, opioids and sedatives are most commonly found,<sup>54,163,204</sup> all of which, like ethanol, are more likely to impair older than younger adults at a given dose. As both medical and recreational marijuana use is becoming legalized and decriminalized across the country, it is logical to ask whether older users might be more seriously affected, whether as drivers, or as those who fall. No research to date has focused on this question but clinicians, patients, and family members are well advised to exercise caution.

According to data from the National Survey of Drug Use and Health (NSDUH), from 2002 to 2014 the proportion of adults aged 50 to 64 years who reported cannabis use in the past month increased from 1.1% to 6.1%, and among those aged 65 years and older from 0.3 to 1.3%.<sup>12</sup> These increases were higher than for any age group; among all age groups combined, the increase was 35% compared to 333% for those aged 50 to 64 years and 455% for the oldest group. Although synthetic cannabinoids and marijuana, where available, are increasingly considered as alternative treatments for conditions such as chemotherapy-induced nausea and vomiting, and muscle spasticity associated with multiple sclerosis,<sup>43,113,168</sup> both medical and recreational marijuana could have more deleterious consequences for older as compared to younger adults. In addition to unwanted cognitive effects, of particular concern are physiologic responses to marijuana that can secondarily affect vulnerable organ systems, notably producing cardiovascular and cerebrovascular problems (Chap. 74).

### Substance Withdrawal

Some caveats are in order when it comes to the older alcoholic patient at risk for withdrawal. Studies suggesting a longer duration or greater severity of the syndrome in the elderly are criticized for their small size, retrospective nature, and absence of middle-aged comparison groups.<sup>106</sup> However, vigilance is essential because delayed assessment and intervention will lead to greater morbidity.<sup>59</sup> Furthermore, because of an age-related decreased physiologic reserve, the adverse physiologic effects of ethanol withdrawal such as elevated blood pressure, sustained tachycardia, and delirium will have a more profoundly negative impact on the elderly. For treatment of withdrawal, some clinicians recommend shorter-acting benzodiazepines, such as lorazepam rather than chlordiazepoxide,<sup>153</sup> because the latter and its metabolites are particularly long acting in the elderly, leading to progressive and excessive sedation as the drug and metabolites accumulate. Long-acting benzodiazepines, moreover, are more often associated with injury, including fractures, than short-acting benzodiazepines.<sup>176</sup> Regardless of which benzodiazepine is used for alcohol withdrawal, careful monitoring with symptom-triggered dosing is preferable to a fixed-dose schedule in elderly patients, as in all other patients being treated for ethanol withdrawal.

Symptoms of withdrawal from other xenobiotics, for example, benzodiazepines, opioids, baclofen, carisoprodol, and cognitive enhancers such as cholinesterase inhibitors, are mistaken for nonxenobiotic manifestations. The medication itself, even judiciously prescribed and monitored, will result in withdrawal symptoms, if the patient makes an uninformed decision to discontinue the medication, forgets to take it, or is unable to refill the prescription in a timely fashion. The failure to consider use of these xenobiotics, whether illicit, nonprescription, or prescription, will have serious consequences. If a careful history is not elicited, withdrawal from these xenobiotics will be missed or misdiagnosed as due to another disease process and be inappropriately managed as a result. Given the ongoing “graying” of the population, greater vigilance and screening will be needed upon presentation to the hospital and reassessed upon admission as an inpatient.

### MANAGEMENT

Management decisions must be made with the foregoing principles in mind. Gastrointestinal (GI) decontamination should proceed as in younger patients. However, because constipation is a more frequent problem in the elderly, when multiple-dose activated charcoal is used, particular attention must be paid to GI function and motility. The specific precautions and contraindications in the basic management and GI decontamination detailed in Chap. 5 are particularly pertinent for the geriatric population.

The presence of clinical or preclinical congestive heart failure or CKD will increase the risk of fluid overload when sodium bicarbonate is used. In the elderly, extracorporeal removal is often indicated earlier in cases of salicylate, lithium, or metformin poisoning, in which elimination will be hampered by a decreased GFR.

A situation that often goes unrecognized in geriatric patients is the problem of ethanol or other substance withdrawal syndromes. Because elderly patients are typically not perceived as substance abusers, or because a physician evaluating an unfamiliar patient is not aware of the patient's chronic use of prescribed benzodiazepines or opioids, the possibility of withdrawal is frequently neglected when unanticipated complications occur during hospitalization. Under updated Geriatric Trauma Management Guidelines,<sup>7</sup> every geriatric trauma patient should be assessed for ethanol use as a cause of delirium. By extrapolation, alcohol withdrawal detection should increase in this particularly vulnerable trauma population.

Strategies to limit unintentional toxic exposures in elderly patients with cognitive or sensory impairment should be similar to those used in young children, who are also at high risk of ingesting toxic xenobiotics or pharmaceuticals prescribed for others in the household (Chap. 129). The strategies should include the removal of potentially dangerous and unnecessary xenobiotics from the patient's environment. A recognition of and reliance on the important role that Emergency Medical Services (EMS) prehospital personnel play in the acquisition of all xenobiotics (whether illicit, prescription, or nonprescription) from the home of a community-dwelling older patient cannot be overstated. Emergency Medical Services often represents a unique opportunity for a medical provider to gain vital information that could impact the diagnosis and management of a toxicologic emergency in the elderly. The physician should request that the patient or caregiver bring all medications to the office in the original bottles. The physician should then make an effort to limit the number of medications prescribed or to seek alternative medications with a safer therapeutic index or appropriate geriatric safety profile. For patients who are unable to reliably take their own medications, administration and control of the medications ultimately becomes the responsibility of the caregiver rather than the patient. Usually the patient's capabilities are obvious, but early dementia can be very subtle, so a caregiver who accompanies the patient should always be involved in the prescribing and counseling encounter.

### CRITERIA FOR ADMISSION AND TIMING OF DISCHARGE

When geriatric patients are evaluated in the ED for poisonings or serious ADEs, the need for hospital admission should be weighed carefully against the known hazards of hospitalization for the elderly.<sup>46</sup> The physician should be particularly alert to certain situations that might mandate admission, including unexplained mental status changes, overdose of a prescribed medication with a prolonged duration of action, or evidence of inadequate home care or elder abuse/neglect, such as poor hygiene or unexplained injury.

When there is concern that the established caregivers at home are abusing or neglecting the patient, the patient requires further observation, removal from the environment, and possibly hospitalization. Signs of actual physical abuse will be more obvious than signs of neglect<sup>110</sup>; however, neglect is more prevalent than physical abuse.<sup>2</sup> Vulnerable elderly who are physically disabled or cognitively impaired are often brought to the hospital because of presumed illness, but the source of the problem may actually be the caregiver. The caregiver, frequently but not necessarily a family member, could be depleting the patient's funds for personal use. Patients may become ill because funds were diverted from the purchase of food or because the patient's prescription drugs were sold on the street. More direct abuse infrequently takes the form of intentional poisoning or oversedation of the patient by overdose of the patient's own prescription drugs, or selling the patient's medications (diversion) or withholding them, resulting in clinical deterioration. Provision for follow-up care, such as an alternative place to live and guardian appointment, is essential because abuse and neglect are associated with serious outcomes.<sup>111</sup>

Unresolved mental status changes require close observation and hospitalization. Elderly patients who are confused or unable to walk are sometimes mistakenly assumed to be chronically impaired. However, incomplete explanation of an altered mental status or physical impairment should prompt careful inquiry into the patient's baseline functional status. Poor function should never be assumed to be "normal aging." Many very elderly patients are cognitively normal, physically robust, and independent in all activities of daily living.

A patient whose problems are attributed to overdose with or due to bioaccumulation of a long-acting medication requires prolonged monitoring. Because the duration of action frequently is markedly prolonged among geriatric patients, a higher degree of vigilance is required. An important example is chlordiazepoxide, which is commonly used for alcohol withdrawal and exhibits a very long half-life in older patients, especially after repeated dosing. The ultra-long-acting sulfonylurea chlorpropamide, rarely used today, but others such as glyburide cause relatively prolonged hypoglycemia compared with other insulin secretagogues, as noted above.

In conclusion, a better understanding of core geriatric emergency medicine principles—including physiologic changes of aging, effects of comorbid disease, cognitive dysfunction, atypical clinical presentations, geriatric syndromes, and the impact of polypharmacy—will advance the goal of providing improved and more humanistic care for older adults with toxicologic emergencies that will ultimately transcend age, leading to improvements in the care for all in need.

## SUMMARY

- Older patients account for only a small fraction of total poisoning victims, but when poisoned, they have a high mortality rate.
- The elderly are much more likely to experience serious ADEs as a consequence of both appropriate and inappropriate use of medications.
- Always consider ADEs as the potential etiology of a medical or traumatic presentation to the hospital.
- Attention to risk factors for ADEs is essential in this vulnerable population.
- Important risk factors include pharmacokinetic and pharmacodynamic changes; the presence of overt or subclinical disease, including dementia; patient and provider error; suicide risk; complex medication; and a general lack of knowledge about the principles of prescribing for the geriatric population.

## Section I A. Analgesics and Antiinflammatory Medications

## 33 ACETAMINOPHEN

Robert G. Hendrickson and Nathanael J. McKeown

MW = 151 Da  
 Therapeutic serum concentration = 10–30 mcg/mL  
 = 66–199 μmol/L

## HISTORY AND EPIDEMIOLOGY

By the late 1800s, both phenacetin and acetanilide were used as analgesics and antipyretics, but their acceptance was limited by significant side effects, including methemoglobinemia. *N*-Acetyl-*p*-aminophenol is a major metabolite of phenacetin and acetanilide and is responsible for both analgesia and antipyresis. *N*-acetyl-*p*-aminophenol was synthesized in 1878 and has a low risk of causing methemoglobinemia. *N*-Acetyl-*p*-aminophenol is abbreviated as APAP (*N*-acetyl-*p*-aminophenol) and is referred to as acetaminophen (*N*-acetyl-*p*-aminophenol) in the United States, Canada, Japan, and several other countries and as paracetamol (**para**-acetylaminophenol) in most other areas of the globe. These terms are all acronyms of the chemical name. Acetaminophen was first used clinically in the United States and the United Kingdom in the mid 1950s, but its widespread acceptance was delayed until the 1970s because of concerns of the toxicities of its precursors. Acetaminophen has since proved to be a remarkably safe medication at appropriate dosage, which has led to its popularity. Acetaminophen is available in myriad single-medication dose formulations and delivery systems and in a variety of combinations with opioids, other analgesics, sedatives, decongestants, expectorants, and antihistamines.<sup>205</sup> The diversity and wide availability of APAP products dictate that the potential for APAP toxicity be evaluated not only after identified ingestions but also after exposure to unknown or multiple xenobiotics in settings of intentional overdose, abuse, and therapeutic misadventures.

Despite enormous experience with APAP toxicity, many controversies and challenges remain unresolved. New formulations and analogs are being introduced, including multiple extended-release and transmucosal formulations that will require reassessments of the available knowledge.<sup>129,261</sup> To best understand the continuing evolution in the approach to APAP toxicity, it is critical to start with certain fundamental principles and then to apply these principles to both typical and atypical presentations in which APAP toxicity must be evaluated.

## PHARMACOLOGY

Acetaminophen is an analgesic and antipyretic with weak peripheral anti-inflammatory and antiplatelet properties. Analgesic activity is reported at a serum [APAP] of 10 mcg/mL and antipyretic activity at 4 to 18 mcg/mL.<sup>379</sup>

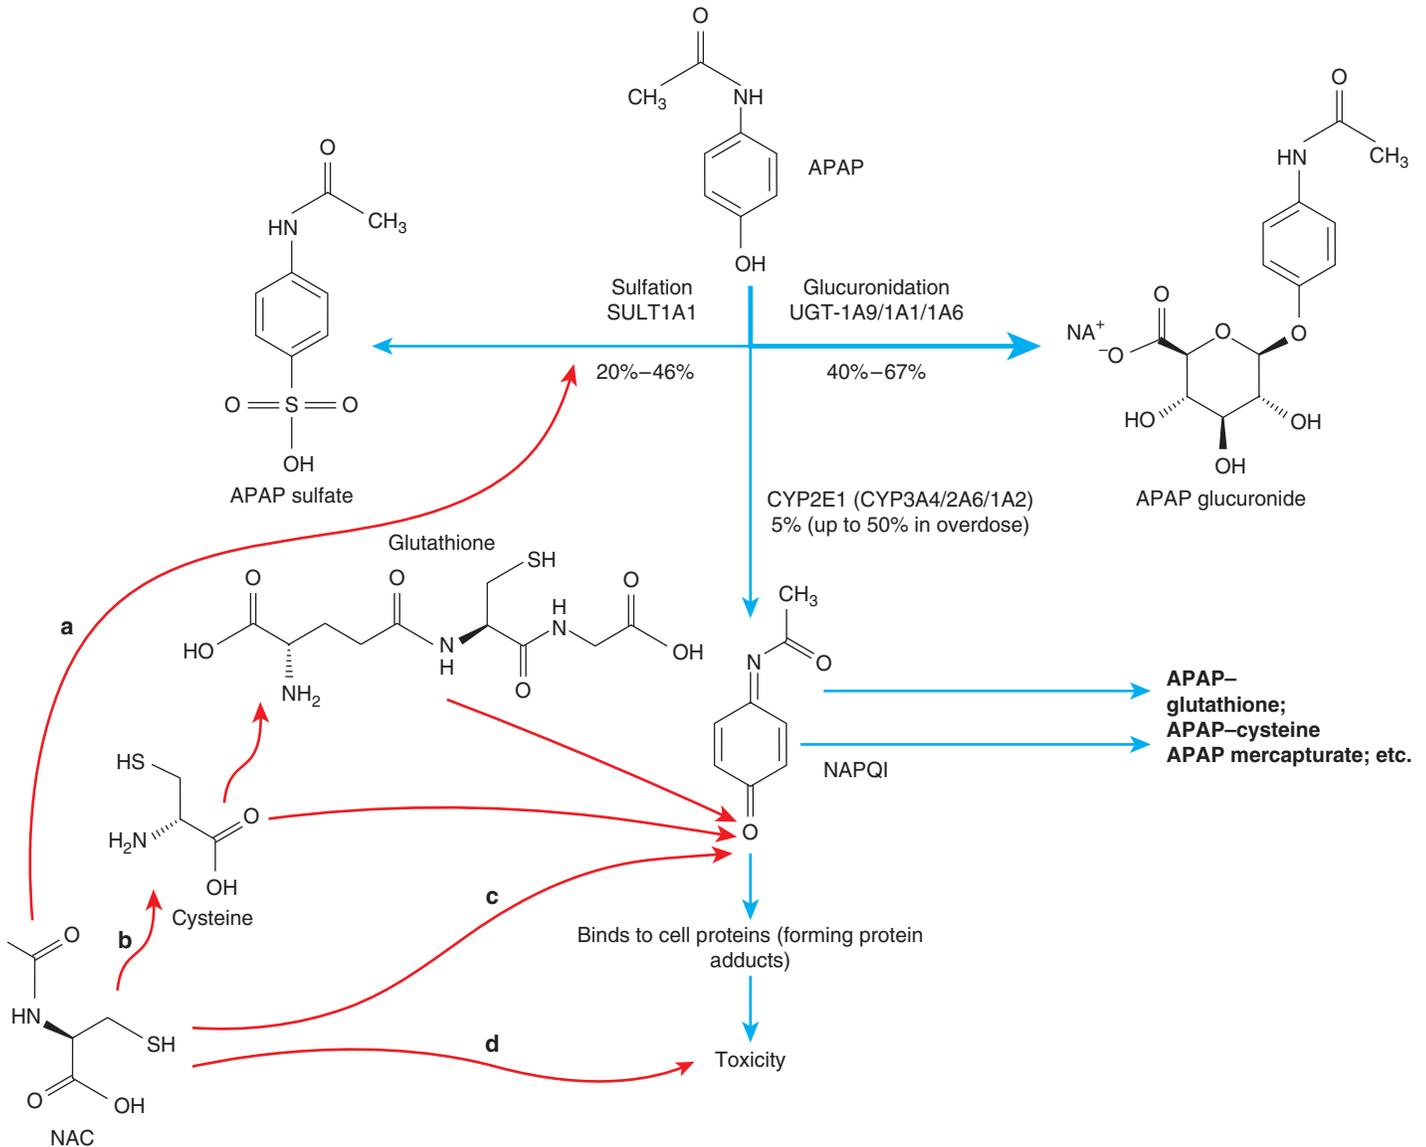

Acetaminophen has a unique mechanism of action among the analgesic antipyretics. Most of the nonsteroidal antiinflammatory drugs (NSAIDs) occupy the cyclooxygenase (COX) binding site on the enzyme prostaglandin H<sub>2</sub> synthase (PGH<sub>2</sub>) and prevent arachidonic acid from physically entering the site and being converted to prostaglandin H<sub>2</sub>. Acetaminophen also inhibits

prostaglandin H<sub>2</sub> production but does so indirectly by reducing a heme on the peroxidase (POX) portion of the PGH<sub>2</sub>,<sup>223</sup> and indirectly inhibiting COX activation.<sup>14,217</sup> In this way, APAP function is highly dependent on cellular location and intracellular conditions.<sup>254</sup> Acetaminophen strongly inhibits prostaglandin synthesis where concentrations of POX and arachidonic acid (“peroxide tone”) are low, such as in the brain.<sup>114</sup> In conditions of high peroxide tone, such as inflammatory cells (macrophages) and platelets, prostaglandin synthesis is less affected by APAP,<sup>14,45,126,217,245,254</sup> although this is not universal.<sup>16</sup> This dissociation explains the strong central antipyretic and analgesic effect of APAP but weak peripheral antiinflammatory and antiplatelet effects. Functionally, APAP predominantly acts as a central indirect inhibitor of COX-2 enzymes,<sup>156,243</sup> with some mild peripheral COX-2 inhibition<sup>206</sup> and minimal COX-1 inhibition (Chap. 35).<sup>59</sup>

Antipyresis and analgesia are predominantly mediated by this central indirect COX-2 inhibition and the resulting decrease in prostaglandin E<sub>2</sub> (PGE<sub>2</sub>) synthesis.<sup>110,126,189,245</sup> Additional analgesic effects are mediated by serotonergic, opioid, cannabinoid, and transient receptor potential vanilloid cation channel subfamily V member 1 (TRPV1) receptors.<sup>219</sup> Stimulation of descending serotonergic pathways is demonstrated in rats<sup>42</sup> and humans,<sup>126,260</sup> and the analgesic effect of APAP is inhibited by several serotonin antagonists or serotonin depletion.<sup>8,260,262,300</sup> In rats, the analgesic effect of APAP is attenuated by opioid receptor antagonists.<sup>54,263,301</sup> However, APAP binds poorly to opioid receptors,<sup>276-278</sup> and the exact opioid mechanism remains unexplained.<sup>301</sup> Activation of the central or peripheral endogenous cannabinoid system, potentially from an APAP metabolite,<sup>158</sup> is theorized but remains controversial.<sup>32,81,138,253</sup> Finally, activation of TRPV1 receptors by a lipoamino metabolite of APAP, and the resulting activation of T-type calcium channels was demonstrated in mice and contributes to analgesia.<sup>179</sup>

## PHARMACOKINETICS

After ingestion of a therapeutic dose, immediate-release APAP is rapidly absorbed from the small intestine with a time to peak [APAP] of approximately 30 minutes for liquid formulations and 45 minutes for tablet formulations.<sup>10,95,116</sup> Extended-release APAP has a time to peak of 1 to 2 hours but is almost entirely absorbed by 4 hours.<sup>98</sup> The time to peak is delayed by food<sup>95</sup> and coingestion of opioids or antimuscarinics.<sup>137</sup> The oral bioavailability is 60% to 98%,<sup>281</sup> and the volume of distribution (V<sub>d</sub>) is 1 L/kg.<sup>10,11</sup> Peak [APAP] after recommended doses typically ranges from 8 to 20 mcg/mL.<sup>10,116</sup> After administration of 20 to 25 mg/kg of rectal suppositories, the peak [APAP] ranges from 4.1 to 13.6 mcg/mL, the time to peak [APAP] is 2 to 4 hours (range, 0.4–8 hours), and the bioavailability is 30% to 40%.<sup>22,39,136</sup> Acetaminophen is available in the intravenous (IV) form in many countries as well as a prodrug (eg, propacetamol) in the United Kingdom. The time to peak of the IV formulations are immediate (< 15 minutes). In adults, peak [APAP] after a 1-g infusion is approximately 30 mcg/mL and after a 2-g infusion is approximately 75 mcg/mL with a large range of 31 to 161 mcg/mL.<sup>7,113,133,259</sup> Acetaminophen enters the cerebrospinal fluid within 15 minutes after IV dosing and within 45 minutes after oral or rectal doses.<sup>326</sup> Whereas the V<sub>d</sub> is higher in both pregnant women and neonates, clearance rates are higher in pregnant women and lower in neonates.<sup>6,7,193</sup> Acetaminophen has total protein binding of 10%

**FIGURE 33-1.** Important routes of acetaminophen (APAP) metabolism in humans and mechanisms of *N*-acetylcysteine (NAC) hepatoprotection. *N*-acetylcysteine augments sulfation (a), NAC is a glutathione (GSH) precursor (b), NAC is a GSH substitute (c), and NAC improves multiorgan function (d) during hepatic failure and possibly limits the extent of hepatocyte injury. APAP = *N*-acetyl-*p*-aminophenol; NAPQI = *N*-acetyl-*p*-benzoquinoneimine.

to 30% that does not change in overdose.<sup>234</sup> Acetaminophen crosses the placenta and enters breast milk in small amounts (< 2% of ingested dose).<sup>208,250</sup>

After absorption, approximately 90% of APAP normally undergoes hepatic conjugation with glucuronide (40%–67%), mostly via UGT1A9/1A1/1A6, and sulfate (20%–46%), mostly via SULT1A1, to form inactive metabolites, which are eliminated in the urine.<sup>71</sup> A small fraction of unchanged APAP (< 5%) and other minor metabolites reach the urine.<sup>237</sup> The remaining fraction, approximately 5% in therapeutic doses, is oxidized by CYP2E1 (and, to a lesser extent, CYP3A4, CYP2A6, and CYP1A2),<sup>146,222</sup> resulting in the formation of *N*-acetyl-*p*-benzoquinoneimine (NAPQI).<sup>70</sup> Glutathione (GSH) quickly combines with NAPQI,<sup>236</sup> and the resulting complexes are converted to nontoxic cysteine or mercaptate conjugates, which are eliminated in the urine (Fig. 33-1).<sup>233,237</sup> The elimination half-life of APAP is approximately 2 to 3 hours after a nontoxic dose<sup>5,270</sup> but is prolonged in patients who develop hepatotoxicity.<sup>270</sup>

## TOXICOKINETICS

After most oral overdoses, the majority of APAP absorption occurs within 2 hours, and peak plasma concentrations generally occur within 4 hours. Later peaks or double peaks are occasionally documented in overdoses and have generally occurred after large ingestions (> 50 g) with or without coingested antimuscarinics.<sup>38,154,340,368</sup> After overdose, NAPQI production is largely

the result of activity of the CYP2E1 enzyme,<sup>142,146</sup> and the amount of NAPQI formed is increased out of proportion to the APAP dose and accounts for up to 20% to 50% of metabolism in patients with hepatotoxicity.<sup>271</sup> Contributions of CYP1A2, CYP3A4, and CYP2A6 to the production of NAPQI in humans are small and insignificant in most cases but depend on individual host factors and dosage.<sup>146,256,280,359</sup> After clinically significant overdose, nontoxic sulfation metabolism of APAP becomes saturated.<sup>2,186,284</sup> Rates of metabolism through glucuronidation are highly variable, increase proportionately in overdose, and are not saturatable in humans (Fig. 33-1).<sup>24,90,186,267,284</sup>

The toxicokinetics of IV APAP are largely unknown. Doses of 15 mg/kg, 75 mg/kg, and 146 mg/kg produce [APAP] of 10 mcg/mL, 35 mcg/mL, and 117 mcg/mL, respectively, at 4 hours, with half-lives ranging from 2 to 6 hours.<sup>27,68,87</sup>

## PATHOPHYSIOLOGY

The safety of appropriate APAP dosing results from the availability of electron donors such as reduced GSH and other thiol (S-H)-containing compounds. After therapeutic APAP dosing, GSH supply and turnover far exceed that required to detoxify NAPQI. With ample GSH supply, NAPQI is largely bound by GSH, and no toxicity occurs, although NAPQI-cysteine protein adducts do form within the liver, and some are released into the serum

within hours.<sup>152,232,251</sup> After overdose, the rate and quantity of NAPQI formation outstrip supply and turnover of GSH, resulting in the release of NAPQI within the cell. *N*-acetyl-*p*-benzoquinoneimine then rapidly binds to hepatocyte constituents, including the cysteine portion of intramitochondrial proteins, producing protein adducts within the liver. In animal experiments, hepatotoxicity becomes evident only when hepatic [GSH] decreases to 30% of baseline or below.<sup>236</sup>

When NAPQI formation overwhelms the supply of thiol-containing compounds, it covalently binds<sup>142,266</sup> and arylates proteins throughout the cell,<sup>67,172,174,266</sup> inducing a series of events that result in cell death.<sup>54,67,174</sup> Both covalent binding and GSH deficiency are necessary for hepatotoxicity; however, the selective arylation of specific cellular proteins is more predictive of toxicity than total covalent binding.<sup>67,163,167</sup>

Protein binding of NAPQI and the formation of protein adducts does not imply toxicity as adducts are formed and detected in the serum at a therapeutic [APAP].<sup>151,251</sup> However, highly elevated concentrations of protein adducts in the serum are likely indicative of cellular necrosis and hepatotoxicity. Protein binding of NAPQI leads to a cascade of events that alters mitochondrial function and impairs cell defenses against endogenous reactive oxygen species.<sup>174,285</sup> This cascade is ameliorated with *N*-acetylcysteine (NAC) even after covalent binding occurs.<sup>50,120,167,285</sup>

The cascade begins with NAPQI binding to mitochondrial proteins,<sup>384</sup> which leads to activation of MAP kinases (eg, MLK-3, RIP-1, ASK-1, GSK3B) and<sup>182,393</sup> phosphorylation and translocation of c-Jun N-terminal kinase (JNK).<sup>384</sup> These effects lead to opening of mitochondrial permeability transition (MPT) pores, causing mitochondrial membrane permeability,<sup>283,285</sup> decreased mitochondrial respiration, and decreased adenosine triphosphate (ATP) synthesis.<sup>96,283</sup> Furthermore, MPT opening leads to release of intermembrane proteins (endonuclease G, apoptosis inducing factor) and ultimately leads to DNA fragmentation<sup>72</sup> and cellular necrosis. Fragmentation of DNA is partially caused by inhibition of topoisomerase 2- $\alpha$ <sup>25,321</sup> as well as calcium dyshomeostasis.<sup>240,360,361</sup> Additional mechanisms of toxicity include nitric oxide release<sup>298</sup> and regulation of protein expression.<sup>35,163,164,283,297</sup> Which specific events are critical and irreversibly commit the cell to death are not known.

The final pathway of hepatic cell death is predominantly cellular necrosis.<sup>135</sup> Cellular injury leads to release of damage-associated molecular patterns (DAMPs), including DNA fragments, heat shock proteins, and high-mobility group box 1 protein (HMGB-1), which activate Toll-like receptors (TLRs) on Kupffer cells, leading to further cytokine release, and nitric oxide release.<sup>298</sup> Some of the intracellular components that are released from necrotic cells are biomarkers of hepatic injury and include aspartate aminotransferase (AST), alanine aminotransferase (ALT), microRNA 122 (miRNA-122), HMGB-1, keratin-18 protein (K-18), and protein adducts.<sup>12,13,92,152,209</sup> Apoptosis occurs early in APAP toxicity<sup>221,265,282</sup> or after activation of the immune system in response to cellular necrosis<sup>1,12</sup> but is not likely the major mechanism of cellular toxicity. Macrophages, neutrophils, and inflammatory cells infiltrate after necrosis<sup>160,162,196,199</sup> followed by a cascade of inflammatory cytokines such as interleukin (IL) 1, IL-6, IL-8, leukotrienes, Toll-like receptor-9 (TLR-9),<sup>220</sup> and monocyte chemoattractant protein-1 (MCP-1).<sup>166,167,196,213,220,274</sup> Cellular infiltration contributes to further hepatocellular destruction<sup>213</sup> but is not necessary for hepatic injury.<sup>72,199</sup> Hepatocyte recovery, repair, and proliferation are modulated by inflammatory mediators, cellular infiltration, and bile acids. The balance of necrosis and regeneration is an important area of current research.<sup>36,37,165</sup>

Hepatotoxicity initially and most profoundly occurs in hepatic zone III (centrilobular) because this zone is the area with the largest concentration of oxidative metabolism (CYP2E1; Fig. 21–1). In more severe hepatotoxicity, necrosis extends into zones II and I, destroying the entire hepatic parenchyma.

Kidney injury after acute overdose is typically acute tubular necrosis that is most likely caused by local production of NAPQI by renal CYP2E1 enzymes.<sup>47,144,159</sup> However, several other nephrotoxic mechanisms are proposed.<sup>143</sup> Conversion of APAP and hepatically derived APAP–GSH<sup>239</sup> to nephrotoxic

*p*-aminophenol<sup>58</sup> and *p*-benzoquinone are demonstrated in animal models.<sup>227</sup> *N*-acetyl-*p*-benzoquinoneimine formation via renal COX-2 and prostaglandin-mediated renal medullary ischemia<sup>273</sup> are also suspected of contributing to chronic analgesic nephropathy from APAP alone or in combination with other analgesics.<sup>115,299</sup> In patients with hepatic failure, volume depletion and hepatorenal syndrome are the most important contributory cofactors.<sup>378</sup> Dose-related renal potassium wasting<sup>255,369</sup> after acute APAP overdose is caused by APAP-induced renal vasoconstriction due to COX inhibition, a NAC effect, or both.<sup>255</sup>

Direct injury to organs other than the liver and kidney is rarely reported. The mechanism of early central nervous system (CNS) depression after APAP ingestion is undefined, but theoretical mechanisms include serotonin and opioid effects as well as APAP-induced CNS GSH depletion.<sup>56</sup> Early after massive APAP ingestion, metabolic acidosis and elevated lactate result from alterations in mitochondrial respiratory function.<sup>53,107,114,327,350</sup> Rare cases of metabolic acidosis with 5-oxoprolinemia and 5-oxoprolinuria are reported and are more likely in women with chronic APAP use and chronic kidney disease.<sup>49,111,157</sup> In this rare condition, chronic APAP use combined with acute oxidative stress and inflammatory mediators lead to an alteration of the  $\gamma$ -glutamyl cycle and elevations of  $\gamma$ -glutamylcysteine and 5-oxoprolin (Fig. 33–2).<sup>49,157,212</sup> Cases of APAP-induced oxoprolinemia may be indicative of genetic polymorphisms of GSH synthetase and 5-oxoprolinase, and genetic testing is reasonable in these patients.<sup>212</sup>

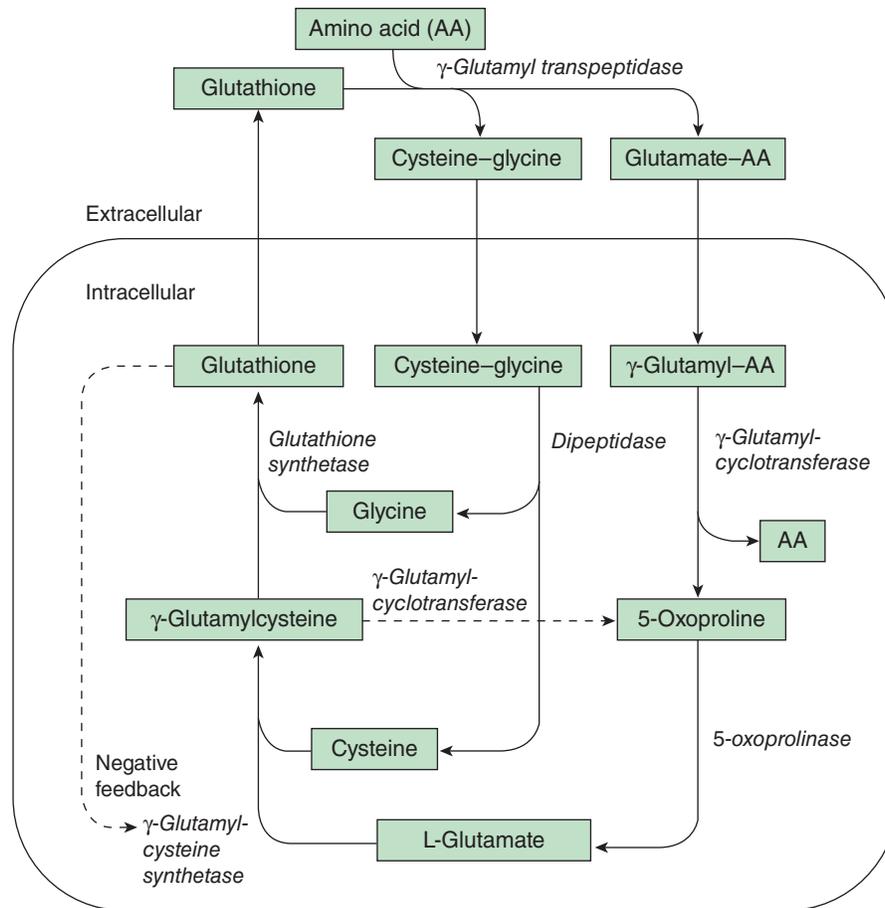

The remaining sequelae of severe toxicity are secondary effects of fulminant hepatic failure rather than direct APAP effects, and the pathophysiology of these complex multisystem problems is well described.<sup>204</sup> The ability of NAC to ameliorate secondary multiorgan failure via extrahepatic mechanisms suggests that the oxidation of vital thiols and the loss of normal microvascular function are important components of secondary organ failure.<sup>141,177</sup>

## CLINICAL MANIFESTATIONS

Early recognition and treatment of patients with APAP poisoning are essential to minimize their morbidity and mortality. This task is made difficult by the lack of early predictive clinical findings. The first reliable clinical findings of toxicity after APAP overdose are often those of hepatic injury, which develop many hours after the ingestion, when antidotal therapy will have diminished efficacy.

The clinical course of acute APAP toxicity is typically divided into four stages.<sup>291</sup> During stage I, hepatic injury has not yet occurred, and even patients who ultimately develop severe hepatotoxicity are often asymptomatic. Clinical findings, when present, are nonspecific and include nausea, vomiting, malaise, pallor, and diaphoresis. Laboratory indices of hepatic function are normal. In cases of massive overdose, a decreased level of consciousness,<sup>100,131,188,290,327,348</sup> metabolic acidosis, and even death<sup>43,325</sup> may occur during this stage in the absence of clinical findings of hepatotoxicity.<sup>43,112,188,290,318,392</sup> The metabolic acidosis is associated with elevated lactate concentrations<sup>131,188,231,290,318,327,377,391</sup> and is caused by inhibition of electron transport by APAP, NAPQI, or both.<sup>106,107,131,318</sup> These clinical findings should never be attributed to APAP alone without thorough evaluation for other possible causes.

Stage II represents the onset of hepatic injury, which occurs in fewer than 5% of those who overdose.<sup>334</sup> The AST is the most sensitive widely available measure to detect the onset of hepatotoxicity, and [AST] abnormalities always precede evidence of actual hepatic dysfunction (prolonged prothrombin time {PT}, international normalized ratio {INR}, elevated bilirubin concentration, hypoglycemia, encephalopathy, and metabolic acidosis). When stage II occurs, [AST] elevation most commonly begins within 24 hours after ingestion and is nearly universal by 36 hours.<sup>132,323</sup> In the most severely poisoned patients, AST may increase as early as 12 hours after ingestion.<sup>132,323</sup> The ALT begin to elevate shortly after the AST, but they peak at similar concentrations, and AST decreases earlier than the [ALT]. Of note, both AST and [ALT] are markers of hepatotoxicity, but because [AST] rises and decreases earlier than [ALT], we recommend using AST for detecting early hepatotoxicity and for determining hepatic recovery. In all other cases, AST and ALT are interchangeable and are described generically as aminotransferases in this chapter.

**FIGURE 33-2.**  $\gamma$ -Glutamyl cycle. The  $\gamma$ -glutamyl cycle is the primary pathway for glutathione synthesis and degradation. In rare cases, or massive acetaminophen (APAP) use combined with acute oxidative stress may lead to decreased glutathione concentrations, which via a feedback loop, increases  $\gamma$ -glutamylcysteine concentrations, which is then converted to 5-oxoproline, leading to acidosis and elevated 5-oxoproline concentrations. (Reproduced with permission from Duewall JL, Fenves AZ, Richey DS, et al. 5-Oxoproline (pyroglutamic) acidosis associated with chronic acetaminophen use. *Proc (Bayl Univ Med Cent)* 2010 Jan;23(1):19-20.)

Concentrations of APAP-protein adducts (APAP-CYS) become detectable within hours of ingestion,<sup>170</sup> peak with AST, and have an elimination half-life of about 27 hours.<sup>77,170</sup> Symptoms and signs during stage II vary with the severity of hepatic injury. Acetaminophen-induced *hepatotoxicity* is defined as a peak [AST] or [ALT] above 1,000 IU/L. Although lower peak concentrations of [AST] or [ALT] represent some injury to hepatic tissue, they rarely have any clinical relevance.

Stage III, defined as the time of maximal hepatotoxicity, most commonly occurs between 72 and 96 hours after ingestion. The clinical manifestations of stage III include fulminant hepatic failure with encephalopathy and coma, and, rarely, hemorrhage. Results of laboratory studies are variable; AST and ALT concentrations above 10,000 IU/L are common, even in patients without other evidence of hepatic failure. Much more important than the degree of [aminotransferase] elevation, abnormalities of PT and INR, glucose, lactate, creatinine, and pH are essential determinants of prognosis and treatment.

Renal function abnormalities are rare (< 1%) overall,<sup>62,272,372</sup> but they occur in as many as 25% of patients with significant hepatotoxicity<sup>153,272</sup> and in 50% to 80% of those with hepatic failure.<sup>195,287,378</sup> Renal abnormalities are more common after repeated excessive dosing<sup>195</sup> and in adolescents and older adults.<sup>46,62,226,241</sup> After acute ingestions, elevations of serum creatinine typically occur between 2 and 5 days after ingestion, peak on days 5 to 7 (range, 3–16 days),<sup>372</sup> and normalize over 1 month.<sup>226</sup> When severe acute kidney injury (AKI) necessitating hemodialysis occurs, it nearly always occurs in patients with marked hepatic injury. Patients with hepatorenal syndrome are commonly treated with continuous renal replacement therapy, and among those who survive, kidney failure generally resolves within 1 month.<sup>211,287</sup> Infrequently, mild AKI occurs without elevations in [aminotransferase].<sup>4,46,66,104</sup>

Fatalities from fulminant hepatic failure generally occur between 3 and 5 days after an acute overdose. Death results from either single or combined complications of multiorgan failure, including acute respiratory distress syndrome, sepsis, cerebral edema, or, rarely, hemorrhage. Patients who survive this period reach stage IV, defined as the recovery phase. Survivors have complete hepatic regeneration, and no cases of chronic hepatic dysfunction are reported. The rate of recovery varies; in most cases, [AST], pH, PT, and INR, and [lactate] are normal by 7 days in survivors of acute overdoses. [Alanine Aminotransferase] remains elevated longer than [AST], and creatinine may be elevated for more than 1 month. The recovery time is much longer in severely poisoned patients, and hepatic histologic abnormalities potentially persist for months.<sup>207,225,264</sup>

## DIAGNOSTIC TESTING

### Assessing the Risk of Toxicity

#### Principles Guiding the Diagnostic Approach

Most patients with APAP exposures do not develop toxicity, and the overall mortality rate after acute APAP ingestion is less than 0.5%.<sup>334</sup> However, APAP is now the leading cause of acute liver failure (ALF) in the United States and much of the developed world.<sup>195</sup> To maintain the seemingly divergent goals of avoiding the enormous cost of overtreatment while minimizing patient risk, clinicians must understand the basis for and sensitivity of current toxicity screening methods. A discussion of the diagnostic approach follows.

When evaluating risk, it is useful to separate different categories of APAP exposure. There is an extensive body of experience and literature on acute overdose in typical circumstances, permitting a systematic approach with demonstrated efficacy. For issues related to repeated supratherapeutic APAP dosing,

uncertain circumstances, new APAP formulations, and many other permutations, there is an important conceptual framework for decision making but little in the way of validated strategies. For these challenges, the central concepts and one approach are presented here, with the understanding that the challenges continue to evolve and that more than one approach may have validity.

The ideal model for determining risk after APAP overdose would assess the individual's metabolic enzyme activity (CYP2E1, UDP-glucuronyl transferase, and sulfotransferase activity), the amount and rate of NAPQI formation, the availability of hepatic GSH, early markers of cellular disruption, and the balance of NAPQI formation and hepatic GSH turnover. At present, none of these measures is available to clinicians.

### Risk Determination After Acute Overdose

Determining risk in a patient with acute overdose consists of determining the initial risk based on dosing history and then potentially further risk stratifying with serum [APAP].

Acute overdose usually is defined as a single ingestion, although many patients actually overdose incrementally over a brief period of time. For purposes of this discussion, an *acute overdose* is somewhat arbitrarily defined as one in which the entire ingestion occurs within a single 4-hour period. Doses of 7.5 g in an adult or 150 mg/kg in a child are widely disseminated as the lowest acute dose capable of causing toxicity.<sup>271</sup> These standards are likely quite conservative but have stood the test of time as sensitive markers and are corroborated with human data.<sup>370,395</sup> However, it is more likely that doses of at least 12 g (~150 mg/kg) in an adult or 200 to 350 mg/kg in a child are necessary to cause hepatotoxicity in most patients.<sup>238,365,370</sup>

The adult standard is less controversial than that for children because massive ingestions, unreliable histories, and factors that might predispose to toxicity occur primarily in adults, justifying continued use of 7.5 g as a screening amount to avoid missing serious toxicity. In patients younger than 6 years of age, with unintentional ingestions, use of a higher 200-mg/kg cutoff is reasonable<sup>57,85,238,352</sup> and is likely appropriate but is incompletely studied.

The dose history should be used in the assessment of risk only if there is reliable corroboration or direct validation. Although the amount ingested by history linearly correlates with risk of toxicity and an [APAP] over the treatment line,<sup>26,370,395,102,200</sup> historic information is not sufficiently reliable in every patient to exclude significant ingestion, particularly in patients with the intent of self-harm.<sup>102,200,395</sup> Reported ingested doses of 6 g, 13 g, 30 g, and 50 g infer a risk of about 5%, 10%, 50%, and 90%, respectively, that the [APAP] will be above the treatment line.<sup>102</sup> However, suicidal patients with ingestions who do not confirm an ingestion of APAP have a measurable concentration in 1.4% to 8.4% of cases<sup>15,216</sup> and a concentration over the treatment line in 0.2% to 2.2%.<sup>15,216</sup> Therefore, when the history suggests possible risk, the patient should be further assessed with measurement of a serum [APAP].

Interpretation of [APAP] after acute exposures is based on an adaptation of the Rumack-Matthew nomogram (Fig. 33–3).<sup>293</sup> The original nomogram was based on the observation that untreated patients who subsequently developed an [AST] above 1,000 IU/L could be separated from those who did not on the basis of their initial [APAP]. A nomogram was constructed that plotted the initial concentration versus time since ingestion, and a discriminatory line was drawn to separate patients who developed hepatotoxicity from those who did not. The initial discriminatory line stretched from an [APAP] of 300 mcg/mL at 4 hours to 50 mcg/mL at 12 hours but was lowered to between 200 mcg/mL at 4 hours and 50 mcg/mL at 12 hours after evaluation of additional patients.<sup>293</sup> The half-life of APAP was not a factor in the development of the nomogram, and the slope of the treatment line is based on empirical clinical data and does not reflect any discriminatory APAP half-life or APAP kinetics.<sup>293</sup> The nomogram is designed and validated using a single value obtained at or greater than 4 hours after ingestion to allow for complete APAP absorption. Although patients who develop hepatotoxicity typically have APAP half-lives greater than 4 hours,<sup>270,329</sup> plotting multiple points on the nomogram or using an APAP half-life to determine risk is not adequately studied and has significant limitations.<sup>185,338</sup> The nomogram

was later extrapolated to 24 hours using the same slope of the original nomogram line.<sup>293</sup>

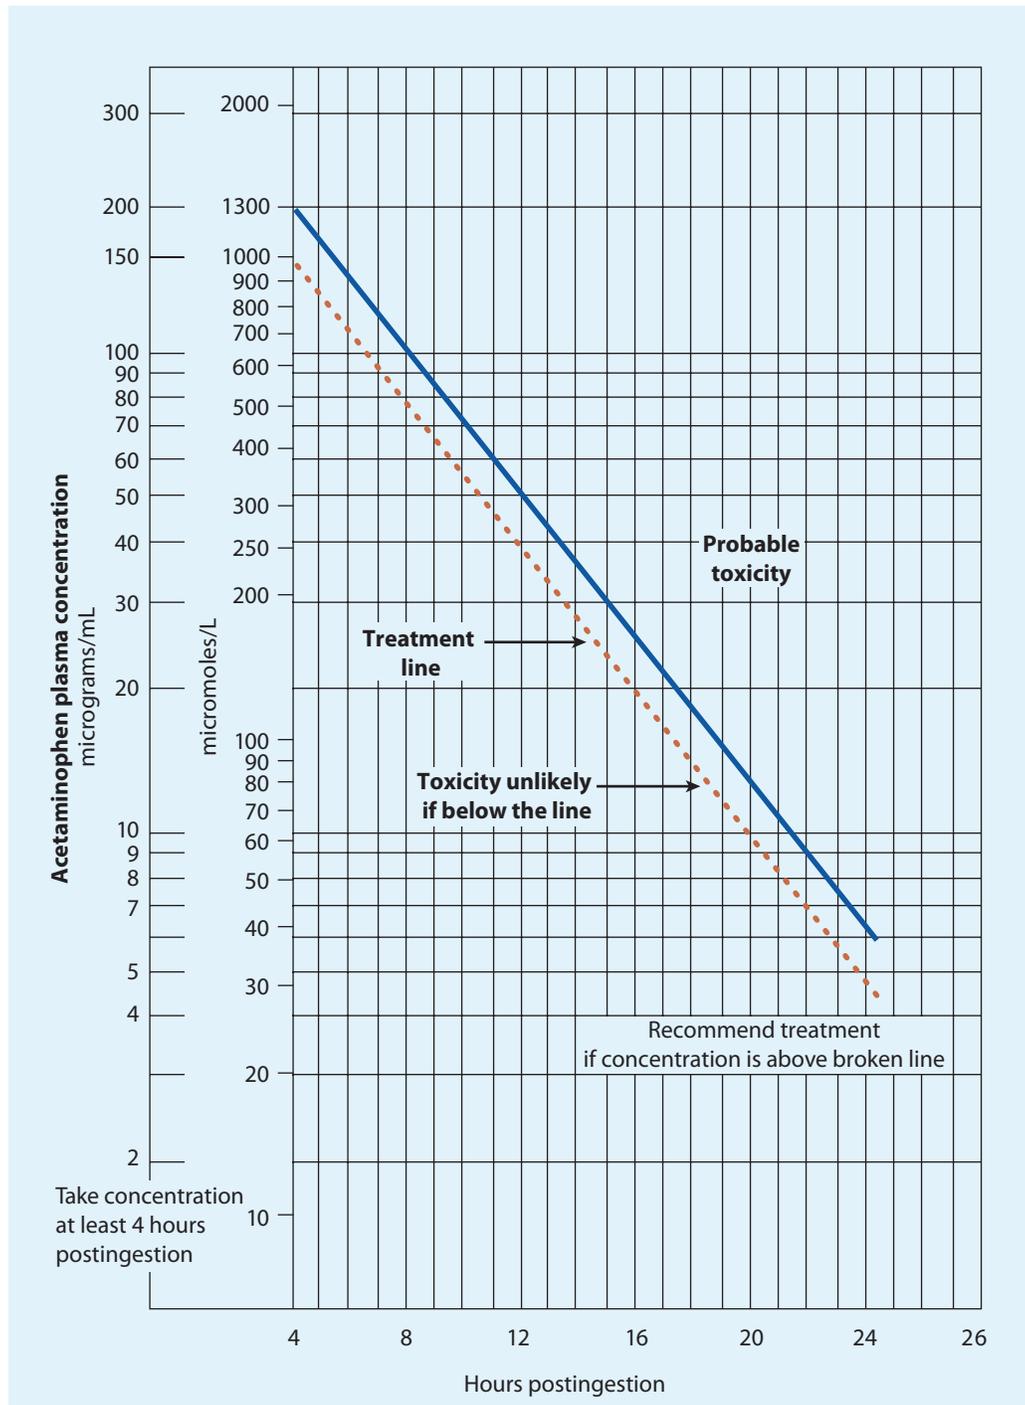

It is important to realize that the line was based on [aminotransferase] elevation rather than on hepatic failure or death, and it was chosen to be very sensitive, with little regard to specificity. Without antidotal therapy, only 60% of those with an initial APAP above this original line will develop hepatotoxicity as defined by [aminotransferases] above 1,000 IU/L, but the risk of hepatotoxicity is not the same for all such patients. Elevated [aminotransferase] develops in virtually all untreated patients with [APAP] far above the line, and serious hepatic dysfunction occurs frequently; the incidence of hepatotoxicity among patients with an [APAP] immediately above the line is very low, and the risk of hepatic failure or death is far less.<sup>272,328</sup>

The line used in the United States runs parallel to the original but was arbitrarily lowered by 25% to add even greater sensitivity.<sup>291,293</sup> The lower line, subsequently referred to as the *treatment line* or *150 line*, starts at a concentration of 150 mcg/mL at 4 hours following ingestion and ends at 4.7 mcg/mL 24 hours following the overdose. The treatment line is one of the most sensitive screening tools used in medicine. The incidence of nomogram failures using this line in the United States is only 1% to 3% (depending on time to treatment).<sup>293</sup> These infrequent “failures” result from inaccurate ingestion histories, or patients with currently undefined risk factors for toxicity, including unique GSH handling or CYP enzyme activities.<sup>230,293</sup>

The United Kingdom uses a single nomogram line starting at 100 mcg/mL at 4 hours (“100 line”) for all acute APAP ingestions.<sup>122</sup> This single 100 line replaced a two-tiered treatment protocol that treated low-risk patients if either their [APAP] exceeded the “200 line” or high risk patients if their [APAP] exceeded the “100 line.”<sup>373</sup> The change was motivated by concern with regard to a small number of patients with an [APAP] between the 100 and 200 lines who developed hepatotoxicity<sup>23,48,89,293,337,373</sup> and a desire to simplify the treatment protocol. The change led to an increase in adult and pediatric admissions,<sup>20,248</sup> anaphylactoid reactions to NAC, and millions of additional dollars in treatment costs.<sup>19</sup>

Based on these observations and more than 25 years of use, the 150 line is adequate in nearly all cases and is reliable when rigorously followed. When using the APAP nomogram, it is essential to precisely define the time window during which APAP ingestion occurred and, if the time is unknown, to use the *earliest possible time* as the time of ingestion. Using this approach, patients with an [APAP] below the treatment line, even if only slightly so, do not require further evaluation or treatment for acute APAP overdose. Reports of patients developing hepatotoxicity with an [APAP] below the treatment line are exceedingly rare, and risks are estimated as less than 1% risk of hepatotoxicity and less than 0.05% of liver failure.<sup>23,293</sup> This also applies to most patients with factors that predispose them to APAP-induced hepatotoxicity. There is adequate experience with acute APAP overdose in the settings of potentially predisposing factors such as chronic heavy ethanol use, chronic medication with CYP-inducing xenobiotics, and inadequate nutrition to recommend that no special approach is required in such cases. Further study is needed to determine if rare events, such as acute APAP ingestion in the setting of chronic isoniazid (INH) use,<sup>105,244,390</sup> might uniquely predispose patients to toxicity and require alteration of this approach.

