Treatment of sponge exposures usually requires only removal of spicules using adhesive tape or the edge of a credit card. Antihistamines and topical corticosteroids often provide no relief from stinging sponges.<sup>15</sup>

## VERTEBRATES

### Snakes

Sea snakes are elapids and are divided into 2 subfamilies: Hydrophiinae and Laticaudinae. They are close relatives of the cobra and krait. Length typically does not exceed 1 m. Their tails are flattened, and their bodies often are brightly colored. Distinction from eels is made by the presence of scales and the absence of fins and gills. All 52 species of sea snakes are venomous and at least 6 species are implicated in human fatalities. The most common species cited in human envenomation are *Enhydrina schistosa*, the beaked sea snake, and *Pelamis platurus*, the yellow-bellied sea snake.

### Epidemiology

Sea snakes are common to the tropical and temperate Indian and Pacific Oceans, but they are also found along the eastern Pacific Coast of Central and South America and the Gulf of California. In the eastern Pacific region, the yellow-bellied sea snake is the only species known. There are no venomous sea snakes in the Atlantic Ocean or Mediterranean. Sea snakes come ashore to replenish somatic water stores with fresh water.<sup>86</sup> The majority of envenomations occur along the coasts of Southeast Asia, the Persian Gulf, and the Malay Archipelago (Malaysia). Snakes tend to inhabit the turbid coastlines and deeper reefs of these regions. Workers of the fishing industry are at greatest risk as snakes frequently get trapped in fishing nets. Sea snakes generally are docile, except when provoked, or during the mating season. Two species, the Stokes' sea snake (*Astoria stokesii*) and Beaked sea snake (*Enhydrina schistosa*), are known for aggression.

The true incidence of sea snake envenomation is unknown because many bites are not recorded. Worldwide, the number of deaths per year approaches 150, with an overall mortality rate estimated between 3.2% and 30%.<sup>144</sup> In a review of 120 documented bites, 51.7% of victims were fishermen handling nets.<sup>121</sup> The remainder of victims were wading or swimming along the coastline. In a review of 101 bites occurring from 1957 to 1964 in Northwest Malaysia, more than 50% of bites were from the beaked sea snake, including 7 of the 8 fatal bites in that series, bringing the mortality to 8% prior to the availability of antivenom.<sup>122</sup> However, 31 "dry bites" were excluded, suggesting that the overall mortality is somewhat lower. Among the 20% of patients in that series suffering "serious envenomation," half died despite supportive care. A follow-up series of patients after the introduction of antivenom described 2 deaths out of 11 "serious envenomations," suggesting a decreased mortality resulting from this intervention. These were all retrospective reviews of published or personally communicated cases.

### Pathophysiology

All sea snakes have small front fangs. Their venom is neurotoxic, myotoxic, nephrotoxic, and hemolytic. Known components of the venom include acetylcholinesterase, hyaluronidase, leucine aminopeptidase, 5'-nucleotidase, phosphodiesterase, and phospholipase A. The neurotoxin is a highly stable 6,000- to 8,000-Da protein similar to that of cobra and krait venom. The low molecular weight of sea snake toxins allows for high penetrance of membrane barriers.<sup>145</sup> In mice, beaked sea snake venom is 4 to 5 times more potent than cobra venom based on a microgram-per-kilogram ratio; however, cobra venom yield is greater.<sup>26</sup> Venom homology exists across many species. The neurotoxin targets postsynaptic acetylcholine (ACh) receptors, creating a blockade at the neuromuscular junction.<sup>143</sup> Presynaptic effects include initial enhanced ACh release and subsequent inhibition of ACh release.<sup>157</sup> In vitro research confirms direct nephrotoxicity of crude venom and partially explains the nephrotoxicity described clinically.<sup>134</sup> Rhabdomyolysis likely contributes to this clinical finding.

### Clinical Manifestations

Bites typically are painless or inflict minimal discomfort initially despite significant envenomation as venom contains few inflammatory or necrotic factors.<sup>81</sup> Between one and 4 fang marks are common; however, up to 20 fang marks are possible as a result of multiple bites. The diagnosis often is obscured because victims do not associate the slight prick following the bite with later onset of ascending paralysis. Symptoms progress within minutes, although a delay of up to 6 hours is possible. Painful muscular rigidity and myoglobinuria are hallmarks of sea snake myotoxicity. Myoglobinuria develops between 30 minutes and 8 hours after the bite. This is followed by ascending paralysis from acetylcholine receptor blockade by the neurotoxic venom fraction and muscle destruction from myotoxic fraction. Massive potassium release from damaged muscle tissue coupled with impaired kidney function from myoglobin nephropathy predisposes to fatal dysrhythmias. Other classic symptoms include dysphagia, trismus, ptosis, aphonia, nausea, vomiting, fasciculations, and ultimately respiratory insufficiency, seizures, and coma.

### Diagnostic Testing

Laboratory diagnostics are directed toward identifying hemolysis, myonecrosis, hyperkalemia, and acute kidney injury. Serum electrolytes, creatinine, and creatine phosphokinase, as well as hematocrit and urinalysis, should be obtained. Elevated concentrations of hepatic enzymes indicate severe envenomation. Serial measurement of these parameters is recommended. Testing for serum concentrations of venom is not routinely available. Electromyography (EMG) often shows myopathic features for several weeks after envenomation.<sup>81</sup> Muscle biopsy, although not typically needed for diagnosis, shows myonecrosis in up to 60% of muscle mass.<sup>81</sup>

### Management

Prehospital management of sea snake bites mirrors treatment of terrestrial snakebites (Chap. 119) and includes immobilization of the extremity and consideration of a pressure immobilization bandage to impede lymphatic drainage. Currently no data regarding the efficacy of this technique for sea snake envenomations are available. Tourniquets that impede venous or arterial flow are not recommended. Airway and respiratory effort require close monitoring because paralysis develops rapidly.

Currently, only one antivenom specific to sea snake bites is available, produced by Commonwealth Serum Laboratories (CSL). The equine IgG Fab fragments are produced using the venom of beaked sea snake (*E. schistosa*) or terrestrial tiger snake (*Notechis scutatus*) (Table 116–3). In vitro experiments demonstrate that CSL sea snake antivenom is effective for neutralizing all species of sea snakes tested (*Praescutata viperina* in Thailand, *Pelamis platurus* in Central America, *Laticauda semifasciata* in the Philippines, *Laticauda laticaudata* in Japan, *Hydrophis cyanocinctus*, *Lapemis hardwickii*).<sup>153</sup> Optimal neutralization occurs within the subfamily Hydrophiinae, which contains *E. schistosa*; however, effective neutralization is demonstrated within the

**TABLE 116–3 Antivenom, Initial Dosing by Route**

Organism	Intravenous Dosing	Intramuscular Dosing
<i>Box jellyfish</i>		
<i>C. fleckeri</i>	1 vial as 1:10 dilution <sup>a</sup>	3 vials (undiluted)
<i>Sea snake</i>		
<i>E. schistosa</i> (beaked sea snake)	1–3 vials as 1:10 dilution, <sup>a</sup> up to 10 vials in severe cases	Not recommended
<i>N. scutatus</i> (terrestrial tiger snake)	1 vial as 1:10 dilution <sup>a</sup>	Not recommended
<i>Stonefish</i>		
<i>S. trachynis</i>	1 vial as 1:10 dilution, <sup>a</sup> high risk of anaphylactoid reaction	1 vial (undiluted) for every 2 punctures

<sup>a</sup>Dilution in pediatric patients 1:5 to avoid volume overload.

subfamily Laticaudinae. Commonwealth Serum Laboratories sea snake antivenom is relatively costly and requires continuous refrigeration during transport and storage. No controlled human trials have evaluated the efficacy of CSL sea snake antivenom, although case reports suggest improved outcomes and more rapid recovery with its use.<sup>105,122</sup> Anecdotal experience in Malaysia using CSL sea snake antivenom suggests slow recovery from myalgias and weakness over 48 hours, compared with resolution over 2 weeks without antivenom (2 cases, one control).<sup>120</sup>

In the event that sea snake antivenom is not available, several other treatment options exist because of the potential cross-reactivity of certain terrestrial antivenoms with sea snake venom. A murine rescue trial found Thai neuro polyvalent antivenom (NPAV) to be equipotent compared with Australian CSL sea snake antivenom after envenomation by the beaked sea snake or the spine-bellied sea snake (*Hydrophis curtus*).<sup>145</sup> Terrestrial tiger snake antivenom also neutralizes sea snake venom in vitro. Based on the volume of antivenom required, tiger snake antivenom was superior for neutralization of all sea snake venoms tested except that of the beaked sea snake, for which CSL sea snake antivenom was more effective.<sup>7</sup> In contrast to volume comparisons, measurements of unit dosing demonstrate CSL sea snake antivenom is more effective for all venoms tested. Another in vitro study comparing tiger snake and CSL sea snake antivenom against venom *E. schistosa* demonstrated tiger snake antivenom was 10 times more effective in terms of milligram of venom neutralized per milliliter of antivenom.<sup>106</sup> In the same study, the use of 17 different types of elapid antivenom resulted in poor neutralization of beaked sea snake venom.

In rescue experiments with mice using 11 sea snake venoms and 4 different antivenoms (*E. schistosa*, *E. schistosa-N. scutatus*, *N. scutatus*, and polyvalent sea snake *L. hardwickii*, *L. semifasciata*, *H. cyanocinctus*), tiger snake antivenom was superior to all others with respect to volume amount required to prevent death.<sup>2,8,62</sup> Another finding of the study was improved efficacy with early administration of antivenom.

Based on in vitro and in vivo research, selection of the optimal antivenom for treatment of sea snake bites is unclear. CSL sea snake antivenom, tiger snake antivenom, and NPAV are effective in neutralizing a wide variety of sea snake venoms. Therefore, the most readily available antivenom should be used when needed. The manufacturer's guidelines for use of monovalent CSL sea snake antivenom recommend administration of one vial (1,000 units) for systemic symptoms. However, because symptoms are often delayed and early administration is more likely to result in venom neutralization, antivenom is recommended if there is any evidence of envenomation. The antivenom requires a 1:10 dilution with 0.9% sodium chloride solution followed by intravenous administration over 30 minutes. A 1:5 dilution can be used for small children. Skin testing is not recommended. Epinephrine and antihistamines should be readily available. No upper limit is suggested for the number of vials to administer, although larger amounts are more likely to result in serum sickness. Patients have received up to 7 vials without adverse effect directly attributable to the antivenom.<sup>105</sup> Administration of one vial

(3,000 units) of tiger snake antivenom is an alternative if CSL sea snake antivenom is unavailable. Other treatments should focus on wound care, tetanus prophylaxis, analgesia, and fluid administration to minimize nephrotoxicity from myoglobinuria.

## Fish

Several fish utilize defensive venoms. Stingrays and spiny fish are known to pose a threat to fishermen, surfers, swimmers, waders, and divers. Although rare, death is typically the result of mechanical trauma rather than toxicological effects of venom, as was the case in the death of animal activist Steve Irwin. Stingrays are members of the class Chondrichthyes (order Rajiformes: skates and rays). Families include Dasyatidae (whip ray or sting ray), Urolophidae (round ray), Myliobatidae (batfish or eagle ray), Gymnuridae (butterfly ray), and Potamotrygonidae (river ray, freshwater).

Spiny fish of the family Scorpaenidae include a variety of venomous creatures (Table 116-4). Fish of the genus *Pterois* are commonly called lionfish (*P. volitans* and *P. lunulata*). Stonefish are grouped under the genus *Synanceja* and include *S. trachynis* (Australian estuarine stonefish), *S. horrida* (Indian stonefish), and *S. verrucosa* (reef stonefish). Stonefish display a mottled color and are covered in mucus that allows for growth of algae, making them well camouflaged among rocks and reefs (Fig. 116-4). Scorpionfish have a similar appearance and belong to the genus *Scorpaena* (eg, *S. guttata*: California sculpin). Other Scorpaenidae include *Notesthes robusta* (bullrout) and *Gymnapistes marmoratus* (cobble). The European weeverfish produce toxicity similar to members of Scorpaenidae and are classified under the family Trachinidae. This includes *Trachinus vipera* (lesser weever) and *Trachinus draco* (greater weever, aka adderpike, stingfish, seacat). These bottom dwellers are smaller and have fewer spines than Scorpaenidae and are much less ghoulish in appearance. Catfish also envenomate humans. Although most live in freshwater, marine catfish such as *Plotosus lineatus* can inflict injury. Other venomous spiny fish include rabbitfish, stargazers, toadfish, ratfish, and even some sharks that have spines on their dorsal fins (Port Jackson shark, dogfish shark).

Latin Name	Common Name	Habitat (Coastal Waters)
<b>Scorpaenidae family</b>		
<i>Pterois</i>		
<i>P. volitans</i>	Lionfish (also zebrafish, turkeyfish, or red firefish)	Indo-Pacific region, Florida to North Carolina (nonnative to US coast)
<i>P. lunulata</i>	Lionfish or butterfly cod	
<i>Synanceja</i>		
<i>S. trachynis</i>	Australian estuarine stonefish	Indo-Pacific region (Pacific and Indian Oceans)
<i>S. horrida</i>	Indian stonefish	
<i>S. verrucosa</i>	Reef stonefish	
<i>Scorpaena</i>		
<i>S. cardinalis</i>	Red rock cod, scorpionfish	Australia
<i>S. guttata</i>	California sculpin, scorpionfish	California
<i>Notesthes robusta</i>	Bullrout	Australia
<i>Gymnapistes marmoratus</i>	Cobbler	Australia
<b>Trachinidae family</b>		
<i>Trachinus</i>		
<i>T. vipera</i>	Lesser weeverfish	Great Britain to Northwest Africa, throughout
<i>T. draco</i>	Greater weeverfish (also adderpike, stingfish, or seacat)	Mediterranean and Black Seas

## Epidemiology

There are 11 different species of stingrays in US coastal waters (7 in the Atlantic, 4 in the Pacific). In the southeastern United States, *Dasyatis americana* is a common inhabitant. *Urolophus halleri* is the most common species on the western coast of the United States. Some estimates suggest 1,500 to 2,000 stingray injuries occur yearly in the United States. Most envenomations occur when the animal is inadvertently stepped on. In one review, a total of 17 fatalities resulting from trunk wounds, hemorrhage, or tetanus were identified worldwide.<sup>45</sup> Another review of 603 cases of stingray injuries identified 2 deaths resulting from intraabdominal trauma.<sup>127</sup>

Three populations are at highest risk for spiny fish envenomation: fishermen sorting the catch from nets, waders, and aquarium enthusiasts. Only 5 deaths from Scorpaenidae are reported; all resulted from stonefish and are poorly documented.<sup>36</sup> No deaths from stonefish are reported in Australia, a country where they are commonly found in coastal waters.<sup>38</sup> The incidence of weeverfish stings is unknown, but they are a common occurrence in the summertime among Italian coastal towns.<sup>25,137</sup> Scorpaenidae inhabit waters throughout the tropical and temperate oceans. They exist as far north as the Gulf of Oman and Southern Japan and extend south beyond New Zealand. In the United States, Scorpaenidae stings occur in the Florida Keys, in the Gulf of Mexico, off the coast of California, and in Hawaii.

**FIGURE 116-5.** (A) The lionfish, *Pterois volitans*. (B) This patient's hand was envenomated by his pet lionfish while cleaning his aquarium. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

Lionfish (genus *Pterois*) (Fig. 116-5) are common to home aquariums and account for most poison control center calls involving spiny fish envenomation in the United States. The bullrout inhabits the eastern coast of Australia, along with the cobbler, which is found only in Australia. Weeverfish inhabit shallow temperate waters with sandy or muddy bottoms in the eastern Atlantic and Mediterranean, including the European Coast extending to the southern tip of Norway.<sup>24</sup> The marine catfish lives in the tropical Indo-Pacific waters.

### Pathophysiology

Tapered, bilaterally retroserrated spines covered by an integumentary sheath emanate from the stingray tail. The ventrolateral groove contains venom glands that saturate the spine with venom and mucus. Puncture of the victim disrupts the integrity of the integument overlying the stinger. This releases the venom which contains several amino acids, serotonin, 5'-nucleotidase, and phosphodiesterase.<sup>5</sup> In animal models, venom induces local vasoconstriction, bradycardias, atrioventricular nodal block, subendocardial ischemia, seizures, coma, cardiovascular collapse, and death.<sup>4,127</sup> A rabbit model demonstrates initial vasodilation followed by vasoconstriction and cardiac standstill, suggesting a direct cardiac effect.<sup>128</sup> Wound specimens reveal necrotic muscle and neutrophilic infiltrates.<sup>6</sup> Other reports show central hemorrhagic necrosis with surrounding lymphoid and eosinophilic infiltrates indicating an immune-mediated cause of delayed wound healing.<sup>64</sup>

Scorpaenidae have 12 to 13 dorsal, 2 pelvic, and 3 anal spines that are covered with an integumentary sheath. Glands at the base contain 5 to 10 mg of venom each; the amount of venom released is proportional to the pressure applied to the spine. Ornate pectoral fins are not venomous. Venom can remain stable for 24 to 48 hours after the fish dies.<sup>101</sup> Three main toxins are isolated from various species of stonefish: stonustoxin (SNTX), verrucotoxin (VTX), and trachynilysin (TLY). SNTX, from *S. horrida*,<sup>65</sup> has 2 subunits,  $\alpha$  and  $\beta$  (71,000 and 79,000 Da, respectively). It induces formation of hydrophilic pores in cell membranes.<sup>29</sup> Toxicity in animals includes hemolysis, local edema, vascular permeability, platelet aggregation, endothelium-dependent vasodilation, and hypotension. Decreased myocardial contractility occurs in rabbits.<sup>132</sup> Heating stonefish venom to 122°F (50°C) for 5 minutes prevents wound necrosis and hypotension in animal models.<sup>159</sup> Verrucotoxin, isolated from *S. verrucosa*, shares homology with SNTX in that both block cardiac Ca<sup>2+</sup> channels.<sup>65</sup> trachynilysin, isolated from *S. trachynis*, is a 159-kDa protein that forms pores in cell membranes. It allows Ca<sup>2+</sup> entry and causes Ca<sup>2+</sup>-dependent release of ACh from nerve endings at motor end plates and increased catecholamine release.<sup>79,113,133</sup> *Synanceja trachynis* venom causes endothelium-dependent vasodilation and cardiovascular collapse in rats, which appears to be mediated by muscarinic and adrenergic receptors.<sup>30</sup> Hemolysis is demonstrated in animals but does not occur in humans.<sup>80</sup> Stonefish venom also contains a powerful hyaluronidase inducing local tissue destruction and systemic absorption of venom. Other venoms of Scorpaenidae include proteinase, phosphodiesterase, alkaline phosphomonoesterase, arginine esterase, arginine amidinase, 5'-nucleotidase, acetylcholinesterase, and biogenic amines. Crude venom from *G. marmoratus*, *P. volitans*, and *S. trachynis* leads to increased intracellular Ca<sup>2+</sup> and muscle contracture in vivo.<sup>33</sup> Toxins from other spiny fish include dracotoxin (*T. draco*), trachinine (*T. vipera*), and nocitoxin (*N. robusta*).<sup>32</sup> Effects mirror those of Scorpaenidae toxins.<sup>137</sup>

### Clinical Manifestations

Stepping on the body of a stingray causes a reflexive whip of the tail leading to wounds in the lower extremity. Intense pain out of proportion to the appearance of the wound is characteristic. Symptoms peak 30 to 90 minutes after injury and may persist for 48 hours. In a retrospective review of cases reported to the California Poison Control System, 9% of victims had retained stingers in their wound, and 9% of wounds became infected.<sup>34</sup> Local edema, cyanosis and ischemia due to vasospasm, erythema, and petechiae follow rapidly. Tissue hypoperfusion results in necrosis and ulceration. Symptoms include weakness, nausea, vomiting, diarrhea, vertigo, headache, syncope, seizures, muscle cramps, fasciculations, hypotension, and dysrhythmias. Chest and abdominal wounds, as well as tetanus, have caused death.<sup>119</sup>

Stings from stonefish produce immediate, severe pain with rapid wound cyanosis and edema that progresses up the injured extremity. Pain reaches a maximum after 30 to 90 minutes and usually resolves over 6 to 12 hours, although some patients experience pain for days. Headache, vomiting, abdominal pain, delirium, seizures, limb paralysis, hypertension, respiratory distress, dysrhythmias, congestive heart failure, and hypotension characterize systemic toxicity.<sup>84</sup> Wound healing requires months.

A poison control center case series from 1979 to 1988 identified 23 cases of *P. volitans* envenomation.<sup>152</sup> Reported symptoms included pain, swelling, nausea, numbness, joint pain, anxiety, headache, dizziness, and cellulitis. Another Poison Control Center series identified 51 Scorpaenidae stings (45 *P. pterois*, 6 *S. guttata*).<sup>77</sup> Intense pain was reported in 98%, extension of pain to the limb in 22%, swelling in 58%, and systemic signs (nausea, diaphoresis, dyspnea, chest pain, abdominal pain, weakness, hypotension, and syncope) in 13%. Thirteen percent of patients in the series developed wound infection; one patient's wound healing was delayed several weeks. Stings from weeverfish are similar to Scorpaenidae envenomation and rarely result in death.<sup>13</sup> Injury from catfish stings is comparable to that of other stinging fish.<sup>39</sup>

### Diagnosis

The most commonly affected area is the lower extremities. Imaging of the affected body part is indicated because of the potential of retained

foreign bodies. Stingray spines are denser than human tissue and easily identified on radiographs. However, if only the sheath of the spine remains in the wound, radiography is unlikely to reveal this foreign body. Ultrasonography is recommended for patients with a negative radiography. Stings from stone fish are associated with compartment syndrome. Compartment pressures should be evaluated for a patient with significant pain, pallor, poikilothermia, paresthesias, or loss of distal pulses. Disparate pulse oximetry measurements between an affected and unaffected extremity herald a developing compartment syndrome.<sup>147</sup>

### Management

Wounds inflicted by stingrays and spiny fish should be carefully examined for imbedded foreign material. Stingray wounds have the potential to be extensive and require surgical attention for vascular or tendinous disruption. Tetanus immune status should be addressed. Prophylactic antibiotics decrease rates of wound infection; a quinolone and cefazolin are the recommended therapy.<sup>35</sup> In a series of 576 stings from stingrays off the Californian coast, 69% of patients reported significant relief of local pain with HWI.<sup>34</sup> In patients undergoing HWI due to stonefish envenomation, antibiotics should be administered early due to the theoretical increased rate of growth of *Vibrio vulnificus* and subsequent necrotizing fasciitis.<sup>146</sup> Although patients occasionally required a single dose of oral or parenteral analgesia, clinicians rarely prescribed analgesics on discharge. In a human volunteer study in which subjects received a subcutaneous injection of stingray venom, severe pain developed immediately, and was alleviated with water heated to 122°F (50°C).<sup>127</sup> Pain increased with application of cold water. Local lidocaine infiltration provides a reasonable alternate modality for pain control.<sup>54</sup> Severe vasospasm can generate limb-threatening ischemia. Infusion of prostaglandin E<sub>1</sub> has resulted in successful salvage of an ischemic leg,<sup>136</sup> but insufficient data exist to recommend this as routine therapy.

Stonefish antivenom, an equine-derived IgG Fab, is raised against the venom of *S. trachynis*. Each vial contains 2,000 units and neutralizes 20 mg venom. Between 1965 and 1981, antivenom was used in at least 267 cases.<sup>38</sup> Anecdotal reports suggest it provides effective relief from pain.<sup>38,158</sup> In a review of 26 documented cases in Australia where antivenom was administered IM, no acute adverse effects were identified.<sup>142</sup> Two of 15 patients who had follow-up visits suffered serum sickness. Rash develops several days postinjection.<sup>158</sup> In vitro and in vivo research with the antivenom demonstrates neutralization of venom from *G. marmoratus*<sup>31</sup> and *P. volitans*<sup>32</sup>; however, the application for human therapy remains untested.

The manufacturer recommends IM administration of stonefish antivenom, and advises against IV administration because of increased risk of anaphylactoid reaction. Administration is indicated for systemic toxicity or refractory pain. The number of puncture wounds guides therapy: one vial for one to two punctures, two vials for three to four punctures, and three vials for five or more punctures. Epinephrine and diphenhydramine should be readily available for treatment of anaphylactic reactions.

### SUMMARY

- Fatalities from marine envenomations are rare. However, significant morbidity results from bites and stings, including severe pain, retained foreign bodies, infection, respiratory compromise, hemodynamic instability, and a variety of other end organ toxicities.
- Special attention is required when treating envenomations inflicted by box jellyfish or sea snakes. These injuries are common and result in serious harm or even death. Knowledge of the clinical manifestations and available antidotes will reduce morbidity.
- A thorough understanding of the mechanisms of toxicity and expected clinical course following envenomations from marine creatures will provide clinicians with the ability to manage these injuries effectively.
- Interventions should focus on patient comfort and recognition of potential complications.
- Hot water immersion provides adequate analgesia for a number of different species of *Cnidaria*, as well as stings from a variety of spiny fish.

The diversity of mushroom species is evident in our grocery stores, our restaurant menus, and our environment. The enhanced culinary interest in mushrooms has led to experimentation by young and old—old citizens and our newest immigrants and our young children reaching for what might become an innocuous (common) or a serious (rare) ingestion. Rigor in analyzing the possible ingestion is indispensable for those treating a patient who has ingested a mushroom of concern. This chapter offers general information on the most consequential toxicologic groups of mushrooms and emphasizes clinical diagnosis over mushroom identification.

### EPIDEMIOLOGY

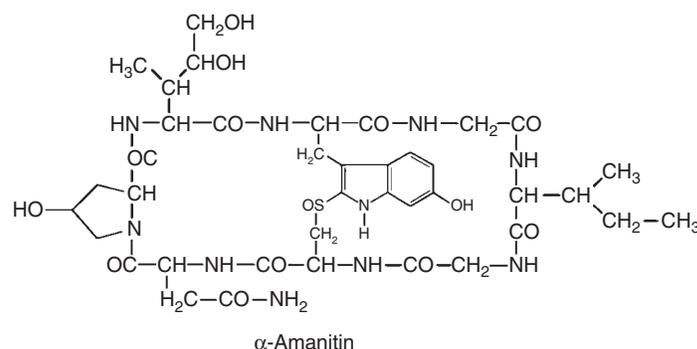

Unintentional ingestions of mushrooms particularly in children represent a small but relatively constant percentage of consultations requested from poison control centers (Chap. 130). A summary of a quarter century of American Association of Poison Control Centers (AAPCC) data reveals that mushrooms represent less than 0.25% of the reported human exposures. Combined data accumulated by the AAPCC and the Mushroom Poisoning Registry of the North American Mycological Association indicates that approximately 5 patient exposures to toxic mushrooms are called into Poison Control Centers or reported to the Registry per 100,000 persons per year. Some variations result from geographic and climatic conditions and mycologic habitats.<sup>141</sup> Although the methods of codification of patients with mushroom exposure have changed over the past 35 years, cumulative AAPCC data consistently demonstrate the relative benignity of the vast majority of exposures. The inability of most health care providers to correctly identify the ingested mushroom and the rarity of lethal outcomes are also demonstrated by the accumulated data. In 75% to 95% of exposures, the exact species was unidentified<sup>141</sup> (Chap. 130). More than 50% of exposed individuals had no symptoms. Most patients were treated at home and rarely had major toxicity. During the 35 years covered by the AAPCC data, fewer than 100 patients died of their mushroom ingestion. Of the mushrooms associated with death, most were *Amanita* spp and several were hallucinogens, *Boletus* spp, or gyromitrin-containing mushrooms, while others remained unidentified. All reported deaths occurred in adults. Those containing either hallucinogens or gastrointestinal (GI) toxins were the most common reported exposures, yet they accounted for less than 10% of all mushroom exposures. All other presumed exposures represented less than 2% of those actually identified. A distinctly different analysis is presented by a retrospective study from the Krakow Department of Medical Toxicology suggesting that following mycological analysis 87% of their 457 adult poisoning cases over an 8-year period were related to edible species. They suggested that extended storage in plastic prior to preparation, long storage following cooking, or simply delay to use led to mild gastrointestinal manifestations.<sup>60</sup> Because more than 75% of mushrooms involved in exposures are never identified—more than 100,000 mushroom species exist, less than 0.1% of these are known to be toxic, and many species are poorly studied—a strategy for making significant decisions with incomplete data is essential.

### CLASSIFICATION AND MANAGEMENT

This chapter does not address molds, mildews, and yeasts, which in addition to mushrooms are all categorized as fungi. The unifying principle for fungi is the lack of the photosynthetic capacity to produce nutrition. Survival is achieved by the enzymatic capacity of these organisms to integrate into living materials and digest them. Molds are ubiquitous and often associated with varied adverse health effects such as rhinitis, rashes, headaches, and asthma.<sup>22</sup> Trichothecenes are mold-related mycotoxins that are discussed in Chap. 127 as potential biological weapons. All other molds are not associated with toxicologic emergencies and are not addressed in this chapter.

Because mushroom species vary widely with regard to the xenobiotics they contain, and because identifying them with certainty is difficult, a system of classification based on clinical effects is more useful than one based on taxonomy (Table 117-1). The text and tables that follow associate the most common species with a particular syndrome or xenobiotic and are not meant to be inclusive of all the exceptionally diverse mushrooms associated with many xenobiotics. In many instances the taxonomy has changed, confusing readers and investigators. For example, the text will use the current nomenclature, whereas the citations will obviously use prior nomenclature. In many cases, management and prognosis can be determined with a high degree of confidence from the history and the geographic origin of the mushroom, the initial signs and symptoms, the organ system or systems involved, and coexistent factors or conditions.<sup>32,65,84,121</sup> Most unintentional ingestions in small children involve at the most tasting common backyard mushrooms, which almost invariably result in no symptoms and no risks. Identification of the mushroom by photography will permit enhancement of the toxicologists' efforts at reassurance.

### GROUP I: CYCLOPEPTIDE-CONTAINING MUSHROOMS

Worldwide most mushroom fatalities are associated with cyclopeptide-containing species.<sup>5,33,138</sup> Approximately 50 to 100 cases are reported annually in Western Europe with fewer in Asia, Australia, Africa, and North and South America.<sup>34</sup> There are many fewer cases in the United States with far less certainty of amatoxin poisoning and with limited precise data of those patients ill enough to be transferred to transplant centers for acute liver injury or acute liver failure.<sup>75</sup> In North America, there are 2 distinct ranges of the *Amanita* species along the West Coast (California to British Columbia) and along the East Coast (Maryland to Maine).<sup>157</sup> These mushrooms include a number of *Amanita* species, including *A. verna*, *A. virosa*, and *A. phalloides*; *Galerina* spp, including *G. autumnalis*, *G. marginata*, and *G. venenata*; and *Lepiota* species, including *L. helveola*, *L. josserandi*, and *L. brunneoincarnata* (Fig. 117-1). Early differentiation of cyclopeptide poisonings from other types of mushroom poisoning is difficult (Fig. 117-2). Patients poisoned with cyclopeptides may be ill enough to seek health care for nausea, vomiting, abdominal pain, and diarrhea, which in the absence of a carefully focused history often is attributed to other causes as the patient improves with supportive care. Such patients are occasionally sent home, only to return moribund in 1 to 2 days. The delayed onset of more serious symptoms is typical of cyclopeptide toxicity and is a critical consideration in assessing the toxicologic potential of any exposure.

*A. phalloides* contains 15 to 20 cyclopeptides, each with an approximate weight of 900 Da. The amatoxins (cyclic octapeptides), phallotoxins (cyclic

TABLE 117-1 Mushroom Toxicity Overview

heptapeptides), and virotoxins (cyclic heptapeptides) are the best studied.<sup>38,58,80,152</sup> There is no evidence for the toxicity of virotoxins in humans. Of these 3 chemically similar cyclopeptide molecules, phalloidin (the principal phallotoxin) appears to be rapid-acting, whereas amanitin tends to cause more delayed manifestations.<sup>125</sup> Phalloidin crosses the sinusoidal plasma membranes of hepatocytes by a carrier-mediated process. This process is shared by bile salts and can be prevented in the presence of extracellular bile salts, suggesting competitive inhibition. A sodium-independent bile salt transporting system may be responsible for phalloidin hepatic uptake, elimination, and detoxification.<sup>97</sup> Phalloidin interrupts actin polymerization and impairs cell membrane function, but because of its very limited oral absorption it has minimal systemic toxicity, but results in the initial GI dysfunction noted following *Amanita* spp ingestion.

The amatoxins are the most toxic of the cyclopeptides, leading to liver, kidney, and central nervous system (CNS) damage. These polypeptides are heat stable.<sup>36</sup>  $\alpha$ -Amanitin is the principal amatoxin responsible for human toxicity following ingestion. Approximately 1.5 to 2.5 mg of amanitin can be obtained from 1 g of dry *A. phalloides*, and as much as 3.5 mg/g can be obtained from some *Lepiota* spp.<sup>107,111,152</sup> A 20-g mushroom contains well in excess of the 0.1 mg/kg amanitin considered lethal for humans.<sup>35</sup>  $\alpha$ -Amanitin and  $\beta$ -amanitin have comparable toxicity in animal models.<sup>39</sup>

The amanitins are highly bioavailable and rapidly absorbed from the GI tract.<sup>70</sup> Amatoxins show limited protein binding and are present in the plasma at low concentrations for 24 to 48 hours.<sup>70</sup> Hepatocellular entry of  $\alpha$ -amanitin is facilitated by a sodium-dependent bile acid transporter. Several studies demonstrate that the sodium taurocholate cotransporter polypeptide, a member of the organic anion-transporter (OAT) polypeptide family localized in the sinusoidal membranes of human hepatocytes, facilitates hepatocellular  $\alpha$ -amanitin uptake.<sup>64,86</sup> Once inside the cells, the cytotoxicity of amanitin results from its interference with RNA polymerase II, preventing the transcription of DNA thereby suppressing protein synthesis resulting in cell death.<sup>89,133</sup>  $\alpha$ -Amanitin is enterohepatically recirculated. Target organs are those with the highest rate of cell turnover, including the GI tract epithelium, hepatocytes, and kidneys. Amatoxins do not cross the placenta, as demonstrated by the absence of fetal toxicity in severely poisoned pregnant women.<sup>7,13,138</sup>

In an intravenous radiolabeled amatoxin study in dogs, 85% of the amatoxin was recovered in the urine within the first 6 hours, whereas less than 1% was

**FIGURE 117-2.** In the more highly specialized and evolved mushrooms, various protective tissues cover the fruit body and its constituent parts during its development. In the mushroom shown, an *Amanita* species, 2 veils of tissue are involved—one an outer enclosing bag, the universal veil, which ruptures as the fruit body expands to leave a volva at the base and fragments on the cap; the other an inner partial veil covering the developing gills that is pulled away as the cap opens to leave a ring on the stem. (Adapted with permission from Kibby G. *Mushrooms and Toadstools, A Field Guide: Oxford: Oxford University Press; 1979.*)

found in the blood at that time.<sup>40</sup> Some of the toxicokinetic analyses following unquantified ingestions demonstrate 12 to 23 mcg amanitin excretion in the urine over 24 to 66 hours, of which 60% to 80% occurred during the first 2 hours of collection. The extreme variabilities of the type and quantity of amanitin ingested, the host, the delay from the time of ingestion to collection, and the management make interpretations exceedingly difficult.<sup>145</sup> In another series, total maximal urinary  $\alpha$ - and  $\beta$ -amanitin excreted over 6 to 72 hours were 3.19 and 5.21 mg, respectively. Two-thirds of the patients had total amanitin excretion greater than 1.5 mg.<sup>70</sup> Urinary amanitin excretion concentrations differ by several orders of magnitude. Whether the variation results from exposure dose, time following ingestion, or laboratory technique is unclear.

Several variable techniques for quantitative and qualitative evaluation of amatoxins are utilized. Amatoxins can be detected by high-performance liquid chromatography,<sup>70</sup> thin-layer chromatography, ion trap mass spectrometry,<sup>44</sup> and radioimmunoassay in gastroduodenal fluid, serum,<sup>111</sup> urine,<sup>17,18</sup> stool, and liver and kidney biopsies for several days following an ingestion.<sup>38,39,79</sup>

### Clinical

Phase I of cyclopeptide poisoning resembles severe gastroenteritis, with profuse watery diarrhea that is delayed until 5 to 24 hours after ingestion. Some consider the early onset (< 8 hours) of diarrhea as a predictive factor for hepatic failure and the need for liver transplantation,<sup>36</sup> whereas this is not supported by most other case series reviewed. Early onset of gastrointestinal distress before 5 hours is strong support for another non-*Amanita* species or an etiology other than mushroom ingestion.

Transient improvement occurs during phase II from 12 and 36 hours after ingestion although hepatic injury begins during this phase.<sup>111,159</sup> Acute liver injury is defined by (a) a moderately severe coagulopathy (international normalized ratio {INR}  $\geq 2.0$ ), (b) presumed onset of acute illness less than 26 weeks, and (c) the absence of cirrhosis.<sup>75,104</sup> Acute liver failure can be defined as (a) the presence of hepatic encephalopathy of any degree, (b) evidence of moderately severe coagulopathy (INR  $\geq 1.5$ ), (c) presumed onset of illness of less than 26 weeks, and (d) the absence of cirrhosis.<sup>104</sup> Pathologic manifestations include steatosis, central zonal necrosis, and centrilobular hemorrhage, with viable hepatocytes remaining at the rims of the larger triads. Lobular architecture remains intact (Fig. 21-3).<sup>5</sup> Gastrointestinal manifestations including nausea, vomiting, abdominal pain and diarrhea may persist during the entirety of the clinical course.<sup>66</sup>

However, despite supportive care, phase III, manifested by hepatic and renal toxicity and death, may ensue 2 to 6 days after ingestion.<sup>5</sup> Although

hepatotoxicity begins within the second phase of toxicity, clinical hepatotoxicity (Chap. 21) with elevated concentrations of bilirubin, aspartate aminotransferase (AST), and alanine aminotransferase (ALT), hypoglycemia, jaundice, and hepatic coma are not manifest until 2 to 3 days after ingestion. Pancreatic toxicity rarely occurs.<sup>51</sup>

Cyclopeptide toxicity alters the hormones that regulate glucose, calcium, and thyroid homeostasis, resulting in widespread endocrine abnormalities.<sup>76</sup> Insulin and C-peptide concentrations are elevated at a stage of poisoning prior to hepatic and renal compromise.<sup>30,76</sup> These findings are suggestive of direct toxicity to pancreatic  $\beta$  cells, resulting in release of preformed hormone or induction of hormone synthesis. This insulin release necessitates vigilance for hypoglycemia prior to hepatocellular damage.

In a series of 10 patients exposed to diverse *Lepiota* spp, 50% developed a mixed sensory and motor polyneuropathy. Most of the patients spontaneously recovered within one year, although a single patient developed progressive clinical and electromyographic deterioration.<sup>114</sup> These neuropathic findings are not noted in other case reports.

### Treatment

The search for treatments has been vigorously pursued in Europe because of the persistently large number of amatoxin exposures each year.<sup>52</sup> Survival rates in case series of variable numbers of patients poisoned by *A. phalloides* who received supportive care, fluid and electrolyte repletion, high-dose penicillin G, dexamethasone, or thiocetic acid are between 70% and 100%.<sup>52,62,69,100,105,116,159</sup> Many of these case series have excellent survival rates with extremely variable therapeutic interventions, limiting the capacity to determine the need for or efficacy of most of the standard conservative therapeutic regimens.

Fluid and electrolyte repletion and treatment of hepatic compromise are essential. Intravenous 0.9% sodium chloride solution and electrolytes usually are necessary because of substantial fluid losses due to vomiting and diarrhea. Dextrose repletion titrating to serum glucose concentration (>100 mg/dL) is reasonable because of nutritional compromise, hepatic failure, or glycogen depletion. Activated charcoal both adsorbs the amatoxins and improves survival in laboratory animals.<sup>39</sup> Emesis, lavage, and catharsis are not necessary unless the patient presents within several hours after the ingestion because any substantial quantity of ingested toxin almost invariably induces emesis and catharsis. In an analysis<sup>10</sup> of the AAPCC Toxic Exposure Surveillance System (TESS) database of unintentional mushroom exposures in children from 1992 to 2005, it is suggested that a syrup of ipecac-treated subgroup compared to an activated charcoal or no intervention group showed the smallest percentage of moderate or major

outcomes. Activated charcoal is safe, logical, and a valuable therapeutic strategy at least during the first 12 to 24 hours following mushroom ingestion. Although the clinical presentation often is delayed, 1 g/kg body weight of activated charcoal is reasonable for oral administration every 2 to 4 hours (if the patient is vomiting, an antiemetic is indicated) or by continuous nasogastric infusion. Continuous nasogastric duodenal aspiration is used by multiple groups (mainly European) to remove amatoxins secreted in the bile; others use an even more difficult biliary drainage approach to disrupt the enterohepatic recirculation of the amatoxin.<sup>95</sup> Although there is theoretical support for early quantitative toxin removal due to substantial biliary concentration, the total quantity and actual gastroduodenal concentration remains low, offering inadequate clinical data to support high-risk invasive procedures such as gastroduodenal or biliary drainage.<sup>71</sup>

Thioctic ( $\alpha$ -lipoic) acid previously was reported to be beneficial in treating the amatoxin-induced liver toxicity in several different animal models, and a number of uncontrolled clinical trials in humans followed.<sup>5,62</sup> Despite the initial success, thioctic acid was not effective in various other studies and is no longer recommended.<sup>47,49</sup>

A randomized murine model of intraperitoneal  $\alpha$ -amanitin poisoning comparing treatment with rescue postexposure *N*-acetylcysteine, benzylpenicillin, cimetidine, thioctic acid, or silybin was unable to show benefit of any therapy with regard to hepatotoxic manifestations such as aminotransferase concentrations or histologic evidence of hepatonecrosis.<sup>139</sup>

Several laboratory investigations in mice and rats suggest that 1 g/kg penicillin G (1 g = 1,600,000 units) may have a time- and dose-dependent protective effect.<sup>46,50</sup> These results are limited because the amatoxins were administered intraperitoneally, resulting in the death of untreated animals 12 to 24 hours later. Additional investigations demonstrated that 1 g/kg penicillin G administered 5 hours after sublethal doses of  $\alpha$ -amanitin decreased clinical and laboratory toxicity.<sup>50</sup> The mechanisms suggested include displacing  $\alpha$ -amanitin from albumin, blocking its uptake from hepatocytes, binding circulating amatoxins, and preventing  $\alpha$ -amanitin binding to RNA polymerase. None of these mechanisms is substantiated.<sup>34</sup> We no longer recommend penicillin G as a first-line regimen and it only recommend it if none of the following regimens are available.

The active complex of milk thistle (*Silybum marianum*) is silymarin, which is a lipophilic extract composed of 3 isomeric flavonolignans: silibinin, silychristin, and silydianin. Silibinin represents approximately 50% of the extract, but represents about 70% to 80% of the marketed products.<sup>68</sup> Silibinin, a mixture of Silibinin A and B, competitively inhibits the organic anion transporter (OATP1B3) that is responsible for the uptake and enterohepatic recycling of  $\alpha$ -amanitin.

One of the earliest animal studies was conducted in mice using sublethal doses of *Amanita phalloides* extract administered intraperitoneally (IP) every 24 hours for 3 doses.<sup>2</sup> Silymarin was administered intravenously (IV) at 16 and 24 hours, with the highest dose resulting in a 58% survival compared to 11% in the control group. When the experiment was repeated using a purified  $\alpha$ -amatoxin, time was the most important factor in predicting survival. All of the mice treated with silymarin one hour before exposure survived, whereas none survived when treatment was started 8 hours after exposure.<sup>48</sup> A similar study in mice treated with IP  $\alpha$ -amatoxin followed 4 hours later with IP silibinin dosed every 4 to 6 hours for 48 hours was not able to show a benefit in reducing the increase in aminotransferases or a difference in the liver histopathology.<sup>139</sup>

Although in an experimental model of cultured canine hepatocytes silibinin was not able to reduce cytotoxicity, 2 experiments using cultured human hepatocytes demonstrated that the addition of silibinin was able to protect against lipid peroxidation and cytotoxicity, and also stimulate cell proliferation and attachment.<sup>91-93</sup>

Another study conducted in canines utilized an oral sublethal dose of *Amanita phalloides* extract and IV silymarin administered at 5 and 24 hours postingestion. Silymarin prevented or reduced the elevation in liver enzymes and the fall in clotting factors and reduced the severity of liver failure.<sup>50</sup> A similar protocol, but this time using silibinin instead of silymarin, demonstrated similar biochemical findings and a 100% survival.<sup>147</sup> These studies

suggest that silibinin diminishes  $\alpha$ -amanitin enterohepatic circulation and may competitively inhibit the organic anion transporter.

A 20-year retrospective review of European and American case reports of more than 2,000 hospitalized patients with amatoxin-induced mushroom poisoning concluded that silibinin alone or in combination with *N*-acetylcysteine showed the most promise as hepatoprotective therapies.<sup>34</sup> The authors acknowledged the difficulty in determining efficacy of various therapies given the lack of randomized controlled trials. A more recent review included the data from the previous authors and any subsequent hospitalized patients. A multidimensional multivariate statistical analysis of the data reached a similar conclusion.<sup>112</sup>

Although silibinin is routinely available as a nonprescription supplement in most pharmacies and appears to be safe and well tolerated in patients with chronic liver disease, no reduction in mortality, improvement in histology at liver biopsy, or biochemical marker was identified in a systematic review and meta-analysis of diverse patients with chronic liver disease.<sup>68</sup> A dose of silibinin 20 to 50 mg/kg/d is suggested in humans, even though it is not approved as a therapeutic for hepatic disease by the Food and Drug Administration (FDA) in the United States.<sup>79,150</sup> Currently there is an amatoxin poisoning clinical trial utilizing Legalon SIL (silibinin) through an FDA-approved open treatment investigational new drug administration.<sup>25</sup> Legalon SIL, silibinin-C-2',3-dihydrogen succinate disodium salt, is a microcrystalline water-soluble powder for injection manufactured by Rottapharm/Madaus, a German pharmaceutical company.<sup>63</sup> Silibinin is a mixture of cis and trans diastereomers of silibinin A and B extracted from milk thistle fruit and then esterified with succinic anhydride to form the water-soluble salt. There are currently inadequate data to support recommending silibinin for *Amanita* poisoning.

Because of its hepatoprotective effects, *N*-acetylcysteine is recommended, but no evidence for any specific benefit as an antidote is demonstrated. When fulminant hepatic failure is present, it is reasonable to administer *N*-acetylcysteine in standardized dosing regimens for non-acetaminophen-poisoned patients until the patient recovers from the encephalopathy because of its presumptive benefits under these circumstances (Antidotes in Depth: A3).

In animals, cimetidine (a potent CYP2C9/2D6 inhibitor) may have a hepatoprotective effect against  $\alpha$ -amanitin,<sup>124</sup> but it shows no protective effect against phalloidin toxicity.<sup>125</sup> Cimetidine is proposed as a therapeutic intervention,<sup>123</sup> but no available human data support its use, and it is not currently recommended.

In a response to the continuing quest for a successful antidote for  $\alpha$ -amanitin poisoning, a group of investigators with computer modeling and simulation screened clinical drugs sharing bioisosterism with  $\alpha$ -amanitin.<sup>59</sup> They subsequently found in an *in silico* study that polymyxin B had significant chemical similarities and molecular dynamics that successfully competed at the same interface and displaced  $\alpha$ -amanitin from binding sites with RNA polymerase II. Polymyxin B was then used in vivo to demonstrate that all mice given a specified dose of  $\alpha$ -amanitin died, whereas when polymyxin B was given simultaneously all mice survived. When polymyxin followed  $\alpha$ -amanitin by 4, 8, and 12 hours, 50% of the mice survived up to 30 days.<sup>59</sup> Polymyxin B has potential to protect RNA polymerase II from inactivation, thereby preventing hepatic injury leading to survival. The investigators plan to utilize clinically approved polymyxin B dosing in suspected  $\alpha$ -amanitin poisoning. This novel analysis and subsequent interesting success in mice appears to suggest a more rational strategy than most current antidotal interventions, and the authors' approach should stimulate extensive investigations. In the absence of any proven antidote, polymyxin B at a dose of at least 0.75 mg/kg body weight is reasonable to administer as a life-saving gesture when there is assuredness that *Amanita* species were ingested. Polymyxin is a highly nephrotoxic antibiotic when used parenterally for prolonged clinical treatments, which necessitates that fluid resuscitation is achieved and maintained during a course of therapy, which should be briefly occurring during the 12 to 24 hours following amatoxin ingestions potentially limiting hepatotoxicity and nephrotoxicity. Roger L. Nation, PhD, Professor of Drug Disposition and Dynamics, Monash Institute of Pharmaceutical Sciences (written communication, July 21, 2016)

stated that short-term therapy at the cited dose would not be expected to cause polymyxin B–associated nephrotoxicity. Although polymyxin B accumulates extensively in renal tubular cells, the concentration is lower in the liver. However, this novel research provides excellent evidence that polymyxin B reaches hepatocytes.<sup>59</sup>

Forced diuresis, hemodialysis, plasmapheresis,<sup>71,72</sup> hemofiltration, and hemoperfusion<sup>42</sup> are often considered shortly after ingestion, but most studies offer neither clinical evidence of benefit nor supportive pharmacokinetic data for any of these therapies.<sup>79,110,111,128,145,149</sup> “Shortly after” is not defined, although hemodialysis and hemoperfusion are reasonable for toxin removal within 24 hours of a documented ingestion.<sup>43</sup> Plasmapheresis, which is dependent on effective clearance, high plasma protein binding, and a low volume of distribution, does not remove more than 10 mcg of amatoxin. Because of the absence of prospective, controlled studies of exposure to amatoxins, in addition to the extreme variability of success with many regimens, multiple-dose activated charcoal, and supportive care remain the standard therapy. Early recognition (<24 hours) of exposure to amanitin is an indication for hemodialysis or hemoperfusion, but most patients at the time they develop clinical manifestations of toxicity likely will no longer have the potential for benefit.<sup>72</sup>

Future therapeutic interventions, such as the use of silibinin, may be dependent on improved understanding of the hepatocellular bile acid transporter, which is a member of the OAT polypeptide family.<sup>64,83,86</sup> The interesting theoretical benefit of the FDA-approved drug polymyxin B, which in silico and in vivo animal models competed with and displaced  $\alpha$ -amanitin from RNA polymerase II–binding sites makes this a mechanistically sound antidote.

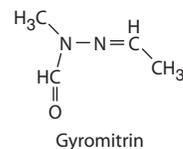

Extracorporeal albumin dialysis,<sup>41</sup> molecular adsorbent recirculating system (MARS),<sup>27,95,132,156</sup> and fractionated plasma separation and adsorption system (FPSA; Prometheus system),<sup>37,144,146</sup> are variant detoxification techniques used in patients with fulminant hepatic failure to remove water-soluble and albumin-bound xenobiotics while providing renal support. The typical delayed time to onset of use of MARS and other extracorporeal liver assist devices in amanitin poisoning invariably limits the potential effects of these systems on correction or stabilization of hepatic dysfunction not to toxin removal. None of the available studies of these bridging systems are randomized or controlled. The clinical experience is solely in the care of patients with grave hepatotoxicity at a delayed stage limiting any potential for significant conclusions. These 2 techniques permit time for hepatic regeneration or sufficient bridging time to orthotopic liver transplantation.

The criteria and timing for liver transplantation following amatoxin poisoning are far less established than for fulminant viral hepatitis, where grade III or IV hepatic encephalopathy, marked hyperbilirubinemia, increased INR and azotemia are the well-established criteria for transplantation (Chap. 21).<sup>109</sup> From 1998 to 2014 the United States Acute Liver Failure Study group of 2,224 patients had only 18 patients (acute liver injury {5} and acute liver failure {13}) who were suggested to have had severe hepatotoxicity secondary to an amatoxin.<sup>75</sup> These data do not address those patients who died in the primary hospital of hepatic failure, those who had acute liver injury and survived without transfer. The authors recognize that this observational study represents an exceptionally small sample over many years, but many survived acute liver failure without transplant, and all those with liver transplant survived. Successful transplantations were performed in individuals whose resected livers showed 0% to 30% hepatocyte viability. In these cases, the authors did not wait for progression to exceed grade II encephalopathy or for development of azotemia or marked hyperbilirubinemia.<sup>109</sup> Criteria for patient selection are essential to avoid unnecessary risk while offering the potential for survival to appropriate candidates who have no functional liver. The grim prognosis associated with hepatic coma secondary to *Amanita* spp poisoning has led several transplant groups to consider hepatic transplantation for encephalopathic patients with prolonged INRs (>6), persistent hypoglycemia, metabolic acidosis, increased concentrations of serum ammonia and AST, and hypofibrinogenemia.<sup>36,55-57,75,78,109,120</sup> Each of these major studies has critical flaws including selection bias, retrospective observational series,

absence of controls, survival of those who did not receive transplantation, and lack of definitive evidence of amatoxin exposure. Most studies suggest that no circulating amatoxins are present by the time the need for transplantation is evident.<sup>31</sup> Therefore, there are no definitive transplant criteria for amatoxin-associated acute liver injury and acute liver failure, and the surgeon's judgment in a transplant center is essential. There are now case reports of successful liver transplantation for fulminant<sup>70,74,109</sup> hepatic failure from presumed *A. ocreata*,<sup>78,158</sup> *A. phalloides*, *A. virosa*,<sup>16</sup> *Lepiota helveola*,<sup>98</sup> and *L. brunneincarnata* poisoning.<sup>114</sup>

To enhance the likelihood of success, individuals who manifest symptoms suggestive of hepatotoxic *Amanita*, *Galerina*, or *Lepiota* spp exposure should be told of the severity of their toxic exposure, the advantage of care in a center for those with liver failure, and the potential need for transplantation, and it is our belief that rapid transfer to a regional liver transplantation center offers the safest site for high-quality care and for decision making with regard to timing for liver transplantation in the face of advancing liver failure.<sup>16,36,109</sup>

## GROUP II: GYROMITRIN-CONTAINING MUSHROOMS

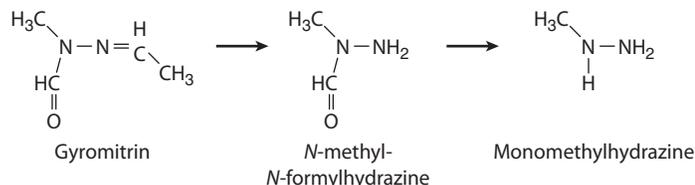

Members of the gyromitrin group include *Gyromitra esculenta*, *G. ambigua*, and *G. infula*. *G. esculenta* enjoys a reputation of being edible in the Western United States but of being toxic in other areas. The most common error occurs in the spring, when an individual seeking the nongilled, brainlike *Morchella esculenta* (morel) finds the similar *G. esculenta* (false morel) (Fig. 117–3).

These mushrooms are found commonly in the spring under conifers and are easily recognized by their brainlike appearance. Poisonings with these mushrooms are exceptionally uncommon in the United States, representing less than 1% of all recognized events, whereas these poisonings are considered more common in Europe. Certain cooking methods may destroy the toxin, but because of the potential for toxicity, all members of this mushroom family should be avoided.

*Gyromitra* mushrooms contain the nonvolatile insoluble gyromitrin. Gyromitrin on hydrolysis yields a family of *N*-methyl-*N*-formyl hydrazones, which on subsequent hydrolysis split into aldehydes and

**FIGURE 117–3.** Group II: Gyromitrin-containing mushrooms. A true morel (*Morchella* spp) on the left is compared to a false morel (*Gyromitra esculenta*) on the right. (Used with permission from John Trestrail.)

**FIGURE 117-4.** *Gyromitra* mushrooms contain gyromitrin, which undergoes hydrolysis to yield a family of *N*-methyl-formylhydrazines. These molecules on subsequent hydrolysis yield *N*-methyl-*N*-formylhydrazine and monomethylhydrazine.

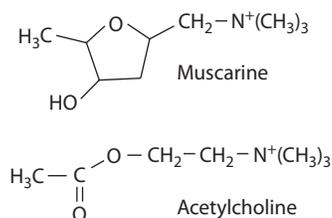

*N*-methyl-*N*-formylhydrazine.<sup>3</sup> Subsequent hydrolysis of *N*-methyl-*N*-formylhydrazine yields monomethylhydrazine (Fig. 117-4). The hydrazine moiety reacts with pyridoxine, resulting in inhibition of pyridoxal phosphate–related enzymatic reactions (Figs. 56-2 and 56-3). This interference with pyridoxal phosphate synthesis impairs the production of the inhibitory neurotransmitter  $\gamma$ -aminobutyric acid (GABA).<sup>84</sup> This decrease in GABA is thought to contribute to the diverse neurologic manifestations typically associated with the ingestion of *Gyromitra* spp.

The initial signs and symptoms of toxicity from these mushrooms occur 5 to 10 hours after ingestion and include nausea, vomiting, diarrhea, and abdominal pain. Patients manifest headaches, weakness, and diffuse muscle cramping. Rarely in the first 12 to 48 hours, patients develop nystagmus, ataxia, delirium, stupor, convulsions, and coma. Most patients improve dramatically and return to normal function within several days.

Activated charcoal 1 g/kg body weight is recommended for administration. Benzodiazepines are appropriate for initial management of seizures. Under most circumstances, supportive care is adequate treatment. Pyridoxine (vitamin B<sub>6</sub>) in doses of 70 mg/kg IV up to 5 g is recommended, as in the management of isoniazid poisoning, to limit seizures and other neurologic symptoms (Antidotes in Depth: A15).

There are no rapid diagnostic strategies in the laboratory, although thin layer chromatography, gas-liquid chromatography, and mass spectrometry can be used for subsequent identification of hydrazine and hydrazine metabolites.

### GROUP III: MUSCARINE-CONTAINING MUSHROOMS

Mushrooms that contain muscarine include numerous members of the *Clitocybe* species, such as *C. dealbata* (the sweater) and *C. illudens* (*Omphalotus olearius*) (Fig. 117-5A and 5B), and the *Inocybe* species, which include *I. iacera*, *I. lanuginosa*, and *I. geophylla*. *A. muscaria* and *A. pantherina* contain limited quantities of muscarine, although *A. muscaria* contains substantial amounts of muscimol.

Clinical manifestations, which typically are mild, usually develop within 0.25 to 2 hours, typically last several additional hours with complete resolution within 24 hours. Muscarine and acetylcholine are similar structurally and have comparable clinical effects at the muscarinic receptors. Peripheral manifestations typically include bradycardia, miosis, salivation, lacrimation, vomiting, diarrhea, bronchospasm, bronchorrhea, and micturition. Central muscarinic manifestations do not occur because muscarine, a quaternary ammonium compound, does not cross the blood–brain barrier. No nicotinic manifestations such as diaphoresis or tremor occur. The effects of muscarine often last longer than those of acetylcholine. Because muscarine lacks an ester bond, it is not hydrolyzed by acetylcholinesterase.

**A**

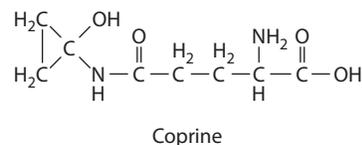

**B**

**FIGURE 117-5.** Group III: Muscarine-containing mushrooms. (A) *Clitocybe dealbata*. (B) *Omphalotus olearius*. (Used with permission from John Plischke III.)

Significant toxicity is uncommon, limiting the need for more than supportive care. Rarely, atropine (1–2 mg given IV slowly for adults or 0.02 mg/kg IV for children) is reasonable when titrated and repeated as frequently as indicated to reverse symptomatology. No current, clinically available, analytic techniques can identify muscarine, although high-performance liquid chromatography would be appropriate for investigative purposes.

### GROUP IV: COPRINE-CONTAINING MUSHROOMS

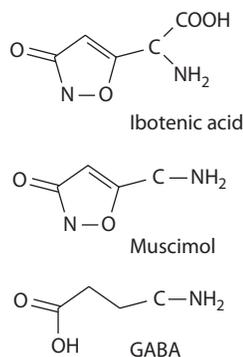

*Coprinus* mushrooms, particularly *C. atramentarius* (*Coprinopsis atramentaria*), contain the toxin coprine (Fig. 117-6A). These mushrooms grow abundantly in temperate climates in grassy or woodland fields. They are known as “inky caps” because the gills that contain a peptidase autolyse into an inky liquid shortly after picking. The edible member of this group, *Coprinus comatus* (shaggy mane) (Figs. 117-6B and 6C) is nontoxic, and probably its misidentification results in collectors’ errors. Coprine, an amino acid, its primary metabolite, 1-aminocyclopropanol,<sup>20,94,140</sup> or, more likely, a secondary in vivo hydrolytic metabolite, cyclopropanone hydrate, has a disulfiramlike effect (Fig. 117-7 and Chap. 78).<sup>155</sup> Although both of these metabolites appear to inhibit aldehyde dehydrogenase, the most stable in vivo inhibitory effect is manifested by cyclopropanone hydrate.<sup>155</sup> Inhibition of acetaldehyde dehydrogenase results in accumulation of acetaldehyde and its associated adverse effects, which takes at least 0.5 to 2 hours if the patient ingests alcohol concomitantly or subsequent to eating a coprine-containing mushroom. For the subsequent 48 to 72 hours following coprine-containing mushroom ingestion, if ethanol ingestion occurs, toxicity ensues. Within 0.5 to 2 hours of ethanol ingestion, an acute disulfiram effect is noted, with tachycardia, flushing, nausea, and vomiting. The simultaneous ingestion of the mushroom and alcohol does not result

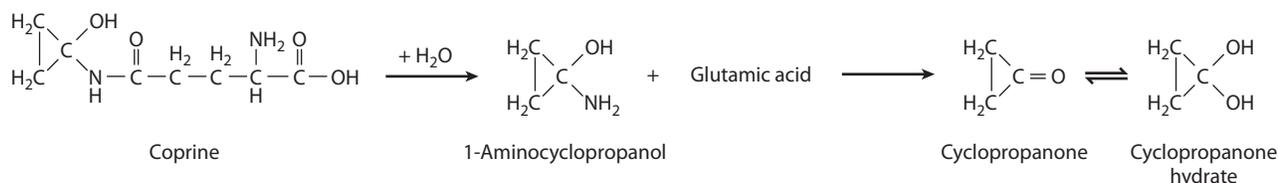

**FIGURE 117-6.** Group IV: Coprine-containing mushrooms. (A) *Coprinopsis atramentaria*; (B) and (C) show *Coprinus comatus* (shaggy mane). Image B shows an early form, which later is self-digested, demonstrating the gill liquefaction in image C. (Image A Used with permission from John Plischke III, and images B and C used with permission from Lewis Nelson.)

in immediate clinical manifestations because inhibition of aldehyde dehydrogenase occurs following coprine metabolism and the in vivo production of cyclopropane hydrate. Treatment is symptomatic with fluid repletion and antiemetics such as metoclopramide or ondansetron, although clinical manifestations usually are mild and resolve within several hours. Prophylactic use of fomepizole (Antidotes in Depth: A3) immediately following ingestion of ethanol and coprine-containing mushrooms would be reasonable, and therapeutic use would be appropriate if persistent toxicity occurs associated with an elevated ethanol concentration, although no case reports or studies are published. This group of mushrooms rarely causes fatalities.