The goal should be to determine an [APAP] at the earliest point at which it will be meaningful in decision making. Therefore, measurement of an [APAP] 4 hours after ingestion or as soon as possible thereafter is used to confirm the patient's risk of toxicity and thus the need to initiate NAC. Although it is optimal to start NAC therapy as soon as possible after confirmation of risk, NAC is nearly 100% effective if started before 8 hours after ingestion.<sup>328,333</sup> This allows clinicians some leeway to wait for the laboratory results before starting therapy in patients in whom the history of ingestion suggests that the 4-hour [APAP] will fall below the treatment line. However, it should be noted that delaying NAC therapy longer than 8 hours after ingestion increases the patient's risk. If there is any concern about the availability of an [APAP] before this time, then treatment with NAC should be initiated. In such cases, the [APAP] still should be determined as soon as possible. When the results become available, they should be interpreted according to

**FIGURE 33-3.** Rumack-Matthew nomogram (reconstructed) for determining the risk of acetaminophen (APAP)-induced hepatotoxicity after a single acute ingestion. Serum [APAP] above the treatment line on the nomogram indicates the need for *N*-acetylcysteine therapy. (Reproduced with permission from Tintinalli JE, Stapczynski S, Ma OJ, et al. *Tintinalli's Emergency Medicine: A Comprehensive Study Guide, 8th ed.* New York, NY: McGraw-Hill Education; 2016.)

the treatment line on the APAP nomogram and NAC either continued or discontinued on the basis of this result. In the unusual circumstance in which no determination of an [APAP] can ever be obtained, evidence of possible risk by history alone is sufficient to initiate and complete a course of NAC therapy postingestion.

#### Early Measurement of [APAP]

Measurement of the [APAP] between 2 and 4 hours after ingestion is only helpful to exclude ingestion of APAP. If an [APAP] is undetectable in this time frame, significant APAP overdose is likely excluded.<sup>387</sup> However, an [APAP] that is detectable between 2 and 4 hours cannot be definitively interpreted and, unless undetectable, mandates repeat testing at 4 hours. An [APAP]

before 2 hours should not be interpreted because of several cases of low or undetectable [APAP] in this time period with a resulting 4-hour [APAP] over the treatment line.<sup>118,347</sup>

#### Determination of Risk When the Acetaminophen Nomogram Is Not Applicable

##### Risk Determination When Time of Ingestion Is Unknown

With careful questioning of the patient, family, and others, it is almost always possible to establish a time window during which the APAP ingestion must have occurred. The *earliest possible time* of ingestion ("worst-case scenario") is used for risk-determination purposes. If this time window cannot be established or is so broad that it encompasses a span of more than 24 hours,

then the following approach is suggested. Determine both the [APAP] and [AST]. If the [AST] is elevated, regardless of the [APAP], treat the patient with NAC. If the time of ingestion is completely unknown and the [APAP] is detectable, it is prudent to assume that the patient is at risk and to initiate treatment with NAC. If the [APAP] is undetectable and the AST is normal, there is little evidence that subsequent consequential hepatic injury is possible,<sup>325</sup> and NAC is unnecessary.

### Risk Assessment After Extended-Release Acetaminophen

Extended-release formulations of APAP exist in the United States, Australia, New Zealand, and other countries worldwide. The pills available in the United States consists of a 325-mg immediate-release APAP dose and an additional 325-mg dose designed for delayed dissolution.<sup>83</sup> The pills found in Australia and New Zealand (all three have identical contents) consist of a 665-mg bilayer tablet with 206 mg in the immediate-release form and 459 mg in a sustained-release gel matrix.<sup>127,128</sup> Both products result in the immediate release of APAP with delayed release of an additional dose. Pharmacokinetic analysis of the US product reveals that the majority of APAP is absorbed within 4 hours,<sup>98,363</sup> the peak [APAP] is within 4 hours,<sup>61,98,349</sup> and a small number of overdose patients have an initial [APAP] below the treatment line but then have a subsequent [APAP] above the treatment line (“nomogram crossing”).<sup>61,363</sup> “Nomogram crossing” is also described with the Australian and New Zealand products.<sup>128,129</sup> This “nomogram crossing” is not unique to the extended-release products and occurs in up to 10% of patients with acute ingestions of immediate-release APAP<sup>52</sup> and those with ingestions of APAP with diphenhydramine or opioids.<sup>184</sup> There is little evidence that nomogram crossing is correlated outcome<sup>83</sup> and no evidence that an alternate approach to extended-release products should be used. In a 9-year review of 2,596 extended-release APAP overdoses in the United States, one death was reported from acute overdose, and there was no increased risk over immediate-release APAP.<sup>76</sup> In Australia and New Zealand, 48 cases of overdose are described with only 2 cases of hepatotoxicity, but with some evidence of altered kinetics, including one case of a double-hump [APAP] and 15% line crossers.<sup>127-129</sup> It is reasonable to plot a single [APAP] on the treatment nomogram after ingestion of the US APAP extended-release ingestion. Australian protocols suggest treatment with NAC for any patient who ingests 10 g or 200 mg/kg and continuing NAC for patients who have one of two [APAP] above the treatment line. Whether an alternative approach will be necessary for the Australian and New Zealand products, or any other new formulation, will require additional study.

### Intravenous Acetaminophen

Several IV APAP and prodrug APAP products exist worldwide and the US Food and Drug Administration (FDA) approved an IV APAP product in 2004 (IV APAP, 1 g in 100 mL).<sup>130</sup> Experience with patients with IV APAP overdose is limited. Hepatotoxicity and liver failure are described after single erroneous supratherapeutic doses of 75 to 150 mg/kg.<sup>27,130,249</sup> These errors most commonly occur in young children and include 10-fold dosing errors, confusion between mg and mL, and incorrect route (oral product given intravenously).<sup>28,130</sup> Cases of hepatotoxicity with liver failure are reported after repeated therapeutic dosing (59–77 mg/kg/d) in severely catabolic patients over 3 to 5 days.<sup>202,315</sup>

Although the nomogram is extensively studied in patients with oral APAP ingestion, there is no evidence for its use in those with IV overdose. Intravenous administration of APAP leads to a higher initial [APAP] and higher bioavailability than oral use and should theoretically expose the liver to less APAP.<sup>87</sup> Both routes lead to similar 4-hour [APAP],<sup>7,10,87</sup> and cases of hepatotoxicity and liver failure have occurred in patients whose [APAP] was well below the treatment line.<sup>27,87</sup> Given the limited data and that iatrogenic errors are usually quantifiable, it seems reasonable to treat a patient with NAC if he or she was exposed to more than 60 mg/kg of IV APAP in a single dose and to treat until the [APAP] is undetectable. Finally, it is also reasonable to treat patients receiving multiple therapeutic doses of IV APAP with NAC if there is evidence of hepatotoxicity or if there is evidence of APAP accumulation (eg, the [APAP] is above therapeutic concentrations that are expected for the last dose).<sup>130,315 202</sup>

### Risk Determination After Repeated Supratherapeutic Ingestions (or Chronic Overdose)

No well-established guidelines are available for determining risk after chronic exposure to APAP. Conceptually, several factors must be evaluated to determine an individual's risk of toxicity. It is well established that therapeutic dosing of APAP is safe; however, some risk factors put individual patients at risk for toxicity at supratherapeutic doses.

The chronic ingestion of “maximal therapeutic” doses (3–4 g/day) in normal adults without special circumstances is safe. Several randomized, controlled trials used maximal therapeutic doses of APAP (4 g/day) in thousands of patients over periods from 4 weeks to 2 years with no reported increase in adverse events or hepatic injury. A transient increase in aminotransferases of one to three times normal, but rarely up to 10 times normal, is detected in some patients taking therapeutic doses,<sup>3,149,374</sup> but these abnormalities resolve spontaneously despite continued use and have not led to hepatic dysfunction.<sup>149,191,374</sup> Finally, several studies have evaluated abstaining chronic alcoholics administered APAP 4 g/day for up to 10 days with no evidence of hepatic damage, although elevations in aminotransferases were detected in both APAP and control groups.<sup>80,191</sup>

Although therapeutic dosing appears to be safe, repeated supratherapeutic ingestions (RSTIs) may lead to toxicity. Given the amount of APAP use, the incidence of serious APAP toxicity after repeated doses is small, and hepatotoxicity appears to occur only after massive dosing or prolonged excessive dosing. The risk of hepatotoxicity is likely proportional to both the total amount of APAP ingested and the duration of the exposure; however, exact cutoffs for safe dosing are difficult to determine and are likely subject to factors related to the individual.

Although short-term prospective studies of supratherapeutic dosing (6–8 g/day) have not identified alterations in APAP kinetics or hepatotoxicity,<sup>119</sup> several series and case reports identify patients with hepatotoxicity who retrospectively reported therapeutic or slightly supratherapeutic doses. Retrospective dosage reporting is prone to significant errors and issues in which those giving the history are unable or unwilling to report or estimate ingestions accurately. Cases describing hepatic toxicity after in-hospital therapeutic doses exist but are exceedingly rare, involve unusual risk factors, and demonstrate multifactorial hepatic injury.<sup>60,65,315</sup> Furthermore, because APAP is commonly used in patients with chronic heavy ethanol use and viral infections, it is unclear in which cases APAP was causative, contributory, or unrelated to hepatotoxicity.

Conceptually, the groups that are at “high risk” for hepatotoxicity after RSTI of APAP have potentially increased activity of CYP2E1 and therefore proportionally increased NAPQI formation or have decreased GSH stores and turnover rate. Many reported cases of APAP toxicity from RSTI involve patients who have a factor or factors that influence their GSH supply or turnover, NAPQI production, or both, including infants with febrile illness who received excessive dosing, chronic heavy ethanol users, catabolic postsurgical patients, and patients chronically taking CYP-inducing medications. Catabolic states enhance CYP2E1 activity and shunt hepatic metabolism to gluconeogenesis, leading to decreased glucose precursors for glucuronidation and subsequent increased production of NAPQI.

There is significant individual variability in genetic factors that are usually unknown to the clinician that increase or decrease the risk of toxicity.<sup>24</sup> A small subset of patients are able to ingest large amounts of APAP chronically without hepatotoxicity, possible because of increased ability to detoxify NAPQI (increased GSH-S-transferase P and NADPH quinone 1 activity) and decreased NAPQI production (reduced CYP2E1 activity and distribution).<sup>24,103</sup>

To determine the need for NAC, evaluate the patient's risk based on dosing history and other risk factors and then use limited laboratory testing that consists of an [APAP] and [AST], with additional testing as indicated by these results and other clinical features. The objective is to identify the two conditions that warrant NAC therapy—remaining APAP yet to be metabolized and potentially serious hepatic injury.

### Role of History and Physical Examination in Repeated Supratherapeutic Ingestions

The first consideration when evaluating a patient with a history of repeated supratherapeutic APAP dosing is the presence or absence of signs or symptoms of hepatotoxicity. Regardless of risk factors or dosing history, such findings should prompt treatment with NAC and laboratory evaluation. This is particularly important because most reported cases of serious toxicity after repeated dosing are symptomatic for more than 24 hours before diagnosis, and earlier treatment improves outcome.

In asymptomatic patients, a reasonable approach is to perform laboratory evaluation for those who have ingested more than 200 mg/kg/day (or 10 g/day, whichever is less) in a 24-hour period or more than 150 mg/kg/day (or 6 g/day, whichever is less) in a 48-hour period.<sup>80,84,218</sup> In children younger than 6 years of age, laboratory evaluation is reasonable if the reported ingestion is more than 100 mg/kg/day during a 72-hour period or longer.

Several factors or characteristics place patients at higher risk for APAP toxicity from repeated supratherapeutic dosing. Theoretical high-risk factors include chronic heavy ethanol use; chronic ingestion of INH; febrile illnesses in infants and young children; and malnutrition, catabolic states (eg, post-surgical), AIDS, and anorexia. In some cases, animal or basic science studies show evidence of increased risk, and there have been multiple anecdotal reports of toxicity at slightly supratherapeutic doses.

### Role of Laboratory Evaluation in Repeated Supratherapeutic Ingestions

After a patient is determined to be at risk, the [APAP] and [AST] should be determined. These should be interpreted using the concept that a patient is at risk of hepatotoxicity if there is evidence of hepatic injury (elevation of [AST]) or there remains enough APAP to produce further hepatic damage.

Using the strategy described here, patients with an elevated AST are considered at risk, regardless of their [APAP]. An [APAP] is useful in patients with a normal [AST] as a tool to determine only whether sufficient APAP remains to lead to subsequent NAPQI formation and delayed hepatotoxicity. In many cases, the [AST] is normal, and the [APAP] is undetectable, obviating the need for NAC. If the AST is normal, then the patient is considered at risk if the [APAP] is 10 mcg/mL or above.

Higher thresholds for nontreatment, such as an [APAP] below 30 mcg/mL or an [AST] twice as high as normal, have been suggested but have not been studied, and their sensitivity is unknown. The multiplicative sum of the [APAP] and the higher of the [AST] or the [ALT] ( $< 1,500 \text{ mg/L} \cdot \text{IU/L}$ ) predicts a low likelihood of hepatotoxicity in patients treated with NAC.<sup>329,381</sup> This tool is less conservative than the method described and should not be used to determine the need for NAC, but it has some use in prognosticating risk after NAC is started.

Patients who develop a highly elevated [AST] after chronic APAP overdose should be treated and further evaluated with laboratory tests to assess hepatotoxicity and prognosis ([creatinine], PT, INR, pH, [phosphate], and [lactate]). Initial elevations of INR or creatinine are markers of poor prognosis in RSTI of APAP.<sup>5</sup>

The measurement of APAP protein adducts in urine is described and theoretically could quantify NAPQI production in the liver. It is also suggested that adduct concentration identifies APAP-induced hepatotoxicity in undifferentiated patients with an elevated AST; however, adducts are elevated after both therapeutic and RSTI APAP ingestions and a clear defining value has not been determined.<sup>133</sup> In addition, the test remains largely unavailable and is insufficiently studied.<sup>88,167,242</sup> Several other biomarkers, including miRNA-122, nK18, and acetylated HMGB-1, have been tested in acute overdoses, but their utility in RSTI is unclear.<sup>92</sup>

Patients who are identified as at risk, with either an elevated [AST] or an elevated [APAP], should be treated with NAC.

### Risk Determination After Acetaminophen Exposure in Children

Serious hepatotoxicity or death after acute APAP overdose is extremely rare in children.<sup>292,352</sup> Predominant theories<sup>5</sup> for resistance to toxicity include a relative hepatoprotection in children because of increased sulfation capacity<sup>233</sup>

or differences in the characteristics of childhood poisonings, including smaller ingested doses, overestimation of liquid doses, and unique formulations (pediatric elixirs contain propylene glycol, which inhibits CYP2E1).<sup>178,354</sup> This has led some to suggest higher screening values and a higher nomogram line for children.<sup>40</sup> However, no significant change in NAPQI production is demonstrated in children, and a more liberal approach to children's acute APAP ingestions is inadequately studied and not recommended. After repeated supratherapeutic APAP dosing, there is no evidence that children are relatively protected. Hepatic injury after supratherapeutic APAP is likely exceedingly rare in children.<sup>198</sup> However, infants and children with acute febrile illnesses comprise one of the few groups in which toxicity after repeated excessive dosing is well described.<sup>270</sup> Common sources of dosing errors include substitution of adult for pediatric preparations, overzealous dosing by amount or frequency in attempts to maximize effect, and failure to read the label and dose carefully.<sup>257,270</sup> Age younger than 2 years is an independent risk factor for development of toxicity.<sup>176</sup> These rare cases of toxicity in febrile children with repeated supratherapeutic dosing likely reflect that these children constitute the most common setting for pediatric APAP use and that children are at greater relative risk for excessive dosing because of their size. Although logically one can argue that inflammatory oxidant stress and short-term fasting during febrile infectious illnesses affect oxidative drug metabolism and decrease GSH supply, these relationships are complex and not well defined. Of the reported cases of repeated supratherapeutic APAP dosing in children with hepatic injury, the cause was likely an isolated infectious illness in some, APAP in others, and a combination of the two in still others.

### Risk Determination After Acetaminophen Exposure in Pregnancy

The initial risk of toxicity in a pregnant woman is similar to that of a non-pregnant patient with a few exceptions. No alteration of the treatment line is necessary. In fact, there are no reported cases of fetal or maternal toxicity in women with an [APAP] below the treatment line<sup>228</sup> or in those treated with NAC within 10 hours of an acute ingestion.<sup>286</sup> However, there is controversy in assessing the risk of fetal toxicity after the mother is determined to be at risk. To better understand the issues, a review of maternal-fetal physiology and pharmacokinetics related to APAP and NAC is necessary.

Acetaminophen crosses the human placenta,<sup>208,247,288</sup> and an [APAP] in fetuses is similar to maternal serum concentrations within hours after ingestion.<sup>247,288</sup> Fetal metabolism of APAP probably is inefficient but is not completely understood. Sulfation is the primary method of metabolism of APAP in fetuses, but sulfation capacity decreases in the second half of pregnancy.<sup>2</sup> Oxidative metabolism of APAP occurs in the second and third trimesters but is slower than in adults, and glucuronidation is undetectable until 23 weeks of gestation.<sup>289</sup> Cytochrome P450 enzymes (CYPs) that are capable of oxidizing APAP are present in fetuses as early as 18 weeks gestation.<sup>289</sup> However, the activity of these enzymes is less than 10% that of adult enzymes at 18 weeks of gestation and increases to only 20% activity at 23 weeks.<sup>289</sup> How the opposing forces of decreased overall metabolism of APAP and decreased NAPQI formation impact fetal risk is unclear.

The mechanism of fetal risk in women with APAP toxicity and the degree of fetal toxicity that is attributable to fetal metabolism of APAP or to maternal illness are unclear. In clinical case series, the majority of pregnant women who overdose on APAP have uneventful pregnancies.<sup>228,286</sup> Pregnant women who develop APAP toxicity in the first trimester have an increased risk of spontaneous abortion,<sup>286</sup> fetal demise is described in the second trimester,<sup>117,355</sup> and those who develop APAP toxicity after about 20 weeks of gestation have a potential risk of fetal hepatotoxicity because of fetal metabolism.<sup>117</sup> However, reports of third-trimester fetal hepatotoxicity are rare<sup>228,286</sup> and are only associated with severe maternal toxicity.<sup>286,367</sup> The factors associated with poor fetal outcome after a large APAP overdose are delayed treatment with NAC and young gestational age.

The decision to treat a pregnant woman with NAC requires evaluation of the known efficacy and beneficial effects as well as the adverse events of NAC for both the fetus and the mother. Every indication suggests that NAC is both safe and effective in treating the mother,<sup>286</sup> but there are inadequate

data to evaluate efficacy in fetuses, although fetal outcome is generally excellent after maternal treatment with NAC.<sup>286</sup> Given that NAC is safely used in many pregnancies<sup>228,286</sup> and fetal mortality is linked to delays to treatment, NAC should be initiated in pregnant women who meet the same criteria as nonpregnant patients. The necessary length of NAC therapy is difficult to determine. The 21-hour IV protocol probably is the most commonly recommended NAC protocol used for pregnant women worldwide; however, there is a paucity of published experience supporting NAC treatment courses shorter than the oral 72-hour protocol (Chap. 31).<sup>228,286</sup>

### Ethanol and Risk Determination

The effects of ethanol on APAP toxicity are complex and are best described by clearly separating experimental animal data from actual human overdose experience, acute ethanol use from chronic heavy ethanol use or alcoholism, and single from repeated supratherapeutic APAP dosing. Ethanol use itself is difficult to define, and many studies use different definitions. For the purpose of this section, the term *chronic heavy ethanol use* is defined as a person who ingests a mean of greater than two to three standard ethanol-containing drinks per day.<sup>309</sup> Moderate ethanol use is defined as a mean of one to two standard ethanol-containing beverages per day. The term *alcoholic* will be used to define people who either self-define as alcoholics or are identified as an alcoholic by the CAGE questionnaire, the Michigan Alcohol Screening Test, or a similar screen.<sup>86,190,192</sup>

Although not entirely consistent, both animal and human data suggest that acute ethanol coingestion with APAP is hepatoprotective. Ethanol coingestion decreases NAPQI formation presumably by inhibiting CYP2E1 in both humans<sup>357,358</sup> and animals.<sup>302,358</sup> In large retrospective evaluations of overdoses, acute ethanol ingestion independently decreases the risk of severe hepatotoxicity in chronic heavy ethanol users<sup>309</sup> and in nonchronic heavy ethanol users<sup>328</sup> but did not significantly decrease the risk of hepatotoxicity ([ALT] > 1,000 IU/L) in a smaller prospective study.<sup>371</sup>

However, chronic ethanol administration increases the risk of hepatotoxicity from APAP dosing in animals.<sup>362,394</sup> This is due to induction of CYP2E1 metabolism after the ethanol is metabolized,<sup>356</sup> resulting in increased NAPQI formation, as well as decreased mitochondrial GSH supply impairing hepatocyte protection and regeneration.<sup>394</sup>

After *acute APAP overdose*, chronic heavy alcohol users who have not coingested ethanol are at a slightly increased risk; however, this elevated risk is of little clinical importance given the sensitivity of the treatment line.<sup>335</sup> There is no credible evidence that chronic heavy alcohol use should alter the approach after an acute APAP overdose using the treatment line. In fact, the treatment line was developed with clinical data that included chronic heavy ethanol users.<sup>270,291</sup> Given the paucity of data linking chronic heavy ethanol use to nomogram failures, the treatment line is adequately sensitive for screening after an acute APAP overdose, regardless of the patient's history of chronic heavy ethanol use.

The relationship between chronic heavy ethanol use and *chronic APAP use* is complex. Patients with chronic heavy ethanol use and repeated supratherapeutic APAP dosing have developed hepatotoxicity. Complicating these reports are the clinical challenges of obtaining accurate histories in chronic heavy ethanol users, failure to exclude non-APAP causes of hepatotoxicity, and other factors. Alcoholics are at higher risk of both using supratherapeutic doses of APAP and using combinations of multiple APAP-containing products.<sup>314</sup> In contrast, prospective evidence demonstrates minimal risk of hepatotoxicity in alcoholic patients who ingest therapeutic doses of APAP.<sup>18,147,190,192</sup> In prospective trials of ingestion of 4 g/day of APAP or placebo in chronic moderate to heavy ethanol users for up to 10 days, no clinically relevant increases in [AST] versus placebo were identified.<sup>18,86,147,190,192</sup> However, it should be noted that in studies involving persons who abuse alcohol, mild elevations of an [AST] (< 120 IU/L) were noted in 40% of both study and control participants, and more significant increases (> 120 IU/L, or three times normal) were noted in 4% to 6% of participants.<sup>171,173</sup> In addition, in all studies, a small group of patients developed significant increases in [AST], but most were unchanged. Patients who develop elevated [AST] after therapeutic dosing who are then rechallenged with additional APAP develop similar

increases in [AST],<sup>147</sup> implying that individual factors are likely more important than the chronic heavy ethanol use itself.

### CYP Inducers and Risk Determination

Isoniazid is an inducer of CYP2E1 that has been theorized to proportionally increase the production of NAPQI from APAP. Similarly, several other medications, including phenytoin, carbamazepine, and phenobarbital, are theorized to increase APAP toxicity because of nonspecific CYP induction or induction of other CYPs. None of these antiepileptics induces CYP2E1, although there is some evidence that they increase NAPQI formation in cultured human hepatocyte and animal models, possibly through inhibition of glucuronidation.<sup>99,236</sup> However, clinical experience suggests that there is no need to change the approach to these patients.

### Risk Assessment of Hepatotoxicity When the Diagnosis is Uncertain

In some cases, patients present with, or develop, hepatotoxicity with no clear ingestion history. Because APAP is the most common cause of ALF, the most reasonable approach to patients with evidence of liver failure or highly elevated aminotransferase concentrations is to consider them at risk of APAP-induced ALF even with an undetectable [APAP]. Other common causes of acute elevations of [aminotransferase] should be considered, including rhabdomyolysis and hepatotoxicity related to hypoperfusion or hypoxemia.

Up to 20% of adult and up to 50% of pediatric patients with ALF have an undetermined cause. Several biomarkers differentiate APAP ALF from other causes but are not yet clinically available. Protein adduct measurements have some utility in determining cases of adult APAP ALF, but they are not clinically available and have poor sensitivity and specificity in pediatric ALF.<sup>9</sup> The pattern of laboratory tests suggest that ALF is from APAP but are not absolutely diagnostic.<sup>229</sup> Cases of APAP ALF tend to have higher [AST] and [ALT] and lower [bilirubin] than other common causes of ALF.<sup>9</sup>

### Assessing Actual Toxicity: Critical Components of the Diagnostic Approach

#### Initial Testing

[APAP] should be measured in patients with acute APAP overdose and no evident hepatotoxicity, but no other initial laboratory assessment is required. AST should be measured in patients who are considered to be at risk for APAP toxicity according to the nomogram or history (in the case of repeated supratherapeutic dosing) or in those suspected of already having mild hepatotoxicity by history and physical examination.

Unless evidence of serious hepatotoxicity is present, the [AST] is a sufficient indication of hepatic conditions, and no additional testing is initially needed. [ALT] increases after [AST] and is not necessary to determine early toxicity. Death of hepatocytes, resulting in release of measurable hepatic enzymes, precedes all cases of serious hepatic dysfunction. Mild AKI rarely occurs without hepatotoxicity;<sup>46</sup> however, at least minimal elevation of the [AST] generally precedes evidence of clinically significant nephrotoxicity.<sup>4,56</sup> Exceptions are rare,<sup>46,182</sup> and routine screening of kidney function in the absence of an elevated [AST] is probably unnecessary.

Acetaminophen overdose often leads to minor prolongation of PT even without causing hepatotoxicity.<sup>376</sup> This most commonly occurs between 4 and 24 hours after ingestion and is the result of NAPQI-related inhibition of vitamin K–dependent  $\gamma$ -carboxylation of factors II, VII, IX, and X.<sup>353,376</sup> These minor prolongations (resulting in a PT that usually is less than twice control) are rarely clinically relevant, are not evidence of hepatotoxicity, and should not be used as prognostic factors or indications for NAC treatment. In fact, treatment with NAC also prolongs PT<sup>171,187</sup> by interfering with the PT assay, by reversing an APAP/NAPQI effect,<sup>353</sup> or by direct NAC effects.<sup>353</sup>

#### Ongoing Monitoring and Testing

If no initial elevation of AST is noted, then repeated determination of AST alone—without other biochemical testing—is sufficient to exclude the development of hepatotoxicity. The [AST] should be determined before the

end of the protocol or every 24 hours if using a longer protocol. If an elevated [AST] is noted, then PT, INR, and [creatinine] should be measured and repeated every 24 hours or more frequently if clinically indicated. Results of other hepatic tests, such as plasma  $\gamma$ -glutamyl transferase (GGT), alkaline phosphatase, lactate dehydrogenase, and bilirubin, which are useful when determining the cause of hepatic abnormalities, will be abnormal in cases of serious APAP-induced hepatotoxicity but provide little additional useful information if the cause is certain (Chap. 21).

If evidence of hepatic failure is noted, then careful monitoring of blood glucose, pH, PT, INR, creatinine, lactate, and phosphate concentrations are important in assessing extrahepatic organ toxicity and are vital in assessing hepatic function and the patient's potential need for hepatic transplant (see Assessing Prognosis). In addition, meticulous bedside evaluation is necessary to determine and document vital signs, neurologic status, and evidence of bleeding.

### Role of Biomarkers and Risk Determination

Although the risk of hepatotoxicity is generally low when NAC is started in the appropriate timeframe, there are cases in which risk assessment is difficult or impossible. In cases with unknown time of ingestions, late presenters, or multiple (staggered) ingestions, it may not be possible to accurately determine risk, and the current practice is to proceed conservatively. However, the conservative practice of treatment with NAC for unclear risk scenarios carries with it a risk of adverse reactions to NAC (which are more common in these scenarios) as well as excessive health care resource management. In these cases, use of a biomarker allows for targeted therapy to select individuals at high risk of adverse outcomes or allow early and safe discharge of well and low-risk groups. Although these biomarkers will be discussed here, none is currently rapidly clinically available for use and data are insufficient to recommend their use.

### Protein Adducts

Protein adducts indicate intracellular binding of NAPQI to hepatocyte proteins<sup>88,168,275</sup> and can be determined experimentally. While there is a bedside tool in development, protein adducts are inadequately studied to be currently useful in risk assessment. After over-exposure to APAP, NAPQI is not immediately bound to GSH and is released within the cell to bind with the cysteine components on proteins. One of these protein-APAP adducts is 3-(cysteinyl-S-yl)-APAP. However, hepatic toxicity from APAP requires not only protein binding, and therefore protein adducts, but an inflammatory cascade to produce cell necrosis.<sup>44</sup> Therefore, protein adducts are signs of NAPQI binding, but not necessarily of toxicity. Animals exposed to APAP overdose develop elevated concentrations of serum protein adducts.<sup>41,152,167</sup>

In humans with therapeutic dosing of APAP, protein adducts are usually detected in small quantities in the blood (< 0.5 nmol/mL), likely from intrahepatic protein binding followed by hepatic cellular turnover or protein adduct export from the cell. However, some patients with therapeutic dosing have concentrations of up to 1.0 nmol/mL.<sup>152</sup> In humans after overdose, protein adducts are released into the serum and largely parallel the [aminotransferase] in their time course. Peak concentrations are detected in 2 to 3 days and decrease with an elimination half-life of 27 hours (41 hours with kidney failure);<sup>77</sup> however, protein adducts remain detectable for up to 2 weeks.<sup>169</sup> A protein adduct concentration above 1.0 nmol/mL is suggested as being consistent with an acute APAP overdose, but this recommendation requires further validation.<sup>152</sup>

Plasma GSH can be measured or approximated using [GGT] but have an uncertain relationship to hepatic GSH availability.<sup>314,339</sup>

### Micro RNA

Micro RNAs (miRNAs) are small, noncoding RNAs that regulate cell proteins by repressing mRNA.<sup>209</sup> miRNA-122 is the most abundant hepatic microRNA and is specific to the liver.<sup>209</sup> In human studies, miRNA-122 increases before other markers, such as ALT, and is actively released from hepatocytes before cell lysis.<sup>92,210</sup> The [miRNA-122] correlates with peak [ALT]<sup>13</sup> and peak INR.<sup>13</sup>

In patients with acute APAP overdose whose initial [ALT] is normal and in patients who are treated within 8 hours, [miRNA-122] is higher in those who develop hepatic injury,<sup>13</sup> suggesting that it may be useful in differentiating low-risk patients from high-risk patients earlier than other markers.

### High-Mobility Group Box-1

Another biomarker, HMGB-1, is passively released by hepatocytes during necrosis. HMGB-1 targets TLRs and initiates an inflammatory cascade that leads to cell necrosis or apoptosis. This biomarker is elevated in patients with APAP hepatotoxicity but not in those without hepatotoxicity, rises earlier than the [ALT],<sup>92</sup> and correlates with both peak [ALT] and INR. An acetylated form of HMGB-1 is secreted as an inflammatory mediator by macrophages and monocytes and increases only in patients with APAP toxicity who later either meet transplant criteria (King's College criteria {KCC}), die, or receive a hepatic transplant. This biomarker requires further study but has promise as an earlier marker for more intensive treatment or for transplant.<sup>12</sup>

### Keratin-18

Keratin-18 (K18, or nK18 {necrosis K18}) is an epithelial and hepatic cell filament protein that is released passively during cell necrosis. Caspase-cleaved K18 (aK18, or apoptosis K18) fragments are released passively during apoptosis. The [K18] is elevated in patients who develop hepatotoxicity, even before [ALT] elevation.<sup>13,91</sup>

## MANAGEMENT

### Gastrointestinal Decontamination

In cases of very early presentation or coingestion of xenobiotics that delay gastrointestinal (GI) absorption, gastric emptying is appropriate for some patients. In general, however, gastric emptying is not appropriate for patients with isolated APAP overdose because of the very rapid GI absorption of APAP and the availability of an effective and safe antidote.

Administration of activated charcoal (AC) shortly after APAP ingestion decreases the number of patients who have an [APAP] above the treatment line.<sup>51,102</sup> Although AC is most effective when given within the first 1 to 2 hours after APAP ingestion, it is reasonable to give AC at later times provided there are no contraindications.<sup>102,344,345</sup> Interactions between AC and orally administered NAC are likely clinically unimportant. In the majority of cases, there should be no interaction because GI absorption of APAP, and therefore the necessity to give AC, is complete by 4 hours after ingestion, and NAC typically is administered between 4 and 8 hours after ingestion. As a result, there is generally no difficulty separating the doses. If delayed or repeated AC dosing is indicated because of suspected delayed absorption or coingestants, then a strategy using an IV NAC protocol is recommended. Alternatively, oral NAC and AC doses may be separated by 1 to 2 hours, with NAC given the priority for the first dose because time to administration of NAC correlates with risk of hepatotoxicity.<sup>328,333</sup> N-Acetylcysteine is absorbed high in the GI tract and is not likely to interact with AC if they are not administered simultaneously.

### Supportive Care

General supportive care consists primarily of managing the hepatic injury, AKI, and other manifestations. Treatment of these problems is based on general principles and is not APAP dependent. Discussion of the management of hepatic failure is clearly beyond the scope of this chapter, but certain aspects deserve mention. Monitoring for and treatment of hypoglycemia are critical because hypoglycemia is one of the most readily treatable of the life-threatening effects of hepatic failure. If adequate viable hepatocytes are present, vitamin K produces some improvement in coagulopathy; thus, trial dosing is reasonable as hepatic injury develops and as it resolves. Administration of fresh-frozen plasma (FFP) and prothrombin complex concentrates (PCCs) should be based on specific indications rather than PT and INR alone. Hemorrhage is rare in APAP-induced hepatic failure, and correction of coagulopathy should only be necessary for procedures and life-threatening bleeding. Supportive therapies for cerebral edema, including

cooling, hypertonic saline, elevation of the head, and support of the cerebral perfusion pressure, are all indicated.

### Antidotal Therapy with *N*-Acetylcysteine

**Mechanism of Action of *N*-Acetylcysteine.** Conceptually, it is helpful to think of NAC as serving three distinct roles. During the metabolism of APAP to NAPQI, NAC *prevents toxicity* by limiting the formation of NAPQI. More important, it *increases the capacity to detoxify* NAPQI that is formed (Fig. 33–1). In fulminant hepatic failure, NAC *treats toxicity* through nonspecific mechanisms that preserve multiorgan function (Antidotes in Depth: A3).

*N*-Acetylcysteine prevents toxicity mostly by serving as a GSH precursor<sup>197</sup> and as a GSH substitute,<sup>320</sup> combining with NAPQI and being converted to cysteine and mercaptate conjugates.<sup>33,48</sup> *N*-Acetylcysteine also supplies cysteine as a substrate for sulfation, allowing less metabolism by oxidation to NAPQI.<sup>330</sup> Each of these preventive mechanisms must be in place early, and none is of benefit after NAPQI has initiated cell injury. Time is required to saturate nontoxic metabolism, form excessive NAPQI, deplete GSH, and overcome GSH production; thus, there is a window of opportunity after exposure to an APAP overdose during which NAC is initiated before the onset of hepatic injury without any loss of efficacy. Based on large clinical trials, NAC efficacy is nearly complete as long as it is initiated within 8 hours of an acute overdose.<sup>180,328,332,333</sup> However, the relationship between the time to administration of NAC and the risk of hepatotoxicity is a continuous variable. The risk of hepatotoxicity begins to increase at 6 hours for patients with an [APAP] greater than 600 mcg/mL and is closer to 8 hours for patients with an [APAP] just over the treatment line.<sup>328,346</sup> For this reason, NAC therapy should be initiated as soon as possible after 4 hours and not delayed past 8 hours.

Several observations illustrate the effectiveness of NAC by other mechanisms of action even after NAPQI formation and binding. *N*-Acetylcysteine actually reverses NAPQI oxidation in an in vitro human hepatocyte model,<sup>221</sup> and even after cell injury is initiated, NAC diminishes hepatocyte injury.<sup>49</sup> Most significantly, a prospective, randomized trial found that even after fulminant hepatic failure was evident, IV NAC diminished the need for vasopressors and the incidences of cerebral edema and death.<sup>177</sup> In this study, despite improved organ function and survival in the NAC-treated group, there was no apparent difference in the degree of hepatic injury, implying that much of the benefit of NAC in this setting is not derived from hepatic effects. Whether based on its nonspecific antioxidant effects, its increase in oxygen delivery and utilization, its ability to enhance GSH supply and mitochondrial ATP production, or its role in mediating microvascular tone,<sup>93,140,173,296,343,366,367</sup> *N*-Acetylcysteine improves function in several organs affected by multisystem failure.<sup>93,364</sup> In fact, NAC preserves cerebral blood flow and perfusion in the setting of cerebral edema<sup>375</sup> more effectively than traditional therapies such as mannitol and hyperventilation, which may produce detrimental adverse effects.

Although NAC has a defined role in preventing and treating APAP-induced hepatic injury, its role in treating APAP-induced AKI is less clear. When used early after ingestion in animals, NAC produces a small reduction in kidney injury.<sup>299,331</sup> In retrospective reviews of human data, NAC has little effect on kidney injury<sup>90</sup> but does not appear to be harmful.<sup>241</sup> However, few data are available to recommend NAC therapy in treating isolated AKI or after resolution of hepatic injury.

***N*-Acetylcysteine Administration.** *N*-Acetylcysteine is administered via the oral or IV routes and in protocols that have historically varied in length. The most common regimens are a 12-hour IV infusion, a 21-hour IV infusion, and a 72-hour oral dosing protocol. However, the concept of a set-length protocol is obsolete. Conceptually, practitioners should start NAC when the patient is at risk of toxicity, continue NAC while the patient remains at risk or has hepatotoxicity, and stop NAC when that risk or toxicity is gone. Most institutions now use either oral or IV NAC in a variable length protocol, using indicators of patient toxicity rather than a set protocol length.<sup>148</sup>

With the exception of established hepatic failure, for which only the IV route has been investigated,<sup>177</sup> the IV and oral routes of NAC are equally efficacious in preventing or treating APAP toxicity.<sup>51,269</sup> In brief, whereas IV NAC

is associated with rare but severe anaphylactoid reactions and medication errors,<sup>145</sup> oral NAC is associated with a greater than 20% risk of vomiting. There are three scenarios in which IV NAC is preferentially recommended: (1) APAP toxicity in pregnant women, (2) APAP-induced hepatic failure, and (3) intractable vomiting preventing oral treatment.

**Duration of *N*-Acetylcysteine Treatment.** Known mechanisms of action and the observation that all studied durations of NAC are effective when started within 8 hours<sup>51</sup> suggest that all courses of treatment currently published are effective when NAC is used for its early preventive actions. There is some suggestion that there is a slightly decreased risk of hepatotoxicity if IV NAC, as opposed to oral NAC, is used before 10 hours after the ingestion, but this remains controversial.<sup>386</sup> Results from use of the traditional 21-hour IV NAC protocol, the 48-hour and 36-hour IV NAC protocols studied in the United States,<sup>336</sup> one 20-hour protocol,<sup>389</sup> a 12-hour protocol,<sup>21</sup> and other “short-course” dosing protocols<sup>34,33,382</sup> indicate that these therapies are likely safe and effective in these low-risk scenarios.<sup>351,388</sup>

It is important to realize that even in low-risk patients (those treated within 8 hours), regardless of the protocol length (12, 21, 36, 48, or 72 hours) or route of delivery, NAC therapy should be continued until APAP metabolism is complete (the [APAP] is below detection) and there are no signs of hepatotoxicity.

With this concept in mind, it is reasonable to *shorten* a set course of NAC if the patient is at low risk and the above criteria are met ([APAP] undetectable, [AST] normal, PT/INR less than twice normal, and no encephalopathy).<sup>33,85,328</sup> This approach is conceptually reasonable and is aimed at decreasing unnecessary therapy as there is no evidence that prolonged NAC is helpful and there is one animal study that suggested that prolonged NAC inhibits hepatic recovery;<sup>385</sup> however, adequate studies have not definitively confirmed its safety.<sup>319,328</sup>

*N*-Acetylcysteine therapy should be continued *beyond* the prescribed “protocol length” if there is evidence of hepatic injury ([AST] > 1,000 IU/L, PT/INR greater than twice normal, or encephalopathy is present) or APAP metabolism is incomplete (the [APAP] detectable). This likely will not be an issue in the vast majority of cases because the [ALT] of approximately half of all NAC-treated patients with an [APAP] above the treatment line will remain below 100 IU/L, and only 4% of patients treated with NAC develop hepatotoxicity ([ALT] > 1,000 IU/L).<sup>21,332</sup> The IV NAC dosing protocol that has proved beneficial in patients with hepatic failure is the same initial dosing as the traditional IV protocol but with the third IV infusion continued until there is resolution of hepatic failure. These observations suggest that rather than a single duration of therapy for all patients, it is appropriate to extend treatment protocols based on the clinical course of the patient.<sup>85</sup>

After NAC therapy is extended beyond a set-length protocol, the decision to discontinue therapy should be entirely based on the patient’s condition. For patients who develop hepatic failure, we recommend continuing IV NAC until the PT or INR is below twice normal and encephalopathy, if present, is resolved.<sup>218</sup> For patients without hepatic failure but with an elevated [AST], we recommend continuing NAC until hepatic abnormalities improve (eg, [AST] is decreasing and < 1,000 IU/L or the [AST]/[ALT] ratio < 0.4).<sup>229</sup> The [AST] should be used to determine whether to stop NAC, as the [AST] decreases earlier upon recovery than [ALT] (half-life of 15 h for [AST] and 40 h for [ALT]).<sup>78</sup>

### Assessing Risk of Hepatotoxicity

Most patients who are treated with NAC do not develop hepatotoxicity and have short hospital stays; a small percentage develop hepatotoxicity and an even smaller group develop hepatic failure. It is helpful to predict the risk of hepatotoxicity based on initial findings to direct the intensity of monitoring and therapy (see Dose Adjustment) and patient disposition.

In general, both the time from ingestion to the initiation of NAC and the [APAP] are directly proportional to the patient’s risk of developing hepatotoxicity and hepatic failure.<sup>305,328,333</sup> Even in patients treated early after their ingestion, the risk of hepatotoxicity is significant if their [APAP] is highly elevated.<sup>224,293</sup> In patients who are treated with NAC, the risk of hepatotoxicity

increases from below 5% to about 10% if the [APAP] is over the “300 line” and to 20% to 40% if over the “500 line.”<sup>55,224</sup> Using these principles, a nomogram is used to determine the risk of hepatotoxicity on patient arrival. Unfortunately, this only predicts the risk of a peak [aminotransferase] above 1,000 IU/L and cannot determine the risk of death or need for transplantation. The multiplicative sum of the AST (or ALT) and the [APAP] also predicts hepatotoxicity (sensitivity of 91% and specificity of 63% if the sum is > 1,500 mg/L\*IU/L).<sup>329</sup> Acetylated HMGB-1 is a promising biomarker for detecting patients who will go on to have severe hepatic failure and may become useful for early prognostication, but it requires further study.<sup>12</sup> In initial human studies, acetylated HMGB-1 increased only in patients who later met the KCC for hepatic transplant, received a transplant, or died.<sup>12</sup>

### Dose Adjustment

In rare cases, patients with massive ingestions with or without antimuscarinic coingestants have a highly elevated [APAP] for prolonged periods or secondary elevations of the [APAP].<sup>97,100,154,313,368</sup> Several of these patients developed hepatotoxicity despite early (< 6 hours) IV NAC therapy,<sup>55,100,154,224,313,368</sup> raising the question of whether the traditional IV NAC infusion (6.25 mg/kg/h) provides enough NAC for these rare patients with a late elevated [APAP] or massive ingestions. Patients who are treated with NAC within 8 hours have a risk of hepatotoxicity that increases linearly with increasing [APAP] with abrupt increases in risk at the 300 line and 500 line and an increase in risk of coagulopathy at the 900 line, suggesting increased NAC dosing at these intervals is appropriate.<sup>55</sup> In these rare patients, we recommend treating with greater amounts of NAC when prolonged, massive [APAP] is evident.<sup>313,341</sup> No data exist to determine which, if any, alternative NAC dosing strategy is superior. For a detailed description of increased dosing for massive ingestions, highly elevated [APAP], and prolonged elevations of [APAP], see Antidotes in Depth: A3. A brief synopsis is described below and is based on calculations that use logical inferences, but none of these concepts has been studied and should not be considered standard therapy.<sup>224,294</sup>

The following is reasonable give a patient who presents with an [APAP] above the “500” line the traditional IV NAC dosing in addition to traditional oral NAC dosing. In the event a patient cannot take the oral NAC (eg, somnolent, coingestion of a caustic), we recommend the IV loading dose followed by the 4-hour dose (12.5mg/kg/h) for the duration of the treatment regimen. In the event a patient presents later than 8 hours and the [APAP] is above the theoretical 500 line, then we also recommend the IV loading dose followed by 12.5 mg/kg/h for the duration of the treatment regimen.

### Hepatic Transplantation

Hepatic transplantation increases survival for a select group of severely ill patients who have APAP-induced fulminant hepatic failure.<sup>125,218</sup> Tremendous improvements in transplantation and supportive hepatic care have increased immediate survival rates after hepatic transplantation to 69% to 83% with 3- to 5-year survival rates of 50% to 66%,<sup>29,181,279,317,322</sup> respectively, which is similar to transplant survival for other causes of acute hepatic failure. Patients who meet criteria for transplant but do not receive an organ have survival rates of 25% to 40%.<sup>94,195,306</sup>

Concerns that patients who receive transplants for APAP-induced fulminant hepatic failure will have lower survival rates and be unable to maintain posttransplant medication regimens have resulted in the majority of patients not being listed for transplant.<sup>29,322</sup> However, those who meet psychosocial criteria for transplantation have high rates of survival,<sup>29,69,218,322</sup> and only 12% later die from intentional rejection or suicide attempts.<sup>26</sup> Techniques that allow subtotal hepatectomy with transplantation and eventual weaning of immunosuppressants have demonstrated high 5-year survival rates (63%) and allow for higher rates of transplantation if further studies support these findings.<sup>215,279</sup>

### Assessing Prognosis

Determining a patient’s prognosis and predicting patients who require transplantation early in the course of the disease is an important area of current research.