### GROUP V: IBOTENIC ACID- AND MUSCIMOL-CONTAINING MUSHROOMS

Most of the mushrooms in this class are primarily in the *Amanita* species, which includes *A. muscaria* (fly agaric), *A. pantherina*, and *A. gemmata* (Fig. 117-8). They exist singly scattered throughout the US woodlands. The brilliant red or tan cap (pileus) is that of the mushroom commonly depicted in children's books and is easily recognized in the fields during summer and fall. These mushrooms have been used in religious ceremonies throughout history. Small variable quantities of the isoxazole derivative ibotenic acid and its decarboxylated metabolite muscimol are found in these mushrooms. Ibotenic acid is an amino acid that acts as a glutamate antagonist at *N*-methyl-D-aspartate (NMDA) receptors. Muscimol acts as a  $\gamma$ -aminobutyric acid type A (GABA<sub>A</sub>) agonist.

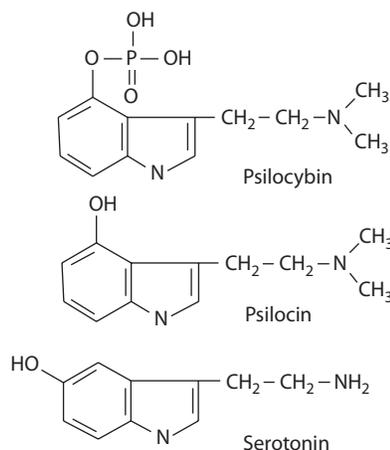

**FIGURE 117-7.** The *Coprinus* mushrooms contain coprine, an amino acid, which is rapidly hydrolyzed to 1-aminocyclopropanol and subsequently cyclopropanone hydrate. It is this last metabolite that most likely has the disulfiramlike effect.

Most patients who develop symptoms have intentionally ingested large quantities of these mushrooms while seeking a hallucinatory experience. Within 0.5 to 2 hours of ingestion, these mushrooms produce the GABAergic manifestations of somnolence, dizziness, auditory and visual hallucinations, dysphoria seizures and agitated delirium in adults, and the excitatory glutamatergic manifestations of myoclonic movements. Seizures and other neurologic findings predominate in children.<sup>8</sup>

Treatment is invariably supportive. Most symptoms respond solely to supportive care, although a benzodiazepine is recommended for excitatory CNS manifestations.

### GROUP VI: PSILOCYBIN-CONTAINING MUSHROOMS

Psilocybin-containing mushrooms include *Psilocybe cyanescens*, *Psilocybe cubensis*, *Conocybe cyanopus*, *Panaeolus cyanescens*, *Gymnopilus spectabilis*, and *Psathyrella foenicicii* (Fig. 117-9). These mushrooms have been used for native North and South American religious ceremonies for thousands of years. They grow abundantly in warm, moist areas of the United States. They are readily available through drug culture magazines and the Internet.

Toxicity from this group is probably directly correlated with the popularity of hallucinogens in the community.<sup>11</sup> Psilocybin is rapidly and completely

**FIGURE 117-8.** Group V: Muscimol-containing mushrooms. This image of *Amanita muscaria* highlights different development forms and colors. (Used with permission from John Plischke III.)

hydrolyzed to psilocin in vivo. Serotonin, psilocin, psilocybin, bufotenine, dimethyltryptamine, and lysergic acid diethylamide (LSD) are very similar structurally and presumably act at a similar 5-HT<sub>2</sub> receptor site. The effects of psilocybin as a serotonin agonist and antagonist are discussed in Chaps. 13 and 79.

The psilocybin and psilocin indoles, like those of LSD, rapidly (within one hour of ingestion) produce CNS effects, including ataxia, hyperkinesia, visual illusions, and hallucinations. Some patients manifest gastrointestinal distress, tachycardia, mydriasis, anxiety, lightheadedness, tremor, and agitation. Most manifestations are recognized within 4 hours of ingestion with a return to normalcy within 6 to 12 hours.<sup>14</sup> Rare cases of acute kidney failure,<sup>53,113</sup> seizures, and cardiopulmonary arrest<sup>11</sup> are associated with psilocybin-containing species. However, such associations should always be questioned when reported in a substance-using individual potentially simultaneously exposed to other xenobiotics.

A single patient who intravenously administered an extract of *Psilocybe* mushrooms experienced chills, weakness, dyspnea, headache, severe myalgia and vomiting associated with hyperthermia, hypoxemia, and mild methemoglobinemia.<sup>28</sup>

Treatment for hallucinations usually is supportive, although administering a benzodiazepine is reasonable when reassurance proves inadequate.

### GROUP VII: GASTROINTESTINAL TOXIN-CONTAINING MUSHROOMS

By far the largest group of mushrooms is a diverse group that contains a variety of ill-defined GI toxins. Many of the hundreds of mushrooms in this group fall into the “little brown mushroom” category. Some *Boletus* spp, *Lactarius* spp, *O. olearius*, *Rhodophyllus* spp, *Tricholoma* spp, *Chlorophyllum molybdites*, and *Chlorophyllum esculentum* are mistaken for edible or

**TABLE 117-2** Mushroom Toxicity: Correlation Between Organ System Affected, Time of Onset of Toxic Manifestations, and Mushroom Xenobiotic Responsible

Organ System	Time of Onset		
	Early: <5 h	Middle: 5–24 h	Late: >24 h
Cardiac muscle			2R-amino-4,5-hexynoic acid
Gastrointestinal	Allenic norleucine 2R-amino-4,5-hexynoic acid Coprone Group VII Psilocybin Muscarine	Allenic norleucine  Amatoxin Gyromitrin	Orellanine and orellanine
Liver			Amatoxin
Immunologic	Involutin Spores		
Nervous	Ibotenic acid and muscimol Psilocybin	Gyromitrin	Acromelic acid  Gyromitrin Polyporic acid
Kidney			Allenic norleucine Orellanine and orellanine
Skeletal muscle	Cycloprop-2-enecarboxylic acid		

hallucinogenic species. A frequently reported error<sup>4,54,143</sup> is the confusion of the jack-o'-lantern (*Omphalotus olearius*) with the edible species of chanterelle (*Cantharellus cibarius*).

The toxins associated with this group are not identified. The malabsorption of proteins and sugars, such as trehalose, and the ingestion of a mushroom infected or partially digested by microorganisms or allergy may be responsible for symptoms. Gastrointestinal toxicity occurs 0.3 to 3 hours after ingestion when epigastric distress, malaise, nausea, vomiting, and diarrhea are evident. Treatment includes fluid resuscitation with control of vomiting and diarrhea. The clinical course is brief and the prognosis excellent. Those mushroom ingestions resulting in gastrointestinal toxicity more than 5 hours after ingestion are considered in Table 117-2. When symptoms seem to persist, the clinician must consider a mixed ingestion of another potentially toxic mushroom group.

Rarely, clinical presentations are life threatening, with hypovolemic shock necessitating fluids and vasopressors.<sup>134</sup> Resolution of symptoms usually occurs within 6 to 24 hours. The clinical courses associated with specific mushroom ingestions are variable.<sup>8</sup> Death is rare.

## GROUP VIII: ORELLANINE- AND ORELLININE-CONTAINING MUSHROOMS

*Cortinarius* mushrooms, such as *C. rubellus* (Fig. 117–10) and *C. orellanus*, are commonly found throughout North America and Europe.<sup>19,73,126</sup> The *C. orellanus* toxin orellanine is reduced by photochemical degradation to orellinine, a bipyridyl molecule that is further reduced to the nontoxic orelline.<sup>2,33,106,117</sup> The toxic compound orellanine is a hydroxylated bipyridine compound activated by its metabolism through the cytochrome P450 system. Toxicologically, these molecules are similar to paraquat and diquat and may have comparable mechanisms of action, although precise knowledge is limited (Chap. 109). Other nephrotoxins, such as cortinarines, are isolated from certain *Cortinarius* spp<sup>123</sup> and result in tubular damage, interstitial nephritis, and tubulointerstitial fibrosis.

Orellanine is rapidly removed from the plasma within 48 to 72 hours and concentrated in the urine in a soluble form. It can be detected in the plasma at the time of clinical symptoms by some<sup>115</sup> but not other investigators.<sup>118</sup> Thin-layer chromatography on renal biopsy material can detect orellanine long after clinical exposure.<sup>115,118</sup>

Initial manifestations occur 24 to 72 hours after ingestion and initially include headache, nausea, vomiting, and diarrhea followed by chills, polydipsia, anorexia, oliguria, and flank and abdominal pain. The largest case review demonstrated that numerous patients repetitively ingested the *Cortinarius* spp prior to diagnosis.<sup>29</sup> Oliguric kidney failure develops several days to weeks after initial symptoms.<sup>12</sup> The only initial laboratory abnormalities include hematuria, pyuria, and proteinuria. Nephrotoxicity is characterized by interstitial nephritis with tubular damage and early fibrosis of injured tubules with relative glomerular sparing.<sup>19,126</sup>

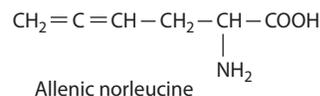

Hepatotoxicity is rarely reported.<sup>12</sup> Hemoperfusion, hemodialysis, and renal transplantation are used for the treatment of acute kidney failure.<sup>12,29</sup> No evidence suggests that secondary detoxification by plasmapheresis or hemoperfusion is of any benefit in preventing chronic kidney failure even when initiated in the first 48 hours.<sup>29,79,115</sup> The data are inadequate to define management or prognosis precisely, as many patients improve rapidly,

**FIGURE 117–10.** Group VIII: Orellanine- and orellinine-containing mushrooms: *Cortinarius rubellus*. (Used with permission from Astrid Holmgren, Swedish Poisons Information Centre.)

whereas some require temporary intermittent hemodialysis and others require chronic therapy for persistent kidney failure.<sup>12</sup> No laboratory or clinical parameters predicting the individual reactions to the toxins are available. Although case reports in the literature commonly lack definitive proof of ingestion or confirmation of toxin presence, the more rapid the onset of GI and kidney manifestations, the greater the risk of both acute and chronic kidney failure.<sup>29</sup>

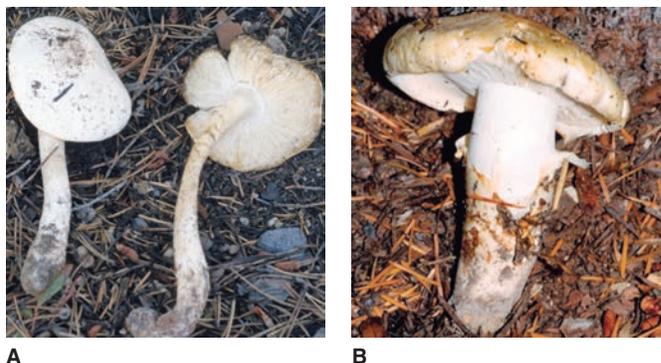

## GROUP IX: ALLENIC NORLEUCINE-CONTAINING MUSHROOMS

*Amanita smithiana* poisoning is reported in the Pacific Northwest and the Mediterranean area (Fig. 117–11).<sup>77,85,142,148,151</sup> Because the mature specimen often lacks any evidence of a partial or universal veil, these mushrooms are not recognized as *Amanita* species. It appears that all of the poisoned individuals were seeking the edible pine mushroom matsutake (*Tricholoma magnivelare*), a highly desirable lookalike. The *A. smithiana*, *A. proxima*, *A. abrupta*, and *A. pseudoporphyria* possess 2 amino acid toxins: allenic norleucine (2-amino-4,5-hexadienoic acid) and possibly 1,2-amino-4-pentynoic acid.<sup>23,108,160</sup> A case report following ingestion of *A. proxima* in Southern France also showed gastrointestinal and renal manifestations.<sup>26</sup> In vitro renal epithelial tissue cultured with allenic norleucine developed necrotic morphologic changes similar to those that occur following *A. smithiana* ingestion.<sup>108</sup> In mice, the extract of *A. abrupta* is hepatotoxic, which suggests that hepatotoxins and nephrotoxins are present in this species.<sup>160</sup>

Initial effects were noted from 0.5 to 12 hours following ingestion of either raw or cooked specimens. Gastrointestinal manifestations, including anorexia, nausea, vomiting, abdominal pain, and diarrhea, occurred frequently, accompanied by malaise, sweating, and dizziness. In some cases, vomiting and diarrhea persist for several days. The patients typically presented for care 3 to 6 days after ingestion, at which time they were oliguric or anuric. Acute kidney injury manifested 4 to 6 days following ingestion, with marked elevation of BUN and creatinine. Lactate dehydrogenase and ALT concentrations frequently were elevated, whereas amylase, AST, alkaline phosphatase, and bilirubin were only infrequently abnormal.

There is no known antidote for these nephrotoxins. Activated charcoal, although of no proven benefit, is recommended in standard doses when a patient in the northwest United States presents with early GI manifestations after mushroom ingestions. The clinician will be forced to consider the circumstances of ingestion to assess the probability of *A. smithiana* ingestion as opposed to ingestion of mushrooms containing a GI toxin.

**FIGURE 117–11.** Group IX: Allenic norleucine-containing mushrooms: (A) *Amanita smithiana* compared to (B) *Tricholoma magnivelare* (matsutake, the mushroom with which it has been mistaken). (Used with permission from John Pflischke III.)

In view of the substantial morbidity associated with *A. smithiana* ingestions, historic, clinical, and/or temporal evidence of this ingestion would be a reasonable indication for charcoal hemoperfusion or hemodialysis when the patient presents in the early phase (12–24 hours) of exposure. When a patient presents with renal compromise several days, as opposed to weeks, following mushroom ingestion and with a history of early, as opposed to delayed, GI manifestations, the clinician may be able to suggest *A. smithiana* as the etiology compared to *Cortinarius* spp exposure. Risk of toxicity was greatest in older patients and in patients with chronic kidney disease. Patients who required hemodialysis underwent the procedure 2 to 3 times per week for approximately one month until recovery. None of the patients in the 3 series died.

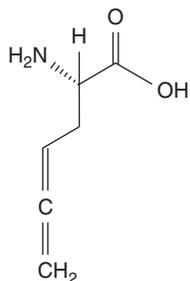

### GROUP X: CYCLOPROP-2-ENECARBOXYLIC ACID-CONTAINING MUSHROOMS

There are several reports of *Tricholoma equestre* (*Tricholoma flavovirens*) ingestions in Poland and France, where although this mushroom is considered edible it has resulted in significant skeletal muscle myotoxicity.<sup>24,103</sup> In the first report, 12 patients who ingested *T. equestre* mushrooms for 3 consecutive days developed severe rhabdomyolysis that was lethal in 3 cases.<sup>6</sup> All patients developed fatigue, muscle weakness, and myalgias 24 to 72 hours following the last mushroom meal. The individuals also developed facial erythema, nausea without vomiting, and profuse sweating. The mean maximal creatine phosphokinase (CK) was 226,067 U/L in women and 34,786 U/L in men, with some values greater than 500,000 U/L. Electromyography and biopsies showed myofibrillar injury and edema consistent with an acute myopathy.

Dyspnea, muscle weakness, acute myocarditis, dysrhythmias, congestive heart failure, and death ensued in 3 patients. Autopsy demonstrated myocardial lesions identical to those found in the peripheral muscles. Although muscle toxicity was reproduced using *T. equestre* extracts in a mouse model, the etiology of the toxicity is not defined.<sup>6</sup> All the triterpenoids, sterols, indoles, and acetylenic compounds extracted from these mushrooms previously were assumed to be without toxicity. Currently all the clinical experience originates from Europe where these mushrooms are considered choice and eaten extensively; no cases are reported in the United States.

Similar clinical presentations are reported in China, Taiwan, and Japan associated with the ingestion of *Russula subnigricans*. Patients also manifest nausea, vomiting, diarrhea, malaise, fatigue, muscle weakness, dark urine, and oliguria. In these reports, rhabdomyolysis (CK in 100s–10,000s) and oliguric kidney failure necessitating hemodialysis occurred in several patients with rare deaths.<sup>86</sup> A toxin—cycloprop-2-enecarboxylic acid extracted from *R. subnigricans*—caused severe myotoxicity in mice,<sup>96</sup> but a mechanism is not defined and there are other proposed myotoxins also recognized in this species.

### GROUP XI: 2R-AMINO-4,5-HYDROXY-5-HEXYNOIC ACID AND 2R-AMINO-5-HEXYNOIC ACID-CONTAINING MUSHROOMS

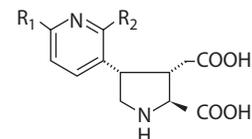

Two clinical syndromes both associated with diffuse myotoxicity with cardiac preference are described in China. They are associated with myocarditis and sudden cardiovascular collapse. The myocardial toxin and

presumably skeletal muscle toxins found in *T. venenata* are 2R-amino-4,5-hydroxy-5-hexynoic acid and 2R-amino-5-hexynoic acid which are unsaturated amino acids. The first syndrome has been called Yunnan Sudden Unexplained Death (SUD) and has been recognized for 4 decades. Hundreds of individuals may have succumbed following the ingestion of an abundant flowerlike mushroom *Trogia venenata* that is typically eaten by many during the summer rainy season.<sup>130</sup> The few closely studied cases have minor gastrointestinal manifestations, including nausea and vomiting, followed by dizziness, dyspnea, myalgias, abdominal pain, dysesthesias, and tremor (myoclonic movements). Hypotension and syncope occur within several days of exposure. A number of these patients have presumably had ventricular fibrillation and sudden death. Most patients had significant leukocytosis, CK elevation (1,000–18,000), CKMB elevation (50–1,700), and a troponin I positivity on qualitative testing. Electrocardiographs were done infrequently and showed no conduction abnormalities. Although there is a high degree of suspicion and clinical correlation, others have had Yunnan SUD without ingestions, leading some investigators to suggest that viral etiologies, barium toxicity, and other foods as well as the previously unsuspected mushroom *T. venenata* were causative.<sup>135,136,161</sup>

The pathologic studies are limited; no skeletal muscle pathology was performed whereas mild myocardial necrosis with lymphocyte infiltration and focal myocardial interstitial hemorrhage was observed in several cases. The first of these amino acids was found at autopsy in an individual, and both hexynoic amino acids when administered to mice resulted in death.<sup>129</sup> The investigators suggest that these amino acids have a molecular similarity to hypoglycin A of the ackee fruit and that hypoglycemia occurred in the mice that succumbed. Hypoglycemia has not occurred in any of the patients with sudden deaths studied in China.<sup>130</sup> Since 2010, public health education has focused on the communities and their health care providers where these mushrooms are abundant.<sup>129</sup> There have been extensive public health interventions warning patients not to eat these mushrooms, and there have been no additional cases since this public health effort began.

A second epidemic with a similar clinical constellation of signs and symptoms occurred in Jiangxi Province with *Amanita franchetti* and *Ramaria rufescens* presumed to be etiologic.<sup>67</sup> In these cases, patients developed nausea, vomiting, malaise, dizziness, abdominal distress, myalgia, and tremors within 2 to 15 hours after ingestion. Within several days, they also developed tachycardia, hypotension, and experienced sudden death. There is less laboratory data in these cases, with little ECG evidence compared to SUD. There is little evidence to suggest a management approach other than observation, cardiac monitoring, and extensive cardiac evaluation, which has been limited in the Yunnan SUD heretofore.

### GROUP XII: ACROMELIC ACID-CONTAINING MUSHROOMS

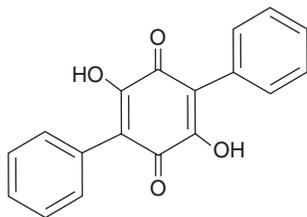

Acromelic acids D and E

D: R<sub>1</sub> = COOH; R<sub>2</sub> = H  
E: R<sub>1</sub> = H; R<sub>2</sub> = COOH

Erythromelalgia is a poorly defined syndrome originally recognized in Japan,<sup>99,102</sup> recently in France<sup>9</sup> following the ingestion of various *Clitocybe* species (*C. acromelalga* and *C. amoenolens*), and not recognized currently in the United States. The toxic substances acromelic acids A to E have been isolated. These molecules are similar to kainic acid and are of the pyrrolidine dicarboxylic acid family, which act as ionotropic glutamate receptors. Erythromelalgia typically occurs more than 24 hours following ingestion. Patients develop paraesthesias of distal extremities followed by paroxysms of severe burning dysesthesias lasting several hours. The extremities show edema and erythema.

These manifestations respond variably to symptomatic and supportive care and resolve completely within several months. A single patient given nicotinic acid (niacin) at intermittent high IV doses initially demonstrated resolution of erythema and edema. The patient continued oral nicotinic acid as treatment for 3 months.<sup>102</sup> Varied hypotheses<sup>101,127</sup> for the improvement are suggested as related to nicotinic acid such as improved peripheral blood flow and resolution of neurovascular dysfunction associated with acromelic acid. The description of the evidence of resolution over a 3-month period is limited.

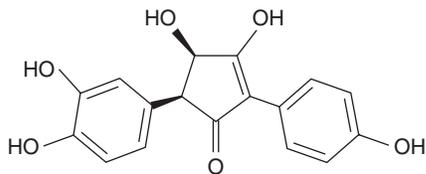

### GROUP XIII: POLYPORIC ACID-CONTAINING MUSHROOMS

Two groupings of toxic mushroom ingestion syndromes result in encephalopathy. The first group of mushrooms associated with encephalopathy is the *Hapalopilus rutilans* reported in a German case series. More than 12 hours after ingestion, an adult and 2 children developed nausea, vomiting, and abdominal pain. Central nervous system abnormalities including vertigo, ataxia, visual disturbances, and somnolence were reported.<sup>81,121</sup> Aminotransferase and creatinine concentrations were elevated. In each case, the urine was a violet color, the color being noted when polyporic acid is placed in an alkaline solution. Polyporic acid, a dihydroquinone derivative (2,5-dihydroxy-3,6-diphenyl-1,4-benzoquinone), a constituent of these mushrooms, is a dihydroorotate dehydrogenase (an enzyme in the biosynthesis of pyrimidine) inhibitor that resulted in comparable clinical and biochemical manifestation when administered to rats.<sup>81</sup> Symptomatic treatment is indicated with more specific therapy should hepatic or renal compromise be significant.

In the second group, *Pleurocybella porrigens*, a mushroom species commonly eaten in Japanese miso soup, without any adverse effects, is suggested to be etiologic. However, their ingestion by patients with chronic kidney injury resulted in delayed manifestations of encephalopathy.<sup>61</sup> Three-quarters (24 of 32) of the affected patients were undergoing hemodialysis at the time of the presumed poisoning. The delay from time of ingestion to the development of an altered consciousness, convulsions, myoclonus, dysarthria, dysesthesias, ataxia, respiratory failure, or death was between 1 and 31 days. No prior toxic link or known xenobiotic in these commonly ingested mushrooms is recognized.

### GROUP XIV: INVOLUTIN-CONTAINING MUSHROOMS

A small number of patients with ingestions of *Paxillus involutus*, and possibly *Clitocybe claviceps* and *Boletus luridus*, develop early-onset mild GI symptoms followed by an immune-mediated hemolytic anemia, hemoglobinuria, oliguria, and acute kidney injury. Immunoglobulin G antibodies to a *Paxillus* extract containing involutin<sup>71</sup> were detected by a hemagglutination test in these patients.<sup>153,154</sup> This syndrome occurs in Europe, typically among those who have eaten *P. involutus* on numerous occasions.

### GROUP XV: LYCOPERDONOSIS

Puffball mushrooms (*Lycoperdon perlatum*, *Lycoperdon pyriforme*, or *Lycoperdon gemmatum*) are edible in the fall and can (upon decay or drying) release large numbers of spores following compression, fracture, or

A

B

**FIGURE 117-12.** Puffballs: (A) *Lycoperdon pyriforme* and (B) *Lycoperdon perlatum*. (Used with permission from John Plischke III.)

shaking (Fig. 117-12). Lycoperdonosis is directly related to massive exposure to spores, although many consider the syndrome an allergic bronchoalveolitis. This syndrome occurs in patients following acute inhalation of spores as an alternative or complementary therapy for epistaxis<sup>137</sup> and in adolescents for various experimental reasons.<sup>21</sup> Massive inhalation, insufflation, and chewing of spores can lead to the development of nasopharyngitis, nausea, vomiting, and pneumonitis within hours. Over a period of several days, cough, shortness of breath, myalgias, fatigue, and fever develop. Rarely, patients require intubation because of pulmonary compromise associated with diffuse reticulonodular infiltrates.<sup>21</sup> Lung biopsy demonstrates an inflammatory process with the presence of *Lycoperdon* spores.<sup>137</sup> Patients treated with corticosteroids such as prednisone and antifungals such as amphotericin B recovered within several weeks without sequelae although there are no controlled studies of the merits of this approach.

### GENERAL MANAGEMENT ISSUES

Because ingestion of certain mushrooms may lead to toxicity with substantial morbidity or mortality, patients with suspected mushroom ingestions require rigorous management. A serious effort at precise identification of the genus and species involved will make assessment, management, and follow-up easier and more logical. Unintentional ingestions in children “in their yards” are usually limited exposures to nontoxic mushrooms resulting in no symptoms necessitating solely reassurance by the certified specialist in Poison Information. Beuhler and coworkers utilizing the AAPCC Toxic Exposure Surveillance System suggest that the treatment of exposures to mushrooms in children with syrup of ipecac decreases morbidity.<sup>10</sup> It is unlikely that the syrup of the ipecac will be useful and it is not recommended. It is recommended that charcoal be administered if potentially toxic mushrooms are ingested. If nausea and vomiting persist, an antiemetic is recommended to ensure that the patient can retain activated charcoal. Appropriate life

support measures recommended as necessary. Fluids, electrolytes, and dextrose repletion, as needed, are essential.

There is a wide variability in quantity and type of xenobiotic present in mushrooms according to geography, climate, and local conditions. The clinical course for *A. smithiana* poisoning has led us to suggest an alteration in the initial approach to patients in the northwest United States who have early onset (0.5–5 hours) of GI distress following mushroom ingestion as *A. smithiana* has a significant risk of kidney failure. Prior to the recognition of this mushroom poisoning, all patients who had early onset of nausea, vomiting, diarrhea, and abdominal cramps were presumed to be poisoned by a member of the groups containing either the GI toxins or muscarine. The more we learn and study, the more it is obvious that these clinical time courses as described in Table 117–2 are rough estimates of most likely estimates and the clinician should recognize that the quality of our understanding of mushroom toxicology is improving, but speciation, time course, actual mycologic chemistry, and management are based on limited evidence.

## DISPOSITION

It is important to remember that many patients with mushroom ingestions present with mixed and incomplete signs and symptoms. Whereas some ingestions produce “purer” symptom complexes than others, some ingestions, such as those of *A. muscaria*, produce GI and CNS effects, and still other ingestions, such as those of *Cortinarius* spp, have acute GI and delayed kidney manifestations. Treatment or partial treatment may further confound the assessment. In addition, it is essential to remember that any acute GI disorder actually may be the manifestation of mushroom toxicity. In the spring and fall, in areas with temperate weather and humidity, it is particularly important to consider intentional or unrecognized exposure to mushroom toxins, although a logical approach to management is impossible in the absence of a precise history.

Because the clinical course of mushroom poisoning can be deceptive, all patients who manifest early gastrointestinal symptoms (<5 hours) and remain symptomatic for several hours despite supportive care (Tables 117–1 and 117–2) should be admitted to the hospital. In this group of patients inhabiting the Pacific northwest, *A. smithiana* is particular concern. Although acute kidney injuries will likely not occur for several days necessitating careful follow-up. Patients whose delayed initial presentation (≥5 hours) is suggestive of amatoxin exposure should be hospitalized, as should any patient postingestion who cannot be followed safely or reliably as an outpatient. Tables 117–1 and 117–2 list the characteristic times of appearance and evolution of symptoms caused by mushroom xenobiotics. Confusion may result from atypical clinical manifestations or, commonly, ingestion of several different mushrooms species, some of which may produce early symptoms and others delayed toxicity. Patients with certain types of ingestions may appear to improve initially with only supportive care. This latency period, which is characteristic of *Amanita* spp, may not be appreciated when several different species are eaten simultaneously. However, because hepatotoxicity leading to death may not appear until 2 to 3 days after ingestion (amatoxins) and nephrotoxicity may not appear for 3 to 21 days (orellanine and allenic norleucine), all patients with symptoms following unknown ingestions require subsequent follow-up.

## IDENTIFICATION

### General

Visualizing and analyzing the gross, microscopic, or chemical characteristics of the ingested mushroom remain vital strategies that are infrequently used. When the whole mushroom or parts are unavailable, the diagnosis must be based on the clinical presentation. No rapidly available studies in emergency departments or clinical chemistry laboratories are available to assist with identification. The development of a rapid clinical test for amatoxins,<sup>17,18,79</sup> gyromitrin, orellanine, and allenic norleucine would be useful and permit early use of hemodialysis or hemoperfusion and greater vigilance with regard

to use of hemodialysis. We have not yet achieved the ability to use thin-layer chromatography, high-performance liquid chromatography, gas chromatography, or gas chromatography–mass spectrometry in a clinically relevant manner. In Italy and Japan, real-time polymerase chain reaction (PCR) technology has been developed for multiple species for experimental evaluations of cooked mushrooms and gastric aspirates. Future development of this technique may prove clinically useful.<sup>34,90</sup>

Although mushroom identification is a difficult task, this section may be helpful to the clinician dealing with a suspected case of mushroom toxicity. However, it is generally best to rely on symptomatology, not mushroom appearances, to confirm a diagnosis. As a general rule, positive identification of the mushroom should be left to the mycologist or toxicologist.<sup>45</sup> The most important anatomic features of both edible and poisonous mushrooms are their pileus, stipe, lamellae or gills, and volva (Fig. 117–2).

- Pileus: Broad, caplike structure from which hang the gills (lamellae), tubes, or teeth.
- Stipe: Long stalk or stem that supports the cap; the stipe is not present in some species.
- Lamellae: Platelike or gilllike structures on the undersurface of the pileus that radiate out like the spokes of a wheel. The spores are found on the lamellae. Some mushrooms have pores or toothlike structures on their pili, which contain the spores. The mode of attachment of the lamellae to the stipe is noteworthy in making an identification.
- Volva: Partial remnant of the veil found around the base of the stipe in some species.
- Veil: Membrane that may completely or partially cover the lamellae, depending on the stage of development. The “universal” veil covers the underside, the spore-bearing surface of the pileus.
- Annulus: Ringlike structure that may surround the stipe at some point below the junction, with the cap that is a remnant of the partial veil.
- Spores: Microscopic reproductive structures that are resistant to extremes in temperature and dryness, produced in the millions on the spore-bearing surface (see Lamellae). Of all the characteristics of a particular mushroom species, spores are the least variable, although many mushrooms have similar-appearing spores. A spore print is helpful in establishing an identification. A spore print viewed microscopically is comparable to a bacterial Gram stain. Spore colors range from white to black and include shades of pink, salmon, buff, brown, and purple. Spore color in general is constant for a species.

## THE UNKNOWN MUSHROOM

1. The most important determinant is whether the ingested mushroom is one of the high-morbidity varieties, especially *Amanita*.
2. An attempt should be made to obtain either the collected mushrooms, a photograph, or a detailed description of their features. Arrange for transport of the mushroom in a dry paper bag (not plastic). Ensure that the mushroom is neither moistened nor refrigerated, either of which will alter its structure. Remember that gastric contents may contain spores that are very difficult to find, but can be crucial for analysis.
3. If the mushroom cap is available, make a spore print by placing the pileus spore-bearing surface side down on a piece of paper for at least 4 to 6 hours in a windless area. The spores that collect on the paper can be analyzed for color. White spore prints can be visualized more easily on white paper by tilting the paper and looking at it from an angle.
4. Concomitant with step 3, contact a mycologist and use the best resources available for identification. A botanical garden usually has expert mycologists on staff, or a local mycology club can locate a mycologist. A regional poison control center almost always can provide this expertise or locate an expert.

## POISONING PRINCIPLES: MYTHS AND SCIENCE

Differentiating myths from science is a difficult task in any field of medicine. This effort is even more complex when discussing mushrooms. The following principles are of great value in developing a logical approach to a potential ingestion.

1. Wild mushrooms should never be eaten unless an experienced mycologist can absolutely identify the mushroom. Even experts have trouble identifying some mushrooms, yet some foragers boldly indicate that distinguishing edible from toxic mushrooms is “as easy as telling brussels sprouts from broccoli.” Remember the saying, “There are old mushroom hunters, and bold mushroom hunters; but there are no old, bold mushroom hunters.”
2. The toxicology of any species can vary, depending on geographic location. This species confusion is obvious among American immigrants stating unequivocally that “this particular mushroom” was absolutely safe and routinely eaten in the individual’s Asian or European country of origin.
3. If toxicity is suspected, attempt to obtain samples of the mushrooms eaten, and identify them. Every emergency department can have a readily available resource on mushrooms found on many Internet Web sites. The older, more comprehensive mycology field guides can be most useful as well.<sup>1,15,87,88,119,131</sup> In any case, identification is best made with the aid of the poison control center’s consultant mycologist.
4. Mushrooms often are implicated as the cause of an illness when, in fact, infections or other diseases are responsible. Other etiologies include the mode of preparation (the sauce or wine) or the cooking utensil.
5. There are no absolute generic approaches for evaluating the potential toxicity of a mushroom. Myths suggesting the safety or lack of safety by staining of silver, presence of insects or slugs, peeling off the mushroom cap, or the area of mushroom growth are unreliable or false. Neither odor nor taste is a good predictor of toxicity. Pure white mushrooms, little brown mushrooms, large brown mushrooms, and red- or pink-spored boletus (a mushroom without lamellae) should be considered potentially toxic.
6. Cooking may inactivate some toxins contained in mushrooms but not others. In general, no wild mushroom should be eaten raw or in large quantities. Examples of toxicity associated with lack of cooking include *Armillariella mellea* (honey mushroom), which usually is well tolerated when cooked but not raw, and *Verpa bohemica* (a morellike mushroom), which is edible but causes illness if eaten in excess. Even the *Morchella esculenta*, the edible-choice morel, is well recognized to cause dizziness, tremor, and ataxia when eaten raw in large quantities.<sup>122</sup>
7. Associated phenomena may be responsible for or contribute to toxicity. Could insecticides have been sprayed on the mushrooms? Is it an alcohol-related response? Besides the well-known disulfiram-like reaction involving *C. atramentarius*, other good edibles, including the black morel (*Morchella angusticeps*) and the sulfur polypore (*Laetiporus sulfureus*), can cause adverse reactions if consumed with alcohol. The etiology of these adverse reactions is not understood.
8. “Edible” mushrooms that are allowed to deteriorate during collection, transport, and storage prior to or subsequent to preparation become toxic. Therefore, only young, recently matured specimens should be eaten when adequate mycologic support is available.
9. The finding that only some people who ate a mushroom species manifested characteristic toxicity should not exclude the diagnosis of mushroom poisoning. The degree of toxicity may be dose related or genetically determined, or a person may have a preexistent pathologic disposition to toxicity.
10. Mushroom allergy can manifest as an anaphylactic reaction.
11. Most poisonous mushrooms resemble edible mushrooms at some phase of their growth. For this reason, even careful examination of the ring, cap, consistency, form, and color may not reliably identify the edible species. Also, characteristic features of specific toxic mushrooms may not be present under certain conditions. Although the deadly

*A. phalloides* and *A. virosa* usually have remnant patches of tissue from the universal veil that envelops the mushroom in its “button” stage, rain may wash these remnants away. Similarly, a subterranean basal cup may not be noticed if the mushroom is cut at the ground level by a novice forager (Fig. 117–1).

12. Even the new in-vogue “wild mushrooms” in the specialty markets may not be entirely safe (personal observations).

## SUMMARY

- It is essential to determine whether the ingested mushroom is one of the high morbidity/mortality varieties such as the *Amanita* spp.
- The onset of GI symptoms within 5 hours of ingestion makes exposure to a hepatotoxic *Amanita* species less likely.
- Several mushroom species including *Amanita smithiana* containing allenic norleucine and *Cortinarius orellanus* containing orellanine and orellanine result in acute kidney injury more than 24 hours after ingestion.
- Slibinin, the active component of the milk thistle, is suggested to competitively inhibit the organic anion transporter polypeptide that is responsible for the uptake and enterohepatic recycling of  $\alpha$ -amanitin thereby inhibiting  $\alpha$ -amanitin hepatocellular penetration. The evidence is limited and we withhold recommendation.
- The potential morbidity and mortality associated with *amanitin* hepatotoxicity necessitates rapid assessment by a hepatic transplantation service, even though the clinical evolution is unpredictable and criteria for transplantation under these circumstances are not established.
- The novel research of Polymyxin B a US FDA approved antibiotic is a reasonable therapeutic intervention for presumed *Amanita* species ingestion. A brief course of 12-24 hours of Polymyxin B given as a single dose 0.75 mg/kg body weight has the potential to limit hepatotoxicity without significant risk of nephrotoxicity.

Approximately 5% of all human exposures reported to poison control centers involve plants. The large number of exposures probably occur because plants are so accessible and attractive to youngsters. Approximately 80% of these cases involve individuals younger than 6 years. As indoor plants have become ever more popular, the incidence of plant exposures has increased. Data compiled by the American Association of Poison Control Centers (AAPCC) give some indication of which plants are more commonly involved (Chap. 130), but these plants typically have relatively limited toxicity. More than 80% of patients reported to the AAPCC as being exposed were asymptomatic, less than 20% had minor to moderate symptomatology, and less than 7% necessitated a health care visit. The benignity of these exposures in the United States, largely due to the unintentional nature of the event, is represented by a fatality rate of less than 0.001%. However, in other parts of the world, plant exposures, particularly those taken for self-harm and where health care is less accessible, carry a significant risk and public health burden.<sup>12</sup> This chapter addresses the toxicologic principles associated with the most potentially dangerous plants.

### HISTORY AND CLASSIFICATION OF PLANT XENOBIOTICS

Aconitine, from monkshood, exemplifies the rich history of plant toxicology. It was believed by the Greeks to be the first poison—"lycotonum"—created by the goddess Hecate from the foam of the river Cerebrus. Alkaloid constituents are responsible for its toxic (and therapeutic) effects. Alkaloids represent one of several classes of organic molecules found in plants as defined by the science of pharmacognosy, which is the science of medicines derived from natural sources. The pharmacognosy approach is consistent with the literature of plant efficacy and is applied here to their toxicity (Table 118–1). Unfortunately, the science of pharmacognosy is not always straightforward, and systems of classification may vary depending on the pharmacognosist. Hence, our approach borrows primarily from 2 groups of authors to keep the classification as consistent as possible.<sup>51,128</sup> The major groups are as follows:

1. Alkaloids: Molecules that react as bases and contain nitrogen, usually in a heterocyclic structure. Alkaloids typically have strong pharmacologic activity that defines many major toxidromes.
2. Glycosides: Organic compounds that yield a sugar or sugar derivative (the glycone) and a nonsugar moiety (the aglycone) upon hydrolysis. The aglycone is the basis of subclassification into saponin or steroidal glycosides (including steroidal cardiac glycosides, cyanogenic glycosides, anthraquinone glycosides), and others such as atractyloside and salicin.
3. Terpenes and resins: Assemblages of 5-carbon units (isoprene unit) with many types of functional groups (eg, alcohols, phenols, ketones, and esters) attached. This is the largest group of secondary metabolites; approximately 20,000 are identified. Most essential oils are mixtures of monoterpenes, and the terpene name depends on the number of isoprene assemblages. Monoterpenes have 2 units ( $C_{10}H_{16}$ ), sesquiterpenes have 3 isoprene units ( $C_{15}$ ), diterpenes have 4 isoprene units ( $C_{20}$ ), and triterpenes have 6 ( $C_{30}$ ). These molecules often play an active role in plant defense mechanisms.
4. Proteins, peptides, and lectins: Proteins consist of amino acid units with various side chains, and peptides consist of linkages among amino acids. Lectins are glycoproteins classified according to the number of protein chains linked by disulfide bonds and by binding affinity for specific carbohydrate ligands, particularly galactosamines. The toxalbumins (eg, ricin) are lectins. These components tend to be neurotoxins, hemagglutinins, or cathartics.

5. Phenols and phenylpropanoids: Phenols contain phenyl rings and have one or more hydroxyl groups attached to the ring. Phenylpropanoids consist of a phenyl ring attached to a propane side chain. These compounds are devoid of nitrogen, even though some are derived from phenylalanine and tyrosine. They constitute a major group of secondary metabolites and among plant toxins include coumarins (lactone side chains), flavonoids (built upon a flavan 2,3-dihydro-2-phenylbenzopyran nucleus, such as naringenin and rutin), lignans (2 linked phenylpropanoids, such as podophyllin), lignins (complex polymers of lignans that bind cellulose for woody bark and stem), and tannins (polymers that bind to protein and can be further hydrolyzed or condensed).

Plant chemistry is complex. The simplified presentation of one xenobiotic per plant per symptom group used in Table 118–1 demphasizes the fact that plants contain multiple xenobiotics that work independently or in concert. Additionally, different plant families may contain similar, if not identical, xenobiotics (either from conservation of biochemical pathways inherited from a common ancestor or through convergent evolution). In some cases, xenobiotics remain unidentified and are grouped in the section Unidentified Toxins.

Our focus is on exposures to flowering plants (angiosperms) related to foraging, dietary, or occupational contact, except for some gymnosperms or algae and, rarely, medicinal contact (Chap. 43).<sup>92</sup> Because our understanding of plant xenobiotics is poor relative to that of pharmaceuticals, animal research is included to provide a more comprehensive foundation for comparison with human experiences that may otherwise go unrecognized without such precedent, or may likewise prove ultimately incorrect. The science of plant toxicology formally began in the United States as a response to significant poisonings of livestock. The overall quality of literature for human exposures is poor and primarily available as case reports. Many of these cases lack clear links between toxin exposure and illness, and qualitative or quantitative analyses are generally unavailable. Uncertainty is compounded by the fact that plants themselves are inherently variable, and potency and type of xenobiotic depend on the season, geography, growing environment, plant part, and methods of processing.

### IDENTIFICATION OF PLANTS

Positive identification of the plant species should be attempted whenever possible, especially when the patient becomes symptomatic. Communication with an expert botanist, medical toxicologist, or poison control center is highly recommended and can be facilitated by transmission of digital images. Provisionally, simple comparison of the species in question with pictures or descriptions from a field guide of flora may help exclude the identity of the plant from among the most life-threatening in Table 118–1. A plant identification can also be compared with those searched in the PLANTOX database (<http://www.accessdata.fda.gov/scripts/plantox/index.cfm>) managed by the Food and Drug Administration (FDA). However, with some exceptions, laboratory analysis is generally not timely enough to be useful except as a tool in an investigatory or forensic analysis. As the state of analytical science advances, however, it is often possible to confirm a diagnosis based on DNA analysis of unidentifiable or degraded plant material.<sup>106</sup>

In cases where expert identification cannot be immediately achieved, preliminary recognition of taxonomic families of poisonous plants is the simplest first step to identify or exclude poisonous plants, but is most easily achieved when the plant is in flower or fruit. For instance, if the flower is described or looks like a flower from a tomato or potato, it probably is in the Solanaceae family. Plants of this family typically contain solanaceous

TABLE 118-1 Primary Toxicity of Common Important Plant Species

Plant Species (Family)	Typical Common Names	Primary Toxicity	Xenobiotic(s)	Class of Xenobiotic
<i>Abrus precatorius</i> (Euphorbiaceae) <sup>a</sup>	Prayer beans, rosary pea, Indian bean, crab's eye, Buddhist's rosary bead, jequirity pea	Gastrointestinal	Abrin	Protein, lectin, peptide, amino acid
<i>Aconitum napellus</i> and other <i>Aconitum</i> spp (Ranunculaceae) <sup>a</sup>	Monkshood Friar's cap Wolfsbane	Cardiac, neurologic	Aconitine and related xenobiotic	Alkaloid
<i>Acorus calamus</i> (Araliaceae)	Sweet flag, rat root, flag root, calamus	Gastrointestinal	Asarin	Phenol or phenylpropanoid
<i>Aesculus hippocastanum</i> (Hippocastanaceae)	Horse chestnut	Hematologic	Esculoside (6-β-D-glucopyranosyloxy-7-hydroxycoumarin)	Phenol or phenylpropanoid
<i>Agave lecheguilla</i> (Amaryllidaceae)	Agave	Dermatitis	Aglycones, smilagenin, sarsasapogenin	Saponin glycoside
<i>Aloe barbadensis</i> , <i>Aloe vera</i> , others (Liliaceae/Amaryllidaceae)	Aloagave	Gastrointestinal	Barbaloin, iso-barbaloin, aloinosides	Anthraquinone glycoside
<i>Anabaena</i> and <i>Aphanizomenon</i> <sup>a</sup>	Blue-green algae	Neurologic	Saxitoxinlike	Guanidinium
<i>Anacardium occidentale</i> , many others (Anacardiaceae)	Cashew, many others	Contact dermatitis	Urushiol oleoresins	Terpenoid
<i>Anthoxanthum odoratum</i> (Poaceae)	Sweet vernal grass	Hematologic	Coumarin	Phenol or phenylpropanoid
<i>Areca catechu</i> (Arecaceae)	Betel nut	Cholinergic	Arecoline	Alkaloid
<i>Argemone mexicana</i> (Papaveraceae)	Mexican pricklepoppy	Gastrointestinal	Sanguinarine	Alkaloid
<i>Argyrea nervosa</i>	Hawaiian baby woodrose seeds	Neurologic	Lysergic acid amide	Alkaloid
<i>Argyrea</i> spp (Convolvulaceae)	Morning glory	Neurologic	Lysergic acid derivatives	Alkaloid
<i>Aristolochia reticulata</i> , <i>Aristolochia</i> spp (Aristolochiaceae) <sup>a</sup>	Texan or Red River snake root	Renal, carcinogenic	Aristolochic acid	Alkaloid relative as derivative of isothebaine
<i>Artemisia absinthium</i> (Compositae/Asteraceae) <sup>a</sup>	Absinthe	Neurologic	Thujone	Terpenoid
<i>Asclepias</i> spp (Asclepiadaceae) <sup>a</sup>	Milk weed	Cardiac	Asclepin and related cardenolides	Cardioactive steroid
<i>Astragalus</i> spp (Fabaceae) <sup>a</sup>	Locoweed	Metabolic, neurologic	Swainsonine	Alkaloid
<i>Atractylis gummifera</i> (Compositae) <sup>a</sup>	Thistle	Hepatic	Atractyliside, gummiferine	Glycoside
<i>Atropa belladonna</i> (Solanaceae) <sup>a</sup>	Belladonna	Anticholinergic	Belladonna alkaloids	Alkaloid
<i>Azalea</i> spp (Ericaceae) <sup>a,b</sup>	Azalea	Cardiac, neurologic	Grayanotoxin	Terpenoid
<i>Berberis</i> spp (Ranunculaceae)	Barberry	Oxytotic, cardiovascular	Berberine	Alkaloid
<i>Blighia sapida</i> (Sapindaceae) <sup>a</sup>	Ackee fruit	Metabolic, gastrointestinal, neurotoxic	Hypoglycin	Protein, lectin, peptide, amino acid
<i>Borago officinalis</i> (Boraginaceae) <sup>a</sup>	Borage	Hepatic (venoocclusive disease)	Pyrrrolizidine alkaloids	Alkaloid
<i>Brassaia</i> spp <sup>b</sup>	Umbrella tree	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid
<i>Brassica nigra</i> (Brassicaceae)	Black mustard	Dermatitis, irritant	Sinigrin	Glucosinolate (isothiocyanate glycoside)
<i>Brassica oleracea</i> var. capitata	Cabbage	Metabolic (precursor to goittrin, antithyroid compound)	Progoittrin	Isothiocyanate glycoside
<i>Cactus</i> spp <sup>b</sup>	Cactus	Dermatitis, mechanical	Nontoxic	None
<i>Caladium</i> spp (Araceae) <sup>b</sup>	Caladium	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid
<i>Calotropis</i> spp (Asclepiadaceae) <sup>a</sup>	Crown flower	Cardiac	Asclepin and related cardenolides	Cardioactive steroid

(Continued)

TABLE 118-1 Primary Toxicity of Common Important Plant Species (Continued)

Plant Species (Family)	Typical Common Names	Primary Toxicity	Xenobiotic(s)	Class of Xenobiotic
<i>Camellia sinensis</i> (Theaceae)	Tea, green tea	Cardiac, neurologic	Theophylline, caffeine	Alkaloid
<i>Cannabis sativa</i>	Cannabis, marijuana, Indian hemp, hashish, pot	Neurologic	Tetrahydrocannabinol	Terpenoid, resin, oleoresin
<i>Capsicum frutescens</i> , <i>Capsicum annuum</i> , <i>Capsicum</i> spp (Solanaceae) <sup>b</sup>	Capsicum, cayenne pepper	Dermatitis, irritant	Capsaicin	Phenol or phenylpropanoid
<i>Cascara sagrada</i> , <i>Rhamnus purshiana</i> , <i>Rhamnus cathartica</i> (Rhamnaceae)	Cascara, sacred bark, Chittern bark, common buckthorn	Gastrointestinal	Cascarosides, <i>O</i> -glycosides, emodin	Anthraquinone glycoside
<i>Cassia senna</i> , <i>Cassia angustifolia</i> (Fabaceae)	Senna	Gastrointestinal	Senosides	Anthraquinone glycoside
<i>Catha edulis</i> (Celastraceae)	Khat	Cardiac, neurologic	Cathinone	Alkaloid
<i>Catharanthus roseus</i> (formerly <i>Vinca rosea</i> ) (Apocynaceae)	Catharanthus, vinca, madagascar periwinkle	Gastrointestinal	Vincristine	Alkaloid
<i>Caulophyllum thalictroides</i> (Berberidaceae)	Blue cohosh	Nicotinic	<i>N</i> -methylcytisine and related compounds	Alkaloid
<i>Cephaelis ipecacuanha</i> , <i>Cephaelis acuminata</i> (Rubiaceae) <sup>a</sup>	Syrup of ipecac	Gastrointestinal, cardiac	Emetine/cephaline	Alkaloid
<i>Chlorophytum comosum</i> <sup>b</sup>	Spider plant	Dermatitis, contact, and allergic	Urushiol oleoresins	Terpenoid
<i>Chondrodendron</i> spp, <i>Curarea</i> spp, <i>Strychnos</i> spp <sup>a</sup>	Tubocurare, curare	Neurologic	Tubocurarine	Alkaloid
<i>Chrysanthemum</i> spp, <i>Taraxacum officinale</i> , other Compositae (Asteraceae) <sup>b</sup>	Chrysanthemum, dandelion, other Compositaceae	Contact dermatitis	Sesquiterpene lactones	Terpenoid
<i>Cicuta maculata</i> (Apiaceae/ Umbelliferae) <sup>a</sup>	Water hemlock	Neurologic	Cicutoxin	Alcohol
<i>Cinchona</i> spp (Rubiaceae) <sup>a</sup>	Cinchona	Cardiac, cinchonism	Quinidine	Alkaloid
<i>Citrus aurantium</i> (Rutaceae) <sup>a</sup>	Bitter orange	Cardiac, neurologic	Synephrine	Alkaloid
<i>Citrus paradisi</i> (Rutaceae)	Grapefruit	Drug interactions	Bergamottin, naringenin, or naringen	Phenol or phenylpropanoid
<i>Claviceps purpurea</i> , <i>Claviceps paspali</i> (Claviceptaceae = fungus) <sup>a</sup>	Ergot	Cardiac, neurologic, oxytocic	Ergotamine and related compounds	Alkaloid
<i>Coffea arabica</i> (Rubiaceae)	Coffee	Cardiac, neurologic	Caffeine	Alkaloid
<i>Cola nitida</i> , <i>Cola</i> spp (Sterculiaceae)	Kola nut	Cardiac, neurologic	Caffeine	Alkaloid
<i>Colchicum autumnale</i> (Liliaceae) <sup>a</sup>	Autumn crocus	Multisystem	Colchicine	Alkaloid
<i>Conium maculatum</i> (Apiaceae/ Umbelliferae) <sup>a</sup>	Poison hemlock	Nicotinic, neurologic, respiratory, renal	Coniine	Alkaloid
<i>Convallaria majalis</i> <sup>a</sup>	Lily of the valley	Cardiac	Convallatoxin, strophanthin (~40 others)	Cardioactive steroid
<i>Coptis</i> spp (Ranunculaceae)	Goldenthread	Oxytocic, cardiovascular	Berberine	Alkaloid
<i>Crassula</i> spp <sup>b</sup>	Jade plant	Gastrointestinal	Nontoxic	None
<i>Crotalaria</i> spp (Fabaceae) <sup>a</sup>	Rattlebox	Hepatic (venoocclusive disease)	Pyrrolizidine alkaloids	Alkaloid
<i>Croton tiglium</i> and <i>Croton</i> spp (Euphorbiaceae)	Croton	Carcinogen, gastrointestinal	Croton oil	Lipid and fixed oil, also contains tropane alkaloid and diterpene
<i>Cycas circinalis</i> <sup>a</sup>	Queen sago, indu, cycad	Neurologic	Cycasin	Glycosides
<i>Cytisus scoparius</i> (Fabaceae) <sup>a</sup>	Broom, Scotch broom	Nicotinic, oxytocic	Sparteine	Alkaloid

(Continued)

TABLE 118-1 Primary Toxicity of Common Important Plant Species (Continued)

Plant Species (Family)	Typical Common Names	Primary Toxicity	Xenobiotic(s)	Class of Xenobiotic
<i>Datura stramonium</i> (Solanaceae) <sup>a</sup>	Jimson weed, stramonium, locoweed	Anticholinergic	Belladonna alkaloids	Alkaloid
<i>Delphinium</i> spp (Ranunculaceae) <sup>a</sup>	Larkspur	Cardiac, neurologic	Methyllycaconitine	Alkaloid-related xenobiotic
<i>Dieffenbachia</i> spp (Araceae) <sup>b</sup>	Dieffenbachia	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid
<i>Digitalis lanata</i> <sup>a</sup>	Grecian foxglove	Cardiac	Digoxin, lanatosides A–E (contains ~70 cardiac glycosides)	Cardioactive steroid
<i>Digitalis purpurea</i> <sup>a</sup>	Purple foxglove	Cardiac	Digitoxin	Cardioactive steroid
<i>Dipteryx odorata</i> , <i>Dipteryx oppositifolia</i> (Fabaceae)	Tonka beans	Hematologic	Coumarin	Phenol or phenylpropanoid
<i>Ephedra</i> spp, especially <i>sinensis</i> (Ephedraceae/Gnetaceae = Gymnosperm) <sup>a</sup>	Ephedra, Ma-huang	Cardiac, neurologic	Ephedrine and related xenobiotics	Alkaloid
<i>Epipremnum aureum</i> (Araceae) <sup>b</sup>	Pothos	Dermatitis, mechanical, and cytotoxic	Oxalate raphides	Carboxylic acid
<i>Erythroxylum coca</i>	Coca	Neurologic, cardiac	Cocaine	Alkaloid
<i>Eucalyptus globus</i> or spp <sup>b</sup>	Eucalyptus	Dermatitis, contact, and allergic	Eucalyptol	Terpenoid
<i>Euphorbia pulcherrima</i> , <i>Euphorbia</i> spp (Euphorbiaceae) <sup>b</sup>	Poinsettia	Dermatitis, contact, and allergic	Phorbol esters	Terpenoid
<i>Galium triflorum</i> (Rubiaceae)	Sweet-scented bedstraw	Hematologic	Coumarin	Phenol or phenylpropanoid
<i>Ginkgo biloba</i> (Ginkgoaceae)	Ginkgo	Dermatitis, contact, and allergic Hematologic Neurologic	Urushiol oleoresins Ginkgolides A–C, M 4-Methoxypyridoxine in seeds only	Terpenoid Terpenoid Alkaloid, pyridine
<i>Gloriosa superba</i> (Liliaceae) <sup>a</sup>	Meadow saffron	Multisystem	Colchicine	Alkaloid
<i>Glycyrrhiza glabra</i> <sup>a</sup>	Licorice	Metabolic, renal	Glycyrrhizin	Saponin glycoside
<i>Gossypium</i> spp	Cotton, cottonseed oil	Metabolic	Gossypol	Terpenoid
<i>Hedeoma pulegioides</i> (Lamiaceae) <sup>a</sup>	Pennyroyal	Hepatic, neurologic, oxytoxic	Pulegone	Terpenoid
<i>Hedera helix</i> (Araliaceae) <sup>b</sup>	Common ivy	Not absorbed	Hederacoside C, $\alpha$ -hederin, hederagenin	Cardioactive steroid
<i>Hedysarium alpinum</i> (Fabaceae)	Wild potato	Metabolic, neurologic	Swainsonine	Alkaloid
<i>Heliotropium</i> spp (Compositae/Asteraceae) <sup>a</sup>	Ragwort	Hepatic (venoocclusive disease)	Pyrrrolizidine alkaloids	Alkaloid
<i>Helleborus niger</i> <sup>a</sup>	Black hellebore, Christmas rose	Cardiac	Hellebrin	Cardioactive steroid
<i>Hydrastis canadensis</i> (Ranunculaceae) <sup>a</sup>	Goldenseal	Neurologic, oxytocic, cardiovascular, respiratory	Hydrastine, berberine	Alkaloid
<i>Hyoscyamus niger</i> (Solanaceae) <sup>a</sup>	Henbane, hyoscyamus	Anticholinergic	Belladonna alkaloids	Alkaloid
<i>Hypericum perforatum</i> (Clusiaceae)	St John's wort	Dermatitis, photosensitivity, neurologic, xenobiotic interactions	Hyperforin, hypericin	Terpenoid
<i>Ilex paraguariensis</i> (Aquifoliaceae)	Maté, Yerba Maté, Paraguay tea	Cardiac, neurologic	Caffeine	Alkaloid
<i>Ilex</i> spp berries (Aquifoliaceae) <sup>b</sup>	Holly	Gastrointestinal	Mixture. Alkaloids, polyphenols, saponins, steroids, triterpenoids	Unidentified
<i>Illicium anisatum</i> (Illiciaceae) <sup>a</sup>	Japanese Star anise	Neurologic	Anasatin	Terpenoid

TABLE 118-1 Primary Toxicity of Common Important Plant Species (Continued)

Plant Species (Family)	Typical Common Names	Primary Toxicity	Xenobiotic(s)	Class of Xenobiotic
<i>Ipomoea tricolor</i> and other <i>Ipomoea</i> spp (Convolvulaceae)	Morning glory	Neurologic	Lysergic acid derivatives	Alkaloid
<i>Jatropha curcas</i> (Euphorbiaceae)	Black vomit nut, physic nut, purging nut	Gastrointestinal	Curcin	Protein, lectin, peptide, amino acid
<i>Karwinskia humboldtiana</i> <sup>a</sup>	Buckthorn, wild cherry, tullidora, coyotillo, capulincillo, others	Neurologic, respiratory	Toxin T-514	Phenol or phenylpropanoid
<i>Laburnum anagyroides</i> (syn. <i>Cytisus laburnum</i> ; Fabaceae) <sup>a</sup>	Golden chain, laburnum	Nicotinic	Cytisine	Alkaloid
<i>Lantana camara</i> (Verbenaceae)	Lantana	Dermatitis, photosensitivity	Lantadene A and B, phylloerythrin	Terpenoid
<i>Lathyrus sativus</i> <sup>a</sup>	Grass pea	Neurologic, skeletal	β-N-oxalylamino-L-alanine (BOAA); β-aminopropionitrile (BAPN)	Protein, lectin, peptide, amino acid
<i>Lobelia inflata</i> (Campanulaceae)	Indian tobacco	Nicotinic	Lobeline	Alkaloid
<i>Lophophora williamsii</i>	Peyote or mescal buttons	Neurologic	Mescaline	Alkaloid
<i>Lupinus latifolius</i> and other <i>Lupinus</i> spp (Fabaceae)	Lupine	Nicotinic	Anagyrene	Alkaloid
<i>Lycopersicon</i> spp (Solanaceae) <sup>a</sup>	Tomato (green)	Gastrointestinal, neurologic, anticholinergic	Tomatine, tomatidine	Glycoalkaloid
<i>Mahonia</i> spp (Ranunculaceae)	Oregon grape	Oxytotic, cardiovascular	Berberine	Alkaloid
<i>Mandragora officinarum</i> (Solanaceae) <sup>a</sup>	European or true mandrake	Anticholinergic	Belladonna alkaloids	Alkaloid
<i>Manihot esculentus</i> (Euphorbiaceae) <sup>a</sup>	Cassava, manihot, tapioca	Metabolic, neurotoxic, motor spastic paresis and visual disturbances	Linamarin	Cyanogenic glycoside
<i>Mellilotus</i> spp (Fabaceae/Legumaceae)	Sweet clover (spoiled moldy)	Hematologic	Dicumarol	Phenol or phenylpropanoid
<i>Mentha pulegium</i> (Lamiaceae) <sup>a</sup>	Pennyroyal	Hepatic, neurologic, oxytotic	Pulegone	Terpenoid
<i>Microcystis</i> and <i>Anabaena</i> spp	Blue-green algae (cyanobacteria)	Hepatotoxic, dermatitis, photosensitivity	Microcystin	Protein, lectin, peptide, amino acid
<i>Myristica fragrans</i>	Nutmeg, pericarp = mace	Neurologic (hallucinations)	Myristicin, elemicin	Terpenoid
<i>Narcissus</i> spp and other (Amaryllidaceae, Liliaceae)	Narcissus	Dermatitis, mechanical, and cytotoxic	Lycorine, homolycorin	Alkaloid
<i>Nerium oleander</i> <sup>a</sup>	Oleander	Cardiac	Oleandrin	Cardioactive steroid
<i>Nicotiana tabacum</i> , <i>Nicotiana</i> spp (Solanaceae) <sup>a</sup>	Tobacco	Nicotinic	Nicotine	Alkaloid
<i>Oxytropis</i> spp (Fabaceae)	Locoweed	Metabolic, neurologic	Swainsonine	Alkaloid
<i>Papaver somniferum</i>	Poppy	Neurologic	Morphine/other opium derivatives	Alkaloid
<i>Paullinia cupana</i> (Sapindaceae)	Guarana	Cardiac, neurologic	Caffeine	Alkaloid
<i>Pausinystalia yohimbe</i> (Rubiaceae) <sup>a</sup>	Yohimbe	Cardiac, cholinergic	Yohimbine	Alkaloid
<i>Philodendron</i> spp (Araceae) <sup>b</sup>	Philodendron	Dermatitis, mechanical, and cytotoxic	Oxalate raphides	Carboxylic acid
<i>Phoradendron</i> spp (Loranthaceae or Viscaceae)	American mistletoe	Gastrointestinal	Phoratoxin, ligatoxin	Protein, lectin, peptide, amino acid
<i>Physostigma venenosum</i> (Fabaceae) <sup>a</sup>	Calabar bean, ordeal bean	Cholinergic	Physostigmine	Alkaloid
<i>Phytolacca americana</i> (Phytolaccaceae) <sup>a</sup>	American cancer Pokeweed, poke	Gastrointestinal	Phytolaccotoxin	Protein, lectin, peptide, amino acid
<i>Pilocarpus jaborandi</i> , <i>Pilocarpus pinnatifolius</i> (Rutaceae) <sup>a</sup>	Pilocarpus, jaborandi	Cholinergic effects	Pilocarpine	Alkaloid

(Continued)

TABLE 118-1 Primary Toxicity of Common Important Plant Species (Continued)

Plant Species (Family)	Typical Common Names	Primary Toxicity	Xenobiotic(s)	Class of Xenobiotic
<i>Piper methysticum</i> <sup>a</sup>	Kava kava	Hepatic, neurologic	Kawain, methysticine yanonin, other kava lactones	Terpenoid, resin, oleoresin
<i>Plantago</i> spp	Plantago (seed husks)	Gastrointestinal	Psyllium	Carbohydrate
<i>Podophyllum emodi</i> (Berberidaceae) <sup>a</sup>	Wild mandrake	Gastrointestinal and neurologic effects	Podophyllin (lignan)	Phenol or phenylpropanoid
<i>Podophyllum peltatum</i> (Berberidaceae) <sup>a</sup>	Mayapple	Gastrointestinal and neurologic effects	Podophyllin (lignan)	Phenol or phenylpropanoid
<i>Populus</i> spp (Salicaceae)	Poplar species	Salicylism	Salicin	Glycoside
<i>Primula obconica</i> (Primulaceae)	Primrose	Dermatitis, contact, and allergic	Primin	Phenol or phenylpropanoid
<i>Prunus armeniaca</i> , <i>Prunus</i> spp, <i>Malus</i> spp (Rosaceae) <sup>a</sup>	Apricot seed pits, wild cherry, peach, plum, pear, almond, apple, and other seed kernels	Metabolic acidosis, respiratory failure, coma, death	Amygdalin, emulsin	Cyanogenic glycoside
<i>Pteridium</i> spp (Polypodiaceae)	Bracken Fern	Carcinogen, thiaminase	Ptaquiloside	Terpenoid
<i>Pulsatilla</i> spp (Ranunculaceae)	Pulsatilla	Dermatitis, contact	Ranunculin, protoanemonin	Glycoside
<i>Quercus</i> spp	Oak	Metabolic, livestock toxicity	Tannic acid	Phenol or phenylpropanoid
<i>Ranunculus</i> spp (Ranunculaceae)	Buttercups	Dermatitis, contact	Ranunculin, protoanemonin	Glycoside
<i>Rauwolfia serpentine</i> (Apocynaceae)	Indian snakeroot	Cardiac, neurologic	Reserpine	Alkaloid
<i>Remijia pedunculata</i> (Rubiaceae) <sup>a</sup>	Cuprea bark	Cardiac, cinchonism	Quinidine	Alkaloid
<i>Rhamnus frangula</i> (Rhamnaceae)	Frangula bark, alder buckthorn	Gastrointestinal	Frangulins	Anthraquinone glycoside
<i>Rheum officinale</i> , <i>Rheum</i> spp (Polygonaceae)	Rhubarb	Gastrointestinal Metabolic	Rhein anthrones Oxalic/Acid (soluble)	Anthraquinone glycoside Carboxylic acid
<i>Rheum</i> spp (Polygonaceae)	Rhubarb species	Urologic	Oxalates	Carboxylic acid
<i>Rhododendron</i> spp (Ericaceae) <sup>a</sup>	Rhododendron	Cardiac, neurologic	Grayanotoxins	Terpenoid including resin and oleoresin
<i>Ricinus communis</i> (Euphorbiaceae) <sup>a</sup>	Castor or rosary seeds, purging nuts, physic nut, tick seeds	Gastrointestinal	Ricin, curcin	Protein, lectin, peptide, amino acid
<i>Robinia pseudoacacia</i> (Fabaceae) <sup>a</sup>	Black locust	Gastrointestinal	Robin (robinia lectin)	Protein, lectin, peptide, amino acid
<i>Rumex</i> spp (Polygonaceae)	Dock species	Urologic	Oxalates	Carboxylic acid
<i>Salix</i> spp (Salicaceae)	Willow species	Salicylism	Salicin	Glycosides, other
<i>Sambucus</i> spp (Caprifoliaceae)	Elderberry	Metabolic	Anthracyanins	Cyanogenic glycoside
<i>Sanguinaria canadensis</i> (Papaveraceae)	Sanguinaria, bloodroot	Gastrointestinal	Sanguinarine	Alkaloid
<i>Schefflera</i> spp (Araceae) <sup>b</sup>	Umbrella tree	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid
<i>Schlumbergera bridgesii</i> <sup>b</sup>	Christmas cactus	Dermatitis, mechanical	Nontoxic	None
<i>Senecio</i> spp (Compositae/Asteraceae) <sup>a</sup>	Groundsel	Hepatic (venoocclusive disease)	Pyrrrolizidine alkaloids	Alkaloid
<i>Sida carpinifolia</i> (Malvaceae)	Locoweed	Metabolic, neurologic	Swainsonine	Alkaloid
<i>Sida cordifolia</i> (Malvaceae) <sup>a</sup>	Bala	Cardiac, neurologic	Ephedrine and related compounds	Alkaloid
<i>Solanum americanum</i> (Solanaceae) <sup>a</sup>	American nightshade	Gastrointestinal, neurologic, anticholinergic	Solasodine, soladulcidine, solanine, chaconine	Glycoalkaloid
<i>Solanum dulcamara</i> (Solanaceae) <sup>a,b</sup>	Bittersweet woody nightshade	Gastrointestinal, neurologic, anticholinergic	Solanine, chaconine, belladonna alkaloids	Alkaloid
<i>Solanum nigrum</i> (Solanaceae) <sup>a</sup>	Black nightshade, common nightshade	Gastrointestinal, neurologic, anticholinergic	Solanine, chaconine, belladonna alkaloids	Alkaloid

**TABLE 118–1 Primary Toxicity of Common Important Plant Species (Continued)**

Plant Species (Family)	Typical Common Names	Primary Toxicity	Xenobiotic(s)	Class of Xenobiotic
<i>Solanum tuberosum</i> (Solanaceae) <sup>a</sup>	Potato (green), leaves	Gastrointestinal, neurologic, anticholinergic	Solanine, chaconine	Alkaloid
<i>Spathiphyllum</i> spp (Araceae) <sup>b</sup>	Peace lily	Dermatitis, mechanical and cytotoxic	Oxalate raphides	Carboxylic acid
<i>Spinacia oleracea</i> (Chenopodiaceae)	Spinach, others	Urologic	Oxalates	Carboxylic acid
<i>Strychnos nux-vomica</i> , <i>Strychnos ignatia</i> (Loganiaceae) <sup>a</sup>	Nux vomica, Ignatia, St Ignatius bean, vomit button	Neurologic	Strychnine, brucine	Alkaloid
<i>Swainsonia</i> spp (Fabaceae)	Locoweed	Metabolic, neurologic	Swainsonine	Alkaloid
<i>Symphytum</i> spp (Boraginaceae) <sup>a</sup>	Comfrey	Hepatic (venoocclusive disease)	Pyrrrolizidine alkaloids	Alkaloid
<i>Tanacetum vulgare</i> (= <i>Chrysanthemum vulgare</i> ; Compositae/Asteraceae) <sup>a</sup>	Tansy	Neurologic	Thujone	Terpenoid
<i>Taxus baccata</i> , <i>Taxus brevifolia</i> , other <i>Taxus</i> spp (Taxaceae) <sup>a</sup>	English yew, Pacific yew	Cardiac	Taxine	Alkaloid
<i>Theobroma cacao</i> (Sterculiaceae)	Cocoa	Cardiac, neurologic	Theobromine	Alkaloid
<i>Thevetia peruviana</i> <sup>a</sup>	Yellow oleander	Cardiac	Thevetin	Cardioactive steroid
<i>Toxicodendron radicans</i> , <i>Toxicodendron toxicarium</i> , <i>Toxicodendron diversilobum</i> , <i>Toxicodendron vernix</i> , <i>Toxicodendron</i> spp, many others (Anacardaceae) <sup>b</sup>	Poison ivy, poison oak, poison sumac	Dermatitis, contact and allergic	Urushiol oleoresins	Terpenoid
<i>Tribulus terrestris</i> (Fabaceae)	Caltrop, puncture vine	Dermatitis, photosensitivity in animals	Steroidal saponins (aglycones, diosgenin, yamogenin)	Saponin glycoside
<i>Trifolium pratense</i> and other (Fabaceae/Legumaceae)	Red clover	Phytoestrogen, hematologic	Formononetin, Biochanin A, coumarin	Phenol (isoflavone)
<i>Tussilago farfara</i> (Compositae/Asteraceae) <sup>a</sup>	Coltsfoot	Hepatic (venoocclusive disease)	Pyrrrolizidine alkaloids	Alkaloid
<i>Urginea maritima</i> , <i>Urginea indica</i> <sup>a</sup>	Red, or Mediterranean squill, Indian squill, sea onion	Cardiac	Scillaren A, B	Cardioactive steroid
<i>Veratrum viride</i> , <i>Veratrum album</i> , <i>Veratrum californicum</i> (Liliaceae) <sup>a</sup>	False hellebore, Indian poke, California hellebore	Cardiac	Veratridine	Alkaloid
<i>Vicia fava</i> , <i>Vicia sativa</i> (Fabaceae)	Fava bean, vetch	Hematologic	Vicine, convicine	Glycoside
<i>Viscum album</i> (Loranthaceae or Viscaceae)	European mistletoe	Gastrointestinal	Viscumin	Protein, lectin, peptide, amino acid, lignan, polypeptide
<i>Wisteria floribunda</i> (Fabaceae)	Wisteria	Gastrointestinal	Cystatin	Protein, lectin, peptide, amino acid

<sup>a</sup>Reports of life-threatening effects from plant use. <sup>b</sup>Plants reported commonly among calls to poison control centers.

alkaloids that produce gastrointestinal signs and symptoms following ingestion. This approach will be less useful for xenobiotics such as pyrrolizidine alkaloids that occur in numerous different families.

## APPROACH TO THE EXPOSED PATIENT AND UNDERSTANDING RISK

Identified plant species most frequently reported to poison control centers are indicated in Table 118–1. In most cases, these species provide reassurance because most exposures result in benign outcomes, and only a few among these are regularly life threatening depending on the circumstances of the exposure. Given the relatively poor understanding of toxins and in the absence of complete information about an exposure, expectant management and supportive care are the rule. Even if a plant is not marked as life

threatening or commonly reported, the patient should undergo a period of observation and follow-up, given the relatively immature science of plant toxicology relative to that of pharmaceuticals.

The difficult task in human plant toxicology is the lack of adequate data to determine risk (Chap. 133). Typically, evaluations of risk are based on poison control center data and usually cite the numerous calls without clinical consequence as a part of the risk equation (Chap. 130). However, poison control center data are predominantly unconfirmed exposures and cases with unsubstantiated clinical manifestations (Chap. 130). These cases often represent small or nonexistent exposures, and their inclusion in the database may mask actual risks by diluting hazardous exposures with trivial or nonexistent exposures.<sup>69</sup> Furthermore, misidentification of the plant can occur because of either similar appearance or similar nomenclature.

Basic decontamination and supportive care should be instituted as appropriate for the clinical situation, with poison control center consultation. The most consequential and dangerous plant xenobiotics for humans are discussed here, and those that can produce life-threatening signs acutely are denoted in Table 118–1.

Potential clinical effects listed in Table 118–1 are organized by plant name and the associated major organ system effects for quick reference as to the type of symptoms and their potential for morbidity or mortality. For instance, life-threatening effects such as dysrhythmias or seizures can be searched by “cardiac-” or “neurologic-” in the third column and compared with the plant(s) in question. The plants and xenobiotics that present life-threatening symptoms are so noted. Exposures associated with one of these plants or xenobiotics or major organ system symptoms dictate the need for possible prompt gastric emptying, decontamination, individualized therapy, and hospitalization. Nonspecific symptoms such as nausea and vomiting are listed only when they are a major cause of morbidity or mortality (toxalbumins such as ricin), but nausea and vomiting are exceptionally common in those individuals with consequential acute poisonings.

## TOXIC CONSTITUENTS IN PLANTS, TAXONOMIC ASSOCIATIONS, AND SELECTED SYMPTOMS

### Alkaloids

Alkaloids figure prominently in the history of human–plant interaction, ranging from epidemics of poisoning caused by ergot-infected rye bread in the Middle Ages to dependency on cocaine, heroin, and nicotine in contemporary time. Numerous examples of toxic constituents of these families are given in the following discussion, which begins with a description of the major toxidromes that involves alkaloids

#### Anticholinergic: Belladonna Alkaloids

The belladonna alkaloids are from the family Solanaceae and the plants are identified as members of this family by their characteristic flowers (most familiar from nightshade, potato, or tomato flowers). The belladonna alkaloids have potent antimuscarinic effects, manifested by tachycardia, hyperthermia, dry skin and mucous membranes, skin flushing, diminished bowel sounds, urinary retention, agitation, disorientation, and hallucinations (Chap. 3). Since the 1970s, the quest for recreational “highs” has surpassed unintentional ingestions as the main source of toxicity.<sup>153</sup> Hallucinatory effects are sought in seeds and teas, especially in late summer, when jimsonweed (*Datura stramonium*) seeds (Fig. 118–1) become available.

**FIGURE 118–1.** Jimsonweed (*Datura stramonium*) initially has a showy white tubular flower that becomes a prickly fruit (pod) following maturation. Inset: The pod (inset) of jimsonweed holds multiple small seeds containing atropine and scopolamine. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

One hundred of these seeds contain up to 6 mg atropine and related alkaloids, and an ingestion of this amount can be fatal.<sup>21</sup>

Although several anticholinergic alkaloid-containing species and even individual plants within species contain differing concentrations of several different phytochemicals, the clinical manifestations usually are similar. The onset of symptoms typically occurs one to 4 hours postingestion, and more rapidly if the plants are smoked or consumed as a brewed tea. The duration of effect is partly dose dependent and may last from a few hours to days.<sup>25</sup> The course of anticholinergic poisoning is not substantially altered by use of physostigmine, though this may be lifesaving in patients with seizures or an agitated delirium (Antidotes in Depth: A11).<sup>43,135</sup> Although methods for detection of atropine and scopolamine in clinical specimens are improving, anticholinergic toxicity is observed without detectable atropine, scopolamine, or hyoscyamine concentrations in biological fluids.

Solanine and chaconine are glycoalkaloids contained in many members of the Solanaceae family, but they are structurally and pharmacologically dissimilar to the belladonna alkaloids. The aglycone solanidine, which lacks the sugar moiety, is a steroidal alkaloid. Solanine inhibits cholinesterase in vitro, although cholinergic symptoms are not noted clinically. Nonetheless, reports of solanine-induced central nervous system (CNS) toxicity include hallucinations, delirium, and coma.<sup>148</sup> However, most symptomatic patients typically develop nausea, vomiting, diarrhea, and abdominal pain that begins 2 to 24 hours after ingestion, which, like CNS toxicity, infrequently persist for several days. Although solanine is present in most of the 1,700 species in the genus *Solanum*, solanine toxicity in humans is rarely encountered. The content of glycoalkaloids in tubers is usually 10 to 100 mg/kg and the maximum concentrations do not exceed 200 mg/kg. Green potatoes and the green potato plant itself are most commonly associated with toxicity, which is not surprising because the alkaloids are most concentrated in those items. The ingestion of 1 to 3 mg of glycoalkaloid per kilogram of body weight is likely to produce clinical symptoms.<sup>133</sup> Most reports of death come from the older literature,<sup>2</sup> and consumption of 2 to 5 g of green components of potatoes per kilogram of body weight per day is not predicted to cause acute toxicity.<sup>120</sup>

#### Nicotine and Nicotinlike Alkaloids: Nicotine, Anabasine, Lobeline, Sparteine, N-Methylcytisine, Cytisine, and Coniine

Nicotine toxicity (other than from inhaled sources) occurs via ingestion of leaves of *Nicotiana tabacum*, cigarettes and their remains, e-cigarette refill, organic insecticidal products, and transdermally among farm workers harvesting tobacco (green tobacco sickness) (Chap. 82).<sup>17</sup> A topical folk remedy made from the leaf of *Nicotiana glauca* (tree tobacco) caused anabasine toxicity in an infant.<sup>113</sup> The alkaloids of nicotine and anabasine are pale yellow oils at room temperature and readily penetrate the intact dermis. A dose of nicotine as small as 1 mg/kg of body weight can be lethal although it is more likely with doses >4 mg/kg.<sup>101</sup> Overstimulation of the nicotinic receptors by high doses of the alkaloid produces nicotinism, a toxidrome that progresses from gastrointestinal (GI) symptoms to diaphoresis, mydriasis, fasciculations, tachycardia, hypertension, hyperthermia, seizures, respiratory depression, and death (Chap. 82). Wearing of protective clothing is essential for tobacco farm workers to prevent green tobacco sickness.<sup>7</sup>

These manifestations are also produced by alkaloids other than nicotine. There are no recent reports of nicotinic toxicity from lobeline (found in all parts of *Lobelia inflata*), although its use in the 18th century resulted in morbidity and mortality.

Sparteine from broom (*Cytisus scoparius*) and N-methylcytisine from blue cohosh (*Caulophyllum thalictroides*)<sup>124</sup> are examples of alkaloids that produce nicotinlike effects. Laburnum or golden chain (*Cytisus laburnum*) contains cytisine, which reportedly is responsible for mass poisonings and fatalities in children and adults who eat the plants or parts thereof (even as little as 0.5 mg/kg, or a few peas).<sup>111</sup> Unfortunately, such reports have resulted in thousands of unnecessary hospital admissions for patients without morbidity and mortality after ingestion of this plant, demonstrating the difficulty in separating hazard from risk and in obtaining accurate dose–response information in the setting of plant exposures and human variability.

The most famous description of the end stages of nicotinic toxicity dates from approximately 2,400 years ago by an observer of Socrates' fatal ingestion of a decoction of poison hemlock (*Conium maculatum*).<sup>125</sup>

*the person who had administered the poison went up to him and examined for some little time his feet and legs, and then squeezing his foot strongly asked whether he felt him. Socrates replied that he did not and said to us when the effect of the poison reached his heart, Socrates would depart.*

Birds do not experience coniine toxicity but provide a vector for poisoning. According to the book of Exodus, quail that fed on seeds (presumably from poison hemlock) became toxic and passed the toxicity on to the Israelites who ate the fowl.<sup>19</sup> In the 20th century, this is especially well documented in Italy, where the toxic alkaloid coniine was detected in bird meat, as well as in the blood, urine, and tissue of some individuals.<sup>139</sup>

The age of the plant seems to be directly correlated with increasing concentrations of coniine, whereas the toxin  $\gamma$ -coniceine occurs in greater amounts in new growth; hence, the plant remains toxic over the entire growing season. Fatal poisonings are reported on multiple continents frequently resulting from respiratory arrest. Of 17 poisoned Italian patients, all had elevated liver aminotransferases and myoglobin concentrations, and 5 had acute tubular necrosis.<sup>127</sup> Death developed 1 to 16 days following ingestion.

#### Cholinergic Alkaloids: Arecoline, Physostigmine, and Pilocarpine

Betel chewing has been a habitual practice in the tropical Pacific, Asia and East Africa. The "quid" consists of betel nut (*Areca catechu*) and other ingredients. The effects of acute exposure to arecoline, the major alkaloid, include sweating, salivation, hyperthermia, and rarely death.<sup>40</sup> Prolonged use is linked to dental decay and oral cancer. Physostigmine is an alkaloid derived from the Calabar bean (*Physostigma venenosum*), where it is present in concentrations of 0.15% (Antidotes in Depth: A11). Pilocarpine is derived from *Pilocarpus jaborandi* from South America. Its stimulatory effects on muscarinic receptors have proven valuable in the treatment of glaucoma. Reversal of toxicity can be achieved by atropine.

#### Psychotropic Alkaloids: Lysergic Acid and Mescaline

Hallucinations from the direct serotonin effects of lysergic acid diethylamide (LSD) and its derivatives, and from the amphetaminelike serotonin effects of the mescaline alkaloids are reported following ingestion of morning glory seeds (*Ipomoea* spp) and peyote cactus (*Lophophora williamsii*), respectively (Chap. 79). Despite their chemical relatedness to LSD, molecules such as lysergic acid amide and lysergic acid ethylamide, found in Hawaiian babywoodrose seeds (*Argyrea nervosa*) produce findings that may appear anticholinergic.<sup>20</sup>

#### Alkaloidal Central Nervous System Stimulants and Depressants: Ephedrine, Synephrine, Cathinone, and Opioids

The use of ephedrine-containing *Ephedra* spp in herbal dietary supplement products was banned by the FDA in 2004 because of the associated cardiovascular toxicity and deaths. Varieties of *Sida cordifolia* also contain ephedrine. Synephrine, a xenobiotic structurally related to ephedrine, occurs in bitter orange (*Citrus aurantium*), which is ingested as a plant, in foods such as marmalades, as a dietary supplement, or as a traditional medicine. Deaths and drug interactions can ensue from their use. Although illegal in the United States, another plant ingested for its CNS-stimulant activity is khat (*Catha edulis*). The plant contains cathinone ( $\alpha$ -aminopropiophenone) and cathine ((+)-norpseudoephedrine). In addition, opioids derived from the poppy plant (*Papaver* spp) are prototypic CNS depressants and analgesics (Chap. 36).

#### Pyrrolizidine Alkaloids

Pyrrolizidine alkaloids are widely distributed both botanically and geographically. Approximately half of the 350 different pyrrolizidine alkaloids characterized to date are toxic when ingested. Pyrrolizidine alkaloids are found in 6,000 plants and in 13 plant families, but are most heavily represented within the Boraginaceae, Compositae, and Fabaceae families. Within these families,

the genera *Heliotropium*, *Senecio*, and *Crotalaria*, respectively, are particularly notable for their content of toxic pyrrolizidine alkaloids, including the unsaturated 1-hydroxymethyl pyrrolizidine.<sup>59</sup> The hepatic cytochrome P450 (CYP) system converts these compounds to highly reactive pyrroles in vivo. Chronic exposures stimulate the proliferation of the intima of hepatic vasculature and result in hepatic venoocclusive disease (HVOD). Poisonings occur as a result of the use of pyrrolizidine-rich plants for medicinal purposes and by contamination of food grain with seeds of pyrrolizidine-alkaloid-containing plants.<sup>47</sup> Acute hepatocellular toxicity can occur following ingestion of 10 to 20 mg of pyrrolizidine alkaloid and is probably caused by an oxidant effect producing hepatic necrosis. An estimated 20% of patients with acute pyrrolizidine alkaloid poisoning die, 50% recover completely, and the rest develop subacute or chronic manifestations of HVOD. Pyrrolizidine alkaloids are teratogenic and are also transmitted through breast milk. Pyrrolizidine alkaloids may be present in bee pollen and have been reported in honey. Other types of plant-associated hepatic disorders are discussed in Effects Shared Among Different Classes of Xenobiotics.

#### Isoquinoline Alkaloids: Sanguinarine, Berberine, and Hydrastine

Adverse effects on human health due to consumption of edible mustard oil adulterated with argemone oil are reported. Sanguinarine was detected in 26 family members who consumed a mustard oil contaminated with seeds of Mexican pricklypoppy (*Argemone mexicana*).<sup>146</sup> All patients suffered GI distress followed by peripheral edema (dropsy), skin darkening, erythema, skin lesions, perianal itching, anemia, and hepatomegaly. Ascites developed in 12%, and myocarditis and congestive heart failure occurred in approximately a third of affected individuals. Alterations in redox potentials and antioxidants in plasma are responsible for the histopathologic changes, including swollen hepatocytes and fluid accumulation in the spaces of Disse, and Kupffer cell hyperplasia.<sup>11</sup> Medicinally, sanguinarine is used for dental hygiene.<sup>73</sup> In North America, sanguinarine is found in bloodroot (*Sanguinaria canadensis*), which like *Argemone*, is in the Ranunculaceae family.

Berberine is structurally similar to sanguinarine and also has cardiac depressant effects.<sup>89</sup> A number of medicinal plants contain berberine, including goldenseal (*Hydrastis canadensis*), Oregon grape (*Mahonia* spp), and barberry (*Berberis* spp). It causes myocardial and respiratory depression and contraction of smooth muscle vasculature and the uterus. Strychninelike movement disorders are described following ingestion of hydrastine, which makes up 4% of goldenseal.

#### Other Alkaloids: Emetine/Cephaline, Strychnine/Curare, and Swainsonine

Emetine and cephaline are derived from *Cephaelis ipecacuanha*, a tropical plant native to the forests of Bolivia and Brazil. They are the principal active constituents in syrup of ipecac, which produces emesis. Chronic use of syrup of ipecac, typically by patients with eating disorders or Munchausen syndrome by proxy, has caused cardiomyopathy, smooth muscle dysfunction, myopathies, electrolyte, and acid-base disturbances related to excessive vomiting, and death. Poisoning in patients ingesting plant material is not reported.

Curare was used as an arrow poison derived from plants of the genus *Strychnos* as well as *Chondrodendron*, but the plants and their phytochemicals produce very different clinical effects. The convulsant alkaloids strychnine and brucine are found in various members of the genus *Strychnos*. Although used to produce arrow poison, the more widespread use of *Strychnos* spp in Africa was for trial by ordeal.<sup>119</sup> The seeds of *Strychnos nux-vomica* are especially rich in strychnine, which causes muscular spasms and rigidity by antagonizing glycine receptors in the spinal cord and brain stem. The plant is used as an herbal remedy for arthritis pain called "maqianzi," which if improperly processed produces muscle spasm and weakness, including respiratory muscles (Chap. 114).

Curare is an extract of the bark of *Chondrodendron tomentosum* and certain members of the genus *Strychnos*. The physiologically active xenobiotic of curare from *Chondrodendron* is D-tubocurarine chloride, a competitive antagonist of acetylcholine at nicotinic receptors in the neuromuscular

junction. Curare is the molecule from which most nondepolarizing neuromuscular blockers are derived (Chap. 66). Plant poisoning is recorded solely with its traditional use as a hunting poison.

Swainsonine is isolated from *Swainsonia canescens*, *Astragalus lentiginosus* (spotted locoweed), *Sida carpinifolia*, other species of *Swainsonia* and *Astragalus*, as well as several species in the genera *Oxytropis* and *Ipomoea*, and several fungi. After subsisting on seeds containing swainsonine for nearly 4 months, a naturalist forager manifested profound muscular weakness and died in the wilderness.<sup>84</sup> The compound is teratogenic and causes chronic neurologic disease called “locoism,” with weakness and failure to thrive in livestock. Swainsonine inhibits the glycosylation of glycoproteins by  $\alpha$ -mannosidase II of the Golgi apparatus, resulting in a lysosomal storage disease. Adverse effects included hepatic, pancreatic, and respiratory manifestations, as well as lethargy and nausea.

## Glycosides

Glycosides yield a sugar or sugar derivative (the glycone) and a nonsugar moiety (the aglycone) upon hydrolysis. The nonsugar or aglycone group determines the subtype of glycoside. For instance, the cardiac glycosides have saponin (steroid) aglycone groups and are placed among the saponin glycosides.

### Saponin Glycosides: Cardiac Glycosides, Glycyrrhizin, Ilex Saponins

Poisoning by virtually all cardioactive steroidal glycosides is clinically indistinguishable from poisoning by digoxin (Chap. 62), which itself is a cardioactive steroid derived from *Digitalis lanata*. However, compared with toxicity from pharmaceutical digoxin, toxicity resulting from the cardioactive steroidal glycosides found in plants has markedly different pharmacokinetic characteristics. For example, digitoxin in *Digitalis* species has a plasma half-life as long as 192 hours (average 168 hours).

The pharmacologic properties are true across taxonomic boundaries. Poisonings by *Digitalis* spp,<sup>123,147</sup> squill (*Urginea* spp),<sup>161</sup> lily of the valley,<sup>3</sup> oleander (*Nerium* spp),<sup>168</sup> yellow oleander (*Thevetia* spp),<sup>44</sup> and *Cerbera manghas*<sup>45</sup> are clinically similar (Fig. 118–2). The potency of these effects depends on the specific cardioactive glycoside constituents and their dose. For instance, lily of the valley is rarely associated with morbidity or mortality (except those mistaking lily of the valley for ramps [*Allium tricoccum*]) whereas ingestion of only 2 seeds of yellow oleander by adults can produce severe symptoms, and expected outcome is grave with several more.<sup>44</sup> Poisonings by oleander and yellow oleander occur predominantly in the Mediterranean and in the Near and Far East. These 2 plants are popular attractive ornamentals and commonly result in poisoning in the United States and Europe.

Patients experience vomiting within several hours, followed by hyperkalemia, cardiac conduction delays, and increased automaticity (bradycardia and tachydysrhythmias). Interestingly, the cardiac manifestations may be difficult to distinguish from those produced by plants containing sodium channel blockers (see section Sodium Channel Effects). Activated charcoal was beneficial in preventing death after suicide attempts with yellow oleander in Sri Lanka and its use should not be delayed in the face of uncertain plant identity.<sup>38</sup> Antibody therapy reduces mortality threefold from yellow oleander poisoning but is too expensive for developing countries, where oleander-induced mortality is highest.<sup>46</sup> In addition, various cardioactive steroids respond differently to therapeutic use of digoxin-specific antibody fragments. Use of very large doses of digoxin-specific antibody (up to 37 vials reported in one case<sup>126</sup>) may be necessary to capitalize on the therapeutic cross-reactivity between digoxin-specific antibody and the nondigoxin cardioactive steroids, such as oleander.<sup>134</sup> The potential for success should lead to use of antibody therapy without delay when available. Similarly, there is variable cross-reactivity among the individual plant cardioactive steroids with regard to the degree to which each elevates diagnostic polyclonal digoxin assay measurements in clinical laboratories.<sup>35</sup> These measurements can be used only as qualitative proof of exposure but not as quantitative indicators of the exposure, because the elevations can result in marked

A

B

**FIGURE 118–2.** Saponin-glycoside containing plants: (A) Lily of the valley (*Convallaria majalis*) contains the cardioactive steroid convallatoxin. (B) Yellow oleander (*Thevetia peruviana*) contains a cardioactive steroid, thevetin. (Used with permission from Darren Roberts, MD.)

underestimation of the “functional digoxin concentrations.” Until additional technologic advances occur, any positive digoxin concentration following exposure to a plant should be assumed to be significant.

### Glycyrrhizin

Glycyrrhizin is a saponin glycoside derived from *Glycyrrhiza glabra* (licorice) and other *Glycyrrhiza* spp. Glycyrrhizin inhibits 11- $\beta$ -hydroxysteroid dehydrogenase, an enzyme that converts cortisol to cortisone. When large amounts of licorice root are consumed chronically, cortisol concentrations rise, resulting in pseudo-hyperaldosteronism because of its affinity for renal mineralocorticoid receptors.<sup>53</sup> Chronic use eventually leads to hypokalemia with muscle weakness, sodium and water retention, hypertension, and dysrhythmias.<sup>177</sup> Assessment involves evaluation of the patient’s fluid and electrolytes, and electrocardiogram. Potassium replacement is the most common necessary intervention.

### Ilex Species

Holly berries from more than 300 *Ilex* spp are commonly ingested by children, especially during winter holidays. They contain a mixture of alkaloids, polyphenols, saponin glycosides, steroids, and triterpenes. Saponin glycosides appear to be responsible for GI symptoms such as nausea, vomiting, diarrhea, and abdominal cramping that result from ingestion of the berries. Central nervous system depression was reported in a case in which a child

consumed a “handful” of berries; however, this child was also treated with syrup of ipecac.<sup>130</sup> The toxic quantity is undefined, but it is typically suggested that no untoward effects are to be expected for ingestions of fewer than 6 berries. Symptoms may be expected to be restricted to GI effects, and treatment is supportive.

### Cyanogenic Glycosides: (S)-Sambunigrin, Amygdalin, Linamarin, and Cycasin

Cyanogenic glycosides yield hydrogen cyanide on complete hydrolysis. These glycosides are represented in a broad range of plant species.<sup>164</sup> The species that are most important to humans are cassava (*Manihot esculenta*), which contains linamarin, and *Prunus* spp, which contain amygdalin.<sup>14</sup> Cycad toxins are neurotoxic or pseudocyanogenic. Rare reports of cyanide poisoning associated with (S)-sambunigrin in European elderberry (*Sambucus nigra*; sambunigrin) are more severe when these ingestions include leaves as well as berries.<sup>22</sup>

Many North American species of plants contain cyanogenic compounds, including ornamental *Pyracantha*, *Passiflora*, and *Hydrangea* spp, which either do not release cyanide or are rarely consumed in quantities sufficient to result in toxicity. On the other hand, although the fleshy fruit of *Prunus* spp in the Rosaceae are nontoxic (apricots, peaches, pears, apples, and plums), the leaves, bark, and seed kernels contain amygdalin, which is metabolized to cyanide. Sufficient cyanide can be absorbed to cause acute poisoning.<sup>156</sup> Amygdalin was the active ingredient of Laetrile, an apricot pit extract promoted in the 1970s for its supposed selective toxicity to tumor cells. Its sale was restricted in the United States because it lacked efficacy and safety.<sup>107,109</sup> However, patients went to other countries for Laetrile therapy, which was marketed as “vitamin B-17,” and available through alternative medicine providers. The manifestations of cyanide poisoning and treatment involving use of the cyanide antidote kit are detailed elsewhere (Chap. 123 and Antidotes in Depth: A41, A42).

Acute and chronic cyanide toxicity (including deaths) associated with consumption of inadequately prepared cassava (*M. esculenta*) are reported worldwide (Chap. 123).<sup>1</sup> Chronic manifestations include visual disturbances (amblyopia), upper motor neuron disease with spastic paraparesis, and hypothyroidism. These findings are associated with protein deficiency and the use of tobacco and alcohol. The ataxic neuropathy resembles that produced by lathyrism (see section Proteins, Peptides, and Lectins). A unifying hypothesis about the etiology of these 2 similar diseases from seemingly very different sources is that thiocyanate accumulation may lead to degeneration of the  $\alpha$ -amino-3-hydroxy-5-methyl-isoxazole-4-propionic acid (AMPA)-containing neurons that are first stimulated and then destroyed in neurolathyrism.<sup>151</sup>

Similarly, seeds of cycads contain cycasin and neocycasin, which belong to the family of cyanogenic glycosides, as well as neurotoxins. The cyanogenic glycosides of cycads are pseudocyanogenic, with little potential to liberate hydrogen cyanide, but most typically produce violent vomiting 30 minutes to 7 hours after ingestion of one to 30 seeds.<sup>28</sup> On the island of Guam, indigenous peoples develop a devastating amyotrophic lateral sclerosis-parkinsonism dementia complex (ALS-PDC) that appears associated with ingestion of *Cycas circinalis* seeds or the flying foxes that feed extensively upon the cycads.<sup>32</sup> The implicated xenobiotic originally was believed to be an excitatory amino acid, but more recently is identified as a sterol glycoside. Research on the mechanism of this cycad-induced disease is ongoing, with the goal of understanding potential mechanisms of this disease and its links to ALS and Parkinson disease.<sup>22,30</sup>

### Anthraquinone Glycosides: Sennoside and Others

Anthraquinone laxatives are regulated both as nonprescription pharmaceuticals and as dietary supplements. These glycosides, such as sennoside, are metabolized in the bowel to produce derivatives that stimulate colonic motility, probably by inhibiting  $\text{Na}^+, \text{K}^+$ -adenosine triphosphatase (ATPase) in the intestine, which also promote accumulation of water and electrolytes in the gut lumen, producing fluid and electrolyte shifts that can be life threatening.<sup>155</sup>

### Other Glycosides: Salicin, Atractyloside, Carboxyatractyloside, Vicine, and Convicine

Salicin is an inactive glycoside until it is hydrolyzed to produce salicylic acid (Chap. 37). The glycosidic bond is relatively resistant to stomach acid, and the hydrolysis must be accomplished by gut flora. The ability of individual human flora to produce the necessary enzymes varies significantly, resulting in variable clinical effects for salicin or plant material that contains salicin. However, sufficient hydrolytic capacity for some transformation of the glycoside into salicylic acid occurs in all individuals.

*Atractylis gummifera* was a favorite agent for homicide during the reign of the Borgias. Atractyloside, the toxic xenobiotic, primarily inhibits oxidative phosphorylation in the liver by inhibiting the ADP/ATP antiporter blocking influx of adenosine diphosphate (ADP) into hepatic mitochondria and outflow of ATP to the rest of the cell (Chap. 11). Death or severe illness as a result of liver failure or hepatorenal disease following ingestion is reported.<sup>34</sup> *Callilepis laureola* is a South African medicinal plant that contains atractyloside and carboxyatractyloside and is reported to cause human poisonings. Cocklebur (*Xanthium strumarium*) is a herbaceous plant with worldwide distribution. The seeds contain the glycoside carboxyatractyloside. The toxic mechanism is similar to that for atractyloside, and seed ingestion has resulted in human fatalities. Nine patients presented with acute-onset abdominal pain, nausea and vomiting, drowsiness, palpitations, sweating, and dyspnea. Several patients developed hepatocellular damage, acute kidney injury, and myocardial injury and 3 developed convulsions followed by loss of consciousness and death.<sup>162</sup>

Favism is a potentially fatal disorder brought about by eating fava beans or vetch seeds (*Vicia faba*, *Vicia sativa*, respectively). These seeds contain the pyrimidine glycosides vicine and convicine (divicine is the aglycone of vicine). Consumption of these compounds by individuals with an inborn error of metabolism (glucose-6-phosphate dehydrogenase deficiency) can cause acute hemolytic crisis (Chap. 20).<sup>143</sup>

The effects of the glycosides sinigrin (from *Brassica nigra* seed and *Alliaria officinalis* {horseradish} root) and naringin (a polyphenolic glycoside from the grapefruit *Citrus paradisi*) are discussed in the sections on Plant-Induced Dermatitis and Plant-Xenobiotic Interactions, respectively.

### Terpenoids and Resins: Ginkgolides, Kava Lactones, Thujone, Anisatin, Ptaquiloside/Thiaminase, and Gossypol

Ginkgolides in *Ginkgo biloba* result in antiplatelet aggregation effects. Reports of spontaneous bleeding associated with ingestion of Ginkgo leaf products as a herbal medicine are perhaps explained by this property.<sup>131</sup> Another xenobiotic found only in the seed, 4-methoxypyridoxine (pyridine alkaloid), is associated with seizures.<sup>81</sup> A mechanism similar to isoniazid-induced seizures is plausible, suggesting treatment with pyridoxine phosphate (Chap. 56 and Antidotes in Depth: A15). The dermal effects of *Ginkgo* are discussed in the section Plant-Induced Dermatitis.

Kava lactones are a family of terpene lactones found in kava (*Piper methysticum*) that cause central and peripheral nervous system effects. Kava has enjoyed a long, ceremonial history among islanders of the South Pacific, and observers visiting Oceania have recorded its acute and chronic effects (both pleasant and unpleasant) over the centuries. Importation of kava to Australia in 1983 was a measure to assist Aborigines with alcohol abuse problems. However, the kava itself became abused, and its subsequent ban has resulted in the growth of a black market for kava. Proposed mechanisms to explain the effects of kava lactones include effects at  $\gamma$ -aminobutyric acid type A ( $\text{GABA}_A$ ) and  $\text{GABA}_B$  receptors or local anesthetic effects.<sup>137</sup> Acute effects following ingestion include peripheral numbness, weakness, and sedation. Chronic use leads to kava dermatopathy and weight loss. More than 70 cases of hepatotoxicity, several requiring liver transplantation, are associated with both acute and chronic effects of kava extracts on cytochrome oxygenases or other yet-to-be-defined etiologies and prompted regulatory health measures in Europe and North America.<sup>159</sup>

Thujone is one of many terpenes associated with seizures. It is found in the wormwood plant (*Artemisia absinthium*), in absinthe (the liquor flavored with *A. absinthium*), and in some strains of tansy (*Tanacetum vulgare*). The  $\alpha$ - and  $\beta$ -isomers of thujone likely work similarly to camphor to produce CNS depression and seizures. Invoking the structural similarity of thujone to tetrahydrocannabinol (THC), one of the terpenoids of marijuana, to explain the psychoactive effects is controversial (Chap. 74).<sup>105</sup>

Absinthism is characterized by seizures and hallucinations, permanent cognitive impairment, and personality changes. Acute and chronic absinthism led to a worldwide ban of the alcoholic beverage absinthe, which contained thujone, in the early 1900s.<sup>117</sup> Over the past several years, there was a reexamination of the role of absinthe in the seizure disorders previously attributed to this liquor. Modern analytical procedures analyzed the thujone content of vintage absinthe and modern products made using vintage recipes. Results largely conclude that thujone content in the liquor was likely to be too low to have produced the claimed effects.<sup>86</sup> However, because the essential oil of wormwood is composed almost exclusively of thujone, it, but not absinthe, is a potent cause of seizures.<sup>117</sup> Wormwood oil for making homemade absinthe is currently available and is responsible for at least 2 reports of adverse reactions in people seeking its hallucinatory or euphoriant effects.<sup>170</sup>

Anisatin is found in *Illicium* spp. This terpenoid produces seizures as a noncompetitive GABA antagonist. The Chinese star anise (*Illicium verum*) is sometimes used in teas and occasionally is confused or contaminated with other species of *Illicium*, particularly Japanese star anise *Illicium anisatum*.<sup>77</sup> These contaminations caused small epidemics of tonic-clonic seizures, particularly, but not exclusively, in infants after use of the tea to treat their infantile colic. Recently, in the United States, a case series of at least 40 individuals who consumed teas brewed from “Star anise” experienced seizures, motor disturbances, other neurologic effects, and vomiting.<sup>77</sup> These cases include at least 15 infants treated for infantile colic with this home remedy. This trend prompted the FDA to issue an advisory regarding the health risk from remedies sharing the common name “star anise.”

Ptaquilosides are found in the bracken fern (*Pteridium aquilinum*), a plant that is extending its range and density worldwide. In foraging animals, consumption of ptaquilosides results in acute hemorrhage secondary to profound thrombocytopenia, whereas thiaminases that are also found in the bracken fern result in cerebral disease.<sup>50</sup> Although no acute human poisonings are reported, these xenobiotics are transmitted through cow's milk and are associated with increased prevalence of gastric and esophageal cancer in areas where fern is endemic and consumed by cows whose milk is not diluted.<sup>175</sup> Chronic toxicity through spore inhalation also produces pulmonary adenomas in animals. More recently, research defined links between alimentary cancer in humans who previously consumed bracken fern fiddleheads.

Gossypol is a sesquiterpene that is derived from cottonseed oil. It was used experimentally as a reversible male contraceptive. The mechanism for its spermicidal effect is unclear, but the effects were attributed to inhibition of plasminogen activation and plasmin activity in acrosomal tissue. These effects are not currently reported to produce systemic bleeding. Gossypol also inhibits  $11\beta$ -hydroxysteroid dehydrogenase, as does glycyrrhizin, and may result in hypokalemia.<sup>176</sup>

### Proteins, Peptides, and Lectins: Ricin and Ricinlike, Pokeweed, Mistletoe, Hypoglycin, Lathyrins, and Microcystins

Lectins are glycoproteins that are classified according to their binding affinity for specific carbohydrate ligands, particularly galactosamines, and by the number of protein chains linked by disulfide bonds. Toxalbumins such as ricin and abrin are lectins that are such potent cytotoxins that they are used as biologic weapons (Chap. 133). Ricin, extracted from the castor bean (*Ricinus communis*; Fig. 118–3A), exerts its cytotoxicity by 2 separate mechanisms.<sup>10</sup> The compound is a large molecule that consists of 2 polypeptide chains bound by disulfide bonds. It must enter the cell to exert its toxic effect. The B chain binds to the terminal galactose of cell surface glycolipids and glycoproteins. The bound toxin then undergoes endocytosis and

A

B

C

**FIGURE 118–3.** Protein-, peptide-, and lectin-containing plants: (A) The castor bean plant. The seedpods come in bunches, 2 of which appear near the center of the image. Each seedpod typically contains 3 seeds. Inset: Castor beans (*Ricinus communis*) which contain the toxalbumin ricin. By interfering with protein synthesis, ricin may cause multiorgan system failure when administered parenterally. However, its oral absorption is poor, and most oral poisonings cause gastroenteritis. (B) Rosary pea (*Abrus precatorius*) containing abrin, a toxalbumin that inhibits protein synthesis. The peas are shown strung together as a rosary. (C) Pokeweed (*Phytolacca americana*) has a large rootstock. The unripe berries contain phytolaccotoxin that produces gastroenteritis, but the mature, purple berries are often consumed. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

is transported via endosomes to the Golgi apparatus and the endoplasmic reticulum. There the A chain is translocated to the cytosol, where it stops protein synthesis by inhibiting the 28S subunit of the 60S ribosome. In addition to the GI manifestations of vomiting, diarrhea, and dehydration, ricin can cause cardiac, hematologic, hepatic, and renal toxicity. All contribute to death in humans and animals.<sup>10</sup> Despite the obvious toxicity of this compound, death probably can be prevented by early and aggressive fluid and electrolyte replacement after oral ingestion (but not injection or inhalation; Chap. 127). Allergic reactions to some of these lectin-bearing plants and their toxic constituents are noted. Given the potential for use in bioterrorism events, a vaccine is being developed primarily for military use.<sup>121</sup>

The highest concentration of xenobiotic in ornamental seeds is in the hard, brown-mottled seeds. These seeds are both tempting and available, even to children in the United States, because they are attractive enough

to be used to make jewelry, and their parent plants are showy enough to be exported to many countries outside of their native India, including the United States, for horticultural purposes. Although mastication of one seed by a child liberates enough ricin to produce death, this outcome (or even serious toxicity) is uncommon, even if the seeds are chewed, probably because GI absorption of the ricin is poor and supportive care is effective.<sup>6</sup> Activated charcoal should be administered promptly following ingestion. Plasma exchange was utilized to remove ricin in 7 poisoned children with good effect.<sup>166</sup> However, the case data are uncontrolled and there are no analytical data on the presence of ricin, or its clearance, preventing a recommendation for its use.

Other ricinlike lectins are found in *Abrus precatorius* (jequirity pea, rosary pea (Fig. 118–3B)),<sup>41</sup> *Jatropha* spp.,<sup>91</sup> *Trichosanthes* spp (eg, *T. kirilowii* or Chinese cucumber), *Robinia pseudoacacia* (black locust),<sup>76</sup> *Phoradendron* spp (American mistletoe), *Viscum album* (European mistletoe), and *Wisteria* spp (wisteria). These all produce at least one double-chain lectin that binds to galactose-containing structures in the gut or inhibits protein synthesis in a manner similar to ricin.

The most commonly ingested toxic plant lectins in the United States are from pokeweed (*Phytolacca americana*) (Fig. 118–3C), which is eaten as a vegetable but rarely causes toxicity or death. The mature, deep purple berries are less toxic. Pokeweed leaves are consumed after boiling without toxic effect if the water is changed between the first and second boiling (parboiling). When this detoxification technique is not followed, as in preparation of poke salad or pokeweed tea, violent GI effects can ensue 0.5–6 hours after ingestion. Nausea, vomiting, abdominal cramping, diarrhea, hemorrhagic gastritis, and death may occur. In addition, bradycardia and hypotension, perhaps induced by an increase in vagal tone, may be associated with nausea and vomiting.<sup>70,129</sup> Phytolaccatoxin and pokeweed mitogen are found in all plant parts, but the highest concentrations are found in the plant root. Pokeweed mitogen is a single-chain protein that inhibits ribosomal RNA by removing purine groups.<sup>16</sup> It produces a lymphocytosis 2 to 4 days after ingestion that may last for 10 days, but this is without clinical consequence.

Mistletoe berries, both American and European, produce severe gastroenteritis, especially when delivered as teas or extracts, or particularly as parenteral antineoplastic medicinal agents in Europe. As festive holiday plants they become seasonally available for children. Poison control center data suggest that ingestion of 3 to 5 berries or one to 5 leaves of the American species may not cause toxicity, but these suggestions are based on limited evidence (Chap. 130). Despite single reports of seizure, ataxia, hepatotoxicity, and death, most authors performing such retrospective examinations conclude that mistletoe exposures are not a highly consequential risk.<sup>152</sup>

Hypoglycin A ( $\beta$ -methylene cyclopropyl-L- $\alpha$ -aminopropionic acid) and hypoglycin B (dipeptide of hypoglycin A and glutamic acid) are found in the unripe fruit and seeds of *Blighia sapida* (Euphorbiaceae), or ackee. The tree is native to Africa but was imported to Jamaica in 1778, and subsequently naturalized in Central America, southern California, and Florida. The scientific name of the plant derives from Captain William Bligh, the British explorer. Epidemics of illness (Jamaican vomiting sickness) associated with consumption of the unripe ackee fruit (raw and cooked) occur in Africa but are more common in Jamaica, where ackee is the national dish.<sup>80</sup> The most toxic part is the yellow oily aril of the fruit,<sup>29</sup> which contains 3 large, shiny black seeds. Cases of hypoglycin A poisoning are also associated with canned ackee fruit,<sup>104</sup> and recently to epidemic poisonings from litchi fruit in India.<sup>144</sup> Hypoglycin A is metabolized to methylene cyclopropyl acetic acid, which competitively inhibits the carnitine-acyl coenzyme (CoA) transferase system.<sup>13</sup> This prevents importation of long-chain fatty acids into the mitochondria, preventing their  $\beta$ -oxidation to precursors of gluconeogenesis.  $\beta$ -Oxidation and gluconeogenesis are further arrested by inhibition of various enzymes, such as glutaryl CoA dehydrogenase, which blocks the malate shunt (Chap. 11). In addition, increased concentrations of glutaric acid may inhibit glutamic acid decarboxylase, which produces GABA from glutamic acid. This not only depletes GABA but also increases concentrations of excitatory glutamate to produce seizures. Insulin concentrations remain unaffected by hypoglycin

and metabolites. Carboxylic and other organic acid substrates build up in the urine and serum as a result of these metabolic disturbances. Detection of these acids helps corroborate the diagnosis.<sup>13</sup> Jamaican vomiting sickness is characterized by epigastric discomfort and the onset of vomiting starting 2 to 6 hours after ingestion. Convulsions, coma, and death can ensue, with death occurring approximately 12 hours following consumption. Laboratory findings are notable for profound hepatic aminotransferase and bilirubin abnormalities, and aciduria and acidemia without ketonemia. Cholestatic hepatitis is reported with chronic use.<sup>88</sup> Autopsy reveals fatty degeneration of liver, particularly microvesicular steatosis, and other organs with depletion of glycogen stores. Left untreated, patient mortality reaches 80%, with 85% of the fatal cases suffering seizures. Treatment with dextrose and fluid replacement is essential. Benzodiazepines control seizures, but may fail if the seizures are related to depletion of GABA. In this situation, an alternative anticonvulsant, such as a barbiturate or propofol, should be utilized. L-Carnitine therapy may exert a theoretical therapeutic role similar to that noted with valproic acid toxicity (Chap. 48 and Antidotes in Depth: A10).<sup>94</sup> Its use, however, in this situation is not studied.

The lathyrins  $\beta$ -N-oxalylamino-L-alanine (BOAA) and  $\beta$ -aminopropionitrile (BAPN) are peptides from the grass pea (*Lathyrus sativus*) found in the seeds and leaves, respectively.  $\beta$ -N-Oxalylamino-L-alanine produces neuro-lathyrism and BAPN produces osteolathyrism in individuals with a dietary dependence on this plant. Neuro-lathyrism is nearly indistinguishable from spastic paresis associated with consumption of improperly prepared cassava (see section Cyanogenic Glycosides).<sup>15,33</sup> Thiol oxidation with depletion of nicotinamide adenine dinucleotide (NADH) dehydrogenase in neuronal mitochondria (ie, excitatory AMPA receptors) may be the common etiology.<sup>151</sup> Epidemics have occurred in Bangladesh, Ethiopia, Israel, and India. Exposure to BOAA results in degeneration of corresponding corticospinal pathways that becomes irreversible if consumption of undetoxified grass peas is not stopped early.  $\beta$ -N-Oxalylamino-L-alanine stimulates the AMPA class of glutamate receptors to provide constant neuronal stimulation, eventual degeneration, and hence spasticity.<sup>174</sup>  $\beta$ -Aminopropionitrile affects bone matrix and leads to bone pain and skeletal deformities that develop in adulthood. These diseases occur in areas where the plants are endemic, the food is consumed for 2 months or more, and when diets are otherwise poor in protein and possibly in zinc.<sup>18,61</sup>

Microcystins are found in several cyanobacteria (blue-green algae) belonging to various species of the genera *Microcystis*, *Anabaena*, *Nodularia*, *Nostoc*, and *Oscillatoria*. They elaborate a series of peptides called microcystins and nodularins (*Nodularia spumigena*).<sup>42</sup> These compounds produce hepatotoxicity by inhibiting phosphatases and causing deterioration of the microfilament function in hepatocytes, leading to cell shrinkage and bleeding into the hepatic sinusoids. Evidence indicates that these peptides are carcinogenic to humans. Although most cases of untoward effects from blue-green algae occur in animals, the potential for harm was demonstrated by use of microcystin-contaminated water in a dialysis unit in Brazil.<sup>79</sup> Unfiltered water was identified as the risk factor for liver disease in 100 patients who attended the dialysis center (Chap. 6). Fifty of these patients died of acute liver failure following early signs of nausea, vomiting, and visual disturbances. Of concern, certain species of *cyanobacteria* are harvested and consumed as health foods or may be consumed secondarily in fish.<sup>62</sup>

### Phenols and Phenylpropanoids: Coumarins, Capsaicin, Karwinskia Toxins, Naringenin and Bergamottin, Asarin, Nordihydroguaiaretic Acid, Podophyllin, Psoralen, and Esculoside

Phenols and phenylpropanoids represent one of the largest groups of plant secondary metabolites. Coumarins and their isomers are phenylpropanoids that are discussed in Chap. 58. Some coumarins are warfarinlike in their activity and are capable of producing a bleeding diathesis when plants containing them are consumed in sufficiently large quantities.<sup>74</sup> Lignans are formed when phenylpropanoid side chains react to form bisphenylpropanoid derivatives. Lignans are high-molecular-weight polymers of phenylpropanoids that bind to cellulose and provide strength to cell walls of stem and bark. Tannins

are polymers that bind to proteins and divide into 2 groups: hydrolyzable and condensed forms.

Capsaicin is derived from *Capsicum annuum* or other species of chili or cayenne peppers. Capsaicin is a simple phenylpropanoid that causes release of the neuropeptide substance P from sensory C-type nerve fibers that act upon transient receptor potential (TRP) channels in diverse human tissues.<sup>165</sup> The immediate response to capsaicin is intense local pain and is the rationale for its use as “pepper spray.” Eventual depletion of substance P prevents local transmission of pain impulses from these receptors to the spinal cord, blocking perception of pain by the brain, explaining its use in postherpetic neuralgia.

Painful exposures to capsaicin-containing peppers are among the most common plant-related exposures presented to poison control centers. They cause burning or stinging pain to the skin. If ingested in large amounts by adults or small amounts by children, they can produce nausea, vomiting, abdominal pain, and burning diarrhea. Eye exposures produce intense tearing, pain, conjunctivitis, and blepharospasm. Fatality is rare, but is reported following inhalation and infusion.<sup>150</sup>

Skin irrigation, dermal aloe gel, analgesics, and oral antacids are therapeutic agents that may be helpful as appropriate, but patients can be reassured that the effects are transitory and produce no long-term damage. Irritated eyes should be treated with irrigation and, if severe, topical analgesia, but the pain generally resolve without sequelae within 24 hours.

Karwinskia toxins are found in plants commonly named Buckthorn, coyotillo, tullidora, wild cherry, or capulincillo (*Karwinskia humboldtiana*). These xenobiotics are identified by their molecular weights (T-514, T-496, T-516, T-544). Toxicity has been known for more than 200 years. In 1920, an epidemic of deaths was reported after 20% of 106 Mexican soldiers died following ingestion of foraged *Karwinskia* fruits.<sup>100</sup> The fruits are attractive to children. Epidemic poisonings have been reported in Central America and are possible wherever the shrub is found, typically in semidesert areas throughout the southwestern United States and in the Caribbean, Mexico, and Central America.<sup>9</sup> Uncoupling of oxidative phosphorylation or dysfunction of peroxisome assembly and integrity is described as the mechanism of action of T-514 on Schwann cells. Each xenobiotic exhibits similar cytotoxic effects at the cellular level, but with tropism for different organs in animal models.<sup>100</sup>

Within a few days of ingestion, a symmetric motor neuropathy ascends from the lower extremities to produce a bulbar paralysis that may lead to death. Deep-tendon reflexes are abolished in affected areas, but cranial nerve findings are absent. Distinction of this demyelinating motor neuropathy from Guillain-Barré syndrome, poliomyelitis, solvent, and other polyneuropathies is difficult without a history of the fruit ingestion,<sup>115</sup> but can be assisted by detection of T-514 in the blood of affected patients. The other recognized toxins are not detected in blood. Occasionally, axonal damage is observed, but demyelination is the predominant finding on biopsy. Nerve conduction studies generally demonstrate loss or abolition of function in fast-conducting axons. Cerebrospinal fluid demonstrates normal protein, glucose, and cytology. Treatment is supportive, with mechanical ventilation as needed, and recovery typically is slow.

Naringin and naringenin are flavonoid, whereas bergamottin and 6',7'-dihydroxybergamottin are furanocoumarin, phenylpropanoids derived from grapefruit that inhibit CYP3A4 in gut and liver. Grapefruit juice consumption can increase circulating concentrations of drugs reliant on CYP3A4 for metabolic elimination, including carbamazepine, felodipine, and the statins. The most plausible mechanism is inhibition of enteric CYP3A4 and P-glycoprotein.<sup>118</sup> These effects are maximally achieved by a single glass of grapefruit juice.<sup>98</sup>

Comedication with St John's wort (*Hypericum perforatum*) resulted in decreased plasma concentrations of a number of xenobiotics.<sup>99</sup> Hyperforin is a phenylpropanoid found in St John's wort and is associated with plant-xenobiotic interactions through strong induction of CYP3A4 mediated drug metabolism as well as induction of P-glycoprotein. These combined mechanisms can cause subtherapeutic concentrations of xenobiotics metabolized via these pathways.

Asarin is a term sometimes used for the naturally occurring mixture of  $\alpha$ - and  $\beta$ -asarones found in the root of *Asarum europaeum*, *Asarum arifolium*, and *Acorus calamus* (sweet flag). Essential oils of the plants have anthelmintic and nematocidal activity, but putative euphoric and hallucinogenic effects that motivate recreational ingestion are in contrast to confirmed reports of unpleasant GI effects.<sup>163</sup>

Nordihydroguaiaretic acid (NDGA) is associated with hepatotoxicity after ingestion of chaparral (*Larrea tridentata*).<sup>64</sup> Podophyllin and psoralens are phenylpropanoids discussed in the sections Antimitotic Alkaloids and Resins, and Plant-Induced Dermatitis, respectively.

Esculoside (also called esculin or aesculin) has triterpene saponin side chains and is believed to be the toxic component in horse chestnut (*Aesculus hippocastanum*). Horse chestnut extracts are used medicinally in patients with venous insufficiency. The therapeutic use of these extracts at high doses (>340 mcg/kg) is associated with acute kidney injury or a lupuslike syndrome.<sup>65</sup> Leaves, twigs, or horse chestnuts ingested by children or infused as teas result in a syndrome that resembles nicotine toxicity. The syndrome consists of vomiting, diarrhea, muscle twitching, weakness, lack of coordination, dilated pupils, paralysis, and stupor. The mechanism of toxicity is not defined.

### Carboxylic Acids: Aristolochic Acids, Oxalic Acid, and Oxalate Raphides

Nitrophenanthrene carboxylic acids, collectively called aristolochic acids, are present in most members of the genus *Aristolochia*, including those used ornamentally and as traditional medicines. Consumption of these compounds can cause aristolochic acid nephropathy (AAN), a progressive renal interstitial fibrosis frequently associated with urothelial malignancies (Chap. 43).<sup>99</sup> Sources of exposure are via consumption of flour made from wheat contaminated with the seeds of *Aristolochia clematis* or other *Aristolochia* species (so called Balkan endemic nephropathy),<sup>67</sup> or through use of certain traditional Asian medicines made from *Aristolochia* spp (Chinese herb nephropathy).<sup>36</sup>

Oxalic acid is the strongest acid among the carboxylic acids found in living organisms. It forms poorly soluble chelates with calcium and other divalent cations. Higher plants have varying ability to accumulate these, include both soluble and insoluble oxalates, and many contain crystals of calcium oxalate called raphides. Certain plant families, such as the Araceae, Chenopodiaceae, Polygonaceae, and Amaranthaceae, and several of the grass families, are rich in oxalates. Human dietary sources include rhubarb, spinach, strawberries, chocolate, tea, and nuts. Human consumption of soluble oxalate-rich foods correlates with kidney stone formation.<sup>93</sup>

The insoluble calcium oxalate raphides that are present in certain plants, usually in the Araceae family, are found in conjunction with a protein toxin that increases the painful irritation to skin or mucous membranes. This special manifestation is discussed in greater detail in the section Plant-Induced Dermatitis.

### Alcohols: Cicutoxin

Cicutoxin, a diacetylenic diol, is found in *Cicuta maculata* (water hemlock), *Cicuta douglasii* (western water hemlock), and *Oenanthe crocata* (hemlock water dropwort). *Oenanthe crocata* is native to Europe, where intoxications have been reported, and is now naturalized in the United States. Ingestion of any part of these plants constitutes the most common form of lethal plant ingestion in the United States. Hemlock is among the most prominent causes of plant-related fatalities among the most recent 10-year reviews of the AAPCC data and Centers for Disease Control and Prevention (CDC) plant poisoning records (Chap. 130).<sup>85</sup> In contrast to most plant exposures in humans, which tend to involve children, these ingestions usually involve adults who incorrectly identify the plant as wild parsnip, turnip, parsley, or ginseng.<sup>142</sup> All plant parts are poisonous at all times, but the tuber is especially toxic, and more so during the winter and early spring. Absorption of cicutoxin is rapid and occurs through the skin as well as through the gut. Although the mechanism is not fully understood, cicutoxin may noncompetitively inhibit GABA receptors or block potassium channels.<sup>142</sup>

Clinical findings of mild or early poisonings consist of GI symptoms (nausea, vomiting, epigastric discomfort) and begin as early as 15 minutes after ingestion. Diaphoresis, flushing, dizziness, excessive salivation, bradycardia, hypotension, bronchial secretions with respiratory distress, and cyanosis occur and rapidly progress to violent seizures. Ingestion of as little as a 2-cm section of the sweet-tasting root of *Cicuta* can produce status epilepticus.<sup>142</sup> Other complications include rhabdomyolysis with acute kidney injury and severe acidemia. Immediate gastric lavage should be performed if practical, and benzodiazepines should be administered for seizures. No specific antidote exists; supportive and symptomatic care should be provided.