**TABLE 33–1 King’s College Criteria**

Either of the following historically predicted a survival rate <20% and the need for immediate transplantation, currently the survival rate for these patients is 25–40% without transplantation.

1. Arterial pH <7.3 or [lactate] >3.0 mmol/L after fluid resuscitation
- OR
2. All of the following:
    - a. [Creatinine] >3.3 mg/dL
    - b. Prothrombin time >100 sec (or international normalized ratio >6.5)
    - c. Grade III or IV encephalopathy (somnolence to stupor, responsive to verbal stimuli, confusion, gross disorientation)

The most commonly used prognosticator of mortality is the KCC (Table 33–1), which was developed and validated on patients with APAP-induced fulminant hepatic failure. The criteria include a serum pH below 7.30 after fluid resuscitation or the combination of creatinine above 3.3 mg/dL, PT above 100 sec (INR > 6.5 is commonly used), and grade III or IV encephalopathy. The survival rate of patients who meet the KCC but are not transplanted is 25% to 40%.<sup>17,29,63,74,76,94,125,195,305</sup> Survival rates have significantly increased since the original studies, likely because of the utilization of prolonged NAC therapy and improved supportive care for patients with acute hepatic failure.<sup>124,306</sup>

When determining the KCC, interpretation of PT and INR must include awareness of concurrent NAC therapy as well as therapy with vitamin K, PCCs, factor VII, and FFP. The use of vitamin K, if effective, implies that transplant is unnecessary because viable liver remains. If vitamin K is ineffective, then PT and INR can be used, as discussed in the previous paragraph. Transfusion of exogenous clotting factors, such as FFP or PCCs, alters interpretation because the resulting improvement in PT and INR does not indicate improvement in hepatic function. The prognostic importance of monitoring PT and INR in this setting suggests that FFP should be given only for evidence of bleeding, with risk of bleeding from known concomitant trauma, or before invasive procedures, and not based merely on the PT or INR.

A [lactate] above 3.5 mmol/L at a median of 55 hours after APAP ingestion or [lactate] above 3.0 mmol/L after fluid resuscitation is both a sensitive and specific predictor of patient death without transplant.<sup>30,79</sup> Additional studies confirmed [lactate] as an independent predictor of prognosis but suggest that it does not add significantly to the KCC.<sup>63,311</sup> Others have confirmed a lower specificity than initially reported.<sup>124,311</sup> Using a higher cutoff (> 4.7 mmol/L) has a high sensitivity (98%) and negative predictive value (NPV) (95%), but moderate specificity (58%) for determining death or transplant.<sup>63,311</sup>

Unfortunately, patients often meet the KCC and lactate criteria quite late in their course of disease, so these criteria are not useful as early predictors or as standards for transfer to a facility that performs hepatic transplant. General factors that are associated with increased mortality include unintentional overdose, repeated supratherapeutic dosing, and delays to receiving NAC therapy.<sup>73,75</sup> Additional predictors of severity of hepatic toxicity in patients treated with NAC include a rapid doubling of the [AST] or [ALT] (doubling < 8 hours)<sup>132</sup> and an [AST] or [ALT] reaching 1,000 IU/L within 20 hours of NAC treatment.<sup>117</sup> Several attempts at determining early predictors of death or the need for transplant have proven to be no more effective than the KCC, including serum [phosphate] on day 2,<sup>31,308</sup> Model for Endstage Liver Disease (MELD) score of 32 or above,<sup>63,214,312</sup> serum Gc-globulin,<sup>203,304</sup> factor V concentration,<sup>161,258</sup> factor VIII:V ratio,<sup>258,269</sup> worsening day 4 PT and INR,<sup>139</sup> and PT (in seconds) larger than the number of hours since ingestion.<sup>246</sup>

An Acute Physiology and Chronic Health Evaluation (APACHE) II score above 15 in patients with isolated APAP ingestions is as specific as the above KCC criteria and slightly more sensitive.<sup>63,235</sup> These criteria are beneficial in determining whether to transfer a patient to a transplant center because the score is easily calculated, is sensitive, and is available within the first day of admission; however, confounders such as coingestants decrease its utility. Furthermore, an APACHE II score above 60 identifies additional patients with multiorgan dysfunction who require transplantation.<sup>29</sup>

**TABLE 33–2** Prediction of Death or Transplant in 125 Patients With Acetaminophen-Induced Liver Failure<sup>63</sup>

Score	Sensitivity (%)	Specificity (%)	PPV	NPV
King's College Criteria	47	83	0.70	0.65
Acute Physiology and Chronic Health Evaluation II (>12)	67	76	0.69	0.75
Sequential Organ Failure Assessment (>12)	67	80	0.74	0.74
Model for Endstage Liver Disease (>32)	89	25	0.49	0.77
[Lactate] (>3.3 mmol/L)	91	52	0.69	0.83

NPV = negative predictive value; PPV = positive predictive value.

Several measurements of organ failure are postulated as indications for transfer to a regional transplant center from a nontransplant facility. The Sequential Organ Failure Assessment (SOFA) score higher than 7 within the first 96 hours after *acute* overdose and evidence of the systemic inflammatory response syndrome both predict increased mortality (a 100% sensitivity and a 74% to 77% specificity).<sup>74</sup> Conversely, a patient with a SOFA score of 7 or less during the first 96 hours after *acute* overdose has a low mortality risk (< 2%), low risk of requiring renal replacement therapy (< 4%), and low risk of requiring intracranial pressure monitoring (< 2%).<sup>74</sup> Additionally, a SOFA score below 6 after RSTI of APAP predicts survival and a low risk of the need for renal replacement therapy or intracranial pressure monitoring (< 10%).<sup>76</sup>

The KCC, APACHE II, SOFA, and MELD scores, as well as serum [lactate] 12 hours after admission, are all helpful in making patient decisions.<sup>63</sup> The MELD score (> 32) and [lactate] (> 4.7 mmol/L) are the most sensitive to determine death or transplant in APAP-induced hepatic failure. These scores predict high mortality and the need for a higher level of care (Table 33–2), but the most specific scores are the KCC, APACHE II (> 11), and SOFA (> 12). These are most helpful in determining patients who need transplant (Table 33–2).

The multiplicative sum of the [APAP] and the higher of the AST or ALT (> 1,500 mg/dL \* IU/L) is highly sensitive at predicting coagulopathy (INR > 2) in patients treated with NAC,<sup>64</sup> although specificity is only 57% (81% in patients treated longer than 8 hours after ingestion).<sup>329,381</sup> The Psi parameter, which uses the [APAP] and time to NAC, is useful for predicting hepatotoxicity (sensitivity, 97%; specificity, 92%; likelihood ratio (LR), 11.4), but its usefulness in predicting coagulopathy is limited (sensitivity, 71%; specificity, 85%; LR, 4.8).<sup>64</sup>

Acetylated HMGB-1 is a biomarker that is released as a proinflammatory mediator from monocytes and macrophages and in one small study was highly correlated with patients who met transplantation criteria or died.<sup>12</sup>

All of these studies are promising, but will require validation before clinical use is postulated.

### Additional Elimination Techniques

Several clinical scenarios benefit from increasing clearance of APAP from the body. Indications early after APAP overdose include patients with an exceedingly high [APAP] who are at high risk of hepatotoxicity despite NAC therapy as well as those with hyperlactatemia and metabolic acidosis. Later in the course of APAP toxicity, elimination techniques are used to remove the remaining [APAP] in patients who are imminently receiving a hepatic transplant or for removal of toxins related to hepatic failure (Table 33–3).

### Hemodialysis

Both intermittent hemodialysis and continuous venovenous hemodialysis increase elimination of APAP. Intermittent hemodialysis has been used early after overdose to eliminate a highly elevated [APAP], typically above

**TABLE 33–3** Management of Patients at Risk for APAP Toxicity

- Start NAC on patients at risk of hepatotoxicity:
  - In acute overdose, plot a single [APAP] on the nomogram using the earliest possible time of ingestion. If the plot is over the treatment line, initiate NAC
    - If patient is at risk for massive and prolonged exposure to APAP (eg, ingestion > 30 g and/or coingested antimuscarinics), higher-dose NAC therapy is reasonable
  - In RSTI, if [AST] is elevated, initiate NAC
  - If AST is normal and [APAP] > 10 mcg/mL, initiate NAC
  - If patient has evidence of liver failure (encephalopathy, INR/prothrombin time elevation), transfer to liver transplant center
- Initiate IV NAC or rarely oral NAC.
- Laboratory evaluation at 20 to 24 hours (20 hours if IV NAC is used, 20–24 hours if PO NAC is used). Continue NAC on patients who remain at risk of toxicity or have developed toxicity.
  - If patient remains at risk of toxicity ([APAP] detectable) or if toxicity is evident ([AST] elevated), then continue NAC for 16–24 hours more
  - If the [APAP] at 20 to 24 hours is very elevated, consider higher dose NAC therapy
- Continue laboratory evaluation every 16–24 hours.
- Stop NAC when the patient is no longer at risk of toxicity:
  - If liver failure was evident, continue NAC until INR < 2, encephalopathy resolves, and the [APAP] is undetectable
  - If liver failure was not evident, but the [AST] was elevated, then continue NAC until the [AST] has decreased to < 1,000 IU/L, no evidence of liver failure, and the [APAP] is undetectable

AST = aspartate aminotransferase; INR = international normalized ratio; IV = intravenous; NAC = *N*-acetylcysteine; PO = oral; RSTI = repeated supratherapeutic ingestion.

500 mcg/mL<sup>108,134,327,377</sup> and in patients with slow clearance of APAP late after overdose.<sup>383</sup> A systematic review suggests hemodialysis for patients with altered mental status, elevated [lactate], or metabolic acidosis with an [APAP] greater than 700 mcg/mL or for an [APAP] greater than 900 mcg/mL if the patient is treated with NAC. Furthermore, they recommend hemodialysis for an [APAP] greater than 1,000 mcg/mL regardless of therapy.<sup>123</sup> Clearance averages 150 to 300 mL/min.<sup>108,134,327,383</sup> In several cases, hemodialysis has removed gram quantities of APAP (4–20 g),<sup>327</sup> and the amount that hemodialysis removes varies directly with the [APAP].<sup>108,327,383</sup> Hemodialysis reduces the APAP elimination half-life by approximately 50% to 80%<sup>134,252,327,383</sup> and has an extraction ratio of 50% to 80%.<sup>134,327,380,383</sup>

Hemodialysis also removes NAC with a clearance (CL<sub>HD</sub>) of 114 mL/kg/h and an extraction ratio of 50% to 76%.<sup>155,327</sup> We recommend doubling NAC infusion rates during hemodialysis to compensate.<sup>134,155,327</sup> Hemodialysis does not remove APAP protein adducts.<sup>77</sup>

*N*-Acetylcysteine clearance during CVVH (CL<sub>CVVH</sub>) is 42 mL/kg/h with an extraction ratio of 13%.<sup>155,377</sup> In one case, CVVH removed 24 g of APAP over 16 hours.<sup>377</sup> No dosing adjustment is likely necessary during CVVH.<sup>77,155</sup>

### Plasmapheresis and Plasma Exchange

Plasmapheresis removes small amounts (5%) of APAP with therapeutic dosing, but few data exist with regard to overdose.<sup>109</sup> Plasmapheresis is useful in patients with ALF to correct coagulopathy, but it does not reliably correct encephalopathy.<sup>324</sup>

Exchange transfusion was used in one 1.22-kg neonate who had an [APAP] of 75 mcg/mL after maternal oral overdose and subsequent delivery.<sup>201</sup> Exchange transfusion eliminated a portion of total APAP as evidenced by a reduced [APAP] and a rebound [APAP] after transfusion. For example, in one exchange of 210 mL blood (1.22 kg patient), the serum [APAP] decreased from 32 mcg/mL to zero and then rebounded to 30 mcg/mL.<sup>201</sup>

### Liver Dialysis

Liver dialysis devices include extracorporeal albumin dialysis (eg, molecular adsorbent recirculation system {MARS}), fractionated plasma separation and adsorption, and single-pass albumin dialysis (SPAD). The MARS system is used as a bridge to transplantation, for hemodynamic stabilization before

hepatic transplant, or as a bridge to spontaneous recovery in patients with APAP-induced hepatic failure. Although MARS improves encephalopathy,<sup>316</sup> cerebral blood flow,<sup>307</sup> hemodynamics (increases in systemic vascular resistance, mean arterial pressure, and decreases in cardiac index and pulse),<sup>194,310</sup> and intracranial pressure,<sup>342</sup> a meta-analysis concluded that MARS has no effect on mortality in multiple causes of ALF.<sup>183</sup> One report notes complete removal of APAP from the blood. The ([APAP] decreased from 40 mcg/mL to 0 mcg/mL from inflow to outflow) during MARS with a rebound [APAP], suggesting that MARS improves APAP clearance.<sup>121</sup>

Fractionated plasma separation, albumin adsorption, and hemodialysis is also used as a bridge to transplantation but is relatively unstudied in APAP induced acute hepatic failure. Fractionated plasma separation, albumin adsorption, and hemodialysis (eg, Prometheus system) produces higher clearance of ammonia than MARS but does not improve hemodynamics.<sup>194</sup>

Single-pass albumin dialysis is venovenous hemodialysis with a dialysate containing 4.4% albumin. Single-pass albumin dialysis (SPAD) more effectively clears ammonia than MARS,<sup>303</sup> but there were no changes in hemodynamics or encephalopathy after therapy with SPAD in one study of patients with acute hepatic failure.<sup>175</sup>

We recommend treatment with MARS, if available, in patients with fulminant hepatic failure who meet clinical criteria for transplantation or high mortality (eg, KCC) regardless of whether or not they will be transplanted.

## SUMMARY

- The decision to treat a patient with an acute APAP overdose requires plotting a single [APAP] onto the modified Rumack-Matthew nomogram and treating patients with NAC if the [APAP] plots above the treatment “150” line.
- We recommend treating patients with NAC after RSTIs of APAP if their [AST] is greater than normal or their [APAP] is detectable.
- The KCC identify patients with high mortality and is an indication for evaluation for hepatic transplantation.
- Following massive ingestions of APAP, after NAC therapy is started, an informed decision should be made when to stop NAC: which requires an assessment of the [AST] and [APAP], that the risk of developing toxicity is low ([APAP] is undetectable and [AST] is normal), and any toxicity that occurred has now resolved ([AST] has decreased and is near normal and there is no evidence of hepatic failure). This method may result in NAC therapy that is either shorter or longer than the traditional protocol length.

## N-ACETYLCYSTEINE

Robert G. Hendrickson and Mary Ann Howland

## INTRODUCTION

N-Acetylcysteine (NAC) is the cornerstone of therapy for patients with potentially lethal acetaminophen (APAP) overdoses. If administered early, NAC can prevent APAP-induced hepatotoxicity. If administered after the onset of hepatotoxicity, NAC improves outcomes and decreases mortality. N-Acetylcysteine appears to also limit hepatotoxicity from other xenobiotics that result in glutathione (GSH) depletion and free radical formation, such as cyclopeptide-containing mushrooms, carbon tetrachloride, chloroform, pennyroyal oil, clove oil, and possibly liver failure from chronic valproic acid use. Finally, NAC is routinely useful in the management of adults with fulminant hepatic failure caused by nontoxicologic etiologies.<sup>20,36,64,76,82,84,96,145,149,165</sup>

## HISTORY

Shortly after the first case of APAP hepatotoxicity was reported, Mitchell et al described the protective effect of GSH.<sup>94</sup> Prescott<sup>106</sup> first suggested NAC for APAP poisoning in 1974. Early experiments demonstrated that NAC could prevent APAP-induced hepatotoxicity in mice and that the oral (PO) and intravenous (IV) routes were equally efficacious when treatment was initiated early after ingestion.<sup>102</sup> Several groups<sup>106,110,118</sup> performed human research with PO and IV NAC in the 1970s. The US Food and Drug Administration (FDA) approved NAC for PO use in 1985, for IV use in 2004; an effervescent tablet was approved for PO use in 2016.

## PHARMACOLOGY

## Chemistry

N-Acetylcysteine is a thiol-containing (R-SH) compound that increases intracellular cysteine concentrations by deacetylating into cysteine as well as causing release of intracellular protein- and membrane-bound cysteine.<sup>175</sup> The amino acids cysteine, glycine, and glutamate are used to synthesize GSH, the primary intracellular antioxidant.

## Related Xenobiotics

Cysteamine, methionine, and NAC, which are all GSH precursors or substitutes, have been used successfully to prevent hepatotoxicity, but cysteamine and methionine both produce more adverse effects than NAC, and methionine is less effective than NAC. Therefore, NAC has emerged as the preferred treatment.<sup>109,136,156,157</sup>

Both liposomal NAC and NAC amide have been studied in animals and are being developed with the intent of increasing intracellular delivery of NAC and decreasing adverse effects.<sup>8,73,153</sup> N-Acetylcysteine amide is an NAC molecule with the carboxyl group replaced by an amide.

## Mechanism of Action

N-Acetylcysteine has several distinct roles in the treatment of APAP poisoning. Early after ingestion when APAP is being metabolized to N-acetylbenzoquinoneimine (NAPQI), NAC prevents toxicity by rapidly detoxifying NAPQI. After hepatotoxicity is evident, NAC decreases toxicity through several nonspecific mechanisms, including free radical scavenging, increasing oxygen delivery, increased mitochondrial adenosine triphosphate (ATP) production, antioxidant effects, and alteration of microvascular tone.

N-Acetylcysteine effectively prevents APAP-induced hepatotoxicity if it is administered before GSH stores are depleted to 30% of normal. This level of depletion occurs approximately 6 to 8 hours after toxic APAP ingestion.<sup>110,116</sup> In this preventive role, NAC acts primarily as a precursor for the synthesis of GSH.<sup>78</sup> The availability of cysteine is the rate-limiting step in the synthesis of GSH, and NAC is effective in replenishing diminished supplies of both cysteine and GSH. In this way, NAC concentration ([NAC]) has a direct relationship with the amount of NAPQI detoxified and therefore higher [NAPQI] (and presumably [APAP] require higher [NAC]). Additional minor mechanisms of NAC in preventing hepatotoxicity include acting as a substrate for sulfation,<sup>135</sup> as an intracellular GSH substitute by directly binding to NAPQI,<sup>27</sup> and by enhancing the reduction of NAPQI to APAP.<sup>79,132</sup>

After NAPQI covalently binds to hepatocytes and other tissues,<sup>116</sup> NAC modulates the subsequent cascade of inflammatory events in a variety of ways.<sup>53,146</sup> N-Acetylcysteine may act directly as an antioxidant or as a precursor to GSH.<sup>122</sup> Glutathione protects cells against electrophilic compounds by acting as both a reducing agent and an antioxidant. N-Acetylcysteine improves oxygen delivery<sup>40,53,142,160,161</sup> and utilization in extrahepatic organs such as the brain, heart, and kidney, probably by improving blood flow in the microvasculature, although the exact mechanism is unclear. In addition, NAC increases hepatic mitochondrial ATP production in mice<sup>124</sup> and demonstrates a suppressive action on macrophages, neutrophils, leukocyte endothelial cell adhesion, and cytokines.<sup>76</sup>

## Pharmacokinetics and Pharmacodynamics

When NAC is present in plasma it exists reduced or oxidized state, either free or bound to plasma proteins or with other thiols and -SH groups resulting in the formation of mixed disulfides such as NAC-cysteine.<sup>111</sup> N-Acetylcysteine has a relatively small volume of distribution (0.5 L/kg), and protein binding is 83%. N-Acetylcysteine is metabolized to many sulfur-containing compounds such as cysteine, GSH, methionine, cystine, and disulfides, as well as conjugates of electrophilic compounds, that are not routinely measured.<sup>101,111</sup> Thus, the pharmacodynamic study of NAC is complex. In addition, the pharmacokinetics of NAC are complicated based on whether total or free NAC is being measured.<sup>111</sup>

### Pharmacokinetics of Oral *N*-Acetylcysteine

Oral NAC is rapidly absorbed, but its bioavailability is low (10%–30%) because of significant first-pass metabolism.<sup>101,111</sup> The mean time to peak serum concentration is  $1.4 \pm 0.7$  hours. The mean elimination half-life is  $2.5 \pm 0.6$  hours and is linear with increasing dose up to 3,200 mg/m<sup>2</sup>/day given as a single daily dose. Intersubject serum NAC concentrations vary tenfold.<sup>101</sup> Chronic administration leads to a decrease in peak plasma concentration ( $C_{\max}$ ) from 8.9 mg/L (55  $\mu\text{mol/L}$ ) at the end of 1 month to 5.1 mg/L (31  $\mu\text{mol/L}$ ) at the end of 6 months.<sup>101</sup>

Conflicting *in vitro*<sup>30,74,123</sup> and *in vivo*<sup>36,44,99,114</sup> data regarding the concomitant use of PO NAC and activated charcoal suggest that the resultant bioavailability of NAC is either decreased or unchanged. This interaction is likely of limited clinical importance, and PO or IV NAC can be initiated without concern for activated charcoal interaction (Chap. 33).

The effervescent NAC formulation (when dissolved in water) has a mean time to peak serum concentration of 1.8 hours with similar peak concentration and area under the plasma drug concentration versus time curve (AUC) as an equivalent dose of the PO NAC solution.<sup>3,49</sup>

### Pharmacokinetics of Intravenous *N*-Acetylcysteine

When only free NAC was analyzed, healthy volunteers given 600 mg of IV NAC achieved peak serum NAC  $C_{\max}$  49 mg/L (300  $\mu\text{mol/L}$ ) with a half-life of 2.27 hours compared with a  $C_{\max}$  of 2.6 mg/L (16  $\mu\text{mol/L}$ ) after 600 mg PO.<sup>23</sup> Serum concentrations after IV administration of an initial loading dose of 150 mg/kg over 15 minutes reach approximately 500 mg/L (3,075  $\mu\text{mol/L}$ ).<sup>111</sup> A steady-state serum concentration of 35 mg/L (10–90 mg/L) is reached in approximately 12 hours with the standard IV protocol.<sup>111</sup> Several alternative protocols exist with variable kinetics. In general, slower loading doses lead to lower peak [NAC],<sup>65,167</sup> and shorter protocols (eg, 12 hour protocol)<sup>19</sup> lead to lower 20-hour [NAC] than longer protocols.<sup>29</sup> Approximately 30% of NAC is eliminated renally.

When in the blood, IV and PO NAC have a similar half-life (2–2.5 hours). This half-life is increased in the setting of severe liver failure or end-stage kidney disease because of a reduction in clearance.<sup>68,98</sup>

### Intravenous versus Oral Administration

As in the case of many issues related to APAP toxicity, the choice of PO versus IV NAC is complex. The available information suggests that each has advantages and disadvantages, and that one is more appropriate than the other in certain settings. Because no controlled studies have compared IV with PO NAC, conclusions about the relative benefit of each are difficult.

With the exception of fulminant hepatic failure, for which only the IV route has been investigated, IV and PO NAC administration are equally efficacious in treating patients with APAP toxicity.<sup>108</sup> Some data suggest that IV NAC is slightly more efficacious when given less than 12 hours after an overdose and that PO NAC is more efficacious when given after 16 hours after overdose; however, this study compared patient groups that differed by decade of treatment and by country. It remains unclear if these differences are true or clinically relevant.<sup>107,170</sup> In addition, any difference in outcome for patients who are treated after 16 hours almost certainly is related to the duration and total dose of NAC therapy rather than the route itself. The route of NAC should not be a factor when considering efficacy.

Although the route of NAC does not affect efficacy, rarely, in massive APAP overdoses with highly elevated [APAP] and altered kinetics, the dose of NAC in the traditional three-bag system appears to be inadequate to bind to the NAPQI that is produced. This rare scenario is an issue of the dose of NAC, not the route of NAC. *N*-Acetylcysteine must be supplied in a quantity that is consistent with the amount of NAPQI that is being produced, and the traditional IV NAC three-bag system's 6.25 mg/kg/h will need to be increased or PO NAC dosing used in these cases.

The decision of which route to use should not be affected by questions of efficacy but should depend on the rate of adverse events, safety, availability, and ease of use. Safety is the best understood of these issues. Nausea and vomiting occurs in up to 20% of patients treated with PO NAC compared with

7% with the traditional three-bag IV NAC protocol.<sup>55</sup> Diarrhea and headache are prevalent, but there is no credible evidence of more serious complications resulting from PO NAC. Reports of skin rash and unusual complications are rare. In contrast, IV NAC is associated with a 14% to 18%<sup>19,72</sup> rate of anaphylactoid reactions, although rates of 2% to 6% are reported in retrospective trials.<sup>62,69,164,173</sup> Several alternative IV NAC protocols report lower rates of anaphylactoid reactions that required treatment when compared with the traditional three-bag protocol.<sup>19,65,167</sup> Most anaphylactoid reactions are mild and include rash, flushing, nausea, and vomiting.<sup>19,72,126,174</sup> Anaphylactoid reactions are severe in approximately 1% of cases,<sup>19,72,172</sup> and in rare instances lead to hypotension and death.<sup>9,13,18,56,95</sup> Anaphylactoid reactions are attributed to both the dose and concentration of NAC and are caused by a non-IgE-mediated release of histamine from mast cells and mononucleocytes.<sup>32</sup> Acetaminophen inhibits mast cell histamine release; therefore, a higher APAP concentration at the time of NAC delivery decreases the risk of anaphylactoid reactions.<sup>32,128,162</sup> The anaphylactoid reaction rate is decreased by using a more dilute NAC solution<sup>62,69,72,173</sup> and by slowing NAC infusions in some studies.<sup>26</sup> In one prospective study, prolongation of the 150-mg/kg loading infusion from 15 to 60 minutes did not decrease the anaphylactoid rate significantly (from 18% to 14%),<sup>72</sup> but another prospective study that used a lower dose (100 mg/kg) and slower infusion (2 hours) decreased anaphylactoid reactions significantly (31% to 5%) compared with 150 mg/kg infused over 15 minutes.<sup>19</sup>

Minor reactions, such as rash, generally do not require treatment, rarely recur, and do not preclude administration of subsequent NAC doses.<sup>12,137,176</sup> Even when urticaria, angioedema, and respiratory symptoms develop, they usually are easily treated, and NAC can be subsequently restarted with a very low incidence of recurrence.<sup>12,103,126,176</sup> Although proper dosing of IV NAC is very safe, it nevertheless is less safe than PO NAC because of the possibility of severe anaphylactoid reactions, the risk of dosing errors,<sup>54,56,95</sup> and the possibility of incomplete or delayed treatment because of anaphylactoid reactions.<sup>19</sup>

Intravenous NAC is dosed using a complex three-bag preparation system (see Dosing and Administration section later) that has led to an up to 33% error rate, including 19% of patients having a greater than 1-hour interruption of NAC.<sup>54</sup> Attempts at simplifying this system are described, but are not adequately studied for general use.<sup>19,65,133,167</sup> (Table A3–1).

Additional safety concerns involve dosing for both small children and obese adults. The IV NAC dosing regimen includes a milligrams per kilogram dose in a fixed water volume, leading to variability of IV NAC concentration.<sup>25,62</sup> This leads to a large solute-free water administration in children, with the potential for hyponatremic seizures.<sup>147</sup> The high [NAC] in obese adults potentially risks an increased rate of anaphylactoid reactions. Thus, alternative dosing strategies were developed for children (constant 3% concentration)<sup>25</sup> and obese adults (ceiling weight of 100 kg; see Dosing) are utilized.<sup>43</sup>

The main disadvantages of the PO NAC formulation are the high rate of vomiting and the concern that vomiting delays therapy.<sup>107</sup> Delays in administration of NAC are correlated with an increased risk of hepatotoxicity.<sup>136</sup> The IV route has a lower rate of vomiting than PO NAC and may decrease the use of antiemetics, which are associated with altered mental status, and a higher rate of [ALT] elevation.<sup>19</sup> A potential disadvantage of PO NAC is that its absorption is delayed up to 1 hour compared with IV NAC.<sup>60</sup> Finally, PO NAC doses are difficult to administer to patients with altered mental status because of aspiration risks; IV NAC offers a distinct advantage in these instances.

One theoretical, albeit unproven, advantage of PO NAC early in the course of toxicity is that direct delivery via the portal circulation yields a higher concentration of NAC in the target compartment of toxicity, the liver. Because of this first-pass clearance, PO NAC results in circulating NAC 20- to 30-fold lower than after IV dosing, suggesting that most PO NAC is taken up by the liver.<sup>23,60</sup> However, an elevated serum NAC concentration may be an advantage of IV NAC administration when the liver is not the only target organ of NAC, such as liver failure accompanied by cerebral edema or in pregnancy.

**TABLE A3-1** Three-Bag Method Dosage Guide for *N*-Acetylcysteine by Weight for Patients Weighing  $\geq 40$  kg<sup>a</sup>

Body Weight		Loading Dose (150 mg/kg in 200 mL D <sub>5</sub> W over 60 minutes)	Second Dose (50 mg/kg in 500 mL D <sub>5</sub> W over 4 hours)	Third Dose (100 mg/kg in 1000 mL D <sub>5</sub> W over 16 hours)
(kg)	(lb)	<i>N</i> -Acetylcysteine 20% (mL) <sup>b</sup>	<i>N</i> -Acetylcysteine 20% (mL) <sup>b</sup>	<i>N</i> -Acetylcysteine 20% (mL) <sup>b</sup>
100	220	75	25	50
90	198	67.5	22.5	45
80	176	60	20	40
70	154	52.5	17.5	35
60	132	45	15	30
50	110	37.5	12.5	25
40	88	30	10	20

<sup>a</sup>The total volume administered should be adjusted for patients weighing  $< 40$  kg and for those requiring fluid restriction. <sup>b</sup>Acetadote (acetylcysteine) is available in 30-mL (200-mg/mL) single-dose glass vials. D<sub>5</sub>W = 5% dextrose in water.

Several economic analyses conclude that IV NAC is less expensive than PO NAC,<sup>90,92</sup> but others conclude the opposite.<sup>80</sup> However, the majority of cost is associated with length of hospital stay, and because none of these studies have taken into account that many patients treated with PO NAC now receive shorter courses than 72 hours,<sup>22,35</sup> the studies do not represent current use.

Before the availability of the current IV formulation in the United States, the PO formulation was used intravenously with an excellent safety profile<sup>42,69,173</sup> and without published evidence of infectious or febrile consequences.<sup>42,69</sup> We recommend against the IV use for this purpose, but note that it was historically effective and necessary in cases in which only the PO formulation was available and the patient had intractable vomiting or APAP-induced fulminant hepatic failure.<sup>5</sup>

### Specific Indications for Intravenous *N*-Acetylcysteine

In addition to decisions based on cost, duration, safety, and ease of use, three situations exist for which the available information suggests IV NAC is preferable to PO NAC: (1) fulminant hepatic failure, (2) inability to tolerate PO NAC, and (3) APAP poisoning in pregnancy. Each of these requires further study for validation, but all three seem well supported by current information.

Fulminant hepatic failure is an important indication for IV NAC. Intravenous is the only route that has been studied in liver failure.<sup>71</sup> Although PO NAC may be effective, it has not been formally studied. Second, evidence that (some or all of) the benefit of NAC in liver failure is extrahepatic suggests that IV NAC is preferable.<sup>52</sup> Intravenous NAC results in higher serum [NAC], which presumably leads to more NAC delivery to critical organs. Finally, concomitant gastrointestinal bleeding, use of lactulose, and other factors make IV NAC more practical.

Common indications for IV NAC include patients with very high [APAP] who are approaching or are more than 6 to 8 hours from the time of ingestion as well as those who are unable to tolerate PO NAC after a brief aggressive trial of antiemetic therapy. Use of IV NAC is recommended to prevent further delays and resultant loss of NAC efficacy, even without proof that continued vomiting significantly limits NAC absorption.

The most controversial indication for IV NAC use is during pregnancy. Administration of IV NAC to the mother has the theoretical advantage of increased delivery to the fetus over PO NAC use. Intravenous administration circumvents first-pass metabolism, presumably exposing the fetal circulation to higher maternal serum concentrations. Some studies suggest that placental transfer of NAC to the fetus is limited.<sup>67,130</sup> However, one case series found that the NAC concentration in cord or neonatal blood after PO maternal NAC administration equaled the NAC concentration that is achieved in patients treated with PO NAC.<sup>63</sup> Of course, an equivalent serum [NAC] does not prove adequacy of therapy. Unlike the neonates studied, patients treated with PO NAC have extensive first-pass hepatic uptake before NAC entry into the serum, in which [NAC] was measured.<sup>23,60</sup> Whether serum [NAC] in the neonates studied reflects any significant hepatic NAC delivery is uncertain.

### ROLE IN ACETAMINOPHEN TOXICITY

In acute overdose, treatment with NAC should be initiated if the serum [APAP] is plotted on or above the treatment line on the Rumack-Matthew nomogram or the patient's history suggests an acute APAP ingestion of 150 mg/kg or greater and the results of blood tests will not be available within 8 hours of ingestion. In patients with chronic APAP ingestions, treatment with NAC should be initiated if either aspartate aminotransferase (AST) is above normal, or the [APAP] is higher than expected given the dose and time (Chap. 33).

Intravenous NAC is approved by the FDA for treatment of potentially hepatotoxic quantity of APAP within 8 to 10 hours after ingestion. Both the PO liquid formulation and the newer PO effervescent formulation are approved for use in a 72-hour protocol for APAP toxicity.<sup>3</sup>

### ROLE IN NONACETAMINOPHEN POISONING

Diverse investigations of NAC as a treatment for a number of xenobiotics associated with free radical or reactive metabolite toxicity are reported. Some of these xenobiotics include acrylonitrile, amatoxins, cadmium, chloroform, carbon tetrachloride, cyclophosphamide, 1,2-dichloropropane, doxorubicin, eugenol, pulegone, ricin, and zidovudine. *N*-Acetylcysteine has not been studied well enough for any of these xenobiotics in humans to definitively recommend it as a therapeutic intervention. However, the best evidence supports the use of NAC in cases of acute exposures to cyclopeptide-containing mushrooms and carbon tetrachloride.<sup>31,45,47,158</sup> *N*-Acetylcysteine also decreased cisplatin-induced nephrotoxicity in both rats and human cell cultures, although in vivo human data are sparse.<sup>10,125</sup> *N*-Acetylcysteine is reasonable in cases of acute pennyroyal oil (ie, pulegone) or clove oil (eg, eugenol) ingestions based on their similarities to APAP-induced hepatotoxicity. Both pulegone and eugenol are converted to reactive metabolites that deplete GSH, leading to centrilobular hepatic necrosis.<sup>151,152</sup> *N*-Acetylcysteine may be effective in treating patients with hepatotoxicity from chronic valproate use, given the evidence that the 2,4-diene valproic acid metabolite acts as an electrophile and reduces hepatic GSH. However, there is no evidence that NAC is effective in treating patients with acute valproate toxicity and no evidence or theoretical efficacy in treating valproate-induced hyperammonemia. In animal studies, NAC increases the excretion of several metals and other elements, including boron, cadmium, chromium, cobalt, gold, and methylmercury.<sup>14,16,31,57</sup> The clinical usefulness of this effect remains unclear. *N*-Acetylcysteine reduced hepatic graft failure when used during organ procurement for hepatic transplant.<sup>34</sup>

*N*-Acetylcysteine was studied as an oncologic chemopreventive and antineoplastic<sup>6,39,97,125</sup> as well as for lung injury,<sup>38,39</sup> cardiac injury,<sup>139,140</sup> myocardial infarction,<sup>46</sup> multiorgan failure from trauma and sepsis,<sup>50,113,127,141</sup> traumatic brain or spine injury,<sup>15,150,172</sup> chronic obstructive pulmonary disease,<sup>144</sup> ifosfamide-induced nephrotoxicity,<sup>51</sup> postcardiac surgery,<sup>87</sup> hepatorenal

syndrome,<sup>61</sup> *Helicobacter pylori* infections,<sup>88</sup> necrotizing enterocolitis,<sup>148</sup> sickle cell disease,<sup>100</sup> and bipolar disorder.<sup>21</sup> Rescue NAC therapy was also studied with high-dose APAP (> 20 g/m<sup>2</sup>) used as chemotherapy in patients with select advanced malignancies.<sup>75,97,166</sup>

N-Acetylcysteine was extensively studied to determine its effects on IV contrast-induced nephropathy. Pretreatment with either PO or IV formulations was also been studied before angiography with mixed results. Absolute creatinine change in the positive studies remains quite small and is typically below 0.2 mg/dL.<sup>48,77,83</sup> Large randomized trials found no reduction in the risk of nephrotoxicity after intravascular angiographic procedures<sup>2</sup> or in emergency department computed tomography,<sup>155</sup> and current knowledge suggests that NAC is ineffective for these indications.<sup>2,48,77,155</sup>

N-Acetylcysteine was studied in the treatment of patients with non-APAP-related acute liver failure with mixed results. In a randomized trial in adults, NAC improved transplant-free survival in early non-APAP-related acute liver failure (eg, mild encephalopathy) but had no effect in those with severe encephalopathy.<sup>82</sup> A more recent study of patients with acute liver failure noted a significantly higher transplant-free survival rate in patients who received NAC compared with historical control participants.<sup>36</sup> Although another study using historic control participants suggests that NAC improves survival in children with non-APAP-related acute liver failure,<sup>76</sup> a prospective randomized study showed no difference in 1-year survival rates and a lower 1-year transplant-free survival rate, particularly in children younger than 2 years of age.<sup>143</sup>

N-Acetylcysteine is used in cases of cyclopeptide-containing mushroom poisoning, particularly poisoning with *Amanita phalloides*. N-Acetylcysteine therapy for amatoxin poisoning is largely based on the similarity of toxicity of amatoxin to APAP, specifically delayed onset of centrilobular hepatic necrosis. Decreases in intracellular GSH stores were identified in isolated rat hepatocytes that were exposed by amanita extracts,<sup>70</sup> leading to the reasonable conclusion that supplying the tissue with thiols decreases toxicity. In retrospective studies, patients treated with NAC had lower mortality rates than those treated with supportive care;<sup>45</sup> however, in animal studies, NAC has little effect on hepatotoxicity.<sup>154</sup>

We recommend the use of NAC in the treatment of xenobiotic hepatotoxicity associated with free radical or reactive metabolite toxicity. The evidence is limited, but the toxicity of xenobiotic associated hepatotoxicity is consequential and the minimal risk of NAC merits utilization.

## ADVERSE EVENTS AND SAFETY ISSUES

Liquid or effervescent NAC cause nausea, vomiting, flatus, diarrhea, gastroesophageal reflux, and dysgeusia; generalized urticaria occurs rarely. Generalized anaphylactoid reactions described after IV NAC dosing<sup>19,18,37,89</sup> are not noted after PO therapy and are likely related to rate, concentration, or high serum [NAC].<sup>17</sup>

Although the IV route ensures delivery, rate-related anaphylactoid reactions occur in 14% to 18% of patients,<sup>19,72,167</sup> and up to one-third of patients have the infusion stopped because of reactions.<sup>19,54,86</sup> Most reactions are mild (6%) or moderate (10%) such as cutaneous reactions, nausea, and vomiting; severe reactions such as bronchospasm, hypotension, and angioedema are rare (1%).<sup>19,65</sup> Anaphylactoid reactions are more common in patients with lower [APAP] (25% if APAP is < 150 mcg/mL) than in those with high [APAP] (3% if APAP is > 300 mcg/mL)<sup>128,162</sup> because APAP decreases histamine release from mononucleocytes and mast cells in a dose-dependent manner.<sup>32</sup>

If hypotension, dyspnea, wheezing, flushing, or erythema occurs, then NAC should be stopped. Adverse reactions, confined to flushing and erythema, are usually transient, and we recommend continuing NAC with meticulous monitoring for systemic symptoms that indicate the need to stop the NAC. Urticaria can be managed with diphenhydramine with the same precautions.<sup>12</sup> Iatrogenic overdoses with IV NAC resulted in severe reactions, including hypotension, hemolysis, cerebral edema, seizures, and death.<sup>9,13,56,89,95</sup>

After the reaction resolves, we recommend carefully restarting NAC at a slower rate after 1 hour, assuming NAC is still indicated. If the reaction

persists or worsens, IV NAC should be discontinued and a switch to PO NAC is recommended. We recommend against stopping NAC because of mild anaphylactoid reactions because there is evidence of poor outcomes in patients who are undertreated with NAC in these scenarios.<sup>86</sup> Intravenous NAC decreases clotting factors and increases the prothrombin time in healthy volunteers and overdose patients without evidence of hepatic damage.<sup>66,85,104,163</sup> This effect occurs within the first hour, stabilizes after 16 hours of continuous IV NAC, and rapidly returns to normal when the infusion is stopped.<sup>66</sup> International normalized ratio (INR) elevations are mild and are typically below 1.5 to 2.0. Because the INR is used as a marker of the severity of toxicity and is one of the criteria for transplantation, this adverse effect of NAC should always be considered when evaluating the patient's condition. An elevated INR that remains below 2 without other indicators of hepatic damage is probably related to the NAC.

There is little experience with the use of the effervescent NAC tablets in APAP toxicity. There is one case of throat edema in a patient who directly ingested an effervescent tablet.<sup>171</sup> Although no cases of fluid overload or hypernatremia have been reported, the Cetylev PO effervescent tablet contains 438 mg of sodium per 2.5-g tablet, which equates to 7 g of sodium during the first day of treatment for a 60-kg patient. Caution should be exercised and the PO effervescent tablet avoided when treating small children and patients with sodium restriction.

## SAFETY IN PREGNANCY AND NEONATES

Untreated APAP toxicity is a far greater threat to fetuses than is NAC treatment.<sup>33,115</sup> N-Acetylcysteine traverses the human placenta and produces cord blood concentrations comparable to maternal blood concentrations.<sup>63</sup> For treatment of pregnant patients with APAP toxicity, IV NAC (not PO NAC) has the advantage of assuring fetal delivery of NAC because of reduction of the first pass metabolism. N-Acetylcysteine is FDA Pregnancy Category B.

Limited data exist with regard to the management of neonatal APAP toxicity,<sup>11,81,117,131</sup> although IV and PO NAC have been used safely.<sup>1,11</sup> No adverse events were observed when preterm newborns were treated with IV NAC (Chaps. 30 and 33).<sup>1,7,105</sup> The elimination half-life of NAC in preterm neonates was 11 hours compared with 5.6 hours in adults.<sup>7</sup> When treating neonates, IV administration has the advantage of assuring adequate antidotal delivery and has been administered without adverse effects.<sup>7,105,165</sup>

## DOSING AND ADMINISTRATION

The standard IV NAC protocol is a loading dose of 150 mg/kg up to a maximum of 15 g in 200 mL of 5% dextrose in water (D<sub>5</sub>W) (for adults) infused over 60 minutes followed by a first maintenance dose of 50 mg/kg up to a maximum of 5 g in 500 mL D<sub>5</sub>W (for adults) infused over 4 hours followed by a second maintenance dose of 100 mg/kg up to a maximum of 10 g in 1,000 mL D<sub>5</sub>W (for adults) infused over 16 hours (6.25 mg/kg/h) (Tables A3-1 and A3-4).

When NAC is administered either as the liquid formulation or the dissolved effervescent tablet, the patient should receive a 140-mg/kg loading dose either orally or by enteral tube. Starting 4 hours after the loading dose, 70 mg/kg should be given every 4 hours, for an additional 17 doses, for a total dose of 1,330 mg/kg. The liquid formulation should be diluted to 5% and can be mixed with a soft drink to enhance palatability (Tables A3-2 and A3-3). The effervescent tablets are dissolved in either 150 mL or 300 mL of water depending on the dose.<sup>3</sup> If any dose is vomited within 1 hour of administration, then we recommend repeating the dose or using the IV route. Antiemetics (eg, metoclopramide or ondansetron) are reasonable to ensure absorption; however, one study noted an increased rate in aminotransferase elevation in patients who were randomized to ondansetron.<sup>19</sup> Whether this is an ondansetron-specific association, an effect of decreased gastric emptying, or another association is unknown.

Several other regimens, including 48-hour IV, 36-hour IV, 12-hour IV, 36-hour PO, and 20-hour PO protocols, are described; however, none of these has been adequately studied for general use (Chap. 33).<sup>19,35,133,137,167,168</sup>

Three protocols have been developed with the intent of decreasing peak [NAC] and decreasing adverse effects, particularly anaphylactoid

TABLE A3-2 Calculating the Loading Dose of Oral *N*-Acetylcysteine Solution<sup>a</sup>

Body Weight		<i>N</i> -Acetylcysteine (g)	mL of 20% <i>N</i> -Acetylcysteine Oral Solution	Diluent (mL)	5% Solution (Total mL)
(kg)	(lb)				
100–109	220–240	15	75	225	300
90–99	198–218	14	70	210	280
80–89	176–196	13	65	195	260
70–79	154–174	11	55	165	220
60–69	132–152	10	50	150	200
50–59	110–130	8	40	120	160
40–49	88–108	7	35	105	140
30–39	66–86	6	30	90	120
20–29	44–64	4	20	60	80

<sup>a</sup>If the patient weighs < 20 kg (usually patients younger than 6 years), calculate the dose of *N*-Acetylcysteine. Each milliliter of 20% *N*-Acetylcysteine solution contains 200 mg of *N*-Acetylcysteine. The loading dose is 140 mg per kilogram of body weight. Three mL of diluent is added to each milliliter of 20% *N*-Acetylcysteine solution. Do not decrease the proportion of diluent.

reactions. The SNAP protocol infuses an initial 100 mg/kg over 2 hours and then 200 mg/kg over 10 hours.<sup>19</sup> In a randomized controlled trial, this protocol decreased severe anaphylactoid rates from 31% with the traditional IV NAC “three-bag” protocol to 5%. Although the study was not large enough to prove equivalent efficacy, hepatotoxicity rates were similar (2% SNAP protocol versus 3% IV NAC “three-bag” protocol).<sup>19</sup> Another protocol infused 200 mg/kg over 4 hours and then 100 mg/kg over 16 hours, and found a lower rate of anaphylactic reactions (4.3% versus 10%) and no difference in hepatotoxicity.<sup>167</sup> A third group suggested infusing 200 mg/kg at the time of presentation and over a variable time (4–9 h) and then 100 mg/kg over 16 hours but had a high rate of overtreatment.<sup>65</sup> Although these protocols seem to decrease adverse events and severe anaphylactic reactions, their efficacy has not been studied against the standard protocol. It is not known precisely how much NAC is needed early after overdose when [APAP] are high, and there remains concern that protocols that reduce the initial dose or rate of NAC loading will not be matching early [NAC] with early [NAPQI].

Conceptually, NAC therapy should be started if the patient is at risk of toxicity, continued as long as is necessary, and it should be stopped when the patient is no longer at risk of toxicity.<sup>169</sup> For a detailed description of the

indications for treating APAP toxicity with NAC, see Chap. 33. Briefly, in acute overdoses (from 4–24 h after ingestion), NAC therapy should be initiated if the initial APAP concentration falls above the treatment line of the Rumack-Matthew nomogram. In acute overdoses when the patient arrives more than 24 hours after ingestion, we recommend starting NAC if the APAP concentration is detectable or if the [AST] is elevated. In repeated supratherapeutic ingestions, NAC therapy should be initiated if *either* the APAP concentration is detectable *or* the AST is elevated (Chap. 33).

After the protocol is initiated, an [APAP] and [AST] are evaluated before the end of the NAC infusion (<20 hours for IV NAC) or at 24 hours (for PO NAC). If a shortened protocol is being used (eg, SNAP), then an [APAP] and [AST] should be evaluated at the end of the infusion. If the [APAP] is undetectable and the [AST] is normal, then we recommend discontinuing NAC. NAC beyond the “protocol length” if the [APAP] remains detectable or the [AST] is significantly elevated. There are no data to support what degree of AST elevation should be used as a cutoff for treatment. We recommend continuing the NAC protocol until the [APAP] is undetectable; there is no evidence of hepatic failure; and the [AST], if it was elevated, has significantly decreased. There is no validated criteria to define a significant decrease in [AST], but two consecutive decreasing values, an [AST] less than 1,000 IU/L,

TABLE A3-3 Calculating the Maintenance Dose of Oral *N*-Acetylcysteine Solution<sup>a</sup>

Body Weight		<i>N</i> -Acetylcysteine (g)	20% <i>N</i> -Acetylcysteine Oral Solution (mL)	Diluent (mL)	5% Solution (Total mL)
(kg)	(lb)

10	22	7.5	30	2.5	70	5	140

<sup>a</sup>Acetadote (*N*-Acetylcysteine) is hyperosmolar (2,600 mOsm/L) and is compatible with D<sub>5</sub>W, one-half normal saline (0.45% sodium chloride injection), and water for injection. <sup>b</sup>Acetadote is available in 30-mL (200-mg/mL) single-dose glass vials.