### Unidentified Toxins

Consistent with the inherent complexity of plants and the relatively early stage of the science, identification of the active ingredient(s) involved in poisoning is not always possible. An epidemic of the irreversible lung disease bronchiolitis obliterans developed in Taiwan in 1994 that involved more than 200 dieters who had been eating *Sauropus androgynus* as a weight-loss vegetable. The effects were dose related (usually approximately 100 g/d) and manifested by month 7 after approximately 10 weeks of use.<sup>75</sup> The cases were associated with at least 4 deaths and, in addition to pulmonary disease, resulting in lung transplantation.<sup>97</sup> Torsade de pointes occurred in 3 patients, consistent with the plant's high concentration of papaverine, which produces dysrhythmias in animals. Corticosteroid and bronchodilator therapy consistently failed to improve pulmonary symptoms. A report of a later outbreak in Japan followed consumption of uncooked plant.<sup>116</sup>

Milk sickness is a historic poisoning described by pioneer farmers. It was caused by transmission of the nontoxic ketone tremetone to humans via milk of animals grazing on white snake-root plants (*Ageratina altissima*, formerly *Eupatorium rugosum*). Tremetone is transformed into an unknown, unstable toxin by hepatic microsomal enzymes.<sup>90</sup> Toxicity is cumulative. Milk sickness can be fatal in one to 21 days or is associated with a slow recovery marked by weakness for months or years, relapsing sometimes to death. A delay in the development of the lactating animal's symptoms provided a lag time when xenobiotic-laden milk was taken from asymptomatic animals and thereby transmitted to humans before the problem was detected.

Ingestion of the air potato (*Breynia officinalis*) or bitter yam (*Dioscorea bulbifera*) is associated with hepatotoxicity.<sup>96</sup> Black cohosh (*Actaea racemosa*) hepatotoxicity is suggested in case reports, but causality is not established.<sup>158</sup>

Consumption of the star fruit (*Averrhoa carambola*) as a food in patients with chronic kidney disease is associated with development of intractable hiccups, vomiting, motor disabilities, paresthesias, confusion, seizures, and death unless patients receive supportive care and hemodialysis.<sup>160</sup> The unidentified toxin appears to be neuroexcitatory and may be oxalate.<sup>24,52</sup> Charcoal hemoperfusion is reported to be successful but clearance was not determined and causality not confirmed.<sup>26</sup> Given its limited availability and the poor potential outcomes, hemodialysis should be performed in affected patients.

## EFFECTS SHARED AMONG DIFFERENT CLASSES OF XENOBIOTICS

### Plant–Xenobiotic Interactions

By increasing the expression and function of CYP 3A4 enzymes and P-glycoprotein, hyperforin in St John's wort (*H. perforatum*) decreases concentrations of several drugs including amitriptyline, cyclosporine, digoxin, indinavir, irinotecan, warfarin, phenprocoumon, alprazolam, dextromethorphan, simvastatin, theophylline, and oral contraceptives.<sup>122</sup> Bergamottins and naringenin from grapefruit reduce activity of CYP 3A4 enzymes and increase drug concentrations. Other *Citrus* species also appear to increase drug concentrations.<sup>72</sup>

Pharmacodynamic interactions may be responsible for serotonin excess or mild serotonin syndrome when St John's wort is used concurrently with tryptophan or serotonin reuptake inhibitors.<sup>140</sup> Additive effects also appear

to be responsible for increased prothrombin time in patients taking *G. biloba* and various drugs that affect coagulation (eg, warfarin or aspirin) because the ginkgolides have antiplatelet activity.<sup>37</sup> Hawthorn (*Crataegus* spp), used medicinally for cardiac disorders, may produce an additive effect when taken concomitantly with digoxin, producing bradycardia. Excessive intake of broccoli provides enough vitamin K to competitively inhibit the effects of warfarin on vitamin K activation.

### Sodium Channel Effects: Aconitine, Veratridine, Zygacine, Taxine, and Grayanotoxins

Several unrelated plants produce xenobiotics that affect the flow of sodium at the sodium channel. The mechanism of action depends on the individual alkaloid. For instance, aconitine and veratrum alkaloids tend to open the channels to influx of sodium, whereas others (eg, taxine) tend to block the flow, and grayanotoxins both increase and block sodium flow.<sup>167</sup> The sodium channel opener aconitine from *Aconitum* spp or *Delphinium* spp has the most persistent toxicity and the lowest therapeutic index among the many active alkaloid ingredients of these toxic plants called aconite. Some of the related alkaloids are controlled medicinal substances in the People's Republic of China and Taiwan.<sup>27</sup> Aconite has been abused for its psychoactive “out of body” effects and for suicide and homicide. These alkaloids should be suspected in potentially poisoned patients who manifest cardiac toxicity, paresthesias, and seizures.

Aconitine itself opens the voltage-dependent sodium channel at binding site 2 of the  $\alpha$ -subunit, initially increasing cellular excitability.<sup>58</sup> By prolonging sodium current influx, neuronal and cardiac repolarization eventually slows. It also has calcium channel-opening effects. Those alkaloids are used in Asian prescription medicines to treat dysrhythmias and pain by reducing the excitability of the cardiac conducting system and sensory neurons, respectively.<sup>27</sup>

Approximately one teaspoon (2–5 g) of the root may cause death. The aconitine alkaloids are rapidly absorbed from the GI tract, and the calculated half-life of aconitine is 3 hours.<sup>110</sup> Central nervous system effects typically progress from paresthesias to CNS depression, respiratory muscle depression, paralysis, and seizures. Nausea, vomiting, diarrhea, and abdominal cramping occur.<sup>95</sup> Cardiotoxicity resembles that caused by cardioactive steroidal glycosides, and typically progresses from bradycardia with atrioventricular conduction blockade to increased ventricular automaticity resulting in diverse tachydysrhythmias. Multifocal premature ventricular contractions, bidirectional ventricular tachycardia,<sup>149</sup> torsade de pointes, and ventricular fibrillation may occur.<sup>95</sup>

A history of paresthesias or muscle weakness may be useful in differentiating aconitine toxicity from that caused by a cardioactive steroids. Aconite poisoning is confirmed by detection of the alkaloids in urine by liquid chromatography–mass spectrometry.

Antidysrhythmic success with lidocaine is limited, and amiodarone or flecainide are currently the antidysrhythmics of choice, with both drugs demonstrating more frequent return to sinus rhythms.<sup>31,95</sup> Orogastric lavage and/or administration of activated charcoal should be performed for any patient displaying signs or symptoms consistent with poisoning, or in those who are believed to have a potentially toxic exposure. Given the potential for rapid cardiovascular deterioration, equipment and staff for cardiac pacing, bypass, or balloon pump assist should be prepared and used for conventional indications.

Ingestion of veratridine and other veratrum alkaloids (from *Veratrum viride* and other *Veratrum* spp) generally results from foraging errors where the root appears similar to leeks (*Allium porrum*) and above-ground parts appear similar to gentian (*Gentiana lutea*) used for teas and wines in Europe.<sup>141</sup> Typical symptoms develop within an hour of ingestion and include headache followed by nausea, vomiting, and less frequently bradycardia and diarrhea. The mechanism of action is similar to that of aconitine (sodium channel opening) but the duration of effects is shorter.<sup>167</sup> Although severe toxicity is reported, management is supportive with fluids, atropine, and vasopressors. Deaths are rare.

**FIGURE 118-4.** The Yew (*Taxus* sp.) is a common garden shrub that produces taxine, a cardiotoxin. Though the fleshy red aril is nontoxic, the hard seed it contains is toxic. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

**FIGURE 118-5.** Mountain laurel (*Kalmia latifolia*), an evergreen shrub, contains the sodium channel opener grayanotoxin, which produces dysrhythmias. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

Zygacine from *Zigadenus* spp (death camas) and other members of the lily family produces the same toxic effects as veratridine alkaloids (vomiting, hypotension, and bradycardia).<sup>171</sup> Symptoms begin one to 2 hours after ingestion and usually result from errors while foraging for onions because of the plant's lookalike bulb.<sup>154</sup> Treatment options are the same as above with *Veratrum* alkaloids.

Taxine, derived from the yew, is another alkaloid mixture of sodium channel effectors that tend to close the channel (*Taxus baccata*) (Fig. 118-4). The toxicity of *Taxus* has been known since antiquity. Toxic alkaloids are contained within the bark, leaves, and hard central seed but not in the surrounding fleshy red aril, which partly explains the low rate of toxicity in reported cases of unintentional exposure.<sup>173</sup> Taxine-derived alkaloids (eg, taxine A and B, isotaxine B, paclitaxel), taxane-derived substances (eg, taxol A and B), and glycosides (eg, taxicatine) are responsible for the toxicity of *Taxus* spp. Lethal oral doses (LD<sub>50</sub>) of yew leaves in humans are estimated to be 0.6 to 1.3 g/kg of body weight, or 3.0 to 6.5 mg taxines/kg of body weight.<sup>172,173</sup> Suicide using leaves is reported despite the large number of leaves required.<sup>169</sup> Clinical manifestations of yew poisoning include dizziness, nausea, vomiting, diffuse abdominal pain, tachycardia (initially), and convulsions followed by bradycardia, respiratory paralysis, and death. Several small European series report fatal and nonfatal cases with precise documentation of the yew alkaloids and metabolites in various tissues and their elimination half-lives.<sup>83</sup>

Paclitaxel (Taxol) is an alkaloid component of the relatively rare Pacific yew (*Taxus brevifolia*) that is used as an antitumor chemotherapeutic xenobiotic because of its ability to promote the assembly of microtubules and to inhibit the tubulin disassembly process in mitotic cells. Within one hour after ingestion, toxicity progresses from nausea, abdominal pain, bradycardia, and cardiac conduction delays to wide-complex ventricular dysrhythmias, paresthesias, ataxia, and depressed mental status.<sup>66</sup> Four prisoners who drank an extract of yew experienced profound hypokalemia, and 2 died of cardiac arrest.<sup>54</sup> Animal models indicate that bradycardia is responsive to atropine, but wide-complex tachydysrhythmias are unresponsive to sodium bicarbonate.<sup>132</sup>

Grayanotoxins (formerly termed andromedotoxins) are a series of 18 toxic diterpenoids present in leaves of various species of *Rhododendron*, *Azalea*, *Kalmia* (Fig. 118-5), and *Leucothoe* (Ericaceae). They exert their toxic effects via sodium channels, which they open or close, depending on the toxin.<sup>167</sup> Grayanotoxin I increases membrane permeability to sodium and affected calcium channels in a manner similar to that of veratridine (and batrachotoxin).<sup>78</sup> Grayanotoxins are concentrated in honey made in areas with densely populated grayanotoxin-containing plants, mainly in the Mediterranean. Accounts of poisoning by honey date back to at least 401 B.C., when Xenophon's troops were incapacitated after they consumed honey made from nectar of

*Rhododendron luteum*.<sup>145</sup> Occasionally, grayanotoxin-containing plants or plant preparations rather than honey cause human poisonings. Bradycardia, hypotension, GI manifestations, mental status changes ("mad honey"), and seizures are described in patients or animals suffering grayanotoxin toxicity.<sup>68</sup>

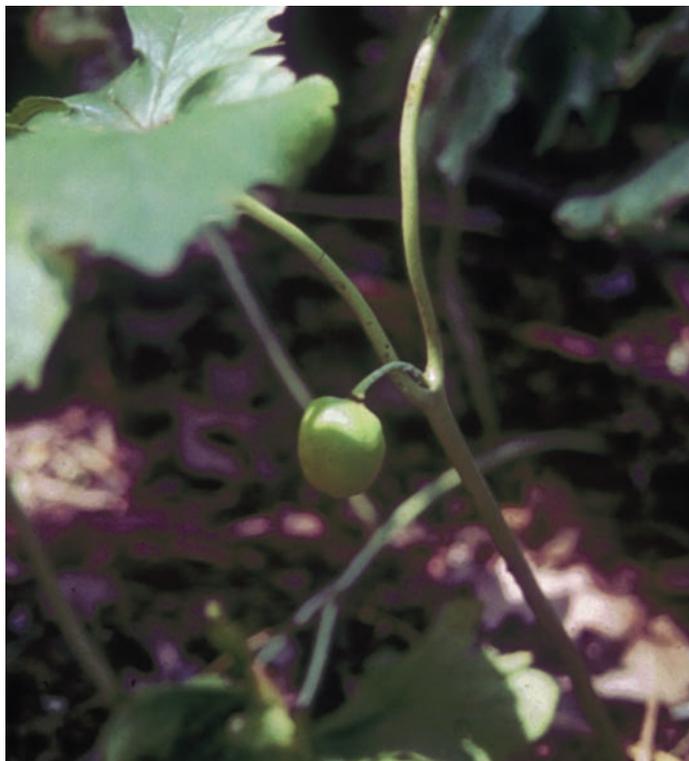

### Antimitotic Alkaloids and Resins: Colchicine, Vincristine, and Podophyllum

Consumption of colchicine from plant sources such as autumn crocus (*Colchicum autumnale*) produces a spectrum of effects, including nausea, vomiting, watery diarrhea, hypotension, bradycardia, electrocardiographic abnormalities, diaphoresis, alopecia, bone marrow depression, acute kidney injury, hepatic necrosis, hemorrhagic acute lung injury, convulsions, and death.<sup>157</sup>

Confusion of the bulbs or leaves of this plant with those of wild onions or garlic occur as a foraging error.<sup>60</sup> Unintentional consumption by children and ingestion for self-harm account for the other cases involving morbidity or mortality. The mechanism of toxicity is disruption of microtubule formation in mitotic cells.<sup>56</sup>

Vincristine and vinblastine are 2 other indole alkaloids that are used as antineoplastics and are both isolated from the Madagascar periwinkle (*Catharanthus roseus*). No reports of poisoning by these alkaloids following ingestion of the plant could be found (Chap. 34).

Podophyllum resin is the dry, alcoholic extract of the rhizomes and roots of mayapple (*Podophyllum peltatum*) (Fig. 118-6). The dry resin consists of up to 20% podophyllotoxin,  $\alpha$ - and  $\beta$ -peltatin, desoxypodophyllotoxin, and dehydropodophyllotoxin. These xenobiotics are originally present in the plant as  $\beta$ -D-glucosides. Podophyllum resin containing podophyllin is available by prescription for topical treatment of venereal warts. Its medicinal derivative, etoposide, is used for a range of neoplastic diseases. Podophyllum is used as a popular traditional Chinese medicine. Podophyllotoxins make up 20% of the resin from the roots of mayapple (*P. peltatum*). As a group, they disrupt tubulin formation, producing multisystem organ failure. Poisonings are caused by misidentification and adulteration, possibly because the list of common names by which it is known includes mayapple, as well as mandrake, wild mandrake, American mandrake, and European mandrake.<sup>37</sup> Catharsis is prominent after ingestion, but onset of symptoms may be significantly delayed. Acute, severe sensorimotor neuropathy and bone marrow suppression following transient leukocytosis can occur even after acute exposures and may be directly related to inhibition of microtubule assembly. Lethargy, confusion, encephalopathy, autonomic instability, sensory ataxia, and death are described following large exposures,<sup>114</sup> but poisoning can also occur after "therapeutic" doses of a popular traditional Chinese medicine.<sup>114</sup>

**FIGURE 118-6.** The mayapple (*Podophyllum peltatum*) develops from an initial nodding flower that grows from the stem of this low-lying ground cover plant. The whole plant contains podophyllotoxin (podophyllin), though the apple is generally considered the least toxic part. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

### Plant-Induced Dermatitis

A large number of plants result in undesirable dermal, mucous membrane, and ocular effects and they represent the most common adverse effects reported to US poison control centers and occupational health centers. Plant-induced dermal disorders are readily categorized into 4 mechanistic groups, that is, dermatitis that results from (1) mechanical injury, (2) irritant molecules that penetrate the skin, (3) allergy, or (4) photosensitivity (direct and hepatogenous) (Chap. 17).<sup>138</sup>

There is much overlap between these categories (some plants can produce all types). Clinicians may have difficulty distinguishing between plant-induced dermatitis and skin disorders<sup>102</sup> or between plant-induced dermatitis and pseudophytoprotopodermatitis caused by arthropods, pesticides, or wax (used in fruit and vegetable packaging). Agents that cause adverse skin reactions also cause eye and local gastric mucosal irritation.

Dermatitis from mechanical injury often is combined with primary or allergic contact dermatitis. Stinging nettles (*Urtica dioica* and other species) have a specialized apparatus in the form of an elongated silicious cell (glandular trichome) that acts like a hypodermic syringe to deliver irritant chemicals into the skin. Contact with these stinging hairs shears off the tip of the hair, producing micromechanical injury and releasing irritant contents: acetylcholine, histamine, and 5-hydroxytryptamine.<sup>5</sup> Acute motor polyneuropathy associated with cutaneous exposure to *Urtica ferox* is reported within 48 hours of walking through a patch of the nettles, with recovery occurring over several weeks.<sup>71</sup> The barbed trichomes (spicules) of *Mucuna pruriens* (velvet bean, cowhage) evoke a histamine-independent itch that is mediated by a cysteine protease, mucunain.<sup>87</sup> Workers who handpick pineapples are subject to fissuring and loss of fingerprints after proteolytic enzyme bromelain exposure following dermal abrasion by raphides.

Exposures to commonly available household plants such as dumbcane (*Dieffenbachia* spp), *Philodendron* spp, and *Narcissus* bulbs can lead to mechanical injury and painful microtrauma produced by bundles of tiny

**FIGURE 118-7.** This dumbcane (*Dieffenbachia* sp) plant is representative of the Arum family, which typically have variegated, waxy leaves. Many contain insoluble crystals of calcium oxalate arranged in idioblasts, which may be ejected following trauma to the leaf. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

needlelike calcium oxalate crystals called raphides.<sup>106</sup> Packages of hundreds of raphides called idioblasts contain proteolytic enzymes. *Dieffenbachia* (more than 30 species) (Fig. 118-7) exposures are commonly reported household or malicious plant exposures, although such exposures are rarely serious.<sup>112</sup> When the leaves are chewed, immediate oropharyngeal pain and swelling occur.<sup>4</sup> Severe oral exposures can be excruciating and progress to profuse salivation, dysphagia, and loss of speech. Soothing liquids, ice, parenteral opioids, corticosteroids, and airway protection may be indicated, but antihistamines provide little relief. The edema and pain typically begin to subside after 4 to 8 days. Ocular exposure to the sap may produce chemical conjunctivitis, corneal abrasions, and, rarely, permanent corneal opacifications.

Similar exposures to oxalate raphide-containing household plants in the same family (*Philodendron*, *Brassaia*, *Epipremnum aureum*, *Spathiphyllum*, and *Schefflera* spp) are not as painful as those to dumbcane, presumably because the crystals are packaged differently and do not simultaneously deliver proteolytic enzymes.<sup>106</sup> One exception to their lower severity is a report of death in an 11 month-old following complications arising from esophageal lesions induced by *philodendron*.<sup>103</sup>

Irritant dermatitis results from low-molecular-weight xenobiotics such as phorbol esters (from Euphorbiaceae) that directly penetrate the skin without antecedent mechanical injury. Similar penetrance is achieved by products of glycoside hydrolysis. For instance, hydrolysis of ranunculin gives rise to anemonin in Ranunculaceae, the buttercup family, and hydrolysis of sinigrin in plants in the mustard family Brassicaceae yields allyl isothiocyanate. Exposures to primary irritants in Brassicaceae and Ranunculaceae usually are mild. Alternatively, airborne contact dermatitis occurs in typically exposed sites such as the upper eyelids; neck; uncovered extremities, including antecubital fossae; and other skin folds (Chap. 17).<sup>108</sup>

Phorbol esters found in spurges (Euphorbiaceae) are contained in milky sap that is capable of producing erythema, desquamation, and bullae. The saps of some species are more irritating than others. For instance, the manchineel tree (*Hippomane mancinella*), found in the Caribbean and Florida, once was planted on graves to deter grave robbers, and juice from the tree has been used to brand animals and to blind people. In addition to dermal and ocular injury,<sup>49</sup> ingestion of some spurges induces severe GI injury. Poinsettia (*Euphorbia pulcherrima*), crown of thorns (*Euphorbia splendens*), candleabra cactus (*Euphorbia lactea*), and pencil tree (*Euphorbia tirucalli*) are spurges found in the home as holiday or other ornamentation that rarely produce serious injury, despite reputations to the contrary. The poinsettia plant, for instance, gained a reputation of significant toxicity based on a single, inadequately documented case report from Hawaii in 1919, involving the death of a 2-year-old child.<sup>6</sup> In a subsequent case, an 8-month-old child developed oral mucosal burns after chewing poinsettia.<sup>48</sup> Contact dermatitis,

irritation of mucous membranes, and GI complaints such as nausea, vomiting, and abdominal pain are rare findings among the many reported exposures to poinsettia.

Allergic contact dermatitis results from type IV hypersensitivity response and, unlike irritant dermatitis, requires prior exposures to the agent before symptoms manifest. The most infamous of these xenobiotics are the urushiol oleoresins derived from catechols that are found in *G. biloba* (Ginkgoaceae) and members of the Proteaceae (eg, *Macadamia integrifolia*) and the Anacardaceae. The latter family is notable for inclusion of poison ivy (*Toxicodendron radicans*), poison oak (*Toxicodendron toxicarium*, *Toxicodendron diversilobum*), and poison sumac (*Toxicodendron vernix*),<sup>63</sup> as well as mango (*Mangifera indica*), pistachio (*Pistacia vera*), cashew (*Anacardium occidentale*), and Indian marking nut “Bhilawanol” (*Semecarpus anacardium*). Upon first exposure, urushiol resins penetrate the skin and react with proteins to form antigens to which the body forms antibodies. Upon reexposure to urushiol resins, inflammatory mediators are released, leading to urticaria, itching, swelling, and pain. In extreme cases, these reactions can progress to type I hypersensitivity. Cross-reactivity between allergens is possible, and particular vigilance is required in sensitive individuals.<sup>55</sup> Prevention by removal of exposed objects that act as fomites for the oils and use of protective liniments are appropriate. Therapy includes washing with soap and water, application of topical corticosteroids and, for those at risk for frequent exposure (eg, forestry workers), desensitization (Chap. 17).<sup>63</sup>

Allergic contact dermatitis is the most common plant-induced occupational injury. In the United States, 33% of 462 floral shops surveyed reported that at least one employee had developed contact dermatitis.<sup>136</sup> Reactions are reported following exposure to tulips, Narcissus, Peruvian lily (*Alstroemeria* spp), and primroses (*Primula* spp). Exposure to the glycoside tuliposide A results in “tulip fingers,” the dry, painfully fissured hyperkeratosis of fingers observed in horticultural workers who chronically handle tulips.<sup>23</sup> Upon hydrolysis, this compound yields  $\alpha$ -methylene-butylolactone, the true allergen. Cross-reactivity is possible among some of these xenobiotics. *Alstroemeria* spp, a common ornamental called Peruvian lily, contain tuliposide A and thus can cross-react with antigens in those persons already allergic to tulips, producing an allergic contact dermatitis. Primin (2-methoxy-6-*n*-pentyl-*p*-benzoquinone) from members of the Primulaceae family was responsible for the most frequently reported allergic plant dermatitis in northern Europe until workers refused to stock primroses. The “wood cutters dermatitis” of loggers occurs with development of sensitivity to compounds in liverwort (*Frullania* spp), which is cross-reactive to usnic acid in lichens and mosses found on the wood. Cross-reactivity with common weeds such as ragweed (*Ambrosia* spp) or dandelion (*Taraxacum* spp) initiate the risk of hypersensitivity from members of the Compositae family.<sup>62</sup> A myriad of other types of plants are involved in producing occupational dermatitides.<sup>136</sup> Sensitivity to Compositae (daisy family) involves more than 600 sesquiterpene lactones in at least 200 of the 25,000 species in the family and is as ubiquitous as the distribution of species. *Chrysanthemum* allergy is a common occupational hazard in Europe.

Direct photosensitivity dermatitis is produced when compounds such as psoralens or other linear furcoumarins come into direct contact with the skin or are digested and become bloodborne to dermal capillary beds, where they interact with sunlight. These photosensitizing agents are activated by ultraviolet A radiation (320–400 nm), producing singlet oxygen and DNA adducts. In addition to severe sunburnlike symptoms (erythema, epidermal bullae), hyperpigmentation lasting for several months may result from exposure to these compounds. The mechanism by which this reaction is produced is unknown, but depletion of glutathione is postulated to indirectly stimulate melanogenesis by disinhibiting the normally suppressant tyrosinase.<sup>91</sup> More than 200 of these xenobiotics have been identified in at least 15 plant families, including food sources, such as Apiaceae (anise, caraway, carrot, celery, chervil, dill, fennel, parsley, and parsnip), Rutaceae (grapefruit, lemon, lime, bergamot, and orange), Solanaceae (potato), and Moraceae (figs) family.

Hepatogenous photosensitivity is produced when a xenobiotic that normally is harmlessly ingested, absorbed, and hepatically excreted gains access to the peripheral circulation through failure of a liver excretion or

detoxification mechanism. An example is the photosensitivity that occurs when phylloerythrin, a product of chlorophyll digestion normally eliminated in the bile, accumulates in the blood as a result of liver dysfunction. The cyanobacterium *Microcystis aeruginosa*, as well as the plants *Lantana camara*, *Tribulus terrestris*, and *Agave lechuguilla* reportedly cause this type of photosensitization in animals.

## SUMMARY

- Plant exposures are among the commonest human exposures but also typically have little morbidity and mortality.
- Plant xenobiotics can be organized by the principles of pharmacognosy (the study of drugs of natural origin).
- Many plants share mechanisms of toxicity with available pharmaceuticals, and many pharmaceuticals are derived from plants.
- Understanding the mechanism of the potential plant toxin exposure will assist in guiding management.
- Confusion among lookalike plants, soundalike common names, and shared clinical findings among different plant species complicates management.
- Some reassurance can be achieved by excluding exposure to the most life-threatening plants.

## NATIVE (US) VENOMOUS SNAKES AND LIZARDS

Anne-Michelle Ruha and Anthony F. Pizon

### EPIDEMIOLOGY

#### Snakes

More than 3,000 species of snakes are identified worldwide, with nearly 800 species considered venomous. All venomous species are classified taxonomically into one of 4 general groups. These include the families Viperidae, Elapidae, and Colubridae, as well as the Atractaspidinae, a subfamily of the Lamprophiidae family. The United States is home to nearly 30 species and subspecies of venomous snakes (Table 119–1), with many more found throughout Mexico. All belong to either the Crotalinae subfamily of Viperidae or the Elapidae family.

Venomous snakes possess glands that are associated with specialized teeth, or fangs, which allow delivery of venom for the purpose of prey immobilization or defense. Fangs are located in the front of the mouth in most venomous species. In addition to fangs, venomous snakes have rows of small teeth that may cause additional injury during a bite.

The majority of snake species in North America are rear-fanged, non-venomous members of the Colubridae family. Bites by these species, which include corn snakes, gopher snakes, and garter snakes, are usually harmless. Colubrids do not possess venom glands, but some produce secretions from Duvernoy’s glands that contain toxins similar to those found in the venom of venomous species. Although the vast majority of bites by nonvenomous colubrids do not produce symptoms, rare cases of envenomation are documented following a bite by a nonvenomous species.<sup>62</sup>

Venomous snakes are found throughout most of the United States. They are much more common in the southern and western states than in the northern states. Though venomous species are not endemic to Maine, Alaska, or Hawaii, bites are reported in every state except for Hawaii. The true number of bites that occur each year is not accurately known, but an average of 5,000 native venomous snakebites are reported to US poison control centers annually.<sup>49</sup> Mortality is rare in the United States, with fewer than 10 deaths per year reported. Epidemiologic data on snakebites in Mexico is poor, but the number of bites and deaths is thought to be higher. Internationally, snakebites are an important and common cause of morbidity and mortality (Special Considerations: SC10).

The majority of snakebites in the United States occur between April and September, with the peak number reported in July. Men comprise 75% of snakebite victims and children represent about 10% to 15% of reported cases.<sup>49</sup> Most victims are bitten on an extremity, although bites to the torso, face, and tongue also occur. Bites often occur when an individual is purposely handling a known venomous snake. Herpetologists, those who capture and keep wild snakes, and religious snake handlers are at highest risk. Occasionally people are envenomed after killing and decapitating a rattlesnake. This is likely due to persistent reflexes in the venom apparatus.

Snake handlers and collectors are at risk for multiple bites during their lifetime. There is no convincing evidence that immunity develops as a result of repeated envenomation. Victims of repeat bites actually have a greater risk for anaphylaxis because of prior sensitization and the development of IgE antibodies to venom.<sup>45</sup>

Snake enthusiasts often keep nonnative (exotic) species as pets. Approximately 30 to 50 bites from a large variety of exotic venomous snakes are reported to poison control centers each year.<sup>51</sup>

**TABLE 119–1 Medically Important Snakes of the United States**

Genus	Species	Common Name
<b>Crotalinae</b>		
<i>Crotalus</i>	<i>adamanteus</i>	Eastern diamondback rattlesnake
	<i>atrox</i>	Western diamondback rattlesnake
	<i>cerastes</i>	Sidewinder <sup>a</sup>

<b>Elapidae</b>		
<i>Micrurus</i>	<i>fulvius</i>	Eastern coral snake
	<i>tener</i>	Texas coral snake <sup>a</sup>

<sup>a</sup>Subspecies identified for this species.

#### Pit Vipers

The majority of native venomous snakes are members of the Crotalinae subfamily of Viperidae. These crotaline species are variably referred to as crotalids, New World vipers, or pit vipers. The term “pit viper” describes the presence of a pitlike depression behind the nostril that contains a heat-sensing organ used to locate prey. Native pit vipers include the rattlesnakes (genera *Crotalus* and *Sistrurus*) and the cottonmouths and copperheads (genus *Agkistrodon*). These pit vipers can be distinguished from native nonvenomous species by a triangular-shaped head, vertically elliptical pupils, and easily identifiable fangs (Fig. 119–1). Crotalinae have front, mobile fangs that are paired, needlelike structures that can retract on a hingelike mechanism into the roof of the mouth. Rattlesnakes have the longest fangs, reaching 3 to 4 cm. Pit vipers are also identifiable by their scale patterns. Their undersurface has a single row of plates or scales, as opposed to the double row found on nonvenomous species. Rattlesnakes may or may not have rattles, depending on maturity. A rattling sound is often, but not always, heard before a strike. Copperheads and cottonmouths do not have rattles, but shake their tails similarly to rattlesnakes. Cottonmouths, which are also commonly known as water moccasins, are semiaquatic and have a distinct white mouth. Copperheads are known for their reddish-brown (copper) heads and dark hourglass-shaped bands contrasting with a lighter background on their bodies (Fig. 119–2).

Of crotalid bites for which the type of snake is reported, about half are rattlesnake species, and the remainder copperheads and cottonmouths. Rattlesnakes are found throughout most of the United States, but encounters are most common in western and southern states. Rattlesnakes account for the greatest morbidity among the various types of pit vipers. Deaths

**FIGURE 119-1.** Pit vipers have a triangular-shaped head, vertically elliptical pupils, and heat-sensing pits behind the nostril.

following snakebite are almost always due to rattlesnakes, although rare deaths are reported from copperhead bites.<sup>41</sup> Copperhead bites are most often reported in the eastern and southeastern United States, although they also occur in the northeast. Cottonmouths are found mainly in the southeastern United States.

### Coral Snakes

Coral snakes (genera *Micrurus* and *Micruroides*) represent the Elapidae family in North America. These brightly colored snakes typically have easily identifiable red, yellow, and black bands along the length of their bodies. In the United States, coral snakes and the similarly colored nonvenomous scarlet king snake are often confused. Coral and king snakes can be distinguished by their color patterns. Whereas coral snakes have black snouts, king snakes have red snouts. Both species have red, yellow, and black rings, but in different sequences: the red and yellow rings touch in the coral snake but are separated by black rings in king snakes (“Red on yellow kills a fellow; red on black, venom lack”) (Fig. 119-3). This general rule for identifying coral snakes does not apply to Mexican species, some of which have different color patterns.

Elapids possess front-fixed fangs. The fangs of coral snakes are small, and discrete fang marks may not be obvious after envenomation. Coral snakes often latch on to a victim or “chew” for a few seconds in an attempt to deliver venom. A history of this activity may help identify a coral snakebite when the offending reptile cannot be located.

**FIGURE 119-2.** Copperhead (*Agkistrodon contortrix*). (Used with the permission from Michelle Ruha, MD.)

**FIGURE 119-3.** Coral snake with characteristic black snout and red bands bordered by yellow bands. (Used with permission from Banner Good Samaritan Medical Center Department of Medical Toxicology.)

Coral snakes are responsible for approximately 2% of bites reported to US poison control centers.<sup>49</sup> *Micrurus* species are found in 11 southeastern states, where up to 100 bites are reported per year. *Micrurus fulvius* (the Eastern coral snake) is responsible for the greatest morbidity and mortality, whereas *M. tener* (the Texas coral snake) seems to be less dangerous. The Sonoran coral snake (*Micruroides euryxanthus*) does not produce envenomation necessitating medical intervention.<sup>61</sup>

### Lizards

There are 2 species of lizard that are known to produce envenomation in humans. These are the Gila monster (*Heloderma suspectum*) (Fig. 119-4), which is native to the desert southwestern United States, and the beaded lizard (*H. horridum*), which is found in Mexico. Both species are members of the Helodermatidae family. Bites by the Gila monster and beaded lizard are extremely uncommon, even in areas where the lizards are endemic. These lizards are slow moving, nocturnal, and thick bodied. Adults reach a maximum length of 60 cm and are generally shy, so bites are relatively rare and usually occur as a result of handling. Bites almost always occur from captive animals, whether found in the wild or kept in a zoo or personal collection. Gila monsters are known for their forceful bites. They can hang on and “chew” for as long as 15 minutes, and they may be difficult to disengage. The great majority of reported cases have involved adult men.

The helodermatid lizards have a less effective venom delivery system than venomous snake species. The lizards possess paired venom glands that are located on either side of the anterior lower mandible. Venom ducts carry the venom from the glands to the base of grooved teeth. When a tooth produces a puncture wound, the venom travels by capillary action into the grooves and then into the wound.<sup>47</sup>

## PHARMACOLOGY

### Snakes

Snake venom is a complex mixture of proteins, peptides, lipids, carbohydrates, and metal ions. Venom contains a variety of enzymes including phospholipases A<sub>2</sub> (PLA<sub>2</sub>s), metalloproteinases (SVMPs), serine proteases, acetylcholinesterases, L-amino acid oxidases, and hyaluronidases. Nonenzymatic proteins include 3-finger toxins (3FTXs), sarafotoxins, disintegrins, and C-type lectins among others. The content and potency of venom in any

A

B

**FIGURE 119-4.** (A) Young Gila monster (*Heloderma suspectum*). (Used with the permission from Steven Curry, MD.) (B) Beaded lizard (*Heloderma horridum*). (Used with the permission from Michelle Ruha, MD.)

given snake varies depending on age, diet, and geography. Thus, an adult snake may have significantly different venom composition than a young snake of the same species.<sup>59</sup>

Snakes typically produce about 100 to 200 mg dry venom in a single milking, although some produce several hundred mg to over 1 g.<sup>59</sup> Many venom components are pharmacologically active and target receptors, ion channels, enzymes, or other proteins in mammals. The actions of only a fraction of snake venom components are fully understood. Identification of individual snake venom toxins, understanding of pharmacologic mechanisms, and potential medicinal uses for venom are areas of ongoing research.

### Lizards

Helodermatid venom contains a complex mixture of components similar to those of snake venoms, including numerous enzymes such as hyaluronidase, phospholipase A<sub>2</sub>, and serotonin.<sup>47,57</sup> Nonenzymatic components include helospectins and helodermin, which are vasoactive peptides that activate adenylate cyclase, and exendin-3 and exendin-4, which stimulate glucose-dependent insulin secretion. Discovery of exendins in *Heloderma* venom lead to development of exenatide (Byetta), a glucagonlike peptide-1 (GLP-1) receptor agonist used in the management of diabetes.<sup>25,57</sup> Another important component of *Heloderma* venom is gilatoxin. Gilatoxin is a serine protease with kallikreinlike activity, thought to be responsible for the hypotension and angioedema that occur in some human envenomations.<sup>57</sup>

## PHARMACOKINETICS AND TOXICOKINETICS

### Snakes

Very few pharmacokinetic studies of snake venom exist, and much remains unknown regarding absorption, distribution, and elimination of venom following a bite. When a snake bites, venom is usually deposited subcutaneously. In some cases fangs reach muscle or even directly access vasculature. Systemic absorption of venom usually occurs via the lymphatic system. Available human and animal data suggest that venom antigens are absorbed into blood within minutes of envenomation, with peak concentrations detected within 4 hours.<sup>10,31,50</sup> Venom antigen concentrations measured in the first 4 hours following a bite correlate roughly with grade of envenomation.<sup>3,9,31</sup> Venom antigens are also detected in urine as early as 30 minutes after envenomation.<sup>31</sup> After administration of adequate doses of antivenom, venom antigens are no longer detected in blood; however, antigenemia may recur, and such recurrence is associated with reemergence of clinical effects.<sup>31,50</sup>

The elimination half-life of snake venom appears to be long. Following subcutaneous injection of *C. atrox* venom in a rabbit model, mean half-life was 20 hours, and venom was still detectable in blood at 96 hours.<sup>10</sup>

### Lizards

Pharmacokinetic studies of helodermatid venom are not available. Clinical reports suggest that venom is absorbed systemically within minutes of a bite.

## PATHOPHYSIOLOGY

### Snakes

#### Pit Vipers

Crotaline venom has the potential to simultaneously damage tissue, affect blood vessels and blood, and alter transmission at the neuromuscular junction. It is difficult to attribute specific pathology or pathophysiology to any particular component of snake venom. In fact, clinical effects often occur as the result of several venom components (Table 119-2). For instance, local tissue damage results from venom metalloproteinases and hyaluronidase, which both contribute to swelling through disruption of the extracellular matrix and basement membrane surrounding microvascular endothelial cells.<sup>29</sup> As a result of reduced blood flow through damaged capillaries, they also contribute to myonecrosis, which results primarily from the action of phospholipase A<sub>2</sub> enzymes (PLA<sub>2</sub>) on muscle.<sup>29</sup> Additionally, venom metalloproteinases contribute to dermatonecrosis, both directly and through activation of endogenous inflammatory mediators.<sup>29,55</sup>

Venom effects on the hematologic system are especially complex. Numerous components act as anticoagulants, and many others act as procoagulants. Similarly, platelets are inhibited, activated, agglutinated, aggregated,

**TABLE 119-2** Major Venom Components of Crotalinae Snakes

General Clinical Effect	Responsible Venom Components
Local tissue damage	Metalloproteinases Phospholipases A <sub>2</sub> Hyaluronidase
Coagulation effects <sup>a</sup>	C-type lectinlike proteins Metalloproteinases <sup>b</sup> Serine proteases <sup>b</sup> Phospholipases A <sub>2</sub>
Platelet effects <sup>c</sup>	Disintegrins C-type lectinlike proteins Metalloproteinases Phospholipases A <sub>2</sub>
Neurotoxic effects	Phospholipases A <sub>2</sub>

<sup>a</sup>Venom contains both pro- and anticoagulants, with anticoagulant effects predominating in North American crotaline envenomation. <sup>b</sup>Include thrombinlike enzymes as well as fibrinolytic enzymes. <sup>c</sup>Venom may contain factors that inhibit, activate, or affect aggregation of platelets.

or inhibited from aggregating by various venom components. Venom components can be grouped according to certain characteristics, such as structure and enzymatic activity, but as noted above with local tissue damage, components within several groups may contribute to similar effects. For instance, anticoagulants in snake venoms are found among the C-type lectinlike proteins (CLPs), PLA<sub>2</sub> enzymes, serine proteases, and metalloproteinases. Conversely, components within a single group may have many different actions. Various CLPs in venom act as anticoagulants, procoagulants, or platelet modulators. PLA<sub>2</sub> enzymes are especially diverse, acting as anticoagulants and platelet modulators in addition to producing myotoxic and neurotoxic effects. Platelet effects result mainly from the action of disintegrins, although CLPs, PLA<sub>2</sub> enzymes, and other proteinases also have platelet-modulating effects.<sup>40,65</sup>

Specific hematologic effects are species dependent, with no single venom containing all of the identified hemostatically active components. Of particular importance to North American rattlesnake envenomation are the thrombinlike enzymes and fibrinogenolytic enzymes. Thrombinlike enzymes are metalloproteinases and serine proteases that preferentially cleave fibrinopeptide A or fibrinopeptide B from fibrinogen. Unlike thrombin, they do not activate factor XIII. The end result is production of a poorly cross-linked fibrin clot that easily degrades. Multiple other venom components exist, some of which affect the vascular system and contribute to the hypotension that sometimes occurs clinically. Examples include bradykinin-potentiating peptides and vascular endothelial growth factors (Chaps. 20 and 58).<sup>53,65</sup>

Snake neurotoxins act at the neuromuscular junction and do not cross the blood–brain barrier. They are classified as  $\alpha$ -neurotoxins, which act postsynaptically, and  $\beta$ -neurotoxins, which act presynaptically. Certain populations of the Mojave rattlesnake, *C. scutulatus*, possess a neurotoxin, Mojave toxin, which is a PLA<sub>2</sub> that acts at the presynaptic terminal of the neuromuscular junction to inhibit acetylcholine release. The presence of Mojave toxin in venom appears to be geographically distributed, with Mojave rattlesnake populations in California and southeast Arizona possessing functional Mojave toxin, and central Arizona populations lacking the neurotoxin.<sup>28,64</sup> Mojave toxin is also identified in the venom of some Southern Pacific rattlesnakes (*C. oreganus helleri*) found in southern California, and envenomations by this species are reported to produce neurologic symptoms in some victims.<sup>14,24</sup>

### Coral Snakes

Coral snake venom contains neurotoxins that produce systemic neurotoxicity. Unlike crotaline venom, coral snake venom does not cause local tissue injury. Similar to neurotoxins present in other elapid species,  $\alpha$ -neurotoxins bind and competitively block postsynaptic acetylcholine receptors at the neuromuscular junction, leading to weakness and paralysis. Phospholipase A<sub>2</sub> can also cause myotoxicity, although this appears to be of less clinical importance. The LD<sub>50</sub> of *M. fulvius* venom (0.279 mg/kg) is lower than that of *M. tener* venom (0.779 mg/kg), which corresponds to the more severe effects noted in humans following Eastern coral snake envenomations.<sup>48</sup>

### Lizards

The pathophysiology of helodermatid venom is poorly understood. It is suggested that hyaluronidase contributes to spreading of venom throughout tissue.<sup>52</sup> Gilatoxin is believed to produce hypotension and other findings such as angioedema by increasing bradykinin levels.<sup>57</sup>

## CLINICAL MANIFESTATIONS

### Snakes

The clinical presentation of North American snake envenomation is highly variable and depends upon many factors, including the species of snake, the amount and potency of venom deposited, the location of the bite, and patient factors, such as comorbidities. It is important for the clinician to be familiar with endemic venomous snake species in order to anticipate clinical effects when presented with an envenomed patient. For bites by nonnative species, it is important to identify the species so that specific antivenom can be sought.

### Pit Vipers

Envenomation by North American pit vipers is characterized by local swelling and cytotoxic effects. Hematologic effects are common, and there is the potential for development of systemic illness and neurotoxicity. Most patients exhibit only a subset of possible effects of envenomation. In addition, some of the signs and symptoms in a given individual, such as nausea or tachycardia, may be related to fear rather than to envenomation.

The clinical presentation following a pit viper bite can range from benign to life threatening (Table 119–3). One finding common to nearly all victims

**TABLE 119–3** Evaluation and Treatment of Crotaline Envenomation

Extent of Envenomation	Clinical Observations	Antivenom Recommended <sup>a</sup>	Other Treatment	Disposition
None (“dry bite”)	Fang marks are present, but no local or systemic effects after 8–12 hours	No	Local wound care Tetanus prophylaxis	Discharge after 8–12 hours of observation
Minimal	Minor, nonprogressing, local swelling and discomfort without systemic effects or hematologic abnormalities	No	Local wound care Tetanus prophylaxis	Admit to monitored unit for 24-hour observation
Moderate	Progression of swelling beyond area of bite with or without local tissue destruction, hematologic abnormalities, or non–life-threatening systemic effects	Yes	Intravenous fluids Cardiac monitoring Analgesics Follow laboratory parameters Tetanus prophylaxis	Admit to intensive care unit
Severe	Marked progressive swelling, pain with or without local tissue destruction  Systemic effects such as diarrhea, weakness, shock, or angioedema, and/or pronounced thrombocytopenia or coagulopathy	Yes	Intravenous fluids Cardiac monitoring Analgesics Follow laboratory parameters Oxygen Vasopressors Tetanus prophylaxis	Admit to intensive care unit

<sup>a</sup>See Antidotes in Depth: A39 for dosing recommendations.

is the presence of an identifiable disruption of skin integrity. Most commonly, one or 2 distinct punctures are present, though occasionally, patients exhibit multiple punctures, small lacerations, or scratches.

Because pit viper bites result in injection of venom only about 75% of the time, approximately 25% of bites do not result in envenomation and are considered “dry bites.” Unfortunately, it is impossible to diagnose a dry bite without an extended period of observation, because some patients have delayed onset of findings for as much as 8 to 10 hours following the bite and some subsequently develop serious illness. Even patients who do present with symptoms require a number of hours for the full extent of clinical illness to become evident. As a general rule, however, it is assumed that envenomation from a pit viper has not occurred if no findings develop within 8 to 10 hours from the time of the bite.

Of the North American pit vipers, rattlesnakes are responsible for the most severe clinical presentations. *Agkistrodon* (cottonmouth and copperhead) bites generally tend to produce less severe local and systemic pathology than rattlesnake bites. Copperhead bites in particular rarely cause systemic effects, and pathology is usually limited to soft tissue swelling without necrosis.<sup>60</sup> However, serious copperhead envenomations occasionally occur, and at least one death is associated with a bite from this species.<sup>49</sup>

**Local reactions.** Generally, within minutes after pit viper envenomation, the area around the puncture site becomes swollen and painful, and oozing of blood from the wound may occur. Edema stabilizes quickly in mild envenomations, but more commonly, edema will gradually worsen over hours. In severe cases, edema progresses to involve an entire extremity within just a few hours. Swelling can worsen for days when untreated, extending proximally to involve the torso following bites to a distal extremity. Rarely, onset of appreciable swelling is delayed for as long as 10 hours. This is most often noted in lower extremity envenomations.

Ecchymosis may develop early at the wound site. Bites to the feet often exhibit a characteristic bluish tinge over the entire dorsal surface of the foot. Toes remain pink and well perfused, allowing distinction of this ecchymosis from cyanosis (Fig. 119-5). In the days to weeks following the envenomation, ecchymosis will often extend or new ecchymosis develops proximally, even in the absence of significant venom-induced hemotoxicity.

Erythema often develops at the envenomation site and sometimes spreads proximally from the wound along lymphatic pathways. Lymphangitic streaks are rare but may occur early after the envenomation in the absence of infection.

Hemorrhagic blisters (blebs or bullae) often form at the site of a rattlesnake bite. This most commonly occurs after bites to digits but in rare instances occurs at other bite locations or dependent areas distant from the bite (Fig. 119-6). Blebs usually do not appear for several hours after the envenomation but when they do develop they often progress for several days. The tissue underlying blebs is often healthy, but extensive bleb development may signify underlying tissue necrosis (Fig. 119-7).

Myonecrosis is not a feature of most native pit viper envenomations but does sometimes occur. In rare cases, fangs directly penetrate muscle leading to localized necrosis. With subfascial envenomation, there is a risk for compartment syndrome, which could lead to deep tissue necrosis. Compartment

**B**

**FIGURE 119-6.** (A) Hemorrhagic bullae involving the entire digit after rattlesnake bite to the second digit. (Used with the permission from Michelle Ruha, MD.) (B) Hemorrhagic bullae involving the antecubital fossa after rattlesnake bite to the hand. (Used with the permission from Michelle Ruha, MD.)

**FIGURE 119-7.** Debridement of hemorrhagic bullae revealed the underlying tissue to be dark and necrotic in this patient. (Used with the permission from Michelle Ruha, MD.)

syndrome is very rare following North American snakebite and cannot be reliably diagnosed in envenomed extremities without directly measuring compartment pressures. More often than not, envenomation simply mimics a compartment syndrome by producing distal paresthesias, tense superficial soft tissue swelling, pain on passive stretch of muscles within a compartment, and muscular weakness. One study using noninvasive vascular arterial studies and skin temperature determinations in patients with rattlesnake envenomation, demonstrated that pulsatile arterial blood flow to an envenomed extremity actually increased after envenomation, even distal to the site of envenomation.<sup>19</sup>

In addition to local myonecrosis, generalized severe rhabdomyolysis occurs in the absence of impressive muscular swelling following some pit viper envenomations. This finding is considered characteristic after envenomation by the Canebrake rattlesnake (*Crotalus horridus atricaudatus*), which was previously classified as a subspecies of the Timber rattlesnake (*C. horridus*). Current prevailing opinion is that they are the same species.<sup>16,56</sup>

**Hematologic toxicity.** Venom-induced effects on the hematologic system are common following bites by North American pit vipers, in particular rattlesnakes. In rare cases, coagulopathy, thrombocytopenia, or a combination of the 2, are present despite a paucity of other local or systemic effects. The onset, progression, and severity of thrombocytopenia and coagulopathy in patients who exhibit this effect is quite variable. Drops in platelets and fibrinogen are sometimes mild initially, yet continue to worsen for several days following the envenomation. Alternatively, severe decreases in platelet counts (in the 5,000–50,000/mm<sup>3</sup> range) and fibrinogen concentrations (to near zero) with immeasurably high prothrombin times (PTs) can occur within minutes to hours of crotaline envenomation. A rise in PT generally follows a drop in fibrinogen, as concentrations of clotting factors remain normal in victims of North American crotaline envenomation with coagulopathy.<sup>15</sup> The likelihood of thrombocytopenia or coagulopathy occurring after a given snakebite depends on the particular species and venom populations present in the geographic area. In the desert southwest, coagulopathy occurs in approximately half and thrombocytopenia in one-third of patients presenting with envenomation.<sup>46</sup> Thrombocytopenia appears to be especially common and often severe after the bite of the Timber rattlesnake (*Crotalus horridus*).<sup>4</sup> The protein crotalocytin that is found in Timber rattlesnake venom causes platelet aggregation and is thought to be at least partially responsible for the thrombocytopenia.

Despite the high rate of hematologic effects following rattlesnake envenomations, the vast majority of patients have no clinical bleeding, even when severe laboratory abnormalities are present. Bleeding appears to be more common when platelets are very low or when both coagulopathy and thrombocytopenia are present and severe.

**Systemic toxicity.** Clinical findings following most pit viper bites are limited to local tissue damage or hematologic pathology, but systemic symptoms occur. When present, systemic signs and symptoms are often mild and include nausea, metallic taste, restlessness, and nonspecific weakness. More concerning are tachycardia, vomiting, diarrhea, or confusion, which sometimes precede severe systemic toxicity. In the most severe cases, patients quickly develop circulatory shock or airway edema with obstruction, which is thought to be caused by anaphylactoid responses to venom components.

Rarely, patients bitten by crotalids experience classic anaphylaxis from the venom itself, which complicates evaluation or mimics a severe systemic reaction to venom. Previous sensitization to venom results in development of IgE antibodies to venom in these patients. This is thought to occur more frequently in patients who have previously experienced a snakebite, but is also observed in snake handlers who are thought to be sensitized to snake proteins through inhalation or skin contact. The presence of pruritus and urticaria or wheezing, uncommon with envenomation, should suggest anaphylaxis.

There are rare reports of true disseminated intravascular coagulation (DIC) with spontaneous bleeding along with significant hypotension and multiorgan system failure following rattlesnake bite. In such cases of true

DIC, the patient has evidence of organ infarction and hemolysis. This is reported after intravascular envenomation.<sup>20</sup>

**Neurotoxicity.** Although local tissue destruction dominates the picture of Crotalinae envenomations, neurotoxic effects sometimes occur. The Mojave rattlesnake (*C. scutulatus*) is best known for its neurotoxic venom. Some populations of the Mojave rattlesnake possess a neurotoxin, Mojave toxin, which can result in weakness, cranial nerve dysfunction, and respiratory paralysis in victims.<sup>33</sup> The Timber rattlesnake (*C. horridus*) is noted to commonly cause rippling fasciculations of the skin (myokymia), particularly of the facial muscles.<sup>6</sup> Fasciculations are reported following envenomation by several other species of rattlesnake, including the Western diamondback (*C. atrox*), Mojave (*C. scutulatus*), and the Southern Pacific (*C. o. helleri*).<sup>17</sup> Fasciculations involving the shoulders, chest wall, and torso are associated with development of respiratory failure.<sup>58</sup>

### Coral Snakes

Coral snake fangs are small and nonmobile, and as a result, bites are less likely than pit viper bites to lead to envenomation. An estimated 40% of patients bitten by a coral snake are subsequently determined to be envenomed, with rates for the Eastern coral snake species possibly higher.<sup>35</sup> The venom of the Eastern coral snake (*Micrurus fulvius*) and Texas coral snake (*M. tener*) are more potent than that of the Sonoran coral snake (*Micruroides euryoxanthus*). In fact, there are no reported cases of serious toxicity after the bite of the Sonoran coral snake, which is found primarily in Arizona and western New Mexico.

Coral snake fangs do not always produce easily identifiable puncture wounds. In addition to the absence of a discernable wound in some victims, coral snake envenomations are characterized by potentially serious neurotoxicity without impressive local symptoms. The effects of envenomation are characteristically delayed for a number of hours. One report described a patient who had an asymptomatic period of 13 hours followed by rapid development of paralysis severe enough to require ventilatory support.<sup>35</sup> Neurologic abnormalities reported with coral snake envenomation include paresthesias, slurred speech, ptosis, diplopia, dysphagia, stridor, muscle weakness, fasciculations, and paralysis. The major cause of death is respiratory failure secondary to neuromuscular weakness. Muscle weakness takes weeks to months to resolve completely. With respiratory support, however, paralysis is completely reversible. Pulmonary aspiration is a common sequela in the subacute phase.

### Lizards

The rate of envenomation following Gila monster bites is not known, but one case series reported 40% dry bites.<sup>47</sup> *Heloderma* species are known for hanging on to their victims when they bite. Multiple reports are documented where Gila monsters were attached to the victim for up to 15 minutes, and in some cases teeth have broken off in the wound.

Pain is immediate following a bite, and local soft tissue edema often develops within minutes. Swelling extends from the puncture site, though not as commonly or dramatically as occurs following pit viper envenomation. Helodermatid venom does not produce local tissue necrosis, but erythema at the wound site and extension of erythema to an entire extremity is well described. Lymphangitic streaking is also reported.<sup>23,32,52</sup>

Nausea, vomiting, and diaphoresis are reported following helodermatid envenomation. Patients are often tachycardic and hypotension is common. There are numerous reports of upper airway angioedema developing after bites by both Gila monsters and beaded lizards. There is a single report of a young man developing a myocardial infarction after a Gila monster envenomation.<sup>44</sup> This patient also exhibited a coagulopathy although Gila monster venom does not typically produce abnormalities in platelet counts or clotting factors. It is suggested that the coagulopathy occurred as a result of endothelial damage rather than direct effect of venom on the hematologic system.<sup>52</sup> Leukocytosis is common following Gila monster envenomation, with reported white blood cell counts as high as 48,000/mm<sup>3</sup>.<sup>44</sup>

## DIAGNOSTIC TESTING

### Snakes

Diagnosis of North American snake envenomation is based on a history of a snakebite and presence of clinical signs of envenomation. There are no available laboratory assays for detection of venom in a wound. Although it is possible to measure blood and urine venom antigen concentrations using enzyme-linked immunosorbent assay (ELISA), this is only available in research settings and is not useful for early diagnosis or clinical management of envenomation.

Platelet counts, fibrinogen concentrations, and PTs are useful in the diagnosis of pit viper envenomation if they are abnormal. However, normal results do not exclude envenomation because thrombocytopenia and coagulopathy do not develop in all patients with pit viper envenomation.

A validated severity score for the objective assessment of crotaline envenomation has been developed and can be useful in a research setting.<sup>21</sup> Its purpose is to assess the clinical condition of patients with snakebite, but it is not intended as a diagnostic tool. Caution should be used when applying this scale because envenomation is a dynamic process and severity can worsen or improve with time, limiting the utility of the score obtained at any given point in time.

### Lizards

The diagnosis of helodermatid envenomation is based on the history of a bite and presence of physical examination findings consistent with envenomation. There are no laboratory studies that are available to confirm or exclude the diagnosis, but a complete blood count may reveal leukocytosis.

## MANAGEMENT

### Snakes

When a patient with a snake bite presents for care, the initial objectives are to determine the presence or absence of envenomation, provide basic supportive therapy, treat the local and systemic effects of envenomation, and limit tissue loss or functional disability (Table 119-3). A combination of medical therapy (mainly supportive care and, often, antivenom) and in some cases conservative surgical treatment (mainly debridement of devitalized tissue), individualized for each patient, will provide the best results. In general, the more rapidly treatment is instituted, the shorter the period of disability.

### Pit Vipers

*Prehospital care.* No first aid measure or specific field treatment has been proven to positively affect outcome following a crotaline envenomation. Prehospital care should generally be limited to immobilization of the affected limb, placement of an intravenous catheter, treatment of life-threatening clinical findings, and rapid transport to a medical facility. If transport time is long and pain is severe, administration of analgesics is recommended. Patients who are volume depleted, vomiting, or experiencing systemic effects such as diarrhea should be given an intravenous fluid bolus. Hypotension that does not quickly respond to a fluid bolus should be treated with epinephrine, since early hypotension is most likely due to anaphylaxis, anaphylactoid reaction to venom, or venom-induced vasodilation. Epinephrine counteracts these effects through stimulation of  $\alpha$ -adrenergic receptors on vasculature as well as through inhibition of release of inflammatory mediators.

In the past, various methods were advocated to prevent systemic absorption of venom after snakebites. All of these methods are either ineffective, delay time to definitive care, or are potentially harmful. Such useless and potentially dangerous therapies include tourniquets, incision and suction, venom extractors, electrotherapy, and cryotherapy.<sup>1,12</sup>

Pressure immobilization bandages (PIBs), which are lymphatic-restricting bandages that are applied to the bitten extremity prior to immobilization with a splint, should not be used in patients with North American Crotalinae bites. A randomized, controlled study of pressure immobilization versus observation in a porcine model with intramuscular injection of *Crotalus atrox* venom showed markedly increased compartment pressures in the pressure immobilization group. All animals died in this study, but

the pressure immobilization group showed a prolonged time to death as compared to the control group. With local tissue necrosis being the major morbidity associated with pit viper envenomations in humans, not death, the authors concluded that PIB application cannot be recommended as a routine field procedure.<sup>11</sup> The American College of Medical Toxicology, along with 5 other international organizations, released a position statement recommending against use of PIB for North American Crotalinae bites.<sup>2</sup>

*Hospital care.* When a patient presents to the hospital with history of crotaline snakebite, it is important to first determine whether an envenomation has occurred. Although most patients do show early evidence of envenomation, absence of symptoms at presentation is not uncommon, and not all asymptomatic patients ultimately have “dry” bites. Patients who present with puncture wounds but without swelling or other evidence of envenomation must be observed for delayed onset of symptoms. An observation period of 8 hours for *Agkistrodon* bites and 12 hours for rattlesnake bites is recommended.<sup>38</sup> If no swelling develops, and laboratory study samples drawn at least 8 hours from the time of the bite remain normal and unchanged, the bite is likely “dry” and the patient is safe for discharge from medical care with instructions to return if new pain or swelling develops.

*Supportive.* The initial in-hospital assessment of North American crotaline envenomation should focus on airway, breathing, and circulation. Patients with evidence of angioedema or with bites to the face or tongue need to be observed closely for signs of airway compromise and intubated early, before swelling progresses to the point of airway obstruction. All patients, regardless of presenting symptoms, should have an intravenous catheter placed in an unaffected extremity and an IV fluid bolus is recommended. Patients presenting with cardiovascular collapse should receive large volumes of fluid. An epinephrine continuous infusion, starting at 0.1 mcg/kg/min and titrating as needed, is the authors’ vasopressor of choice for signs of shock following envenomation.

Immobilization of the affected extremity in a padded splint in near-full extension and elevation above the level of the heart to avoid dependent edema is recommended. Although there are no studies to determine the effect of limb elevation on outcome the authors find this helpful because it appears to decrease dependent edema, which contributes to increased pain and physical examination findings concerning for compartment syndrome. The authors maximally elevate affected upper extremities by applying stocking net around the limb and attaching the distal end to a raised IV pole.

Marking the leading edge of swelling with a pen or sequentially measuring extremity circumference will help to identify progression of edema. A baseline complete blood count, PT, and fibrinogen concentration should be obtained initially and repeated in 4 to 6 hours. Patients who are systemically ill should also have electrolytes, creatinine phosphokinase, creatinine, glucose, and urinalysis checked.

A comprehensive physical examination should be done, with emphasis on vital signs, cardiorespiratory and neurologic status, neurovascular status of the affected extremity, and evaluation for evidence of bleeding. Pain should be treated with opioid analgesics as needed, and tetanus prophylaxis should be addressed. The patient should be reassessed frequently with repeat physical examinations, specifically noting any progression of swelling. This is best accomplished by taking serial circumferential measurements of the involved extremity at multiple points proximal to the wound.

Prophylactic antibiotics should not be given, as studies show extremely low (0%–3%) rates of wound infections.<sup>39</sup> There is no indication for corticosteroids or antihistamines in the routine treatment of patients with snakebites, except for treatment of anaphylaxis.

*Antivenom.* Patients with dry bites or mild envenomations, such as those who present with only localized swelling that fails to progress, do not meet criteria for antivenom<sup>38</sup> (Table 119-3). Patients who present with progressive swelling, thrombocytopenia, coagulopathy, neurotoxicity, or significant systemic toxicity are candidates for antivenom therapy. Antivenom given in a timely manner can reverse coagulopathy and thrombocytopenia and halt progression of local swelling. Antivenom has also been shown to reduce

compartment pressure and limits venom-induced decreases in perfusion pressure, potentially preventing the need for fasciotomy.<sup>26,54</sup> There is no evidence, however, that antivenom can prevent or reverse the development of tissue necrosis, so patients should be informed of the risk of tissue loss. This is most commonly noted with rattlesnake bites to the fingers, which occasionally lead to amputation of the digit despite appropriate treatment with antivenom.

Until fall of 2018, the only available FDA-approved antivenom for North American pit viper envenomation is Crotalidae polyvalent immune Fab (CroFab, BTG). Crotalidae polyvalent immune Fab is an ovine-derived Fab fragment antivenom developed from commonly encountered North American pit vipers (*C. atrox*, *C. adamanteus*, *C. scutulatus*, *A. piscivorus*). Crotalidae polyvalent immune Fab is administered IV in an initial dose of 4 to 6 vials reconstituted in 0.9% sodium chloride solution. The recommended starting dose for patients who present with cardiovascular collapse or serious active bleeding is 8 to 12 vials.<sup>38</sup> The infusion is initiated at a slow rate for several minutes, and if no signs of an anaphylactoid reaction develop, increased to complete the infusion over one hour. The patient should be reassessed after completion of the infusion for evidence of continued swelling or worsening thrombocytopenia, and, if present, an additional 4- to 6-vial dose is infused. This process is repeated until control of symptoms is achieved. Fibrinogen and PT are sometimes slower to recover in response to antivenom. If these are the only findings that continue to be abnormal after antivenom, it is reasonable to repeat these studies in 4 hours to determine if redosing of antivenom is necessary. Control is generally considered cessation of progression of swelling and systemic symptoms in addition to improvement in coagulopathy and thrombocytopenia. After control is achieved, maintenance doses of antivenom are given as 2 vials every 6 hours for 3 doses (6 total additional vials after control). Although recommended in the package insert for Crotalidae polyvalent immune Fab, maintenance therapy is not routinely administered by all practitioners.<sup>7</sup> The authors recommend use of maintenance doses unless the patient can be observed closely in the hospital for 18 hours after control of the envenomation is achieved. During this observation period, additional antivenom is given as needed for local or hematologic recurrence.

An alternative antivenom for the treatment of North American rattlesnake envenomation was approved by the FDA in 2015 but is not expected to be available until the fall of 2018. This antivenom, Crotalidae equine immune F(ab')<sub>2</sub> (Anavip), is made using venoms of *Bothrops asper* and *Crotalus simus*. A randomized controlled trial comparing Crotalidae polyvalent immune Fab to Crotalidae equine immune F(ab')<sub>2</sub> found less late hematologic toxicity in patients who received Crotalidae equine immune F(ab')<sub>2</sub>.<sup>13</sup> This is likely due to the longer half-life of Fab<sub>2</sub> fragments as compared to Fab fragments. The initial dose of Crotalidae equine immune F(ab')<sub>2</sub> is 10 vials. After infusion, the patient should be reassessed for further progression of swelling, worsening hematologic toxicity, or continuation of other systemic venom effects, such as neurotoxicity. Additional 10 vial doses are administered until control of the envenomation is achieved. Following control, the patient should be observed for another 18 hours for signs of recurrent venom toxicity. If these occur, additional 4 vial doses of Anavip are given (Antidotes in Depth: A39).<sup>22</sup>

Antivenom administration in children follows the same guidelines as adults, with doses based on clinical presentation and laboratory findings rather than weight. Attention should be paid to total amount of fluid received, and if necessary, antivenom can be reconstituted in a smaller total volume of fluid. Generally, patients with severe snake envenomation have large fluid requirements, and pulmonary edema as a result of antivenom administration has not been reported.

Pregnant patients who meet criteria for treatment should also receive antivenom. Crotalidae polyvalent immune Fab (ovine) and Crotalidae equine immune F(ab')<sub>2</sub> are currently listed as pregnancy category C, but the former has been used safely during pregnancy.<sup>36</sup> Given the relative safety of these antivenoms and the potential for fetal demise after envenomation, a low threshold for treatment should be considered. Fetal and maternal monitoring should be carried out throughout the patient's care.<sup>37</sup>

**Surgery.** Surgery is not routinely indicated following snakebites. An extensive review of the literature failed to identify any evidence to support the use of fasciotomy in the treatment of snakebites.<sup>18</sup> There are reported cases of elevated compartment pressure after pit viper envenomation successfully managed without fasciotomy. When compartment syndrome is suspected, intracompartmental pressures should be measured. It is reasonable to attempt to treat moderately elevated compartment pressures with antivenom initially, but clinical examination and compartment pressures should be followed closely. If compartment pressures are rising despite administration of antivenom or if the patient develops evidence of limb ischemia, fasciotomy is recommended.

Patients with bites to the digit sometimes present with evidence of ischemia. The compromised finger appears cyanotic or pale, tense, and lacks sensation. The small diameter of the digit and limited ability of the skin to expand essentially creates a small compartment. In such cases it is recommended to perform a digital dermatomy, where a longitudinal incision is made through the skin on the medial or lateral aspect of the digit in order to decompress the neurovascular structures. Dermotomy should not be performed prophylactically in cases of digital envenomation, as most patients have good outcome without any surgical intervention.<sup>30</sup>

Debridement of hemorrhagic blebs and blisters is often performed to evaluate underlying tissue and relieve discomfort. Some patients require surgical debridement of necrotic tissue or even amputation of a digit 1 to 2 weeks after the bite. Referral to a hand surgeon is appropriate for patients with evidence of extensive tissue necrosis.

**Blood Products.** Immeasurably low fibrinogen concentrations, PTs greater than 100 seconds, and platelet counts lower than 20,000/mm<sup>3</sup> are routinely encountered after rattlesnake envenomation. Such abnormal laboratory results alone should not prompt the clinician to treat with blood products in the absence of clinically significant bleeding. The circulating crotaline venom responsible for the thrombocytopenia and coagulopathy is still present and will likely inactivate any transfused components. For this reason, the mainstay of treatment for crotaline envenomation-induced hematopathology is antivenom, not blood products. Correction of coagulopathy, thrombocytopenia, and bleeding is usually achieved with antivenom alone. Rarely, a patient will have clinically significant bleeding, and antivenom alone will not correct the platelets and fibrinogen. In such cases, fresh-frozen plasma, cryoprecipitate, packed red blood cells, or platelet transfusions are recommended to replace losses.

In some cases, thrombocytopenia is difficult, or impossible, to correct with even large amounts of antivenom. The Timber rattlesnake, for example, is known for producing thrombocytopenia resistant to antivenom. The initial correction of platelet counts after treatment is typically transient (lasting only 12–24 hours), with thrombocytopenia sometimes persisting for days to weeks after normalization of other coagulation parameters. In the absence of bleeding, thrombocytopenia is a benign, self-limiting disorder, resolving within 2 to 3 weeks of envenomation. It is best to closely follow patients with resistant thrombocytopenia who are not bleeding, rather than attempt further platelet transfusions or antivenom administration.<sup>42</sup>

**Follow-up care.** Hospital stays for patients with uncomplicated pit viper envenomations are typically short, lasting approximately 1 to 2 days.<sup>46</sup> Upon discharge from the hospital, patients often have residual swelling and functional disability. Some will have continued progression of hemorrhagic bullae with underlying necrosis. Patients should have an out-patient follow-up evaluation to ensure wounds are healing appropriately and extremity function is returning. If joint mobility does not return to baseline as swelling resolves, the patient should be referred for physical and occupational therapy.

In a significant proportion of rattlesnake bite patients treated with Crotalidae polyvalent immune Fab antivenom, a return of swelling, coagulopathy, or thrombocytopenia is noted days to weeks after initial resolution with effective antivenom treatment. This is termed “recurrence” of venom effect and is attributed to the interrelated kinetics and dynamics of venom and antivenom.<sup>5,46</sup> Simply stated, Fab antivenom has a clinical half-life shorter than that of venom. Administration of maintenance doses of antivenom is

used in an attempt to prevent development of recurrent effects. Maintenance doses appear to be effective in preventing recurrence of local swelling in most cases, but many patients develop hematologic recurrence within 3 to 7 days of antivenom treatment despite administration of maintenance doses. Additionally, some patients who never manifested thrombocytopenia or coagulopathy during their hospital presentation later develop the effect, presumably because of initial “masking” of the effect by early antivenom administration. These recurrent or late hematologic effects have been associated with life-threatening bleeding.<sup>34</sup> No risk factors have been identified to predict which patients will develop late thrombocytopenia or coagulopathy.

The most reasonable way to address possible late hematologic effects of crotaline envenomation is careful outpatient follow-up after hospital discharge. Provide careful discharge instructions and consider all patients who have been treated with Crotalidae polyvalent immune Fab antivenom to be at risk for late hematologic toxicity. Patients who use antiplatelet or anticoagulant medications should be continued on these medications only after a careful risk–benefit analysis. Whenever possible the medications should be discontinued until the risk of recurrent or late hematologic toxicity passes. Patients must be warned not to undergo dental or surgical procedures for up to 3 weeks unless platelet and coagulation studies are documented to be normal immediately prior to the procedure. High-risk activities, such as contact sports, should be avoided. All patients with rattlesnake bites should have platelets and coagulation studies measured 2 to 3 days, and again 5 to 7 days, after the last antivenom treatment. If values are abnormal or trending in the wrong direction, the studies should be repeated every few days until normal and stable. Because copperhead envenomation is much less likely to produce severe hemotoxicity, one set of follow-up laboratory studies to screen for late thrombocytopenia or coagulopathy is reasonable in this population. Patients should be advised to avoid surgical procedures and activities that place them at risk for injury. Opinions on when to retreat patients exhibiting late hematologic toxicity with antivenom vary. The general approach of the authors is to retreat any patient with evidence of bleeding, as well as patients with severe isolated thrombocytopenia (platelets  $<25,000/\text{mm}^3$ ) or moderate thrombocytopenia (platelets  $25,000\text{--}50,000/\text{mm}^3$ ) in combination with severe coagulopathy (fibrinogen  $<80\text{ mg/dL}$ ).<sup>46</sup> Many clinicians choose to observe patients with isolated coagulopathy cautiously as outpatients rather than to retreat them with antivenom. However, if patients with isolated severe coagulopathy have other risk factors for bleeding, such as use of antiplatelet medications, high risk of injury, recent venom-induced shock, or pregnancy, retreatment with antivenom is recommended.

When the decision is made to retreat a patient with late hemotoxicity with antivenom, an initial starting dose of 2 vials is recommended. Late thrombocytopenia appears to be more resistant to antivenom than early venom-induced thrombocytopenia, and it is unclear whether a different mechanism is responsible for the late effect. It is unknown how much antivenom is needed to reverse late thrombocytopenia or at what dose a patient is considered “resistant” to antivenom. Based on anecdotal experience, if platelet counts do not increase after 2 to 3 doses of antivenom, additional antivenom is unlikely to be effective. Response to platelet transfusions is also often poor. Some clinicians give steroids to patients who have not responded to antivenom and platelet transfusions, but there is no evidence to support this treatment, which has not been studied.

### Coral Snakes

As with North American pit viper bites, patients who are bitten by North American coral snakes should be taken to a hospital for definitive medical care as soon as possible. There are no field treatments that have been shown to affect outcome in these patients, although use of PIBs is reasonable if transport to a hospital will be prolonged or delayed. Unlike with crotalid bites, worsening of local tissue injury as a result of PIBs is not a concern with coral snakebite. Pressure immobilization bandages delay the systemic absorption of venom from Australian elapid snakes, and a swine model of coral snake envenomation supports a similar effect.<sup>27</sup> Patients who present for care after a PIB has been placed should have the dressing left in place

until resuscitative equipment and personnel are present and, ideally, antivenom is available. The PIB should be checked to ensure it is not functioning as a tourniquet.

Patients with a history concerning for possible Eastern or Texas coral snakebite should be observed for 24 hours in a monitored unit where resuscitative measures, including endotracheal intubation, can be performed. Because neuromuscular weakness and respiratory paralysis can develop quickly, endotracheal intubation is reasonable at the first sign of bulbar paralysis. In the past, treatment with Wyeth Antivenin (*Micrurus fulvius*) (equine origin) North American Coral Snake Antivenin was recommended for all patients in whom there is strong suspicion of coral snakebite, even in the absence of signs of envenomation. This is mainly because paralysis can develop quickly and symptoms may not reverse following antivenom treatment. However, a study comparing patients who received empiric treatment with antivenom to patients who were treated when symptoms developed suggests that a conservative approach (waiting for symptoms to develop before administering antivenom) does not result in worse outcomes for patients.<sup>63</sup> North American Coral Snake Antivenom (Equine) is now available from Pfizer, and administration to asymptomatic patients is listed as a contraindication in the package insert.<sup>43</sup>

If a patient is symptomatic following a coral snake envenomation, antivenom, if available, is indicated. If antivenom is unavailable, supportive care including mechanical ventilation may be necessary for many weeks. Acetylcholinesterase inhibitors have been inconsistently successful in treating patients with South American coral snakebites.<sup>8</sup> If availability of coral snake antivenom is delayed, a trial of neostigmine to reverse the neurotoxic effects of venom is reasonable.

Sonoran coral snakes, indigenous to Arizona and California, have never been reported to cause significant toxicity, and bite victims do not require observation in the hospital or antivenom administration.

### Lizards

Management of helodermatid envenomation consists of supportive care. There is no antivenom available against lizard venom. Routine wound care should be performed, and the clinician should look for the presence of teeth in the wound. There is no evidence to guide clinicians when deciding whether to administer antibiotics to patients with erythema surrounding and extending from the bite site. Most case reports describing patients with erythema also report empiric use of antibiotics. There are no reports of confirmed infections following these bites.

Patients who are symptomatic following a bite should be attached to a cardiac monitor and have an intravenous catheter placed. Although serious morbidity from lizard bites is unusual, life-threatening manifestations of envenomation are reported. Angioedema, other evidence of respiratory compromise, or airway obstruction should prompt endotracheal intubation. Hypotension should be treated with intravenous fluid boluses as well as vasopressors such as epinephrine. Epinephrine, corticosteroids, and antihistamines are recommended for the treatment of anaphylactoid reactions.

### SUMMARY

- Most native snake envenomations result from bites by Crotalinae species of snakes, also known as pit vipers, and commonly produce local tissue swelling and hematologic toxicity.
- A small percentage of envenomations are due to bites by coral snakes, which are known for producing neurotoxicity without local tissue effects.
- Management of patients with pit viper and coral snake envenomation should focus on aggressive supportive care and specific antivenom when indicated.
- Envenomations by Helodermatid lizards are often associated with local pain, erythema, hypotension, and angioedema.
- Clinicians are encouraged to contact a regional poison control center when a patient presents after a snake or lizard envenomation.

# ANTIVENOM FOR NORTH AMERICAN VENOMOUS SNAKES (CROTALINE AND ELAPID)

Anthony F. Pizon and Anne-Michelle Ruha

## INTRODUCTION

In addition to supportive care, antivenom provides definitive management of North American venomous snakebites. In the past, numerous treatments were advocated to prevent systemic absorption or to neutralize venom. These therapies included tourniquets, incision and suction, venom extractors, electrotherapy, and cryotherapy. All of these treatment modalities are either ineffective, delay time to definitive care, or harmful. The focus of treatment for the snakebite victim is a careful assessment, supportive care, evaluating for signs of envenomation, and ultimately, determining the need for antivenom.

## HISTORY

### Crotalidae Polyvalent Immune Fab (Ovine)

Historically, Wyeth (Marietta, PA) manufactured Antivenin Crotalidae Polyvalent (ACP) for treatment of crotaline snakebites in the United States. It was a poorly purified whole IgG product derived from horse serum with significant risk for acute and delayed allergic reactions.<sup>18</sup> Wyeth stopped production of ACP, and any extant lots expired. Many physicians still recall the use of this product, but new antivenoms have replaced ACP, improving the approach to snakebite treatment. In October 2000, the US Food and Drug Administration (FDA) approved Crotalidae polyvalent immune Fab (Fab antivenom), manufactured by BTG International, marketed as CroFab. This antivenom is derived from sheep serum and formulated as an effective treatment for US Crotalinae species. In addition, because of papain digestion and the affinity purification, which removes extraneous proteins as well as the Fc portion of the antibody, Fab antivenom is a less allergenic alternative to the previously manufactured horse serum product from Wyeth (Table A39–1).<sup>18,37</sup>

### Crotalidae Immune F(ab')<sub>2</sub> (Equine)

Equine-derived Crotalidae immune F(ab')<sub>2</sub> (Anavip; F(ab')<sub>2</sub> antivenom) manufactured by Instituto Bioclon, was recently approved by the FDA as an alternative treatment for North American Crotalidae, but its widespread availability is not expected until the fall of 2018. The historical experience with Fab antivenom has revealed the unexpected problem of recurrent

venom effects that occur hours to days after completing treatment. Unlike the Fab antivenom, this F(ab')<sub>2</sub> product uses pepsin digestion, which keeps the Fab fragments joined to form a larger antibody complex and, as such, is expected to prolong the duration of action. Therefore, the benefits to this new F(ab')<sub>2</sub> antivenom appear to suggest a longer half-life and less recurrent venom effects than the Fab antivenom (Fig. A39–1).<sup>6</sup>

### North American Coral Snake Antivenin (Equine)

For decades, Wyeth Laboratories manufactured Antivenin (*Micrurus fulvius*) (Equine), which is more commonly known as North American Coral Snake Antivenin (NACSA), for treatment of envenomations by the eastern coral snake (*Micrurus fulvius*) and Texas coral snake (*Micrurus tener*). Although Wyeth temporarily discontinued production of this antivenom, Pfizer has since acquired Wyeth and began manufacturing this antivenom again. At the time of this writing, Pfizer will only provide the antivenom on an “as needed basis.”

## PHARMACOLOGY

### Mechanism of Action

In general, the mechanism of action of antivenoms remains the same regardless of the preparation (Fab, F(ab)<sub>2</sub>, or whole IgG). The antibody fragments bind and neutralize venom components. The smaller antibody fragments penetrate tissues and help redistribute the venom from its target tissue.

### Crotalidae Polyvalent Immune Fab (Ovine)

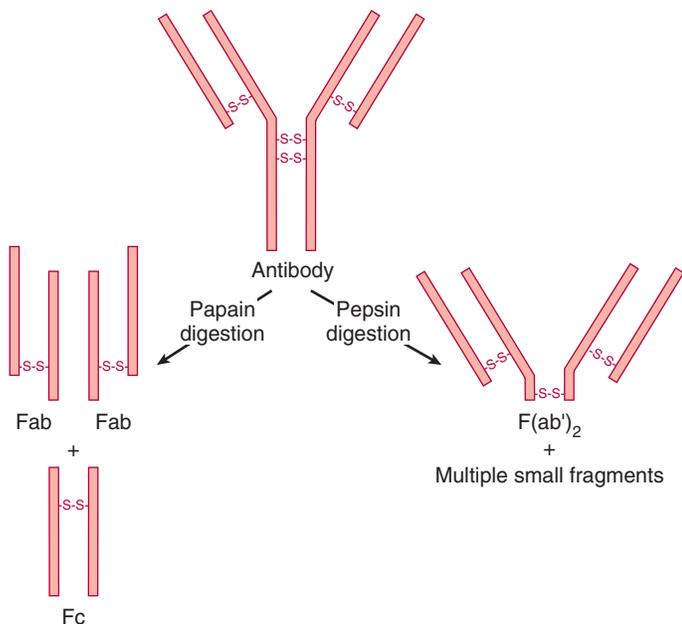

#### Chemistry/Preparation

Crotalidae polyvalent immune Fab (Fab antivenom) is produced by inoculating sheep with the venom of one of the following crotaline snake species: the Eastern diamondback rattlesnake (*Crotalus adamanteus*), Western diamondback rattlesnake (*Crotalus atrox*), cottonmouth (*Agkistrodon piscivorus*), and Mojave rattlesnake (*Crotalus scutulatus*). The species-specific antivenom is then prepared by isolating the antibodies from the sheep serum and digesting the IgG antibodies with papain. The venom-specific Fab antibody fragments are then isolated by affinity purification. This refining process eliminates most of the Fc portion of the immunoglobulin and

TABLE A39–1 Comparison of Crotalid and Elapid Antivenoms

Antivenom	Snake Species Used in Production	Digestion	Origin	Recommended Dosing <sup>a</sup>
Crotalidae Polyvalent Immune Fab (CroFab)	<i>Crotalus atrox</i> <i>C. adamanteus</i> <i>C. scutulatus</i> <i>Agkistrodon piscivorus</i>	Papain	Ovine	4–6 vials repeated as needed to achieve control; then 2 vials every 6 h × 3 doses
Crotalidae Immune F(ab') <sub>2</sub> (Anavip)	<i>Bothrops asper</i> <i>Crotalus durissus</i>	Pepsin	Equine	10 vials repeated as needed to achieve control
North American Coral Snake Antivenin	<i>Micrurus fulvius</i>	None	Equine	3–5 vials repeated as needed for clinical improvement

<sup>a</sup>As recommended by respective package inserts.

**FIGURE A39-1.** Antibody fragments produced from various digestion treatments during the production of antivenoms.

other potentially immunogenic sheep proteins. Manufacturing specifications require less than or equal to 1% w/w for Fc fragments and less than or equal to 0.3% w/w for albumin.<sup>16</sup> All 4 species-specific antivenoms are then combined to form the final polyvalent product. The resultant Fab antivenom is less immunogenic and more potent compared to whole IgG antivenoms used previously.<sup>9,14</sup>

### Pharmacokinetics

The pharmacokinetics of Fab antivenom is poorly studied. Elimination half-life calculations were performed using only 3 patients' samples. From these data, the half-life was estimated between 12 and 23 hours.<sup>10</sup> Although a similarly prepared and sized ovine Fab product yielded a volume of distribution of 0.3 L/kg, a clearance of 32 mL/min, and an elimination half-life of approximately 15 hours, these parameters are not necessarily applicable to Fab antivenom.<sup>40</sup>

### Crotalidae Immune F(ab')<sub>2</sub> (Equine)

#### Chemistry/Preparation

Crotalidae immune F(ab')<sub>2</sub> (F(ab')<sub>2</sub> antivenom) is manufactured by immunizing horses with the venom of the fer-de-lance (*Bothrops asper*) and the Central American rattlesnake (*Crotalus durissus*). The horse serum is then prepared by pepsin digestion to remove the Fc portion of the antibody creating an F(ab')<sub>2</sub> product. As opposed to the papain digestion to make individual Fab fragments for Fab antivenom, pepsin digestion cleaves the antibody so that Fab fragments remain attached in a V configuration, hence the designation F(ab')<sub>2</sub>. The venom-specific antibody fragments are then isolated by nanofiltration and ammonium sulfate precipitation. Each vial contains approximately 120 mg of protein and will neutralize 780 times the LD<sub>50</sub> of *B. asper* venom and 790 times the LD<sub>50</sub> of *C. durissus* venom in a mouse assay.<sup>1</sup>

### Pharmacokinetics

The pharmacokinetics of F(ab')<sub>2</sub> antivenom provides much longer duration of action than its Fab counterpart. Elimination half-life calculations performed on 13 healthy volunteers provided a mean half-life of 133 hours.<sup>1</sup> Moreover, the F(ab')<sub>2</sub> antivenoms have a similar volume of distribution of 0.2 L/kg, but a much slower clearance of 1.6 mL/min than Fab antivenom. These kinetics suggest that the duration of action of the antivenom is more comparable to the clinical effects of the venom.<sup>6</sup>

### North American Coral Snake Antivenin IgG (Equine)

#### Chemistry/Preparation

North American Coral Snake Antivenin (NACSA) is manufactured by immunizing healthy horses with venom from the Eastern coral snake (*Micrurus fulvius*). The horse serum is then purified and concentrated before it is lyophilized for storage. Unlike Fab and F(ab')<sub>2</sub> antivenoms, NACSA is a whole IgG product.

### Pharmacokinetics

The pharmacokinetics of NACSA are unknown and unstudied.

## CLINICAL USE

### Crotalidae Polyvalent Immune Fab (Ovine)

Although crotalidae polyvalent immune Fab (Fab antivenom) is designed using the venoms of 4 North American crotalids, murine lethality studies demonstrate activity against the venom of 6 other crotaline snake species (*Crotalus viridis helleri*, *C. molossus molossus*, *C. horridus horridus*, *C. horridus atricaudatus*, *Agkistrodon contortrix contortrix*, and *Sistrurus miliaris barbouri*).<sup>9</sup> In addition, numerous case reports document benefit after envenomation by many other North American crotalids.

Some case reports and anecdotal experience report venom effects resistant to Fab antivenom. For instance, thrombocytopenia may not respond to Fab antivenom after envenomations by the red diamond (*C. ruber ruber*) and the timber (*C. horridus horridus*) rattlesnakes.<sup>31</sup> In these cases, the thrombocytopenia often responds to initial doses of Fab antivenom, but a subsequent decline in the platelet count is unaffected by repeat dosing of antivenom. Sometimes severe, platelet counts remain extremely low or undetectable until they rebound approximately a week after the envenomation. In rare cases, despite Fab antivenom therapy, late spontaneous bleeding and laboratory abnormalities occurs beyond 2 weeks.<sup>29</sup> Furthermore, some patients envenomated by the Southern Pacific rattlesnake (*C. viridis helleri*) may have refractory neurotoxicity unresponsive to Fab antivenom.<sup>35</sup> In general, Fab antivenom is used to treat envenomations for all North American pit vipers with expected overall benefit despite the occasional refractory envenomation effects noted in select species.<sup>26</sup>

Following an envenomation, the major indications for Fab antivenom administration are (1) progression of swelling, (2) significant coagulopathy or thrombocytopenia, (3) neuromuscular toxicity, or (4) hemodynamic compromise. These indications permit the clinician to interpret the need for antivenom under varying circumstances. If the prothrombin time is elevated, or the fibrinogen or platelet counts are decreased, we recommend antivenom. Furthermore, antivenom is also recommended when patients demonstrate muscle fasciculations, weakness, or shock.

We recommend against giving antivenom prophylactically to individuals without evidence of envenomation or for localized tissue swelling when other signs of envenomation are absent. This is interpreted as swelling localized to only the bite site or swelling that does not cross a major joint, such as a wrist, elbow, ankle, or knee (Chap. 119).<sup>26</sup> Antivenom is avoided in these circumstances because the risk of antivenom administration outweighs any perceived benefits. Nonetheless, the bedside physician should use their best judgment based on the severity of local swelling before providing antivenom when no other signs are present.

When indications are met, antivenom should be administered as soon as possible. Because antivenom will halt but not reverse swelling, it is anticipated that early administration would reduce pain and loss of function associated with a grossly swollen extremity, as compared to delayed administration. Animal studies demonstrate decreased mortality when antivenom is given immediately after envenomation.<sup>9</sup> Similarly, antivenom benefits diminish with delayed treatment of even a few hours in animal models.<sup>14</sup> Antivenom will not reverse swelling and tissue necrosis that has already occurred, and tissue necrosis often continues to develop despite antivenom administration. Antivenom, at least temporarily, reverses systemic effects, coagulopathy, and platelet defects.<sup>5,11,12,25,37</sup> Although no studies exist comparing outcomes of envenomated patients treated with and without antivenom,

it is generally agreed that treatment reduces morbidity in patients with significant crotaline envenomation and in some situations may be a lifesaving therapy.<sup>12</sup> The window of therapeutic efficacy in cases of delayed antivenom administration is unknown.

### Crotalidae Immune F(ab')<sub>2</sub> (Equine)

Although Crotalidae Immune F(ab')<sub>2</sub> (F(ab')<sub>2</sub> antivenom) is derived from the venoms of 2 snake species less commonly encountered in North America, F(ab')<sub>2</sub> antivenom effectively neutralizes the venom from 15 different North American snakes. However, as compared to the Fab counterpart, the dose required for neutralization was higher in nearly every case.<sup>39</sup>

At the time of this writing, F(ab')<sub>2</sub> antivenom has been used only for research purposes in the treatment of North American rattlesnake bites. Yet, clinical indications for use remain the same as for Fab antivenom. However, this antivenom shows promise as a treatment with less concern for recurrent venom effects in both adult and pediatric patients.<sup>6,23</sup>

### North American Coral Snake Antivenin IgG (Equine)

North American Coral Snake Antivenin (NACSA) is the recommended treatment for envenomation by the eastern coral snake (*Micrurus fulvius*) and Texas coral snake (*Micrurus tener*). This antivenom does not treat envenomations from coral snakes found in Mexico, Central America, or South America. Furthermore, bites by the less virulent Arizona coral snake (Sonoran, *Micruroides euryoxanthus*) do not produce significant envenomation requiring treatment with antivenom.<sup>38</sup>

Indications for NACSA administration include the development of any signs or symptoms consistent with coral snake envenomation from the *Micrurus* genus.<sup>30</sup> Patients with coral snake envenomations typically lack significant local tissue injury. Antivenom administration is recommended following the development of any neurologic abnormalities including, but not limited to, paresthesias, slurred speech, ptosis, diplopia, dysphagia, stridor, muscle weakness, fasciculations, and paralysis. Because anxiety is often associated with a snakebite, true signs of envenomation must be differentiated from the anxiety related to a snake encounter. We recommend against treating patients with NACSA empirically prior to symptom development.<sup>1</sup> At least one study demonstrates that treatment of patients after symptom development was not inferior to an empirical approach.<sup>42</sup>

In the absence of antivenom, the mainstay of treatment consists of aggressive supportive care. In particular, if respiratory failure results from muscle weakness prolonged mechanical intubation is often necessary until neurologic recovery. Paralysis is completely reversible; however, it typically takes weeks to months to resolve completely.<sup>20</sup>

## ADVERSE EFFECTS AND SAFETY ISSUES

### Crotalidae Polyvalent Immune Fab (Ovine)

Acute hypersensitivity reactions are the most significant safety concerns when administering antivenom to patients. Crotalidae polyvalent immune Fab (Fab antivenom) was specifically designed to have reduced immunogenicity; however, both acute and delayed hypersensitivity reactions are still reported.<sup>7,8</sup> Urticaria, rash, bronchospasm, pruritus, angioedema, anaphylaxis, and delayed serum sickness are all associated with use of this product.<sup>11,40</sup> An early study reported acute reactions in 14.3% of patients receiving this antivenom, but more current studies suggest an incidence of 5% to 6%.<sup>7,12,25</sup>

When antivenom is administered too rapidly, nonimmunogenically mediated anaphylactoid reactions also occur. Most patients appear to tolerate 4 to 6 vials per hour without developing significant anaphylactoid reactions. If the patient requires rapid administration of antivenom because of the severity of the envenomation, H<sub>1</sub> and H<sub>2</sub> histamine receptor antagonists and an epinephrine infusion should be readily available in case symptoms develop. Clinically differentiating between anaphylactoid and anaphylactic reactions may be difficult, especially when antivenom is administered rapidly. Regardless, the treatment remains the same.

For acute anaphylactic reactions (which often occur shortly following initiation of even low doses of antivenom), the antivenom is stopped, and

aggressive supportive and pharmacologic therapy begun. Intravenous epinephrine at 2 to 4 mcg/min (0.03–0.06 mcg/kg/min for children) should be initiated and then titrated to effect, as well as corticosteroids and H<sub>1</sub> and H<sub>2</sub> histamine receptor antagonists. After the symptoms of hypersensitivity resolve, the antivenom is restarted only in patients at high risk for significant morbidity or mortality from envenomation. In such cases, the antivenom infusion is restarted at 1 to 2 mL/h, while the epinephrine infusion is continued. The antivenom infusion rate is slowly increased as tolerated. If anaphylaxis recurs, the antivenom is stopped and the epinephrine infusion increased until symptoms resolve. Antivenom can then be restarted while epinephrine is continued at the higher rate. With constant physician monitoring at the bedside and careful titration of epinephrine and antivenom infusions, patients with life-threatening envenomation should tolerate the full antivenom dose. Patients have safely received subsequent doses of antivenom after an acute life-threatening reaction.<sup>27</sup>

In addition to acute allergic reactions, delayed hypersensitivity syndromes in the form of serum sickness are reported. Although most episodes of serum sickness are mild, this syndrome has not been well studied.<sup>18</sup> Typical cases of serum sickness include urticaria, pruritus, and malaise. Arthralgias, lymphadenopathy, and fever also develop. In rare severe cases, glomerulonephritis, vasculitis, myocarditis, and neuritis occur. Delayed hypersensitivity reactions are poorly studied following treatment with Fab antivenom, but are reported to occur in 16% (6/38) of patients in 2 clinical trials.<sup>2,11</sup> This number may be falsely high because all but one of the cases came from a single lot of antivenom that was later found to have a high concentration of Fc antibody fragment contamination.<sup>14</sup> We recommend that patients with serum sickness symptoms receive treatment with 2 mg/kg (a maximum dose of 60 mg per day for adults) of oral prednisone divided into 2 daily doses and tapered over 2 to 3 weeks. Oral H<sub>1</sub> receptor antagonists are reasonable to add for symptomatic treatment as well. The vast majority of patients are managed as outpatients, and most respond favorably to this regimen.

According to the package insert, a known allergy to papaya or papain is a contraindication to the administration of Fab antivenom unless the risks of allergy outweigh the benefits of the administration.<sup>10</sup> Patients with known allergy to papaya or papain appear rare. However, patients who are also allergic to latex or a variety of fruits (banana, avocado, kiwi, apricot, chestnut, grape, passion fruit, and pineapple) may have cross-reactivity with papain.<sup>34</sup> Therefore, we recommend administration of Fab antivenom with caution to any patients with atopy, asthma, or known food allergies.

### Crotalidae Immune F(ab')<sub>2</sub> (Equine)

Although its use in the United States is limited, adverse effects and safety issues remain the same for F(ab')<sub>2</sub> as for Fab antivenoms. The package insert suggests itching (43%) and nausea (23%) are among the most common adverse effects.<sup>1</sup> In addition, rashes (12%), arthralgias (11%), peripheral edema (8%), myalgias (7%), vomiting (6%), and headache (6%), were observed in clinical trials.<sup>1</sup> Acute and delayed allergies are reported as well.<sup>6</sup> Monitoring for and treatment of these adverse reactions is the same as described for Fab antivenom.

### North American Coral Snake Antivenin IgG (Equine)

Acute and delayed hypersensitivity reactions are the most significant safety concerns when providing antivenom products to patients. However, little is published concerning NACSA adverse reactions. The risk of acute hypersensitivity reactions with NACSA is approximately 20%.<sup>42</sup> Wyeth's other equine-derived antivenom product, Antivenin Crotalidae Polyvalent (ACP), caused acute allergies in 20% to 50% of cases and the incidence of delayed hypersensitivity reactions increased with increased doses.<sup>19,41</sup> The exact incidence of hypersensitivity with NACSA is unknown, but approaches 100% when more than 40 vials of ACP were administered.<sup>28</sup> Despite these concerns, severe allergic reactions to NACSA are uncommonly reported, but this may reflect infrequent use and reporting bias.<sup>30,42</sup>

Patients with a known horse serum allergy or who have been treated with equine-derived antivenoms previously should only receive treatment

with NACSA if there is a significant risk of severe morbidity or mortality and appropriate management for anaphylactic reactions is readily available.<sup>30</sup> Patients with known horse serum allergies have tolerated equine antivenoms, but they often require more dilute doses of antivenom and pretreatment.<sup>17,27</sup> For these patients we recommend using intravenous H<sub>1</sub> and H<sub>2</sub> receptor antagonists, corticosteroids, and an epinephrine infusion (2–4 mcg/min for adults) prior to antivenom administration. The antivenom is then started at a very low rate of infusion, and if tolerated, the rate is increased. If an acute allergic reaction develops, the antivenom is immediately stopped and the epinephrine drip titrated for symptoms. Only after symptoms abate should the antivenom be restarted by carefully titrating both the antivenom and epinephrine drips. With severe allergic reactions, reserving antivenom for only life-threatening envenomations is recommended. In most cases with severe allergic symptoms, discontinuing antivenom and providing supportive care alone are the preferred recommendations.

## PREGNANCY AND LACTATION

### Crotalidae Polyvalent Immune Fab (Ovine)

Pregnant patients who meet criteria for treatment should also receive antivenom, which is currently listed as category C, and has been used safely during pregnancy.<sup>21</sup> In the pre-Fab antivenom era, one review of 30 pit viper bites from North American and other international snake species during pregnancy reported 43% fetal demise and 10% maternal mortality.<sup>15</sup> Therefore, given the relative safety of this antivenom and the potential for significant fetal compromise after envenomation, the pregnant patient is approached no differently than the nonpregnant patient. Continuous fetal and maternal monitoring is important as well.<sup>22</sup>

It is unknown if Fab antivenom is excreted in breast milk.

### Crotalidae Immune F(ab')<sub>2</sub> (Equine)

Pregnant patients who meet criteria for treatment should also receive antivenom, which is currently listed as category C. No evidence exists concerning use during pregnancy. As mentioned for whole IgG and Fab antivenoms, given the relative safety of this antivenom and the potential for significant fetal compromise after envenomation, the pregnant patient is approached no differently than the nonpregnant patient. Continuous fetal and maternal monitoring is important as well.<sup>22</sup>

It is unknown if F(ab)<sub>2</sub> antivenom is excreted in breast milk.

### North American Coral Snake Antivenin (Equine)

Currently NACSA does not have a pregnancy listing. There are no reports of administration of this antivenom in pregnancy. Knowledge of NACSA's safety in pregnancy is unknown. However, other antivenoms have been used safely in pregnancy, and maternal health is often considered of greater concern and risk due to envenomation than the unknown fetal risk associated with antivenom.<sup>4</sup> Considering this, and the severe morbidity associated with coral snake envenomation, we recommend that pregnant patients who meet criteria for treatment receive antivenom. Continuous fetal and maternal monitoring is important as well.

It is unknown if NACSA is excreted in breast milk.

## DOSING AND ADMINISTRATION

### Crotalidae Polyvalent Immune Fab (Ovine)

A thorough medication history including previous treatment with antivenoms should be obtained. A history of asthma, atopy, or food allergies should be carefully considered when weighing the risks and benefits of antivenom for a particular patient. According to the manufacturer, the only contraindication is an allergy to papaya or papain. These conditions should not exclude the use of antivenom if the patient is suffering from a moderate-to-severe envenomation. Crotalidae polyvalent immune Fab (Fab antivenom) is ovine-derived; therefore, previous reactions to equine-derived antivenoms do not preclude use of this product. In cases of mild envenomation, the risk of allergic reaction to antivenom might outweigh any benefit. Antivenom should be administered in a monitored setting in which resuscitation can be performed

and airway supplies are readily available. Epinephrine, corticosteroids, and antihistamines should be immediately available in the event of a hypersensitivity reaction. If the patient tolerates initial doses without ill effect, subsequent doses may be administered on a medical floor or step-down unit.<sup>26</sup>

Antivenom is packaged in vials as a lyophilized powder, which must be reconstituted. Completely filling each vial with 25 mL of sterile water, rather than the 10 mL advised in the package insert, and then gently hand rolling the vials will result in dissolution times as rapid as one minute. Adding the greater volume also reduces foaming of the product.<sup>10,33</sup> The reconstituted antivenom is further diluted into a 250 mL of 0.9% saline and administered as discussed below.

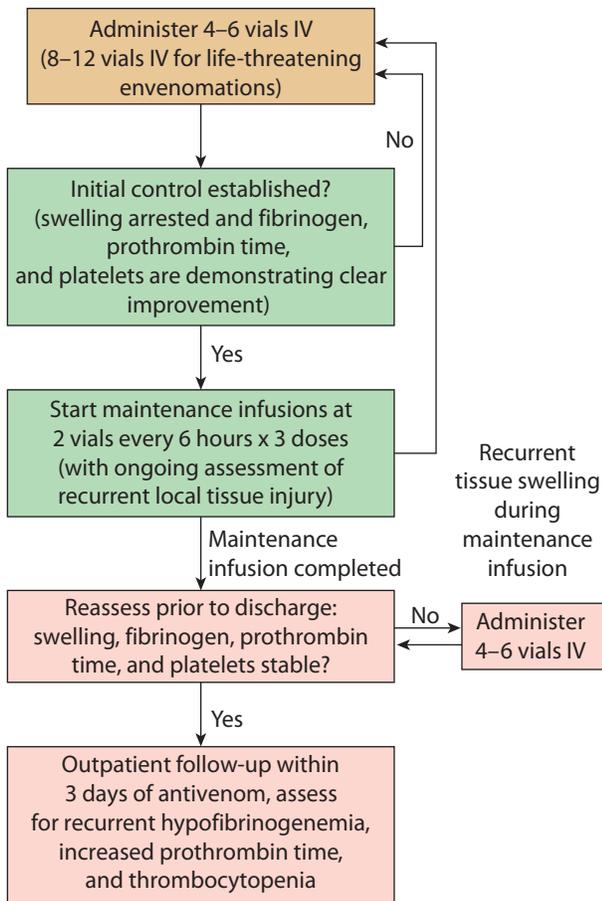

The initial recommended dose is 4 to 6 vials, which is mixed in 250 mL 0.9% sodium chloride solution and administered over one hour. For patients who present with cardiovascular collapse or life-threatening toxicity we recommend a starting dose of 8 to 12 vials of Fab antivenom.<sup>26</sup> The exact concentration of antivenom is not critical. For children, the total volume of fluid in which the antivenom is diluted can be decreased when necessary.<sup>32</sup> No dosing adjustment is required for children or small adults because the amount of venom requiring neutralization is not dependent on the patient's weight. There is no evidence to support partial doses or infusions of one or 2 vials in minor cases.

In order to avoid serious adverse reactions, the first dose of antivenom is administered cautiously at an escalating rate. We recommend against skin testing. The first dose of antivenom (4–6 vials diluted in 250 mL 0.9% saline) is infused at an initial rate of 10 mL/h while the patient is observed carefully for evidence of hypersensitivity. If after 5 minutes no adverse reactions are witnessed, then the rate is doubled every few minutes, as tolerated by the patient, with the goal of infusing the first dose over one hour. If the patient tolerates the initial dose without adverse effects, subsequent doses can be given at a rate of 250 mL/h without a need for rate titration.

The total dose of antivenom required to control an envenomation varies widely. With the introduction of Fab antivenom, *control* was defined as arrest of local tissue manifestations and return of coagulation parameters, platelet counts, and systemic signs to normal. However, clinical experience demonstrated that some patients have venom-induced coagulopathy and thrombocytopenia resistant to antivenom treatment.<sup>37</sup> Some authors advocate *control* to mean clear improvement in hematologic parameters rather than complete normalization.<sup>37</sup> We find that this definition is more realistic for the subset of patients with difficult-to-treat coagulopathy and thrombocytopenia. After each dose of 4 to 6 vials, prothrombin time, fibrinogen, and platelet counts are measured, and the patient's local injury is reexamined. Multiple doses are often required to achieve control. A retrospective study reported 83% of rattlesnake bites and 98% of copperhead bites obtained control with 12 or fewer vials of Fab antivenom.<sup>43</sup> This study emphasizes the need for multiple antivenom doses in rattlesnake envenomations and typically only one initial dose in copperhead bites in order to gain control. If repeat dosing is necessary to control swelling, but fibrinogen, prothrombin time, and platelets remain normal, these laboratory studies do not need repeating.

After achieving control, maintenance doses of 2 vials every 6 hours are recommended, for a total of 3 doses. The 2 vials are added to 250 mL 0.9% sodium chloride solution and administered over one hour. Because the duration of action of Fab antivenom is less than that of venom, the maintenance doses are provided to preclude recurrence of local manifestations, thrombocytopenia, and coagulopathy. An algorithm for Fab antivenom administration for moderate to severe crotaline envenomation is shown in Fig. A39–2. Although recommended in the CroFab package insert, maintenance therapy is not routinely administered by all practitioners.<sup>10</sup> For example, copperhead envenomations may not require maintenance doses.<sup>26</sup> Because of regional variations in the potency of copperhead venom, we recommend consultation with regional poison control centers in order to provide local practices and receive specific recommendations.

Some patients will demonstrate recurrence of swelling during their maintenance infusions. For this reason, close monitoring of extremity swelling is

**FIGURE A39-2.** Algorithm for Crotalidae Polyvalent Immune Fab administration for treatment of moderate-to-severe Crotaline envenomation.

recommended for 18 to 24 hours after apparent control has been achieved. If recurrent swelling occurs, additional doses of 4 to 6 vials are recommended until the swelling again becomes controlled, and then maintenance infusions are resumed.

Despite successful completion of maintenance antivenom doses, some patients also develop a recurrence of coagulopathy and/or thrombocytopenia. Therefore, we recommend repeat prothrombin time, fibrinogen and platelet counts performed 2 to 3 days and again 5 to 7 days in all patients after hospital discharge to ensure late recurrent hematologic effects have not developed. One large retrospective study demonstrated new or recurrent hematologic findings in 32% of patients with rattlesnake envenomations.<sup>36</sup> Another study suggests recurrence is as high as 50%.<sup>3</sup> Close follow-up seems less necessary in copperhead envenomations because hematologic findings are observed less frequently.<sup>24</sup>

### Crotalidae Immune F(ab')<sub>2</sub> (Equine)

Prior to administration, the same preparation should occur for F(ab')<sub>2</sub> administration as for Fab antivenoms. However, there are no contraindications listed on the F(ab')<sub>2</sub> package insert.<sup>1</sup> Antivenom should be administered in a monitored setting where resuscitation can be performed and airway supplies are quickly accessed. Epinephrine, corticosteroids, and antihistamines should be immediately available in the event a hypersensitivity reaction occurs.

Antivenom is packaged in vials as a lyophilized powder, which must be reconstituted. Completely filling each vial with 25 mL of sterile water, rather than the 10 mL advised in the package insert, and then gently hand rolling (not shaking) the vials will result in dissolution times as rapid as one minute. Adding the greater volume also reduces foaming of the product.<sup>10,33</sup>

The initial recommended dose of F(ab')<sub>2</sub> is 10 vials, which is mixed in 250 mL 0.9% sodium chloride solution and administered over one hour. For the first 10 minutes, the infusion rate is 25 to 50 mL/h, which is then increased to the full 250-mL/h rate until completion if no allergic reactions develop. Repeat doses of 10 vials are recommended until control is achieved. Clinical trials suggest maintenance dosing is not needed.<sup>6</sup> However, the package insert recommends 4 vials as needed for recurrent venom effects and 18 hours of monitoring after obtaining control. The caveats for Fab antivenom administration (infusion rate and treatment of allergic reactions) apply to F(ab')<sub>2</sub> antivenom.

Recurrent venom effects still occur in 5% to 10% of case.<sup>6</sup> After hospital discharge, outpatient monitoring is still recommended as experience with this antivenom is limited.

### North American Coral Snake Antivenin IgG (Equine)

Prior to administration, the same preparation should occur for North American Coral Snake Antivenin (NACSA) administration as for the other antivenoms.

Antivenom is packaged in vials as a lyophilized powder, which must be reconstituted. Completely filling each vial with 25 mL of sterile water, rather than the 10 mL advised in the package insert, and then gently hand rolling (not shaking) the vials will result in dissolution times as rapid as one minute. Adding the greater volume also reduces foaming of the product.<sup>10,33</sup>

The initial recommended dose of NACSA is 3 to 5 vials, which is mixed in 250 mL 0.9% sodium chloride solution and administered over one hour.<sup>30</sup> Additional antivenom doses are indicated for the evolution of any neurologic abnormalities including, but not limited to, paresthesias, slurred speech, ptosis, diplopia, dysphagia, stridor, muscle weakness, fasciculations, and paralysis. The caveats for crotaline antivenom administration (infusion rate and treatment of allergic reactions) apply to coral snake antivenom, except less antivenom is usually required for coral snakes. Up to 10 vials can be administered, although dosing recommendations are vague.

## FORMULATION AND ACQUISITION

### Crotalidae Polyvalent Immune Fab (Ovine)

Hospitals with native crotaline species within their region should maintain Fab antivenom at all times.<sup>13</sup> Because the timely administration is the cornerstone of treatment, attempting to obtain antivenom at the time of an emergency will likely introduce a significant delay to treatment and exacerbate morbidity.

### Crotalidae Immune F(ab')<sub>2</sub> (Equine)

Although this is FDA-approved, the availability of F(ab')<sub>2</sub> is not expected until the fall of 2018.

### North American Coral Snake Antivenin IgG (Equine)

In order to obtain NASCA, contact the local poison control center or Pfizer, which currently holds the rights to this antivenom. Poison control centers have access to the online Antivenom Index, which is useful when attempting to locate coral snake antivenom. Otherwise, Pfizer will provide the antivenom on an as needed basis.

## SUMMARY

- Antivenom is a significant benefit for some patients envenomated by North American snakes.
- If crotalid snakes are endemic to a catchment area of a hospital, Crotalidae Fab or F(ab')<sub>2</sub> antivenoms should remain stocked and easily accessible at all times.<sup>13</sup>
- In areas endemic with the eastern or Texas coral snake, North American coral snake antivenin (NACSA) should be stocked and immediately accessible at all times.
- Poison control centers have access to the online Antivenom Index, which is useful when attempting to locate antivenom for a coral snake

or a nonnative snake envenomation. Local zoos may also be useful resources when attempting to locate exotic antivenom. Recommendations for these diverse antivenoms are difficult to make, but available package instructions should be followed, and preparations should be made to treat hypersensitivity reactions.

# EXOTIC NONNATIVE SNAKE ENVENOMATIONS

Keith J. Boesen, Kelly A. Green Boesen,  
Nicholas B. Hurst, and Farshad Mazda Shirazi

### HISTORY AND EPIDEMIOLOGY

The incidence of snakebites worldwide is difficult to ascertain, as there is no systematic reporting mechanism. This fact, when combined with the variable degree of confirmation of snakebites, makes the estimation of an accurate number extremely difficult. Attempts have been made utilizing available data from case reports in the literature, hospital records, surveys, and existing reporting systems. Current estimates place the worldwide annual incidence of snakebites as high as 5.5 million,<sup>13,44</sup> of which roughly 50% are thought to be from venomous snakes.<sup>8</sup> Estimated annual complications include 400,000 amputations<sup>44</sup> and approximately 100,000 deaths.<sup>13,44</sup>

Snakes, although feared by many, are popular around the world as pets. The desire to keep venomous snakes as pets, which is typically illegal in the United States, and the financial, clinical and ethical implications throughout the world make the trade of exotic creatures third only in sales to drugs and weapons on the international black market. In fact, the estimated annual worth of this trade in the United States alone is at least \$15 million.<sup>18</sup>

This Special Consideration will discuss the evaluation and management of patients evenomated in the United States by nonnative snakes (also known as exotic snakes). A review from 2005 through 2011 of the National Poison Data System (NPDS), maintained by the American Association of Poison Control Centers (AAPCC), confirmed 258 exotic snakebites reports, of which 218 were identified by genus and species, from a total of 71 different varieties.<sup>42</sup> The most common envenomations involved male owners bitten in a private residence during feeding or handling the snakes, cleaning the cages, or while milking the snakes for venom.<sup>24,41,42</sup> Of all bites, 82.9% were the result of an Elapidae or Viperidae snakes.<sup>42</sup>

The previous AAPCC study from 1995 to 2004 documented 399 nonnative exposures, of which 350 snakes (87%) were identified by genus and species, comprising at least 77 different varieties. One US expert reported 54 consultations regarding bites from nonnative venomous snakes.<sup>24</sup>

In the most recent AAPCC data, the most common family responsible for envenomations was the Viperidae, making up 43% of these bites. Of the Viperidae, 42 different species were identified, with the top 4 species involved being: gaboon viper (*Bitis gabonica*), bush master (*Lachesis mutus*), the sharpnosed viper (*Deinagkistrodon acutus*), and the hognosed viper (*Bothrops ophroyomegas*). The second most common family responsible for envenomations was the Elapidae, resulting in 39% of US exotic snakebites. Forty-two percent were from 3 different species: monocellate cobra (*Naja naja kaouthia*), black necked spitting cobra (*Naja nigricollis*), and the Black mamba (*Dendroaspis polylepis*). The monocellate cobra was the most common snake identified during this study (17 envenomations). Of note, 79% of patients were male, the average age was 33 years (7% were 12 years of age or younger), 70% occurred in a private residence, 11% occurred at work, and 10% occurred in a public area.<sup>42</sup>

### TAXONOMY

The naming of snakes has evolved and the renaming currently continues at a rapid pace as a result of advances in DNA testing and ongoing research.<sup>29,30,43</sup> There are approximately 2,700 snake species in the world,<sup>29</sup> of which 20% are known to be venomous to humans.<sup>21</sup> Venomous snakes are divided into 4 major families as shown in Table SC10-1.<sup>14,22,29,30,35,43</sup>

The Elapidae family has a wide distribution in primarily tropical or arid desert settings in such continents as Asia, Australia, Africa, North America, and South America, with the sea snakes and sea kraits found in the Pacific and Indian Oceans.<sup>14</sup> Possibly the most well known of this family are the cobras, capable of unique characteristics such as hooding or spitting.<sup>14</sup> In the United States, there are 3 Elapidae snakes; the Eastern coral snake (*Micrurus fulvius fulvius*), the Texas coral snake (*Micrurus fulvius tener*), and the Sonoran coral snake (*Micruroides euryxanthus*).

The Viperidae family, consisting of the 3 subfamilies Azemiopinae, Viperinae, and Crotalinae, exists throughout the world, with a few exceptions. The majority of the snakes in this family are divided into 2 main categories: Old World vipers (also known as true vipers) and pit vipers.<sup>35</sup>

### ANTIVENOM INDEX

The Antivenom Index (AI) was created more than 25 years ago as a joint effort of the Association of Zoos and Aquariums (AZA) and the AAPCC for the purpose of creating a database that would contain the location of all non-native snake antivenoms stored throughout the zoos in the United States. For many years, this was kept in paper format at the Arizona Poison and Drug Information Center in Tucson, Arizona, and in 2006 it was converted to an electronic database.

The AI can be searched by the common name or the scientific name of the venomous snake. This search will result in a list of possible snakes that match the description of the searched term. From there, a list of antivenoms active against that genus and species will be displayed, including which zoos stock them and how many vials are available. With this information, and help from experts or the closest regional poison control center, it can

TABLE SC10-1 Taxonomy of Snakes		
Family	Subfamily	Representative Species
Elapidae	Elipinae	Cobras ( <i>Naja</i> spp) King cobras ( <i>Ophiophagus hannah</i> ) Mambas ( <i>Dendroaspis</i> spp) Kraits ( <i>Bungarus</i> spp) Coral snakes ( <i>Micrurus</i> spp and <i>Micruroides</i> spp)
	Hydrophiinae	Various sea snakes
	Laticaudinae	Sea kraits
Viperidae	Azemiopinae	Fea's viper ( <i>Azemiops feae</i> )
	Viperinae (Old World vipers)	Russell's viper ( <i>Vipera russelii</i> ) Gaboon viper ( <i>Bitis gabonica</i> ) Saw-scaled viper ( <i>Echis carinatus</i> ) Death adders ( <i>Acanthophis</i> spp)
	Crotalinae (pit vipers)	Rattlesnakes ( <i>Crotalus</i> and <i>Sistrurus</i> spp) Copperheads ( <i>Agkistrodon</i> spp)
Atractaspididae		Stiletto snakes ( <i>Atractaspis</i> spp)
Colubridae		African boomslang ( <i>Dispholidus typus</i> ) Twig snake ( <i>Thelotornis</i> spp)

be determined where an adequate supply of antivenom exists and what arrangements are necessary to transport the antivenom to the health care facility where the patient in question is receiving care.

Additional information available in the AI includes package inserts for the antivenoms, many of which are translated into English, the expiration dates of the antivenoms, and additional information such as links to various recommendations on the housing, stocking, or administration of antivenoms.

Access to the AI is limited to the AZA and the AAPCC (all poison control centers have access). Association of Zoos and Aquariums members have the ability to input updated stocking information, whereas the AAPCC members can view antivenom supplies. To access the AI, contact the local poison control center at 1-800-222-1222. Southern Florida is unique in the storage and distribution of exotic antivenoms. The Miami-Dade Fire Rescue Venom Response Program maintains one of the largest repositories of exotic antivenoms for public use in the United States. They work with the local Poison Control Center in Miami for the clinical expertise to facilitate treatment of the envenomated patient.

## VENOM TOXICITY

Common venom components from the Elapidae and Viperidae families are classified as neurotoxic, hemotoxic, and or myotoxic.<sup>6,20,41</sup> The venom from the Elapidae is associated with neurotoxic effects. Signs and symptoms consistent with neurotoxicity include blurred vision, paresthesias, ptosis, paralysis of facial muscles, difficulty swallowing, respiratory paralysis, and generalized flaccid paralysis.<sup>40</sup> The venom from the Viperidae is more commonly associated with hemotoxicity and myotoxicity, although some species also have neurotoxic effects. The hematologic signs and symptoms associated include petechiae, purpura, ecchymosis, bleeding, and changes in blood coagulation parameters, including platelets and fibrinogen, as well as prothrombin and partial thromboplastin time abnormalities. The activity of Viperidae venom on the clotting cascade occurs at multiple steps throughout the cascade, resulting in varying degrees of severity (Fig. 58–1). The signs and symptoms of myotoxins are consistent with local tissue injury and destruction, including swelling, necrosis, and skin blebs, and are accompanied by elevations of creatine kinase and aminotransferases with possible impairment of kidney function. Although there are some classic differences in the presentation between snakes from the Elapidae and Viperidae families, it is important to note that there are also similarities based on tremendous venom variability found from species to species and in snakes within the same species.<sup>20</sup>

## CLINICAL PRESENTATION AND INITIAL MANAGEMENT

It is useful to consult with an expert to help identify the snake and determine specific signs, symptoms, and treatment options. Experts are found within the AAPCC by calling 1-800-222-1222, or a local zoological society or serpentarium.

The clinical presentation of patients with exotic snake envenomation is extremely variable (mentioned in the above section) as the sequelae depend largely on the type of species involved and the same factors that influence the outcome of patients envenomated by better understood local snakes: premorbid condition of the individual, location of the bite, dose of venom delivered, and delay to health care. Local poison control centers or regional experts are likely familiar with species kept in area zoos as part of an emergency response system for treatment of zoo workers. People who maintain these animals as pets and subsequently are envenomated while handling become more difficult to treat. Several basic steps are recommended for the initial management of these patients as outlined in Table SC10–2.<sup>20,41</sup>

### Zoological and Exotic Antivenoms

Hospitals in the United States are not permitted to stock antivenoms for exotic snakes that have not been produced for the US market and submitted to the Food and Drug Administration (FDA) process for drug sale and administration. Zoos are permitted to stock antivenoms for the species of snakes locally housed for the purpose of treating an unintentional exposure. When

**TABLE SC10–2** General Approach to a Patient With an Exotic Snake Envenomation

Immobilize the bitten limb in a dependent position and rapidly transport the patient to a medical facility. Initiate irrigation with water if the eyes are exposed.

Determine the time and location of bite, and mark the borders. Follow and mark the progression over time.

Determine the species responsible for the bite. If the bite occurred at a zoo, the zoo may have a written plan for management of the specific species ready to accompany the patient (often a zoo employee) that includes the name of species, appropriate first aid, other management guidelines, and any antivenom that is available. Patients who own exotic snakes may know the identity but often use misleading or inaccurate common names. In which case, it is necessary to contact a local herpetologist, who often can be found through the PCC or zoo, to identify the snake.

Standard resuscitation techniques are indicated for cardiovascular or respiratory failure. Initiate volume repletion if there is massive hemorrhage or hypotension.

Physical examination should include evaluation of signs of local envenomation (pain, swelling, bleeding, and bruising), painful and tender enlargement of lymph nodes, hypotension, spontaneous bleeding, ptosis, muscle tone, cranial nerve function, myalgias and a complete neurotoxic assessment. Laboratory assessment should include a complete blood count, coagulation profile, electrolytes and kidney function, creatine kinase, aminotransferase, urinalysis for blood and myoglobin, and an electrocardiogram.

Begin the process of locating, obtaining, and receiving permission to administer antivenom, even if it is unclear that foreign antivenom will be available or required.

Prepare for the treatment of anaphylaxis if foreign antivenom is to be administered.

Because of uncertainties in prediction of clinical evolution and severity of symptom presentation, close monitoring in an intensive care unit is preferred for all patients with exotic envenomations. This will allow for appropriate clinical and laboratory monitoring specific to the needs of the patient. A minimum of 24 hours of hospital observation is recommended to assess delayed evolution of signs or symptoms. Follow up for serum sickness is reasonable.

zoological staff import antivenom from other countries, they must collaborate with the US FDA and the Centers for Biologics Evaluation and Research (CBER). The zoo facility imports the antivenoms with a permit from the US Department of Agriculture. Each state may require additional permits to import/stock non-US FDA-approved antivenoms. To administer the antivenoms to a human, the antivenom must have an Investigational New Drug (IND) Application filed with the US FDA. This can either be done ahead of time or with emergency approval by the US FDA. Investigational New Drug requirements include assignment of one or more local physicians who may administer the antivenom, a record of the name of each product and associated lot numbers, retention of copies of the package insert for each product, and completion of a statement that the antivenom is being imported solely for emergency use and will not be resold.<sup>37</sup> In addition, a Statement of Investigator must be prepared if any changes to the list of approved personnel for administration of the antivenom occur. When the antivenom is administered, a complete case report must be submitted to the director of CBER.

Although zoos are permitted to have antivenom stocked at the facility, a 2008 study demonstrated that of the 106 zoos and 19 aquaria whose representatives responded, only 33 facilities stocked antivenom.<sup>39</sup> In the 10 years prior to the study, zoos and aquaria in the United States reported a total of 39 separate incidents associated with venomous animals. It is unclear why so few facilities with potential for employee exposure do not carry the antivenom required for their local exotic species, as it is possible that a commercially available product could prove essential. Most facilities reported some internal process to respond to an envenomated patient, including coordinating with the PCC, the local emergency medical services, and a local hospital, or have individualized protocols.

The American College of Medical Toxicology (ACMT) recommends that a zoo or facility that houses exotic snakes have a written plan for management of an envenomation.<sup>1</sup> A recent study reviewed and tested the effectiveness of an emergency operation procedure established in Atlanta.<sup>27</sup> Zoo Atlanta, the

Georgia Poison Control Center, and the Grady Health System established a procedure to manage an envenomation resulting from any of the 13 species of snakes housed at the zoo. All 3 organizations participated in the simulated drill and were evaluated on the functional aspects of coordinating patient care from the time of envenomation through stabilization. In this scenario, all personnel involved were previously alerted to the drill and had additional training as to staff expectations. Even in this “best case” scenario that included preparation for a patient with an exotic envenomation, barriers to care were still encountered. For instance, the protocol given to the hospital personnel lacked details about specific signs and symptoms expected, clear instructions for antivenom indication, and specific dosing and reconstitution instructions for the antivenom. There were also some general problems with personnel coordination. This study highlights the importance of having an established plan that includes the zoo facility, a PCC, and the treating institution.