D<sub>5</sub>W = 5% dextrose in water.

or an [AST]/[ALT] ratio of 0.4 or are reasonable and are commonly used.<sup>93</sup> If hepatic failure intervenes, then IV NAC is recommended at 6.25 mg/kg/h and continued until the patient has a normal mental status (or recovery from hepatic encephalopathy)<sup>53</sup> and the patient's INR decreases below 2.0 or until the patient receives a liver transplant.<sup>24,34,52,71</sup>

For the rare patient who ingests exceptionally large doses of APAP or who has prolonged and significantly elevated [APAP] consideration should be given to treating with greater amounts of NAC when prolonged, massive APAP concentrations are evident.<sup>41,58,91,129,138</sup> The rationale for increasing NAC dosing include that the IV infusion rate (6.25 mg/kg/h) was derived to treat a 16-g ingestion of APAP.<sup>119</sup> Although it is effective for most patients who ingest APAP, an ingestion that is several times larger than 16 g may require additional NAC. In addition, published cases of patients who have developed hepatotoxicity despite early NAC therapy have ingested more than 16 g of APAP and were treated with the IV (6.25 mg/kg/h) infusion.<sup>41,91,129,138</sup> There are no reported early NAC failures with the PO protocol, which may be attributed to its higher dose (17.5 mg/kg/h) and duration. Finally, the risk of hepatotoxicity increases incrementally if the [APAP] is above the “300 line,” the “450 line,” and the “600 line” when treated with the traditional three-bag method (6.25 mg/kg/h IV NAC infusion),<sup>28,91</sup> suggesting that these are reasonable indications for increased dosing or additional therapy.

No data exist to determine which, if any, alternative NAC dosing strategy is effective; however, it seems reasonable to increase NAC dosing if the hepatic exposure to APAP (and therefore NAPQI) is prolonged and massive. Several strategies are theorized, but none were studied. The following is reasonable:

We recommend that any patient who presents with an [APAP] above the “500” line receive the traditional IV NAC dosing in addition to traditional PO NAC dosing. In the event a patient cannot take the PO NAC (eg, somnolent, caustic coingestion), we recommend that the patient should receive the IV loading dose followed by the 4-hour dose (12.5 mg/kg/h) for the duration of the treatment regimen. In the event a patient presents later than 8 hours and the [APAP] is above the theoretical 500 line, then we recommend that the IV loading dose is followed by 12.5 mg/kg/h for the duration of the treatment regimen.

*N*-Acetylcysteine is efficiently removed by hemodialysis (clearance = 114 mL/kg/min; extraction ratio = 50%–76%),<sup>59,134</sup> and we suggest doubling NAC infusion rates during hemodialysis to compensate.<sup>59,134</sup> *N*-Acetylcysteine clearance during continuous venovenous hemodialysis (CVVHD) is 42 mL/kg/h with an extraction ratio of only 13%, so recommend against dosing adjustment during CVVHD.<sup>59</sup> Although there are few studies on NAC dosing in obese patients, it is reasonable to limit PO and IV NAC dosing using a maximum weight of 100 kg, given that patients who are larger than 100 kg have an equivalent hepatic volume and similar ingestion amounts as patients who weigh less than 100 kg. Although dosing with a maximum weight is logical and the IV NAC package insert now reflects dosing with a maximum weight of 100 kg, it has not yet been adequately studied in obese humans.<sup>112,159</sup>

Previously, dosing information for IV NAC was unavailable for patients weighing less than 40 kg, and problems with osmolarity, sodium concentrations, and fluid requirements became apparent when improper dilutions were used. The package insert now gives specific information for dosing in these patients (Table A3–4).

The IV dosing of NAC is complicated because three different preparations must be prepared with each based on weight. A retrospective study estimated that there was a 33% medication error rate in the preparation and delivery of IV NAC.<sup>54</sup> To limit these errors, Tables A3–1 and A3–4 from the package insert, which give the appropriate doses and dilutions for adults and patients weigh less than 40 kg, should be used.<sup>1</sup> In addition, the following website has a dosage calculator: <http://acetadote.com/dosecalc.php>.

The effervescent PO formulation comes in 2.5-g and 500-mg tablets, which are lemon-mint flavored to increase palatability, and requires mixing the tablets into variable amounts of water, depending on the dose. Tables are provided in the package insert. Dosing is limited to 100 kg. Dosing for 1- to 19-kg patients requires dissolving 5 g (two 2.5-g tablets) in 100 mL of water and then calculating the volume given based on the 50-mg/mL solution (eg, 140 mg/kg × 10 kg = 1,400 mg; 1,400 mg × 1 mL/50 mg = 28 mL).<sup>3</sup>

## FORMULATION

*N*-Acetylcysteine is available as a 20% concentration in 30-mL single-dose vials designed for dilution before IV administration. *N*-Acetylcysteine liquid for PO administration is available in 10-mL vials of 10% and 20% for PO administration and should also be diluted before administration. *N*-Acetylcysteine is also available as 500-mg and 2.5-g PO effervescent tablets (Cetylev), which are dissolved in water before PO ingestion.

## SUMMARY

- *N*-Acetylcysteine is the primary antidote for APAP toxicity.
- We recommend NAC use in cyclopeptide containing mushroom toxicity (eg, *A. phalloides*), carbon tetrachloride, and pulegone toxicity (pennyroyal oil).
- *N*-Acetylcysteine should be started if there is significant risk of toxicity and stopped when the risk of toxicity is gone and any toxicity that had occurred is resolving.
- Oral and IV NAC have essentially equivalent efficacy.
- Intravenous NAC has approximately an 18% risk of anaphylactoid reactions, most of which are mild, and PO NAC has a 20% risk of vomiting.
- Higher doses of NAC are reasonable for cases of massive ingestion or cases in which a prolonged high [APAP] is present.

## COLCHICINE, PODOPHYLLIN, AND THE VINCA ALKALOIDS

Cynthia D. Santos and Capt. Joshua G. Schier

Colchicine, podophyllotoxin, and the vinca alkaloids exert their primary toxicity by binding to tubulin and interfering with microtubule structure and function. The ubiquitous nature of microtubules within human cells and the heavy reliance on them for maintenance of normal cell functions present numerous opportunities for these xenobiotics to cause dysfunction at a cellular, organ, and organ system level in a dose-dependent fashion. This chapter discusses the history, pharmacology, pharmacokinetics, toxicokinetics, pathophysiology, toxic dose, clinical manifestations, diagnostic testing and management of toxicity resulting from these xenobiotics both during therapeutic use and in the overdose setting. Because some information is limited, not all of the aforementioned topics will be discussed for each xenobiotic.

### COLCHICINE

#### History

The origins of colchicine and its history in poisoning can be traced back to Greek mythology. Medea was the evil daughter (and a known poisoner) of the king of Colchis, a country that lay east of the Black Sea in Asia Minor. After being betrayed by her husband Jason (of Jason and the Argonauts), she killed their children and her husband's lover. Medea used plants of the Liliaceae family, of which *Colchicum autumnale* is a member, to poison her victims.<sup>20,132,172</sup> The use of colchicum for medicinal purposes is reported in *Pedanius Dioscorides De Materia Medica*, an ancient medical text, written in the first century A.D.,<sup>132</sup> and subsequently in the 6th century A.D. by Alexander of Tralles, who recommended it for treating arthritic conditions.<sup>110</sup> However, colchicum fell out of favor, perhaps because of its pronounced gastrointestinal (GI) effects, until it was introduced for "dropsy" and various other nonrheumatic conditions in 1763.<sup>20,172</sup> In the late 18th century, a colchicum-containing product known as *Eau Medicinale* appeared, which reportedly had strong antigout effects.<sup>172</sup> Colchicine, the active alkaloidal component in colchicum, was isolated in 1820 and rapidly became popular as an antigout medication.<sup>132,172</sup> Benjamin Franklin reportedly had gout and is credited with introducing colchicine in the United States.<sup>132</sup> Colchicine

is still used in the acute treatment and prevention of gout and is used in other disorders, including amyloidosis, Behçet's syndrome, familial Mediterranean fever, pericarditis, arthritis, pulmonary fibrosis, vasculitis, biliary cirrhosis, pseudogout, certain spondyloarthropathies, calcinosis, and scleroderma.<sup>11,20,121,125</sup> Systematic data supporting the efficacy of colchicine therapy in many of these other diseases are lacking.

Colchicine is derived from two plants of the Liliaceae family, *C. autumnale* (autumn crocus, meadow saffron, wild saffron, naked lady, son-before-the-father) and *Gloriosa superba* (glory lily).<sup>172</sup> The autumn crocus contains different amounts of colchicine by weight, depending on the plant part (bulb, 0.8%; flowers, 0.1%; seeds, 0.8%; and the corm or underground stem, 0.6%).<sup>110,132,151</sup> Colchicine concentrations within the plant peak during the summer months.<sup>132</sup> The leaves of *C. autumnale* closely resemble those of the *Allium ursinum* or wild garlic and are mistaken for them.<sup>39,40,98</sup> The tubers of *G. superba* were confused with *Ipomoea batatas* (sweet potatoes) in one report<sup>172</sup> (Chap. 118).

There is a dearth of good epidemiologic data on colchicine poisoning. The American Association of Poison Control Centers records several hundred overall exposures annually (Chap. 130). The majority of these exposures are in adults and are categorized as unintentional. Of the cases with a recorded outcome, approximately 10% have evidence of moderate or major toxicity or resulted in death.<sup>36</sup> A limited number of cases are caused by intentional suicidal ingestions with colchicine and therapeutic colchicine administration has contributed to adverse health effects, and in some cases death, among hospitalized patients (probably related to failure to adjust dosing for renal impairment).<sup>147</sup> At least 50 adverse events (23 of which were fatalities) were linked to the use of intravenous (IV) colchicine.<sup>4</sup> The United States Food and Drug Administration ordered companies to stop the marketing of unapproved injectable drug compounds containing colchicine in 2009.<sup>4</sup> Serious questions remain about the utility of colchicine in light of its extremely narrow therapeutic index.

#### Pharmacology

Colchicine is a potent inhibitor of microtubule formation and function that interferes with cellular mitosis, intracellular transport mechanisms, and maintenance of cell structure and shape.<sup>125,172</sup> The ubiquitous presence of microtubules in cells throughout the body presents a wide variety of targets for colchicine in poisoning.<sup>125,172</sup> Colchicine accumulates in leukocytes and has inhibitory effects on leukocyte adhesiveness, amoeboid motility, mobilization, lysosome degranulation, and chemotaxis.<sup>20,44,53,167</sup> At doses used clinically, colchicine inhibits neutrophil and synovial cell release of chemotactic glycoproteins.<sup>174,194</sup> Colchicine also inhibits microtubule polymerization, which disrupts inflammatory cell-mediated chemotaxis and phagocytosis.<sup>178</sup> It reduces expression of adhesion molecules on endothelial and white blood cells (WBCs) and affects polymorphonuclear cell cytokine production.<sup>9,21,144</sup> Colchicine also acts as a competitive antagonist at GABA<sub>A</sub> receptors.<sup>216</sup>

#### Pharmacokinetics and Toxicokinetics

Colchicine is rapidly absorbed in the jejunum and ileum and has a bioavailability generally between 25% and 50%.<sup>172,182</sup> It is highly lipid soluble<sup>172</sup> with a volume of distribution that ranges from 2.2 to 12 L/kg, and is reported to increase to 21 L/kg in overdose.<sup>172,175,176,205</sup> Colchicine binding to plasma proteins approaches 50%.<sup>143,172</sup> Protein binding is principally to albumin, although some binding to  $\alpha_1$ -acid-glycoprotein and other lipoproteins is reported.<sup>182</sup> During the first several hours after acute overdose, colchicine is

sequestered in white and red blood cells (RBCs) in concentrations 5 to 10 times higher than serum.<sup>182</sup> Peak serum concentrations after ingestion occur between 1 to 3 hours.<sup>125</sup> Toxic effects usually do not occur with concentrations less than 3 ng/mL.<sup>79,143,212</sup>

Colchicine is primarily metabolized through the liver with up to 20% of the ingested dose excreted unchanged in the urine.<sup>108,172,205</sup> Colchicine undergoes demethylation by CYP3A4.<sup>108,125,157,203</sup> Detoxification mainly occurs through deacetylation, demethylation, biliary secretion, and excretion in the stool.<sup>108,125,141,180,182,203</sup> Enterohepatic recirculation of colchicine occurs.<sup>3,157,172</sup>

Studies reporting on the serum colchicine elimination half-lives range from 9 to 108 minutes.<sup>14,95,172,182,213</sup> On closer examination, however, these times probably more accurately reflect a rapid initial distribution phase. The drug undergoes a more delayed terminal elimination phase, which ranges from 1.7 to 30 hours, depending on the individual compartment model used to estimate elimination and the amount of colchicine absorbed.<sup>3,82,176,180,182,205</sup> These values are on the same order as, and probably reflect the tubulin–colchicine complex disassociation time.<sup>157</sup> Individuals with end-stage kidney disease and liver cirrhosis have elimination half-lives that are prolonged up to 10-fold.<sup>125</sup> Colchicine remains in measurable quantities in certain tissues for a long time, as evidenced by its detection in WBCs after 10 days and in urine 7 to 10 days after exposure.<sup>77,172</sup> Colchicine crosses the placenta and is secreted in breast milk, but it is not dialyzable.<sup>125</sup> Postmortem examination of colchicine-poisoned patients reveals high concentrations within the bone marrow, testicles, spleen, kidney, lung, brain, and heart.<sup>175</sup>

### Drug Interactions

Colchicine metabolism is susceptible to drug interactions. Because colchicine is detoxified by CYP3A4, blood concentrations are susceptible to xenobiotics that alter the function of this enzyme, such as erythromycin, clarithromycin, and grapefruit juice.<sup>45,70,87,125</sup> In particular, coadministration of clarithromycin and colchicine, especially in patients with chronic kidney disease, increases the risk of fatal interaction.<sup>6,107</sup> P-glycoprotein (P-gp) expels and clears colchicine, and drugs that inhibit P-gp directly affect the amount of colchicine eliminated and hence toxicity.<sup>157</sup> For example, cyclosporine increases colchicine toxicity.<sup>75</sup> Coadministration of colchicine with statin or fibrate drugs, cyclosporine, ketoconazole, ritonavir, verapamil ER, diltiazem ER, fluindione (vitamin K antagonist) and nephrotoxic xenobiotics such as nonsteroidal antiinflammatory drugs and angiotensin-converting enzyme inhibitors has resulted in colchicine poisoning.<sup>204,208</sup> Concomitant administration of P-gp or CYP3A4 inhibitors and colchicine should be avoided in patients with abnormal renal or hepatic function. If treatment with a P-gp or a strong CYP3A4 inhibitor is required in patients taking colchicine with normal renal or hepatic function, a dose reduction or temporary cessation of colchicine treatment should be considered.<sup>5,204,208</sup>

### Pathophysiology

Microtubules play a vital role in cellular mitosis and possess a high amount of dynamic instability.<sup>17,76,116,188</sup> Microtubules are made up of tubulin protein subunits, of which three are known to exist:  $\alpha$ ,  $\beta$ , and  $\gamma$ .<sup>116,139,188</sup> These structures are highly dynamic with  $\alpha$ - $\beta$  tubulin heterodimers, constantly being added at one end and removed at the other.<sup>116,117</sup> Microtubules undergo two forms of dynamic behavior: dynamic instability, in which microtubule ends switch between growth and shortening phases, and treadmilling, in which there is a net growth (addition of heterodimers) at one end and a shortening (loss) at the other.<sup>25</sup> Assembly and polymerization dynamics are regulated by additional proteins known as stabilizing microtubule-associated proteins (MAPs) and destabilizing MAPs.<sup>25</sup> These dynamic behaviors and a resultant equilibrium are needed for multiple cell functions, including cell support, transport, and mitotic spindle formation for cell replication.<sup>116</sup> Xenobiotics that bind to specific regions on tubulin can interfere with microtubule structure and function, thereby possibly causing mitotic dysfunction and arrest.<sup>139,188</sup> This leads to cellular dysfunction and death.<sup>188</sup> Xenobiotics that target microtubules can be generally divided into two categories:

polymerization inhibitors (ie, vinca alkaloids, colchicine) and polymerization promoters (ie, taxanes, laulimalides).<sup>25</sup>

Colchicine binds to a tubulin dimer at a specific region known as the *colchicine-binding domain*, which is located at the interphase of the  $\alpha$  and  $\beta$  subunits of the tubulin heterodimer.<sup>25,99</sup> This binding is relatively slow, temperature dependent, and generally irreversible, resulting in an alteration of the protein's secondary structure.<sup>99,116,131</sup> Colchicine binds at a second reversible but lower affinity site on tubulin.<sup>116,131</sup> Current evidence suggests that the colchicine–tubulin complex binds to the microtubule ends and prevents further growth by sterically blocking further addition of dimers.<sup>25</sup> Conformational changes in the tubulin and colchicine complex also result as colchicine concentrations increase, which weakens the lateral bonds at the microtubule end.<sup>25,175</sup> Lateral and longitudinal interactions between dimers within a microtubule help stabilize the structure. The number of colchicine–tubulin dimers incorporated into the microtubule determines the stability of the microtubule ends.<sup>25</sup> All of these processes prevent adequate binding of the next tubulin subunit and result in cessation of microtubule growth.<sup>139,188</sup> Whereas at low concentrations, colchicine arrests microtubule growth, at high concentrations, colchicine actually causes microtubule depolymerization through disassociation of tubulin dimers.<sup>25</sup>

These conformational changes ultimately result in disassembly of the microtubule spindle in metaphase of cellular mitosis, cellular dysfunction, and death.<sup>81,99,116,163,183</sup> The effects of colchicine are dose dependent, with high concentrations inhibiting further microtubule polymerization, as well as inducing depolymerization of already formed microtubules.<sup>128</sup> Low concentrations can simply affect new microtubule formation and have no effect on preestablished polymer mass.<sup>128</sup> Colchicine also inhibits microtubule-mediated intracellular granule transport.<sup>20,125</sup>

### Toxic Dose

The toxic dose for colchicine is not well established. An early case series suggested that patients with ingestions of greater than 0.8 mg/kg uniformly died and those with ingestions above 0.5 mg/kg but less than 0.8 mg/kg would survive if given supportive care.<sup>28</sup> This information was based on a limited series of patients and is not necessarily generalizable.<sup>148</sup> More recent literature suggests that severe toxicity and even death occurs with doses smaller than 0.5 mg/kg, and conversely, some patients survive ingestions reported to be in excess of 0.8 mg/kg.<sup>71,145,148</sup> This inability to accurately quantify the toxic dose in humans is likely due in great part to difficulty in dose estimation from the patient's history and significant advances in supportive care. Furthermore, many comorbid conditions (eg, kidney disease) and other pharmaceuticals, which when coadministered can enhance colchicine's adverse health effects; this complicates the determination of a minimal toxic dose.

### Clinical Presentation

The clinical findings among colchicine poisoned patients are commonly described as triphasic (Table 34–1).<sup>103</sup> GI irritant effects, such as nausea, vomiting, abdominal distress, and diarrhea, occur within several hours after an overdose<sup>38,69</sup> and lead to severe volume depletion.<sup>106,148,150</sup> This first stage usually persists for 12 to 24 hours after ingestion.<sup>106,136</sup> The second stage is characterized by widespread organ system dysfunction, particularly the bone marrow, and lasts for several days.<sup>71,148,150</sup> The final phase is characterized by recovery or death, and the progression is usually defined within 1 week.<sup>103,106</sup>

After overdose, the hematopoietic effects of colchicine are characterized by an initial peripheral leukocytosis, which is often as high as 30,000/mm<sup>3</sup>. This is followed by a profound leukopenia, which is classically lower than 1,000/mm<sup>3</sup>. It is commonly accompanied by pancytopenia, usually beginning 48 to 72 hours after overdose.<sup>82,153</sup> The hematopoietic manifestations occur as a result of colchicine's effects on bone marrow cell division.<sup>138,215</sup> A rebound leukocytosis and recovery of all cell lines occur if the patient survives.

Colchicine toxicity is associated with the development of dysrhythmias and cardiac arrest.<sup>84,103</sup> Complete AV block occurred in a child who ingested 0.4 to 0.5 mg/kg.<sup>78</sup> In a rabbit model, colchicine results in a dose-dependent reduction in effective refractory period while maintaining a stable

**TABLE 34-1** Colchicine Poisoning: Common Clinical Findings, Timing of Onset, and Treatment

Phase	Time <sup>a</sup>	Signs and Symptoms	Therapy or Follow-Up
I	0–24 h	Nausea, vomiting, diarrhea  Salt and water depletion Leukocytosis	Antiemetics GI decontamination for early presentation IV fluids Close observation for leukopenia for 24 h
II	1–7 days	Risk of sudden cardiac death (24–48 h) Pancytopenia Acute kidney injury Sepsis ARDS  Electrolyte imbalances Rhabdomyolysis	ICU admission and appropriate resuscitation G-CSF Hemodialysis Antibiotics Oxygen, mechanical ventilation Repletion as needed IV fluids, hemodialysis
III	>7 days	Alopecia (sometimes delayed 2–3 wk) Myopathy, neuropathy, or myoneuropathy	Follow-up within 1–2 mo EMG testing, biopsy, and neurologic follow-up as needed

<sup>a</sup>The interval time course is not absolute, and overlap of symptom presentations occurs.

ARDS = acute respiratory distress syndrome; EMG = electromyography; G-CSF = granulocyte-colony stimulating factor; GI = gastrointestinal; ICU = intensive care unit; IV = intravenous.

repolarization period and increased inducibility of ventricular fibrillation.<sup>84</sup> Sudden cardiovascular collapse from colchicine typically occurs between 24 to 36 hours after ingestion.<sup>138,148</sup> Profound hypovolemia and shock contribute to this collapse,<sup>148</sup> but colchicine has direct toxic effects on skeletal and cardiac muscle, causing rhabdomyolysis.<sup>31,149,210</sup>

Myopathy,<sup>220</sup> neuropathy,<sup>12,128</sup> and a combined myoneuropathy<sup>10,55,124,193</sup> result from both long-term therapy and acute poisoning.<sup>128</sup> A combined myoneuropathy is reported more often, with myopathy dominating the clinical picture.<sup>124</sup> The myoneuropathy is often initially misdiagnosed as polymyositis or uremic neuropathy (caused by coexistent acute or chronic kidney disease).<sup>124</sup> Myoneuropathy usually develops in the context of chronic, therapeutic dosing in patients with some baseline renal impairment,<sup>124</sup> although it is reported to occur in the presence of normal renal function as well.<sup>170</sup> Patients present with proximal limb weakness, distal sensory abnormalities, distal areflexia, and nerve conduction problems consistent with an axonal neuropathy.<sup>124,165</sup> A small amount of myelin degeneration is reported on autopsy, which suggests a myelinopathic component.<sup>37</sup> The myopathy is characterized by vacuolar changes on biopsy and accompanied by lysosome accumulation.<sup>10,74,124,226</sup> Elevated serum creatine kinase activity is present concurrently with symptoms.<sup>124,150</sup> Weakness usually resolves within several weeks of drug discontinuation.<sup>124</sup> Myopathy has also occurred with concomitant use of hydroxymethylglutaryl-coenzyme A reductase inhibitors (statins) in patients with chronic kidney disease.<sup>7</sup> Myopathy symptoms typically resolve within 4 to 6 weeks, or in some patients, up to 6 to 8 months.<sup>220</sup>

Acute respiratory distress syndrome (ARDS) occurs with colchicine toxicity.<sup>102,141</sup> The cause is not well understood but probably results from several factors, including respiratory muscle weakness, multisystem organ failure, and possibly direct pulmonary toxicity.<sup>61,136,141,187,202</sup> Other indirect effects of colchicine include acute kidney injury and various electrolyte abnormalities.<sup>128</sup>

Alopecia, which is usually reversible, is a well-described complication that occurs 2 to 3 weeks after poisoning in survivors.<sup>82,131</sup> Dermatologic complications range in severity from epithelial cell atypia to toxic epidermal necrolysis.<sup>81,179</sup>

Neurologic effects, including delirium, stupor, coma, delayed encephalopathy, and seizures, are reported in colchicine poisoning.<sup>88,153,216</sup>

Other reported complications of colchicine poisoning include bilateral adrenal hemorrhage,<sup>199</sup> disseminated intravascular coagulation,<sup>189</sup> pancreatitis,<sup>207</sup> and liver dysfunction.<sup>150</sup>

Although uncommon, poisoning from IV colchicine administration has occurred. Clinical and laboratory manifestations are similar to those that occur after oral overdose, including multisystem organ dysfunction and cytopenias.<sup>47</sup>

Colchicine does not appear to be a significant human teratogen, but the limited work on this subject is not definitive.<sup>65</sup>

## Testing

Colchicine concentrations in body fluids are not available in a clinically relevant fashion and have no well-established correlation with severity of illness. However, effective steady-state serum concentrations for treatment of patients with various illnesses are reported as 0.5 to 3.0 ng/mL.<sup>143</sup> Concentrations greater than 3.0 ng/mL are associated with toxicity depending on the clinical situation, and concentrations greater than 24 ng/mL are definitely associated with poisoning.<sup>79,143,212,222</sup> Serum concentrations do not correlate well with the amount of xenobiotic ingested in massive oral overdose settings.<sup>64</sup> Initial laboratory monitoring should include a complete blood count (CBC), serum electrolytes, renal and liver function tests, creatine kinase, phosphate, calcium, magnesium, prothrombin time, activated partial thromboplastin time, and urinalysis. Other laboratory studies, such as a troponin, arterial blood gases, lactate, fibrinogen, and fibrin split products, are helpful in guiding care if cardiotoxicity, ARDS, or coagulopathies, respectively, are present. If cardiotoxicity is present or suspected, serial troponin concentrations (every 6–12 hours) are recommended. There is an association between increasing concentrations and cardiovascular collapse.<sup>85,210</sup> An electrocardiogram and chest radiograph should also be obtained. Serial CBCs are reasonable (at least every 12 hours) to evaluate for the development of depression in cell lines. Bile appears to be the biological matrix of choice for postmortem testing, probably because of normal postmortem biological processes that can increase blood colchicine concentration.<sup>23,152</sup> One colchicine-associated fatality who had a premortem blood colchicine concentration of 50 ng/mL also had a postmortem femoral blood concentration of 137 ng/mL and a bile concentration greater than 600 ng/mL.<sup>222</sup> Another reported a postmortem blood concentration of 60 ng/mL.<sup>2</sup> Two IV colchicine-associated fatalities had postmortem blood colchicine concentrations of 32 and 44 ng/mL.<sup>47</sup>

## Management

Treatment for patients with colchicine toxicity is mainly supportive, which includes IV fluid replacement, vasopressor use, hemodialysis (for acute kidney injury, not for toxin removal), antibiotics for suspected secondary infection, colony-stimulating factors, and adjunctive respiratory therapy (endotracheal intubation, positive end-expiratory pressure) as indicated. Consultation with nephrology and hematology specialists should be obtained in the case of impaired renal function or evidence of hematologic toxicity. In severe, refractory poisoning, it is reasonable to attempt options such as intraaortic balloon pump therapy and extracorporeal membrane oxygenation therapy.<sup>160</sup>

Because most patients with an acute oral colchicine overdose present several hours after their ingestion, vomiting has already begun, and the utility of GI decontamination is inadequately defined. However, given the extensive morbidity and mortality associated with colchicine overdose, orogastric lavage is most helpful and is reasonable in patients presenting within 1 to 2 hours of potentially life-threatening ingestions, who have no contraindications, are not already vomiting, and for which the physician is proficient in the procedure.<sup>1,30,209</sup> A dose of activated charcoal (AC) is recommended after lavage or in its place if lavage is not appropriate or possible. Because limited evidence supports that colchicine undergoes some enterohepatic recirculation, administration of a single dose of AC to a patient presenting to a health care facility beyond 2 hours after ingestion is recommended if no contraindications exist. Multiple-dose activated charcoal (MDAC) is also recommended in these patients as well for the same reason in that the absorption

of colchicine is one of the most beneficial interventions for this exceptionally grave poisoning.<sup>3,172</sup> The delay in presentation to a health care facility coupled with the fact that patients often have GI symptoms such as vomiting significantly complicates using MDAC. Antiemetic medications will control emesis and facilitate AC administration.

Experimental colchicine-specific antibodies can restore colchicine-affected tubulin activity in animal models of colchicine poisoning<sup>166</sup> and was successfully used in a single human case of severe colchicine poisoning.<sup>16</sup> In colchicine-poisoned rats, anticolchicine Fab fragments caused a rapid 7.1-fold increase in serum colchicine concentration followed by increased urinary excretion of both colchicine and Fab anticolchicine. The increased urinary excretion of these fragments was associated with reversal of colchicine-induced diarrhea.<sup>16,166</sup> In the single human case report, administration of anticolchicine Fab fragments 40 hours after a 0.96-mg/kg colchicine ingestion was temporally associated with a dramatic improvement in clinical and hemodynamic status. This improvement was also associated with a significant increase in serum colchicine concentrations, which suggests a redistribution of drug into the intravascular space.<sup>16</sup> Unfortunately, this therapy is not commercially available.

Granulocyte-colony stimulating factor (G-CSF) is useful in the treatment of patients with colchicine-induced leukopenia and thrombocytopenia.<sup>59,97,119,225</sup> The dose of G-CSF, the dosing frequency, and the route of administration were variable in the reported cases.<sup>59,97,119,225</sup> Administration of G-CSF is recommended if the patient begins to manifest evidence of leukopenia. Dosing should be in accordance with the manufacturer's instructions.

Hemodialysis and hemoperfusion are not viable options for patients with colchicine poisoning based on its large volume of distribution, but hemodialysis is required if renal failure is present.<sup>19,26,27,175,176,205,215</sup> The use of whole-blood and plasma exchange for patients presenting with lethal-dose colchicine exposures was tried, but evidence of efficacy is lacking, and it is not recommended for routine care.<sup>160</sup>

Because of the significant morbidity and mortality associated with colchicine toxicity, all symptomatic patients with suspected or known overdoses should be admitted to the hospital for observation. Because these patients have a risk of sudden cardiovascular collapse within the first 24 to 48 hours,<sup>148</sup> intensive care unit monitoring is recommended for at least this initial time period. A troponin concentration is recommended every 6 to 12 hours during this period because increasing results suggest an increased risk of cardiotoxicity and cardiovascular collapse.<sup>85,210</sup> Blood cell counts should be followed at least daily to watch for cytopenias. Poisoned patients manifest GI signs and symptoms within several hours of ingestion and should be observed for at least 8 to 12 hours. Patients who do not manifest GI signs and symptoms within that time period after ingestion are unlikely to be significantly poisoned.

## PODOPHYLLUM RESIN OR PODOPHYLLIN

### History

*Podophyllin* is the name often used to refer to a resin extract from the rhizomes and roots of certain plants of the genus *Podophyllum*.<sup>63,91</sup> Examples include the North American perennial *Podophyllum peltatum* (mayapple or mandrake), the related Indian species *Podophyllum emodi*, and the Taiwanese *Podophyllum pleianthum*<sup>63</sup> (Chap. 118). It is more descriptive to refer to it as podophyllum resin.<sup>63,91</sup> Podophyllum resin, or podophyllin, contains at least 16 active compounds.<sup>49,63,91</sup> These include a variety of lignins and flavonols, including podophyllotoxin, picropodophyllin,  $\alpha$ - and  $\beta$ -pellatins, desoxypodophyllotoxin, and quercetin.<sup>46,49,63,91</sup> Podophyllotoxin, a component of podophyllin, is a potent microtubular poison, similar to colchicine, and causes similar effects in overdose.<sup>63</sup>

The first reported modern era medicinal use of podophyllin preparations was as a laxative in the 19th century.<sup>46,49,168</sup> Its cathartic properties, as well as its potential toxicity, were noted as early as 1890, when the first fatality from podophyllin was recorded.<sup>190,219</sup> Podophyllin was used to treat individuals with a variety of other health issues, including liver disease, scrofula, syphilis, warts, and cancer.<sup>63</sup> Etoposide and teniposide are semisynthetic derivatives of podophyllotoxin used as chemotherapeutics.<sup>63</sup>

Poisoning usually is caused by systemic absorption after topical application, after ingestion of the resin or plant, and after consumption of a commercial preparation of the extract. Systemic toxicity is described after unintentional dispensing of the incorrect herb, as well as after ingestion of herbal preparations containing podophyllin.<sup>50,51,68</sup>

### Pharmacology

Podophyllin is primarily used in modern pharmacopeia as a topical treatment for patients with verruca vulgaris and condyloma acuminatum.<sup>46,127</sup> The active ingredient is believed to be podophyllotoxin.<sup>63,201</sup> Podophyllotoxin exists in the plant as a  $\beta$ -D-glucoside.<sup>190</sup> Numerous synthetic and semisynthetic derivatives of podophyllotoxin exist; however, the most important are probably the chemotherapeutics etoposide and teniposide.<sup>63</sup> The antitumor effect of etoposide and teniposide results from their interaction with topoisomerase II and free radical production, leading to DNA strand breakage, an effect not shared by podophyllin and colchicine.<sup>43,63</sup> Use of etoposide and teniposide leads to a cessation of cell growth in the late S or early G2 phase of the cell cycle.<sup>43,63,86</sup> Further discussion of these xenobiotics can be found in the Chap. 50.

### Pharmacokinetics and Toxicokinetics

Very limited information exists regarding the pharmacokinetics (absorption, distribution, metabolism, and elimination) of podophyllin as a preparation or for its major active ingredient, podophyllotoxin. Podophyllotoxin is highly lipid soluble and easily crosses cell membranes.<sup>89,156,190</sup>

Absorption of podophyllotoxin was measured in seven men after application of various amounts of a 0.5% ethanol podophyllotoxin preparation for condylomata acuminata.<sup>211</sup> Peak serum concentrations of 1 to 17 ng/mL were achieved within 1 to 2 hours after topical administration of doses ranging from 0.1 to 1.5 mL (0.5–7.5 mg).<sup>211</sup> Patients treated with less than or equal to 0.05 mL had no detectable podophyllotoxin in their serum. Topical administration of 0.1 mL yielded peak serum concentrations up to 5 ng/mL within 1 to 2 hours and up to 3 ng/mL at 4 hours. Topical administration of 1.5 mL yielded peak serum concentrations ranging from 5 to 9 ng/mL within 1 to 2 hours, concentrations of 5 to 7 ng/mL at 4 hours, 3 to 4.5 ng/mL at 8 hours, and 3.5 ng/mL at 12 hours.<sup>211</sup>

### Pathophysiology

The components of podophyllin have numerous actions within the cell, including inhibition of purine synthesis, inhibition of purine incorporation into RNA, reduction of cytochrome oxidase and succinoxidase activity, and inhibition of microtubule structure and function.<sup>46,86,214</sup> Podophyllotoxin causes its toxicity similar to colchicine<sup>63,221</sup> because it is able to bind to tubulin subunits and interfere with subsequent microtubule structure and function.<sup>63,221</sup> Interestingly, radiolabeled podophyllotoxin inhibits colchicine binding to tubulin, suggesting that their binding sites overlap.<sup>63</sup> Podophyllotoxin binds more rapidly than colchicine, and binding is reversible in contrast to colchicine.<sup>63</sup> Podophyllotoxin also inhibits fast axoplasmic transport similar to colchicine by interference with microtubule structure and function.<sup>165,208</sup> Many other compounds, such as the vinca alkaloids, cryptophycins, and halichondrins, also inhibit microtubule polymerization in a similar manner.<sup>117</sup>

### Toxic Dose

The minimum toxic dose associated with podophyllin ingestion is unknown. Limited information on the situations surrounding the few case reports of podophyllin poisoning that do exist does not provide sufficient detail from which to estimate it.

### Clinical Presentation

Poisoning is described after ingestion,<sup>42</sup> as well as after absorption from topical application of podophyllin.<sup>137,142</sup> Toxicity also is reported after IV administration of podophyllotoxin<sup>94</sup> and ingestion of mandrake root or herbal remedies containing podophyllin.<sup>68,83,219</sup> Nausea, vomiting, abdominal pain, and diarrhea usually begin within several hours after ingestion.<sup>137,142,196</sup> Symptoms of poisoning is often delayed for 12 hours or more after topical exposure to podophyllin and are typically caused by improper usage (excessive topical

exposure, interruption in skin integrity, or failure to remove the preparation after a short time period).<sup>137,140,190</sup> Initial clinical findings are not necessarily dictated by the route of exposure.<sup>137</sup>

Alterations in central and peripheral nervous system function tend to predominate in podophyllin toxicity. Patients present with confusion, obtundation, or coma.<sup>56,68,142,196,201</sup> Permanent encephalopathy and cerebral atrophy occurred in some cases.<sup>123</sup>

Delirium and both auditory and visual hallucinations have occurred during the initial presentation.<sup>57,80,198</sup> Patients developed paresthesias, lost deep tendon reflexes, and developed a Babinski sign.<sup>52,68,158,190</sup> Cranial nerve involvement, including diplopia,<sup>49</sup> nystagmus,<sup>56</sup> dysmetria,<sup>52</sup> dysconjugate gaze,<sup>198</sup> and facial nerve paralysis,<sup>57</sup> are all reported. Patients who recover from the initial event are at risk of developing a peripheral sensorimotor axonopathy.<sup>52,56,190</sup> The reported duration for recovery from podophyllin-induced axonopathy is variable but is likely to take several months.<sup>56,68,142,156</sup> Dorsal radiculopathy<sup>89</sup> and autonomic neuropathy are reported.<sup>127</sup> A myelopathic component in the neuropathy is reported.<sup>51</sup>

Hematologic toxicity from podophyllin most likely results from its antimetabolic effects. A review of the limited literature suggests that it is similar to colchicine but is not nearly as consistent in its pattern, severity, and frequency. An initial leukocytosis<sup>173,190</sup> commonly occurs after poisoning, which is followed by leukopenia, thrombocytopenia, or generalized pancytopenia.<sup>127,190</sup> In patients who recover, cell lines tend to reach their nadir within 4 to 7 days after exposure.<sup>173,196</sup>

Other complications of poisoning include fever,<sup>140</sup> ileus,<sup>80,140,198</sup> elevated liver function test results,<sup>196</sup> hyperbilirubinemia,<sup>104</sup> coagulopathy,<sup>104</sup> seizures,<sup>57,181</sup> and acute kidney injury.<sup>140,218</sup> Teratogenic effects resulting from exposure during pregnancy are reported.<sup>49,118</sup>

## Testing

Podophyllin or podophyllotoxin concentrations are not readily available. Routine testing for suspected or known podophyllin poisoning should include routine laboratory tests and other targeted testing as needed. Serial cell blood counts should be obtained in cases of poisoning to evaluate for pancytopenia.

## Management

Management primarily consists of supportive and symptomatic care. If the patient presents within the first several hours of ingestion, a dose of AC is reasonable. Any topically applied podophyllin should be removed and the area thoroughly cleansed. Patients either progress to multisystem organ dysfunction and death or recover with supportive care. Blood cell counts should be monitored similarly to colchicine poisoning (at least daily).

A few case reports of treatment with extracorporeal elimination techniques exist. These reports include resin hemoperfusion<sup>101</sup> and charcoal hemoperfusion.<sup>142,190</sup> The role these procedures played in the patients' clinical courses is unclear. As a result, given the lack of evidence and potential risk, they cannot be routinely recommended at this time.

Patients with significant ingestions of podophyllin develop GI symptoms within a few hours,<sup>52,83,104,158,218,219</sup> but patients have also presented with primarily neurologic symptoms, such as confusion or obtundation.<sup>42,46,80,137</sup> The onset of toxicity is reported to be delayed as long as 12 hours after ingestion.<sup>42,46,56,68</sup> Dermal exposure results in even further delayed onset of toxicity because systemic absorption is delayed and symptom onset is more insidious.<sup>173,190,198</sup> Patients should therefore be observed for the onset of toxicity for at least 12 hours after ingestion and at least 24 hours after dermal exposures. We recommended that asymptomatic patients with unintentional exposures and good follow-up who are discharged after 12 to 24 hours have scheduled follow-up with a primary care physician and a repeat cell blood count within 24 hours.

## VINCRIStINE AND VINBLASTINE

### History

More than 150 different alkaloidal compounds have been isolated from the periwinkle plant (*Catharanthus roseus*), most of which were used throughout

history to manage illness from a variety of medical disorders, including cancer, scurvy, diabetes, toothache, and hypertension.<sup>223</sup> Among these 150 are about 20 different compounds that have antineoplastic activity. Vincristine and vinblastine are pharmaceuticals derived from compounds in the periwinkle plant and are among the most commonly used vinca alkaloid derivatives in medicine.<sup>171</sup> They are typically used as part of a chemotherapy regimen for various cancers. The two chemotherapeutics are administered intravenously and should never be administered intrathecally. Intrathecal administration of vinblastine or vincristine is always the result of an error, is a neurosurgical emergency, and is associated with life-threatening complications (Special Considerations: SC7 and SC8).<sup>8</sup> There are a few case reports of intramuscular administration of these antineoplastics, but they will not be discussed because there are so few, and readers are referred to the actual publications for further information.<sup>15,164</sup> Although other vinca derivatives exist, some have oral formulations and share similar modes of action (causing microtubule dysfunction); however, this section focuses primarily on vincristine and vinblastine. Regardless, the pathophysiology of disease, clinical manifestations of illness, and management of poisoning from similar compounds and the plant itself<sup>223</sup> are similar to those of vincristine and vinblastine.

### Pathophysiology

Vincristine and vinblastine are used specifically for the treatment of patients with leukemias, lymphomas, and certain solid tumors. Their mechanism of activity is similar to the mechanisms of activity of colchicine, podophyllotoxin, and the taxoids (eg, paclitaxel, docetaxel).<sup>62,161</sup> These chemotherapeutics disrupt microtubule assembly from tubulin subunits by either preventing their formation or depolymerization, both of which are necessary for routine cell maintenance. Vinblastine binds to the  $\beta$ -subunit of the tubulin heterodimer at a specific region known as the *vinblastine binding site*.<sup>163</sup> Microtubules are responsible for several basic cellular functions, including cell division, axonal transport of nutrients and organelles, and cellular movement. Mitotic metaphase arrest is commonly observed because of the inability to form spindle fibers from the microtubules. Cell death quickly ensues as a result of the interruption of these homeostatic functions, accounting for the clinical manifestations.

The mechanism of neurotoxicity is not well understood but is related to inhibition of microtubular synthesis, which leads to axonal degeneration in the peripheral nervous system.<sup>90,159</sup> A brain biopsy of a patient with a vincristine-related death showed neurotubular dissociation, which is characteristic of vincristine damage in experimental animals.<sup>32,34,54,66</sup>

A single study demonstrated in mice poisoned with a vinca derivative that administration of murine monoclonal antibodies active against vinca alkaloids is protective and significantly improved survival.<sup>93</sup>

Genetic polymorphisms are associated with the development of vincristine-associated neuropathy. A mutation in the *CEP72* gene,<sup>66</sup> which encodes for a protein involved in microtubule formation, and reduced expression of the genes that encode for CYP3A5 are associated with vincristine-induced peripheral neuropathy.<sup>32</sup>

### Pharmacokinetics

After IV administration, vincristine is rapidly distributed to tissue stores and highly bound to proteins and RBCs.<sup>41</sup> The capacity of vincristine to be bound by plasma proteins ranges from 50% to 80%.<sup>169</sup> In more than 50% of children given IV vincristine, serum concentrations were not detected 4 hours after administration.<sup>146</sup> The vinca alkaloids are primarily eliminated through the liver. Patients with hepatic dysfunction are susceptible to toxicity. Elimination of vincristine occurs via the hepatobiliary system,<sup>41</sup> and it has a terminal plasma half-life of about 24 hours.<sup>155</sup> Vincristine overdose is the most frequently reported antineoplastic overdose in the literature. This is because there are at least four different potential inappropriate ways to dose and administer vincristine, including confusing it with vinblastine, misinterpreting the dose, administering it by the wrong route, and confusing two different-strength vials. The normal dose of vincristine is 0.06 mg/kg, and a single dose should not exceed 2 mg for either an adult or child.

### Drug Interactions

Administration of itraconazole with therapeutic doses of intravenously administered vincristine cause toxicity because of at least two primary reasons: (1) itraconazole-induced inhibition of certain cytochrome P450 enzymes (most likely the CYP3A subfamily) delays vincristine metabolism in vivo, and (2) inhibition of P-gp-mediated efflux of vincristine from inside cells, where it then accumulates.<sup>13</sup> Coadministration of other azole antifungals, cyclosporine, isoniazid, erythromycin, mitomycin C, phenytoin, and nifedipine are also implicated in vincristine toxicity for the same aforementioned reasons.<sup>67,185,186</sup> Azole antifungals exacerbate vinblastine-related hyponatremia in children.<sup>228</sup>

### Toxic Dose

The minimum toxic doses associated with adverse health effects from a single dose of vincristine and vinblastine are not well established. However, chemotherapeutic regimens tend to keep single doses at or below 2 mg to decrease the likelihood of peripheral neuropathy. Unfortunately, toxicity occurs with cumulative dosing over time, as that typically occurs with chemotherapeutic regimens. Peripheral neuropathy tends to begin after a cumulative dose (administered over multiple sessions, not all at once) of 30 to 40 mg.<sup>24</sup>

### Clinical Presentation

Despite their similarity in structure, vincristine and vinblastine differ in their clinical toxicity. Vincristine produces less bone marrow suppression and more neurotoxicity than does vinblastine. During the therapeutic use of vincristine, myelosuppression occurs in only 5% to 10% of patients.<sup>105</sup> However, this effect is common in the overdose setting, and when it occurs, the need for replacement blood products and concern for overwhelming infection is apparent.<sup>130</sup> The decrease in cell counts begins within the first week and lasts for up to 3 weeks. Other manifestations of acute vincristine toxicity are mucositis, central nervous system disorders, and syndrome of inappropriate antidiuretic hormone (SIADH).

Central nervous system disorders are varied and unusual during therapeutic vincristine therapy because of its poor penetrance of the blood-brain barrier. They are, however, more common when there is delayed elimination, damage to the blood brain-barrier, overdose, or inadvertent intrathecal administration. Generalized seizures from toxicity or secondary effects generally occur from 1 to 7 days after exposure.<sup>109,115,120,197</sup> Other manifestations are depression, agitation, insomnia, and hallucinations. Vincristine stimulation of the hypothalamus appears to be responsible for the fevers and SIADH noted in overdosed patients.<sup>177</sup> The fevers begin 24 hours after exposure and last 6 to 96 hours. Serum electrolytes need to be monitored, typically for 10 days.

Autonomic dysfunction is observed, and it commonly includes ileus, constipation, and abdominal pain. Paraparesis, paraplegia, atony of the bladder, cranial nerve palsies (specifically ptosis) hypertension, and hypotension also occur.<sup>67,73,120,227</sup>

Ascending peripheral neuropathies occur after inadvertent large ingestions and during routine chemotherapy. The risk is limited somewhat by keeping the total for a single dose below 2 mg.<sup>191</sup> Neuropathy appears after an overdose, starting at about 2 weeks and lasting for 6 to 7 weeks. Paresthesias, neuritic pain, ataxia, bone pain, wrist drop, foot drop, involvement of cranial nerves III to VII and X, and diminished reflexes are observed.<sup>217</sup> Cranial nerve III involvement, manifesting as bilateral ptosis, was reported in several cases of vincristine toxicity in children.<sup>100,162</sup> The incidence of paresthesia increases with dose and is reported to be 56% in patients treated at doses between 12.5 and 25 mcg/kg.<sup>105</sup> At a dose of 75 mcg/kg, the incidence of patients with a sensory disorder increased by sixfold. The loss of reflexes, the earliest and most consistent sign of vincristine neuropathy, is maximal at 17 days after a single massive dose. Muscular weakness is a limiting point in therapy and typically involves the distal dorsiflexors of the extremities, although laryngeal involvement is also reported.<sup>126,184</sup> These severe neurologic symptoms may be reversed by either withholding therapy or reducing the dosage upon manifestation of these findings.<sup>126</sup> Unlike the vinca alkaloids, Taxol-induced

peripheral neuropathy is predominantly sensory and resolves faster with discontinuation.<sup>129</sup> This is because of the different effects on microtubule assembly by these xenobiotics.

Vincristine-induced myocardial infarctions are reported, but their cause is not understood.<sup>134,192,200,224</sup> Although rare, vincristine administration is associated with an allergic-type cutaneous reaction.<sup>154</sup>

### Testing

Vincristine and vinblastine testing is not readily available at most hospitals. Organ-specific toxicity is evaluated through the use of routinely available laboratory tests (eg, cell blood count, electrolytes, renal and liver function tests).

### Management

Generalized seizures are a life-threatening complication of vincristine or vinblastine overdose. Treatment with benzodiazepines is usually successful and is the recommended front-line antiepileptic intervention, although phenytoin was used successfully in a patient with barbiturate hypersensitivity.<sup>120</sup> Prophylactic phenobarbital and benzodiazepines were used to prevent seizures in two patients.<sup>48,122</sup> Supportive and symptomatic care is recommended for organ specific toxicity as needed.<sup>48</sup> Monitoring daily blood counts is recommended daily, and G-CSF is used to treat neutropenia.<sup>48,130,197</sup> Of note is that the RBC response from the use of erythropoietin is limited because of the induction of metaphase arrest in the erythroblasts.<sup>135</sup>

The symptoms of acute toxicity usually last for 3 to 7 days, and the neurologic sequelae lasts for months. Nerve conduction studies are helpful in assessing the extent of any clinical signs and symptoms of peripheral neuropathy.

Clinical findings of a peripheral neuropathy appears after an excessive dose or after multiple small doses in which the cumulative dose exceeds 30 to 40 mg.<sup>24</sup> Treatment for this condition is variable and includes pain and paresthesia management, including opioids, nonsteroidal antiinflammatory drugs, tricyclic antidepressants, vitamin E, gabapentin, and lamotrigine.<sup>24</sup> In a controlled clinical trial for vincristine-induced peripheral neuropathy, glutamic acid therapy had limited efficacy. Patients receiving vincristine therapy were given glutamic acid as 500 mg orally 3 times a day.<sup>113</sup> There was a decreased incidence in loss of the Achilles tendon reflex and a delayed onset of paresthesias in the glutamic acid-treated group. No reported adverse effects with glutamic acid were observed in this investigation. Animal studies involving the administration of glutamic and aspartic acid to mice poisoned with either vinblastine or vincristine demonstrate increased survival and decreased sensorimotor peripheral neuropathy.<sup>33,60,112</sup> The mechanisms of these observed effects with glutamic acid remain unclear, but several authors have suggested the ability of glutamic acid to competitively inhibit a common cellular transport mechanism for vincristine,<sup>29,58</sup> its ability to assist in the stabilization of tubulin and promote its polymerization into microtubules,<sup>35,96</sup> and the ability of glutamic acid to improve cellular metabolism by overcoming the inhibition in the tricarboxylic acid cycle.<sup>72,114</sup> Although the role of glutamic acid in acute toxicity needs further study, it is not harmful and is reasonable to try in this setting. Glutamic acid is given as 500 mg orally three times a day and continued until the serum vincristine concentration is below toxicity.<sup>113</sup> L-Glutamic acid is the preferred stereoisomer because it is biologically active, and this product is available as a powder from various distributors in the United States. Case reports document success in treating bilateral ptosis with combinations of pyridoxine and pyridostigmine<sup>162</sup> or pyridoxine and thiamine.<sup>100</sup> These therapies are also reasonable to institute.

Leucovorin shortens the course of vincristine-induced peripheral neuropathy<sup>92</sup> and myelosuppression.<sup>122</sup> The mechanism is attributed to the ability of leucovorin to overcome a vincristine-mediated block of dihydrofolate reductase and thymidine synthetase (Antidotes in Depth: A12).<sup>92</sup> However, neither leucovorin<sup>18,111,206</sup> nor pyridoxine<sup>111</sup> was definitely shown to be effective. Therefore, there is insufficient evidence from which to make a recommendation regarding its use as a therapy at this time. An initial

experimental investigation evaluating the efficacy of antibody therapy to limit vinca alkaloid toxicity shows promise.<sup>93</sup> Unfortunately, vinca alkaloid specific antibodies for human poisoning are not commercially available.

The rapid distribution and high protein binding characteristics of vincristine favor early intervention and methods other than hemodialysis. Double-volume exchange transfusion was performed at 6 hours postexposure in three children who were overdosed with 7.5 mg/m<sup>2</sup> of IV vincristine.<sup>122</sup> This procedure replaced approximately 90% of the circulating blood volume by exchanging twice the patient's blood volume. Of the two survivors, their respective postexchange serum vincristine concentrations were 57% and 71% lower than their preexchange concentrations. The amount of vincristine removed was not determined. Although these patients developed peripheral neuropathies, myelosuppression, and autonomic instability, the author noted that the duration of illness was shorter than previously reported. Thus, based on the pharmacokinetic profile of vincristine and these two reports, exchange transfusion in children is the preferred method of enhanced elimination when the patient presents soon after the administration of the drug, and plasmapheresis is the preferred method in adults.

Plasmapheresis was attempted with vinca alkaloid overdoses.<sup>130,169</sup> In an 18-year-old patient who received two 8-mg IV doses of vincristine at 12-hour intervals, the procedure was performed 6 hours after the second dose, and 1.5 times the plasma volume was plasmapheresed.<sup>169</sup> Postplasmapheresis serum vincristine concentration was 23% lower than the starting concentration. The patient survived with myelosuppression, neurotoxicity, and SIADH.

One case of IV vinblastine overdose was reported to be successfully managed with plasma exchange procedures performed at 4 hours and 18 hours after vinblastine administration, resulting in markedly less toxicity than what was expected.<sup>195</sup>

Patients receiving an overdose of vincristine intravenously should be admitted to a cardiac-monitored bed and observed for 24 to 72 hours.<sup>133</sup> If patients remain asymptomatic during the observation period, they can be discharged with follow-up for bone marrow suppression and SIADH; otherwise, depending on the patient's clinical condition, continual observation for progression of neurologic symptoms is warranted.<sup>22</sup>

## SUMMARY

- Colchicine toxicity is evident several hours after ingestion and consists of severe nausea, vomiting, diarrhea, and abdominal pain followed by pancytopenia several days later. Colchicine-poisoned patients have a higher risk of sudden cardiac death, especially during the period between 24 and 36 hours after ingestion; increasing serial troponin concentrations in these patients suggest a higher risk of cardiovascular complications. Podophyllum toxicity is less pronounced compared with colchicine and occurs after dermal application (Table 34–2).
- Early GI decontamination and supportive treatment are the hallmarks of therapy for all colchicine and podophyllin exposure because there are no commercially available and proven antidotes.
- Excessive doses of intravenously administered vincristine or vinblastine cause severe toxicity and are managed with supportive and symptomatic care as well.
- Although definitive data confirming clinical benefit is lacking, exchange transfusion, plasmapheresis, and plasma exchange are reasonable in severely poisoned patients as soon as possible; any potential efficacy likely decreases as the interval from exposure to treatment initiation increases.

**TABLE 34–2** Comparison of Antimitotic Overdose

	<i>Colchicine</i>	<i>Podophyllum Resin</i>	<i>Vincristine</i>	<i>Vinblastine</i>
Route of exposure	PO	PO and cutaneous	IV	IV
Initial symptoms	GI effects, <sup>a</sup> neurologic effects (obtundation, confusion, delirium, seizures, myoneuropathy, areflexia)	GI effects, <sup>a</sup> fever, neurologic effects (obtundation, confusion, delirium, paresthesias, lost reflexes, cranial nerve involvement)	GI effects, <sup>a</sup> fever, neurologic effects (depression, agitation, delirium, paresthesias, muscle weakness, lost reflexes, cranial nerve involvement)	GI effects, <sup>a</sup> fever, myalgias, neurologic effects (but <i>less</i> than vincristine)
Initial symptom onset	Several hours after ingestion; delayed onset beyond 12 h very unlikely	Several hours after ingestion; delayed presentation (past 12 h) is possible, especially after cutaneous exposure	Usually within 24–48 h	Usually within 24–48 h
Hematologic effects	Leukocytosis (24–48 h after ingestion); pancytopenia (beginning 48–72 h after ingestion)	Similar to colchicine; however, not well characterized and reported less frequently	Occurs but <i>decreased</i> severity compared with vinblastine	Myelosuppression; <i>increased</i> severity compared with vincristine
CNS effects	Late (48–72 h after ingestion); obtundation, confusion, and lethargy secondary to progression of MSD	Can be early (<12 h after ingestion); typically occur later or secondary to progression of MSD	Variable; cranial neuropathies; seizures; obtundation, confusion, and lethargy; also occur because of progression of MSD	Occurs but <i>decreased</i> severity compared with vincristine
Delayed PNS effects	Myoneuropathy most common (can also occur early); reported most often in chronic colchicine users with kidney dysfunction	Peripheral sensorimotor axonopathy	Autonomic and ascending peripheral neuropathy; <i>increased</i> severity compared with vinblastine	Autonomic and peripheral neuropathy; <i>decreased</i> severity compared with vincristine
Clinical course	Recovery or MSD and death	Recovery or MSD and death	Recovery or MSD and death; SIADH	Recovery or MSD and death; SIADH
Management	Supportive; GI decontamination (activated charcoal, orogastric lavage for life-threatening ingestions if within 1–2 h, no contraindications present, and provider is proficient in the procedure); G-CSF for neutropenia	Supportive; GI decontamination (activated charcoal) for oral exposures and skin decontamination for cutaneous exposures	Primarily supportive; G-CSF for neutropenia For treatment of intrathecal overdoses, see Special Considerations: SC7	Primarily supportive; G-CSF for neutropenia; exchange transfusion, plasmapheresis or plasma exchange are reasonable for severe toxicity For treatment of intrathecal overdoses, see Special Considerations: SC7

<sup>a</sup>Nausea, vomiting, diarrhea, and abdominal discomfort.

CNS = central nervous system; G-CSF = granulocyte-colony stimulating factor; GI = gastrointestinal; IV = intravenous; MSD = multisystem organ dysfunction; PNS = peripheral nervous system; PO = oral; SIADH = syndrome of inappropriate antidiuretic hormone secretion.

## NONSTEROIDAL ANTIINFLAMMATORY DRUGS

William J. Holubek

### HISTORY AND EPIDEMIOLOGY

In the 1950s, the only treatment for rheumatoid arthritis included high-dose aspirin and gold therapy (chrysotherapy). While searching for new compounds that were chemically nonsteroidal and had antiinflammatory properties, Dr. Stewart Adams filed a patent for “Antiinflammatory Agents” in 1961. One of the compounds in this list was 2-(4-isobutylphenyl) propionic acid, which today we call ibuprofen. This discovery created a new class of drugs designated as nonsteroidal antiinflammatory drugs (NSAIDs).<sup>36</sup> Ibuprofen was initially marketed in the United Kingdom in 1969 and was introduced to the US market in 1974. Ibuprofen became available without a prescription in the United States in 1984.

In addition to the numerous benefits of NSAIDs, some deleterious and life-threatening effects are associated with both their therapeutic use and overdose. In an attempt to circumvent some of these adverse effects, selective cyclooxygenase-2 (COX-2) inhibitors were developed, and in 1999, the first selective COX-2 inhibitor, rofecoxib, was approved by the US Food and Drug Administration (FDA), but it was withdrawn from the market in 2004 after postmarketing surveillance concluded that an increase in myocardial infarctions and cerebrovascular accidents were associated with its use.

Nonsteroidal antiinflammatory drugs are considered among the most commonly used and prescribed nonprescription medications in the world.<sup>12,72</sup> An estimated one in seven patients with rheumatologic diseases is given a prescription for NSAIDs, and another one in five people in the United States uses NSAIDs for acute common complaints.<sup>94</sup>

Ibuprofen, naproxen, and ketoprofen are currently the only nonprescription NSAIDs in the United States. Nonsteroidal antiinflammatory drugs are also contained in cough and cold preparations and in prescription combination drugs (eg, ibuprofen with hydrocodone) and are occasionally found as adulterants in herbal preparations.<sup>61</sup>

The American Association of Poison Control Centers (AAPCC) compiles data regarding potentially toxic exposures called into participating poison centers throughout the United States using the National Poison Data System (NPDS) (Chap. 130). The AAPCC Annual Report lists NSAIDs among the top 25 substances associated with the largest number of fatalities.

The term *NSAID* used in this chapter does not refer to salicylates, which are unique members of the NSAID class and are covered in Chap. 37.

### PHARMACOLOGY

These chemically heterogeneous compounds are divided into carboxylic acid and enolic acid derivatives and COX-2 selective inhibitors (Table 35–1). They all share the ability to inhibit prostaglandin (PG) synthesis. Prostaglandin synthesis begins with the activation of phospholipases (commonly, phospholipase A<sub>2</sub>) that cleave phospholipids in the cell membrane to form arachidonic acid (AA). Arachidonic acid is metabolized by PG endoperoxide G/H synthase, otherwise known as COX, to form many eicosanoids, including PGs and the prostanoids, prostacyclin (PGI<sub>2</sub>) and thromboxane A<sub>2</sub> (TXA<sub>2</sub>). Arachidonic acid is also metabolized by lipoxygenase (LOX) to form hydroperoxy eicosatetraenoic acid (HPETE), which is converted to many different leukotrienes (LTs) that are involved in creating a proinflammatory environment (Fig. 35–1).

The COX enzyme responsible for PG production exists in two isoforms termed *COX-1* and *COX-2*. The isoform COX-1 is constitutively expressed by virtually all cells throughout the body but is the only isoform found within platelets. This enzyme produces eicosanoids that govern “housekeeping” functions, including vascular homeostasis and hemostasis, gastric cytoprotection, and renal blood flow (RBF) and function.<sup>11,75</sup> Conversely, COX-2 is rapidly induced (within 1–3 hours) in inflamed tissue and infiltrating cells (largely endothelial cells) by laminar shear or mechanical stress and

cytokines and produces PGs that are responsible for creating the classic inflammatory response with clinical symptoms of warmth, pain, redness, and swelling. Cyclooxygenase-2 is also upregulated by several cytokines, growth factors, and tumor promoters involved with cellular differentiation and mitogenesis, suggesting a role in cancer development.<sup>11,31,81</sup>

Glucocorticoids inhibit phospholipase A (PLA) and downregulate the induced expression of COX-2, which decreases the production of eicosanoids and PGs, respectively, but oral steroids are clinically not the first choice for an antiinflammatory drug regimen given their extensive adverse side effect profile, which includes osteoporosis, hyperglycemia, hypertension, glaucoma, muscle weakness, fluid retention, and mood swings. Most NSAIDs nonselectively inhibit the COX enzymes in a competitive or time-dependent, reversible manner, unlike salicylates, which irreversibly acetylate COX (Chap. 37). Inhibiting COX-1 can interrupt tissue homeostasis, leading to deleterious clinical effects. In what may seem advantageous, some NSAIDs (eg, etodolac, meloxicam, and nimesulide) preferentially inhibit COX-2 over COX-1, while others were specifically designed to selectively inhibit COX-2 (eg, celebrex).<sup>92</sup> As will be discussed later in this chapter, many of the selective COX-2 inhibitors (sometimes referred to as *coxibs*) were removed from the market in the United States because of their increased risk of adverse cardiovascular events.

Nonsteroidal antiinflammatory drugs do not inhibit the LOX enzyme or the production of LTs; however, some data suggest that blocking the COX enzymes allows AA to be shunted toward the LOX pathway, increasing the production of proinflammatory and chemotactic-vasoactive LTs.<sup>34,52,81,94</sup>

### PHARMACOKINETICS AND TOXICOKINETICS

Most NSAIDs are organic acids with extensive protein binding (95%–99%) and small volumes of distribution of approximately 0.1 to 0.2 L/kg. Oral absorption of most NSAIDs occurs rapidly and near completely, resulting in bioavailabilities above 80%. Time to achieve peak plasma concentrations vary widely (Table 35–1).<sup>34</sup>

Taken at therapeutic doses, most NSAIDs widely distribute throughout the body, penetrate inflamed joints, and obtain synovial fluid concentrations about half of plasma concentration, such as ibuprofen, naproxen, and piroxicam. However, some NSAIDs achieve synovial fluid concentrations equal to or greater than their plasma concentrations, such as indomethacin and tolmetin. Dermal preparations of NSAIDs (commonly diclofenac) achieve therapeutic concentrations in localized tissue while maintaining low plasma concentrations.<sup>56</sup> Ketorolac and diclofenac have topical activity and are used in ophthalmologic solutions.<sup>34</sup> Antiinflammatory drugs have the ability to cross the blood–brain barrier, but the specific pharmacologic and physicochemical properties facilitating this ability are not well defined.<sup>3,53</sup>

The plasma elimination half-life in therapeutic dosing varies from as short as 1 to 2 hours for diclofenac and ibuprofen to 50 to 60 hours for oxaprozin and piroxicam (Table 35–1). Most NSAIDs undergo hepatic metabolism with renal excretion of metabolites; however, diclofenac undergoes extensive first-pass metabolism with an oral bioavailability of about 50%, but indomethacin and ketorolac are excreted 10% to 20% unchanged in the urine. Variable amounts of NSAIDs are recovered in the feces.<sup>34</sup>

The kinetics of NSAIDs change in the setting of an overdose. Therapeutic and supratherapeutic doses of naproxen (250 mg–4 g) result in the same half-life and time to peak plasma concentration, but the clearance and volume of distribution increase proportionately.<sup>64,74</sup> When plasma protein binding of naproxen becomes saturated, the free drug concentration increases more rapidly than the total drug concentration, resulting in increased urinary

TABLE 35-1 Classes and Pharmacology of Selected Nonsteroidal Antiinflammatory Drugs<sup>9,17,29,34,53,62</sup>

	Time to Peak Plasma Concentration (hours)	Half-Life (hours)	Pharmacokinetics	Unique Features
<b>CARBOXYLIC ACIDS</b>				
<i>Acetic Acids</i>				
Diclofenac <sup>a,b</sup>	2–3	1–2	First-pass effect; hepatic metabolism (CYP2C 9)	Decreases leukocyte arachidonic acid concentration; topical activity; hepatotoxic
Etodolac	1	7	Hepatic metabolism	Inhibits leukocyte motility; coronary vasoconstrictor effect
Indomethacin	1–2	2.5	Demethylation (50%)	Poor antiinflammatory effect; topical activity
Ketorolac	<1	4–6	Urinary excretion	For parenteral use also
Sulindac	1–2	7	Active metabolite with a half-life of 18 h	Prodrug; hepatotoxic
Tolmetin	< 1	5	Hepatic metabolism	Accumulates in synovia
<i>Fenamic Acids</i>				
Meclofenamate	0.5–2.0	2–3	Urinary excretion (~70%); active metabolite	Seizures; GI inflammation
Mefenamic acid	2–4	3–4	Urinary excretion (50%)	Seizures; prostaglandin antagonist
<i>Propionic Acids</i>				
Fenoprofen	2	2–3	Decreased oral absorption (~85%)	Increased CSF concentration
Flurbiprofen	1–2	6	Urinary excretion unchanged (~20%)	Increased CSF concentration
Ibuprofen <sup>c,d</sup>	<0.5	2–4	Hepatic metabolism; urinary excretion	Also formulated for parenteral use
Indobufen <sup>e</sup>	2	6–7	Urinary excretion (70%–80%)	In Europe, used as prophylaxis for thrombus formation
Ketoprofen <sup>c</sup>	1–2	2	Hepatic metabolism; urinary excretion	Bradykinin antagonist; stabilizes lysosomal membranes
Naproxen <sup>c</sup>	1	14	Increased half-life with kidney dysfunction	Inhibitory effect on leukocytes; prolonged platelet inhibition
Oxaprozin	3–6	40–60	Hepatic metabolism	Once-daily administration
<i>Salicylates (Chap. 37)</i>				
<b>ENOLIC ACIDS</b>				
<i>Oxicams</i>				
Meloxicam <sup>a</sup>	5–10	15–20	Hepatic metabolism (CYP2C9)	High COX-2 selectivity
Nabumetone	3–6	24	Hepatic metabolism; active metabolites	Prodrug
Piroxicam	3–5	45–50	Hepatic metabolism (CYP2C9)	Inhibits neutrophil activation
<i>Pyrazolone</i>				
Phenylbutazone <sup>e</sup>	2	54–99	Hepatic metabolism; active metabolites	Irreversible agranulocytosis; aplastic anemia
<b>CYCLOOXYGENASE-2 SELECTIVE INHIBITORS<sup>f</sup></b>				
Celecoxib	2–4	6–12	Hepatic metabolism (CYP2C9)	Inhibits CYP2D6
Nimesulide <sup>e</sup>	1–3	2–5	Urinary excretion (60%); active metabolites	Inhibits neutrophil activation

<sup>a</sup>COX-2 preferential. <sup>b</sup>Available in combination with misoprostol. <sup>c</sup>Nonprescription. <sup>d</sup>Available in combination with oxycodone and hydrocodone. <sup>e</sup>Not available in the United States for humans. <sup>f</sup>Rofecoxib (Vioxx) and valdecoxib (Bextra) are no longer available.

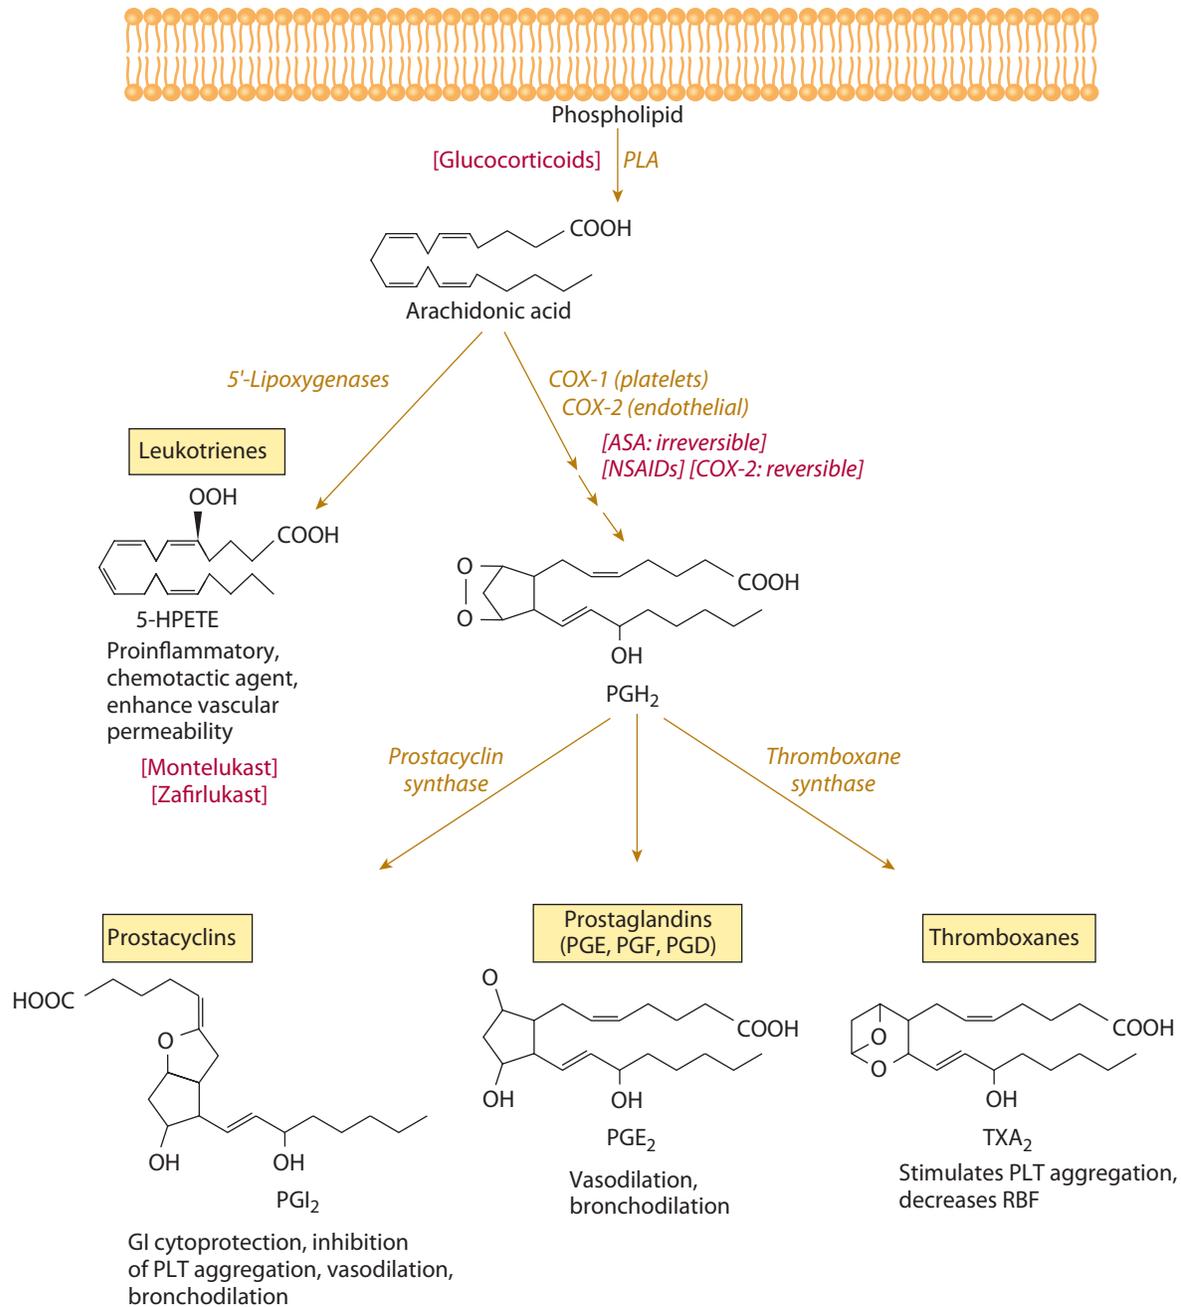

COX = cyclooxygenase; CSF = cerebrospinal fluid; GI = gastrointestinal.

excretion.<sup>74</sup> Overdoses of oral ibuprofen do not appear to prolong its elimination half-life.<sup>37,54,95</sup>

## PATHOPHYSIOLOGY

Gastrointestinal (GI) toxicity is the most common adverse effect from NSAID use (Table 35-2). Normally, the COX-1 enzyme expressed in the gastric epithelial cells leads to the production of PGs (PGE<sub>2</sub> and PGI<sub>2</sub>), which are responsible

for maintaining GI mucosal integrity by increasing cytoprotective mucous production, decreasing stomach acid production, and enhancing mucosal blood flow. Antiinflammatory drugs inhibit the production of these cytoprotective PGs, as well as the platelet aggregatory TXA<sub>2</sub>, and they also have a direct cytotoxic or local irritation effect, increasing the risk of gastric and duodenal ulcers, perforations, and hemorrhage.<sup>24,68,72</sup> Although various enteric coated formulations were created to reduce NSAID contact with the gastric mucosa,

**FIGURE 35-1.** Arachidonic acid (AA) metabolism. This figure also illustrates some of the major differences between cyclooxygenase-1 (COX-1) and cyclooxygenase-2 (COX-2). Phospholipase A (PLA) is stimulated by physical, chemical, inflammatory, and mitogenic stimuli and releases AA from cell membranes. The COX-1 enzyme synthesizes prostaglandins (PGs) that maintain cellular and vascular homeostasis. The COX-2 enzyme produces PGs within activated macrophages and endothelial cells that accompany inflammation. Whereas nonsteroidal antiinflammatory drugs (NSAIDs) reversibly inhibit both COX isoforms, selective COX-2 inhibitors inhibit the COX-2 isoform. Some authors suggest that inhibiting the COX enzymes shunts AA metabolism toward the production of chemotactic-vasoactive leukotrienes. Glucocorticoids inhibit PLA and down regulate induced expression of COX-2. ASA = acetylsalicylic acid; 5-HPETE, hydroperoxy eicosatetraenoic acid; GI = gastrointestinal; PGI<sub>2</sub> = prostacyclin; PGD = prostaglandin D; PGE<sub>2</sub> = prostaglandin E<sub>2</sub>; PGF = prostaglandin F; PGH<sub>2</sub> = prostaglandin H<sub>2</sub>; PLT = platelet; RBF = renal blood flow; TXA<sub>2</sub> = thromboxane.

no significant reduction in GI adverse events resulted.<sup>34</sup> Esophageal and small intestinal ulcers and strictures are also associated with NSAID use. Small intestinal diaphragms (or webs) are concentric weblike septa arising from submucosal fibrosis that eventually cause a small bowel obstruction. These diaphragms rarely occur but are considered pathognomonic for NSAID use.<sup>24</sup>

Selective COX-2 inhibitors decrease the incidence of significant GI toxicity compared with some nonselective NSAIDs, a benefit that is lost in patients concomitantly taking warfarin or low-dose aspirin.<sup>4,13,31,93</sup> Although *Helicobacter pylori* and NSAID use both individually increase the risk of gastroduodenal ulcers, there are conflicting data regarding the relationship between the two, given the wide array of study designs, individual responses to infection and

treatments, and different gastric acid suppressants. However, current evidence suggests that the risk of GI toxicity and peptic ulcer disease is decreased by eradicating *H. pylori* in NSAID users and NSAID-naïve users.<sup>12,19,24,72,86</sup>

The kidney produces locally homeostatic PGs largely via COX-1, including PGI<sub>2</sub>, PGE<sub>2</sub>, and PGD<sub>2</sub>, that maintain adequate glomerular filtration rate (GFR) and RBF and function by augmenting renal vasodilation, inhibiting sodium chloride absorption, and antagonizing the action of antidiuretic hormone (vasopressin). Antiinflammatory drugs oppose this homeostatic renal vasodilation and augment sodium reabsorption, blunting the antihypertensive effect of thiazide and loop diuretics. Antiinflammatory drugs also decrease renin synthesis, a mechanism shared by  $\beta$ -adrenergic antagonists, rendering this

**TABLE 35–2** Selected Adverse Effects of Nonsteroidal Antiinflammatory Drugs

<i>Gastrointestinal</i>
Acute: dyspepsia, ulceration, perforation, hemorrhage, elevated hepatic aminotransferases, hepatocellular injury (rare) Chronic: same as above
<i>Renal</i>
Acute: acute kidney failure, fluid and electrolyte retention, hyperkalemia, hypertension interstitial nephritis, nephrotic syndrome, papillary necrosis, azotemia Chronic: same as above
<i>Hypersensitivity or Pulmonary</i>
Acute: asthma exacerbation, anaphylactoid and anaphylactic reactions, urticaria, angioedema, acute respiratory distress syndrome, drug-induced lupus Chronic: angioedema, drug-induced lupus
<i>Hematologic</i>
Acute: increased bleeding time, agranulocytosis, aplastic anemia, thrombocytopenia, neutropenia, hemolytic anemia Chronic: same as above
<i>Central Nervous System</i>
Acute: headache, dizziness, lethargy, coma, aseptic meningitis, delirium, cognitive dysfunction, hallucinations, psychosis Chronic: same as above
<i>Drug Interactions</i>
Aminoglycosides: increased risk of aminoglycoside toxicity <sup>77</sup> Anticoagulants (eg, warfarin, salicylates, heparins, direct thrombin inhibitors and Xa inhibitors): increased risk of gastrointestinal bleeding <sup>11,75</sup> Antihypertensives (especially diuretics, $\beta$ -adrenergic antagonists, angiotensin receptor blockers and angiotensin-converting enzyme inhibitors): reduced antihypertensive effects <sup>94</sup> Digoxin: increased risk of digoxin toxicity <sup>85</sup> Ethanol: increased bleeding time <sup>75</sup> Lithium: increased risk of lithium toxicity <sup>67</sup> Methotrexate: increased risk of methotrexate toxicity <sup>67</sup> Sulfonylureas: increased hypoglycemic effect <sup>83</sup>

antihypertensive therapy less effective.<sup>31,94</sup> Patients with volume contraction (salt and water depletion) or poor cardiac output (congestive heart failure) have elevated concentrations of renal vasoconstrictor substances from stimulation of both the renin–angiotensin–aldosterone axis and the sympathetic nervous system, so NSAID use in these patients inhibits the synthesis of compensatory vasodilatory PGs, resulting in unopposed renal vasoconstriction and causing decreased RBF and GFR. This effect leads to medullary ischemia and possibly acute kidney injury (AKI), particularly in older adults.<sup>70</sup> This vasoconstrictive effect is also associated with COX-2 selective inhibitors and appears to be reversible upon discontinuation of therapy.<sup>60,70,94</sup>

Normal platelet function depends partly on endothelial-derived PGI<sub>2</sub> (largely via constitutively expressed COX-1), which blocks platelet activation and causes vasodilation, allowing blood to flow freely within vessels. At the site of vascular injury, platelets are activated by binding to collagen-bound von Willebrand factor and synthesize and release TXA<sub>2</sub>, a potent platelet stimulator and vasoconstrictor. The antiplatelet activity of NSAIDs stems from their ability to inhibit COX-1, thereby inhibiting platelet-stimulating TXA<sub>2</sub> synthesis. Selective COX-2 inhibitors also decrease PGI<sub>2</sub> and TXA<sub>2</sub> synthesis but affect TXA<sub>2</sub> synthesis to a lesser degree, creating a more prothrombotic environment, which is the predominant theory of how selective COX-2 inhibitors increase the risk of adverse cardiovascular events (see later for further discussion).<sup>75</sup>

Prostaglandins play a major role during the initiation of parturition. Administration of exogenous PGF<sub>2 $\alpha$</sub>  and PGE<sub>2</sub> is used to induce uterine activity, and indomethacin was used successfully as a tocolytic agent by blunting PG-mediated uterine stimulation. However, a major clinical drawback in using NSAIDs as tocolytics is their potential to cause premature constriction or closure of the ductus arteriosus in utero. Vasodilatory PGs are required to keep the fetal ductus arteriosus patent, and inhibiting these PGs causes fetal ductal constriction, leading to pulmonary hypertension and persistent fetal circulation after birth.<sup>58</sup>

## CARDIOVASCULAR RISK OF SELECTIVE CYCLOOXYGENASE-2 INHIBITORS AND NONSELECTIVE NONSTEROIDAL ANTIINFLAMMATORY DRUGS

Atherosclerosis is a dynamic process of thrombus formation and inflammation involving numerous tissue factors and inflammatory mediators.<sup>32</sup> Given the ability to inhibit synthesis of proinflammatory PGs, selective COX-2 inhibitors would be expected to be antithrombotic; however, their ability to inhibit endothelial-derived PGI<sub>2</sub> combined with their relative inability to inhibit platelet-activating TXA<sub>2</sub> (a predominantly COX-1 effect) shifts the balance toward thrombus formation.<sup>59</sup>

In 2004, Merck pharmaceutical company withdrew rofecoxib from the worldwide market given the prepublication results of a study demonstrating an undisputed elevated cardiovascular risk.<sup>15</sup> Several other studies addressing selective COX-2 inhibitors had similarly increased risk of adverse cardiovascular events, suggesting this to be a class effect.<sup>27,66,82</sup> Valdecoxib was subsequently removed from the market, leaving celecoxib as the only selective COX-2 inhibitor available. The FDA mandated that Pfizer, the manufacturer of celecoxib, include “black box” warnings to customers of the serious cardiovascular risks and conduct a cardiovascular safety trial, which was called the Prospective Randomized Evaluation of Celecoxib Integrated Safety versus Ibuprofen or Naproxen (PRECISION) trial. This noninferiority trial was completed in 2016 and concluded that moderate doses of celecoxib were not inferior to ibuprofen or naproxen in regards to cardiovascular death (hemorrhagic death, nonfatal myocardial infarction, nonfatal stroke).<sup>65,82</sup>

The current data on nonselective NSAID use suggest an increase in cardiovascular risk, yet this risk varies depending on the nonselective NSAID being used. Some nonselective NSAIDs show a trend toward elevated cardiovascular risk (eg, diclofenac, meloxicam, indomethacin, and, to a lesser extent, ibuprofen), but naproxen shows a trend toward minimal cardiovascular risk. In 2015, the FDA strengthened the warning labels required for prescription and nonprescription NSAIDs to include more information regarding the potential risks for heart attack and stroke.<sup>21,33,55,78,91</sup>

## CLINICAL MANIFESTATIONS

Nonsteroidal antiinflammatory drugs are a heterogeneous class of drugs, some carrying a unique toxicity profile. Fortunately, most nonselective NSAIDs behave similarly in overdose, although much of the medical literature specifically describes ibuprofen. Regardless of the particular NSAID ingested, symptoms typically manifest within 4 hours after ingestion.<sup>37–39,51,54,90</sup>

Initial clinical manifestations are usually mild and predominantly include GI symptoms, such as nausea, vomiting, or abdominal pain, or neurologic symptoms, such as drowsiness, headache, tinnitus, blurred vision, diplopia, and dizziness. More moderate and severe findings are rare and include coma, seizures, central nervous system (CNS) depression, metabolic acidosis, hypotension, hypothermia, rhabdomyolysis, electrolyte imbalances, cardiac dysrhythmias, and AKI.<sup>20,37,38,51,54,57,90</sup> Massive NSAID ingestions lead to multi-system organ failure and death.<sup>22,43,80,89,95</sup>

## Neurologic Effects

The neurologic effects of NSAID use vary from the mild drowsiness, headache, and dizziness with therapeutic dosing to the more life-threatening CNS depression, coma, and seizures in overdose. The mechanism associated with the decreased level of consciousness is unknown; however, several animal studies suggest a relationship with opioid receptors, and a human case

report documents a dramatic return of consciousness in a child after intravenous (IV) administration of high-dose naloxone.<sup>28</sup> Other reported neurologic manifestations of toxicity include optic neuritis, amblyopia, color blindness, transient diplopia, other visual disturbances, transient loss of hearing, acute psychosis, and cognitive dysfunction.<sup>40,67</sup>

Drug-induced aseptic meningitis is reported with several NSAIDs, including tolmetin, rofecoxib, naproxen, sulindac, piroxicam, and diclofenac, but ibuprofen is more commonly implicated, perhaps because of its widespread use. The incidence of developing aseptic meningitis is unknown but thought to be very low. Clinical findings appear shortly after exposure and are similar to infectious meningitis, including fever and chills, headache, meningeal signs, nausea, vomiting, and altered mental status. Additionally, patients also display symptoms consistent with an allergic reaction, such as erythema, face edema, and conjunctivitis. Cerebrospinal fluid findings include pleocytosis (mainly neutrophils), elevated protein, normal or low glucose, and negative cultures. Studies suggest an allergic mechanism behind NSAID-induced aseptic meningitis because it appears to occur with select NSAIDs and not the whole class, it is not dose-dependent, and symptoms present much quicker with reexposure. An immunologic mechanism is also suggested because it appears to be more common in patients with systemic lupus erythematosus (SLE) or mixed connective tissue disease.<sup>1,40,63,67</sup>

Some studies describe a condition termed “medication overuse headache” in patients who regularly take NSAIDs for migraine or tension-type headaches and whose headaches resolve after discontinuation of NSAIDs.<sup>1</sup> Muscle twitching and generalized tonic-clonic seizures are described with mefenamic acid overdose and usually occur within 7 hours after ingestion.<sup>2</sup> Seizures are also associated with ibuprofen overdose,<sup>69</sup> although the specific mechanism is unknown.

### Renal and Electrolyte Effects

Both acute overdose and chronic therapeutic dosing of NSAIDs have deleterious effects on kidney function, most of which are reversible. These include sodium retention and edema, hyperkalemia, AKI, membranous nephropathy, nephrotic syndrome, interstitial nephritis, and both acute and chronic renal papillary necrosis.<sup>40,71,94</sup> The incidence of developing these serious side effects is about 1% to 5% of those exposed but approaches 20% in patients with comorbidities, such as congestive heart failure, volume depletion, diabetes mellitus, underlying kidney disease, SLE, cirrhosis, diuretic therapy, and advanced age.<sup>41,52</sup> There is also growing concern over the potential development of AKI with NSAID use in patients who are concurrently taking multiple antihypertensive medications, such as diuretics, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers.<sup>49</sup>

Acute tubulointerstitial nephritis (ATIN) is one of the more common forms of NSAID-induced renal impairment, occurring with short-term therapeutic dosing.<sup>25,52</sup> Many cases of ATIN probably go undiagnosed because clinical symptoms usually do not appear until significant renal impairment occurs.<sup>25,73</sup> Significant elevations in blood urea nitrogen (azotemia) occur in older patients within 5 to 7 days of initiating NSAID therapy and usually return to baseline within 2 weeks of discontinuation.<sup>35</sup>

Analgesic abuse nephropathy is a condition whose pathogenesis is not well defined, but it develops from excessive, chronic therapeutic consumption of NSAIDs. This results in AKI manifested by renal papillary necrosis, often requiring hemodialysis.<sup>79,94</sup> Analgesic abuse nephropathy was originally described with the use of analgesic combinations including phenacetin and aspirin in addition to caffeine and has decreased in prevalence after the removal of phenacetin from many world markets.

Anion gap metabolic acidosis, with and without AKI, complicates many acute, massive ibuprofen ingestions and is often profound.<sup>26,43,95,96</sup> The cause of the acidosis in this setting is most likely multifactorial, involving profound hypotension and tissue hypoperfusion with elevated lactate concentrations and the accumulation of ibuprofen and its two major metabolites, all weak acids.<sup>51</sup> An elevated anion gap metabolic acidosis with elevated lactate concentrations is also described after naproxen overdose, suggesting this to be a class effect given that all NSAIDs are acid derivatives.<sup>14</sup>

Use of NSAIDs by pregnant women is associated with reversible oligohydramnios and is used therapeutically as a treatment modality for polyhydramnios. Decreased fetal urine output and neonatal acute and chronic kidney failure, including transient oligoanuria, are associated with gestational NSAID use, commonly indomethacin.<sup>6,30,45</sup>

### Gastrointestinal Effects

Adverse GI effects from acute and chronic NSAID use range from mild dyspepsia to ulcer formation, which can lead to life-threatening GI hemorrhage and perforation. Factors that influence the risk of developing symptoms include number, duration, and dose of NSAID; concomitant usage of an anti-coagulant, antiplatelet, steroid, or selective serotonin reuptake inhibitor; age; prior history of ulcer; *H. pylori* status; and comorbidities.<sup>76</sup>

Dyspepsia is the most common adverse GI effect, occurring in up to 60% of patients, but most patients with dyspepsia do not have ulcers. Studies suggest 20% to 30% of chronic NSAID users have ulcers, although many are asymptomatic and clinically insignificant. To help prevent the development of ulcers associated with NSAID therapy, concomitant use of misoprostol (a PGE<sub>2</sub> analog), an H<sub>2</sub>-receptor antagonist, or a proton pump inhibitor (PPI) is often used; however, PPIs are superior for both preventing and healing gastroduodenal ulcers resulting from chronic NSAID therapy.<sup>72,76</sup> The annual incidence of developing a symptomatic or clinical significant upper GI ulcer is 2.5% to 4.5%, but that of developing a perforation, hemorrhage, or obstruction is 1% to 1.5%.<sup>76</sup> The relative risk of developing gastroduodenal perforation, ulcer, or hemorrhage during chronic, therapeutic NSAID therapy ranges from 2.7 to 5.4, with ketorolac posing the greatest risk.<sup>68,88</sup> Acute NSAID overdoses cause bloody emesis; fecal occult blood loss; and severe, life-threatening GI hemorrhage.

Nonsteroidal antiinflammatory drug-induced hepatotoxicity is a well-known adverse effect that prompted the removal of several NSAIDs from the market. Hepatotoxicity occurs with an incidence of less than 0.1% and can be quite difficult to diagnose because many patients on chronic NSAID therapy have underlying conditions, such as SLE or rheumatoid arthritis, that cause hepatotoxicity. NSAID-induced hepatotoxicity is an idiosyncratic reaction primarily causing hepatocellular injury and does not depend on the chemical class. Diclofenac and sulindac are most commonly implicated.<sup>87</sup>

### Immunologic and Dermatologic Effects

The nonimmunologic anaphylactoid and the IgE-mediated anaphylactic reactions that are reported with the use of NSAIDs are clinically indistinguishable from one another, producing flushing, urticaria, bronchospasm, edema, and hypotension. Evidence for anaphylactic reactions includes the presence of NSAID-specific IgE antibodies, positive wheal-and-flare skin reactions, and lack of cross-reactivity with oral challenges of aspirin and other NSAIDs.<sup>8</sup> The proposed mechanism of NSAID-induced anaphylactoid reactions involves the inhibition of COX-1, which not only inhibits the production of PGE<sub>2</sub> (which causes bronchodilation and inhibits the release of histamine from mast cells and basophils) but also shunts the AA metabolism to increased production of bronchoconstricting LTs.

The term *aspirin-sensitive asthmatic* is a bit of a misnomer because it refers to anaphylactoid reactions that occur with any COX-1-inhibiting NSAID, not only aspirin. Selective COX-2 inhibitors cause similar clinical reactions but with an unclear mechanism. There is little cross-reactivity between NSAIDs and selective COX-2 inhibitors, and reports of reactions to one COX-2 inhibitor and not another suggest a predominant IgE-mediated mechanism.<sup>8,47,84</sup>

The most common skin reactions include angioedema and facial swelling, urticaria and pruritus, bullous eruptions, and photosensitivity. Although rare, toxic epidermal necrolysis and Stevens-Johnson syndrome are reported.<sup>40</sup>

### Hematologic Effects

As a class, NSAIDs are frequently implicated in the development of drug-induced thrombocytopenia and cause adverse effects on most other cell

lines and function, including agranulocytosis, aplastic anemia, hemolytic anemia, methemoglobinemia, and pancytopenia.<sup>5,23,40,46,62</sup> Specifically, phenylbutazone in chronic, therapeutic doses was associated with agranulocytosis and aplastic anemia,<sup>80</sup> prompting its removal from the US market in the 1970s. The inhibitory effect of NSAIDs on granulocyte adherence, activation, and phagocytosis, in addition to the potential for masking signs and symptoms, is suggested as the mechanism responsible for the association between NSAID use and necrotizing fasciitis.<sup>42</sup>

The ability of a particular type of NSAID to inhibit platelet aggregation and affect bleeding time depends on the dose and half-life because NSAIDs reversibly inhibit COX. One dose of ibuprofen prolongs the bleeding time within 2 hours and persists for up to 12 hours; however, this increase in bleeding time usually remains within the upper limit of normal range. This is in contrast to aspirin, which irreversibly inhibits COX, and typically doubles the bleeding time within 12 hours, returning to normal within 24 to 48 hours.<sup>75</sup> Compared with placebo, flurbiprofen and indobufen clinically inhibit platelet function, thereby decreasing vascular reocclusion after angioplasty and preventing thromboembolic complications.<sup>10,16</sup> The concern over whether ketorolac has clinically significant effects on postoperative bleeding remains controversial depending on the surgical procedure and patient population.<sup>18</sup>

Nonsteroidal antiinflammatory drug use potentiates bleeding in patients already at higher risk. These patients include those with thrombocytopenia, coagulation factor deficiencies, or von Willebrand disease and those ingesting alcohol or on warfarin therapy.<sup>75</sup>

### Cardiovascular Effects

Although no evidence supports a direct cardiotoxic effect of NSAIDs or their metabolites, acute and massive NSAID overdoses are complicated by persistent and severe hypotension; myocardial ischemia; and cardiac conduction abnormalities and dysrhythmias, including bradycardia, ventricular tachycardia or fibrillation, and prolonged QT interval.<sup>26,43,95</sup> The cause of these findings is yet to be elucidated, although these effects are reported only in severely ill patients with acid–base abnormalities and multisystem organ involvement (see Cardiovascular Risk earlier).

### Pulmonary Effects

Although there is no evidence of direct pulmonary toxicity, some case reports describe the development of acute respiratory distress syndrome similar to the clinical manifestations of salicylate toxicity, suggesting an NSAID class mechanism–based process.<sup>26,43,50,57</sup> Although chest radiographic findings such as bilateral pulmonary infiltrates appear to resolve rapidly, one study reported persistent clinical abnormalities associated with exertional dyspnea 1 month later (see Immunologic Effects earlier).<sup>57</sup>

### DIAGNOSTIC TESTING

Serum concentrations of most NSAIDs can be determined but usually only by a specialty laboratory requiring several days to report results. Although ibuprofen nomograms were constructed in an attempt to correlate serum concentrations with clinical toxicity,<sup>37,44</sup> the utility of these nomograms proved limited.<sup>39,54</sup>

We recommend obtaining laboratory measurements, including complete blood count, serum electrolytes, blood urea nitrogen, and creatinine, for all symptomatic patients, patients with intentional ingestions, ibuprofen ingestion of greater than 400 mg/kg in a child, or ibuprofen ingestion of greater than 6 g in an adult.<sup>39</sup> For patients presenting with significant neurologic effects, such as CNS depression, further evaluation of acid–base and ventilatory status by blood gas, hepatic aminotransferases, and prothrombin time are recommended. A computed tomography scan of the head and a lumbar puncture is clinically indicated in cases of suspected aseptic meningitis or when structural or infectious etiologies are suspected. An acetaminophen (APAP) concentration should always be determined in patients with intentional ingestions and in patients presenting with an unclear history because many people mistake APAP for NSAIDs and many variably compounded analgesics because of confusing labeling

and packaging or unawareness that they are completely different types of analgesics. For similar reasons, obtaining a salicylate concentration is reasonable.