### Hospital Use of Exotic Antivenoms

Because exotic antivenoms are not readily available, it is often difficult to obtain the species-specific correct antivenom in the appropriate amount. The PCCs become critical resources during this time. Often they can locate the closest supply and coordinate delivery. In the case of an envenomation at a zoo, the appropriate antivenom may arrive with the patient. In the case of the exotic snake owner, the poison control center may help facilitate acquisition of antivenom from local sources, such as zoos, known to stock the antivenom for emergency use. If there are no local sources, the poison control center staff can easily access the AI to locate the closest available stock of antivenom. In one case report, it took a regional poison control center 5 hours to locate and organize airborne delivery of the appropriate antivenom to the treating facility.<sup>18</sup> A similar report described a 3-hour delay to administration even when the antivenom was present in the local zoo.<sup>10</sup> During that delay, the patient required intubation.

Arranging for transport of the antivenom can be difficult, often requiring fixed wing transportation across state lines. The antivenom must be transported from the zoo, to the airport, and then boarded on a plane. Often, a medical transport team or a commercial airline can assist with the transport. Utilization of commercial airlines often requires extensive justifications, explanations, and authorizations.

Once brought to the facility, a series of steps must occur prior to the patient administration of the non-US FDA-approved antivenom. The treating physician should contact the US FDA to obtain approval to administer the antivenom as an IND under emergency use.<sup>36</sup> Contact numbers are found at <http://www.fda.gov/RegulatoryInformation/Guidances/ucm126491.htm>.

In addition, the treating physician will need to obtain informed consent from the patient prior to administration. Because the antivenom is considered an investigational product, both the Institutional Review Board (IRB) and Drug and Formulary Committee must be notified and provide approval. Many IRBs have emergency processes to expedite such a request. If such approval cannot be obtained in a clinically relevant time, the IRB must be notified of the emergency treatment within 5 working days of the administration.<sup>1,27</sup> The physician must also complete the appropriate IND paperwork (Form FDA 1571) and submit a comprehensive case report.<sup>37</sup>

In addition to the legalities involved in using an investigational product, there are significant operational and logistical issues necessary to ensure appropriate preparation of the product. The pharmacy department should be notified as soon as possible to allow the staff time to begin investigating preparation and administration instructions. Clinical pharmacists provide additional support for both the treating physician and drug preparation aspects in many emergency departments.<sup>27</sup> The utilization of such individuals can greatly facilitate the medication preparation.

The package insert for the specific antivenom will be most helpful for the pharmacist in the preparation process. Specific instructions on diluents, storage, light or heat sensitivities, compatibility, and rate of administration are usually found in the package insert. If the specific antivenom product is known in advance, the pharmacist can begin to research these issues. Many package

inserts are found in the AI and can be obtained with the help of the PCC. However, not all package inserts are in English, and some must be translated or a translated copy must be located.<sup>21</sup> If reconstitution of the antivenom is required, it can take minutes to hours to completely dissolve all the lyophilized particles. In addition to preparation, there is often a significant amount of documentation required when dispensing an IND drug. Having knowledge of the required procedure will expedite the administration of the antivenom.

### Other Therapies

In principle, snake venoms should have some commonality, as they share the purposes of immobilizing or killing prey and beginning the digestive process, and have some common genetic linkage. In practicality, many venoms from snakes found from diverse areas of the globe share constituents or antigenic characteristics.<sup>5,7,33,35</sup> It is therefore possible to use antivenoms derived against specific snakes in the treatment of envenomation from other snakes with related venoms. US FDA-approved coral snake antivenom was used in an experimental model of nonnative elapid envenomation.<sup>32</sup> Similarly, US FDA-approved crotalid antivenom demonstrated efficacy against mice treated with venom from *Crotalus durissus terrificus*, *Bothrops atrox*, and *Bitis gabonica*.<sup>23,31</sup> In fact, a single case report demonstrates utilization of this principle of cross reactivity when a patient envenomated by *C. durissus terrificus* was successfully treated with US FDA-approved Crotalidae Polyvalent Immune Fab (CroFab).<sup>19</sup> Such cross-reactivity should never be assumed based on common or taxonomic identification. The manufacturer of Crotalidae Polyvalent Immune Fab has listed experimental cross-reactivity with a number of species in the AI (Table SC10–3). The clinical decision to use Crotalidae Polyvalent Immune Fab for a patient envenomated by a non-US species of snake with known experimental cross-reactivity should be based on the severity of envenomation, the availability of species-specific antivenom, and the risks associated with administration of species-specific antivenom versus the risks of Crotalidae Polyvalent Immune Fab administration (Antidotes in Depth: A39).

The venom of many neurotoxic snakes interferes with neuromuscular transmission similar to neuromuscular blockers used in clinical medicine (Chap. 66). Neostigmine and other cholinesterase inhibitors increase the LD<sub>50</sub> of animals treated with *Naja haje haje* venom.<sup>11</sup> Additionally, case reports and case series suggest an improvement in neurologic deficits and respiratory failure after neostigmine with or without atropine in humans suffering neurotoxic snake envenomation.<sup>3,9,26,38</sup> In these reports, patients typically received 0.5 to 1 mg of neostigmine IV immediately following pretreatment with 0.5 to 0.6 mg of atropine IV. In some cases, this is repeated every 10 to 30 minutes based on response. Benefits vary and are likely dependent on a number of factors, including differences in the mechanism of neuromuscular blockade between snake species.<sup>2</sup> However, because the complications of atropine and neostigmine at these doses are small and there is a suggestion that they sometimes reverse neuromuscular blockade, administration is reasonable if antivenom is unavailable or delayed. Early trials with mice and intranasal neostigmine use show promise for an alternate route of administration. Animals were injected with an intraperitoneal dose of venom from *Naja naja* at 2.5, 5, and 10 times the LD<sub>50</sub> with subsequent treatment with neostigmine by nasal administration. Treated mice showed an increase in survival time in all groups, with 10 of 15 mice in the 2.5× LD<sub>50</sub> group surviving with normal behavior 6 hours after injection of venom.<sup>16</sup> There is one published case report using intranasal neostigmine in a human after being given mivacurium to mimic the mechanism from a neurotoxic envenomation. Using 2 independent, blinded clinicians, the patient demonstrated improvements in visual acuity, ease of swallowing, and neck flexion shortly after administration of intranasal neostigmine (Chap. 66 and Table 66–5).<sup>15</sup>

Tissue and hematologic toxicity are time-dependent effects that would benefit from early intervention. Worldwide, many envenomed individuals have increased morbidity and mortality secondary to delayed time to treatment.<sup>25</sup> Similarly, the lack of readily available antivenoms for nonnative species in the United States also poses a dilemma. Because of delays in acquiring antivenom, as previously discussed, other supportive measures are needed. There has been research attempting to find xenobiotics capable of

TABLE SC10-3 Experimental Cross-Reactivity Between CroFab and Nonnative Snakes is Suggested for these Species\*

Genus	Species and Sub Species	Common Name	Natural Habitat
<i>Agkistrodon</i>	<i>bilineatus bilineatus</i>	Cantil, common cantil, Mexican moccasin, tropical moccasin, Mexican cantil	Mexico and Central America
	<i>bilineatus howardgloydi</i>	Castellana	Honduras, Nicaragua, and Costa Rica
	<i>bilineatus lemosespinali</i>	Cantil, Mexican moccasin	Mexico and Central America
	<i>bilineatus russeolus</i>	Cantil, common cantil, Mexican moccasin	Mexico and Central America
	<i>bilineatus taylori</i>	Taylor's cantil, ornate cantil	Mexico
<i>Bothriechis</i>	<i>aurifer</i>	Yellow-blotched palm pit viper, Guatemalan palm viper	Mexico and Guatemala
	<i>bicolor</i>	Guatemalan palm pit viper, Guatemalan tree viper	Mexico, Guatemala, and Honduras
	<i>rowleyi</i>	Mexican palm pit viper	Mexico
	<i>schlegelii</i>	Eyelash viper	Central and South America
<i>Bothrops</i>	<i>asper</i>	Fer-de-lance	Mexico and South America
	<i>moojeni</i>	Brazilian lancehead	Brazil
<i>Crotalus</i>	<i>basiliscus</i>	Mexican west coast rattlesnake, Mexican green rattler	Mexico
	<i>cerastes cerastes</i>	Sidewinder, horned rattlesnake, sidewinder rattlesnake	US and Northwestern Mexico
	<i>cerastes cercobombus</i>	Sonoran Desert sidewinder, Sonoran sidewinder	US and Northwestern Mexico
	<i>durissus durissus</i>	South American rattlesnake, tropical rattlesnake	South America
	<i>durissus totonacus</i>	Totonacan rattlesnake	Northern Mexico
	<i>durissus tzabcan</i>	Middle American rattlesnake, Central American rattlesnake, tzabcan	Mexico and Central America
	<i>enyo enyo</i>	Baja California rattlesnake, Lower California rattlesnake	US and Northwestern Mexico
	<i>exsul (Ruber)</i>	Red diamond rattlesnake, red rattlesnake, red diamond snake	Baja California, Mexico
	<i>exsul exsul (Ruber)</i>	Red diamond rattlesnake, red rattlesnake, red diamond snake	Baja California, Mexico
	<i>intermedius gloydi</i>	Oaxacan small-headed rattlesnake	Mexico
	<i>lannomi</i>	Autlán rattlesnake	Mexico
	<i>lepidus castaneus</i>	Rock rattlesnake	US and Mexico
	<i>lepidus klauberi</i>	Banded rock rattlesnake, green rattlesnake, green rock rattlesnake	US and Mexico
	<i>lepidus lepidus</i>	Rock rattlesnake, green rattlesnake, blue rattlesnake	US and Mexico
	<i>lepidus maculosus</i>	Durango rock rattlesnake	Mexico
	<i>lepidus morulus</i>	Rock rattlesnake	Mexico
	<i>mitchelli angelensis</i>	Angel de la Guarda Island speckled rattlesnake	Angel de la Guarda Island, Mexico
	<i>mitchelli mitchelli</i>	Speckled rattlesnake, Mitchell's rattlesnake, white rattlesnake	US and Mexico
	<i>mitchelli muertensis</i>	El Muerto Island speckled rattlesnake	El Muerto Island, Mexico
	<i>mitchelli pyrrhus</i>	Southwestern speckled rattlesnake, Mitchell's rattlesnake	US and Mexico
	<i>molossus estabanensis</i>	San Esteban Island rattlesnake	San Esteban Island, Mexico
	<i>molossus molossus</i>	Northern black-tailed rattlesnake, green rattler	US and Mexico
	<i>molossus nigrescens</i>	Mexican black-tailed rattlesnake	US and Mexico
	<i>molossus oaxacus</i>	Oaxacan black-tailed rattlesnake	Mexico
	<i>polystictus</i>	Mexican lance-headed rattlesnake, lance-headed rattlesnake	Mexico
	<i>pricei miquihuanus</i>	Eastern twin-spotted rattlesnake	Mexico
	<i>pricei pricei</i>	Western twin-spotted rattlesnake	Mexico
	<i>pusillus</i>	Tancitaran dusky rattlesnake	Mexico
	<i>ruber lorenzoensis</i>	San Lorenzo Island rattlesnake	San Lorenzo Island, Mexico
	<i>ruber lucasensis</i>	San Lucan diamond rattlesnake	Mexico
	<i>ruber ruber</i>	Red diamond rattlesnake	US and Mexico
	<i>scutulatus salvini</i>	Huamantlan rattlesnake	Mexico
	<i>scutulatus scutulatus</i>	Mojave rattlesnake	US and Mexico
	<i>stejnegeri</i>	Long-tailed rattlesnake	Mexico
	<i>tigris</i>	Tiger rattlesnake, tiger rattler	US and Mexico
	<i>tortugensis</i>	Tortuga Island diamond rattlesnake, Tortuga Island rattlesnake	Tortuga Island, Mexico

<i>Sistrurus</i>	<i>ravus</i>	Mexican pigmy rattlesnake, Mexican pygmy rattlesnake	Mexico

\*"Cross-reactivity" defined here as experimental evidence supplied by the manufacturer to the Antivenom Index. Although clinical evidence of benefit is lacking, use of Crotalidae Polyvalent Immune Fab is reasonable in these envenomations based on a risk-to-benefit analysis when species specific antivenom is lacking, delayed, or contraindicated (due to allergy), and the envenomation is a risk to life or limb.

minimizing damage in envenomed patients while awaiting definitive care. Snake venom metalloproteinase (SVMP) and phospholipase A<sub>2</sub> (PLA<sub>2</sub>) are 2 venom components responsible for some of the hemorrhagic, cytotoxic, and myotoxic effects contributing to morbidity. Research into inhibitors of those agents are ongoing both in vitro and in animal models and shows promise for delaying damaging effects.<sup>4,17,28</sup>

It is important to remember that there is a wide variation in the standards for preparation of antivenoms around the world. Although many products are highly purified antibody fragments, some continue to use whole immunoglobulins that maintain the risk for anaphylaxis. Prior to antivenom administration, preparations must be made to treat anaphylaxis. The appropriate level of nursing care and monitoring should be available, IV access should be secured, and typical drugs (epinephrine, corticosteroids, antihistamines) and airway management equipment should be immediately available.

## SUMMARY

- Many venomous snakes are found in homes and zoos far from their native habitats.
- It is essential to develop sophisticated systems of care in collaboration with poison control centers and zoos assuring preparedness for worker or hobbyist injury.
- The use of internationally prepared antivenoms may be both life-saving and hazardous. The risks can be limited and benefits maximized through an understanding of available internationally prepared antivenoms.
- The Antivenom Index, available to poison control centers and the Association of Zoos and Aquariums, provides invaluable information about matching an antivenom to a particular snake, location of antivenoms, package inserts, and available English translations of foreign package inserts.
- The use of antivenoms not US FDA approved must follow the rules for an investigational new drug (IND).
- US Food and Drug Administration approved antivenoms may have cross-reactivity against some nonnative snakes.
- The use of prehospital or preantivenom pressure immobilization in the United States is likely of little benefit. Access to a health care facility capable of critical care interventions is of greater value while awaiting antivenom.

## CASE STUDY 12

**History** A 55-year-old man was working at a textile manufacturing site and developed shortness of breath and a “dusky” skin color. The man had a history of a Barrett’s esophagus and obstructive sleep apnea and underwent periodic upper gastrointestinal endoscopy as a screening procedure for esophageal cancer. The foreman who called the rapid response reported that the patient had no complaints before this episode but had been splashed with liquid while connecting a hose coupling to a holding tank containing clothing dye. The identification of the dye was not immediately available, but the employee immediately self-decontaminated with water from an emergency shower before the ambulance arrival. The clothes were removed and disposed of at the work site. No other individuals at the site were potentially exposed.

**Physical Examination** Upon arrival, the patient had blood pressure, 166/112 mm Hg; pulse, 142 beats/min; respiratory rate, 40 breaths/min; and oxygen saturation, 87% on 4 L/min of oxygen via nasal cannula. Physical examination was notable for an ill-appearing man who could only speak in short sentences. His skin and nailbeds were cyanotic; his chest was clear; and his heart was regular and tachycardic without murmurs, gallops, or rubs.

**Initial Management** The patient received oxygen via a 100% nonrebreather mask, and bilevel positive airway pressure was started while preparations were made for endotracheal intubation. Although his respiratory rate and pulse improved somewhat, his oxygen saturation remained between 86% and 88%. An electrocardiogram (ECG) was obtained and showed sinus

tachycardia without ST-segment or T-wave changes suggestive of ischemia or infarction. His clothes were removed and bagged.

A chest radiograph showed no cardiac or pulmonary disease, and an arterial blood gas (ABG) analysis was obtained. The resident commented that although she was certain that the blood was obtained from an artery, it looked dark as if it were venous blood. The results demonstrated the following: pH, 7.32; PCO<sub>2</sub>, 33 mm Hg; PO<sub>2</sub>, 426 mm Hg, and oxygen saturation, 100%. The results were interpreted as a primary metabolic acidosis with respiratory compensation (respiratory alkalosis). This corresponded to a serum bicarbonate concentration of approximately 16 mEq/L (Chap. 12) and reinforced the clinical impression that the patient was significantly ill.

### What Is the Differential Diagnosis?

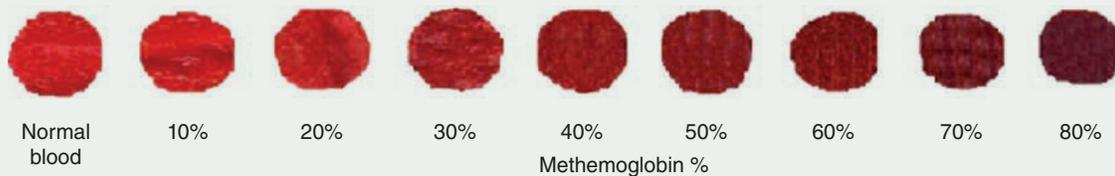

This patient presented with hypertension, tachycardia, tachypnea, cyanosis, and decreased oxygen saturation. The most common causes of these findings in a nonindustrial environment are cardiac and pulmonary disease. Hypoxia and cyanosis in a normal environment (breathing a normal FiO<sub>2</sub>) can result from a shunt, ventilation–perfusion mismatch, diffusion abnormalities, or pump failure (Chaps. 16 and 28). The absence of underlying heart disease, an unremarkable ECG, pulse and blood pressure that are adequate for tissue perfusion, and clear chest examination essentially excludes these disorders, although laboratory ultrasonographic and radiologic confirmation should be obtained.

The combination of cyanosis with a low oxygen saturation by pulse oximetry, failure to respond to supplemental oxygen, dark-colored blood, and a normal or high PO<sub>2</sub> on

the ABG analysis are essentially diagnostic of methemoglobinemia or sulfhemoglobinemia (Chap. 124). When methemoglobinemia is suspected, the color of the blood is related to the methemoglobin level (Fig. CS12–1). Although confirmation can and should be obtained via cooximetry analysis of either venous or arterial blood, the clinical information in this case was sufficient to initiate treatment if cooximetry was either unavailable or delayed.

**Treatment** Venous blood sent for cooximetry revealed a 43% methemoglobin level. The patient was administered 100 mg of methylene blue by slow intravenous administration (Antidotes in Depth: A43). Within about 5 minutes of starting the infusion, his oxygen saturation by pulse oximetry dropped to 64% without a change in his vital signs. Over the next 15 minutes, his oxygen saturation gradually increased to 99%, and his respiratory rate, heart rate, and blood pressure normalized. His shortness of breath resolved. A repeat methemoglobin level taken 30 minutes after the end of the methylene blue administration was 3%. The patient remained well, and subsequent information from the worksite confirmed that the dye material from the tank was aniline.

After the exposure to aniline was determined, the treating staff and first responders expressed concerns over their potential exposure. Additional concerns were expressed about the possible contamination of the ambulance. Because first responders and providers were not wearing protective equipment and the onset of methemoglobinemia may be delayed, they were all screened for elevated methemoglobin levels. In addition, the ambulance was taken out of service and decontaminated.

**FIGURE CS12–1.** The relationship between methemoglobin level and blood color. This figure demonstrates the relationship between methemoglobin level and the color of blood. If anticoagulated blood is placed on a white background, the methemoglobin level can be estimated accurately by comparison with the scale. It is important to note that although normal anticoagulated venous blood oxygenates spontaneously (ie, become redder over time), if exposed to room air, methemoglobin is incapable of extracting oxygen from air and will remain dark over time. (Reproduced with permission from Shihana F, Dissanayake DM, Buckley NA, et al. A simple quantitative bedside test to determine methemoglobin. *Ann Emerg Med.* 2010 Feb;55(2):184-189.)

# SMOKE INHALATION

Nathan P. Charlton and Mark A. Kirk

### HISTORY AND EPIDEMIOLOGY

Smoke is generated as the result of thermal degradation of a material; it is a complex mixture of heated air containing suspended solid and liquid particles (aerosols), gases, and vapors. Particulates and aerosols typically make these thermal degradation products visible to the naked eye, resulting in the black, acrid substance so often thought of as “smoke”; however, thermal decomposition of common materials also results in the generation of gaseous substances that are invisible to the naked eye. The complex and ever-growing variety of materials used in our environment contributes to the broad spectrum of products present in typical smoke.<sup>32,159</sup> The chemical composition of the parent materials, oxygen availability, and temperature at the time of decomposition all help determine the combustion products found in smoke (Table 120–1).<sup>118,127</sup> As a result of these variabilities, specific thermal degradation products resulting from a fire are difficult to predict; in fact, even the composition of smoke is quite variable within the same fire environment.<sup>127</sup>

Smoke inhalation is a complex medical syndrome involving diverse toxicologic injuries, making care of smoke-injured patients very challenging. These injuries occur both locally within the respiratory tract and systemically. It is, in fact, smoke inhalation—not thermal burns—that is the leading cause of death from fires. Cutaneous burns, however, found concurrently with smoke inhalation complicate airway management and fluid resuscitation and increase the risk of infection. Consequently, burn victims with smoke inhalation injury have higher morbidity and mortality rates than those with burns alone.<sup>47,157,159</sup>

Compared with other industrialized countries, the United States has one of the highest rates of fire-related deaths in the world.<sup>159,168</sup> Throughout the United States, a fire department responds to a fire every 23 seconds.<sup>71</sup> In 2015, the National Fire Protection Agency reported 1,345,500 fire incidents in the United States, and approximately 501,500 of these events were structural fires. There were 3,280 fire-related deaths and 15,700 fire-related injuries reported in 2015.<sup>71</sup> On average, a civilian fire death occurs every 160 minutes, and a civilian injury from a structural fire occurs every 34 minutes.<sup>71</sup> Seventy-eight percent of civilian fire deaths occur in home structural fires.<sup>71</sup> An estimated 50% to 80% of fire-related deaths result from smoke inhalation rather than dermal burns or trauma, and deaths related to smoke inhalation occur much more prevalently in an enclosed-space environment.<sup>23,70,118,180</sup> Studies

indicate that from 10% to more than 40% of patients hospitalized in burn units develop complications of concomitant pulmonary injury.<sup>11,50,74,81</sup> The presence of inhalational injury in burn patients correlates with an increased risk of mortality and decreases the total body surface area (TBSA) of a burn that is needed to lead to death, more than doubling the risk of death per TBSA burn in some studies.<sup>11,50,81</sup>

Disastrous enclosed-space fires are a frequent reminder of the role of inhalation injury in fire deaths. Before 1942, toxic inhalation was not considered in the etiology of morbidity and mortality of structural fire victims. However, in that year, a fire at the Coconut Grove Night Club in Boston resulted in a number of fatalities in which victims had no cutaneous burns. This led to the observation that high concentrations of toxic gases are generated in typical enclosed-space structural fires and may result in significant morbidity and mortality.<sup>126</sup> From 1955 to 1972, death from smoke inhalation injury increased threefold and was attributed to abundant use of newer synthetic materials for building and furnishings.<sup>23</sup> From 2006 to 2015 in the United States, an average of 24 catastrophic fires occurred per year, claiming an average of 132 lives each year.<sup>71</sup> Despite improved firefighting resources, mass casualties from smoke inhalation continue. On November 24, 2012, a fire swept through the lower floors of a Bangladesh garment factory, killing 112 and trapping many others on the top floors until rescuers arrived. Hundreds of those trapped above the blaze sustained inhalation injuries.<sup>7</sup> In 2013, 235 people died in a nightclub fire in Brazil when a fire ignited above the concert stage. Smoke inhalation resulted in many of the deaths and forced many others to seek medical treatment.<sup>139</sup> More recently, on December 3, 2016, 36 people were killed when a fire destroyed an Oakland, California, warehouse that was being used to stage a music event.<sup>147</sup> Interestingly, in 2011, explosions caused an unusually high number of catastrophic fires in the United States, highlighting the complex pathologies of fire victims with the potential for victims to have any combination of inhalation injury, burns, and trauma.<sup>6</sup>

### PATHOPHYSIOLOGY

Toxic thermal degradation products are classified into three categories: simple asphyxiants, irritant gases, and chemical asphyxiants (Table 120–2). Simple asphyxiants, such as carbon dioxide, exert their toxicity by displacing oxygen, resulting in an oxygen-deprived environment, thereby decreasing the amount of oxygen available for absorption.<sup>59</sup> To further complicate this issue, combustion also consumes oxygen, further reducing the available oxygen in the environment.<sup>59</sup>

Irritant gases are chemically reactive compounds that exert a local effect on the respiratory tract, primarily through the production of acids, alkalis, or reactive oxygen species (ROS) (Chap. 121). Irritant gases affect all levels of the airway, and in general, their damage leads to swelling and obstruction of the airway, ultimately impairing oxygenation. For irritant gases, the degree of water solubility is the most important chemical characteristic in determining the timing and anatomic location of respiratory tract injury. Highly water-soluble xenobiotics, such as ammonia and hydrogen chloride, primarily injure the upper airway by rapidly combining with mucosal water, leaving little of the parent compound to travel farther down the airway. These xenobiotics quickly damage mucosal cells, which subsequently release mediators of inflammation or ROS.<sup>30,96,113,137</sup> This rapid reaction produces early irritation, potentially providing a warning to the victims that the environment is unsafe and prompting escape. After more than a trivial exposure, the intense inflammatory response increases microvascular permeability

**TABLE 120–1 Toxic Thermal Degradation Products**

Asphyxiants	Irritants
<b>Simple</b>	<b>High Water Solubility (Upper Airway Injury)</b>
Carbon dioxide	Ammonia
<b>Chemical</b>	Hydrogen chloride
Carbon monoxide	Sulfur dioxide
Hydrogen cyanide	<b>Intermediate Water Solubility (Upper and Lower Respiratory Tract Injury)</b>
Hydrogen sulfide	Chlorine
Oxides of nitrogen	Isocyanates
	<b>Low Water Solubility (Pulmonary Parenchymal Injury)</b>
	Oxides of nitrogen
	Phosgene

TABLE 120-2 Common Materials and Their Thermal Degradation Products

Materials	Thermal Degradation Products
Wool	Ammonia, carbon monoxide, chlorine, cyanide, hydrogen chloride, phosgene
Silk	Ammonia, cyanide, hydrogen sulfide, sulfur dioxide
Nylon	Ammonia, cyanide
Wood, cotton, paper	Acetaldehyde, acetic acid, acrolein, carbon monoxide, formic acid, formaldehyde, methane
Petroleum materials	Acetic acid, acrolein, carbon monoxide, formic acid
Polystyrene	Styrene
Acrylic	Acrolein, carbon monoxide, hydrogen chloride
Plastics	Aldehydes, ammonia, chlorine, cyanide, hydrogen chloride, nitrogen oxides, phosgene,
Polyvinyl chloride	Carbon monoxide, chlorine, hydrogen chloride, phosgene
Polyurethane	Cyanide, isocyanates
Melamine resins	Ammonia, cyanide
Rubber	Hydrogen sulfide, sulfur dioxide
Sulfur-containing materials	Sulfur dioxide
Nitrogen-containing materials	Cyanide, isocyanates, oxides of nitrogen
Fluorinated resins	Hydrogen fluoride
Fire retardant materials	Hydrogen bromide, hydrogen chloride

and allows movement of fluid from the intravascular space into the tissues of the upper airway.<sup>17</sup> This inflammation is potentiated by thermal injury, which, because of the efficient cooling mechanisms of the respiratory tract, primarily occurs in the supraglottic airway. The loosely attached underlying tissue of the supraglottic larynx becomes markedly edematous, causing upper airway obstruction within minutes to hours.<sup>79</sup> The obstruction often progresses to the point of complete upper airway occlusion.<sup>144</sup> Xenobiotics with low water solubility, such as phosgene and oxides of nitrogen, react with the upper respiratory mucosa more slowly and do not elicit the irritation and aversion stimulus that prompts an escape response. These xenobiotics more typically reach the distal lung parenchyma, where they react slowly to create delayed toxic effects. Xenobiotics with intermediate water solubility, such as chlorine and isocyanates, are more likely to result in damage to both the upper and lower respiratory tracts. In addition to water solubility, other factors, such as concentration of the inhaled xenobiotic, duration of exposure, particle size, respiratory rate, absence of protective reflexes, and preexisting disease, influence the region of respiratory tract injury. For example, as the concentration of a highly water-soluble irritant gas increases, more chemical is presented to the lower airway, possibly leading to damage of the lower respiratory tract. In addition, patients with loss of consciousness increase their exposure secondary to their loss of protective reflexes.<sup>8,68</sup> Damage to the tracheobronchial tree is mediated by many of the same mechanisms as those of the pharynx and hypopharynx: inhaled particulates and toxic gases result in deposition of corrosives and oxidants. Direct thermal injury is less likely to occur as a result of the efficient cooling ability of the upper airways.<sup>113</sup> Direct injury to the tracheobronchial tree and an intense inflammatory response, evoked in part by airway nociceptive sensory neurons, leads to an increase in airway resistance from mucosal edema, bronchoconstriction, and accumulation of intraluminal debris and airway secretions.<sup>17,83,102,163</sup> Increased tracheobronchial vascular permeability contributes to interstitial edema of the airways and increased airway resistance. Bronchoconstriction and subsequent wheezing are caused by a reflex response to toxic mucosal injury

and a response to mediators of inflammation.<sup>68,164</sup> Damaged cells release chemotactic factors that stimulate production of an exudate rich in protein, including fibrin and inflammatory cells.<sup>54,169</sup> This injury ultimately results in sloughing of the mucosa, which combines with inflammatory cells and exudate to create casts in the airways.<sup>54</sup> Casts can block both the small and large airways, increasing airway resistance and mechanically preventing passage of oxygen to the alveoli.<sup>43</sup>

Irritant xenobiotics that reach the alveoli injure the lung parenchyma.<sup>119</sup> Corrosives, proteolytic enzymes, reactive free radicals, and mediators of inflammation all contribute to acute respiratory distress syndrome (ARDS).<sup>89,132,164,178</sup> Pathophysiologic changes of ARDS decrease lung compliance and bacterial defenses and lead to ventilation-perfusion mismatch with intrapulmonary shunting, increased extravascular lung water, and microvascular permeability.<sup>40,164,169,173</sup> Lung compliance is further decreased by atelectasis when xenobiotics inactivate pulmonary surfactant.<sup>119,129</sup> In animal studies, patchy atelectasis rapidly occurs after smoke inhalation.<sup>119</sup> In addition, ventilation-perfusion mismatch occurs when pulmonary blood flow is diverted both by hypoxia and vasoactive mediators of inflammation.<sup>98,122</sup> Xenobiotics cause additional injury by impairing clearance by the mucociliary apparatus, altering alveolar macrophage function, and impairing phagocytosis of bacteria, all of which predispose to pulmonary infections and sepsis.<sup>18,55,73,143</sup> The combination of the delayed toxic effects of some inhaled xenobiotics and the slowly developing inflammatory response helps explain the progression of parenchymal injury during the first 24 hours after smoke exposure.

Thermal degradation of organic material produces finely divided carbonaceous particulate matter (soot) suspended in hot gases. These carbonaceous particles adsorb other combustion products from the environment, including metals, aldehydes, organic acids, and other reactive chemicals.<sup>88,137</sup> Soot adheres to the mucosa of the airways, allowing adsorbed irritant xenobiotics to desorb and react with the mucosal surface moisture. The deposition of these particles in the respiratory tract depends on their size, with particles of 1 to 3  $\mu\text{m}$  reaching the alveoli.<sup>111</sup> Irritant gases can also adsorb on aerosol droplets and alter the site of gas deposition.<sup>72</sup> This pattern of chemical deposition and desorption from soot or aerosols appears to worsen inhalational injury by enhancing and prolonging exposure to irritants in a fire environment. Accordingly, experimental animals demonstrate markedly decreased lung injury when exposed to toxic gases from smoke that was filtered to remove particulates.<sup>88</sup>

Nitric oxide plays a significant role in the pathogenesis of smoke inhalation-induced lung injury.<sup>51,108,171</sup> Combined smoke inhalation and burn injury results in an upregulation of inducible nitric oxide synthase (iNOS) mRNA synthesis in animal models and subsequently results in increased activity of iNOS.<sup>51,53,108,152</sup> Increased concentrations of nitric oxide results in myocardial contractile dysfunction with subsequent hypotension.<sup>152</sup> Nitric oxide also increases vascular permeability with resultant edema.<sup>108</sup> One possible mechanism is the formation of the highly reactive peroxynitrite (ONOO<sup>-</sup>) radical from the combination of nitric oxide and ROS, which leads to alveolar capillary membrane damage and subsequent ARDS.<sup>51,108</sup> Inhibition of iNOS reduced lung injury in combined smoke inhalation and burn injury in an ovine model.<sup>52</sup>

Chemical asphyxiants considered are primarily carbon monoxide (CO) and cyanide. These chemical asphyxiants impair extrapulmonary oxygen delivery, or utilization, the route of exposure being commonly smoke inhalation, without much, if any direct pulmonary toxicity, *per se*. Incomplete combustion of organic materials generates CO, which is considered the most common serious acute hazard to victims of smoke inhalation injury (Chap. 122).<sup>1,166</sup> Carbon monoxide binds heme and prevents oxygen from binding to the heme of the hemoglobin tetramer; it also hinders the release of oxygen from any remaining oxygenated hemes, shifting the oxyhemoglobin dissociation curve to the left. Overall, this process creates a functional anemia. Carbon monoxide also works at the tissue level, binding myoglobin in cardiac and skeletal muscle and cytochrome oxidase in all tissues.<sup>38,80,160</sup> The combination of these features impairs aerobic respiration systemically. It also

impairs oxygen utilization by the myocardium, contributing to myocardial dysfunction and potentially hypotension, which further hinders oxygen delivery to tissues. Other mechanisms of toxicity induced by CO include induction of oxidative stress and lipid peroxidation of the central nervous system.<sup>160</sup>

Cyanide is produced from combustion of organic nitrogen-containing products that are present in common building materials, such as insulations and laminates.<sup>127</sup> High concentrations of cyanide are measured in air samples from fires, and elevated blood cyanide concentrations occur in both survivors as well as those who die in enclosed space fires.<sup>59,156</sup> Like CO, cyanide impairs aerobic respiration and has at least an additive, if not synergistic, effect with CO in smoke inhalation toxicity (Chaps. 122 and 123).<sup>110,123,136</sup> Combustion of nitrogen-containing materials also generates oxides of nitrogen, which are irritants and rarely induces the formation of methemoglobin (Chap. 124).

Depending on the fuel, other combustion products are aerosolized and act by local irritation or systemic toxicity. Metal oxides, hydrocarbons, hydrogen fluoride, and hydrogen bromide are formed in some fire environments, contributing to toxicity. In addition, antimony, cadmium, chromium, cobalt, gold, iron, lead, and zinc are often recovered from air samples taken during fires and from soot removed from the surface of the trachea and bronchi of fire victims.<sup>19,45</sup> Fires at industrial sites, clandestine drug laboratories, transportation incidents, and natural disasters, (eg, erupting volcanoes) produce additional unique toxic inhalants.

## CLINICAL MANIFESTATIONS

The primary clinical problem in smoke inhalation victims is respiratory compromise; therefore, clinical evaluation should specifically address this issue. Additionally, toxicity from inhaled chemicals, such as CO and cyanide, can lead to cardiovascular dysfunction and hypotension and can directly and indirectly impair mental status. Clinical symptoms suggestive of significant smoke exposure include ocular, mouth, and throat irritation. Cough, chest tightness, and complaints of dyspnea are common.

On examination, soot on the body, face, or airway is suggestive of inhalational injury.<sup>66,68</sup> Burns to the face or singed hairs of the head, face, or nasal passages are associated with an increased risk of inhalational injury but are not present in all patients with significant inhalational injury.<sup>66,68,144</sup> Changes in voice and difficulty managing airway secretions are important signs of progressive airway edema. Visualization of the vocal cords by laryngoscopy is sometimes difficult secondary to soot accumulation, secretions, or edema. Ophthalmic examination should occur in all patients who either complain of ocular symptoms or whose symptoms are unable to be obtained because of unresponsiveness. Thermal and chemical injury results in conjunctival injection, corneal ulcerations and blepharospasm. Rhonchi, crackles, and wheezing on chest auscultation are suggestive of inhalational injury, but these findings are often delayed by 24 to 36 hours and are a poor prognostic indicator if present on initial patient presentation.<sup>66,144</sup> Breath sounds, including wheezing, become virtually inaudible in patients with severe bronchospasm because of gravely diminished air movement.

Tachycardia and tachypnea occur secondary to hypoxemia and systemic xenobiotic toxicity. Hypotension occurs secondary to hypoxemia and systemic toxicity and presents with faint or absent peripheral pulses.<sup>152</sup> Altered mental status, including agitation, confusion, or coma, is most often attributable to hypoxia from either pulmonary compromise or cellular hypoxia, but altered consciousness also results from direct effects of systemic xenobiotics, such as CO, or from concomitant trauma or drug or alcohol intoxication.<sup>8</sup>

## DIAGNOSTIC TESTING

Diagnostic studies should focus on assessing for airway and pulmonary injury as well as the ability of the patient to oxygenate and ventilate. An arterial blood gas (ABG) analysis with cooximetry and chest radiography (CXR) should be obtained initially in all patients with smoke inhalation. Health care professionals should obtain a rapid lactate concentration in all seriously ill patients with smoke inhalation to aid in evaluation of possible cyanide toxicity.

An ABG analysis assesses both pulmonary function (gas exchange) and blood pH. The presence of metabolic acidosis is an early clue to tissue hypoxia

or cyanide poisoning. Serial measurements of arterial oxygenation and ventilation are helpful in identifying progressive hypoxemia or ventilatory failure. The accuracy of oxygen saturation measurement depends on the method used. Measurement of oxygen saturation by transcutaneous pulse oximetry is unreliable in patients with smoke inhalation because it overestimates oxygen saturation in the presence of carboxyhemoglobin.<sup>9,29,167</sup> Similarly, oxygen saturation calculated from standard ABG analysis is unreliable in the setting of an elevated blood CO concentration. An ABG analysis without cooximetry calculates the saturation of hemoglobin from the PaO<sub>2</sub> and does not account for the dysfunctional carboxyhemoglobin. In the setting of smoke inhalation, oxygen saturation is most accurately determined by cooximetry, which directly measures oxygenated and deoxygenated hemoglobin. Acute respiratory distress syndrome is a common complication of smoke inhalation and is defined as acute onset diffuse alveolar filling with hypoxemia not otherwise explained by congestive heart failure or fluid overload.<sup>4</sup> Acute respiratory distress syndrome is classified as mild, moderate, or severe based on the degree of impairment as determined by the ratio of partial pressure of dissolved oxygen (PO<sub>2</sub>) to ratio (Fraction of inspired oxygen {FiO<sub>2</sub>}) (Chap. 28).<sup>4</sup>

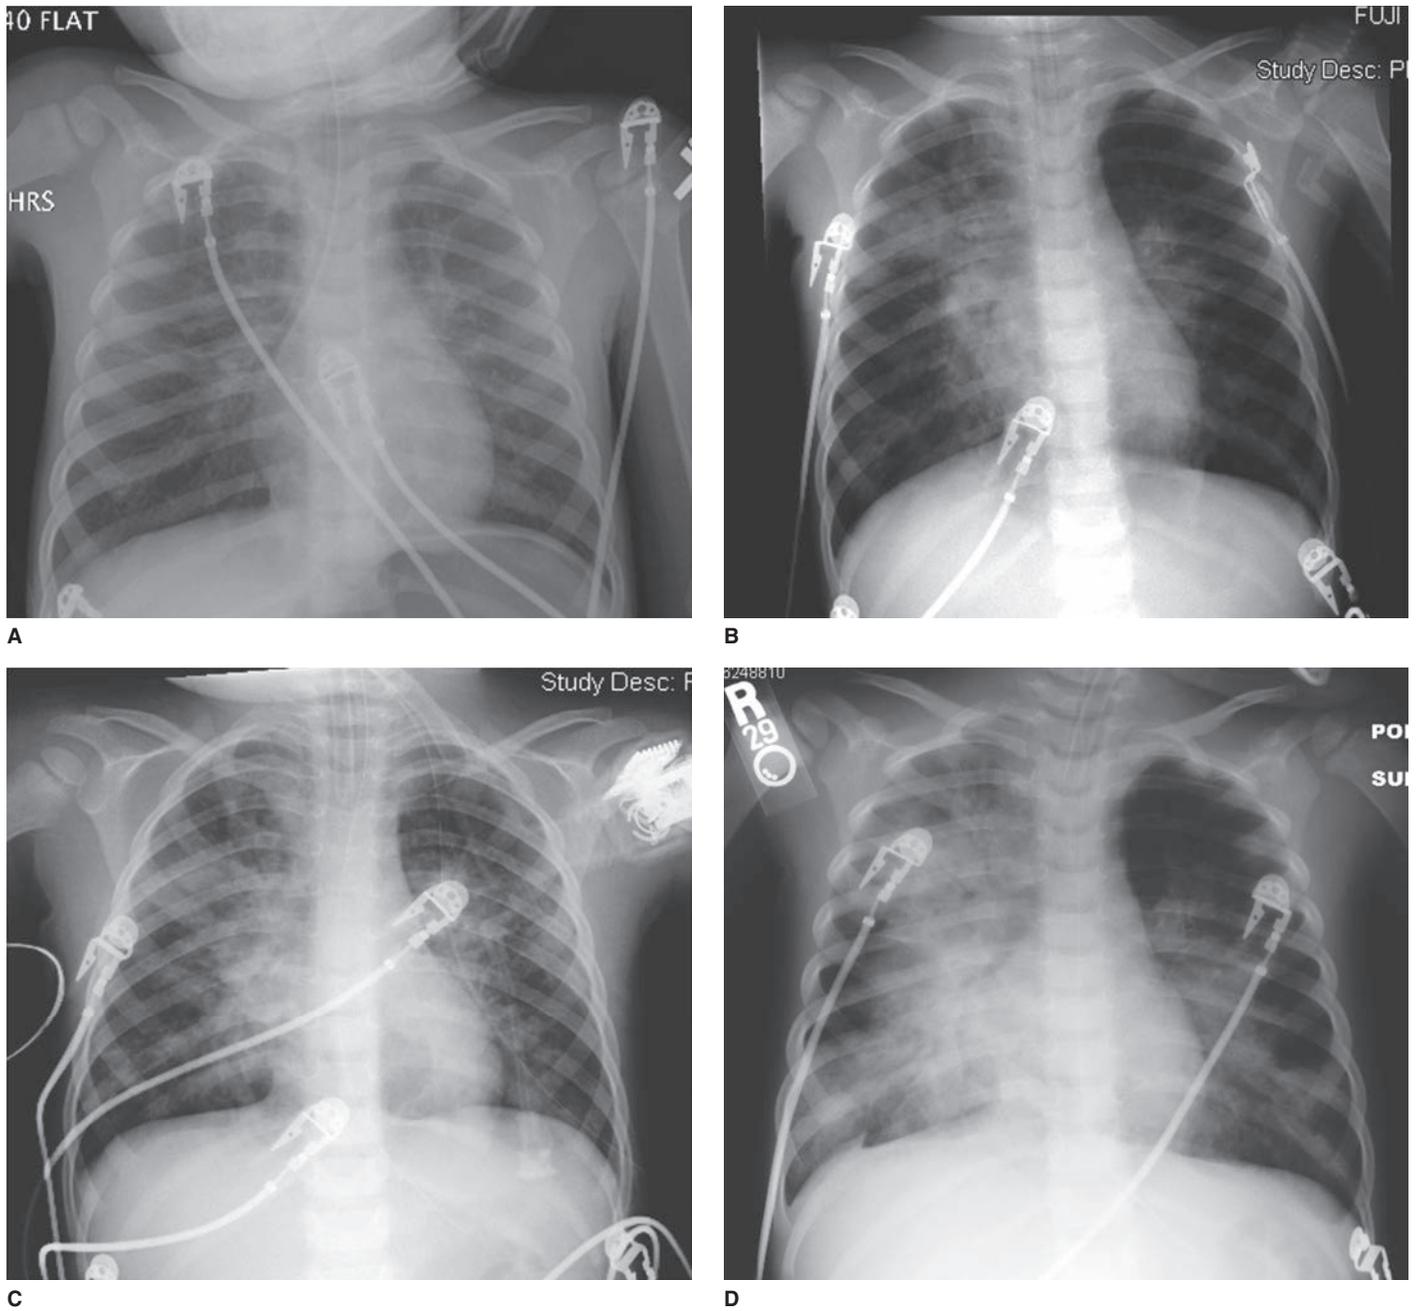

Cooximetry measures both carboxyhemoglobin and methemoglobin levels and is recommended in those with significant exposure or signs or symptoms of smoke inhalation.<sup>39,179</sup> When using blood sampling, either arterial or venous samples will accurately measure carboxyhemoglobin levels.<sup>99</sup> Noninvasive bedside pulse cooximetry is a rapid screening tool for the detection of CO; its use is becoming more prevalent in clinical practice, although device enhancement will be essential (Chap. 28).<sup>146,150</sup> Unfortunately, the carboxyhemoglobin level alone is a poor predictor of the severity of smoke inhalation because a low or nondetectable level does not exclude the possibility of developing inhalation injury.<sup>105,153</sup> Methemoglobin levels are rarely significantly elevated in fire victims. Because methemoglobin can further reduce oxygen-carrying capacity and contribute to morbidity, methemoglobin levels should also be included in the initial laboratory evaluation.<sup>75,149</sup>

Currently, blood cyanide analysis is of little clinical utility because results of analysis are not typically available for hours or days, and therapy should never await laboratory confirmation of the presence of cyanide. Accurate measurement depends on acquiring the sample soon after exposure because cyanide is rapidly eliminated from the blood.<sup>12,85</sup> Blood pH and lactate are more useful tools in acutely assessing for cyanide exposure. A blood lactate concentration of 10 mmol/L or greater suggests cyanide poisoning, as defined by a blood cyanide concentration of 40 micromol/L (1 mg/L), and supports the administration of empiric antidotal treatment to critically ill fire-exposed patients.<sup>12</sup>

Chest radiography is recommended early in the assessment of patients with smoke inhalation but is an insensitive indicator of pulmonary injury.<sup>134,173</sup> In one series of patients admitted to the intensive care unit (ICU) with smoke inhalation, no significant differences in the duration of either mechanical ventilation or duration in the ICU stay were observed between those who exhibited abnormal findings on the first CXR examination and those without abnormalities.<sup>66</sup> The most frequent abnormal findings on initial CXR are diffuse alveolar and interstitial changes, found in up to 34% of patients.<sup>66</sup> Serial CXR after a baseline study are generally more helpful in detecting evolving pulmonary injury after smoke inhalation (Fig. 120–1).<sup>68</sup> Subtle findings within 24 hours of exposure include perivascular haziness, peribronchial cuffing, bronchial wall thickening, and subglottic edema.<sup>92,158</sup> Widespread airway disease usually occurs more than 24 hours after inhalation injury and typically suggests ARDS, aspiration, infection, or volume overload.<sup>158</sup>

Computed tomography (CT) of the lungs is a more sensitive modality than plain radiography for detecting early pulmonary injury after smoke inhalation.<sup>86,131,141</sup> Computed tomography scanning allows for evaluation of the lung parenchyma and emerging data suggests CT scanning has some value as a “virtual bronchoscopy” for diagnosis and prediction of complications. However, no data are currently available to support improved patient outcomes when using this radiographic modality. Therefore, at this time we recommend against the routine use of CT scanning in patients with smoke inhalation.

In intubated patients, diagnostic fiberoptic bronchoscopy remains the standard in assessing smoke inhalational injury.<sup>154</sup> Bronchoscopy allows for

**FIGURE 120-1.** (A) Initial chest radiograph of a 3-year-old boy involved in a structural fire (approximately 60 minutes after the event). (B) Chest radiograph approximately 3 hours after exposure demonstrating the appearance of right upper lobe and perihilar infiltrates. (C) Evolution of chest radiograph findings approximately 17 hours after initial exposure demonstrating evolution of the right upper and perihilar infiltrates. (D) Approximately 60 hours after exposure demonstrating diffuse alveolar and interstitial infiltrates representative of inhalation-induced acute respiratory distress syndrome. (Used with permission from The University of Virginia Medical Toxicology Fellowship Program.)

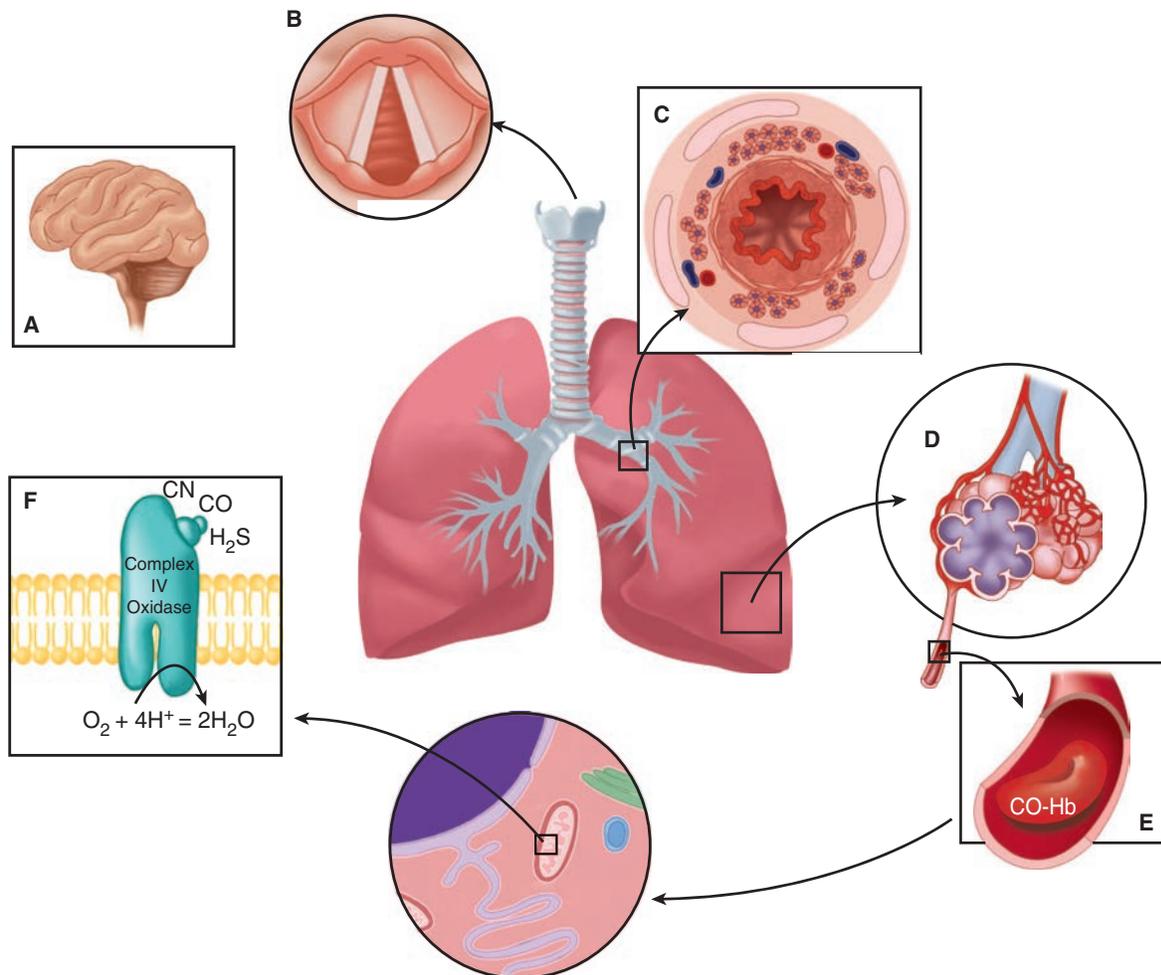

direct visualization of the upper airways, allows for grading of the injury, and helps to determine those at risk for developing inhalational injury.<sup>2,114,154</sup> Bronchoscopy does not visualize the distal airways or lung parenchyma, which helps account for the discrepancies between studies correlating grading of bronchoscopy injury severity and outcome.<sup>154</sup> Early diagnostic bronchoscopy has yet to show an improvement in patient outcome, but because it aids in diagnosis and helps assess the severity of injury, it is reasonable to perform in intubated patients with suspicion of inhalation injury.<sup>2,114,125</sup>

## MANAGEMENT

From oxygen acquisition to cellular utilization, the final common pathophysiologic effect from smoke injury is hypoxia. Basic critical care strategies that optimize oxygen delivery and utilization are of primary importance in

treatment. After the patient is removed from the source of exposure and oxygen is administered, the primary problems that the clinician must treat are the effects of thermal injury and irritant gases on the airway and systemic effects of cellular asphyxiants. High-flow humidified oxygen should accompany initial resuscitation in symptomatic patients. In critically ill patients insert two large-bore intravenous (IV) lines and provide appropriate fluid resuscitation as clinically warranted to optimize perfusion and aid in oxygen delivery. The clinical effects of smoke exposure and their appropriate treatment are described in Fig. 120-2.

Critical airway compromise is often present upon initial hospital presentation or develops in the ensuing hours.<sup>67,144</sup> A major pitfall in the management of smoke inhalation is failing to appreciate the possibility of rapid deterioration. History and physical findings help to determine significant

Pathophysiology	Signs and symptoms	Management
<b>A)</b> Direct CNS toxic effects	Coma Hypoventilation	Oxygen; Endotracheal intubation
<b>B)</b> Upper airway edema	Hypoxemia; respiratory distress Stridor Hoarse voice	Oxygen Direct visualization of vocal cords Endotracheal intubation
<b>C)</b> Bronchiolar airway obstruction Mucosal edema Intraluminal debris and casts Inspissated secretions Bronchospasm	Respiratory distress Hypoxemia Wheezes Cough Increased peak airway pressures	Oxygen Removal of debris and secretions Chest physiotherapy Frequent airway suctioning Therapeutic bronchoscopy Inhaled $\beta$ -adrenergic agonists
<b>D)</b> Atelectasis Surfactant destruction Acute respiratory distress syndrome (ARDS)	Respiratory distress Hypoxemia Crackles Chest radiographic changes	Oxygen Continuous positive airway pressure Mechanical ventilation Lung protective ventilation
<b>E)</b> Impaired oxygen carrying capacity and delivery (carbon monoxide or methemoglobinemia)	CNS depression or seizures Myocardial ischemia Dysrhythmias Metabolic acidosis	Oxygen Hyperbaric oxygen as clinically indicated Methylene blue as clinically indicated
<b>F)</b> Impaired oxygen use at tissues (cyanide, hydrogen sulfide and/or carbon monoxide)	CNS depression or seizures Myocardial ischemia Dysrhythmias Metabolic acidosis	Oxygen Ensure adequate tissue perfusion Treat suspected cyanide toxicity with cyanide antidote Hyperbaric oxygen as clinically indicated

**FIGURE 120-2.** The final common pathway from all pathophysiologic changes that occur in smoke inhalation is hypoxia. All treatments should be focused on improving oxygen delivery and oxygen utilization.

thermal injury or smoke exposure and the potential for clinical deterioration. Early airway intervention is recommended as a seemingly patent airway develops progressive obstruction that can make subsequent intubation difficult or impossible. For signs of current or impending airway compromise, upper airway patency must be rapidly established. When obvious oropharyngeal burns are observed, upper airway injury almost certainly is present. Singed hairs of the head, face, or nasal passages and soot or carbonaceous sputum in the oropharynx or nares signify potential for airway edema.

Direct evaluation of the upper airway, preferably with fiberoptic endoscopy, is essential for assessing patients at high risk for inhalation airway injury.<sup>67,68,79</sup> When evidence of upper airway injury exists, early endotracheal intubation should be performed under controlled circumstances, with preparations for advanced or surgical airway interventions in the event that orotracheal intubation cannot be easily established. Other indications for early intubation include coma, stridor, and full-thickness circumferential neck burns.<sup>10,67,68,144</sup> Edema of injured tissue, including that of the airway, is worsened with substantial fluid resuscitation in burned patients; therefore, we recommend early intubation for patients with any amount of inhalation injury and concomitant dermal burns undergoing fluid resuscitation.<sup>67,68,117,144</sup>

Even if overt injuries are not visualized, distal injury is often present and underestimated.<sup>67</sup> Pathophysiologic changes in the lung results in progressive hypoxia over hours to days. Basic treatment of progressive respiratory failure includes continuous positive airway pressure, mechanical ventilation using lung protective strategies, positive end-expiratory pressure (PEEP), and vigorous clearing of pulmonary secretions.<sup>120</sup> Decreased lung compliance is common secondary to cast formation, tissue damage, and atelectasis.<sup>109,120</sup> Recommendations for limiting barotrauma in mechanically ventilated patients include using a low tidal volume (6–8 mL/kg) and PEEP and allowing permissive hypercapnia as necessary.<sup>97,109,159</sup> The fraction of inspired oxygen should be weaned to below 0.4 as rapidly as tolerated to limit oxygen toxicity.<sup>109</sup> Frequent airway suctioning, chest physiotherapy, and therapeutic bronchoscopy clear inspissated secretions, plugs, and casts.<sup>43,109,116</sup> Because xenobiotics and soot can coat the airway in smoke inhalation victims, early bronchoscopy with bronchoalveolar lavage would intuitively be logical in an attempt to decontaminate the airway, similar to irrigation for dermal exposure. However, because only one study suggests that early and scheduled therapeutic bronchoscopy improves overall morbidity in patients with smoke inhalation, we recommend the use of bronchoscopy and bronchoalveolar lavage for therapeutic purposes on a case-by-case basis as needed for clearing airway obstruction.<sup>34</sup>

High-frequency percussive ventilation (HFPV), a method of ventilation that combines a high-frequency low tidal volume with pressure control ventilation, has been studied as an alternative to conventional forms of ventilation in patients with inhalational injury. Studies suggest that HFPV improves lung function by aiding the clearance of intraluminal airway debris and recruiting alveoli.<sup>148</sup> Several studies have investigated the use of HFPV in ventilated patients with inhalational injury. Limited evidence suggests that HFPV decreases peak pulmonary pressures, limits barotrauma, decreases the incidence of pneumonia, and improves the mortality rate in patients with smoke inhalation injury.<sup>37,42,62,109,140</sup> Therefore, HFPV is reasonable to use in patients in whom conventional low tidal volume lung protective strategies fail to provide adequate oxygenation. The role of extracorporeal membrane oxygenation (ECMO) in victims of smoke inhalation is unclear. Although multiple case reports document its use in patients with inhalational injury, there is limited evidence and no high-quality studies to support its use in smoke inhalation injury.<sup>5,128</sup> However, as expertise in the use of ECMO has greatly progressed in recent years, it seems reasonable to use this modality as a rescue therapy in patients failing more conventional ventilation strategies.

Inhaled  $\beta_2$ -adrenergic agonists are the first-line therapy for acute reversible bronchoconstriction resulting from asthma or chronic obstructive pulmonary disease and are recommended to improve oxygenation and ventilation in victims of smoke inhalation. Pathophysiologic changes induced by irritant gases in smoke are similar to those found in asthma, suggesting that  $\beta_2$ -adrenergic agonists would also improve airflow obstruction in smoke

inhalation.<sup>84,104</sup>  $\beta_2$ -Adrenergic agonists also possess antiinflammatory properties, partially through interaction with  $\beta$ -adrenergic receptors on immune cells.<sup>103,172</sup>  $\beta_2$ -Adrenergic agonists also enhance resolution of alveolar edema by modulating the flow of sodium and potassium across cell membranes.<sup>103,172</sup> Limited data in an ovine model suggest that nebulized albuterol improves pulmonary function after smoke inhalation and burn injury.<sup>130</sup> Nebulized epinephrine improved oxygenation and decreased pulmonary vascular permeability in animal models but differs from albuterol in that it provides both  $\alpha$ - and  $\beta$ -adrenergic agonist activity.<sup>90,100</sup> Although human data on the efficacy of  $\beta_2$ -adrenergic agonists in smoke inhalation injury are lacking, their role is well established in conditions with reversible bronchoconstriction, animal studies lend support for their use, and the potential benefits greatly outweigh the risks.<sup>130,172</sup> Accordingly, we recommend the use of nebulized albuterol in victims of smoke inhalation injury with evidence of bronchospasm.

Corticosteroids have been used for smoke inhalation in an attempt to limit inflammation and improve outcome. One argument for their use is for the treatment of lung injury induced by oxides of nitrogen. Pulmonary sequelae, including bronchiolitis obliterans, are known to occur after significant exposure to oxides of nitrogen, which are sometimes a prominent component of smoke.<sup>77,93</sup> The mixed xenobiotic exposure from smoke inhalation appears to further complicate the outcome. One early rat study showed a trend toward reduced mortality rates in animals given supraphysiologic doses (25–100 mg/kg) of methylprednisolone; however, other tested corticosteroids (hydrocortisone, dexamethasone, cortisone) failed to demonstrate similar improvement. Consequently, this study failed to effectively prove that corticosteroids reduce mortality rates after rat exposure to smoke.<sup>49</sup> Human studies have also failed to show an improvement in clinical outcome and trend toward worsening outcome.<sup>35,94,121,145</sup> Thus, we do not recommend the routine use of corticosteroids for treatment of patients with smoke inhalation.

A significant amount of pulmonary injury after smoke inhalation is attributable to free radical damage. Smoke inhalation decreases systemic concentrations of the antioxidant vitamin E in sheep models, and treatment with nebulized vitamin E ( $\alpha$ - and  $\gamma$ -tocopherol) attenuates smoke inhalation induced pulmonary injury in animal models.<sup>64,112,165,176</sup> Similarly, both nebulized heparin and *N*-acetylcysteine (NAC) are used by some centers to limit pulmonary damage.<sup>106</sup> Heparin is a glycosaminoglycan with anticoagulant and antiinflammatory properties occasionally used both topically and intravenously in burn treatment. In an ovine model of combined cutaneous burn and smoke inhalation, nebulized heparin combined with recombinant human antithrombin reduced airway obstruction and improved gas exchange.<sup>54</sup> The mechanism is likely attributable to decreased airway inflammation and decreased fibrin deposition and, consequently, decreased cast formation in the airway.<sup>54</sup> Although literature regarding the use of inhaled anticoagulants show variable results, a systematic review of both animal and human clinical data found an association between inhaled anticoagulants and improved mortality from smoke inhalation-associated ARDS.<sup>48,76,106,107</sup> The five human studies included were retrospective analyses of smoke-injured patients treated with nebulized heparin and NAC.<sup>107</sup> At the doses used (typically either 5,000 U or 10,000 U of heparin nebulized every 4 hours), patients did not experience changes in systemic coagulation parameters. However, an additional recent retrospective study demonstrated no difference in mortality or length of ICU stay among patients treated with heparin and NAC and a no treatment control group. In this study, the treatment group had a higher rate of pneumonia compared to the control group.<sup>82</sup> Further data are needed to provide evidence regarding inhalational treatment with heparin, NAC, or both. Although human data are currently limited, with only animal studies and human retrospective data available, it would be reasonable to use nebulize heparin and NAC for the treatment of intubated patients with bronchoscopy confirmed smoke inhalation and associated ARDS.<sup>107</sup> Care should be taken to monitor for pneumonia, which, in one study, had a higher incidence in treated patients.

The initial treatment strategy for patients with CO poisoning should focus on optimizing oxygen delivery to the tissues. Oxygen can be administered

by a high-flow tight-fitting mask, endotracheal tube, or hyperbaric oxygen therapy (HBO). Oxygen shortens the half-life of carboxyhemoglobin, the rate of which inversely correlates with the  $PO_2$  of the patient.<sup>135,170</sup> Hyperbaric oxygen can achieve very high arterial oxygen concentrations, enhancing oxygen delivery to tissues and accelerating elimination of CO from blood and tissues.<sup>69,135</sup> Hyperbaric oxygen therapy is recommended as a modality for treatment in certain situations involving CO exposure; however, smoke inhalation injury is much more complex than poisoning solely with CO, such as that caused by a furnace leak.<sup>65</sup> In victims of smoke inhalation, other clinical requirements, such as maintaining a secure airway and the need for additional resuscitative measures to treat ARDS, cardiovascular instability, and metabolic derangements go beyond providing supplemental oxygen to treat CO poisoning. Optimal timing of HBO administration is often during the same period when intensive resuscitative efforts and focused ventilator management are required and could limit attention to these important therapies. Irritant-induced bronchospasm along with exudates and airway casts increase the risk of air trapping, potentially leading to HBO-induced barotrauma.<sup>31,115</sup> In addition, it is known that pulmonary toxicity results from elevated partial pressures of oxygen.<sup>151</sup> Very little information is available to predict the effect of hyperoxygenation on pulmonary toxicity after smoke inhalation.<sup>161,175</sup> The decision to treat a smoke inhalation patient with HBO should take into account risks and other clinical requirements when determining the appropriate therapy because the therapeutic priority is meticulous supportive care and high-flow oxygen therapy. A judicious approach to the treatment of CO poisoning in smoke inhalation is administering 100% oxygen by a tightly fitting mask (or an endotracheal tube if intubated) as long as clinically appropriate (Chap. 122 and Antidotes in Depth: A40).<sup>28,174</sup>

Cyanide is a common product of combustion, with toxic concentrations often measured in fire victims. Because rapid determination of blood cyanide concentrations is not readily available in the prehospital setting or in the emergency department, surrogate markers must be used to help establish the diagnosis. Cyanide poisoning should be suspected in patients involved in enclosed-space fires with evidence of smoke inhalation, particularly in the presence of altered mental status, hemodynamic instability or metabolic acidosis with an elevated lactate concentration.<sup>56,142</sup> Serum lactate concentrations correlate closely with blood cyanide concentrations. In a study of smoke inhalation victims, a blood lactate concentration of 10 mmol/L was reported to be a sensitive indicator of cyanide toxicity as defined by a blood cyanide concentration above 40 micromol/L (1 mg/L).<sup>12</sup> However, in this study, 26% of fatalities occurred in patients with a blood cyanide concentration less than 40 micromol/L (1 mg/L), possibly because of the compounding effects of cyanide and other toxic products of combustion such as CO. Carboxyhemoglobin levels of more than 10% also correlated with elevated cyanide concentrations.<sup>12</sup> Studies also indicate that smoke inhalation victims with cardiac arrest, those who must be rescued from the environment, and those with soot on the face, oral cavity, neck or carbonaceous sputum are more likely to have elevated blood cyanide concentrations.<sup>12,58</sup> For patients with suspected cyanide poisoning, specific treatment of cyanide toxicity should be implemented while other life support measures are instituted. Systematic reviews of various cyanide antidotes conclude that it is possible to survive even cardiorespiratory arrest caused by cyanide poisoning if the patient is provided optimal supportive care and an appropriate antidote.<sup>124</sup>

Cyanide antidotes function as an adjunct to basic critical care strategies that optimize oxygen delivery and utilization. The components of the classic cyanide antidote kit, amyl nitrite and sodium nitrite, hinder this strategy and therefore should not be routinely used in victims of smoke inhalation. Amyl nitrite and sodium nitrite produce methemoglobinemia, (Chap. 124 and Antidotes in Depth: A43). Unfortunately, methemoglobin is a dysfunctional type of hemoglobin that poorly utilizes oxygen, impairing delivery to the tissues.<sup>44</sup> Impairing oxygen-carrying capacity and oxygen delivery to tissues with nitrite-induced methemoglobinemia is a valid concern in the presence of tissue hypoxia from carboxyhemoglobinemia, lung injury, or other factors. Furthermore, rapid infusion of sodium nitrite causes hypotension secondary to vasodilation.<sup>61</sup>

Hydroxocobalamin is a vitamin B<sub>12</sub> (cyanocobalamin) precursor that works by chelating cyanide from the cytochrome system and acting as a nitric oxide scavenger. It comes as a red crystalline powder that must be reconstituted and then administered intravenously over 15 minutes.<sup>162</sup> Animal studies focus on poisoning by cyanide salts over cyanide poisoning from smoke inhalation but demonstrate improvement in blood pressure parameters when hydroxocobalamin was compared with the combination of sodium thiosulfate and sodium nitrite, and improved mortality compared with either placebo or sodium thiosulfate alone.<sup>14,15,20</sup> There are no human studies providing head-to-head data on cyanide antidotes in smoke inhalation. Human studies are limited to retrospective or prospective case series that are poorly controlled. Authors of these articles typically report improved survival and few adverse events, but use either historic controls or typically lethal blood concentrations of cyanide as comparison groups, limiting the strength of the evidence.<sup>21,22,57</sup> Side effects of hydroxocobalamin administration include red or pink discoloration of the skin, red discoloration of the urine, and alteration in some laboratory parameters, including carboxyhemoglobin concentrations.<sup>33,91</sup> In addition, certain hemodialysis machines can be adversely affected by red discoloration or the plasma leading to a blood leak error warning.<sup>155</sup> Although the evidence for the use of hydroxocobalamin for patients with cyanide poisoning from smoke inhalation is limited, this antidote appears to be superior to sodium thiosulfate or supportive care alone.<sup>14,15</sup> Because nitrites have a more detrimental side effect profile and are likely detrimental to patients with concomitant CO poisoning, hydroxocobalamin is recommended as first-line therapy when cyanide poisoning is suspected in victims of smoke inhalation.

In the prehospital setting or if unable to obtain a rapid lactate concentration, for patients involved in an enclosed-space fire with signs of inhalation injury and the presence or altered mental status or hemodynamic instability (systolic blood pressure of 90 mm Hg or less), it is reasonable to administer hydroxocobalamin. If a rapid lactate concentration is available, hydroxocobalamin is recommended for to such patients with a lactate concentration greater than or equal to 10 mmol/L. Few data are available to guide clinicians for patients who have evidence of smoke inhalation and the lactate concentration is elevated but less than 10 mmol/L. For patients with an elevated lactate concentration less than 10 mmol/L with altered mental status or hemodynamic instability, it is reasonable to administer hydroxocobalamin. For patients who are hemodynamically stable and without significantly altered mental status and who have an elevated lactate less than 10 mmol/L, it is reasonable to monitor these patients closely while performing resuscitation and considering other causes of the elevated lactate concentration.<sup>3,57,63,101</sup> The initial dose of hydroxocobalamin is 70 mg/kg (5 g in an adult) intravenously, with the option of subsequent dosing of 70 mg/kg (5 g in an adult) intravenously for signs of continued cyanide toxicity or if in cardiac arrest (Chap. 123 and Antidotes in Depth: A41 and A42).<sup>78</sup> It is reasonable to use sodium thiosulfate as adjunctive therapy, but it should not be given concomitantly through the same IV line.<sup>138</sup>

Victims of fires have respiratory compromise and other pathology not directly related to smoke inhalation, such as trauma or other underlying medical problems. Trauma from falls or explosions must be suspected and treatment started simultaneously with treatment of burns and inhalation injury. Comatose patients should be evaluated for other causes of their status and should receive naloxone, thiamine, and hypertonic dextrose as indicated. Inhaled xenobiotics, such as CO directly, cause altered mental status, but drug and ethanol intoxication also contribute significantly to fire fatalities and injuries. Blood ethanol concentrations in fire victims correlate with elevated levels of CO and concentrations of cyanide, suggesting that intoxication impairs escape and prolongs toxic smoke exposure.<sup>8,19,118</sup> Intracranial pathology should be considered and noncontrast head CT scans obtained as clinically indicated.

Xenobiotics often injure the skin or mucous membranes in addition to the respiratory mucosa.<sup>41</sup> The duration of contact of a xenobiotic with tissue is an important factor in determining the extent of chemical injury to the skin and eyes. Rapid removal of soot from the skin or eyes helps to prevent

continued injury. The eyes should be evaluated for corneal burns caused by thermal or irritant chemical injury. Patients with signs of ophthalmic irritation should have their eyes irrigated, and dermal decontamination performed as necessary to prevent burns from toxin-laden soot adherent to the skin (Special Considerations: SC2).

## SUMMARY

- Smoke inhalation contributes significantly to the morbidity and mortality of fire victims.
- Smoke inhalation is a complex syndrome involving diverse toxicologic injuries. A spectrum of damage occurs, ranging from rapid upper airway occlusion to delayed ARDS.
- The end result of respiratory tract toxicity is tissue hypoxia.
- Goals of treatment should focus on maximizing oxygen delivery while avoiding unnecessary therapies that may hinder oxygenation.
- Early airway management should be implemented for patients with airway compromise. High-flow oxygen will help reverse tissue hypoxia, and fluid resuscitation should be instituted to improve cardiovascular status if indicated.
- Definitive antidotes and procedures for cyanide and carbon monoxide are available in select cases and should be used when appropriate to help stabilize the patient.

## CASE STUDY 13

**History** A 29-year-old bank teller presented to the emergency department in cardiopulmonary arrest. While working an evening shift, she entered the bank vault, and the door closed behind her. She called for help but was unable to get assistance, so she pulled the fire alarm to alert security to her presence. When the fire department arrived, she was found unresponsive and pulseless on the floor.

**Physical Examination** The patient was pulseless on the stretcher with chest compressions in progress. No obvious signs of trauma or other injury were visible.

**Initial Management** The patient was immediately intubated, chest compressions were continued, and intravenous epinephrine 1 mg of 0.1 mg/mL solution was administered. The patient was still pulseless, and the monitor demonstrated asystole, so defibrillation was not performed.

### What is the Differential Diagnosis?

This patient presented in cardiopulmonary arrest with no known history of ingestion or overdose after being in a bank vault. This should make a toxic inhalant high on the differential diagnosis list (Chaps. 121 to 123). Simple asphyxiants lead to toxicity purely through the displacement of oxygen from the air. Simple asphyxiants should

have no independent pharmacologic activity. The severity of symptoms depends on the degree of hypoxia. A few examples of simple asphyxiants are helium, argon, and methane gases. Carbon dioxide is typically also described as a simple asphyxiant; however, a property of carbon dioxide that differentiates it from other simple asphyxiants is that carbon dioxide acts on the body's chemoreceptors, leading to an increased respiratory rate and therefore a more rapid displacement of oxygen from the body.

Inhalants such as carbon monoxide, cyanide and hydrogen sulfide, on the other hand, work through impairing the ability of the body to use oxygen. Hydrogen sulfide, which is found in sewers, is commonly referred to as a "knockdown gas" (Chap. 123). Hydrogen sulfide is a mitochondrial toxin, and the classic description of exposure to hydrogen sulfide includes several people who serially enter an enclosed space and have cardiac arrest. Another example to consider in a patient who has a rapid cardiac arrest, especially in a young, otherwise healthy individual, is cyanide (Chap. 123).

**What Chemical and Laboratory Analyses Help Identify the Cause of This Patient's Presentation?** Unfortunately, in someone who is in active cardiopulmonary arrest, laboratory values will unlikely

return in a rapid enough time to assist in diagnosis. An elevated lactate concentration is typically associated with chemical asphyxiants; however, in the setting of a patient in active cardiopulmonary arrest, the elevation is not specific. The single most important information to acquire is the background as to how the patient collapsed and to use that history to guide management.

**Further Diagnosis and Treatment** The treatment for all toxic inhalants is to remove the patient from the exposure and to administer supplemental oxygen as needed. In patients who were otherwise well and present with sudden cardiac arrest, a high suspicion is necessary for cyanide toxicity, and hydroxocobalamin administration is appropriate (Antidotes in Depth: A41). In this case, the history of the cardiac arrest after pulling the fire alarm makes cyanide less likely.

The patient had pulled a fire alarm, while she was enclosed inside a bank vault. Because bank vaults contain currency and monetary instruments, using water is undesirable, and most fire extinguishers are carbon dioxide based. The patient was unable to be resuscitated and was pronounced dead. The medical examiner listed the cause of death as carbon dioxide intoxication.

# SIMPLE ASPHYXIANTS AND PULMONARY IRRITANTS

Lewis S. Nelson and Oladapo A. Odujebu

The respiratory system is responsible for gas exchange, elimination of certain xenobiotics, insensible water loss, temperature regulation, and minor metabolic processes. The principal function of the respiratory system is gas exchange, which occurs in the more than 300 million alveoli that make up approximately 90% of the human lung volume. The average resting adult inhales about 8 L/min of air (a tidal volume of about 500 mL) and averages 16 breaths/min, and this volume can be increased exponentially by increasing the respiratory rate and tidal volume as occurs during exertion. In a 24-hour period, an average adult human at rest will be exposed to 11,500 L of air. There are a number of protective mechanisms within the respiratory system to prevent exposure to xenobiotics, but these mechanisms can be overwhelmed. The principles of respiratory system function are covered extensively in Chap. 28.

The respiratory tract performs several important physiologic functions. Its most important role involves the transfer of oxygen to hemoglobin across the pulmonary endothelium. This transfer facilitates oxygen distribution throughout the body to permit effective cellular respiration. Diverse xenobiotics act at unique points in this distribution pathway to limit or impair tissue oxygenation. For example, whereas opioids and neuromuscular blockers induce hypoventilation, carbon monoxide and methemoglobin inducers prevent loading and unloading of oxygen onto and off hemoglobin. Certain xenobiotics prevent adequate oxygenation of hemoglobin at the level of pulmonary gas exchange. Two mechanistically distinct groups of xenobiotics are capable of interfering with gas exchange: simple asphyxiants and pulmonary irritants. Impairment of transpulmonary oxygen diffusion, regardless of the etiology, reduces the oxygen content of the blood and results in tissue hypoxia.

## HISTORY AND EPIDEMIOLOGY

Unlike most xenobiotic exposures, simple asphyxiant and pulmonary irritant poisonings frequently occur on a mass scale due to the magnitude of these exposures. For example, the large-scale emission of carbon dioxide (CO<sub>2</sub>) from Lake Nyos, a carbonated volcanic crater lake in Cameroon, West Africa, resulted in nearly 2,000 human deaths and many more livestock deaths (Chap. 2).<sup>8</sup> In this disaster, simple asphyxiation was likely because medical evaluation of both survivors and fatalities demonstrated neither signs of cutaneous or pulmonary irritation nor toxicologic abnormalities.<sup>128</sup> Exposure to compressed liquefied gases, which expand several hundredfold on depressurization or warming, accounts for a substantial number of workplace injuries.<sup>114</sup>

Irritant gases similarly result in mass casualties. For this reason, chlorine and phosgene were used in battle during World War I, resulting in thousands of Allied deaths (Chap. 126). Atmospheric sulfur dioxide and oxides of nitrogen are the primary components of photochemical smog. During the London Fog incident in 1952, 4,000 deaths occurred, primarily from respiratory causes.<sup>102</sup> Similar smog incidents continue to occur around the globe. Relatedly, the diverse irritants found in fire smoke are a major cause of death after smoke inhalation.<sup>113</sup>

Unexpected release of other irritant inhalants leads to large-scale poisoning. In 1984, an inadvertent release of methyl isocyanate (MIC) in Bhopal, India, resulted in immediate and persistent respiratory symptoms in approximately 200,000 local inhabitants, with approximately 2,500 deaths.<sup>82</sup>

Isolated exposures to individuals occur as well, often in workplaces, and more frequently in contained spaces (eg, indoors). Simple asphyxiation as a painless and relatively undetectable method for committing suicide and, paradoxically, for euphoric and erotic experiences, are found in books, on the Internet, and in the medical literature.<sup>39,45,108</sup>

## SIMPLE ASPHYXIANTS

Simple asphyxiants work primarily by displacing oxygen from ambient air, unlike chemical asphyxiants, which cause cellular hypoxia and are discussed in Chaps. 122 to 124. Virtually every gas, excluding oxygen, is capable of acting as a simple asphyxiant.

### Pathophysiology

Simple asphyxiants displace oxygen from ambient air, thereby reducing the fraction of inspired oxygen (FiO<sub>2</sub>) in air to below 21%, and result in a decrease in the partial pressure of oxygen. The partial pressure is a measure of the contribution of oxygen to the total inspired air and is based on both FiO<sub>2</sub> and barometric pressure. For example, because the ambient pressure at sea level (less water vapor, 47 mm Hg) is 713 mm Hg and the percentage of oxygen is 21% (nitrogen 78%), the partial pressure of oxygen in the lungs is 150 mm Hg. However, this relationship is not applicable at other barometric pressures. For example, at the summit of a mountain, the reduced barometric pressure results in a decrease in the partial pressure of oxygen despite a near-normal FiO<sub>2</sub>. The barometric pressure decreases in a linear fashion with altitude (above sea level) and increases with descent below sea level. This reduced partial pressure is insufficient to allow adequate oxygen saturation in certain individuals, and supplemental oxygen becomes necessary. As barometric pressure decreases, exposure to simple asphyxiant gases further reduces the oxygen partial pressure to life-threatening levels. Conversely, underwater divers reduce their FiO<sub>2</sub> to below 21% by adding an inert gas, such as helium, to their breathing mixture to avoid oxygen toxicity, yet they maintain adequate oxygenation. This occurs because the elevated barometric pressure increases the partial pressure of oxygen to normal amounts despite the addition of an asphyxiant. However, systemically poisonous gases that enter the breathing mixture would have a magnified effect, given their increased partial pressure at depth.

Conceptually, simple asphyxiants have no pharmacologic activity. For this reason, exceedingly high ambient concentrations of these gases are necessary to produce asphyxia. Asphyxiation typically occurs in confined spaces or with rapid release of large volumes of simple asphyxiants.

### Clinical Manifestations

A patient exposed to any simple asphyxiant gas will develop characteristic clinical findings of hypoxia, or lack of oxygen at the cellular level (Table 121-1). These clinical findings are directly related to the reduction in the partial

**TABLE 121-1** Clinical Findings Associated with Reduction of Inspired Oxygen

FiO <sub>2</sub> <sup>a</sup>	Signs and Symptoms
21	None
16–12	Tachypnea, hyperpnea, (resultant hypocapnia), tachycardia, reduced attention and alertness, euphoria, headache, mild incoordination
14–10	Altered judgment, incoordination, muscular fatigue, cyanosis
10–6	Nausea, vomiting, lethargy, air hunger, severe incoordination, coma
<6	Gasping respiration, seizure, coma, death

<sup>a</sup>At sea level, barometric pressure; appropriate adjustments must be made for altitude and depth exposures.

FiO<sub>2</sub> = fraction of inspired oxygen.

pressure of oxygen in ambient air, which leads to hypoxemia, or low oxygen content of the blood.<sup>128</sup> Cardiovascular and central nervous system (CNS) complications of simple asphyxiants predominate because these organs have the greatest oxygen requirements. As hypoxemia becomes severe, multisystem organ failure and death from tissue hypoxia occur.<sup>28</sup> Postmortem findings are generally minimal, hampering the cause of death determination without historical evidence or advanced laboratory testing.

Exposure to simple asphyxiants does not impair CO<sub>2</sub> exchange, and hypercapnia does not occur. Because dyspnea develops more rapidly from hypercapnia than hypoxemia, the breathlessness associated with physical or simple chemical asphyxiation does not develop until severe hypoxemia intervenes.<sup>75</sup> In these circumstances, victims frequently succumb to hypoxemia without ever developing the expected warning symptoms. In the case of CO<sub>2</sub> inhalation, hypercapnia occurs very rapidly, which itself produces acute cognitive impairment.

## Specific Xenobiotics

### Noble Gases: Helium, Neon, Argon, and Xenon

Noble gases, which are stored almost exclusively in the compressed form, have numerous industrial and medical roles. Argon is predominantly used as a shielding gas during welding operations, and it is also used in processing titanium and growing crystals. Neon is used in the manufacture of decorative lighting. Xenon, in its radioactive gaseous form, has diagnostic medical applications in ventilation–perfusion scans. Xenon is also used in lighting, solar simulators, digital projectors, and plasma display cells (along with neon). Helium has the lowest molecular weight and is the smallest member of the noble gas family of elements. Because of its lower lipid solubility, helium is often the inert gas used by divers to replace nitrogen to prevent nitrogen narcosis at depth (see Nitrogen). Even using gas mixtures of 50% helium, divers have no adverse effects as long as a normal partial pressure of oxygen is maintained by the mixture at depth. At depth, the quantity (molar quantity, not volume) of air inspired per breath is several-fold greater than at sea level. The lower density of helium than nitrogen results in a lower viscosity of the inhaled air, with a marked decrease in flow resistance. This property of helium is the basis for its use in patients with increased airway resistance (Heliox mixture), such as those with asthma.

Helium is also used in magnetic resonance imaging scanners to keep the coils super cooled. During emergency shutdown of a superconducting electromagnet, an operation known as “quenching,” the liquid helium is rapidly boiled from the device and vented into the scanner room.<sup>54</sup> This displaces oxygen from the environment and causes asphyxia. Helium is also used in lung imaging studies and pulmonary function testing. Similarly, the low viscosity of helium has led to its use as an inflation gas for intraaortic balloons, for which rapid inflation and deflation are critical.

All noble gases, when compressed, form cryogenic liquids, which expand rapidly to their gas phase on decompression. Liberation of these gases in closed spaces results in either asphyxiation or freezing injuries, or both.<sup>54</sup> Xenon, unlike the other noble gases, has unique anesthetic properties because of its high lipid solubility and inhibition of *N*-methyl-D-aspartic acid (NMDA) receptors.<sup>54</sup> The other noble gases have no known direct toxicity.

### Short-Chain Aliphatic Hydrocarbon Gases: Methane, Ethane, Propane, and Butane

The short-chain aliphatic hydrocarbon gases are primarily used in the compressed form as fuel.

Methane (CH<sub>4</sub>) has no known direct toxicity. Animals can breathe a mixture of 80% methane and 20% oxygen without manifesting hypoxic effects because the FiO<sub>2</sub> and thus their oxygen content, essentially is normal. Methane, also known as “natural gas” and “swamp gas,” is present in high ambient concentrations in bogs of decaying organic matter. In addition, compressed natural gas is used as an alternative automotive fuel and poses an asphyxiation hazard if leaked internally. Methane exposure is an occupational hazard for miners who historically carried canaries into their workplace as an “early warning” sign for the presence of toxic gases or

oxygen deficiency. The higher metabolic and respiratory rates of small animals (and children) make them more rapidly susceptible to gas exposures. Methane is also an explosive risk.

Methane is odorless and undetectable without sophisticated equipment. For this reason, natural gas is intentionally adulterated with a small concentration of ethyl mercaptan, a stenching agent, which is responsible for the well-recognized sulfur odor of natural gas. Cooking with natural gas uncommonly causes respiratory symptoms and pulmonary dysfunction.<sup>62</sup> However, methane itself is not the cause because its combustion is generally complete and ambient concentrations are negligible. It is likely that exposure to nitrogen dioxide (NO<sub>2</sub>), one of the products of combustion of methane in air the explanation for these symptoms (see Oxides of Nitrogen).

Ethane (C<sub>2</sub>H<sub>6</sub>) is an odorless component of natural gas and is used as a refrigerant. It has characteristics similar to methane and is occasionally implicated as a simple asphyxiant. Propane (C<sub>3</sub>H<sub>8</sub>) is widely used in its compressed, liquefied form both as an industrial and domestic fuel and as an industrial solvent. Butane (C<sub>4</sub>H<sub>10</sub>) is a common fuel and solvent. Deliberate butane inhalation from cigarette lighters or air fresheners for recreational purposes, predominantly in adolescents, is associated with cardiovascular dysfunction and cerebral damage (Chap. 81).<sup>110</sup>

Fire-eater’s lung (FEL) is a unique form of hydrocarbon pneumonitis caused by aspiration of flammable petrochemical products. Fire-eater’s lung occurs after inhalational exposure to the chemicals used to “breathe fire” or “eat fire” during performances. The hydrocarbons are typically low viscosity and disperse throughout bronchioles fairly easily leading to severe lipid pneumonitis and pneumonia in addition to a systemic inflammatory response. Pulmonary infiltrates occur in as many as 83% of patients studied.<sup>37</sup>

### Carbon Dioxide

Although not a simple asphyxiant gas by definition because it produces physiologic effects, CO<sub>2</sub> closely resembles simple asphyxiants from a toxicologic viewpoint. It is used in laboratories as a painless form of animal euthanasia and as a means of large-scale euthanasia of diseased livestock.<sup>94</sup> Carbon dioxide gas has many practical industrial uses, such as production of carbonation in soft drinks. Because it is nonflammable, CO<sub>2</sub> is used as a shielding gas during welding and in commercial fire suppression systems because it safely displaces oxygen from the local environment.<sup>44</sup> Dry ice, the frozen form of CO<sub>2</sub>, is extremely cold (−141.3°F {−78.5°C}) and undergoes conversion from solid to gas without liquefaction, a process known as sublimation. Poisoning occurs when dry ice is allowed to sublimate in a closed space,<sup>19</sup> such as the cabin of a car or in a cold storage room at 39.2°F (4°C).<sup>32,44</sup> Furthermore, inadvertent connection of respirable gas hoses to CO<sub>2</sub> and other nonrespirable sources is reported in both industrial and medical settings,<sup>63,115</sup> with resultant worker and patient fatalities. This occurrence is uncommon because of mandated engineering controls to prevent the incorrect connection of hose and source terminals.

**Pharmacology and pathophysiology.** Carbon dioxide, an end product of normal human metabolism, dissolves in the plasma and is in equilibrium with carbonic acid (H<sub>2</sub>CO<sub>3</sub>). The pH at the central chemoreceptors, reflective of the dissolved carbon dioxide (PCO<sub>2</sub>), is responsible for our respiratory drive, and PCO<sub>2</sub> is tightly controlled by the CNS through regulation of breathing.<sup>75</sup> For this reason, exogenous CO<sub>2</sub>, combined with oxygen, was at one time used medically as a respiratory stimulant in neonates. Under normal conditions, ambient air contains approximately 0.03% CO<sub>2</sub>. When ambient concentrations increase, uptake of CO<sub>2</sub> occurs, which further stimulates respiration thereby further increasing the uptake of ambient CO<sub>2</sub>.<sup>27</sup> Accordingly, closed anesthesia systems use scrubbers containing sodium hydroxide (NaOH) to chemically eliminate exhaled CO<sub>2</sub>. Failure of the scrubber system results in increasing depth of anesthesia from hypercapnia-induced hyperventilation.

**Clinical manifestations.** Carbon dioxide produces both acute and subacute poisoning syndromes. The latter occurs during hypoventilation when a patient fails to eliminate endogenous CO<sub>2</sub>, develops hypercapnia, and typically presents with gradual somnolence. This is linked to respiratory failure,

as in the case of emphysema or opioid poisoning, or at times is iatrogenic, occurring during permissive hypercapnia.<sup>27</sup> Even in experimental models in which a normal  $\text{FiO}_2$  is maintained, massive  $\text{CO}_2$  inhalation produces CNS and respiratory system manifestations within seconds.<sup>53,61</sup> This occurs because  $\text{CO}_2$  is not solely a simple asphyxiant but also possesses protean physiological effects.

### Nitrogen Gas

Although nitrogen, like  $\text{CO}_2$ , produces clinical effects independently of hypoxemia, most poisonings are characterized by the manifestations of a simple asphyxiant. Nitrogen gas is used as a carrier gas for chromatography, as a fertilizer, as a cryogenic gas for surgery, and extensively in manufacturing. Poisoning by nitrogen gas is uncommon but occurs after rapid evaporation of the supercooled liquid.<sup>66,67</sup>

**Pharmacology and pathophysiology.** Nitrogen is a colorless, odorless, and tasteless gas that makes up 78% by volume of air. Under standard conditions, it is an inert diatomic gas that has no direct physiologic toxicity.

**Clinical manifestations.** Inadvertent connection of air-line respirator hoses to nitrogen and other inert gas sources results in acute asphyxiation, with unconsciousness occurring in approximately 12 seconds<sup>55,80</sup> and death shortly thereafter. More indolent inhalational poisoning by nitrogen is characterized by impairment of intellectual function and judgment, giddiness, and euphoria, which is qualitatively similar to ethanol intoxication.<sup>83</sup> More severely poisoned patients manifest the spectrum of depressed mental status.<sup>70</sup> Systemic absorption is not rapid, however, and prolonged, high-concentration exposure is required for poisoning. Nitrogen poisoning, also known as *nitrogen narcosis*, occurs in underwater divers while they are breathing air that contains 70% nitrogen. It is sometimes called *rapture of the deep* (*l'ivresse des grandes profondeurs*) and causes many deaths in the subaquatic environment. The underlying mechanism of nitrogen narcosis is unknown, but the simple structure and relatively high lipophilicity of nitrogen suggest a mechanism similar to that of the anesthetic gases.<sup>112</sup> To avoid nitrogen narcosis, a less lipid-soluble inert gas such as helium is generally substituted for nitrogen. Substitution with oxygen, although intuitively logical, is inappropriate because of the risk of oxygen toxicity (see Oxygen).

Dermal exposure to liquid nitrogen produces frostbite because liquid nitrogen is extremely cold and ingestion of liquid nitrogen similarly produces a freezing injury of the gastrointestinal (GI) tract.<sup>130</sup>

### Treatment

Treatment of all individuals poisoned by simple asphyxiants begins with immediate removal of the persons from exposure and provision of ventilatory assistance. Provision of supplemental oxygen is preferable, but room air usually suffices. Restoration of oxygenation through spontaneous or mechanical ventilation occurs after only several breaths. Support of vital functions is the mainstay of therapy but is generally unnecessary after a brief exposure. Hyperbaric oxygen therapy offers no benefit.

## PULMONARY IRRITANTS

The irritant gases are a heterogeneous group of chemicals that produce toxic effects via a final common pathway: destruction of the integrity of the mucosal barrier of the respiratory tract (Table 121–2).

### Pathophysiology

In the lung, irritant chemicals damage both the more prevalent type I pneumocytes and the surfactant-producing type II pneumocytes. Neutrophil influx, recruited in response to macrophage-derived inflammatory cytokines such as tumor necrosis factor (TNF)- $\alpha$ , releases toxic mediators that disrupt the integrity of the capillary endothelial cells.<sup>79</sup> This host defense response results in accumulation of cellular debris and plasma exudate in the alveolar sacs, producing the characteristic clinical findings of the acute respiratory distress syndrome (ARDS). The specific mechanisms by which the irritant gases damage the pulmonary endothelial and epithelial cells vary. Many irritant gases require dissolution in lung water to liberate their

ultimate toxicant, which often is an acid, as occurs when hydrogen chloride gas produces hydrochloric acid. The exact mechanism by which acids damage cells and induce an inflammatory response remains uncertain. Oxidation of intracellular proteins results in rapid cytoskeletal shortening, creating spaces between endothelial cells and allowing fluid movement into the alveolar spaces.<sup>119</sup> Other gases, such as oxygen and ozone, induce pulmonary damage primarily through free radical-mediated oxidative stress on the cellular membranes.<sup>13</sup> Nitrogen dioxide ( $\text{NO}_2$ ) and chlorine are characteristic of a group of gases that produce both acid and free radical oxidants. Furthermore, other respirable xenobiotics, such as metals, injure the respiratory tract through oxidant stress and other mechanisms. Because the precise toxicologic and pathophysiologic effects vary widely depending on the physicochemical properties of the xenobiotic, these mechanisms are covered more completely in the following specific discussions.

By virtue of its use as a chemical weapon, phosgene has received more investigation than the other irritant gases. Although the specific mechanisms of toxicity of the other irritants remain poorly defined, they likely cause injury through a similar process. The acids liberated upon dissolution in the mucosal water react with functional groups on epithelial and endothelial cell membranes and, via cellular messengers, result in a complex inflammatory response.<sup>88,99</sup> Phosgene stimulates the synthesis of lipoxygenase-derived leukotrienes and other cytokines such as TNF- $\alpha$ .<sup>99</sup> Leukotrienes are important chemotactic factors for neutrophils, which accumulate, liberate oxidants, and produce ARDS. Experimentally, ARDS is prevented in rabbits by tomelkast, a leukotriene receptor antagonist, and by methylprednisolone, which blocks leukotriene synthesis, both of which are beneficial postexposure.<sup>51</sup> Ibuprofen, an inhibitor of the arachidonic acid cascade, and xenobiotics capable of reducing neutrophil influx, such as colchicine and cyclophosphamide, reduce lung injury and mortality rates in mice when administered shortly after phosgene exposure.<sup>100</sup> When administered 45 minutes after exposure to phosgene-poisoned rabbits, intratracheal *N*-acetylcysteine (NAC) decreases the formation of leukotrienes by an undefined means and limits the development of ARDS.<sup>101</sup> However, nebulized NAC has not proven successful in the majority of published case material despite some success in basic science research and is not recommended at this time.<sup>46</sup> Intravenous (IV) administration of NAC to patients with mild to moderate ARDS, none of whom had irritant-induced pulmonary damage, improved systemic oxygenation and reduced their need for ventilatory support.<sup>116</sup> However, progression to respiratory failure was not altered. There are no human studies evaluating exposure to chemical irritants and the management of ARDS in patients after a chemical irritant exposure is extrapolated from the ARDS literature. Advanced interventions for reducing the morbidity and mortality associated with non-toxin-induced ARDS such as lung protective strategies, high-frequency ventilation, and prone positioning, widely used in patients with trauma- or sepsis-induced ARDS, have not undergone evaluation in patient with toxin-induced ARDS.<sup>17</sup> Given the pathophysiological and clinical similarities<sup>107</sup> and despite the lack of evidence, it seems reasonable to apply these strategies to patients with inhalational injuries.

Free radicals are highly reactive molecular derivatives, typically from oxygen or nitrogen that bind to and destroy tissue near their site of generation. Through initiation of a lipid peroxidative cascade, free radicals destroy lipid membranes and inhibit energy production through the electron transport chain (Chap. 10). Products of lipid peroxidation and cellular damage initiate neutrophilic influx, presumably in an immunologic response to a pathogen. Ironically, free radicals generated by the invading inflammatory cells contribute to pulmonary damage. Fortunately, the lung has both enzymatic (eg, superoxide dismutase, glutathione peroxidase, catalase) and nonenzymatic (eg, glutathione, ascorbate) antioxidant systems, which detoxify virtually all free radicals present in the lung.<sup>136</sup> However, the oxidant burden imposed by oxidant gases can preempt these detoxifying systems and produce cellular damage. For example, nebulization of manganese superoxide dismutase into the airway 1 hour after smoke inhalation, a form of oxidant lung injury, did not improve lung edema or pulmonary gas exchange.<sup>77</sup>

TABLE 121-2 Characteristics of Common Respiratory Irritants

Gas	Source or Exposure	Solubility (g%) <sup>a</sup>	Detection Threshold (ppm)	Regulatory Standard (ppm) <sup>b</sup>	IDLH <sup>c</sup> (ppm)	STEL (ppm)
Ammonia	Fertilizer, refrigeration, synthetic fiber synthesis	H	5	50	300	35
Cadmium oxide fumes	Welding	I	Odorless	0.005 mg/m <sup>3</sup>	9 mg/m <sup>3</sup> (as Cd)	NA
Carbon dioxide	Exhaust, dry ice sublimation	P	Odorless	5000	40,000	30,000
Chloramine	Bleach plus ammonia	H	NA	NR	NR	NR
Chlorine	Water disinfection, pulp, and paper industry	P	0.3	0.5	10	1
Copper oxide fumes	Welding	I	NA	0.1 mg/m <sup>3</sup>	100 mg/m <sup>3</sup> (as Cu)	NA
Ethylene oxide	Sterilant	H	500	1	800	5
Formaldehyde	Chemical disinfection	H	0.8	0.016	20	2
Hydrogen chloride	Chemical	H	1–5	5	50	5
Hydrogen fluoride	Glass etching, semiconductor industry	H	0.042	3 (as F)	30 (as F)	6
Hydrogen sulfide	Petroleum industry, sewer, manure pits	P	0.025		100	50
Mercury vapor	Electrical equipment, thermometers, catalyst, dental fillings, metal extraction, heating or vacuuming elemental mercury	I	Odorless	0.1 mg/m <sup>3</sup>	10 mg/m <sup>3</sup>	0.05
Methane	Natural heating gas, swamp gas	M	Odorless	NR	NR	NR
Methyl bromide	Fumigant	M	20	20	250	NA
Nickel carbonyl	Nickel purification, nickel coating, catalyst	P	1–3	0.001	2 (as Ni)	0.1
Nitrogen		P	Odorless	NR	NR	NR
Nitrogen dioxide	Chemical synthesis, combustion emission	P	0.12	3	20	5
Nitrous oxide	Anesthetic gas, whipping cream dispensers (abuse), racing fuel additive	P	2	25	100	NA
Ozone	Disinfectant, produced by high-voltage electrical equipment	P	0.05	0.1	5	0.1
Phosgene	Chemical synthesis, combustion of chlorinated compounds	P	0.5	0.1	2	0.1
Phosphine	Fumigant, semiconductor industry	P	2	0.3	50	1
Propane	Liquified propane gas	P	Odorless	1000	2100	NR
Sulfur dioxide	Environmental exhaust	H	1	2	100	5
Zinc chloride fumes	Artificial smoke (no longer in use)	H	NA	1 mg/m <sup>3</sup>	50 mg/m <sup>3</sup>	2 mg/m <sup>3</sup>
Zinc oxide	Welding	P	Odorless	5 mg/m <sup>3</sup>	500 mg/m <sup>3</sup>	10 mg/m <sup>3</sup>

<sup>a</sup>g% = grams of gas per 100 mL water; if applicable. Solubility: I = insoluble; P = poor; M = medium; H = high. <sup>b</sup>Standards are either Threshold Limit value-time weighted average (TLV-TWA) set by the American Conference of Governmental Industrial Hygienists (ACGIH) or permissible exposure limits (PELs) set by the Occupational Safety and Health Administration (OSHA). <sup>c</sup>Immediately dangerous to life and health (IDLH): National Institute for Occupational Safety and Health (NIOSH), revised 1995. (Documentation for each IDLH is available at <http://www.cdc.gov/niosh/idlh/idlhintr.html>.)

F = fluorine; NA = not available; NR = no regulatory standard; STEL = short-term exposure limit (15-minute average not to be exceeded).

### Clinical Manifestations

Regardless of the mechanism by which the mucosa is damaged, the clinical presentations of patients exposed to irritant gases are similar.<sup>107</sup> Those exposed to gases that result in irritation within seconds generally develop mucosal injury limited to the upper respiratory tract. The rapid onset of symptoms is usually a sufficient signal to the patient to escape the exposure. Patients present with nasal or oropharyngeal pain in addition to drooling, mucosal edema, cough, or stridor. Conjunctival irritation or chemosis, as well as skin irritation, are often noted because concomitant ocular and cutaneous exposure to the gases usually is unavoidable. Gases that are less rapidly irritating do not typically provide an adequate signal of their presence and therefore do not prompt expeditious escape by the exposed individual. In this case, prolonged breathing allows entry of the toxic gas farther into the bronchopulmonary system, where delayed toxic effects are subsequently

noted. Tracheobronchitis, bronchiolitis, bronchospasm, and ARDS are typical inflammatory responses of the airway and represent the spectrum of acute lower respiratory tract injury.

Experimental models assessing the water solubility of a gas to predict the location of its associated lesions generally agree with the clinical data.<sup>15</sup> However, exceptions to this relationship of a gas and its predicted toxicity are common. For example, in situations in which escape from ongoing exposure is prevented, patients develop lower respiratory tract injury after prolonged exposure to acutely irritating gases. Alternatively, rapid onset of upper respiratory irritation occurs in patients after exposure to concentrated gases that are generally associated with delayed signs and symptoms. Exposure to exceedingly high concentrations of any irritant gas produces hypoxemia analogous to that resulting from exposure to a simple asphyxiant.

**TABLE 121-3** The Berlin Definition of Acute Respiratory Distress Syndrome<sup>4</sup>

Characteristic	Definition
Timing	Within 1 week of a known clinical insult or new or worsening respiratory symptoms
Chest imaging	Bilateral opacities not fully explained by effusions, lobar or lung collapse, or nodules
Origin of edema	Respiratory failure not fully explained by cardiac failure or fluid overload Need objective assessment (eg, echocardiography) to exclude hydrostatic edema if no risk factor is present
Hypoxemia	
Mild	$200 < PaO_2/FiO_2 \leq 300$ with PEEP or CPAP $\geq 5$ cm H <sub>2</sub> O
Moderate	$100 < PaO_2/FiO_2 \leq 200$ with PEEP $\geq 5$ cm H <sub>2</sub> O
Severe	$PaO_2/FiO_2 \leq 100$ with PEEP $\geq 5$ cm H <sub>2</sub> O

CPAP = continuous positive airway pressure;  $FiO_2$  = fraction of inspired oxygen; PEEP = positive end-expiratory pressure;  $PaO_2$  = partial pressure of oxygen.

The most characteristic and serious clinical manifestation of irritant gas exposure is ARDS.<sup>96</sup> Acute respiratory distress syndrome consists of the clinical, radiographic, and physiologic abnormalities caused by pulmonary inflammation and alveolar filling that must be both acute in onset and not attributable solely to pulmonary capillary hypertension as occurs in patients with congestive heart failure.<sup>122</sup> Acute respiratory distress syndrome is a non-specific syndrome resulting from diverse physiologic insults such as sepsis or trauma. Patients with ARDS present with dyspnea, chest tightness, chest pain, cough, frothy sputum, wheezing or crackles, and arterial hypoxemia. Typical radiographic abnormalities include bilateral pulmonary infiltrates with an alveolar filling pattern and a normal cardiac silhouette that differentiate this syndrome from congestive heart failure.

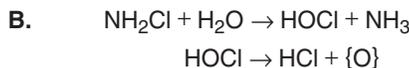

In 2012, the diagnostic criteria for ARDS was updated as a consensus guideline known as the Berlin Definition.<sup>4</sup> The definition created three mutually exclusive strata of ARDS based on the degree of hypoxemia (Table 121-3). Some essential changes of the new definition include acute was defined as 1 week or less, the term *acute lung injury* (ALI) was discontinued, measuring the  $PaO_2/FiO_2$  ratio now requires a specific amount of positive end-expiratory pressure (PEEP), chest radiographic criteria were clarified to improve interrater reliability, the pulmonary capillary wedge pressure (PCWP) criterion was removed, and additional clarity was added to improve the ability to exclude cardiac causes of bilateral infiltrates.

## Specific Xenobiotics

### Acid- or Base-Forming Gases Highly Water-Soluble Xenobiotics

**Ammonia (NH<sub>3</sub>).** Ammonia is a common industrial and household chemical used in the synthesis of plastics and explosives and as a fertilizer, a refrigerant, and a cleanser. The odor and irritancy are characteristic and serve as an effective warning signals of exposure. Dissolution of NH<sub>3</sub> in water to form the base ammonium hydroxide (NH<sub>4</sub>OH) rapidly produces severe upper airway irritation. Patients with exposures to highly concentrated NH<sub>3</sub> or exposures for prolonged periods develop tracheobronchial or pulmonary inflammation. Experimental inhalation of nebulized high-dose ammonia causes ARDS within 2 minutes of exposure.<sup>58</sup> Ultrastructural study of the lungs from two individuals dying acutely of ammonia inhalation revealed marked swelling and edema of type I pneumocytes consistent with ARDS.<sup>16</sup> Chronic inhalation of low concentrations of NH<sub>3</sub> or repetitive exposure to high concentrations of ammonia causes pulmonary fibrosis.<sup>12</sup>

**Chloramines.** This series of chlorinated nitrogenous compounds (Fig. 121-1) includes monochloramine (NH<sub>2</sub>Cl), dichloramine (NHCl<sub>2</sub>), and trichloramine

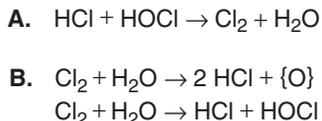

**FIGURE 121-1.** Chloramine chemistry. (A) Sodium hypochlorite (bleach) plus ammonia form monochloramine and dichloramine. (B) Chloramine dissolves in water to liberate hypochlorous acid, hydrochloric acid, ammonia, and nascent oxygen {O}, an oxidant.

(NCl<sub>3</sub>). The chloramines are most commonly generated by the admixture of ammonia with sodium hypochlorite (NaOCl) bleach, often in an effort to potentiate their individual cleansing powers.<sup>81</sup> Interestingly, the addition of bleach to septic systems results in liberation of the chloramines after the reaction of bleach with urinary nitrogenous compounds.<sup>81</sup> On dissolution of the chloramines in the epithelial lining fluid, hypochlorous acid (HOCl), ammonia, and oxygen radicals are generated, all of which act as irritants. Although less water soluble than ammonia, the chloramines typically promptly result in symptoms. Because these initial symptoms are often mild, however, they often do not prompt immediate escape, resulting in prolonged or recurrent exposure with pulmonary and ocular symptoms predominating.<sup>20</sup> Exposure to trichloramine occurs at indoor swimming pools and is responsible for inducing permeability changes in the pulmonary epithelium, the consequences of which are not yet understood.<sup>25</sup>

**Hydrogen chloride (HCl).** The largest and most important use of HCl gas is in the production of hydrochloric acid. Dissolution of HCl gas in lung water after inhalation similarly produces hydrochloric acid.<sup>92</sup> Pyrolysis of polyvinyl chloride (PVC), a plastic commonly used in pipe fabrication, generates HCl and is an occupational hazard for firefighters.<sup>113</sup> By adsorbing to respirable carbonaceous particles generated in the fire, HCl is deposited in the alveoli and produces pulmonary toxicity.

**Hydrogen fluoride (HF).** Hydrogen fluoride and its aqueous form, hydrofluoric acid, are used in the gasoline, glassware, building renovation, and semiconductor industries. Gaseous HF is also liberated, paradoxically by extreme heat, during the release of hydrofluorocarbons from fire suppression systems.<sup>135</sup> Hydrogen fluoride gas dissolves in epithelial lining fluid to form the weak acid hydrofluoric acid. The intact HF molecule is the predominant form in solution, and few free hydronium ions (H<sub>3</sub>O<sup>+</sup>) are liberated. Low-dose inhalational exposures result in irritant symptoms,<sup>41,132</sup> and large exposures cause bronchial and pulmonary parenchymal destruction.<sup>132</sup> Inhalation results in ARDS, but death usually is related to systemic fluoride poisoning independent of the route of exposure caused by hypocalcemia and hyperkalemia (Chap. 104).<sup>30,135</sup>

**Sulfur dioxide and sulfuric acid (SO<sub>2</sub> and H<sub>2</sub>SO<sub>4</sub>).** Sulfur dioxide has multiple industrial applications and is a byproduct found in the smelting and oil refinery industries. It is also generated by the inadvertent mixing of certain chemicals, such as an acid with sodium bisulfite (NaHSO<sub>3</sub>). Sulfur dioxide is highly water soluble and has a characteristic pungent odor that provides warning of its presence at concentrations well below those that are irritating. In the presence of catalytic metals (Fe, Mn), environmental sulfur dioxide is readily converted to sulfurous acid (H<sub>2</sub>SO<sub>3</sub>) within water droplets. Sulfurous acid is a major environmental concern and the cause of "acid rain." Exposure to atmospheric sulfur dioxide results in a roughly dose-related bronchospasm, which is most pronounced and difficult to treat in patients with asthma. Inhalation of sulfurous acid or dissolution of sulfur dioxide in epithelial lining fluid produces typical pathologic and clinical findings associated with ARDS.<sup>95</sup> In addition to the effect of acid generation upon dissolution, sulfur dioxide causes oxidative damage to the lungs.<sup>104</sup> Large acute exposure to either xenobiotic produces the expected acute irritant response of both the upper and lower respiratory tracts,<sup>21</sup> and pulmonary dysfunction (see Asthma and Reactive Airways Dysfunction Syndrome) in some persists for several years.<sup>104</sup>

**FIGURE 121-2.** Chlorine chemistry. (A) Formation of chlorine gas from the acidification of hypochlorous acid. (B) Dissolution of chlorine in mucosal water to generate both hydrochloric and hypochlorous acids (hydrogen chloride {HCl} and hypochlorous acid {HOCl}) and oxidants {O}.

### Intermediate Water-Soluble Xenobiotics

**Chlorine ( $\text{Cl}_2$ ).** Chlorine gas is a valuable oxidizer with various industrial uses, and occupational exposure is common. Chlorine gas was used as a chemical weapon by both the French and the Germans in World War I (Chap. 126). Although chlorine gas is not generally available for use in the home, domestic exposure to chlorine gas is common. The admixture of an acid to bleach liberates chlorine gas (Fig. 121-2).<sup>85</sup> Because the anionic component of the acid is not involved in the reaction, combining hypochlorite with virtually any acid, such as phosphoric, hydrochloric, or sulfuric acid, results in the release of chlorine gas. As such, inappropriate mixing of cleaning products is the cause of most nonoccupational exposures.<sup>85</sup> Rarely, patients intentionally generate chlorine gas in this manner for purportedly “pleasurable” purposes.<sup>93</sup> Chlorine gas is generated when aging swimming pool chlorination tablets, such as calcium hypochlorite [ $\text{Ca}(\text{OCl})_2$ ] or trichloro-*s*-triazinetrione (TST), decompose<sup>134</sup> or are inadvertently introduced to a swimming pool while swimmers are present.<sup>6,126</sup> Inadvertent mixture of  $\text{Ca}(\text{OCl})_2$  and TST results in excessive chlorine gas generation, which is also explosive. Acute chlorine toxicity occurs when there is a failure of the system of compressed chlorine gas which is used for direct chlorination of public swimming pools<sup>6</sup> or for drinking water systems. Occasional mass poisoning has occurred during scientific, industrial, or transportation incidents.<sup>56</sup>

The odor threshold for chlorine is low, but distinguishing toxic from permissible air concentrations is difficult until toxicity manifests. The intermediate solubility characteristics of chlorine result in only mild initial symptoms after moderate exposure and allow a substantial time delay, typically several hours, before clinical symptoms develop. Chlorine dissolution in lung water generates HCl and hypochlorous (HOCl) acids. Hypochlorous acid rapidly decomposes into HCl and nascent oxygen (O). The unpaired nascent oxygen atom produces additional pulmonary damage by initiating a free radical oxidative cascade. Although the majority of life-threatening chlorine poisonings occur after acute large exposures, patients with chronic, low-concentration or recurrent and patients with exposure to moderate concentrations often manifest increased bronchial responsiveness<sup>1,42</sup> (see Reactive Airways Dysfunction Syndrome).

**Hydrogen sulfide ( $\text{H}_2\text{S}$ ).** Hydrogen sulfide exposures occur most frequently in the waste management, petroleum, and natural gas industries,<sup>38</sup> although poisoning occurs in asphalt, synthetic rubber, and nylon industry workers as well. Hydrogen sulfide exposure also rarely occurs in hospital workers using acid cleaners to unclog drains clogged with plaster of Paris sludge. The generation of  $\text{H}_2\text{S}$  by mixing household chemicals in a closed automobile, a trend referred to as “detergent suicide,” produces a potential threat to the responders.<sup>2</sup> Hydrogen sulfide is a decay product of organic material found in sewers or manure pits. Hydrogen sulfide, hydrogen fluoride, and phosphine are differentiated from the other irritant gases by their ability to produce significant systemic toxicity. Hydrogen sulfide inhibits mitochondrial respiration in a fashion similar to that of cyanide<sup>127</sup> (Chap. 123).

Hydrogen sulfide has the distinctive odor of “rotten eggs,” which, although helpful in diagnosis, is not specific. Despite a sensitive odor threshold of several parts per billion,<sup>1</sup> rapid olfactory fatigue ensues, providing a misperception that the exposure and its attendant risk have diminished. At low and moderate concentrations ( $\leq 500$  ppm), upper respiratory tract

mucosal irritation occurs and is the principal toxicity.<sup>118</sup> The rapidity of death in patients exposed to high  $\text{H}_2\text{S}$  concentrations makes it difficult to conclude whether simple asphyxiation or cytochrome oxidase inhibition is causal in most cases. Neither the postmortem  $\text{H}_2\text{S}$  nor thiosulfate concentrations are reliable for determining cause of death.<sup>7</sup>

**Phosgene (carbonyl chloride { $\text{COCl}_2$ }).** During World War I, phosgene was an important chemical weapon that produced countless deaths (Chap. 126).<sup>36</sup> Currently, phosgene is used in the synthesis of various organic compounds, such as isocyanates, and it occasionally produces poisoning. It is a byproduct of heating or combustion of various chlorinated organic compounds.

Exposure to phosgene initially produces limited manifestations, but results in acute mucosal irritation after intense exposure. In fact, the pleasant odor of fresh hay, rather than prompting escape, disturbingly promotes prolonged breathing of the toxic gas. The most consequential clinical effect related to phosgene exposure is delayed ARDS.<sup>10</sup> The accumulation of a significant alveolar burden of phosgene due to the lack of a noxious warning property of the gas, explains why the clinical effects generally are severe. Because the onset is typically delayed up to 24 hours, prolonged observation of patients thought to be phosgene-poisoned is warranted. The mechanism of phosgene toxicity occurs by the dissolution of the gas into the fluid of the epithelial lining with resultant liberation of hydrochloric acid and reactive oxygen species (ROS).<sup>10</sup>

### Oxidant Gases

Rather than acidic or alkaline metabolites, free radicals mediate the pulmonary toxicity of certain irritant gases. Many of the chemicals discussed participate in both acid-base and oxidant types of injury. However, the clinical distinction between acid- or alkali-forming irritants and oxidants is difficult but is therapeutically relevant.

**Oxygen ( $\text{O}_2$ ).** Oxygen toxicity is uncommon in the workplace but, ironically, is common in hospitalized patients. Although prolonged, high concentration exposures to  $\text{O}_2$  produce CNS and retinal toxicity, pulmonary damage is more common.<sup>111</sup> Several clinical studies indicate that humans can tolerate 100%  $\text{O}_2$  at sea level for up to 48 hours without significant acute pulmonary damage.<sup>18,29</sup> Under hyperbaric conditions (2.0 atmospheres absolute), such as during compressed-air diving or while inside a pressurized hyperbaric chamber, oxygen toxicity develops within 3 to 6 hours.<sup>23</sup> Acute respiratory distress syndrome occurs in approximately 5% of patients administered hyperbaric oxygen for therapeutic purposes.<sup>111</sup> Delayed pulmonary fibrosis, presumably from healing of subclinical injury, develops in patients breathing lower concentrations of  $\text{O}_2$  at sea level for shorter periods.

Although it appears paradoxical that  $\text{O}_2$ , an essential molecule, is deleterious at elevated concentrations, it is not. In mitochondria,  $\text{O}_2$  plays a critical role as the ultimate acceptor for electrons completing the electron transport chain. This same potent oxidizing activity allows  $\text{O}_2$  to remove electrons from other compounds generating the reactive oxygen intermediate.<sup>97</sup>

Generation of ROS, including superoxide ( $\text{O}_2^-$ ), hydroxyl radical (OH $\cdot$ ), hydrogen peroxide (HOOH), singlet oxygen ( $\text{O}^*$ ), and nitric oxide (NO), produces cellular necrosis, increases pulmonary capillary permeability, and induces apoptosis.<sup>97</sup> Nitric oxide, produced by inducible NO synthase (iNOS) in the setting of oxidative stress, is directly cytotoxic or it can combine with superoxide anions to form the more reactive oxidant peroxynitrite (ONOO $^-$ ).<sup>57</sup> Experimental prevention of these effects by administration of either parenteral NAC,<sup>129</sup> a chemical antioxidant, or superoxide dismutase, an enzymatic antioxidant,<sup>68</sup> suggests that the mechanism of toxicity relates to the oxidant, or electrophilic, effects of these ROS (Chap. 10). Although several other therapies have shown promise in preventing oxygen-mediated toxicity, none has yet proven to be valuable for patients who already manifest pulmonary toxicity. Current techniques for preventing pulmonary oxygen toxicity emphasize reduction of the inspired oxygen concentration by use of PEEP ventilation. The potential role of liquid ventilation of the lung with perfluorocarbons to prevent or treat pulmonary oxygen toxicity remains under investigation but not highly promising.<sup>40</sup>

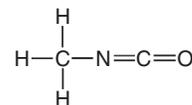

**Oxides of nitrogen (NO<sub>x</sub>).** Oxides of nitrogen are a series of variably oxidized nitrogenous compounds. The most important substances included in this series are the stable free radicals nitrogen dioxide (NO<sub>2</sub>) and NO, as well as nitrogen tetroxide (dinitrogen tetroxide {N<sub>2</sub>O<sub>4</sub>}), nitrogen trioxide (N<sub>2</sub>O<sub>3</sub>), and nitrous oxide (N<sub>2</sub>O). The oxides of nitrogen are of limited concern in industrial operations, although they are generated during welding and brazing.<sup>24</sup> Nitrogen oxide, in addition to hydrogen cyanide, is produced in the pyrolysis of nitrocellulose, which is a substantial component of radiographic film. For example, a fire in the radiology department of the Cleveland Clinic in 1929 resulted in 125 casualties, with virtually all deaths resulting from cyanide or NO<sub>2</sub> gas poisoning.<sup>48</sup> Nitrogen oxide toxicity also occurs when propane-driven ice-cleaning machines are used in indoor ice skating rinks with poor ventilation, thereby allowing accumulation of the generated NO<sub>2</sub>,<sup>72</sup> or after exposure to high NO<sub>2</sub> concentrations in closed space fires, such as in submarines.<sup>78</sup> Nitrogen oxide also causes silo filler's disease, in which the toxic gas generated during decomposition of silage accumulates within the silo shortly after grain storage, eliminating rodents that feast on the grains.<sup>31</sup> In the absence of ventilation, high concentrations of NO<sub>2</sub> accumulate in the silo such that an individual entering the silo is rapidly asphyxiated from the depletion of oxygen.<sup>49</sup> Additionally, substantial quantities of NO<sub>2</sub> remaining after incomplete ventilation are associated with delayed-onset pulmonary toxicity characteristic of silo filler's disease. Chronic indoor exposure to NO<sub>2</sub>, generated during cooking or outdoor exposure to photochemical smog, of which the oxides of nitrogen are a component, predisposes individuals to the development or exacerbation of chronic lung diseases.<sup>62</sup>

The various oxides of nitrogen directly oxidize respiratory tract cellular membranes but more typically generate reactive nitrogen intermediates, or radicals, such as ONOO<sup>-</sup>, which subsequently damage the pulmonary epithelial cells.<sup>90</sup> In addition to generating oxidant cascades, dissolution in respiratory tract water generates nitric acid (HNO<sub>3</sub>) and NO, which produce injury consistent with other inhaled acids.<sup>52</sup> Antioxidants afford significant protection to environmental oxidant exposure including NO<sub>2</sub>, indicating an important role of free radicals in the toxicology of these xenobiotics.<sup>69</sup>

Nitric oxide, an endogenous compound important as a neurotransmitter and vasorelaxant, is used clinically exogenously for inhalational therapy to treat pulmonary hypertension and ARDS.<sup>43</sup> In patients with ARDS not resulting from sepsis (although not specifically from inhalational injury), low concentrations of inhaled NO (5 ppm) did not improve the clinical outcome, although its use in premature infants with respiratory distress syndrome is well accepted.<sup>43</sup> Nitric oxide is less soluble in the fluid lining the epithelial surfaces than are the other oxides of nitrogen and produces irritant effects after large exposures.<sup>124</sup> Its pulmonary oxidative toxicity, the manifestations of which are typical of the oxidant gases, is substantially enhanced by conversion to reactive nitrogen intermediates such as ONOO<sup>-</sup>. This radical selectively interacts with tyrosine to produce nitrotyrosine, which subsequently serves as a marker for oxidant damage. Nitric oxide is absorbed from the lung and is rapidly bound by hemoglobin to form nitrosylhemoglobin, and methemoglobin may also be produced.

**Ozone (O<sub>3</sub>).** Ozone is abundant in the stratospheric region found between 5 and 31 miles above the planet. Ozone is formed by the action of ultraviolet light on oxygen molecules, thus reducing the amount of solar ultraviolet irradiation reaching earth. The ozone concentration in passenger aircrafts is at times above regulatory limit, although a specific relationship with the development of clinical effects in airline crew members is elusive.<sup>133</sup> Ozone is an important component of photochemical smog and, as such, contributes to chronic lung disease. It is produced in significant quantities by welding and high-voltage electrical equipment and in more moderate doses by photocopying machines and laser printers. Because of its high electronegativity (only fluorine is higher), ozone is one of the most potent oxidizers available. For this reason, it is used as a bleach, particularly as an alternative to chlorine in water purification and sewage treatment.

The pulmonary toxicity associated with ozone primarily results from its high reactivity toward unsaturated fatty acids and amino acids with

**FIGURE 121-3.** Methylisocyanate.

sulfhydryl functional groups.<sup>13</sup> Ozonation and free radical damage to the lipid component of the membrane initiate an inflammatory cascade. Reactive nitrogen species are also implicated because NO synthase knockout mice are relatively protected from ozone-induced inflammation and tissue injury.<sup>34</sup> Increased permeability of the pulmonary epithelium results in alveolar filling from the transudation of proteins and fluids characteristic of ARDS.

### Miscellaneous Pulmonary Irritants

**Methylisocyanate.** Methylisocyanate (MIC) (Fig. 121-3) is one of a series of compounds sharing a similar isocyanate (N=C=O) moiety. Toluene diisocyanate (TDI) and diphenyl-methane diisocyanate (MDI) are important chemicals in the polymer industry. In those exposed to MIC in Bhopal, ARDS was evident both clinically and radiographically.<sup>82</sup> Methylisocyanate is a significantly more potent respiratory irritant than the other regularly used isocyanate derivatives such as TDI.