### MANAGEMENT

Management of a patient with an NSAID overdose is largely supportive and guided by the clinical signs and symptoms. Most asymptomatic patients with intentional overdose and those with normal vital signs require observation for 4 to 6 hours and a serum APAP concentration before being medically cleared. Children with ibuprofen ingestions of less than 100 mg/kg can be observed at home, but those who ingest greater than 400 mg/kg are at high risk for toxicity and require medical evaluation.<sup>39</sup> We recommend GI decontamination with activated charcoal (AC) for asymptomatic patients with the potential for a large ingestion, symptomatic patients, and children with a history of ibuprofen ingestion greater than 400 mg/kg.<sup>39,48</sup> Given that serum concentration of ibuprofen continues to increase after the time of emergency department arrival in patients with massive overdose, AC can be administered immediately. For patients with massive overdoses of sustained-release preparations, gastric lavage followed by AC and subsequent multiple-dose AC is reasonable.<sup>95</sup>

Patients who develop severe, life-threatening manifestations usually present with lethargy or unresponsiveness.<sup>26,43,57,69,95</sup> Aggressive, supportive care is indicated in these patients, including stabilization of the airway and IV fluid therapy. An early electrocardiogram is essential to detect any significant electrolyte abnormalities or conduction disturbances. Electrolyte imbalances should be corrected and sodium bicarbonate therapy administered for life-threatening metabolic acidosis. Hypotension should be treated initially with IV fluid therapy followed by direct-acting vasopressors if necessary. Electrocardiograms should be monitored for the development of any life-threatening electrolyte imbalances or cardiac conduction abnormalities.

Given their high protein binding and low volumes of distribution, NSAIDs are not amenable to extracorporeal removal techniques and thus, we recommend not to perform hemodialysis to remove an NSAID; however, in cases of refractory metabolic acidosis or AKI, hemodialysis or continuous renal replacement therapies are useful to correct the acid–base status.<sup>7,50</sup> Patients with seizures, which are characteristic of mefenamic acid overdose,<sup>2</sup> should be treated with IV benzodiazepines.

### SUMMARY

- Antiinflammatory drugs are among the most commonly used drugs in the world.
- Most patients with NSAID overdoses develop nonspecific symptoms, including nausea and abdominal discomfort, requiring little clinical management other than psychiatric assessment.
- Gastrointestinal decontamination is recommended in patients with large intentional ingestions.
- In all cases of intentional NSAID ingestion, APAP coingestion should be excluded.

## OPIOIDS

Lewis S. Nelson and Dean Olsen

Opioids are among the oldest therapies in our pharmacopeia, and clinicians recognize their universal utility to limit human distress from pain. Although opioids are widely used as potent analgesics, they have the potential for abuse because of their psychoactive properties. Although the therapeutic and toxic doses are difficult to predict because of the development of tolerance with chronic use, the primary adverse events from excessive dosing are respiratory depression and sedation.

### HISTORY AND EPIDEMIOLOGY

The medicinal value of opium, the dried extract of the poppy plant *Papaver somniferum*, was first recorded circa 1500 B.C. in the Ebers papyrus. Raw opium is composed of at least 10% morphine, but extensive variability exists depending on the environment in which the poppy is grown.<sup>109</sup> Although reformulated as laudanum (deodorized tincture of opium; 10 mg morphine/mL) by Paracelsus, paregoric (camphorated tincture of opium; 0.4 mg morphine/mL), Dover's powder (pulvis Doveri), and Godfrey's cordial in later centuries, the contents remained largely the same: phenanthrene poppy derivatives, such as morphine and codeine. Over the centuries since the Ebers papyrus, opium and its components have been used in two distinct manners: medically to produce profound analgesia and nonmedically to produce psychoactive effects.

Currently, the widest clinical application of opioids is for acute or chronic pain relief. Opioids are available in various formulations that allow administration by virtually any route: epidural, inhalational, intranasal, intrathecal, oral, parenteral (ie, subcutaneous {SC}, intravenous {IV}, intramuscular {IM}), rectal, transdermal, and transmucosal. Patients also benefit from several of the presumed nonanalgesic effects produced by certain opioids. For example, codeine and hydrocodone are widely used as antitussives and loperamide as an anti-diarrheal.

Morphine was isolated from opium by Armand Séquin in 1804. Charles Alder Wright synthesized heroin from morphine in 1874. Ironically, the development and marketing of heroin as an antitussive agent by Bayer, the German pharmaceutical company, in 1898 legitimized the medicinal role of heroin.<sup>193</sup> Subsequently, various xenobiotics with opioidlike effects were marketed, each promoted for its presumed advantages over morphine. However, in general, the purported advantages of such medications have fallen short of expectations, particularly with regard to their potential for abuse and addiction.

Unfortunately, the history of opium and its derivatives is marred by humankind's endless quest for xenobiotics that produce pleasurable effects. Opium smoking was so problematic in China by the 1830s that the Chinese government attempted to prohibit the importation of opium by the British East India Company. This act led to two Opium Wars between China and Britain. China eventually accepted the importation and sale of the drug and was forced to turn over Hong Kong to British rule. The euphoric and addictive potential of the opioids is immortalized in the works of several famous writers, such as Thomas de Quincey (*Confessions of an English Opium Eater*, 1821),

Samuel Coleridge (*The Rime of the Ancient Mariner*, 1798), and Elizabeth Barrett Browning (*Aurora Leigh*, 1856).

Because of mounting concerns of addiction and overdose in the United States, the Harrison Narcotics Tax Act, enacted in 1914, made nonanalgesic use of opioids illegal. Since that time and despite extensive legislative and other efforts, recreational and habitual use of heroin and other opioids have remained epidemic in the United States and worldwide and currently are one of the leading causes of death in the United States.

Prescription opioids have until recently accounted for approximately 75% of all opioid-related deaths in the US. In 2009, deaths from prescription drugs, mainly opioids, first exceeded those from motor vehicle crashes.<sup>27</sup> From 2000 to 2015, the rate of deaths from drug overdoses increased 137%, including a 200% increase in the rate of overdose deaths involving opioids (opioid analgesics and heroin).<sup>173</sup>

Current data demonstrate that the United States' opioid epidemic includes two distinct but interrelated trends: a 20-year increase in overdose deaths involving prescription opioid analgesics and a recent surge in illicit opioid overdose deaths, driven largely by heroin and other illicit opioids.<sup>173</sup> Beginning around 2013, the rate of drug overdose deaths involving synthetic opioids increased sharply, driven principally by nonpharmaceutical fentanyl, fentanyl analogs, and novel opioid agonists (U47700 and others). All of these opioids are manufactured in illegal laboratories, primarily in China and Mexico, and imported into the United States more readily than heroin. These illicit opioids are either used to adulterate heroin or are, used to create counterfeit prescription opioid pills, which complicates the attribution of the cause of death in heroin decedents.<sup>77,173,174</sup>

Over the past decade, the realization that opioid analgesics are subject to extensive abuse has led to the development of newer formulations of existing opioids that theoretically reduced abuse potential.<sup>32</sup> The use of "tamper-resistant formulations" was emphasized as an approach to reduce the abuser's ability to crush or dissolve the tablet for insufflation or injection, respectively.<sup>177</sup> Although renamed "abuse deterrent formulations" (ADFs), the true clinical benefit of such formulations in reducing abuse is not known. Descriptions of the means to subvert the deterrence mechanism are widely described on the internet. Because the majority of patients who develop addiction or hyperalgesia ingest intact tablets, ADFs are highly unlikely to beneficially impact these adverse outcome. Although primarily a concern with extended-release or long-acting opioid formulations because of their greater content of opioid, abuse-deterrent immediate-release formulations were recently introduced to address this concern.<sup>102</sup>

The terminology used in this chapter recognizes the broad range of xenobiotics commonly considered to be opiumlike. The term *opiate* specifically refers to the alkaloids naturally derived directly from the opium poppy: morphine; codeine; and, to some extent, thebaine and noscapine. *Opioids* are a much broader class of xenobiotics that are capable of either producing opiumlike effects or binding to opioid receptors. A *semisynthetic opioid*, such as heroin or oxycodone, is created by chemical modification of an opiate. A *synthetic opioid* is a chemical, not derived from an opiate, that is capable of binding to an opioid receptor and producing opioid effects clinically. Synthetic opioids, such as methadone and fentanyl, bear little apparent structural similarity to the opiates. Opioids also include the naturally occurring animal-derived opioid peptides such as endorphin and nociceptin/orphanin FQ. The term *narcotic* refers to sleep-inducing xenobiotics and initially was used to connote the opioids. However, law enforcement and the public currently use the term to indicate any illicit psychoactive substance, including, paradoxically, cocaine. The term *opioid* as used hereafter encompasses the opioids and the opiates.

## PHARMACOLOGY

### Opioid-Receptor Subtypes

Despite nearly a century of opioid studies, the existence of specific opioid receptors was not proposed until the mid-20th century. Beckett and Casy noted a pronounced stereospecificity of existing opioids (only the L-isomer is active) and postulated that the drug needed to “fit” into a receptor.<sup>11</sup> In 1963, after studies on the clinical interactions of nalorphine and morphine, the theory of receptor dualism<sup>196</sup> postulated the existence of two classes of opioid receptors. Such opioid binding sites were not demonstrated experimentally until 1973.<sup>159</sup> Intensive experimental scrutiny using selective agonists and antagonists continues to permit refinement of receptor classification. The current, widely accepted schema postulates the coexistence of three major classes of opioid receptors, each with multiple subtypes, and several poorly defined minor classes.

Initially, the reason such an elaborate system of receptors existed was unclear because no endogenous ligand could be identified. However, evidence for the existence of such endogenous ligands was uncovered in 1975 with the discovery of met-enkephalin and leu-enkephalin<sup>129</sup> and the subsequent identification of  $\beta$ -endorphin and dynorphin. As a group, these endogenous ligands for the opioid receptors are called *endorphins* (endogenous morphine). Each is a five-amino acid peptide cleaved from a larger precursor peptide: proenkephalin, proopioidmelanocortin, and prodynorphin, respectively. Additionally, a minor related endogenous opioid (nociceptin/orphanin FQ) and its receptor ORL are described.

All three major opioid receptors have been cloned and sequenced. Each consists of seven transmembrane segments, an amino terminus, and a carboxy terminus. Significant sequence homology exists between the transmembrane regions of opioid receptors and those of other members of the guanosine triphosphate (GTP)-binding protein (G-protein)-binding receptor superfamily. However, the extracellular and intracellular segments differ from one another. These nonhomologous segments probably represent the ligand-binding and signal transduction regions, respectively, which would be expected to differ among the three classes of receptors. The individual receptors have distinct distribution patterns within the central nervous system (CNS) and peripherally on nerve endings within various tissues, mediating unique but not entirely understood clinical effects. Until recently, researchers used varying combinations of agonists and antagonists to pharmacologically distinguish between the different receptor subtypes. However, knockout mice (ie, mutant mice lacking the genes for an individual opioid receptor) promise new insights into this complex subject.<sup>72</sup>

Because multiple opioid receptors exist and each elicits a different effect, determining the receptor to which an opioid preferentially binds should allow prediction of the clinical effect of the opioid. However, binding typically is not limited to one receptor type, and the relative affinity of an opioid for differing receptors accounts for the clinical effects (Table 36-1). Even the endogenous opioid peptides exhibit substantial crossover among the receptors.

Although the familiar pharmacologic nomenclature derived from the Greek alphabet is used throughout this textbook, the International Union of Pharmacology (IUPHAR) Committee on Receptor Nomenclature has twice recommended a nomenclature change from the original Greek symbol system to make opioid receptor names more consistent with those of other neurotransmitter systems.<sup>220</sup> In the first new schema, the receptors were denoted by their endogenous ligand (opioid peptide [OP]), with a subscript identifying their chronologic order of discovery.<sup>52</sup> The  $\delta$  receptor was renamed OP<sub>1</sub>, the  $\kappa$  receptor was renamed OP<sub>2</sub>, and the  $\mu$  receptor was renamed OP<sub>3</sub>. However, adoption of this nomenclature met with significant resistance, presumably because of problems that would arise when merging previously published work that had used the Greek symbol nomenclature. The currently proposed nomenclature suggests the addition of a single letter in front of the OP designation and the elimination of the number. In this schema, the  $\mu$  receptor is identified as MOP. In addition, the latest iteration formally recognizes the nociceptin/orphanin FQ or NOP receptor as a fourth receptor family.

TABLE 36-1 Clinical Effects Related to Opioid Receptors

1996 Conventional Name	Proposed IUPHAR Name	IUPHAR Name	Important Clinical Effects of Receptor Agonists
$\mu_1$	OP <sub>3a</sub>	MOP	Supraspinal analgesia Peripheral analgesia Sedation Euphoria Prolactin release
$\mu_2$	OP <sub>3b</sub>	MOP	Spinal analgesia Respiratory depression Physical dependence Gastrointestinal dysmotility Pruritus Bradycardia Growth hormone release
$\kappa_1$	OP <sub>2a</sub>	KOP	Spinal analgesia Miosis Diuresis
$\kappa_2$	OP <sub>2b</sub>	KOP	Psychotomimesis Dysphoria
$\kappa_3$	OP <sub>2b</sub>	KOP	Supraspinal analgesia
$\delta$	OP <sub>1</sub>	DOP	Spinal and supraspinal analgesia Modulation of $\mu$ -receptor function Inhibit release of dopamine
Nociceptin/orphanin FQ	OP <sub>4</sub>	NOP	Anxiolysis Analgesia

IUPHAR = International Union of Pharmacology Committee on Receptor Nomenclature.

### Mu Receptor ( $\mu$ , MOP, OP<sub>3</sub>)

The early identification of the  $\mu$  receptor as the morphine binding site gave this receptor its designation.<sup>135</sup> Although many exogenous xenobiotics produce supraspinal analgesia via  $\mu$  receptors, the endogenous ligand is elusive. Nearly all of the recognized endogenous opioids have some affinity for the  $\mu$  receptor, although none is selective for the receptor. Endomorphin-1 and -2 are nonpeptide ligands present in brain that may represent the endogenous ligand.

Experimentally, two subtypes ( $\mu_1$  and  $\mu_2$ ) are well defined, although currently no xenobiotics have sufficient selectivity to make this dichotomy clinically relevant. Experiments with knockout mice suggest that both subtypes derive from the same gene and that either posttranslational changes or local cellular effects subsequently differentiate them. The  $\mu_1$  subtype is responsible for supraspinal (brain) analgesia and for the euphoria sometimes engendered by these xenobiotics. Although stimulation of the  $\mu_2$  subtype produces spinal-level analgesia, it also produces respiratory depression. Predictably,  $\mu$  receptors are found in the medullary cough center, peripherally in the gastrointestinal (GI) tract, and on various sensory nerve endings, including the articular surfaces (see analgesia under Clinical Manifestations later). All of the currently available  $\mu$  agonists have some activity at the  $\mu_2$  receptor and therefore produce some degree of respiratory compromise. This localization of  $\mu$  receptors to regions of the brain involved in analgesia (periaqueductal gray, nucleus raphe magnus, medial thalamus), euphoria and reward (mesolimbic system), and respiratory function (medulla) is expected.<sup>89</sup>

### Kappa Receptor ( $\kappa$ , KOP, OP<sub>2</sub>)

Although dynorphins now are known to be the endogenous ligands for these receptors, originally, they were identified by their ability to bind ketocyclazocine and thus were labeled  $\kappa$ .<sup>135</sup> These receptors exist

predominantly in the spinal cords of higher animals, but they also are found in the antinociceptive regions of the brain and the substantia nigra. Stimulation is responsible for spinal analgesia, miosis, and diuresis (via inhibition of antidiuretic hormone release).  $\kappa$ -receptor stimulation is not associated with significant respiratory depression or constipation. The receptor currently is subclassified into three subtypes. The  $\kappa_1$  receptor subtype is responsible for spinal analgesia. This analgesia is not reversed by  $\mu$ -selective antagonists,<sup>143</sup> supporting the role of  $\kappa$  receptors as independent mediators of analgesia. Although the function of the  $\kappa_2$  receptor subtype is largely unknown, stimulation of cerebral  $\kappa_2$  receptors by xenobiotics such as pentazocine and salvinorin A produces psychotomimesis in distinction to the euphoria evoked by  $\mu$  agonists.<sup>186</sup> The  $\kappa_3$  receptor subtype is found throughout the brain and participates in supraspinal analgesia. This receptor is primarily responsible for the action of nalorphine, an agonist-antagonist opioid. Nalbuphine, another agonist-antagonist, exerts its analgesic effect via both  $\kappa_1$  and  $\kappa_3$  agonism, although both nalorphine and nalbuphine are antagonists to morphine at the  $\mu$  receptor.<sup>161</sup>

### Delta Receptor ( $\delta$ , DOP, OP<sub>2</sub>)

Little is known about  $\delta$  receptors, although the enkephalins are their endogenous ligands. Opioid peptides identified in the skin and brain of *Phyllomedusa* frogs, termed *dermorphin* and *deltorphin*, respectively, are potent agonists at the  $\delta$  receptor.  $\delta$  receptors have important roles in spinal and supraspinal analgesia (probably via a noncompetitive interaction with the  $\mu$  receptor) and in cough suppression.  $\delta$  receptors mediate dopamine release from the nigrostriatal pathway, where they modulate the motor activity associated with amphetamine.<sup>90</sup> Conversely these receptors do not modulate dopamine in the mesolimbic tracts and have only a slight behavioral reinforcing role. Subpopulations, specifically  $\delta_1$  and  $\delta_2$ , are postulated based on in vitro studies but presently are not confirmed in vivo.<sup>220</sup>

### Nociceptin/Orphanin FQ Receptor (ORL<sub>1</sub>, NOP, OP<sub>4</sub>)

The ORL<sub>1</sub> receptor was identified in 1994 based on sequence homology during screening for opioid-receptor genes with DNA libraries. It has a similar distribution pattern in the brain and uses similar transduction mechanisms as the other opioid-receptor subtypes. It binds many different opioid agonists and antagonists. Its insensitivity to antagonism by naloxone, often considered the sine qua non of opioid character, delayed its acceptance as an opioid-receptor subtype. Simultaneous identification of an endogenous ligand, called *nociceptin* by the French investigators and *orphanin FQ* by the Swiss investigators, allowed the designation OP<sub>4</sub>. A clinical role has not yet been defined, but anxiolytic and analgesic properties are described.<sup>38</sup>

## Opioid-Receptor Signal Transduction Mechanisms

Figure 36-1 illustrates opioid-receptor signal transduction mechanisms. Research on the mechanisms by which an opioid receptor induces an effect continues to produce confusing and often contradictory results. Despite the initial theory that each receptor subtype is linked to a specific transduction mechanism, individual receptor subtypes use one or more mechanisms, depending on several factors, including receptor localization (eg, presynaptic versus postsynaptic). As noted, all opioid-receptor subtypes are members of a superfamily of membrane-bound receptors that are coupled to G proteins.<sup>220</sup> The G proteins are responsible for signaling the cell that the receptor is activated and for initiating the desired cellular effects. The G proteins are generally of the pertussis toxin-sensitive, inhibitory subtype known as G<sub>i</sub> or G<sub>o</sub>, although coupling to a cholera toxin-sensitive, excitatory G<sub>s</sub> subtype is described. Regardless of subsequent effect, the G proteins consist of three conjoined subunits,  $\alpha$ ,  $\beta$ , and  $\gamma$ . The  $\beta\gamma$  subunit is liberated upon GTP binding to the subunit. When the  $\alpha$  subunit dissociates from the  $\beta\gamma$  subunit, it modifies specific effector systems, such as phospholipase C or adenylate cyclase, or directly affect a channel or transport protein. Guanidine triphosphate subsequently is hydrolyzed by a GTPase intrinsic to the  $\alpha$  subunit, which prompts its reassociation with the  $\beta\gamma$  subunit and termination of the receptor-mediated effect.

## CLINICAL MANIFESTATIONS

Table 36-2 outlines the clinical effects of opioids.

### Therapeutic Effects of Opioids

#### Analgesia and Euphoria

Although classical teaching attributes opioid analgesia solely to the brain, opioids actually modulate cerebral cortical pain perception at supraspinal, spinal, and peripheral levels. The regional distribution of the opioid receptors confirms that  $\mu$  receptors are responsible for most of the analgesic effects of morphine within the brain. They are found in highest concentration within areas of the brain classically associated with analgesia—the periaqueductal gray, nucleus raphe magnus, locus ceruleus, and medial thalamus. Microelectrode-induced electrical stimulation of these areas<sup>167</sup> or iontophoretic application of agonists into these regions results in profound analgesia.<sup>13</sup> Specifically, enhancement of inhibitory outflow from these supraspinal areas to the sensory nuclei of the spinal cord (dorsal roots) dampens nociceptive neurotransmission. Additionally, inactivation of the  $\mu$ -opioid-receptor gene in embryonic mouse cells results in offspring that are insensitive to morphine analgesia.<sup>136</sup>

Blockade of the *N*-methyl-D-aspartate (NMDA) receptor, a mediator of excitatory neurotransmission, enhances the analgesic effects of  $\mu$ -opioid agonists and reduces the development of tolerance (see Dextromethorphan later).<sup>1</sup> Even more intriguing is the finding that low-dose naloxone (0.25 mcg/kg/h) actually improves the efficacy of morphine analgesia.<sup>69</sup> Administration of higher dose, but still low-dose, naloxone (1 mcg/kg/h) obliterated its opioid-sparing effect. Although undefined, the mechanism may be related to selective inhibition of G<sub>s</sub>-coupled excitatory opioid receptors by extremely low concentrations of opioid-receptor antagonist.<sup>39,40</sup>

Xenobiotics with strong binding affinity for  $\delta$  receptors in humans, when given intrathecally, produce significantly more analgesia than morphine administered similarly. Indeed, the use of spinal and epidural opioid analgesia is predicated on the direct administration of opioid near the  $\kappa$  and  $\delta$  receptors in the spinal cord. Agonist-antagonist opioids, with agonist affinity for the  $\kappa$  receptor and antagonist effects at the  $\mu$  receptor, maintain analgesic efficacy.

Communication between the immune system and the peripheral sensory nerves occurs in areas of tissue inflammation. In response to inflammatory mediators, such as interleukin-1, immune cells locally release opioid peptides, which bind and activate peripheral opioid receptors on sensory nerve terminals.<sup>221</sup> Agonism at these receptors reduces afferent pain neurotransmission and inhibits the release of other proinflammatory compounds, such as substance P.<sup>199</sup> Intraarticular morphine (1 mg) administered to patients after arthroscopic knee surgery produces significant, long-lasting analgesia that is prevented with intraarticular naloxone.<sup>198</sup> The clinical analgesic effect of 5 mg of intraarticular morphine is equivalent to 5 mg of morphine given IM.<sup>31</sup> Intraarticular analgesia is mediated by local  $\mu$  receptors.<sup>63</sup>

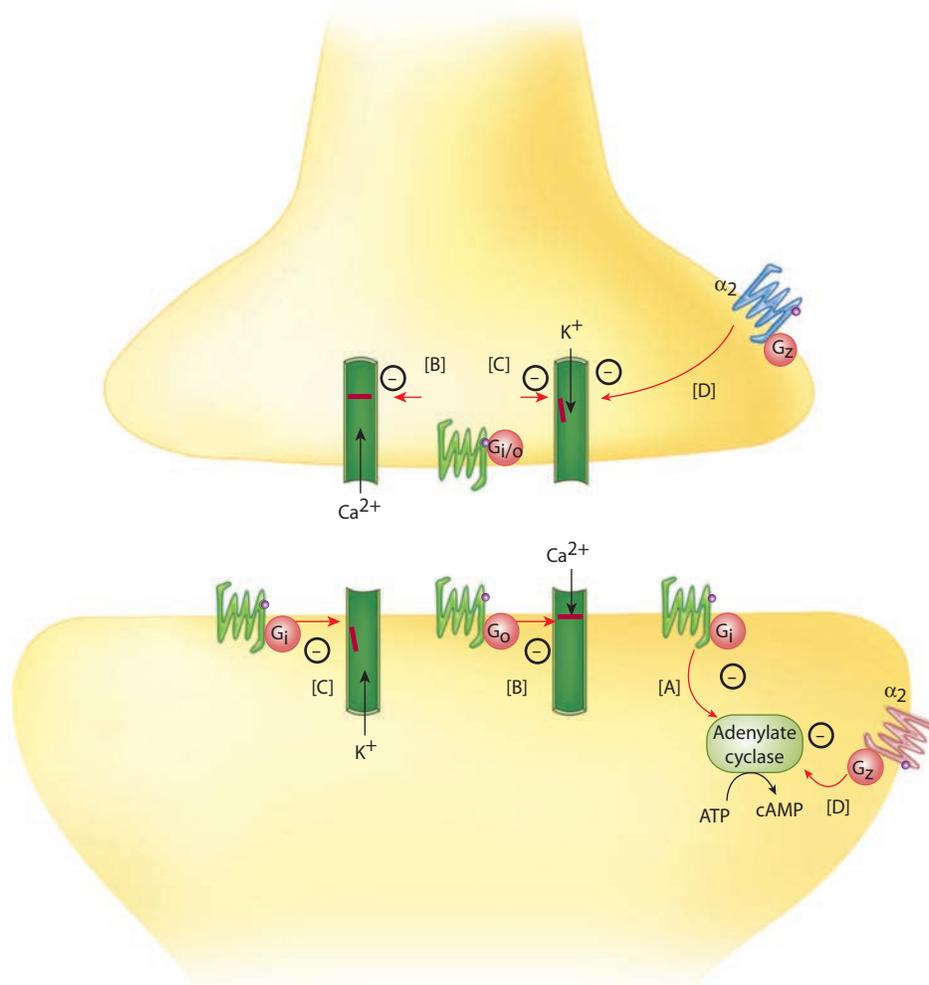

#### Antitussive

Codeine and dextromethorphan are two opioids with a suggestion of cough-suppressant activity. Cough suppression is not likely mediated via the  $\mu_1$  opioid receptor because the ability of other opioids to suppress the medullary cough centers is not correlated with their analgesic effect. Various models suggest that cough suppression occurs via agonism of the  $\mu_2$  or  $\kappa$  opioid receptors or antagonism of the  $\delta$  opioid receptor and that the  $\sigma$  or NMDA receptors also are involved.<sup>205</sup>

## Nontherapeutic and Adverse Effects of Opioids

### Abuse and Addiction

Addiction is defined as a maladaptive pattern of substance use leading to clinically significant impairment or distress. Opioid use disorder (OUD, which replaced the term opioid dependence in the *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition) is defined as a problematic pattern of opioid use leading to clinically significant impairment or distress.<sup>3</sup> Both definitions are determined by a number of diagnostic criteria, including

**FIGURE 36-1.** Opioid-receptor signal transduction mechanisms. Upon binding of an opioid agonist to an opioid receptor, the respective G protein is activated. G proteins (A) reduce the capacity of adenylate cyclase to produce cyclic adenosine monophosphate (cAMP); (B) close calcium channels that reduce the signal to release neurotransmitters; or (C) open potassium channels and hyperpolarize the cell, which indirectly reduces cell activity. Each mechanism is found coupled to each receptor subtype, depending on the location of the receptor (pre- or postsynaptic), and the neuron within the brain (see text). Note that  $\alpha_2$  receptors (D) mediate similar effects using a different G protein ( $G_z$ ).

**Adenylate cyclase/cAMP (A).** Inhibition of adenylate cyclase activity by  $G_i$  or  $G_o$  is the classic mechanism for postsynaptic signal transduction invoked by the inhibitory  $\mu$  receptors. However, this same mechanism is also identified in cells bearing either  $\delta$  or  $\kappa$  receptors. Activation of cAMP production by adenylate cyclase, with subsequent activation of protein kinase A, occurs after exposure to very-low-dose opioid agonists and produces excitatory, antianalgesic effects.<sup>44</sup>

**Calcium ( $Ca^{2+}$ ) channels (B).** Presynaptic  $\mu$  receptors inhibit norepinephrine release from the nerve terminals of cells of the rat cerebral cortex. Adenylate cyclase is not the modulator for these receptors because inhibition of norepinephrine release is not enhanced by increasing intracellular cAMP levels by various methods. Opioid-induced blockade is, however, prevented by increased intracellular calcium concentrations that are induced either by calcium ionophores, which increase membrane permeability to calcium, or by increasing the extracellular calcium concentration. This implies a role for opioid-induced closure of N-type calcium channels, presumably via a  $G_o$  protein. Reduced intraterminal concentrations of calcium prevent the neurotransmitter-laden vesicles from binding to the terminal membrane and releasing their contents. Nerve terminals containing dopamine have an analogous relationship with inhibitory  $\kappa$  receptors, as do acetylcholine-bearing neurons with opioid receptors.

**Potassium( $K^+$ ) channels (C).** Increased conductance through a potassium channel, generally mediated by  $G_i$  or  $G_o$ , results in membrane hyperpolarization with reduced neuronal excitability. Alternatively, protein kinase A-mediated reduction in membrane potassium conductance enhances neuronal excitability.

tolerance, withdrawal, and deleterious social consequences of opioid use (Table 36-3). Both addiction and OUD share a complicated relationship with, and often overlap, depression and occur in at least 5% of patient using classical definitions and may occur in as many as 40%.<sup>146</sup> This wide range is related to the difficulty of diagnosing misuse, abuse, and OUD in this patient population and inconsistent definitions of misuse and abuse between studies.<sup>30</sup>

Opioid abuse or therapeutic misuse dramatically increases addiction and overdose. Although media reports highlight the abuse of prescription opioids by sports figures and other personalities, such use had simultaneously reached epidemic levels in rural regions of the country where heroin is difficult to obtain. Many of these patients develop an opioid use disorder, particularly addiction, through initial use for therapeutic purposes and then are unable to discontinue their use.

The abuse and addiction liabilities of semisynthetic opioids, based on their subjective profile, are generally similar.<sup>222</sup> Although many users initially receive oxycodone or hydrocodone as analgesics, the majority of abusers obtain the drugs illicitly or from friends.<sup>17,83</sup> Significant efforts by regulatory agencies enhance the understanding and reduce the adverse consequences of opioid use. This includes efforts such as those at the U.S. Food and Drug Administration (FDA) through Risk Evaluation and Mitigation Strategies (REMS), individual states through prescription drug monitoring programs,<sup>158</sup> law enforcement at local and national levels, insurers and pharmacy benefit managers, and the drug manufacturers.<sup>80,216</sup> Physicians and pharmacists have been charged criminally for inappropriate prescribing and dispensing, respectively, for patients with the intent to sell or abuse these drugs.<sup>80</sup>

**TABLE 36–2 Clinical Effects of Opioids**

Cardiovascular	Bradycardia Orthostatic hypotension Peripheral vasodilation
Dermatologic	Flushing (histamine) Pruritus
Endocrinologic	Reduced antidiuretic hormone release Increased prolactin release Reduced gonadotrophin release
Gastrointestinal	Increased anal sphincter tone Increased biliary tract pressure Reduced gastric acid secretion Reduced motility (constipation)
Neurologic	Analgesia Antitussive Euphoria Sedation, coma Seizures (meperidine, propoxyphene)
Ophthalmic	Miosis
Pulmonary	Acute respiratory distress syndrome Bronchospasm (histamine) Respiratory depression

It is increasingly clear that the prescribing behavior of physicians has been a driver of the widespread misuse of opioids occurring over the past 2 decades. The reasons for such changes are complex but include a mixture of regulatory, sociological, and financial pressures. Data to support the safety and efficacy of opioids for the management of chronic pain are very limited.

**TABLE 36–3 Criteria for Opioid Use Disorder<sup>3</sup>**

A problematic pattern of opioid use leading to clinically significant impairment or distress, as manifested by at least two of the following, occurring within a 12-month period:

- Opioids are often taken in larger amounts or over a longer period than was intended.
- There is a persistent desire or unsuccessful efforts to cut down or control opioid use.
- A great deal of time is spent in activities necessary to obtain the opioid, use the opioid, or recover from its effects.
- Craving, or a strong desire or urge to use opioids.
- Recurrent opioid use resulting in a failure to fulfill major role obligations at work, school, or home.
- Continued opioid use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of opioids.
- Important social, occupational, or recreational activities are given up or reduced because of opioid use.
- Recurrent opioid use in situations in which it is physically hazardous.
- Continued opioid use despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance.
- Tolerance, as defined by either of the following:
  - A need for markedly increased amounts of opioids to achieve intoxication or desired effect
  - A markedly diminished effect with continued use of the same amount of an opioid

**Note:** This criterion is not considered to be met for those taking opioids solely under appropriate medical supervision.

- Withdrawal, as manifested by either of the following:
  - The characteristic opioid withdrawal syndrome (refer to Criteria A and B of the criteria set for opioid withdrawal).
  - Opioids (or a closely related substance) are taken to relieve or avoid withdrawal symptoms.

Almost all studies of the long-term use of opioids study periods of use measured in weeks, although in clinical practice patients receive opioid therapy for years. Despite a lack of data, many physicians prescribe opioids for the treatment of chronic nonterminal pain, which results in high rates of OUD. In response to this, the Centers for Disease Control and Prevention has issued guidelines for treatment of chronic pain that encourage alternative medications and therapies initially, discussion of risks of addiction with the patient, use of short-acting opioids, periodic pain and function reassessment, screening for use disorder and diversion, and dispensing of naloxone to patients at risk for overdose.<sup>55</sup>

There is an association between opioids prescribed for acute pain and the development of long-term opioid use.<sup>10,24,33,97,184</sup> Although long-term use reflects ongoing pain, hyperalgesia, dependence, or addiction, the lack of data to support continued beneficial effect compared with harm raises concern. One study suggests the intensity of a physician's opioid prescribing in the emergency department (ED) setting is positively associated with the probability that a patient will become a long-term opioid user over the subsequent 12 months.<sup>10</sup> Another concluded that the likelihood of chronic opioid use after receipt of an opioid prescription increases most sharply in the first days of therapy, particularly after 5 days or 1 month of opioids prescribed.<sup>173</sup> This association was also noted in patients prescribed opioids for postoperative pain with 6% of opioid-naïve patients undergoing both minor and major surgical procedures continuing to use opioids after 90 days after surgery.<sup>21</sup> These studies support the theory that OUD often begins through an initial exposure to a physician-prescribed opioid and that some individuals are “programmed” to have greater reward from and more difficulty discontinuing the use of opioids. The risk of long-term opioid use should be factored into the risk–benefit analysis when considering even short-term opioid therapy.

The pleasurable effects of many xenobiotics used by humans are mediated by the release of dopamine in the mesolimbic system. This final common pathway is shared by all opioids that activate the  $\mu$ - $\delta$  receptor complex in the ventral tegmental area, which, in turn, indirectly promotes dopamine release in the mesolimbic region. Opioids also have a direct reinforcing effect on their self-administration through  $\mu$  receptors within the mesolimbic system.<sup>88</sup>

The sense of well-being and euphoria associated with strenuous exercise appears to be mediated by endogenous opioid peptides and  $\mu$  receptors. This so-called “runner's high” is reversible with naloxone.<sup>183</sup> Naloxone reverses euphoria or even produces dysphoria in nonexercising, highly trained athletes.<sup>45,104</sup> Even in normal individuals, high-dose naloxone (4 mg/kg) produces dysphoria.<sup>34</sup>

Exogenous opioids do not induce uniform psychological effects. Some of the exogenous opioids, particularly those that are highly lipophilic such as heroin, are euphorogenic, but morphine is largely devoid of such pleasurable effects.<sup>191</sup> However, morphine administration results in analgesia, anxiolysis, and sedation. Although heroin has little affinity for opioid receptors and must be deacetylated to morphine for effect, these seemingly incompatible properties likely are related to pharmacokinetic differences in blood–brain barrier penetration.<sup>155</sup> Chronic users note that fentanyl produces effects that are subjectively similar to those of heroin.<sup>125</sup> This effect offers an explanation of the higher prevalence of fentanyl, as opposed to other accessible opioids, as an abused drug by anesthesiologists,<sup>15,224</sup> as well as the burgeoning appearance of fentanyl and its analogs as a heroin substitute in the community.<sup>174</sup> In distinction, certain opioids, such as pentazocine, produce dysphoria, an effect that is related to their affinity for  $\kappa$  or  $\sigma$  receptors.

### Hyperalgesia

Chronic use of opioid analgesics is associated with hyperalgesia, or a heightened sensitivity to pain.<sup>35</sup> This effect was described decades ago in methadone-maintained patients<sup>92</sup> and is again recognized because of the increased use of chronic opioid therapy for pain.<sup>22</sup> Clinically, hyperalgesia manifests as the need for increasing doses of analgesics to mitigate pain, and it occurs as part of or is confused with the development of tolerance. Conceptually, as opposed to tolerance, which is the progressive failure of a drug to adequately

treat the pain, hyperalgesia is the intrinsic increase in the degree of pain in response to an analgesic. The exact mechanisms for the development of opioid-induced hyperalgesia are still not clearly understood. The treatment for hyperalgesia should include weaning from opioids and providing alternative modalities of pain relief.

### Miosis

Stimulation of parasympathetic pupilloconstrictor neurons in the Edinger-Westphal nucleus of the oculomotor nerve by morphine produces miosis. Additionally, morphine increases firing of pupilloconstrictor neurons to light,<sup>127</sup> which increases the sensitivity of the light reflex through central reinforcement.<sup>228</sup> Although sectioning of the optic nerve blunts morphine-induced miosis, the consensual reflex in the denervated eye is enhanced by morphine. Because opioids classically mediate inhibitory neurotransmission, hyperpolarization of sympathetic nerves or of inhibitory neurons to the parasympathetic neurons (removal of inhibition) ultimately mediate the classic “pinpoint pupil” associated with opioid use.

Not all patients using opioids present with miosis. Meperidine has a lesser miotic effect than other conventional opioids, and propoxyphene use does not result in miosis.<sup>74</sup> Use of opioids with predominantly  $\kappa$ -agonist effects, such as pentazocine, may not result in miosis. Mydriasis occurs in some severely poisoned patients secondary to hypoxic brain injury. Additionally, concomitant drug use or the presence of adulterants will potentially alter pupillary findings. For example, the combination of heroin and cocaine (“speedball”) produces virtually any size pupil, depending on the relative contribution by each xenobiotic. Similarly, patients ingesting diphenoxylate and atropine (Lomotil) or those using scopolamine-adulterated heroin typically develop mydriasis.<sup>84</sup>

### Gastrointestinal

Historically, the morphine analog apomorphine was used as a rapidly acting emetic whose clinical use was limited by its tendency to depress the patient’s level of consciousness. Emesis induced by apomorphine is mediated through agonism at  $D_2$  receptor subtypes within the chemoreceptor trigger zone of the medulla. Many opioids, particularly morphine, produce significant nausea and vomiting when used therapeutically.<sup>29</sup> Whether these effects are inhibited by naloxone is not clearly established, but they likely are not.

Although loperamide is widely used therapeutically to manage diarrhea, opioid-induced constipation is frequently a bothersome side effect of both medical and nonmedical use of opioids. Constipation, mediated by  $\mu_2$  receptors within the smooth muscle of the intestinal wall,<sup>96</sup> is ameliorated by oral naloxone. Provided the first-pass hepatic glucuronidative capacity is not exceeded (at doses of ~6 mg), enteral naloxone is poorly bioavailable and thus induces few, if any, opioid withdrawal symptoms.<sup>142</sup> Methylnaltrexone and naloxegol are bioavailable, “peripherally restricted” opioids that do not cross the blood–brain barrier except in overdose. Although they antagonize the effects of opioids on the GI tract opioid receptor,<sup>17,200</sup> the opioid withdrawal syndrome only occurs rarely (Antidotes in Depth: A4).<sup>141</sup> Lubiprostone is a bicyclic fatty acid derived from prostaglandin  $E_1$  ( $PGE_1$ ) metabolite that increases fluid secretion in the GI tract. Lubiprostone, methylnaltrexone and naloxegol, are approved by the FDA for treatment of opioid-induced constipation in patients with noncancer pain.<sup>151</sup>

### Movement Disorders

Patients infrequently experience acute muscular rigidity with rapid IV injection of certain high-potency opioids, especially fentanyl and its derivatives.<sup>203</sup> This condition is particularly prominent during induction of anesthesia and in neonates.<sup>65</sup> The rigidity primarily involves the trunk and impairs chest wall movement sufficiently to exacerbate hypoventilation. Chest wall rigidity contributes to the lethality associated with epidemics of fentanyl-adulterated or fentanyl-substituted heroin. Although the mechanism of muscle rigidity is unclear, it is likely related to blockade of dopamine receptors in the basal ganglia. Other postulated mechanisms include  $\gamma$ -aminobutyric acid (GABA) antagonism and NMDA agonism. Opioid antagonists generally are therapeutic but do produce adverse hemodynamic effects, withdrawal phenomena,

or uncontrollable pain, depending on the situation.<sup>65</sup> Also, rapid escalation of methadone doses can result in the development of choreoathetoid movements.<sup>14</sup>

### Endocrine

Chronic use of opioids is associated with hypofunction of the hypothalamic–pituitary–gonadal axis by binding to hypothalamic opioid receptors and decreasing the secretion of gonadotropin-releasing hormone.<sup>18</sup> Clinical findings include reduced libido, erectile dysfunction, hot flashes, and depression, as well as anemia, hair loss, and osteopenia.<sup>181</sup> Additionally, both men and women may have infertility. Furthermore, opioids reduce the release of corticotropin releasing hormone from the hypothalamus, leading to a reduction of adrenocorticotropic hormone (ACTH) release from the pituitary. This reduces adrenal function, and clinically relevant adrenal insufficiency occurs.<sup>18</sup> In addition, prolactin concentrations commonly rise and lead to gynecomastia.<sup>166</sup>

### Hearing Loss

Although relatively rare, rapidly progressive sensorineural hearing loss occurs in heavy users of opioid analgesics.<sup>93</sup> This effect is associated with most opioids, including hydrocodone, oxycodone, and methadone. The mechanism remains unknown, and suggested causes include ischemia, genetic predisposition, direct cochlear toxicity, and hypersensitization that manifests upon reexposure after a period of opioid abstinence.<sup>185</sup> Most patients recover after abstinence, although some are only successfully treated with cochlear implants.<sup>93</sup>

### Toxic and Life-Threatening Effects of Opioids

When used appropriately for medical purposes, opioids are generally safe and effective. However, excessive use in terms of dose or duration results in adverse consequences. Most adverse or toxic effects are predictable based on opioid pharmacodynamics (eg, respiratory depression), although several opioids produce unexpected “nonopioid” responses. Determining that a patient has opioid toxicity is generally more important than identifying the specific opioid involved. Notwithstanding some minor variations, patients poisoned by all available opioids predictably develop a constellation of signs, known as the *opioid toxic syndrome* (Chap. 3). Mental status depression, hypoventilation, miosis, and hypoperistalsis are the classic elements.

### Respiratory Depression

Experimental use of various opioid agonists and antagonists consistently implicates  $\mu_2$  receptors in the respiratory depressant effects of morphine.<sup>186</sup> Through these receptors, opioid agonists reduce ventilation by diminishing the sensitivity of the medullary chemoreceptors to hypercapnea.<sup>227</sup> In addition to loss of hypercarbic stimulation, opioids depress the ventilatory response to hypoxia.<sup>126</sup> The combined loss of hypercarbic and hypoxic drive leaves virtually no stimulus to breathe, and apnea ensues. Equianalgesic doses of the available opioid agonists produce approximately the same degree of respiratory depression.<sup>59,187</sup> This is supported by experiments in MOR-deficient knockout mice.<sup>171</sup> Patients chronically exposed to opioid agonists, such as those on methadone maintenance, experience chronic hypoventilation, although tolerance to loss of hypercarbic drive develops over several months.<sup>133</sup> However, such patients never develop complete tolerance to loss of hypoxic stimulation.<sup>175</sup> Although some opioids, notably the agonist–antagonists and partial agonists, typically demonstrate a ceiling effect on respiratory depression, such sparing generally occurs at the expense of analgesic potency and is incomplete. The different activity profiles likely are a result of differential activities at the opioid-receptor subtypes. That is, agonist–antagonists are predominantly  $\kappa$ -receptor agonists and either partial agonists or antagonists at  $\mu$  sites, and partial agonists produce only limited agonism at the  $\mu$  opioid receptor.

It is important to recognize that ventilatory depression results from a reduction in either respiratory rate or tidal volume. Thus, although respiratory rate is more accessible for clinical measurement, it is not an ideal index of ventilatory depression. In fact, morphine-induced respiratory depression

in humans initially is related more closely to changes in tidal volume.<sup>187</sup> Large doses of opioids also result in a reduction of respiratory rate.

Respiratory depression is the primary cause of death after therapeutic use or overdose. Common reasons for iatrogenic overdose include a failure to appreciate the importance of genetic polymorphisms (see Codeine), sleep apnea, drug interactions, active metabolites (see Morphine), or the complicated pharmacokinetics of the long-acting and extended-release opioids.<sup>153</sup> In a population-based cohort study, higher doses of opioid analgesics were associated with increased overdose risk, and much of the risk at higher doses appears to be associated with co-prescribed benzodiazepines.<sup>51</sup>

### Pulmonary and Acute Respiratory Distress Syndrome

Reports linking opioids with the development of acute pulmonary abnormalities became common in the 1960s, although the first report was made by William Osler in 1880.<sup>156</sup> Almost all opioids are implicated, and opioid-related acute respiratory distress syndrome (ARDS) is reported in diverse clinical situations. Typically, the patient regains normal ventilation after a period of profound respiratory depression, either spontaneously or after the administration of an opioid antagonist, and over the subsequent several minutes to hours develops hypoxemia and crackles on auscultation. Occasionally, classic frothy, pink sputum is present in the patient's airway or in the endotracheal tube of an intubated patient. Decedents often have what is described as a "foam cone" of frothy material extruding from their nose and mouth.<sup>53</sup> Acute lung injury (currently known as ARDS) was described in 71 (48%) of 149 hospitalized heroin overdose patients in New York City,<sup>57</sup> although the current incidence in this patient group appears to be lower. The outcome generally depends on comorbid conditions and the delay to adequate care. Acute respiratory distress syndrome occurs as an isolated finding or in the setting of multisystem organ damage.

No single mechanism can be consistently invoked in the genesis of opioid-associated ARDS. However, several prominent theories are each well supported by experimental data. Rather than causing ARDS, naloxone sometimes unmasks the clinical findings of ARDS that were not apparent because an adequate physical examination could not be performed until breathing was restored. Other evidentiary cases involve surgical patients given naloxone postoperatively who subsequently awoke with clinical signs of ARDS. In addition to presumably receiving the naloxone for ventilatory compromise or hypoxia, these patients received multiple intraoperative medications, further obscuring the etiology.<sup>163</sup> Although naloxone ordinarily is safe when appropriately administered to nonopioid-tolerant individuals, the production of acute opioid withdrawal is often linked with "naloxone-induced" ARDS. In this situation, as in patients with "neurogenic" pulmonary edema, massive sympathetic discharge from the CNS occurs and produces "cardiogenic" pulmonary edema from the acute effects of catecholamines on the myocardium. In a series of experiments, precipitated opioid withdrawal in nontolerant dogs was associated with dramatic cardiovascular changes and abrupt elevation of serum catecholamine concentrations.<sup>144,145</sup> The effects were more dramatic in dogs with an elevated PCO<sub>2</sub> than in those with a normal or low PCO<sub>2</sub>, suggesting the potential benefit of adequately ventilating patients before opioid reversal with naloxone. Similar effects occur in humans undergoing ultrarapid opioid detoxification (UROD; see later).<sup>62</sup>

Even though abrupt precipitation of withdrawal by naloxone contributes to the development of ARDS, it cannot be the sole etiology. Alveolar filling was noted in 50% to 90% of the postmortem examinations performed on heroin overdose patients, many of whom were declared dead before arrival to medical care and thus never received naloxone.<sup>87,91</sup> In addition, neither naloxone nor any other opioid antagonist was available when Osler and others described their initial cases of pulmonary edema, now termed ARDS. Alternatively, the negative intrathoracic pressure generated by attempted inspiration against a closed glottis creates a large pressure gradient across the alveolar membrane and draws fluid into the alveolar space. This mechanical effect, also known as the *Müller maneuver*, was invoked as the cause of ventilator-associated ARDS before the advent of demand ventilators and neuromuscular blockers. In the setting of opioid overdose, glottic laxity prevents

adequate air entry during inspiration. This effect is especially prominent at the time of naloxone administration, in which case breathing will reinstitute before the return of adequate upper airway function.

### Cardiovascular

Arteriolar and venous dilation secondary to opioid use results in a mild reduction in blood pressure.<sup>225</sup> This effect is clinically useful for treatment of patients with acute cardiogenic pulmonary edema. However, although patients typically do not develop significant supine hypotension, orthostatic changes in blood pressure and pulse routinely occur. Bradycardia is unusual, although a reduction in heart rate is common as a result of the associated reduction in CNS stimulation. Opioid-induced hypotension is mediated by histamine release, although induction of histamine release does not appear to occur through interaction with an opioid receptor. It is related to the nonspecific ability of certain xenobiotics to activate mast cell G proteins<sup>9</sup> and induce degranulation of histamine-containing vesicles. Many opioids share this ability, which is conferred by the presence of a positive charge on a hydrophobic molecule. Accordingly, not all opioids are equivalent in their ability to release histamine.<sup>9</sup> After administration of one of four different opioids to 60 healthy patients, meperidine produced the most hypotension and elevation of serum histamine concentrations; fentanyl produced the least.<sup>67</sup> The combination of H<sub>1</sub> and H<sub>2</sub> antagonists is effective in ameliorating the hemodynamic effects of opioids in humans.<sup>160</sup>

Adulterants and coingestants often produce significant cardiovascular toxicity. For example, quinine-adulterated heroin is associated with dysrhythmias. Cocaine, surreptitiously added to heroin, often causes significant myocardial ischemia or infarction. Similarly, concern that naloxone administration may "unmask" cocaine toxicity in patients simultaneously using cocaine and heroin ("speedball") probably is warranted but rarely is demonstrated unequivocally.

Certain opioids at therapeutic concentrations, particularly methadone, interfere with normal cardiac repolarization and produce QT interval prolongation, an effect that predisposes to the development of torsade de pointes.<sup>122,152</sup> Many patients who receive methadone experience minor increases in QT interval, although a small percentage of patients experience a substantial increase to more than 500 ms.<sup>122</sup> Methadone prolongs the QT interval via interactions with cardiac K<sup>+</sup> channels.<sup>113</sup>

### Seizures

Seizures are a rare complication of therapeutic use of most opioids. In patients with acute opioid overdose, seizures most likely are caused by hypoxia. However, experimental models demonstrate a proconvulsant effect of morphine that potentiates the convulsant effect of other xenobiotics.<sup>234</sup> These effects are variably inhibited by naloxone, suggesting the involvement of a mechanism other than opioid receptor binding. In humans, morphine-induced seizures are reported in neonates and are reversed by naloxone,<sup>42</sup> although opioid withdrawal seizures in neonates are more common.

Seizures should be anticipated in patients with meperidine, tapentadol, or tramadol toxicity. The ability of fentanyl and its analogs to induce seizures is controversial. They are used to activate epileptiform activity for localization in patients with temporal lobe epilepsy who are undergoing surgical exploration.<sup>140</sup> However, electroencephalography performed on patients undergoing fentanyl anesthesia did not identify seizure activity even though the clinical assessment suggested that approximately one-third of them had seizures.<sup>192</sup> The rigidity and myoclonus associated with fentanyl use are frequently misinterpreted as a seizure.

## SPECIFIC OPIOIDS

The vast majority of opioid-poisoned patients follow predictable clinical courses that can be anticipated based on an understanding of opioid receptor pharmacology. However, certain opioids taken in overdose produce atypical manifestations. Therefore, careful clinical assessment and institution of empiric therapy usually are necessary to ensure proper management (Table 36–4).

TABLE 36–4 Classification, Potency, and Characteristics of Opioids and Opioid Antagonists

Opioid	Type <sup>a</sup>	Derivation	Analgesic Dose (mg) (via route, equivalent to 10 mg of morphine SC <sup>b</sup> )	Comments <sup>a,c</sup>
Buprenorphine	PA	Semisynthetic	0.3 IM	Medication assisted therapy requires 6–16 mg/day (contains naloxone)
Butorphanol	AA	Semisynthetic	2 IM	
Codeine	Ag	Natural	60 PO	Often combined with acetaminophen; requires demethylation to morphine by CYP2D6
Dextromethorphan	NEC	Semisynthetic	Nonanalgesic (10–30 PO)	Antitussive; psychotomimetic via NMDA receptor
Diphenoxylate	Ag	Synthetic	Nonanalgesic (2.5 PO)	Antidiarrheal, combined with atropine; difenoxin is potent metabolite
Fentanyl	Ag	Synthetic	0.75 IM	Very short acting (<1 h)
Fentanyl analogs	Ag	Synthetic	Variable, but high potency	Examples include furanyl fentanyl and carfentanil
Heroin	Ag	Semisynthetic	5 SC	Used therapeutically in some countries; Schedule I medication in the United States
Hydrocodone	Ag	Semisynthetic	1IM, 2PO	
Hydromorphone	Ag	Semisynthetic	1.3 SC	
Levorphanol	Ag	Semisynthetic	2 SC or IM	
Loperamide	Ag	Synthetic	Nonanalgesic (2 PO)	Antidiarrheal; abuse; P-glycoprotein substrate
Meperidine	Ag	Synthetic	75 SC or IM	Seizures caused by metabolite accumulation
Methadone	Ag	Synthetic	10 IM	Very long acting (24 h)
Methylnaltrexone	Ant	Synthetic	Nonanalgesic (8–12 SC); 15PO	Peripherally acting antagonist; reverses opioid-induced constipation
Morphine	Ag	Natural	10 SC or IM	
Naglexol	Ant	Synthetic	Nonanalgesic (25 PO)	Peripherally acting antagonist; reverses opioid constipation; P-glycoprotein substrate
Nalbuphine	AA	Semisynthetic	10 IM	
Naloxone	Ant	Semisynthetic	Nonanalgesic (0.04 IV or IM)	Short-acting antagonist (0.5 h)
Naltrexone	Ant	Semisynthetic	Nonanalgesic (50 PO)	Very long-acting antagonist (24 h)
Oxycodone	Ag	Semisynthetic	5 PO	Often combined with acetaminophen; OxyContin is extended release
Oxymorphone	Ag	Semisynthetic	1 SC	
Paregoric	Ag	Natural	25 mL PO	Tincture of opium (0.4 mg/mL)
Pentazocine	AA	Semisynthetic	50 SC	Psychotomimetic via receptor
Tapentadol	Ag	Synthetic	50 PO	Seizures
Tramadol	Ag	Synthetic	50–100 PO	Seizures possible with therapeutic dosing

<sup>a</sup>Agonist–antagonists, partial agonists, and antagonists may cause withdrawal in tolerant individuals. <sup>b</sup>Typical dose (mg) for xenobiotics without analgesic effects is given in parentheses. <sup>c</sup>Duration of therapeutic clinical effect 3–6 h unless noted; likely to be exaggerated in overdose.

AA = agonist antagonist ( $\kappa$  agonist,  $\mu$  antagonist); Ag = full agonist ( $\mu_1$ ,  $\mu_2$ ,  $\kappa$ ); Ant = full antagonist ( $\mu_1$ ,  $\mu_2$ ,  $\kappa$  antagonist); IM = intramuscular; IV = intravenous; NEC = not easily classified; NMDA = *N*-methyl-D-aspartate; PA = partial agonist ( $\mu_1$ ,  $\mu_2$  agonist,  $\kappa$  antagonist); PO = oral; SC = subcutaneous.

## Morphine and Codeine

Morphine is poorly bioavailable by the oral route because of extensive first-pass elimination. Morphine is hepatically metabolized primarily to morphine-3-glucuronide (M3G) and, to a lesser extent, to morphine-6-glucuronide (M6G), both of which are cleared renally. Unlike M3G, which is essentially devoid of activity, M6G has  $\mu$ -agonist effects in the CNS.<sup>25</sup> However, M6G administered peripherally is significantly less potent as an analgesic than is morphine.<sup>188</sup> The polar glucuronide has a limited ability to cross the blood–brain barrier, and P-glycoprotein is capable of expelling M6G from the cerebrospinal fluid. The relative potency of morphine and M6G in the brain is incompletely defined, but the metabolite is generally considered to be several-fold more potent.<sup>5</sup>

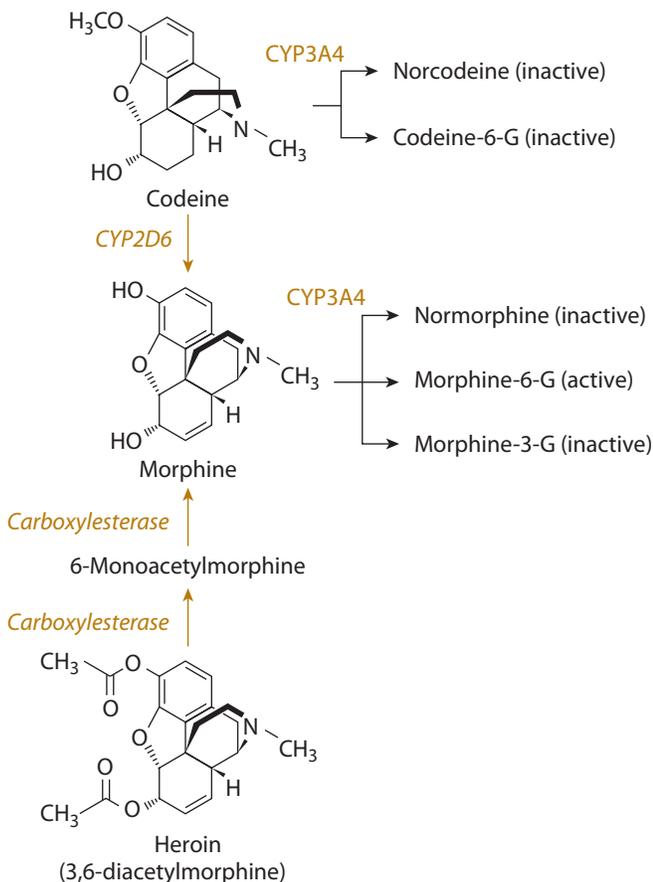

This explains why caution is required when administering morphine to patients with kidney failure.

Codeine itself is an inactive opioid agonist, and it requires metabolic activation by *O*-demethylation to morphine by CYP2D6 (Fig. 36–2). This typically represents a minor metabolic pathway for codeine metabolism. *N*-demethylation into norcodeine by CYP3A4 and glucuronidation is more prevalent but produces inactive metabolites. The need for conversion to morphine explains why approximately 5% to 7% of white patients, who are devoid of CYP2D6 function, cannot derive an analgesic response from codeine.<sup>101,124</sup> An increasingly recognized phenomenon is that ultrarapid CYP2D6 metabolizers produce unexpectedly large amounts of morphine from codeine, with resulting life-threatening opioid toxicity.<sup>70,164</sup>

## Heroin

Heroin is 3,6-diacetylmorphine, and its exogenous synthesis is performed relatively easily from morphine and acetic anhydride. Heroin has a lower affinity for the  $\mu$  opioid receptor than does morphine, but it is rapidly metabolized by plasma cholinesterase and liver human carboxylesterase (hCE)-2 to 6-monoacetylmorphine, a more potent  $\mu$  agonist than morphine (Fig. 36–2).<sup>182</sup> Users claim that heroin has an enhanced euphorogenic effect, often described as a “rush.” This effect likely is related to the enhanced blood–brain barrier penetration that results from the additional organic functional groups of heroin and its subsequent metabolic activation within the CNS. Interestingly, cocaine and heroin compete for metabolism by plasma cholinesterase and the two human liver carboxylesterases hCE-1 and hCE-2. This interaction has pharmacokinetic and clinical consequences in patients who “speedball.”<sup>12,110</sup>

Heroin is available in two distinct chemical forms: base or salt. The hydrochloride salt form typically is a white or beige powder and was the common form of heroin available before the 1980s.<sup>108</sup> Its high water solubility allows simple IV administration. Heroin base, on the other hand, now is the more prevalent form of heroin in most regions of the world. It often is brown or black. “Black tar heroin” is one appellation referring to an impure South American import available in the United States. Because heroin base is virtually insoluble in water, IV administration requires either heating the heroin until it liquefies or mixing it with acid. Alternatively, because the alkaloidal form is heat stable, smoking or “chasing the dragon” is sometimes used as an alternative route. Street-level heroin base frequently contains caffeine or barbiturates,<sup>108</sup> which improves the sublimation of heroin and enhances the yield.<sup>99</sup>

**FIGURE 36–2.** Opiate and opioid metabolism. Codeine is *O*-methylated to morphine, *N*-demethylated to norcodeine, or glucuronidated to codeine-6-glucuronide (codeine-6-G). Morphine is *N*-demethylated to normorphine or glucuronidated to either morphine-3-glucuronide (morphine-3-G) or morphine-6-glucuronide (morphine-6-G). Heroin is converted to morphine by a two-step process involving plasma cholinesterase and two human liver carboxylesterases known as human carboxylesterase-1 and human carboxylesterase-2.

Widespread IV use has led to many significant direct and indirect medical complications, particularly hepatitis, endocarditis and AIDS, in addition to fatal and nonfatal overdose. Nearly two-thirds of all long-term (longer than 10 years) heroin users in Australia have overdosed on heroin.<sup>47</sup> Among recent-onset heroin users, 23% have overdosed on heroin, and 48% were present when someone else overdosed.<sup>79</sup> Risk factors for fatality after heroin use include the concomitant use of other drugs of abuse, particularly ethanol; recent abstinence, as occurs during incarceration, during which time opioid tolerance has waned;<sup>180</sup> and perhaps unanticipated fluctuations in the concentration or purity of the available heroin.<sup>46,169</sup>

Because most overdoses occur in experienced heroin users and about half occur in the company of other users,<sup>47</sup> the prescribing of naloxone to heroin users for bystander administration is an increasingly available form of harm reduction. Naloxone access for opioid overdose rescue is one of the US Department of Health and Human Services’ three priority areas for responding to the opioid crisis,<sup>208</sup> and access to community program-based naloxone distribution for potential overdose bystanders exists in at least 30 states since initial efforts in the late 1990s.<sup>230</sup> Bystanders include people who also use opioids or a friend or family member of a person at risk for overdose. Most community-based naloxone distribution programs provide education on overdose prevention by instructing potential rescuers to recognize known signs of overdose. Naloxone can also be administered by a first responder, such as police or firefighter.

Much of the data proffered to support this practice look at the proportion of those trained that use naloxone within a given time period<sup>137</sup> (maximum potential lives saved) rather than outcomes of overdosed patients with and without bystander intervention. It is possible that many of the patients who receive naloxone did not need the antidote for survival, but that does not mitigate the potential benefit of bystander administration. However, although community-based naloxone distribution programs have gained much momentum in recent years, the cost- and risk-benefit of this practice still remain inadequately understood.<sup>26</sup> For example, despite the acknowledged injection skills of the other users in the “shooting gallery,” their judgment likely is impaired. In one survey, summoning an ambulance was the initial response to overdose of a companion in only 14% of cases.<sup>48</sup> A survey of heroin users suggested they lacked an understanding of the pharmacology of naloxone, which might lead to inappropriate behaviors regarding both heroin and naloxone administration.<sup>179</sup> The Peltzman effect describes the beneficial effect of a public health intervention is offset by other risk-taking behavior, in this case perhaps using larger doses of opioid (Antidotes in Depth: A4 and Special Considerations: SC6).<sup>162</sup>

Recognition of the efficacy of intranasal heroin administration, or snorting, has fostered a resurgence of heroin use, particularly in suburban communities. The reason for this trend is likely related to falling supplies of the prescription opioids. People already misusing or addicted to prescription opioids are acquiring heroin, which is more available and less expensive, as a substitute, but heroin carries distinct risks.<sup>32</sup> It is also widely suggested that the increasing purity of the available heroin renders it more suitable for intranasal use. However, because intranasal administration of a mixture of 3% heroin in lactose produces clinical and pharmacokinetic effects similar to an equivalent dose administered IM, the relationship between heroin purity and price and intranasal use is uncertain.<sup>36,172</sup> Needle avoidance certainly is important, reducing the risk of transmission of various infectious diseases, including HIV. Heroin smoking has also increased in popularity in the United States, albeit not to the extent in other countries (see “Chasing the Dragon” later). In addition, users of prescription drugs such as oxycodone or hydrocodone often change to heroin as the supplies of prescription opioids tighten and prices rise.<sup>106</sup> As such, a component of the recent increase in heroin overdose deaths is likely due to the lack of availability and increased cost of prescription opioids.<sup>173</sup> Celebrities and blogs have popularized intranasal heroin use as a “safe” alternative to IV use. Although intranasal use is less dangerous than IV use from an infectious disease perspective, it is clear that both fatal overdose and drug dependency remain common.<sup>209</sup>

### Adulterants, Contaminants, and “Heroin” Substitutes

Retail (street-level) heroin almost always contains adulterants or contaminants, which are differentiated by the intent of their admixture. Adulterants typically are benign because inflicting harm on the consumer with their addition would be economically and socially unwise, although adulterants occasionally are responsible for epidemic death. Most heroin overdose decedents do not have serum morphine concentrations that substantially differ from those of living users, raising the possibility that the individual death is related to an adulterant or contaminant.<sup>49</sup>

Historically, alkaloids, such as quinine and strychnine, were used to adulterate heroin to mimic the bitter taste of heroin and to mislead clients. Quinine was initially added in a poorly reasoned attempt to quell an epidemic of malaria among IV heroin users in New York City in the 1930s.<sup>87</sup> That quinine adulteration was common is demonstrated by the common practice of urine screening for quinine as a surrogate marker for heroin use. However, quinine was implicated as a causative factor in an epidemic of heroin-related deaths in the District of Columbia between 1979 and 1982. Toxicity attributed to quinine in heroin users includes cardiac dysrhythmias (Chap. 55), amblyopia, and thrombocytopenia. Quinine adulteration currently is much less common than it was in the past. Trend analysis of illicit wholesale and street-level heroin adulteration over a 12-year period in Denmark revealed that although caffeine, acetaminophen, methaqualone, and phenobarbital all were prevalent adulterants, quinine was not found.<sup>108</sup> Analysis of US heroin samples revealed the presence of procaine, quinine, caffeine, acetaminophen, mannitol lactose, and diphenhydramine in significant quantities.<sup>20</sup> Many other adulterants or contaminants, including thallium, lead, sugars, chalk, brick dust, powdered milk, starch, cocaine, and amphetamines, have been reported.<sup>2</sup>

Poisoning by scopolamine-tainted heroin reached epidemic levels in the northeastern United States in 1995.<sup>84</sup> Exposed patients presented with acute psychosis and anticholinergic signs. Several patients were treated with physostigmine, with excellent therapeutic results.

Clenbuterol, a  $\beta_2$ -adrenergic agonist with a rapid onset and long duration of action, was found to be a contaminant in street heroin in the Eastern United States in early 2005. Users rapidly developed nausea, chest pain, palpitations, dyspnea, and tremor. Physical findings included significant tachycardia and hypotension, as well as hyperglycemia, hypokalemia, and increased lactate concentrations on laboratory evaluation, and a few fatalities occurred.<sup>95,233</sup> The initial patients were thought to be cyanide poisoned. Several patients were treated with  $\beta$ -adrenergic antagonists or calcium channel blockers and potassium supplementation with good results.

### “Chasing the Dragon”

Intravenous injection and insufflation are the preferred means of heroin self-administration in the United States. In other countries, including the Netherlands, the United Kingdom, and Spain, a prevalent method is “chasing the dragon” whereby users inhale the white pyrolysate that is generated by heating heroin base on aluminum foil using a handheld flame. This means of administration produces heroin pharmacokinetics similar to those observed after IV administration.<sup>89</sup> Chasing the dragon is not a new phenomenon, but it has gained acceptance among both IV heroin users and drug-naïve individuals. The reasons for this shift are diverse but probably are related to the avoidance of injection drug use with its concomitant infectious risks.

In the early 1980s, a group of individuals who smoked heroin in the Netherlands developed spongiform leukoencephalopathy. Since the initial report, similar cases were reported in other parts of Europe and in the United States.<sup>123,131</sup> Initial findings typically occur within 2 weeks of use and include bradykinesia, ataxia, abulia (inability to make decisions), and speech abnormalities. Of those whose symptoms did not progress, about half recovered. However, in others, progression to spastic paraparesis, pseudobulbar palsy, or hypotonia occurred over several weeks. Approximately half of individuals in this group do not develop further deficits or improve, but death occurs in approximately 25% of reported cases. The prominent symmetric cerebellar and cerebral white matter destruction noted on brain computed tomography and magnetic resonance imaging corresponds to that noted at necropsy.<sup>116,154</sup>

The syndrome has the characteristics of a point-source toxic exposure, but no culpable contaminants were identified, although aluminum concentrations were frequently elevated.<sup>64</sup> A component or pyrolysis product unique to certain batches of “heroin” is possible.<sup>19</sup> Treatment is largely supportive. Based on the finding of regional mitochondrial dysfunction on functional brain imaging and an elevated brain lactate concentration, supplementation with coenzyme Q 300 mg four times a day has purported benefit and is a reasonable treatment, but it has not undergone controlled study.<sup>123</sup>

### Oxycodone, Hydrocodone, Hydromorphone, and Oxymorphone

These semisynthetic opioids are widely used to treat acute and chronic pain. For acute pain, several are sold in fixed combination with acetaminophen (eg, Percocet {oxycodone}, Vicodin {hydrocodone}), raising concerns about the complications of acetaminophen hepatotoxicity as the dose of opioid is escalated. Most are available in extended-release formulations that contain a large quantity of opioid intended to be released over many hours. Up until recently, those intent on abuse were able to crush the tablet, which destroys the controlled-release matrix and liberates large amounts of insufflatable or injectable opioid. New abuse deterrent formulation (ADF) standards required now of all extended release opioids make physical or chemical tampering difficult, limiting but not preventing this practice.<sup>177</sup> Abuse can still occur by ingesting intact pills, which can provide a cumulative amount of opioid.

### Fentanyl and Its Analogs

Fentanyl is a short-acting opioid agonist that has approximately 50 to 100 times the potency of morphine. It is well absorbed by the transmucosal route, accounting for its use in the form of a “lozenge” or spray. Fentanyl is widely abused as a heroin substitute (intentionally or unintentionally because of adulteration).<sup>15</sup> Experienced heroin users cannot easily differentiate fentanyl from heroin, although in one study, heroin was noted to provide a more intense “rush.”<sup>125</sup> There are thousands of deaths attributed to the illicit use of pharmaceutical fentanyl across North America.

Transdermal fentanyl in the form of a patch was approved in 1991 and is widely used by patients with chronic pain syndromes. Fentanyl has adequate solubility in both lipid and water for transdermal delivery (Special Considerations: SC3)<sup>220</sup> A single patch contains an amount of drug to provide a transdermal gradient sufficient to maintain a steady-state plasma concentration for approximately 3 days (eg, a 50-mcg/h patch contains 5 mg). However, even after the patch is considered exhausted, approximately 50% of the total initial fentanyl dose remains. Interindividual variation in dermal drug penetration and errors in proper use, such as use of excessive patches or warming of the skin, leads to an iatrogenic fentanyl overdose. Fentanyl patch misuse and abuse occur either by application of one or more patches to the skin or by withdrawal or extraction of the fentanyl from the reservoir for subsequent administration.<sup>207</sup>

Historically, the largest spontaneous and self-limited fentanyl epidemics, which included more than 1,000 deaths, occurred between 2005 and 2007 primarily in the Philadelphia, Chicago, and Detroit regions because of surreptitiously adulterated or substituted heroin. Fentanyl was identified by postmortem urine and blood testing or through analysis of unused drug found on either the decedent or persons with whom the decedent shared drugs.<sup>28</sup>

Regional epidemics of heroin substitutes with “superpotent” activity occasionally produce a dramatic increase in “heroin-related” fatalities. Epidemic deaths among heroin users first appeared in Orange County, California, in 1979 and were traced to  $\alpha$ -methylfentanyl sold under the brand name China White.<sup>121</sup> Similar epidemics of China White poisoning occurred in Pittsburgh in 1988 and in Philadelphia in 1992, although the adulterant in these cases was 3-methylfentanyl, another potent analog. A later epidemic in New York City marked the reappearance of 3-methylfentanyl under the brand name Tango and Cash. Typically, patients present comatose and apneic, with no opioids detected on routine blood and urine analysis. In such cases, unsuspecting users had administered their usual “dose of heroin,” measured in 25-mg “bags” that contained variable amounts of the fentanyl analog. Because of the exceptional potency of this fentanyl analog (as much as 10,000 times greater than that of morphine), users rapidly developed apnea.

Deaths caused by fentanyl sharply increased in late 2013. During this time period, the fentanyl prescription rate remained relatively stable, suggesting diversion of pharmaceutical fentanyl was not the etiology. Through law enforcement intelligence, it became clear that this increase resulted from the growing availability of nonpharmaceutical (illicitly produced) fentanyl.<sup>77,173,174</sup> In 2015, there was a further sharp increase in opioid fatalities attributable to novel fentanyl analogs, such as acetyl fentanyl, butyryl fentanyl, furanyl fentanyl, and carfentanil (Fig. 36–3). Each of these analogs contains functional groups substituted onto fentanyl that not only changes the pharmacologic effects but also allows the illicit drug to both temporarily skirt controlled substances laws and remain undetectable on traditional opioid immunoassay tests.<sup>148</sup> These highly potent opioids are imported, often through the mail, from synthetic laboratories, primarily in China, in small batches that readily evade detection by law enforcement. Other novel “research” opioids, including compounds such as MT-45, and AH-7921, U-47700, U-50488, which are not fentanyl derivatives, are also associated with significant public health and medical consequences.<sup>148,157,173</sup> Although unconfirmed, the xenobiotic used by Russian authorities to overcome terrorists and subdue a hostage situation in Moscow in October 2002 was carfentanil,<sup>226</sup> a potent  $\mu$ -receptor agonist that is also used as a positron emission tomography scan radioligand.

Although fentanyl is a more potent opioid agonist than heroin, the dose of naloxone required to reverse respiratory depression is similar to that of

clinically equivalent doses of other common opioids.<sup>206</sup> This is because the binding affinity ( $K_d$ ) of fentanyl at the  $\mu$  opioid receptor is similar to that of both morphine and naloxone.<sup>128,218</sup> The responsiveness of the fentanyl analogs to reversal by naloxone appears to be pharmacologically similar,<sup>149</sup> but in the clinical setting, it is very difficult to predict. Given the unpredictability of dosing and the extreme potency of the illicit opioids, administration of a large dose, either in absolute or relative terms, should reasonably be expected to require higher than normal doses of naloxone for reversal (Antidotes in Depth: A4).<sup>128</sup>

### Xenobiotics Used in Medication Assisted Therapy: Methadone and Buprenorphine

Two contrasting approaches to the management of patients with chronic opioid use exist: (1) detoxification and abstinence and (2) maintenance therapy. Detoxification probably is most appropriate for patients motivated or compelled to discontinue opioid use and remain abstinent. It is usually performed by tapered withdrawal of an opioid agonist. Maintenance therapy includes use of a long-acting opioid antagonist, such as naltrexone, to pharmacologically block the effects of additional opioid use. Greater success in reducing recurrent opioid use is achieved through medication-assisted therapy (MAT), which is essentially maintenance therapy using opioid substitution.<sup>25</sup>

#### Methadone

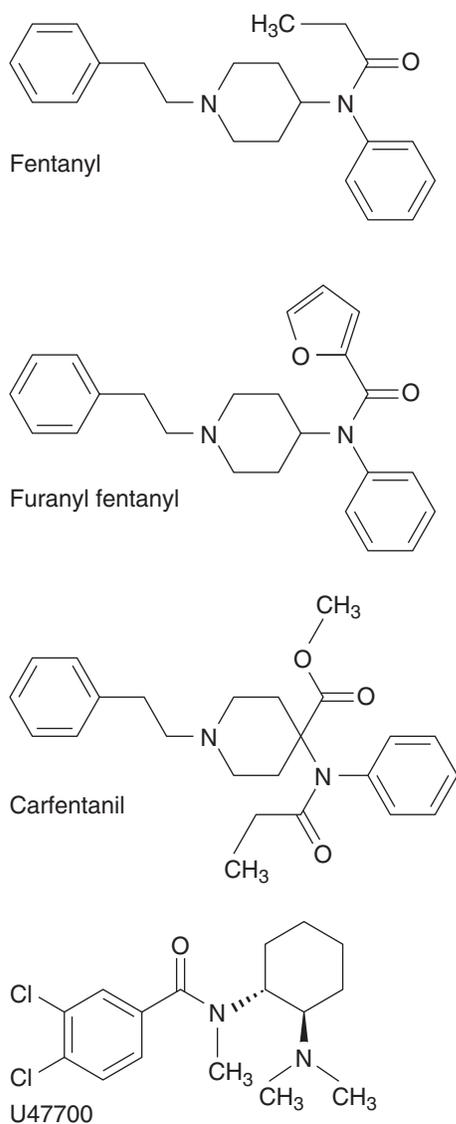

Methadone is a synthetic  $\mu$ -opioid–receptor agonist used both for treatment of chronic pain and as MAT for opioid dependence. Although therapeutic use of methadone, whether for pain or MAT, is generally safe, rapid dose escalation during induction of therapy rarely unintentionally result in toxicity and fatal respiratory depression.<sup>25</sup> This adverse effect is generally the result of the combination of variable pharmacokinetics (unpredictable but generally long half-life) and the time lag for the development of tolerance.

Methadone has been routinely available in many cities for MAT since the 1960s through methadone maintenance treatment programs (MMTPs).<sup>54</sup> In MMTPs, the abused opioid (historically heroin) is replaced by methadone, which is legal, pure, oral, and long acting. Methadone allows patients to abstain from activities associated with procurement and administration of the abused opioid and eliminates much of the morbidity and mortality associated with illicit drug use. Although often successful in achieving opioid abstinence, some methadone users continue to use heroin, other opioids, and other xenobiotics.<sup>112</sup>

Primarily because of its low cost compared with other extended-release opioids, until about 2007, methadone was increasingly used in the treatment of chronic pain.<sup>66</sup> Because such policies led to disproportionate adverse effects in patients receiving Medicaid and a safety warning about methadone issued by the FDA in 2006,<sup>66</sup> many such practices were abandoned. Despite accounting for only 1% of opioid prescriptions in 2014, methadone was implicated in approximately 23% of prescription opioid deaths that year.<sup>66</sup> The majority of methadone-related decedents used methadone for pain indications not as part of MAT.<sup>107</sup>

Methadone is administered as a chiral mixture of (*R,S*)-methadone. In humans, methadone metabolism is mediated by several cytochrome P450 (CYP) isozymes, mainly CYP3A4 and CYP2B6 and to a lesser extent CYP2D6. CYP2B6 demonstrates stereoselectivity toward (*S*)-methadone.<sup>73</sup> In vivo data show that CYP2B6 slow metabolizer status is associated with high (*S*)-, but not serum (*R*)-methadone concentrations.<sup>41</sup> (*R*)-methadone is used in Germany and is both more effective and safer than the chiral mixture or the (*S*) enantiomer because the former is largely devoid of QT effects and is the enantiomer that binds to opioid receptors, but it is not available in the United States at the present time.

Methadone predictably and in a concentration-dependent fashion produces QT interval prolongation because of blockade of the hERG (human *ether-a-gogo* related gene) channel.<sup>134</sup> In the human heart, the hERG voltage-gated potassium channel mediates the rapidly activating delayed rectifier current (Chap. 15). Blocking potassium efflux from the cardiac myocyte prolongs cellular repolarization, prolonging the QT interval. Syncope and

**FIGURE 36–3.** Structural design of novel fentanyl analogs (furanyl fentanyl and carfentanil) and the novel “research” opioid U-47700.

sudden death caused by ventricular dysrhythmias (eg, torsade de pointes) are the result. Genetic factors in the metabolism of methadone<sup>58</sup> and baseline QT status at the initiation of methadone therapy underlie and potentially predict adverse effects. In clinical trials, QT interval prolongation was greater in individuals who were CYP2B6 slow metabolizers, and this population had higher (*S*)-methadone concentrations.<sup>58</sup> (*S*)-methadone binding to hERG is twofold greater than that of (*R*)-methadone.<sup>103</sup>

A major difficulty is identification of individuals who are at risk for life-threatening dysrhythmias from methadone-induced QT interval prolongation. Expert-derived guidelines recommend questioning patients about intrinsic heart disease or dysrhythmias, counseling patients initiating methadone therapy, and obtaining a pretreatment electrocardiogram (ECG) and a follow-up ECG at 30 days and yearly.<sup>122</sup> Patients who receive methadone doses of greater than 100 mg/day necessitate more frequent ECGs, particularly after dose escalation or change in comorbid disease status.<sup>122</sup> Although these guidelines are disputed by some and limited data exist on the utility of the ECG as a screening test for persons at risk for torsade de pointes from methadone, given its low cost, easy availability, and minimal invasiveness, we agree with the guideline recommendations.<sup>111</sup>

Methadone abuse and unintentional overdose is often related to the manner in which MMTPs dispense the drug.<sup>107</sup> Most patients attending MMTPs are given doses of methadone greater than needed to simply prevent withdrawal and to prevent surreptitious heroin or other opioid use.<sup>201</sup> Additionally, most MMTPs provide their established patients with sufficient methadone to last through a weekend or holiday without the need to revisit the program. This combination of dose and quantity permits diversion of portions of the dose without the attendant risk of opioid withdrawal. Furthermore, home storage of this surplus drug in inappropriate containers, such as juice containers or baby bottles,<sup>85</sup> is a cause of unintentional methadone ingestion by children. Such events should be anticipated because methadone is frequently formulated as a palatable liquid, and it is not always stored in child-resistant containers. The primary reason for distribution as a liquid, as opposed to the pill form given to patients with chronic pain syndromes, is to ensure dosing compliance while being dispensed at the MMTP. Unfortunately, death is frequent in children who overdose.<sup>129</sup> Since 2007, the overdose death rate has declined and is associated with actions aimed at reducing methadone use for pain. In 2006, the FDA issued warnings about the risks of prescribing methadone for pain.<sup>107</sup>

### Buprenorphine

Because prescription of methadone for medication assisted therapy is restricted to federally licensed MMTPs, it is inaccessible and inconvenient for many patients. Buprenorphine was approved in 2000 for MAT for office-based prescribing in patients with opioid addiction. It is administered daily at home, providing a more attractive alternative for patients than daily MMTP visits, and it substantially broadened the potential for obtaining outpatient MAT. However, because of the initial limitations on patient volume (which was subsequently expanded), the requirement for physician certification, and possibly the hesitation on the part of community physicians to welcome patients with substance use disorder into their practices, many of the benefits of office-based buprenorphine therapy over methadone are not yet realized.

Buprenorphine, a partial  $\mu$ -opioid agonist, in doses of 8 to 16 mg sublingually, is effective at suppressing both opioid withdrawal symptoms and the covert use of illicit drugs. Buprenorphine, although abused, has a substantially better safety profile than methadone. That is, buprenorphine overdose is associated with markedly less respiratory depression than full agonists such as methadone. Because there is no reported effect on the QT interval, patients on methadone with concerning QT interval prolongation are offered the opportunity to switch to buprenorphine. Reasons for refusal are multifactorial and include the potential to precipitate withdrawal symptoms at induction, loss of the pleasant effects of methadone, and the reluctance of prescribers to escalate dosing regimens.<sup>98</sup>

Buprenorphine competes with the extant opioid for the  $\mu$  receptor; thus, administration of initial doses of buprenorphine in patients taking

methadone for medication assisted therapy or who are dependent on any other opioid can be complicated by opioid withdrawal. For this reason, the initial dose of buprenorphine is often administered in the presence of a physician and only when the patient is in mild to moderate withdrawal. Buprenorphine cessation results in a mild withdrawal syndrome and for this reason should be an advantage in opioid detoxification programs.<sup>6</sup> Buprenorphine is available as a sublingual (SL) tablets or sublingual or buccal films containing both buprenorphine and naloxone (Suboxone), which is added to prevent IV use.

At therapeutic doses, buprenorphine produces nearly complete occupancy of the  $\mu$  opioid receptors, and its receptor affinity is sufficiently strong that it prevents other opioids from binding.<sup>82</sup> Although naloxone prevents the clinical effects of buprenorphine, the reversal of respiratory effects by naloxone appears to be related in a nonlinear fashion. Relatively low bolus doses of IV naloxone have no effect on the respiratory depression induced by buprenorphine, but high doses (5–10 mg) caused only partial reversal of the respiratory effects of buprenorphine. More recently, data in healthy volunteers suggest a bell-shaped dose response to naloxone.<sup>176,215</sup> Although doses that would reverse other opioids were ineffective (0.2–0.4 mg), increasing the dose of naloxone to 2 to 4 mg caused full reversal of buprenorphine respiratory depression. However, the onset of reversal is usually slower than occurs when antagonizing other opioids.<sup>215</sup> Further increasing the naloxone dose to 5 to 7 mg caused a decline in reversal activity and increased the degree of respiratory depression. The reasons for this are unclear. Therefore, it is recommended that the reversal of respiratory depression be treated with a starting dose that is slightly higher than that used to reverse other opioids and increased slowly and titrated to reversal of respiratory depression. For example, a starting dose of naloxone of 0.02 mg/kg, or 1 mg in an adult, is a reasonable initial dose. The dose is then increased incrementally, not to exceed a dose of about 5 mg for concern of decreasing efficacy of naloxone. Because of the difficulty in prediction of naloxone's effect in treatment of buprenorphine-induced respiratory depression, all patients should be closely monitored. Furthermore, because sedation and respiratory depression from buprenorphine may outlast the reversal effects of naloxone, boluses or short infusions or a continuous infusion of naloxone is recommended to maintain respiratory function.<sup>78</sup>

As a partial agonist, buprenorphine has a ceiling effect on respiratory depression in healthy volunteers, with a similar plateau in analgesic effect.<sup>43</sup> However, in some patients, despite the ceiling effect, clinically consequential respiratory depression does occur.<sup>210</sup> Data from multiple case series indicate that most buprenorphine-related deaths are associated with concomitant use of other drugs, most often benzodiazepines, or to the IV injection of crushed tablets.<sup>210</sup> Children are at particularly high risk.<sup>23</sup>

The higher affinity (lower  $K_d$ ) and partial agonism of buprenorphine should allow it to function as an antagonist to the respiratory depressant effects of heroin and improve spontaneous respiration. Although administration of sublingual buprenorphine for opioid overdose is reportedly successful in some case reports,<sup>229</sup> there is not enough evidence to recommend this practice at this time. In fact, some reported deaths involved patients given buprenorphine tablets intravenously by fellow drug abusers for the treatment of heroin-induced respiratory depression.<sup>16</sup>

### Other Unique Opioids Tramadol and Tapentadol

Tramadol and tapentadol are synthetic analgesics with both opioid and nonopioid mechanisms responsible for their clinical effects. Tramadol is a reuptake inhibitor of norepinephrine and 5-HT, and it has an active metabolite, O-desmethyltramadol catalyzed by CYP2D6, which is a  $\mu$  opioid receptor agonist.<sup>165</sup> The expression of CYP2D6 is extremely variable. Thus, the analgesic effect of tramadol is inconsistent among individual patients. Tapentadol, which does not require activation, has relatively strong  $\mu$ -opioid receptor agonism and inhibits the reuptake of norepinephrine but not serotonin.<sup>86</sup> Both are available in immediate- and extended-release formulations.

A large number of spontaneous reports to the FDA describe therapeutic use of tramadol resulting in seizures, particularly on the first day of therapy. However, epidemiologic studies have not confirmed this association.<sup>71</sup> Tramadol-related seizures are not responsive to naloxone but are suppressed with benzodiazepines. In fact, the prescribing information cautions against using naloxone in patients with tramadol overdose because the risk of seizure is increased in animal models. Correspondingly, one patient in a prospective series had a seizure that was temporally related to naloxone administration.<sup>196</sup> Acute overdose of tramadol is generally considered non-life-threatening, and most fatalities were associated with polysubstance overdose. Ultrarapid metabolizers at CYP2D6 will develop complications at conventional doses.<sup>61</sup> Patients using monoamine oxidase inhibitors (MAOIs) are at risk for development of serotonin toxicity after use of tramadol.

Tramadol abuse is reported. Data indicate an increase in tramadol inquires in recent years, and tramadol was the second most common drug inquired about on a user-based website next to oxycodone.<sup>232</sup> In August 2014, tramadol was moved to Schedule IV of the US Controlled Substances Act, reflecting its potential for abuse and diversion. In a review of physician drug abuse in several states, tramadol was the second most frequent opioid reported.<sup>190,212</sup> Opioid abusers recognized tramadol as an opioid only when given in an amount that was six times the therapeutic dose, but at this dose, they did not develop opioidlike clinical effects such as miosis. Patients develop typical opioid manifestations after a large overdose. Significant respiratory depression is uncommon and should respond to naloxone.<sup>196</sup> Hypoglycemia is associated with therapeutic use of tramadol, and it is reasonable to admit all patients with tramadol-induced hypoglycemia because of the uncertainty of continuing risk.<sup>68</sup> Generally, urine drug screening for drugs of abuse is negative for opioids in tramadol-using patients. Tapentadol is relatively new to the market, and although its abuse potential remains concerning and case reports exist,<sup>115</sup> there are insufficient epidemiologic data to identify diversion or abuse.<sup>50</sup>

### Diphenoxylate

Although diphenoxylate is structurally similar to meperidine, its extreme insolubility limits absorption from the GI tract. This factor enhances its use as an antidiarrheal, which presumably occurs via a local opioid effect at the GI  $\mu$  receptor. However, there is significant systemic absorption of the standard adult formulation with resulting toxicity in children, and all such exposures in children should be deemed consequential. Diphenoxylate is formulated with a small dose (0.025 mg) of atropine (as Lomotil), both to enhance its antidiarrheal effect and to discourage illicit use.

Because both components of Lomotil are absorbed and their pharmacokinetic profiles differ somewhat, a biphasic clinical syndrome is occasionally noted.<sup>138</sup> Patients typically manifest atropine poisoning (anticholinergic syndrome), either independently or concomitantly with the opioid effects of diphenoxylate. Delayed, prolonged, or recurrent toxicity is common and is classically related to the delayed gastric emptying effects inherent to both opioids and anticholinergics. However, these effects are more likely explained by the accumulation of the hepatic metabolite difenoxin, which is a significantly more potent opioid than diphenoxylate and possesses a longer serum half-life. Still, the relevance of gastroparesis is highlighted by the retrieval of Lomotil pills by gastric lavage as late as 27 hours postingestion.

A review of 36 pediatric reports of diphenoxylate overdoses found that although naloxone was effective in reversing the opioid toxicity, recurrence of CNS and respiratory depression was common.<sup>138</sup> This series included a patient with an asymptomatic presentation 8 hours postingestion who was observed for several hours and then discharged. This patient returned to the ED 18 hours postingestion with marked signs of atropinism. In this same series, children with delayed onset of respiratory depression and other opioid effects were reported, and others describe cardiopulmonary arrest 12 hours postingestion. Naloxone infusion is indicated for patients with recurrent signs of opioid toxicity. Because of the delayed and possibly severe consequences, all individuals with potentially significant ingestions should be admitted for monitored observation in the hospital.

### Loperamide

Loperamide is another insoluble meperidine analog that is used to treat diarrhea and is available over the counter as a nonprescription medication. At therapeutic doses, it inhibits peristaltic activity through agonism of  $\mu$  opioid receptors, calcium channel blockade, calmodulin inhibition, and decreasing paracellular permeability in the large intestine.<sup>8,197</sup> At therapeutic dosing (< 16 mg/day), loperamide is essentially devoid of central opioid effects because transporter protein P-glycoprotein actively facilitates removal of the drug from the gut and the CNS.<sup>213,217</sup> However, larger than recommended doses overcome these mechanisms, enabling CNS penetration and affording relief of opioid withdrawal symptoms or even opioidlike euphoria and psychotropic effects. These effects are facilitated by coingestion of a P-glycoprotein inhibitor. Central nervous system and respiratory depression are reported after therapeutic oral dosing in infants.<sup>130</sup> Since 2010, loperamide exposures misuse and abuse continue to increase in the United States because prescription opioids are costly and becoming less accessible.<sup>214</sup> Loperamide was initially placed in Schedule II, down scheduled to Schedule V in 1977, and descheduled in 1982.<sup>212</sup> Because it is not tracked as a controlled substance, the true extent of use, diversion, and abuse are largely unavailable. As people with OUD search for alternatives to self-treat opioid dependence and withdrawal symptoms, loperamide is becoming more popular as an easily available inexpensive option.

Deaths are reported at the high doses required for CNS effects (70–400 mg) and are associated with respiratory depression cardiotoxicity.<sup>60,197</sup> Loperamide inhibits human cardiac sodium channels and inhibits delayed-rectifier potassium currents in vitro. Correspondingly, both QRS prolongation and polymorphic ventricular tachycardia are reported after overdose.<sup>60,197</sup> Inhibition of calcium channel function likely contributes to its cardiac toxicity in overdose. Naloxone should be administered to reverse consequential respiratory depression associated with loperamide overdose.<sup>60</sup> In patients who present with wide complex dysrhythmias and polymorphic ventricular tachycardia, it is reasonable to use sodium bicarbonate and magnesium sulfate, as potentially preventive measures but primary treatment is electrical cardioversion. However, data on the optimal treatment of cardiotoxicity associated with loperamide overdose are very limited.

### Dextromethorphan

Dextromethorphan is devoid of analgesic properties altogether, even though it is the optical isomer of levorphanol, a potent opioid analgesic. Based on this structural relationship, dextromethorphan is commonly considered an opioid, although its receptor pharmacology is much more complex. At high doses, dextromethorphan binds to opioid receptors to produce miosis, respiratory depression, and CNS depression, which are at least partially reversed by naloxone. Binding to the phencyclidine (PCP) site on the NMDA receptor, with subsequent inhibition of calcium influx through this receptor-linked ion channel, causes sedation. This same activity accounts for its antiepileptic properties and for its neuroprotective effects in ischemic brain injury. Because NMDA receptor blockade both reduces hyperalgesia and enhances the analgesic effects of  $\mu$ -opioid agonists, combination therapy with morphine and dextromethorphan is increasingly studied and used.<sup>114,119</sup>

Blockade of presynaptic serotonin reuptake by dextromethorphan causes the serotonin toxicity in patients receiving MAOIs or other serotonergics.<sup>194</sup> Movement disorders, described as choreoathetoid or dystonia-like, occasionally occur and presumably result from alteration of dopaminergic neurotransmission. Dextrophan, the active *O*-demethylation metabolite of dextromethorphan, is produced by CYP2D6, an enzyme with a well-described genetic polymorphism.<sup>7</sup> Whereas patients with the “extensive metabolizer” polymorphism appear to experience more drug-related psychoactive effects, poor metabolizers experience more adverse effects related to the parent compound.<sup>237</sup>

Dextromethorphan is available without prescription in cold preparations, primarily because of its presumed lack of significant addictive potential. Despite this, the prevalence of use among high school students

was high but decreased recently.<sup>195</sup> Common street names include “DXM,” “dex,” and “roboshots.” Users often have expectations of euphoria and hallucinations, but a dysphoria comparable to that of PCP commonly ensues. Reports of substantial cold medicine consumption raise concerns, including acetaminophen poisoning, opioid dependency, and bromide toxicity.<sup>100</sup> This last concern relates to the common formulation of dextromethorphan as the hydrobromide salt. At times, the first clue is an elevated serum chloride concentration when measured on certain autoanalyzers (Chaps. 7 and 12).

### Meperidine

Meperidine was previously widely used for treatment of chronic and acute pain syndromes. Its use was dramatically reduced and is either closely monitored in many institutions or eliminated because of its adverse risk-benefit profile. Meperidine produces clinical manifestations typical of the other opioids and may lead to greater euphoria caused by its blockade of presynaptic serotonin reuptake.<sup>236</sup> This most consequential nonopioid-receptor effect causes serotonin toxicity, characterized by muscle rigidity, hyperthermia, and altered mental status, particularly in patients using MAOIs (Chap. 71). Normeperidine, a toxic, renally eliminated hepatic metabolite, accumulates in patients receiving chronic high-dose meperidine therapy, such as those with sickle cell disease or cancer or in those with chronic kidney disease.<sup>204</sup> Normeperidine causes excitatory neurotoxicity, which manifests as delirium, tremor, myoclonus, or seizures. Based on animal studies and human evidence, the seizures do not respond to naloxone.<sup>75</sup>

## DIAGNOSTIC TESTING

### Laboratory Considerations

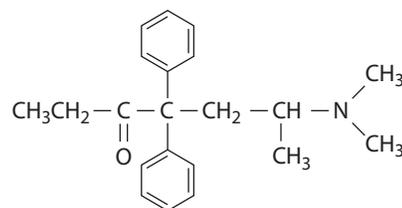

Opioid-poisoned patients are particularly appropriate for a rapid clinical diagnosis because of the unique characteristics of the opioid toxic syndrome. Additionally, even in situations in which the assay results are available rapidly, the fact that several distinct classes of opioids and nonopioids produce similar opioid effects limits the use of laboratory tests, such as immunoassays, that rely on structural features to identify xenobiotics. Furthermore, because opioids are chemically detectable long after their clinical effects have dissipated, assay results cannot be considered in isolation but rather viewed in the clinical context. Several well-described problems with laboratory testing of opioids are described later and in Chap. 7.

### Cross-Reactivity

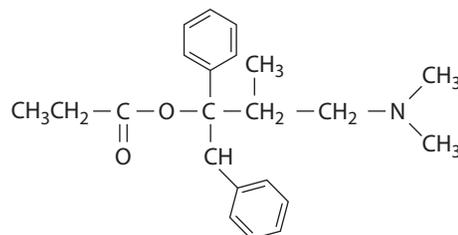

Many opioids share significant structural similarities, such as morphine and oxycodone or methadone and propoxyphene (Fig. 36–4). Because most clinical assays depend on structural features for identification, structurally similar xenobiotics are frequently detected in lieu of the desired one. Whether a similar xenobiotic is noted by the assay depends on the sensitivity and specificity of the assay and the serum concentration of the xenobiotic. Some cross-reactivities are predictable, such as that of hydrocodone with morphine, on a variety of screening tests. Other cross-reactivities are less predictable, as in the case of the cross-reaction of dextromethorphan and the PCP component of the fluorescence polarization immunoassay (Abbott TDx),<sup>178</sup> a widely used drug abuse screening test (Chap. 7).<sup>200</sup>

### Congeners and Adulterants

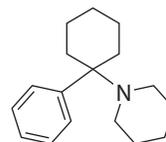

Commercial opiate assays, which are usually specific for morphine (a metabolite of heroin), do not readily detect most of the semisynthetic and synthetic opioids. Epidemic fatalities involving fentanyl derivatives remained unexplained despite obvious opioid toxicity until the ultrapotent fentanyl analog  $\alpha$ -methylfentanyl (although initially misidentified as 3-methylfentanyl) was identified by more sophisticated testing.<sup>121,135</sup> Oxycodone, hydrocodone, and other common morphine derivatives have variable detectability by different opioid screens and generally only when in high concentrations.<sup>132</sup> Currently, because of the public health threat of fentanyl analogs and other potent opioids, reference and forensic laboratories have markedly expanded their detection capabilities by using advanced technologies such as tandem mass spectroscopy.<sup>148</sup>

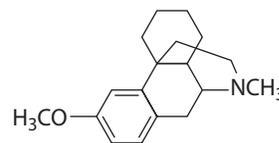

Methadone

Propoxyphene

Phencyclidine

Dextromethorphan

**FIGURE 36–4.** Structural similarity between methadone and propoxyphene and between phencyclidine and dextromethorphan.

### Drug Metabolism

A fascinating dilemma often arises in patients who ingest moderate to large amounts of poppy seeds.<sup>118</sup> These seeds, which are widely used for culinary purposes, are derived from poppy plants and contain both morphine and codeine. After ingestion of a single poppy seed bagel, patients infrequently develop elevated serum morphine and codeine concentrations and test positive for morphine.<sup>147,170</sup> Because the presence of morphine on a drug abuse screen supports illicit heroin use, the implications are substantial. Federal workplace testing regulations thus require corroboration of a positive morphine assay with assessment of another heroin metabolite, 6-monoacetylmorphine, before reporting a positive result.<sup>150,219</sup> Humans readily deacetylate heroin, which is diacetylmorphine but cannot acetylate morphine and therefore cannot synthesize 6-monoacetylmorphine.

Similar problems occur in patients taking therapeutic doses of codeine. Because codeine is demethylated to morphine by CYP2D6, a morphine screen will be positive as a result of metabolism and not structural cross-reactivity.<sup>71</sup> Thus, determination of the serum codeine or 6-monoacetylmorphine concentration is necessary in these patients. Determination of the serum codeine concentration is not foolproof, however, because codeine is present in opium, which is used to synthesize heroin.

### Forensic Testing

Decision making regarding the cause of death in the presence of systemic opioids often is complex.<sup>44</sup> Variables that often are incompletely defined contribute substantially to the difficulty in attributing or not attributing the

cause of death to the opioid. These variables include the specifics regarding the timing of exposure, the preexisting degree of sensitivity or tolerance, the role of cointoxicants (including parent opioid metabolites), and postmortem redistribution and metabolism.<sup>56,112</sup> Techniques to help further elucidate the likely cause of death include the application of postmortem pharmacogenetic principles<sup>105</sup> and the use of alternative specimens (Chap. 140).

## MANAGEMENT

The consequential effects of acute opioid poisoning are CNS and respiratory depression. Although early support of ventilation and oxygenation is generally sufficient to prevent death, prolonged use of bag-valve-mask ventilation and endotracheal intubation can often be avoided by cautious administration of an opioid antagonist. Opioid antagonists, such as naloxone, competitively inhibit binding of opioid agonists to opioid receptors, allowing the patient to resume spontaneous respiration. Naloxone competes at all receptor subtypes, although not equally, and is effective at reversing almost all adverse effects mediated through opioid receptors (Antidotes in Depth: A4).

Because many clinical findings associated with opioid poisoning are nonspecific, the diagnosis requires clinical acumen. Differentiating acute opioid poisoning from other etiologies with similar clinical presentations is challenging. Patients manifesting findings of opioid poisoning, found in an appropriate environment, or with characteristic physical clues such as fresh needle marks require little corroborating evidence. However, subtle presentations of opioid poisoning are encountered, and other xenobiotics can simulate opioid poisoning. Hypoglycemia, hypoxia, and hypothermia result in clinical manifestations that share features with opioid poisoning and often exist concomitantly. Many other xenobiotics are rapidly identifiable with routinely available, point-of-care testing, but their existence does not exclude opioid poisoning. Other xenobiotics responsible for similar clinical presentations include clonidine, PCP, phenothiazines, and sedative-hypnotics (primarily benzodiazepines). In such patients, clinical evidence usually is available to assist in diagnosis. For example, nystagmus nearly always is noted in PCP-toxic patients, hypotension or ECG abnormalities in phenothiazine-poisoned patients, and coma with virtually normal vital signs in patients poisoned by benzodiazepines. Most difficult to differentiate on clinical grounds is toxicity produced by the centrally acting antihypertensives such as clonidine (see later and Chap. 61). Additionally, myriad traumatic, metabolic, and infectious etiologies may occur simultaneously and must always be evaluated appropriately.

### Antidote Administration

The goal of naloxone therapy is not necessarily complete restoration of normal consciousness; rather, the goal is reinstatement of adequate spontaneous ventilation. Because precipitation of withdrawal is potentially detrimental and often unpredictable, we recommend administering the lowest practical naloxone dose initially, with rapid escalation as warranted by the clinical situation. Most patients respond to 0.04 of naloxone administered IV,<sup>117</sup> although the requirement for ventilatory assistance is often slightly prolonged because the onset will be slower than with larger doses. We recommend repeating this dose for several doses at 3-minute intervals, as needed for persistent findings, with escalation up to 0.4-mg and 2-mg doses.<sup>37</sup> Infrequently if the presumption of opioid overdose persists repetitive bolus doses of naloxone of 2 mg up to a total of 10 mg is indicated. In patients who do not respond to high doses, opioid-induced hypoventilation is excluded (Antidotes in Depth: A4). Administration in this fashion usually avoids endotracheal intubation and allows for timely identification of patients with nonopioid causes of their clinical condition yet diminishes the risk of precipitation of acute opioid withdrawal. Subcutaneous administration allows for smoother arousal than the high-dose IV route, but is unpredictable in onset and prolonged in offset.<sup>223</sup> Prolonged effectiveness of naloxone by the SC route can be a considerable disadvantage if a withdrawal syndrome develops or if discharge from the ED is dependent on the duration of effect of the antagonist, so we recommend IV dosing and titration to effect whenever feasible (Antidotes in Depth: A4).

In the absence of a confirmatory history or diagnostic clinical findings, the cautious empiric and titrated administration of naloxone will be both diagnostic and therapeutic. Naloxone, even at extremely high doses, has an excellent safety profile in opioid-naïve patients receiving the medication for nonopioid-related indications, such as spinal cord injury or acute ischemic stroke. However, administration of naloxone to opioid-dependent patients often results in adverse effects; specifically, precipitation of an acute withdrawal syndrome should be anticipated. The resultant agitation, hypertension, and tachycardia produce significant distress for the patient and complicate management for the clinical staff and occasionally is life threatening. Additionally, emesis, a common feature of acute opioid withdrawal, is particularly hazardous in patients who do not rapidly regain consciousness after naloxone administration. For example, patients with concomitant ethanol or sedative-hypnotic exposure and those with head trauma are at substantial risk for pulmonary aspiration of vomitus if their airways are unprotected.

Identification of patients likely to respond to naloxone conceivably would reduce the unnecessary and potentially dangerous precipitation of withdrawal in opioid-dependent patients. Routine prehospital administration of naloxone to all patients with subjectively assessed altered mental status or respiratory depression was not beneficial in 92% of patients.<sup>235</sup> Alternatively, although not perfectly sensitive, a respiratory rate of 12 breaths/min or less in an unconscious patient presenting via emergency medical services best predicted a response to naloxone.<sup>94</sup> In contrast, neither respiratory rate below 8 breaths/min nor coma was able to predict a response to naloxone in hospitalized patients.<sup>231</sup> It is unclear whether the discrepancy between the latter two studies is a result of the demographics of the patient groups or whether patients with prehospital opioid overdose present differently than patients with iatrogenic poisoning. Regardless, relying on the respiratory rate to assess the need for ventilatory support or naloxone administration is not ideal because hypoventilation secondary to hypopnea may precede that caused by bradypnea.<sup>168,189</sup>

The decision to discharge a patient who awakens appropriately after naloxone administration is based on practical considerations. Patients presenting with profound hypoventilation or hypoxia are at risk for development of ARDS or posthypoxic encephalopathy. We recommend observing these patients for at least 24 hours in a medical setting. Based on the pharmacokinetics of naloxone, patients manifesting only moderate signs of opioid poisoning who remain normal for at least 2 hours after a standard parenteral dose of naloxone are likely safe to discharge (Antidotes in Depth: A4). Patients requiring larger doses of naloxone should be observed longer, although 6 hours should generally be sufficient. Patients with uncontrolled drug use or after a suicide attempt often need psychosocial interventions before discharge from the ED. Patients who have used methadone or an extended-release opioid formulation often require continuous infusion of naloxone or administration of a long-acting opioid antagonist is indicated to maintain adequate ventilation. Patients receiving a naloxone infusion should be maintained for 12 to 24 hours and then observed an additional 4 to 6 hours after discontinuation of the naloxone infusion (Antidotes in Depth: A4).

Patients with recurrent or profound poisoning by long-acting opioids, such as methadone, or patients with large GI burdens (eg, “body packers” or those taking extended-release preparations) often require continuous infusion of naloxone to ensure continued adequate ventilation (Table 36–5). An hourly infusion rate of two-thirds of the initial reversal dose of naloxone is usually sufficient to prevent recurrence.<sup>78</sup> Titration of the dose is often necessary as indicated by the clinical situation. Although repetitive bolus dosing of naloxone is effective, it is labor intensive and subject to error.

Despite the availability of long-acting opioid antagonists (eg, naltrexone) that theoretically permit single-dose reversal of methadone poisoning, the attendant risk of precipitating an unrelenting withdrawal syndrome hinders their use as antidotes for initial opioid reversal. We recommend against their use for opioid overdose in almost all circumstances. However, these opioid antagonists have a clinical role in the maintenance of consciousness and ventilation in opioid-poisoned patients already awakened by naloxone who are not experiencing opioid withdrawal. Prolonged observation and perhaps antidote readministration will be required to match the pharmacokinetic

**TABLE 36–5 Recommended Use of a Naloxone Infusion**

1. If a naloxone bolus (start with 0.04 mg IV and titrate) is successful, for those determined to need an infusion administer two-thirds of the effective bolus dose per hour by IV infusion; frequently reassess the patient's respiratory status.
2. If respiratory depression is not reversed after the initial bolus dose:  
Increase dose slowly and titrate to reversal of respiratory depression. Administer up to 10 mg of naloxone as an IV bolus.  
If the patient does not respond, do not initiate an infusion.  
AND prepare for  
Intubation of the patient, as clinically indicated.
3. If the patient develops withdrawal after the bolus dose:  
Allow the effects of the bolus to abate.  
If respiratory depression recurs, administer half of the initial bolus dose and begin an IV infusion at two-thirds of the new bolus dose per hour. Frequently reassess the patient's respiratory status.
4. If the patient develops withdrawal signs or symptoms during the infusion:  
Stop the infusion until the withdrawal symptoms abate.  
Restart the infusion at half the initial rate; frequently reassess the patient's respiratory status.  
Exclude withdrawal from other xenobiotics.
5. If the patient develops respiratory depression during the infusion:  
Readminister half of the initial bolus and repeat until reversal occurs.  
Increase the infusion by half of the initial rate; frequently reassess the patient's respiratory status.  
Exclude continued absorption, readministration of opioid, and other etiologies as the cause of the respiratory depression.

IV = intravenous.

parameters of the agonist and antagonist. For example, it is reasonable to give well children who ingest short-acting opioids a long-acting opioid antagonist such as naltrexone because they are not expected to develop delayed opioid toxicity beyond the duration of the antagonist. However, the same caveats remain regarding the need for extended hospital observation periods if ingestion of methadone or other long-acting opioids is suspected.

### Body Packers

In an attempt to transport illicit drugs from one country to another, body packers ingest large numbers of multiple-wrapped packages of concentrated cocaine or heroin. When the authorities discover such individuals or when individuals in custody become ill, they may be brought to a hospital for evaluation and management. Although these patients generally are asymptomatic on arrival, they are at risk for delayed, prolonged, or lethal poisoning as a consequence of packet rupture.<sup>211</sup> In the past, determining the country of origin of the current journey was nearly diagnostic of packet content. However, because most of the heroin imported into the United States now originates from South America, which is also the major source of imported cocaine, the discernment from cocaine on this basis is impossible. Given the current greater revenue potential of heroin, the majority of body packers carry heroin (Special Considerations: SC5).<sup>76</sup>

### Rapid and Ultrarapid Opioid Detoxification

The concept of antagonist-precipitated opioid withdrawal is promoted extensively as a "cure" for opioid dependency, particularly heroin and oxycodone, but has fallen out of favor in recent years. Rather than slow, deliberate withdrawal or detoxification from opioids over several weeks, antagonist-precipitated withdrawal occurs over several hours or days.<sup>81</sup> The purported advantage of this technique is a reduced risk of relapse to opioid use because the duration of discomfort is reduced and a more rapid transition to naltrexone maintenance can be achieved. Although most studies find some beneficial short-term results, relapse to drug use is very common.<sup>139</sup> Rapid opioid detoxification techniques are usually offered by outpatient clinics and typically consist of naloxone- or naltrexone-precipitated opioid withdrawal tempered with varying amounts of clonidine, benzodiazepines, antiemetics, or other drugs. Ultrarapid opioid detoxification uses a similar concept but involves the use of deep

sedation or general anesthesia for greater patient control and comfort. The risks of these techniques are not fully defined, but are of substantial concern. Massive catecholamine release, ARDS, acute kidney injury, and thyroid hormone suppression does occur after UROD, and many patients still manifest opioid withdrawal 48 hours after the procedure. As with other forms of opioid detoxification, the loss of tolerance after successful completion of the program paradoxically increases the likelihood of death from heroin overdose if these individuals relapse. That is, recrudescence of opioid use in predetoxification quantities is likely to result in overdose.<sup>202</sup> Both techniques are costly; UROD under anesthesia commonly costs thousands of dollars. We agree with the professional medical organizations involved in addiction management that have publicly expressed concern for this form of detoxification.<sup>4</sup>

### SUMMARY

- Opioid poisonings, both intentional and unintentional, remain major causes of drug-related morbidity and mortality.
- Although the therapeutic and toxic doses are difficult to predict because of the development of tolerance with chronic use, the primary adverse event from excessive dosing is respiratory depression.
- Mechanical ventilation, or administration of a short-acting opioid antagonist such as naloxone, are adequate initial therapies. Naloxone dosing requires cautious escalation.
- An appreciation of the pharmacologic differences among the various opioids allows for the identification and appropriate management of patients poisoned or otherwise adversely affected by these xenobiotics.

## OPIOID ANTAGONISTS

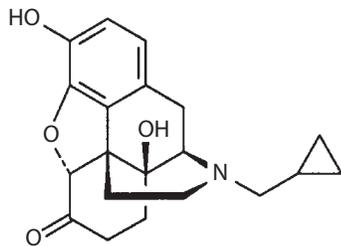

Lewis S. Nelson and Mary Ann Howland

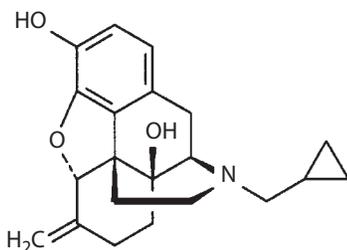

Morphine

Naloxone

Naltrexone

Nalmefene

**INTRODUCTION**

Naloxone, naltrexone, and methylnaltrexone are pure competitive opioid antagonists at the mu ( $\mu$ ), kappa ( $\kappa$ ), and delta ( $\delta$ ) receptors. Opioid antagonists prevent the actions of opioid agonists, reverse the effects of both endogenous and exogenous opioids, and cause opioid withdrawal in opioid-dependent patients. Naloxone is the primary opioid antagonist used to reverse respiratory depression in patients manifesting opioid toxicity. The parenteral dose should be titrated to maintain adequate airway reflexes and ventilation. By titrating the dose, in small increments based on clinical response, abrupt opioid withdrawal should be prevented. This

titrated low dose method of administration limits withdrawal-induced adverse effects, such as vomiting and the potential for aspiration pneumonia, and a surge in catecholamines with the potential for cardiac dysrhythmias and the acute respiratory distress syndrome (ARDS). Because of its poor oral bioavailability, oral naloxone was previously suggested as treatment for patients with opioid-induced constipation. Methylnaltrexone, a parenteral medication, and naloxegol, an oral formulation, are effective in reversing opioid-induced constipation without inducing opioid withdrawal. This is because their central nervous system (CNS) entry is restricted. Naltrexone is used both orally and intramuscularly in patients after opioid detoxification to maintain opioid abstinence and as an adjunct to achieve ethanol abstinence.

**HISTORY**

The understanding of structure–activity relationships led to the synthesis of many new molecules in the hope of producing potent opioid agonists free of abuse potential. Although this goal is not yet realized, opioid antagonists and partial agonists resulted from these investigations. *N*-Allylnorcodeine was the first opioid antagonist synthesized (in 1915), and *N*-allylnormorphine (nalorphine) was synthesized in the 1940s.<sup>40,82</sup> Nalorphine was recognized as having both agonist and antagonist effects in 1954. Naloxone was synthesized in 1960, and naltrexone in 1963. The synthesis of opioid antagonists that are unable to cross the blood–brain barrier (sometimes called peripherally restricted) allowed patients receiving long-term opioid analgesics to avoid opioid-induced constipation, one of the most uncomfortable side effects associated with opioid therapy. Since the mid-1990s and the reappearance of the opioid epidemic of the 21st century, there has been a steady increase in the use of naloxone that is prescribed or directly dispensed to users of any opioid who are at risk of overdose as well as for administration by bystanders.<sup>14</sup>

**PHARMACOLOGY****Chemistry**

Minor structural alterations are used to convert an agonist into an antagonist. The substitution of the *N*-methyl group on morphine by a larger functional group led to nalorphine and converted the agonist levorphanol to the antagonist levallorphan.<sup>38</sup> Naloxone and naltrexone are derivatives of oxycodone with antagonist properties resulting from addition of organic or other functional groups.<sup>38,42</sup>

**Mechanism of Action**

The mu receptors are responsible for analgesia, sedation, miosis, euphoria, respiratory depression, and decreased gastrointestinal (GI) motility. Kappa receptors are responsible for spinal analgesia, miosis, dysphoria, anxiety, nightmares, and hallucinations. Delta receptors are responsible for analgesia and hunger. The currently available opioid receptor antagonists are most potent at the mu receptor, with higher doses required to affect the kappa and delta receptors. They all bind to the opioid receptor in a competitive fashion, preventing the binding of agonists, partial agonists, or mixed agonist–antagonists without producing any independent action.

**Pharmacokinetics**

Naloxone and naltrexone differ primarily in their pharmacokinetics. Naltrexone has a longer duration of action and sufficient oral bioavailability to produce systemic effects. At therapeutic doses, methylnaltrexone is relatively

effectively excluded from the CNS and only produces peripheral effects in overdose. Selective antagonists for mu, kappa, and delta are available experimentally and are undergoing investigation.

The oral bioavailability of naloxone is less than 2%,<sup>30,76</sup> rectal bioavailability is 15%,<sup>76</sup> and the sublingual bioavailability is only 10%.<sup>8</sup> The bioavailability of a concentrated intranasal naloxone formulation is approximately 44% that of naloxone administered by the intramuscular (IM) route.<sup>1</sup> In the same study, the apparent half-life of 4 mg of the 40 mg/mL formulation sprayed into one or both nostrils was approximately 2.1 hour compared with 1.24 hour for 0.4 mg administered IM into the thigh. In contrast, naloxone is well absorbed by all parenteral routes of administration. The approximate onset of action with the various routes of administration are as follows: intralingual, 30 seconds; intravenous (IV), 1 to 2 minutes; endotracheal, 60 seconds; intranasal, 3.4 minutes; inhalational (nebulized), 5 minutes; subcutaneous (SC), 5.5 minutes; and IM, 6 minutes.<sup>26,44,62,91</sup> The distribution half-life is rapid (~5 minutes) because of its high lipid solubility. Protein binding is low,<sup>1</sup> and the volume of distribution ( $V_d$ ) is 0.8 to 2.64 L/kg.<sup>34</sup>

An IV naloxone dose of 13 mcg/kg (~1 mg in an 80-kg opioid-naïve adult) occupies approximately 50% of the available opioid receptors.<sup>57</sup> The duration of action of naloxone is approximately 20 to 90 minutes and depends on the dose and route of administration of naloxone and the rates of elimination of the agonist and naloxone.<sup>8,28,85</sup> Naloxone is hepatically metabolized to several compounds, including a glucuronide conjugate. The elimination half-life after IV administration is 60 to 90 minutes in adults and approximately two to three times longer in neonates.

Naltrexone is rapidly absorbed with an oral bioavailability of 5% to 60% because of extensive first pass effects, and peak serum concentrations occur at 1 hour.<sup>37</sup> Distribution is rapid, with a  $V_d$  of approximately 15 L/kg and low protein binding.<sup>48</sup> Naltrexone is metabolized in the liver to  $\beta$ -naltrexol (major metabolite with 2%–8% activity) and 2-hydroxy,3-methoxy- $\beta$ -naltrexol and undergoes an enterohepatic cycle.<sup>54,89</sup> The plasma elimination half-lives are 4 hours for naltrexone and 13 hours for  $\beta$ -naltrexol, with a terminal phase of elimination of 96 hours and 18 hours, respectively.<sup>87</sup> The terminal elimination half-life corresponds most closely with the clinical effects of naltrexone.<sup>51</sup> Naltrexone for extended-release injectable suspension (Vivitrol, Alkermes) displays an initial peak concentration at approximately 2 hours after injection; a second peak 2 to 3 days later; and approximately 14 days after dosing, the concentration slowly declines over the subsequent month.<sup>4</sup>

Methylnaltrexone is a quaternary amine methylated derivative of naltrexone that is peripherally restricted because of its poor lipid solubility and limited ability to cross the blood–brain barrier.<sup>99</sup> After SC administration, peak serum concentrations occur in about 30 minutes. The drug has a  $V_d$  of 1.1 L/kg and is minimally protein bound (11%–15%). Although there are several metabolites, 85% of the drug is eliminated unchanged in the urine.<sup>99</sup>

Naloxegol is an orally bioavailable, pegylated derivative of naloxone. Pegylation reduces its ability to cross the blood–brain barrier and allows its removal by the P-glycoprotein efflux pump. Peak serum concentration occurs at about 2 hours. Elimination is primarily through CYP3A4 metabolism, and the half-life is 6 to 11 hours.

## Pharmacodynamics

In the proper doses, pure opioid antagonists reverse all of the effects at the mu, kappa, and delta receptors of endogenous and exogenous opioid agonists. Buprenorphine, a partial agonist that behaves clinically like an antagonist in opioid dependent people, has a very high affinity for and slow rate of dissociation from the mu receptor.<sup>65</sup> Actions of opioid agonists that are not mediated by interaction with opioid receptors, such as direct mast cell liberation of histamine and the potassium channel blocking effects of methadone, are not reversed by these antagonists.<sup>5</sup> Chest wall rigidity from rapid fentanyl infusion is usually reversed with naloxone.<sup>19</sup> Opioid-induced seizures in animals, such as from propoxyphene, are antagonized by opioid antagonists, although seizures caused by meperidine (normeperidine) and tramadol are not.<sup>33</sup> The benefit of naloxone for opioid-induced seizures in humans is less clear. A report of two newborns

who developed seizures associated with fentanyl and morphine infusion demonstrated abrupt clinical and electroencephalographic resolution after administration of naloxone.<sup>22</sup>

Opioids operate bimodally on opioid receptors.<sup>20</sup> At very low concentrations, mu opioid receptor agonism is excitatory and increases pain. This antianalgesic effect of opioids is modulated through a  $G_s$  protein and usually is less important clinically than the well-known inhibitory actions that result from coupling to a  $G_o$  protein at usual analgesic doses. For this reason, extremely low doses of opioid antagonists (ie, 0.25 mcg/kg/h of naloxone) enhance the analgesic potency of opioids, including morphine, methadone, and buprenorphine.<sup>21,32</sup> Naloxone also attenuates or prevents the development of tolerance and dependence.<sup>32</sup> Coadministration of these very low doses of antagonists with the opioid also limits opioid-induced adverse effects such as nausea, vomiting, constipation, and pruritus.<sup>99</sup>

Opioid antagonists reverse the effects of endogenous opioid peptides, including endorphins, dynorphins, and enkephalins with variable effectiveness. Endogenous opioids are found in tissues throughout the body and work in concert with other neurotransmitter systems to modulate many physiologic effects.<sup>29,84</sup> For instance, during shock, the release of circulating endorphins produces an inhibition of central sympathetic tone by stimulating kappa receptors within the locus coeruleus, resulting in vasodilation. Vagal tone is also enhanced through stimulation of opioid receptors in the nucleus ambiguus. Naloxone continues to be explored in resuscitation from cardiac arrest,<sup>71</sup> which appears to be related to its effects at the delta-opioid receptor. The data do not support its routine administration at this time.<sup>55,64</sup>

## ROLE IN OPIOID TOXICITY

Naloxone use by medical personnel for the management of patients with opioid toxicity has evolved over the past 50 years. Initial studies found the use of naloxone to be relatively safe and highly effective in awakening opioid-toxic patients.<sup>43,97</sup> Although once recommended to be administered empirically to nearly every patient with a depressed level of consciousness and respiratory depression,<sup>41</sup> as complications of precipitated opioid withdrawal in opioid-dependent patients became more apparent, such aggressive use diminished dramatically.<sup>9</sup> Currently, the empiric parenteral dose that we recommend for all opioid-dependent patients is 0.04 mg,<sup>18</sup> although in non-dependent patients, higher doses are administered without concern for precipitating withdrawal. The goal of reversal of opioid toxicity is to improve the patient's ventilation while avoiding withdrawal (see later discussion).

Take-home naloxone distribution and naloxone prescribing for bystander administration in addition to programs for nonmedical first responders continue to significantly expand around the world.<sup>90</sup> The majority of the naloxone available for community-based use is intended for administration by the intranasal route.<sup>3,7</sup> Increasing the availability of naloxone leads to an increased rate of reversal from opioid-induced unresponsiveness, although the absolute numbers and rates of preventing death are unknown.<sup>94</sup> However, debates exist on best approaches to this public health attempt at harm reduction (see Adverse Effects and Safety Issues). See further discussion in Special Considerations: SC6 on harm reduction.

## ROLE IN MAINTENANCE OF OPIOID ABSTINENCE

Opioid dependence is managed either by substitution of the primary opioid, typically heroin or a prescription opioid, with methadone or buprenorphine or by detoxification and subsequent abstinence. Maintenance of abstinence is facilitated by the administration of daily or depot formulations of naltrexone.<sup>74</sup> This is of particular importance in patients whose opioid tolerance has waned because of abstinence, whether voluntary or forced, such as in the immediate period after incarceration.<sup>50</sup>

Before naltrexone is administered for abstinence maintenance, the patient must be weaned from opioid dependence and be a willing participant. Naloxone should be administered intravenously to confirm that the patient is no longer opioid dependent and is therefore safe for naltrexone administration. With naloxone, opioid withdrawal, if it occurs, will be short

lived instead of prolonged as it is after the administration of naltrexone. Prolonged treatment with naltrexone (and naloxone) results in upregulation and supersensitivity of opioid receptors.<sup>75</sup> Although the clinical implications are undefined, concern should be heightened for enhanced clinical response to an opioid after resumption of opioid use in patients who discontinue naltrexone therapy.

## ROLE IN ETHANOL ABSTINENCE

Naltrexone, particularly the IM depot form, is used as adjunctive therapy in ethanol dependence based on the theory that the endogenous opioid system modulates ethanol intake.<sup>13,81</sup> Naltrexone reduces ethanol craving, the number of drinking days, and relapse rates.<sup>52,68</sup> Naltrexone induces moderate to severe nausea in 15% of patients, possibly as a result of alterations in endogenous opioid tone induced by prolonged ethanol ingestion.

## OTHER USES

Poorly orally bioavailable opioid antagonists (eg, naloxone) and peripherally restricted opioid antagonists (eg, methylnaltrexone) are used to prevent or treat the constipation occurring as a side effect of opioid use, whether for pain management or addiction therapy.<sup>11</sup> Evacuation resulted from methylnaltrexone, within 4 hours, and naloxegol, within 6 hours, but the beneficial effect was small by absolute standards, and the drugs are expensive.<sup>15,80</sup>

Opioid antagonists are sometimes used in the management of overdoses with nonopioids such as ethanol,<sup>25</sup> clonidine,<sup>73</sup> captopril,<sup>86</sup> and valproic acid.<sup>79</sup> In none of these instances is the reported improvement as dramatic or consistent as in the reversal of an opioid. The mechanisms for each of these, although undefined, is suggested to relate to reversal of endogenous opioid peptides at opioid receptors.

Naloxone was used to reverse the effects of endogenous opioid peptides in patients with septic shock, although the results were variable.<sup>24</sup> Treatment is often ineffective and will result in adverse effects in patients who are opioid tolerant.

Opioid antagonists at low doses are used for treatment of morphine-induced pruritus resulting from systemic or epidural exposure and for treatment of pruritus associated with cholestasis.<sup>61,66</sup>

## ADVERSE EFFECTS AND SAFETY ISSUES

Pure opioid antagonists produce no clinical effects in opioid-naïve or non-dependent patients even when administered in massive doses (grams) in a spinal cord injury study.<sup>10</sup> Although in another study when naloxone was administered to opioid-naïve patients in large doses (2 mg/kg), a variety of symptoms, including anxiety, difficulty concentrating, sadness, irritability, sweating, and GI manifestations were reported.<sup>2</sup> Some of these findings lasted for a few days.

When patients dependent on opioid agonists are exposed to opioid antagonists, agonist-antagonists, or partial agonists, they exhibit opioid withdrawal, including yawning, lacrimation, diaphoresis, rhinorrhea, piloerection, mydriasis, vomiting, diarrhea, myalgias, mild elevations in heart rate and blood pressure, and insomnia. Antagonist-precipitated withdrawal also sometimes results in an “overshoot” phenomenon, from a transient increase in circulating catecholamines, resulting in hyperventilation, tachycardia, and hypertension.<sup>47</sup>

Under these circumstances, there is a potential for related withdrawal-related complications. In the cardiovascular system, myocardial ischemia and infarction, myocardial stunning (takotsubo, stress cardiomyopathy), heart failure, hypertension, and dysrhythmia are rarely reported.<sup>46</sup> In the CNS, agitation should be expected and is occasionally profound, and seizures, although rare, may occur. Delirium, although rarely reported in patients withdrawing because of opioid abstinence, occur during precipitated opioid withdrawal.<sup>35</sup>

In the lungs, case reports describe acute respiratory distress syndrome (ARDS) in association with naloxone administration, almost uniformly in opioid-dependent patients.<sup>67,72</sup> The clinical complexities of the setting make

it difficult to analyze and attribute these adverse effects solely to naloxone.<sup>12</sup> Adult respiratory distress syndrome occurs after heroin overdose in the absence of naloxone,<sup>27</sup> making the exact contribution of naloxone unclear. Rather, in certain patients, naloxone likely unmasks ARDS previously induced by the opioid but unrecognized because of the patient's concomitant opioid-induced respiratory depression.

If the patient's airway is unprotected during withdrawal and vomiting occurs, aspiration pneumonitis may complicate the recovery.<sup>17</sup> Given the frequency of polysubstance abuse and overdose associated with altered consciousness, the risk of precipitating withdrawal-associated vomiting should always be a concern.

These severe manifestations of precipitated opioid withdrawal also occur with ultra-rapid opioid detoxification and are associated with fatalities occurring in the postdetoxification period.<sup>39</sup> This rapid form of deliberate detoxification differs significantly from the opioid withdrawal associated with volitional opioid abstinence (Chap. 14).

Many of the adverse effects observed in patients with precipitated opioid withdrawal are the result of excessive circulating catecholamines. The catecholamine response to naloxone is significantly greater in dogs with hypercapnia compared with those that are normocapnic or hypocapnic.<sup>59</sup> Although not studied in humans, this highlights the potential ability of manual ventilation before the administration of naloxone to ameliorate the aforementioned complications.

Resedation is a function of the relatively short duration of action of the opioid antagonist compared with the opioid agonist. Most opioid agonists have durations of action longer than that of naloxone and shorter than that of naltrexone (with the exception of methadone). A long duration of action is advantageous when the antagonist is used to promote abstinence (naltrexone) but is undesired when inappropriately administered to an opioid-dependent patient (see Observation Period After Antagonist Administration).

Unmasking underlying cocaine or other stimulant toxicity may explain some of the cardiac dysrhythmias that develop after naloxone-induced opioid reversal in a patient simultaneously using both opioids and stimulants (Chaps. 73 and 75).<sup>58</sup>

Antagonists stimulate the release of hormones from the pituitary, resulting in increased concentrations of luteinizing hormone, follicle-stimulating hormone, and adrenocorticotrophic hormone and stimulate the release of prolactin in women.<sup>69</sup>

## Observation Period After Antagonist Administration

What constitutes an appropriate observation period after antagonist administration depends on many factors. After IV bolus naloxone at doses less than 2 mg, observation for 2 hours is typically adequate to determine whether sedation and respiratory depression will return as the naloxone effect diminishes and the initial opioid effects return. Therefore, although the matched pharmacokinetics of heroin and naloxone suggest potential utility for this practice, the high frequency of methadone, extended-release prescription opioids, transdermal fentanyl, and novel opioids such as the fentanyl derivatives in many communities raises concern for this practice.<sup>49</sup> That is, the pharmacokinetic mismatch between naloxone and these other opioids would expectedly result in recurrent opioid toxicity from long acting and extended release opioids.<sup>88</sup>

Although no fatalities were identified in death certificate searches after the rapid prehospital release of patients who were administered naloxone after presumably overdosing with heroin, these studies are limited by the use of heroin primarily, and not methadone, the potential for incomplete follow-up, the low death rate following heroin overdose and the minimization of the nonfatal consequences of resedation.<sup>16,88,95</sup> In clinical practice, it is common for patients with opioid overdose to receive repetitive doses of naloxone, raising questions about the safety of releasing patients before transport.<sup>16,95</sup> Additionally, the benefit of the observation period in the emergency department permits harm reduction education, recognition of suicidal ideation, evaluation and referral for long-term addiction treatment, and initiation of preventive intervention (Chap. 36 and Special Considerations: SC6).

Similarly, patients discontinued from a continuous naloxone infusion or those who received large total initial doses of naloxone by any route, including intranasal, typically necessitate subsequent observation for at least 4 hours, and perhaps 6 hours, to ensure that respiratory depression or sedation does not recur. Observation should be meticulous and include periodic direct assessment of arousability and ventilatory rate and effort, as well as continuous pulse oximetry off supplemental oxygen. Optimally, continuous capnometry should be used.

### Management of Iatrogenic Withdrawal

Excessive administration of an opioid antagonist to an opioid-dependent patient will predictably result in opioid withdrawal. When induced by naloxone, all that is generally required is protecting the patient from harm and reassuring the patient that the effects will be short lived. Supportive care is valuable during the transient withdrawal. After inadvertent administration of naltrexone, the expected duration of the withdrawal syndrome generally mandates the use of pharmacologic intervention.<sup>31,53</sup> Overcoming the opioid receptor antagonism is difficult, but if used in titrated doses, fentanyl or morphine is often successful. Fentanyl has the advantage over morphine of causing less histamine release. Although the use of buprenorphine was only indirectly studied in this role,<sup>83</sup> it has several potential advantages, including high receptor affinity, long duration of action, low risk of oversedation and the possibility of converting to long term buprenorphine treatment. If only moderate withdrawal is present, the administration of metoclopramide, clonidine, or a benzodiazepine is usually adequate.<sup>46</sup>

### PREGNANCY AND LACTATION

Naloxone and naltrexone are pregnancy Category C medications. A risk-to-benefit analysis must be performed for pregnant women, particularly those who are opioid tolerant, and their newborns. Inducing opioid withdrawal in the mother probably will induce withdrawal in the fetus and should be avoided. Similarly, administering naloxone (or naltrexone) to newborns of opioid-tolerant mothers may induce neonatal withdrawal and should be used cautiously (Chaps. 30, 31, and 36).<sup>60</sup>

### DOSING AND ADMINISTRATION

Before administration of naloxone, the patient should receive adequate ventilation to ensure that the patient is not hypercapnic (see Adverse Effects and Safety Issues). The initial dose of antagonist is dependent on the dose of agonist, the amount that reaches the brain, and the relative binding affinity of the agonist and antagonist at the opioid receptors. The presently available antagonists have a greater affinity for the mu receptor than for the kappa or delta receptors. Some opioids, such as buprenorphine, require greater than expected doses of antagonist to reverse the effects at the mu receptor and exhibit a bell-shaped response to naloxone (see later).<sup>85,96</sup> The duration of action of the antagonist depends on many drug and patient variables, such as the dose and the clearance of both antagonist and agonist.<sup>63</sup>

A dose of naloxone 0.4 mg IV will reverse the respiratory depressant effects of most opioids and is an appropriate starting dose in non-opioid-dependent patients. However, this dose in an opioid-dependent patient usually produces withdrawal, which should be avoided if possible. The goal is to produce a spontaneously and adequately ventilating patient without precipitating significant or abrupt opioid withdrawal. Therefore, 0.04 mg IV is a reasonable starting dose in most patients, with incremental increases by 0.04 mg, while supporting the patient's ventilation and oxygenation, up to a dose of 0.12 mg. The readily available 0.4 mg/mL formulation of parenteral naloxone can be diluted with 9 mL of 0.9% sodium chloride for a total volume of 10 mL, yielding a concentration of 0.04 mg/mL. In those without response, increasing by 0.2 or 0.4 mg up to a dose of 2 mg is a reasonable approach.<sup>9</sup> Dosing beyond 2 mg for those who have an opioid toxidrome is often suggested by 2 mg additional doses, even up to 10 mg,<sup>9</sup> but this is not prospectively validated and rarely required. In situations in which an ultra-potent opioid, often a fentanyl derivative, has been administered, there are reports of response after very large naloxone doses of 10 mg. Whether this

is due to the relatively large dose or unique receptor kinetics of these opioids is unknown, but this practice seems reasonable. Failure of the patient to respond to 8 to 10 mg of naloxone suggests that a conventional opioid is not responsible for the respiratory depression and sedation, an additional respiratory depressant is present, or the patient has hypoxic encephalopathy. In this latter situation, pupillary dilation may help in the assessment.

The dose in children without opioid dependence is essentially the same as for adults (ie, 0.1 mg/kg to the adult dose of 2 mg). However, for those with opioid dependence and the possibility of precipitated withdrawal or recrudescence of severe underlying pain, a more gentle reversal with 0.04 mg, with concomitant supportive care, is warranted. Although both the adult and pediatric doses recommended here are lower than those conventionally suggested in other references, the availability of safe and effective interim ventilatory therapy permits these lower doses and lowers the acceptable risk of precipitating withdrawal (Chaps. 4 and 36).

When 1 mg of naloxone is administered IV, it prevents the action of 25 mg of IV heroin for 1 hour; 50 mg of oral naltrexone antagonizes this dose of heroin for 24 hours, 100 mg of oral naltrexone has a blocking effect for 48 hours, and 150 mg of oral naltrexone is effective for 72 hours.<sup>54</sup>

The use of low doses of IV naloxone to reverse opioid overdose prolongs the time to improvement of ventilation, and during this period, assisted ventilation is appropriate. The same limitation exists with SC naloxone administration, and the absorbed dose is more difficult to titrate than when administered IV.<sup>91</sup> Naloxone is also administered intranasally, although this route results in the delivery of unpredictable doses. In the prehospital setting, the time to onset of clinical effect of intranasal naloxone is comparable to that of IV or IM naloxone, largely because of the delay in obtaining IV access and slow absorption, respectively.<sup>6,44</sup> Intranasal naloxone is not recommended as first-line treatment by health care providers in hospitals but is reasonable for prehospital providers when other routes of administration are unavailable or undesirable.<sup>45</sup> Nebulized naloxone (2 mg is mixed with 3 mL of 0.9% sodium chloride solution) has similar limitations in dose accuracy and is further limited in patients with severe ventilatory depression, the group most in need of naloxone. Although reports suggest successful use of nebulized naloxone, patients with opioid overdose are not optimal candidates for inhalation therapy because of both the poor respiratory effort and to the likelihood of over- or underdosing of naloxone.<sup>92</sup> Although needleless delivery is a clear prehospital advantage,<sup>56</sup> the lack of the ability to titrate substantially reduces the usefulness of intranasal or nebulized naloxone in the hospital.

Evaluation for the redevelopment of respiratory depression after naloxone administration requires nearly continuous monitoring. This is significantly more likely to occur after an extended-release or long-acting opioid and is increasingly a concern with the unique fentanyl derivatives that currently appear as adulterants in the illicit opioid supply.<sup>78</sup> Resedation should be treated with either repeated dosing of the antagonist or, in some cases, such as after a long-acting opioid agonist, with another bolus followed by a continuous infusion of naloxone.<sup>78</sup> Two-thirds of the total bolus dose of naloxone that resulted in reversal, when given hourly, usually maintains the desired effect.<sup>36</sup> Titration upward or downward is easily accomplished as necessary to both maintain adequate ventilation and avoid withdrawal. A continuous infusion of naloxone is not a substitute for continued vigilance. A period of 12 to 24 hours often is chosen for observation based on the presumed opioid, the route of administration, and the dosage form (sustained release). Body packers are a unique subset of patients who, because of the reservoir of drug in the GI tract, require individualized antagonist management strategies (Special Considerations: SC5).

Use of longer acting opioid antagonists, such as naltrexone, places the patient at substantial risk for protracted withdrawal syndromes. The use of a long-acting opioid antagonist in acute care situations should be reserved for carefully considered special indications, such as unintentional exposures to short acting opioids in nondependent patients, together with extended periods of observation or careful follow-up. An oral dose of 150 mg of naltrexone generally lasts 48 to 72 hours and should be adequate as an antidote for the majority of patients with opioid toxicity.<sup>51</sup> As noted, this drug should not

be administered to a patient with opioid dependence. Discharge of patients with opioid toxicity after successful administration of a long-acting opioid antagonist, although theoretically attractive, is not well studied. There are concerns about attempts by patients to overcome the opioid antagonism by administering high doses of opioid agonist,<sup>39</sup> with subsequent respiratory depression as the effect of the antagonist wanes.

Naltrexone is administered orally in a variety of dosage schedules for treatment of opioid dependence. A common dosing regimen is 50 mg/day Monday through Friday and 100 mg on Saturdays. Alternatively, 100 mg every other day or 150 mg every third day can be administered. The IM extended-release suspension is injected monthly at a recommended dose of 380 mg.

Methylnaltrexone SC dosing for opioid-induced constipation is weight based.<sup>98</sup> The dose is 0.15 mg/kg for patients who weigh less than 38 kg and more than 114 kg. For patients who weigh between 38 and less than 62 kg, 8 mg is administered, and for those between 62 and 114 kg, 12 mg is provided. Dosing for patients with stage 4 or 5 chronic kidney disease is established at half the standard recommended dose.

Naloxegol tablets should be swallowed whole and not be crushed or chewed. The daily dose is 25 mg once in the morning at least 1 hour before or 2 hours after a meal, and the dose halved in patients who develop signs and symptoms of opioid withdrawal with the higher dose. The starting dosage for patients with a stage 4 or 5 kidney disease is 12.5 mg once daily.

Alvimopan is approved by the US Food and Drug Administration for the management of postoperative ileus in the hospital setting and is not indicated for outpatient or long-term use. It is contraindicated in patients who have taken opioids for more than 7 days. The dose is 12 mg orally 0.5 to 5 hours preoperatively. The day after surgery, the maintenance dose is 12 mg twice a day. The total maximum number of doses is 15 during hospitalization.

## Buprenorphine

Naloxone reverses the respiratory depressant effects of buprenorphine in a unique dose–response curve.<sup>23,70,85,96</sup> Bolus doses of naloxone of 2 to 3 mg followed by a continuous infusion of 4 mg/h in adults were able to fully reverse the respiratory depression associated with IV buprenorphine administered in a total dose of 0.2 and 0.4 mg over 1 hour.<sup>85</sup> Reversal was not apparent until about 45 to 60 minutes after the infusion. A reappearance of respiratory depression occurred when the naloxone infusion was stopped because the distribution of naloxone out of the brain and its subsequent elimination from the body are much faster than those of buprenorphine. Consistent with the unique response curve, doses of naloxone greater than 4 mg/h actually led to the redevelopment of respiratory depression. It is postulated that buprenorphine has differential effects on the mu opioid receptor subtypes (Chap. 36), with agonist activity at low doses and antagonist action at high doses. Therefore, excess naloxone antagonizes the opioid antagonistic effects of high dose buprenorphine and worsens the respiratory depression.

Interestingly, there is support for the use of buprenorphine to manage patients with opioid overdose.<sup>93,100</sup> Perhaps not surprisingly, the antagonistic effects of buprenorphine are not dose related, and the maximal effects occurring at 1 mg IM (which equates to about 0.4 mg sublingually).<sup>77</sup> Given the partial agonist effects of buprenorphine, the resulting withdrawal syndrome is less severe than that after a pure opioid antagonist.<sup>77</sup> This practice requires additional study before recommending its use.

## FORMULATION AND ACQUISITION

Naloxone (Narcan) for IV, IM, or SC administration is available in concentrations of 0.4 and 1 mg/mL, with and without parabens in 1- and 2-mL ampoules, vials, and syringes and in 10-mL multidose vials with parabens. Naloxone is frequently diluted in 0.9% sodium chloride solution or 5% dextrose to facilitate continuous IV infusion. Naloxone is stable in 0.9% sodium chloride solution at a variety of concentrations for up to 24 hours. An auto-injector containing 2 mg of naloxone is available. Intranasal formulations vary and include the use of the 1-mg/mL solution with a mucosal atomizer device (MAD) and a 2-mg/0.1 mL (20 mg/mL concentration) and 4-mg/0.1 mL (40 mg/mL concentration) naloxone administration device.

Naltrexone is available as a 50-mg capsule-shaped tablet. It is also available as a 380-mg vial for reconstitution with a carboxymethylcellulose and polysorbate diluent to form an injectable suspension intended for monthly IM administration.<sup>4</sup>

Methylnaltrexone is available as a 12-mg/0.6-mL solution for SC injection.<sup>67</sup>

Naloxegol is available as an oral tablet, in 12.5 mg and 25 mg strengths.

## SUMMARY

- Naloxone and naltrexone are pure competitive opioid antagonists at the mu ( $\mu$ ), kappa ( $\kappa$ ), and delta ( $\delta$ ) receptors.
- Methylnaltrexone (parenteral) and naloxegol (oral) are peripherally acting opioid antagonists used to counteract opioid induced constipation and do not have CNS effects except in overdose.
- Naloxone is the primary opioid antagonist used to reverse respiratory depression in patients manifesting opioid toxicity.
- A titrated low-dose method of IV administration, starting at 0.04 mg in an adult, limits withdrawal-induced adverse effects, such as vomiting and the potential for aspiration pneumonitis, and a surge in catecholamines with the potential for cardiac dysrhythmias and ARDS.
- Naltrexone is used orally for patients after opioid detoxification to maintain opioid abstinence and as an adjunct to achieve ethanol abstinence. It is used in specific circumstances to prevent recurrent opioid toxicity in nondependent patients with otherwise uncomplicated opioid overdoses.
- Intranasal naloxone is increasingly used by bystanders for the emergency reversal of patients with opioid-induced CNS and respiratory depression.