**Riot control agents: capsaicin, chlorobenzylidene malononitrile, and chloroacetophenone.** Historically, riot control agents (Fig. 126-5), commonly called Mace, consisted primarily of chloroacetophenone (CN) or chlorobenzylidene malononitrile (CS).<sup>9</sup> Both are white solids that are dispersed as aerosols. The dispersion is generally accomplished through mixture with a pyrotechnic agent such as a grenade or with a volatile organic solvent in a personal protection canister. Because the delivery systems of these agents are of limited sophistication and are subject to prevailing environmental conditions, dosing is unpredictable, and unintended self-poisoning is common.<sup>9</sup> After low-concentration exposure, ocular discomfort and lacrimation alone are expected, accounting for the common appellation *tear gas*. The effects are transient, and complete recovery within 30 minutes is typical, although long lasting pulmonary effects are described (see Asthma and Reactive Airways Dysfunction Syndrome). Closed-space or close-range exposure, as well as physical exertion during exposure, is associated with significant ocular toxicity, dermal burns, laryngospasm, ARDS, or death.<sup>120</sup> Because of their high potential for severe toxicity, CN and CS were replaced for civilian use by oleoresin capsicum (OC), also known as *pepper spray* or *pepper mace*. Although capsaicin, its active component, is considerably less toxic, it is occasionally responsible for pneumonitis and death.

Capsaicin interacts with the vanilloid receptor-1 (VR1), which was recently renamed the transient receptor potential vanilloid-1 (TRPV1).<sup>117</sup> Stimulation of this receptor invokes the release of substance P, a neuropeptide involved with transmission of pain impulses. Substance P also induces neurogenic inflammation, which, in the lung, results in ARDS and bronchoconstriction (see Asthma and Reactive Airways Dysfunction Syndrome).

**Metal pneumonitis.** Acute inhalational exposures to certain metal compounds produce clinical effects identical to those of the chemical irritants. For example, zinc chloride (ZnCl<sub>2</sub>) fume is used as artificial smoke because of the dense white character of the fume, and an aqueous solution is still used as a soldering flux. Exposure to zinc chloride fumes for just a few minutes is associated with ARDS and death (Chap. 100).<sup>59</sup> Cadmium oxide (CdO) is generated during the burning of cadmium metal in an oxygen-containing environment, as occurs during smelting or welding (Chap. 88). The refining of nickel using carbon monoxide (Mond process) produces nickel carbonyl [Ni(CO)<sub>4</sub>], a volatile pulmonary oxidant (Chap. 96).<sup>103</sup> Inhalation of volatilized elemental mercury occurs during the vacuuming of mercury spills or home extracting of precious metals (Chap. 95).<sup>87</sup> Although at high concentrations many of these metal exposures produce warning symptoms, severe toxicity may occur even in the absence of warning symptoms. The mechanism of toxicity typically relates to overwhelming oxidant stress with a pronounced inflammatory response as measured by serum cytokine (eg, TNF-α)

concentrations, consistent with the role of metals in redox reactions (Chap. 10). Patients with metal-induced pneumonitis present with chest tightness, cough, fever, and signs consistent with ARDS. Metal pneumonitis is distinguishable from other causes of ARDS only by history or, retrospectively, by elevated serum or urine metal concentrations.<sup>3</sup> In particular, metal pneumonitis should be differentiated from the more common and substantially less consequential metal fume fever, discussed later in this chapter. In addition to standard supportive measures, patients with acute metal-induced pneumonitis should be hospitalized, and it is reasonable to administer corticosteroids.<sup>60</sup> Chelation therapy has no documented benefit for treatment of patients with ARDS but is indicated based on conventional indications.

## MANAGEMENT

### Standard and Supportive Measures

Management of patients with acute respiratory tract injury begins with meticulous support of airway patency by limiting bronchial and pulmonary secretions and maintaining oxygenation. Although various new treatment modalities are available,<sup>17</sup> supportive care remains a cornerstone of therapy. Supplemental oxygen, bronchodilators, and airway suctioning should be used for standard indications. Nitrovasodilators and diuretics have no role in the management of patients with ARDS, although light sedation is recommended as an anxiolytic.<sup>105</sup> Corticosteroid therapy, designed to reduce the inflammatory host defense response, frequently improves surrogate markers of pulmonary damage,<sup>122</sup> such as oxygenation status, but generally offers little outcome enhancement in patients with ARDS.<sup>91</sup> Clinical data on the efficacy of corticosteroids used in human beings exposed to pulmonary irritants are limited and inconclusive.<sup>26</sup> Importantly, most studies of ARDS involve predominantly septic or traumatized patients, with few patients having inhalational poisoning. Because the inflammatory response initiated by bacterial endotoxin differs from that caused by irritant gases, the applicability of these studies to the treatment of poisoned individuals is limited. There is an interesting report of simultaneous, presumably equivalent chlorine exposure in two sisters, with improved outcome in the sister who received steroid treatment.<sup>22</sup> Most available research evaluates parenterally administered corticosteroids, although animal models demonstrate a beneficial effect of nebulized beclomethasone or budesonide after acute chlorine poisoning.<sup>26,50,131</sup> Nebulized budesonide compared to IV betamethasone had similar effects.<sup>26</sup> However, a human pretreatment model of inhaled budesonide fails to document a substantive alteration of the effects of ozone inhalation.<sup>86</sup> Furthermore, most of the aforementioned studies assess acute outcome and not long-term effects in survivors. Because corticosteroids experimentally reduce the late fibroproliferative phase during lung recovery, with additional study, they are thought by some to be beneficial. Overall, there is little reason to suspect any specific benefit of corticosteroids in most poisoned patients. However, because many studies demonstrate little identifiable risk and some potential benefit, corticosteroid use is reasonable whether inhaled or intravenous, and based largely on institutional practices for the management of patients with ARDS.

The clinical similarities among patients with irritant gas exposure and other etiologies of ARDS suggest that similar management principles are reasonable to apply. Although not specifically evaluated in any of these studies, there are sound theoretical reasons to believe that all of these modalities should improve oxygenation in poisoned patients as well. Prone positioning during ventilation; PEEP; early neuromuscular blockade; and low-volume, low-pressure, lung protective strategies are successful in enhancing the oxygenation of patients with ARDS of various causes but are not necessarily successful in improving outcome.<sup>17</sup> Lower tidal volume mechanical ventilation using 6 mL/kg and plateau pressures of 30 cm H<sub>2</sub>O attenuated the inflammatory response and resulted in a lower mortality rate and less need for mechanical ventilation than traditional volume ventilation with 12 mL/kg.<sup>84</sup> It is reasonable to reduce the inspired concentration of oxygen to below 50% as rapidly as possible because patients poisoned by irritant gases have enhanced susceptibility to oxygen toxicity as a result of depletion of endogenous antioxidant barriers.<sup>109</sup>

### Neutralization Therapy

A therapy unique to several of the acid- or base-forming irritant gases is chemical neutralization. Although contraindicated in acid or alkali ingestion because of concern of an exothermic reaction in the process of neutralization, the large surface area of the lung and the relatively small amount of xenobiotic present allow dissipation of the heat and gas generated during neutralization. Case studies suggest that nebulized 2% sodium bicarbonate is beneficial in patients poisoned by acid-forming irritant gases.<sup>123</sup> The vast majority of these cases involve chlorine gas exposure, and most patients received other symptomatic therapies as well.<sup>5,74</sup> Although there appears to be no specific benefit for patients exposed to chloramine, nebulized bicarbonate therapy appears to be safe and is reasonable to administer. A prospective evaluation of patients poisoned with chloramine and chlorine gas did not show any clinically significant difference between the group getting nebulized sodium bicarbonate and the control group, although there was a small but statistical improvement in forced expiratory volume in 1 second (FEV<sub>1</sub>) at 120 and 240 minutes in the group that received nebulized sodium bicarbonate.<sup>5</sup> The sodium bicarbonate solution should be used in a sufficiently dilute form to prevent irritation. Typically, 1 mL of 7.5% or 8.4% sodium bicarbonate solution is added to 3 mL sterile water (resulting in an ~2% solution for nebulization).

Whether nebulized sodium bicarbonate therapy alters the natural course of irritant-induced pulmonary damage remains uncertain. The fact that many irritant gases produce concomitant oxidant injury suggests otherwise. Therefore, patients receiving nebulized bicarbonate therapy require observation beyond the time of symptom resolution. Because administration of neutralizing acids for alkaline irritants, such as ammonia, has not been attempted, we recommend against their use at this time (Antidotes in Depth: A5).

### Antioxidants

Antioxidants include reducing agents such as ascorbic acid,<sup>35</sup> *N*-acetylcysteine, free radical scavengers such as vitamin E, and enzymes such as superoxide dismutase. Studies in humans identify both increased<sup>98</sup> and decreased<sup>11</sup> endogenous antioxidant concentrations in bronchoalveolar lavage fluid in patients with ARDS. Although the concept of treating pulmonary oxidant stress with antioxidants or free radical scavengers is intriguing, most currently available evidence suggests that these xenobiotics offer negligible benefit in humans. The rapid onset of the self-perpetuating destructive effects initiated by redox reactions hinders the success of postexposure therapy. This interpretation is supported by pretreatment models in which antioxidants are effective at preventing or at least limiting the pathologic effects. Use of these and other newer therapies targeted against inflammatory mediators or the oxidative cascade are in the earliest investigative stages and not yet ready to be recommended.

### Xenobiotic-Directed Therapy

Patients with inhalational exposure to hydrogen fluoride should undergo frequent electrocardiographic evaluations and correction of serum electrolytes. Administration of nebulized 2.5% calcium gluconate, prepared as 1.5 mL 10% calcium gluconate plus 4.5 mL 0.9% sodium chloride solution or sterile water, is suggested to limit systemic fluoride absorption, and is reasonable to administer. By binding fluoride ion locally, nebulized calcium prevents fluoride-induced cellular and systemic toxicity. Systemic calcium salts should be administered as needed to correct hypocalcemia (Chap. 104 and Antidotes in Depth: A32).

Current therapy for inhalation of capsaicin or of any tear gas, is primarily supportive. Extracorporeal membrane oxygenation was used in children to maintain oxygenation in the presence of severe pulmonary toxicity resulting from capsaicin exposure. There are no antidotes currently available.

### Advanced Pharmacologic Therapy

#### Perfluorocarbon Partial Liquid Ventilation

Partial liquid ventilation involves the intrapulmonary administration of perfluorocarbons, which are inert liquids with low surface tension and excellent

oxygen-carrying capacity. Patients with nonchemically induced ARDS have exfoliated tissue, and presumably persistent xenobiotic, effectively lavaged from the bronchopulmonary tree with this method. Perfluorocarbons improve oxygenation and have an antiinflammatory effect, as demonstrated by reduced oxidant lung injury after liquid ventilation in animals. Although perfluorocarbons have interesting potential to be a highly useful therapy in the future, the limited availability, high cost, and lack of demonstrated efficacy of this therapy make it reasonable only if readily available.<sup>40,64</sup>

## OTHER INHALED PULMONARY XENOBIOTICS

A particulate, or dust, is a solid dispersed in a gas. Dust is a substantial source of occupational particulate exposure and is an important cause of acute pulmonary toxic syndromes. A respirable particulate must have an appropriately small size (generally <10 microns) and aerodynamic properties to enter the terminal respiratory tree. Nonrespirable particulates, also called *nuisance dusts*, are trapped by the upper airways and are not generally thought to cause pulmonary damage. In distinction from the irritant gases, there is no unifying toxic mechanism among the respirable particulates. Many of the particulate diseases, such as asbestos exposure and its sequelae, are chronic in nature; only the acute and subacute syndromes are discussed here.

### Inorganic Dust Exposure

Silicosis, which is pulmonary diseases associated with inhalation of crystalline silica (SiO<sub>2</sub>), or quartz, is representative of a range of lung diseases associated with inorganic silica dust inhalation.<sup>71,89</sup> The aftermath of the World Trade Center attack and building collapse resulted in substantial acute silica exposure to residents and rescuers. Exposure-related effects include several acute and delayed-onset pulmonary consequences, such as cough, asthma, chronic obstructive pulmonary disease, and sarcoidlike lung changes.<sup>73,89</sup> More typically, silica exposure occurs in workers involved in occupations in which rock or granite is pulverized, including mining, quarry work, and sandblasting. Although typically a chronic disease, intense subacute silica dust exposure produces acute silicosis in a few weeks and even death within 2 years. The mechanism of toxicity relates to the relentless inflammatory response generated by the pulmonary macrophages.<sup>65</sup> These cells engulf the indigestible particles and are destroyed, releasing their lytic enzymes and oxidative products locally within the pulmonary parenchyma. Patients present with dyspnea, cor pulmonale, restrictive lung findings, and classic radiographic findings. Treatment is limited and includes steroids and supportive care.

Silica combined with other minerals is referred to as *silicates*, the most important of which include asbestos and talc. Talc, or magnesium silicate [(Mg<sub>3</sub>Si<sub>4</sub>)O<sub>10</sub>(OH)<sub>2</sub>], is widely used in industry, but its use in the home was curtailed over the past two decades because of cases of severe pulmonary injury. Much of the toxicity of talc is related to free silica or asbestos contamination. Improvement after acute massive exposure is sometimes accompanied by progressive pulmonary fibrosis.

### Organic Dusts

Inhalation of dusts from cotton or similar natural fibers, usually during the refinement of cotton fibers (byssinosis), produces chest tightness, dyspnea, and fever that typically begin within 3 to 4 hours of exposure. Similar reactions occur after inhalation of hay, silage, grain, hemp, or compost dust. Symptoms often resolve during the workweek but return after a weekend hiatus. Byssinosis is caused by an endotoxin present on the cotton and is not immunologic in nature.<sup>210</sup> "Grain fever" is caused by a respirable compound associated with grain dust, as occurs during harvesting, milling, and transporting.

### Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis, also known as extrinsic allergic alveolitis, is the final common pathway for many different organic dust exposures.<sup>125</sup> The name attached to the individual syndrome typically identifies the associated occupation or substrate. For example, *bagassosis* is the term associated with sugar cane (bagasse), and *farmer's lung* is the term associated with moldy

hay, although both conditions are caused by thermophilic *Actinomyces* spp. When associated with puffball mushroom spores (*Lycoperdon* spp), the syndrome is called *lycoperdonosis*; when caused by bird droppings, it is called *bird fancier's lung*. The implicated allergen is capable of depositing in the pulmonary parenchyma and eliciting a cell-mediated (type IV) immunologic response. Clinical findings include fever, chills, and dyspnea beginning 4 to 8 hours after exposure. The chest radiograph is typically normal but also reveals diffuse or discrete infiltrates. Progressive disease is associated with a honeycombing pattern on the radiograph and a restrictive lung disease pattern on formal pulmonary function testing. It is reasonable to administer corticosteroids and recommended to avoid the antigen.

### Metal Fume Fever and Polymer Fume Fever

Metal fume fever is a recurrent influenzalike syndrome that develops several hours after exposure to metal oxide fumes generated during welding, galvanizing, or smelting.<sup>47</sup> Although most symptoms of metal fume fever are similar to those expected with irritant gas exposures (dyspnea, cough, chest pain), the presence of fever, typically 100.4°F to 102.2°F (38°C–39°C), distinguishes the syndromes. In addition, patients experience headache, a metallic taste, myalgias, and chills. Direct pulmonary toxicity does not occur, and patients with metal fume fever generally have normal chest radiographs. Interestingly, acute tolerance develops, so repeat daily exposures produce progressively milder symptoms. However, the tolerance disappears rapidly, and after a short work hiatus such as a weekend, the original intensity resumes, thus accounting for the designation "Monday morning fever." Many metal oxides are capable of eliciting this syndrome, but it is noted most frequently in patients who weld galvanized steel, which contains zinc. Metal fume fever also occurs commonly after the high-temperature welding of copper-containing compounds, thus accounting for the historical appellation "brass foundry workers' ague." There is a strong association between welding-related metal fume fever and welding-related respiratory symptoms suggestive of occupational asthma.<sup>33</sup> Serum and urine metal concentrations typically are not elevated after the acute event, although they are also found to be chronically elevated following daily occupational exposure. The etiology of metal fume fever is debated, but the syndrome has features suggestive of both an immunologic and a toxic etiology.<sup>47</sup> Antigen release with immunologic response appears to be responsible for the induction of symptoms. On subsequent exposure, proinflammatory cytokines, such as TNF- $\alpha$ , and various interleukins are detected in bronchoalveolar lavage fluid.<sup>70</sup> However, because symptoms often occur with the first exposure to fumes, a direct toxic effect on the respiratory mucosa presumably exists.<sup>122</sup> Exposure to certain metal fumes, such as cadmium oxide or other zinc compounds, produce direct toxic effects on the pulmonary parenchyma.

The management of patients with metal fume fever is supportive and includes analgesics and antipyretics. There is no specific antidote, and chelation therapy we recommend against unless otherwise indicated. For example, patients with ARDS after metal fume inhalation most likely have metal toxicity (eg, cadmium pneumonitis). The natural course of metal fume fever involves spontaneous resolution within 48 hours. Persistent symptoms are rare and should prompt investigation for metal toxicity.

A remarkably similar syndrome occurs subsequent to inhaling pyrolysis products of fluorinated polymers (eg, Teflon), which is aptly termed *polymer fume fever*.<sup>47</sup> Patients develop self-limited influenzalike symptoms several hours after exposure to the fumes. As with metal fumes, very large exposures to polymer fumes result in direct pulmonary toxicity. Supportive care is the therapy of choice.

### Asthma and Reactive Airways Dysfunction Syndrome

Asthma, or *reversible airways disease*, is a clinical syndrome that includes intermittent episodes of dyspnea, cough, chest pain or tightness, wheezes on auscultation, and measurable variations in expiratory airflow. Episodes typically are triggered by a xenobiotic or physical stimulus and resolve over several hours with appropriate therapy. The underlying process is immunologic in most cases, with allergen-triggered release of inflammatory mediators

TABLE 121-4 Common Xenobiotic Sensitizers Producing Occupational Asthma		
Molecular Weight	Example	Primary Risk Occupations
<b>High</b>		
Proteins	Crab shell protein	Seafood processors
<b>Low</b>		
Acrylate	Plastics	Adhesives, plastics
Glutaraldehyde	Sterilant	Health care workers
Isocyanates	Toluene diisocyanate	Polyurethane foam, automobile painters
Metals	Nickel sulfate	Nickel platers
Trimellitic anhydride	Curing agent for epoxy and paint	Chemical workers
Wood dust	Western red cedar ( <i>Thuja plicata</i> )	Foresters, carpenters

causing bronchiolar smooth muscle contraction and subsequent inflammation. Because asthma affects 5% to 10% of the world's population and the triggers often are nonspecific, it is not surprising that work-aggravated asthma is extremely common. The patients are previously sensitized, and the initial irritant exposure causes bronchospasm or similar symptoms. Thus, work-aggravated asthma is discovered early in the worker's employment, and a more appropriate workplace or occupation can be pursued.

Occupational asthma, or asthma occasioned by a workplace exposure to a sensitizing xenobiotic, accounts for perhaps up to 25% of all newly diagnosed asthma in adults.<sup>121</sup> Casual exposure to one of the 250 or more known sensitizers (Table 121-4) is usually associated with a latency period of weeks or months of exposure before symptom onset.<sup>76</sup> After symptoms begin, however, they recur consistently after reexposure to the inciting trigger agent. Occupational asthma with latency is either IgE dependent, in which case it is identical to allergic asthma, or IgE independent.<sup>121</sup> The IgE-dependent form is most commonly associated with high-molecular-weight compounds (>5,000 Da) or with certain haptenic low-molecular-weight agents (eg, acetic anhydride). The low-molecular-weight compounds (eg, nickel, isocyanates) more typically cause IgE-independent disease, which manifests as the delayed reaction pattern of cell-mediated, or type IV, hypersensitivity. Because contact with a trigger is difficult to avoid in either case, reassignment or an outright occupational change is occasionally required. Treatment for exacerbations is comparable to standard asthma therapy and should include bronchodilators and corticosteroids as appropriate.

Acute exposure to irritant gas results in the development of a persistent asthmalike syndrome also termed *reactive airways dysfunction syndrome* (RADS), *irritant-induced asthma*, or *occupational asthma without latency*. Virtually every irritative xenobiotic is reported to cause this syndrome, and those not yet described probably are likely unrecognized. Although asthma typically is associated with massive inhalational exposure, as occurred with irritant dust exposure after the World Trade Center collapse,<sup>73</sup> occasional patients are susceptible to low-level exposure. Reactive airways dysfunction syndrome is often compared to occupational asthma because both disorders are chemically induced and most frequently occur after chemical exposure in the workplace. However, in comparison with those who develop occupational asthma, patients who develop RADS have a lower incidence of atopy and are exposed to agents not typically considered to be immunologically sensitizing.<sup>106</sup> In addition, the airflow improvement with  $\beta_2$ -adrenergic agonist therapy is significantly better in patients with occupational asthma. Bronchial biopsy performed in patients with RADS generally reveals a chronic inflammatory response.<sup>14</sup> Reactive airways dysfunction syndrome also has a neurogenic etiology, as opposed to an immunologic origin as in patients with occupational asthma, which differentiates these clinically similar diseases

on a mechanistic basis. Neurogenic inflammation results from increased vascular permeability, presumably secondary to release of substance P from unmyelinated sensory neurons (C fibers). The role of corticosteroids is undefined, but animal models suggest an antiinflammatory benefit, and they are recommended as for any other patient with acute bronchospasm. Recovery often takes months, with the delay related to either ongoing low level exposures to endopeptidase inhibitors or persistent irritation of impaired tissue by environmental irritants such as pollution.

## SUMMARY

- Although the spectrum of xenobiotics capable of causing pulmonary toxicity is large, the pathologic changes are rather limited.
- Gases that have little or no irritant potential or systemic toxicity cause simple asphyxiation, a situation in which the ambient atmosphere has a diminished oxygen concentration.
- Parenchymal irritation occurs after exposure to acid-forming or free radical-generating gases and severe toxicity manifesting such as ARDS occur.
- Reactive airways dysfunction syndrome and occupational asthma are clinically similar diseases that are described in patients after inhalational exposure. Whereas asthma is typically immunologic in origin, RADS is irritant in origin.
- Treatment of all such exposures centers on symptomatic and supportive care, which includes both interventional and pharmacologic interventions. There is little support for corticosteroids, but if used for a short course of therapy, there is limited risk of harm.

## CARBON MONOXIDE

Christian Tomaszewski

### Carbon Monoxide (CO)

MW	=	28.01 Da
Gas density	=	0.968 (air = 1.0)
Blood carboxyhemoglobin level		
Nonsmokers	=	1%–2%
Smokers	=	5%–10%
Action level	>	10%
TLV–TWA	=	50 ppm

### HISTORY AND EPIDEMIOLOGY

Carbon monoxide (CO) is formed during the incomplete combustion of virtually any carbon-containing compound. Because it is an odorless, colorless, and tasteless gas, it is remarkably difficult to detect in the environment even when present at high ambient concentrations and is a leading cause of poisoning morbidity and mortality in the United States. Based on US national death certificate data, there were 439 annual deaths from unintentional non-fire exposure to CO from 1999 to 2004.<sup>27</sup> The groups with the highest risk were male gender and elderly age, possibly because of occupational exposure and inability to discern CO symptoms, respectively. The CO-related mortality rate has remained essentially unchanged over the years despite increased CO detector use.<sup>22,26,28</sup> More than half of these cases (64%) occurred in homes with faulty furnaces, usually in the fall or winter months. Many clusters were associated with power failures during catastrophic weather, such as ice storms, blizzards, and hurricanes.<sup>24,25</sup> Analysis of the Centers for Disease Control and Prevention wide-ranging online data for epidemiologic research (WONDER) database showed total non-fire-related CO poisoning deaths decreased from 1,967 in 1999 to 1,319 in 2014.<sup>88</sup> Of these non-fire-related deaths, unintentional cases continue at a rate of approximately 450 annually from 1999 to 2015.<sup>29,187</sup>

Just as important as mortality rates are the greater number of survivors from CO poisoning. Despite increased awareness for CO poisoning, there were still an average of 20,636 nonfatal, unintentional, non-fire-related CO exposures treated annually in the United States.<sup>28</sup> More than 40% of cases occurred in the winter, with almost 75% occurring in residences. However, exclusion of intentional and fire-related cases severely underestimates the extent of the problem. Based on firsthand hospital data, a minimum of 50,000 patients with CO poisoning present to US emergency departments (EDs) each year, up to half resulting in hospitalization.<sup>96,111</sup> More recent data using probable and suspected cases suggest that there were more than 230,000 ED visits in 2007 alone that were unintentional and related to non-fire CO poisoning.<sup>112</sup>

The bigger problem with CO poisoning is the associated morbidity that survivors risk even after acute treatment. The most serious complication is persistent or delayed neurologic sequelae (DNS) or delayed neurocognitive sequelae, which occurs in up to 50% of patients with symptomatic acute poisonings.<sup>81,174,226</sup> At 1 year after exposure, of the 1,643 patients not treated with HBO 42% had cognitive sequelae at 6 weeks, 30% at 6 months and 18% at 12 months. Of the 75 treated with HBO 24% had cognitive sequelae at 6 weeks, 17% at 6 months and 14% at 12 months.<sup>228</sup> There is still no highly reliable method of predicting who will have a poor outcome, requiring the threshold for HBO therapy for CO poisoning and follow-up be particularly low.

Potential sources of CO abound in our society, often resulting in unintentional poisoning<sup>28</sup> (Table 122-1). Although CO is found naturally in the body as a byproduct of hemoglobin degradation by heme oxygenase found in the liver and spleen,<sup>47</sup> it is readily available for inhalation from the incomplete

combustion of virtually any carbonaceous fuel. Alternatively, absorption (dermal, ingestion, or inhalation) of methylene chloride results in CO toxicity after hepatic metabolism (Chap. 105).<sup>156</sup> Despite catalytic converters and other emission controls, more than 50% of unintentional CO deaths are still caused by motor vehicle exhaust.<sup>45,151</sup> The introduction of catalytic converters with emissions controls is associated with a decrease in suicide attempts and deaths using automobile exhaust.<sup>91</sup> Occupants of motor vehicles are not the only victims of exhaust gases; CO poisoning is also reported in occupants of the beds of pickup trucks and on boats.<sup>22,95,130</sup> Workers are at risk from use of propane-powered equipment indoors such as ice skating rink resurfacers<sup>21,52</sup> and forklifts.<sup>66,104</sup> For optimal performance, propane-powered forklifts are typically adjusted to produce less than 10,000 ppm of CO in exhaust but in fact average more than 30,000 ppm, which could lead to unsafe concentrations in an enclosed warehouse within 1 hour.<sup>67</sup>

In the past 10 years, nonvehicular sources of CO have increasingly accounted for the majority of unintentional poisonings.<sup>151</sup> More than one-third of the deaths from unintentional CO poisoning occur in winter months (December, January, and February) in the US.<sup>29</sup> Predominantly, these involve the burning of charcoal, wood, or natural gas for heating and cooking.<sup>92</sup> Furnaces that burn natural gas (methane or propane) for heating are often implicated, especially when the flue is blocked.<sup>100,101</sup> Gas kitchen stoves are also an important source of CO in indigent populations with marginal heating systems.<sup>101</sup> In fact, the use of gas stoves for supplemental heat is predictive of CO poisoning in patients who present to the ED with headache and dizziness.<sup>100</sup>

Absence of fuel-burning devices is not necessarily protective for CO poisoning. In multifamily homes, CO can diffuse through drywall, which is actually quite porous.<sup>89</sup> During ice storms, blizzards, hurricanes, and other natural disasters with power loss, the indoor use of gasoline-powered generators<sup>115,218</sup> and charcoal-burning grills, the latter particularly in immigrant populations, leads to epidemic CO poisoning outbreaks.<sup>23,25,234</sup>

Fires are another important source of CO exposure, contributing substantially to the approximate 5,613 smoke inhalation deaths each year.<sup>45</sup> Carbon monoxide is considered to be the most common hazard to smoke inhalation victims.<sup>72,186</sup> These cases are further compounded by the high incidence of hydrogen cyanide poisoning (Chap. 123).<sup>84</sup>

**TABLE 122-1** Sources of Carbon Monoxide Implicated in Poisonings

Anesthetic absorbents
Banked blood
Camp stoves and lanterns
Charcoal grills
Coffee roasting
Fires
Formic acid decomposition mixed in sulfuric acid
Gasoline-powered equipment (eg, generators, power washers)
Ice-resurfacing machines (propane powered)
Internal combustion engine (boat, car, truck)
Methylene bromide
Methylene chloride
Natural gas combustion furnaces (water heaters, ranges, and ovens)
Propane powered forklifts
Underground mine explosions
Wood pellet storage

## TOXICOKINETICS

Carbon monoxide is readily absorbed after inhalation. The Coburn-Forster-Kane (CFK) model allows approximate prediction of carboxyhemoglobin (COHb) levels based on exposure history.<sup>46,48</sup> A simplification of the model allows for estimation of the equilibrium based on the ambient concentration of CO in ppm:  $\text{COHb} (\%) = 100 / \{1 + (643/\text{ppm CO})\}$ .<sup>214</sup> This assumes that the individual weighs 70 kg and is not anemic. With exponential uptake, it takes more than 4 hours for equilibrium to be attained. Therefore, within minutes of high CO exposures, the arterial COHb level actually overshoots predicted estimates before equilibration.<sup>9,15</sup> Endogenous production of CO is not factored in because its contribution to COHb is only 2%.

After its absorption, CO is carried in the blood, primarily bound to hemoglobin. The Haldane ratio states that hemoglobin has approximately a 200 to 250 times greater affinity for CO than for oxygen. Therefore, CO is primarily confined to the blood compartment, but eventually up to 15% of total CO body content is taken up by tissue, primarily bound to myoglobin.<sup>46</sup> Therefore, the dissolved CO concentration in the plasma better reflects the ultimate potential for poisoning because it is available for diffusion into all tissue compartments, including the muscle and brain.<sup>135</sup>

Elimination of CO, like absorption, from the blood is modeled mathematically using the CFK model. The equation predicts a half-life of 252 minutes. In actual volunteer studies, means of 249 and 320 minutes breathing room air are reported.<sup>171</sup> With 100% oxygen, these half-lives can be reduced significantly to means ranging 47 to 80 minutes in studies of volunteers who attain COHb levels of 10% to 12%.<sup>171,195</sup> Patients poisoned with CO showed actual mean half-lives ranging from 74 to 131 minutes when treated with 100% oxygen.<sup>226,227</sup>

Methylene chloride, a paint stripper, is another source of CO. It is readily absorbed through the skin or by ingestion or inhalation and is metabolized in the liver to CO.<sup>191</sup> Carboxyhemoglobin levels peak 8 hours or later and range from 10% to 50%.<sup>134,177</sup> Because of ongoing production of CO, the apparent COHb half-life is prolonged to 13 hours in these patients.<sup>176</sup> Carboxyhemoglobin levels after methylene chloride exposure are proportional to the concentration and duration of exposure.<sup>176</sup>

## PATHOPHYSIOLOGY

The most obvious deleterious effect of CO is binding to hemoglobin, rendering it incapable of delivering oxygen to the cells. Therefore, despite adequate partial pressures of oxygen in blood ( $\text{PO}_2$ ), there is decreased arterial oxygen content. Further insult occurs because CO causes a leftward shift of the oxyhemoglobin dissociation curve, thus decreasing the offloading of oxygen from hemoglobin to tissue (Fig. 28–2).<sup>180</sup> This results in part from a decrease in erythrocyte 2,3-bisphosphoglycerate (2,3-BPG) concentration. The net effect of all these processes is the decreased ability of oxygen to be delivered to tissue.

Carbon monoxide toxicity cannot be attributed solely to COHb-mediated hypoxia. Neither clinical effects nor the phenomena of delayed neurologic deficits is completely predicted by the extent of binding between hemoglobin and CO.<sup>90,209</sup> Furthermore, such a model fails to explain why even minimal levels of COHb (4%–5%) occasionally result in cognitive impairment. An early study showed that dogs breathing 13% CO died within 1 hour and had COHb levels of 54% to 90%. However, exchange transfusion of this same blood into healthy dogs to reach similar COHb levels caused no untoward effects.<sup>73</sup> Hemorrhaging the dogs to comparable degrees of anemia also produced no adverse effects. The appropriate conclusion was that inherent to CO toxicity is its delivery to target organs such as the brain and heart and that although COHb is easily measured, it rarely has a significant contribution to clinical toxicity. For CO to reach tissue, it has to be dissolved in the plasma rather than bound to hemoglobin.<sup>79,80</sup>

Carbon monoxide interferes with cellular respiration by binding to mitochondrial cytochrome oxidase. Initial studies show that this binding is especially exaggerated under conditions of hypoxia and hypotension. In vitro rat models demonstrate that this oxidative stress causes mitochondrial damage with protein oxidation and lipid peroxidation, particularly in the hippocampus and corpus striatum.<sup>196</sup> In vivo models reveal that CO poisoning causes cell loss in the frontal cortex, which is associated with decrements in learning

and memory.<sup>172</sup> Although no comparable brain studies exist in humans, the peripheral lymphocytes and monocytes of CO-poisoned patients show cytochrome oxidase inhibition accompanied by increased lipid peroxidation.<sup>71,146</sup> In a small clinical series of CO-poisoned patients, normalization of this cytochrome activity lagged behind and seemed to agree better with symptom severity than COHb levels.<sup>147</sup>

Inactivation of cytochrome oxidase is only an initial part of the cascade of inflammatory events that results in ischemic reperfusion injury to the brain after CO poisoning (Fig. A40–1). During recovery from the initial poisoning, white blood cells are attracted to and adhere to the damaged brain microvasculature.<sup>201–203</sup> This attraction is partly attributable to endothelial changes from initial cytochrome oxidase dysfunction, mediated primarily through the free radical nitric oxide (NO).<sup>201,207</sup> Carbon monoxide displaces NO from platelets that in turn form peroxynitrites, which are even stronger inactivators of cytochrome oxidase.<sup>207</sup> Multiple animal studies demonstrate that NO is ultimately responsible for much of the endothelial damage from CO and that NO synthase inhibitors can prevent toxicity.<sup>205,207</sup> The NO formation promotes platelet–neutrophil aggregates that in turn lead to neutrophil adhesion to the brain microvasculature.<sup>202</sup> Myelin peroxidase activation in the area further promotes neutrophil adhesion with degranulation and release of proteases that convert xanthine dehydrogenase to xanthine oxidase, an enzyme that promotes formation of oxygen free radicals.<sup>200</sup> Also, mouse studies suggest that circulating microparticles play a proinflammatory role in activation of neutrophils.<sup>237</sup> The end result of this process is delayed lipid peroxidation of the neurons, and the extent of destruction correlates with decrements in learning in rodents.<sup>200</sup> Rats depleted of xanthine oxidase through a tungsten modified diet show no changes in myelin basic protein and cognitive function after CO poisoning.<sup>98</sup>

Simultaneously, with all this perivascular oxidative stress in the brain, there is activation of excitatory amino acids, which ultimately is responsible for the subsequent neuronal cell loss.<sup>207</sup> In fact, in rat brains, glutamate concentrations increase after CO poisoning. Glutamate is an excitatory amino acid that binds at *N*-methyl-D-aspartate (NMDA) receptors and causes intracellular calcium release, resulting in delayed neuronal cell death (Chap. 13). Blockade of NMDA receptors prevents the neuronal death and learning deficits that accompany serious CO poisoning in mice.<sup>113</sup> Increases in the glutamate concentrations in rat brain in the first hour after severe CO poisoning are followed by a later increase in hydroxyl radicals.<sup>172</sup> Ultimately, at 1 to 3 weeks, the animals show histologic evidence of both neuronal necrosis and apoptosis in the frontal cortex, globus pallidus, and cerebellum that are accompanied by deficits in learning and memory.

Carbon monoxide neuronal cell death is partly attributable to apoptosis. In bovine pulmonary artery cells, CO exposure is accompanied by activation of caspase-1, a protease implicated in delayed cell death.<sup>206</sup> Confirmatory evidence was provided in the same study because both caspase-1 and NO synthase inhibitors blocked apoptosis. The end result of all these cellular processes is brain injury, particularly in the basal ganglia and hippocampus.<sup>221</sup> In some studies, this is accompanied by learning impairment.<sup>202</sup> Thus, animal models correlate well with what ultimately occurs in victims of serious CO poisoning, namely, persistent or delayed deficits in learning and memory associated with structural changes in the brain.

Myoglobin, another heme protein, binds CO with an affinity about 60 times greater than it binds oxygen.<sup>49</sup> About 10% to 15% of the total body store of CO is extravascular, primarily binding to myoglobin.<sup>15,46</sup> A dog model demonstrates that this binding is enhanced under hypoxic conditions.<sup>49</sup> This binding partially explains the myocardial impairment that occurs in both animal studies and low concentration exposures in patients with ischemic heart disease. The combination of COHb formation, which decreases oxygen-carrying capacity, and reduced myoglobin in the heart, which decreases oxygen extraction, contributes to the preterminal dysrhythmias that occurs in poisoned animals.

Several studies suggest that CO effects on the cardiovascular system are necessary for ischemic reperfusion injury of the brain. Hypotension is an essential component and results from a combination of myocardial depression and vasodilation. Carbon monoxide, perhaps because of its similarity

to NO, activates guanylate cyclase, which in turn relaxes vascular smooth muscle. Also, CO further displaces NO from platelets, resulting in additional vasodilation.<sup>205</sup> These factors contribute to the hypotension that occurs in animal experiments with exposure to high concentrations of CO.<sup>73</sup> Such an episode of hypotension leads to syncope, portending a worse clinical outcome.<sup>40</sup> In rhesus monkeys, cerebral white matter lesions correlate better with decreases in blood pressure than with COHb level.<sup>78</sup> Lipid peroxidation of the brain in rats develops 1 hour after a CO exposure that has produced syncope and hypotension.<sup>199</sup> This delay is comparable to the time that is necessary to produce mitochondrial destruction from oxidative stress in rats exposed to CO. In a feline model, central nervous system (CNS) damage from CO is reproduced only when hypoxia is accompanied by an interval of ischemia, confirming the ischemia reperfusion model.<sup>159</sup>

Endogenous CO behaves like NO, binding to guanylate cyclase and thereby increasing cyclic guanosine monophosphate (cGMP) concentrations.<sup>114</sup> Although low endogenous concentrations are physiologic, excessive concentrations of CO from exogenous sources are problematic because CO persists much longer than NO. Carbon monoxide appears to be a neuronal messenger by virtue of the fact that as a gas, it can diffuse and signal adjacent cells.<sup>141</sup>

**CLINICAL MANIFESTATIONS**

**Acute Exposure**

The earliest symptoms associated with CO poisoning are often nonspecific and readily confused with other illnesses, typically a viral syndrome<sup>223</sup> (Table 122–2). The initial symptom reported by volunteers within 4 hours of exposure to 200 ppm CO (producing COHb levels of 15%–20%) is headache; shorter exposures at 500 ppm also produce nausea.<sup>192</sup> The incidence of CO poisoning in symptomatic patients presenting to EDs in the winter with an influenzalike illness ranges from 3% to 24% in some series.<sup>61,101</sup> The typical presenting complaints include headache, dizziness, and nausea, and the most frequent exposures occur during the winter, explaining why influenza is the most common misdiagnosis.<sup>61</sup> The most common symptom, headache, is usually described as dull, frontal, and continuous. Carbon monoxide poisoning is also frequently misdiagnosed as food poisoning, gastroenteritis, and even colic in infants. Similar to adults, children tend to develop nonspecific symptoms, complicating diagnosis.

Continued exposure to CO leads to symptoms attributable to oxygen deficiency in the heart. Low-concentration exposures, leading to COHb levels of 2% to 4%, in volunteers with stable angina result in decreased exercise tolerance as well as signs and symptoms of myocardial ischemia.<sup>2</sup> At higher levels (COHb of 6%), there is a greater frequency of premature ventricular contractions during exercise. Myocardial infarction and dysrhythmias are described in victims of CO poisoning, and acute mortality from CO is usually a result of ventricular dysrhythmias.<sup>2,3</sup> Prolonged exposure to CO or high COHb levels are associated with temporary myocardial stunning, manifested as global hypokinesia or Takotsubo cardiomyopathy lasting usually less than 24.<sup>116,118</sup> In some cases stunning, with decreased left ventricular ejection fraction, can last several days and is associated with increased concentrations of β-type natriuretic peptide, lactate, and troponin.<sup>132</sup> Troponin elevations often occur even in the absence of any coronary artery disease or even electrocardiographic (ECG) or echocardiographic changes.<sup>31,55</sup>

These patients have an increased propensity for cardiac mortality, with almost one-third dying within 8 years after serious CO poisoning.<sup>102</sup> A nationwide population based cohort study in Taiwan found an increased incidence

of dysrhythmias, mostly paroxysmal tachycardia and ventricular fibrillation, in decade after CO poisoning of 8,381 subjects.<sup>131</sup> Although serious CO exposures are associated with increased long-term mortality beyond 90 days, there was no association with increased cardiac death.<sup>87</sup>

The CNS is the organ system that is most sensitive to CO poisoning. Acutely, otherwise healthy patients may manifest headache, dizziness, and ataxia at COHb levels as low as 15% to 20%, with higher levels or longer exposures causing syncope, seizures, or coma.<sup>223</sup> Focal neurologic findings suggest a cerebrovascular accident. Some cases have diffuse frontal slow-wave activity on electroencephalogram. Within 1 day of exposures that result in coma, many patients show decreased density in the central white matter and globus pallidus on computed tomography (CT) (Fig. 122–1) or magnetic resonance imaging (MRI).<sup>137</sup> Autopsies show involvement of other areas, including the cerebral cortex, hippocampus, cerebellum, and substantia nigra.<sup>129</sup>

Metabolic changes reflect the toxic effects of CO better than any particular COHb level. Patients with mild CO poisoning develop respiratory alkalosis in an attempt to compensate for the reduction in oxygen-carrying capacity and delivery. More substantial exposures result in metabolic acidosis with lactate production that accompanies tissue hypoxia.<sup>189</sup> Even in the absence of hypotension, lactate was an independent predictor of worse mental status and inpatient complications.<sup>30,60,150</sup> The importance of metabolic acidosis was highlighted in a retrospective series of 48 CO-poisoned patients, in whom hydrogen ion concentration was a better predictor of poor recovery during initial hospitalization than was COHb level.<sup>216</sup>

Although the brain and heart are the most sensitive, other organs also manifest the effects of CO poisoning. One-fifth to one-third of patients with severe CO poisoning, particularly those requiring endotracheal intubation, develop pulmonary edema.<sup>82</sup> This is caused by cardiac depression directly from CO or ARDS from associated smoke inhalation.<sup>118,186</sup> This does not appear to be a direct effect of CO on lung tissue because sheep with prolonged exposure to CO, resulting in COHb levels greater than 50%, showed no anatomic or physiologic changes in lung function.<sup>185</sup> Although myonecrosis and even compartment syndromes occur, patients rarely develop acute kidney injury (AKI). Retinal hemorrhages occur with exposures longer than 12 hours.<sup>120</sup> Cherry-red skin coloration occurs only after excessive exposure (2%–3% of cases referred to one hyperbaric center) and represents a combination of CO-induced vasodilation, concomitant tissue ischemia, and failure

Ataxia	Myocardial ischemia
Cardiac dysrhythmias	Nausea
Chest pain	Syncope
Confusion	Tachypnea
Dizziness	Visual blurring
Dyspnea	Vomiting
Headache	Weakness

**FIGURE 122–1.** Computed tomography scan of the brain showing bilateral lesions of the globus pallidus (arrows) in a patient with poor recovery from severe carbon monoxide poisoning. to extract oxygen from arterial blood.<sup>178</sup> Another classic but uncommon phenomenon is the development of cutaneous bullae after severe exposures. These bullae are thought to be caused by a combination of pressure necrosis and possibly direct CO effects in the epidermis.

## NEUROCOGNITIVE SEQUELAE

The persistent or delayed effects of CO poisoning are varied and include dementia, amnesic syndromes, psychosis, parkinsonism, paralysis, chorea, cortical blindness, apraxia and agnosia, peripheral neuropathy, and incontinence.<sup>133,233</sup> If not diagnosed at initial poisoning, neurologic deterioration is delayed and preceded by a lucid period of 2 to 40 days after the initial poisoning.<sup>40</sup> In patients admitted to an intensive care unit (ICU) for severe CO poisoning and treated with 100% oxygen, 14% of survivors had permanent neurologic impairment.<sup>123</sup> In a Korean series of 2,360 CO-poisoned patients, 3% continued to show memory failure or parkinsonian features 1 year after exposure.<sup>40</sup> Another series of 63 seriously poisoned patients showed memory impairment in 43% and deterioration of personality in 33% at 3-year follow-up.<sup>189</sup> Children also develop behavioral and educational difficulties after severe poisoning.<sup>128</sup> However, patients older than 30 years of age are more susceptible to the development of delayed sequelae.<sup>41,228</sup> Most cases of delayed neurocognitive sequelae are associated with loss of consciousness (LOC) in the acute phase of toxicity.<sup>51</sup>

Neurocognitive sequelae probably involve lesions of the cerebral white matter.<sup>75</sup> Weeks after exposure, autopsies show necrosis of the white matter, globus pallidus, cerebellum, and hippocampus. Magnetic resonance imaging studies confirm the damage to the white matter and hippocampus.<sup>70,137,223</sup> Animal studies show that having a markedly elevated COHb level alone cannot cause similar white matter lesions but that there must also be an episode of hypotension.<sup>78,159</sup> The fact that the areas permanently damaged in serious CO poisoning cases are the areas with the poorest vascular supply in the brain is consistent with these findings.

## CHRONIC EXPOSURE

Often, patients complain of persistent headaches and cognitive problems after long-term exposure to low concentrations of CO. Unfortunately, to date, there have been no controlled studies demonstrating that in the absence of a severe acute poisoning episode, this type of exposure results in any long-term sequelae. Warehouse workers who are chronically exposed to CO from propane combustion have intermittent problems with headache, nausea, and lightheadedness.<sup>66</sup> Fortunately, unless the individual had an episode of severe poisoning with acute deterioration, most workers achieve resolution of their symptoms.<sup>67</sup> One series of patients with chronic CO poisoning demonstrates a high incidence of headache and memory complaints in addition to motor slowing and memory problems on neuropsychologic testing.<sup>153</sup> Although many of the objective deficits improved with elimination of the exposure and HBO treatment, many continued to have posttraumatic stress and conversion disorders. Although it is uncertain whether chronic exposure to low concentrations of CO causes permanent damage, health care providers should be vigilant for symptomatic individuals to prevent continued or catastrophic outcomes.

## DIAGNOSTIC TESTING

The most useful diagnostic test obtainable in a suspected CO poisoning is a COHb level. Normal levels of COHb range from 0% to 5%. Levels at the high end of this range occur in neonates and patients with hemolytic anemia because CO is a natural byproduct of the breakdown of protoporphyrin to bilirubin.<sup>33</sup> Of note, in blood samples from neonates, falsely high COHb levels up to 8% can occur because of interference of fetal hemoglobin with spectroscopy (Chap. 28).<sup>220</sup> Carboxyhemoglobin levels average 6% in one-pack-per-day smokers but may range as high as 10%.<sup>190</sup> Although high COHb levels confirm exposure to CO, particular levels are not necessarily predictive of symptoms or outcome.<sup>90,170</sup>

The usual method for measuring COHb is with a cooximeter, a device that spectrophotometrically reads the percentage of total hemoglobin saturated

with CO. Traditionally, arterial blood was used for this determination; however, venous blood levels are accurate because there is little CO extraction from hemoglobin across the capillary bed.<sup>214</sup> Refrigerated heparinized samples yield accurate COHb levels for months and at room temperature for 28 days, making retrospective clinical and postmortem evaluations reliable.<sup>86,125</sup> The prior administration of hydroxocobalamin, commonly given for cyanide poisoning after smoke inhalation, negatively interferes with COHb levels on selected cooximeters, which could lead to false reassurance.<sup>136,164</sup>

Bedside tests using ammonia or sodium hydroxide are unable to differentiate reliably various levels of COHb versus control participants.<sup>161</sup> Because of the similarities in extinction coefficients, COHb is misinterpreted as oxyhemoglobin on most types of pulse oximetry (Chap. 28).<sup>8</sup> Thus, the pulse oximetry reading is usually normal in the setting of even severe CO poisoning.<sup>85</sup> Some newer pulse oximeters, called pulse cooximeters, have the ability to measure COHb noninvasively.<sup>6</sup> A study in 10 healthy volunteers who inhaled CO at 500 ppm until they reached a peak COHb level of 15% found good agreement between pulse cooximetry and cooximetry.<sup>7</sup> Early models of a commercial bedside pulse cooximeter showed very poor agreement, mischaracterizing half the patients with levels over 15% as lower.<sup>214</sup> Subsequently, two other cohorts of ED patients, using a later model of the same device, found that it measured COHb well, with a bias of 0.6% to 3% and precision of 3.3%.<sup>179,183</sup> Because it tends to overestimate COHb, the authors recommend a normal upper limit of 6.6% as triggering intervention. Because the pulse cooximeter is noninvasive, it can be used for initial screening of ED patients for occult CO poisoning who present with nonspecific symptoms.<sup>37</sup> Likewise, the device is useful for field screening, especially with mass casualties. But because of potential errors with its use, we agree with the American College of Emergency Physicians (ACEP) recent clinical guideline on CO poisoning that recommended it not be used independently to diagnose CO toxicity and therefore cannot substitute for a standard blood COHb measurement.<sup>232</sup>

Breath-sampling methods are used for screening patients.<sup>50,53,64</sup> Cutoffs of 53 ppm in patients breathing air and 43 ppm in those breathing oxygen have a reliability of approximately 80% in predicting COHb levels above 10%.<sup>69</sup> Limited data from French prehospital screening show no correlation between severity of CO poisoning and exhaled CO concentrations.<sup>109</sup> Therefore, because of its poor reliability, we do not recommend breath sampling for screening of hospitalized CO-poisoned patients.

Some clinical laboratories measure CO directly in blood samples rather than COHb. This technique involves assaying CO directly with infrared spectrophotometry after it is extracted from the blood sample with a manometer. Based on calculations rather than true experimental data, the assumption is made that for a patient with a normal hemoglobin, a CO level of 1 mmol/L corresponds to an 11% COHb concentration. A simpler method to measure serum CO content is to add a known solution of hemoglobin followed by sodium dithionite to form COHb. The resulting COHb is measured spectrophotometrically with the assumption that 1 mole of hemoglobin binds 4 moles of CO. Interestingly, in one study, serum CO ranged from 0.14 to 0.6 mg/L but was the same in smokers (average, 4.6% COHb) and nonsmokers (average, 1% COHb).<sup>230</sup> At this time, further research is required to determine the clinical importance of serum CO content.

Additional laboratory tests are useful in severe poisoning cases. Metabolic acidosis with elevated lactate concentration is a more reliable index of severity than a measurement of the COHb concentration.<sup>189</sup> Unfortunately, even arterial pH does not correlate well with either initial neurologic examination or the COHb level, making it a poor criterion for deciding the need for HBO treatment.<sup>152</sup> Specificity of lactate is low in smoke inhalation victims, in whom it is used to indicate concomitant cyanide poisoning (Chap. 123).

Continuous cardiac monitoring and a 12-lead ECG are essential to identify ischemia or dysrhythmias in symptomatic patients with preexisting coronary artery disease or severe exposure. Mild elevations of creatine phosphokinase are common (ranging 20–1,315 IU/L in one series of 65 cases), usually because of rhabdomyolysis rather than cardiac sources.<sup>184</sup> However, because CO causes myocardial infarction in the presence of normal coronaries,<sup>118</sup>

nonspecific increases in troponin concentrations may reflect diffuse cardiac myonecrosis rather than focal coronary artery disease.<sup>34</sup> Congestive heart failure or hypotension can be evaluated with a  $\beta$ -type natriuretic peptide or echocardiography (or both), looking for evidence of myocardial stunning.<sup>33,118</sup> Because of the potential for increased cardiovascular mortality,<sup>102</sup> patients with ECG changes or elevated cardiac markers benefit from further cardiac testing, a stress test, or angiography.

The problem with using COHb levels to base treatment is that there is a wide variation in clinical manifestations across patients with identical COHb levels. Furthermore, particular COHb levels are not predictive of symptoms or final outcome.<sup>142,157,189</sup> In a large prospective study of CO poisoning, COHb levels did not correlate with LOC and were not predictive of delayed neurologic sequelae.<sup>174</sup> Admission COHb levels are inaccurate predictors of peak levels, and the use of nomograms to extrapolate to earlier levels is not validated. Their credibility is also suspect because of the great variability in COHb half-lives and differences in treatment with oxygen. To avert this problem, France equips prehospital personnel with coximeters (model not stated), which, although imprecise do help them distinguish the severity of poisoning.<sup>109</sup>

Because of the inherent unreliability of COHb levels in predicting outcome, researchers are searching for other surrogate markers. Rats have early increases in glutathione released from erythrocytes, a potential marker for CO oxidative stress that could ultimately lead to brain injury.<sup>208</sup> Another promising marker is serum S100B, a structural protein in astroglia that is released from the brain after hypoxic stress. A series of 38 consecutive patients poisoned with CO showed that those who presented with normal neurologic findings and no LOC had normal S100B concentrations.<sup>17</sup> Patients who presented with LOC and neurologic deficits all had elevated concentrations. Carbon monoxide poisoned rats treated with HBO did not develop elevated S100B concentrations unlike those treated with ambient oxygen therapy.<sup>16</sup> Levels at the target organ, the brain, show that S100B in the cerebrospinal fluid (CSF) predicted extreme neurologic sequelae, that is, persistent vegetative state only.<sup>110</sup> Enolase, a byproduct of neuronal destruction, has a longer half-life than S100B and independently predicts delayed neurologic sequelae.<sup>32</sup> Although markers used for cerebral injury, specifically S100B and neuron-specific enolase, rise after CO poisoning, they have not been shown to be reliable enough to predict final outcome or need for treatment.<sup>1,19,175</sup> A recent pilot study concluded that almost 100 different plasma proteins—cytokines, chemokines, and other biomarkers—increase after CO poisoning in patients; their significance awaits more definitive studies.<sup>204</sup>

## NEUROPSYCHOLOGIC TESTING

The extent of neurologic insult from CO can be assessed with a variety of tests. The most basic is documentation of the normal neurologic examination, including a quick mini mental status examination. A more sensitive indicator of the acute effects of CO on cortical function is a detailed neuropsychologic test battery developed specifically for CO patients.<sup>145</sup> The advantages of such testing, which usually takes about 30 minutes, are that it can reliably distinguish 79% of the time between CO-poisoned patients and control participants, and it shows improvement with appropriate HBO treatment.<sup>145</sup> Unfortunately, such testing shows a sensitivity of only 77% and a specificity of 80% for CO poisoning. The patient can show practice effects as well with repeated testing. Another study suggested that the degree of impairment CO patients had on a test of short-term rote and context-aided verbal memory correlated well with the number of HBO treatments needed.<sup>144</sup> The biggest problem with such neuropsychiatric testing is that it is uncertain whether the determined deficits found during the acute CO poisoning phase are at all predictive of the development of neurologic sequelae and therefore the necessity of HBO treatment.

## NEUROIMAGING

Acute changes on CT scans of the brain occur within 12 hours of CO exposure that resulted in LOC.<sup>137,148</sup> Symmetric low-density areas in the region of the globus pallidus, putamen, and caudate nuclei are frequently noted.<sup>105</sup> Changes in the globus pallidus and subcortical white matter early within the

first day after poisoning are associated with poor outcomes<sup>167</sup> (Fig. 122–1). Alternatively, in one series of 18 patients, a negative CT within 1 week of admission was associated with favorable outcome.<sup>213</sup> The use of contrast enhances the early isodense changes not visible on initial CT scan<sup>240</sup> but is not routinely performed.

Magnetic resonance imaging is superior to CT in detecting cerebral white matter basal ganglia lesions after CO poisoning.<sup>137</sup> One study found a much higher incidence of periventricular white matter changes on MRIs done within the first day after exposure. However, such changes had no correlation with COHb level or cognitive sequelae.<sup>167</sup> These periventricular changes are more common and probably more sensitive than globus pallidus lesions. Globus pallidus lesions were present on MRI in only one patient (1.4%) in a prospective study of CO-poisoned patients, half of whom had LOC.<sup>105</sup> Diffusion-weighted, or even diffusion tensor imaging MRI, has more promise in detecting changes in subcortical white matter within hours of serious CO poisoning.<sup>10,197</sup> Regardless, neuroimaging usually does not influence patient management and can be reserved for patients who show poor response or have an equivocal diagnosis.

The most promising area of neuroimaging after CO poisoning is the assessment of regional cerebral perfusion.<sup>43,163</sup> Single-photon emission CT (SPECT) gauges regional blood flow noninvasively using an iodine or technetium tracer. In one series of 13 patients with delayed neurologic sequelae (DNS), all cases showed patchy hypoperfusion throughout the cerebral cortex within 11 days of poisoning.<sup>41</sup> These changes in perfusion occur as early as 1 day after poisoning and primarily involve watershed regions such as the temporoparietooccipital area.<sup>58</sup> Perfusion defects on SPECT scanning are associated with neuropsychological impairment months after serious CO poisoning.<sup>70</sup> In a recent series of CO-poisoned patients who required HBO, patients with DNS, rather than persistent neurologic sequelae, were more likely to show frontal hypoperfusion on SPECT scanning.<sup>107,215</sup> Unfortunately, because of the scant availability of the procedure and the lack of comprehensive studies, SPECT scanning is not the definitive tool at this time for determining prognosis or need for HBO. In addition, when imaging patients 1 to 2 years after poisoning, T2-weighted imaging on MRI is more sensitive than SPECT scanning.<sup>38</sup>

Positron emission tomography (PET) can also be used to evaluate regional blood flow as well as oxygen metabolism in the brain after CO exposure. In one series of severely CO-poisoned patients, PET examination after HBO treatment showed increased oxygen extraction and decreased blood flow in the frontal and temporal cortices.<sup>56</sup> Of note, patients with permanent deficits persisted in showing these abnormalities on PET scanning. One delayed PET study demonstrated that increases in dopamine D<sub>2</sub> receptor binding in the caudate and putamen after CO poisoning were improved with bromocriptine, at which time neuropsychiatric symptoms resolved.<sup>239</sup> Although PET scanning cannot be used to predict outcome, abnormalities that persist on the scan are associated with permanent neurologic sequelae. The same is true for proton magnetic resonance spectroscopy in which abnormalities within 1 week of exposure can predict DNS.<sup>126</sup>

Electroencephalograms (EEGs) complement perfusion studies in the evaluation of CO-poisoned patients. Although initial studies demonstrate that many patients have regional EEG abnormalities after poisoning, it is unknown if these are predictive of persistent or delayed neurologic problems. Electroencephalograms mapping may be discrepant relative to SPECT scanning because EEG preferentially demonstrates subcortical lesions.

## MANAGEMENT

The mainstay of treatment is initial attention to the airway. One hundred percent oxygen should be provided as soon as possible by either nonrebreather face mask or endotracheal tube. Although concerns have been raised regarding toxicity from excess oxygen, patients poisoned with CO can still have cellular hypoxia despite normal oxygen saturation.<sup>14,85</sup> It is important to remember that a nonrebreathing mask only delivers 70% to 90% oxygen; a positive-pressure mask or an endotracheal tube is necessary to achieve higher oxygen concentrations. The immediate effect of oxygen is to

enhance the dissociation of COHb.<sup>180</sup> In volunteers, the half-life of COHb is reduced from a mean of 5 hours (range, 2–7 hours) when breathing room air (21% oxygen) to approximately 1 hour (range, 36–137 minutes) when breathing 100% oxygen at normal atmospheric pressure.<sup>171</sup> Actual poisoned patients show a range in half-lives of 36 to 137 minutes (mean, 85 minutes) when breathing 100% oxygen; the longer elimination half-lives appear to be most often associated with long, low-level exposures.<sup>155,227</sup> With oxygenation and intensive care treatment, hospital mortality rates for serious exposures range from 1% to 30%. The duration of treatment is unclear, with a valid end point being the resolution of symptoms, usually accompanied by a COHb below 5%.

Continuous cardiac monitoring and intravenous (IV) access are necessary in any patient with systemic toxicity from CO poisoning. Hypotension should initially be treated with IV fluids, with the addition of inotropes for persistent myocardial depression. An evaluation for cardiac ischemia, including ECG and cardiac markers, is recommended in symptomatic patients at risk: prolonged exposure (>2 hours), altered mental status, or male gender.<sup>31</sup> Echocardiography is reasonable in such cases; almost three-quarters of CO-poisoned patients with elevated troponins showed cardiomyopathy with global dysfunction or Takotsubo like changes.<sup>33</sup> Standard advanced cardiac life support protocols should be followed for the treatment of patients with life-threatening dysrhythmias. Patients with a depressed mental status should have a rapid blood glucose checked. Animal studies of CO poisoning suggest that hypoglycemia can be deleterious.<sup>168</sup> We recommend not giving sodium bicarbonate for correction of any acidemia unless profound because it will cause left shift of the oxyhemoglobin dissociation curve, further impairing tissue oxygenation.<sup>62</sup>

### Hyperbaric Oxygen

Hyperbaric oxygen (HBO) therapy is still the treatment of choice for patients with significant CO exposures.<sup>210</sup> But its most obvious effect is not the most important. One hundred percent oxygen at ambient pressure reduces the half-life of COHb from about 320 minutes to 85 minutes; at 2.5 atmospheres absolute (ATA), it is reduced to 20 minutes.<sup>171,227</sup> Actual CO-poisoned victims treated with HBO have COHb half-lives ranging from 4 to 86 minutes.<sup>155</sup> Hyperbaric oxygen also increases the amount of dissolved oxygen by about 10 times, which is sufficient alone to supply metabolic needs in the absence of hemoglobin (Chap. 28).<sup>12</sup> This is rarely an important clinical issue because most patients are already stabilized and have appreciably decreased COHb with ambient oxygen before preparation for an HBO treatment.

Therefore, HBO is more than just a modality to clear COHb more quickly than ambient oxygen (Antidotes in Depth: A40). More importantly, in rats after LOC from CO exposure, hyperbaric, but not normobaric, oxygen

therapy prevents brain lipid peroxidation.<sup>166</sup> Hyperbaric oxygen therapy prevents ischemic reperfusion injury by a variety of mechanisms. First, in animal models, HBO accelerates regeneration of inactivated cytochrome oxidase, which is the initiating site for CO neuronal damage.<sup>12</sup> Unlike 100% oxygen at room pressure, in clinical trials, HBO was much more effective than room pressure oxygen at restoring mitochondrial function within peripheral white blood cells in CO-poisoned patients.<sup>59</sup> Hyperbaric oxygen also prevents  $\beta$ -integrin-mediated neutrophil adhesion to brain microvascular endothelium, a process essential for amplification of CNS damage from CO.<sup>178</sup> In vitro studies of rat astrocytes show protective effects of HBO versus 100% oxygen in preventing impairment of neurotrophic activity after CO poisoning.<sup>117</sup> All these animal studies explain why HBO, but not 100% oxygen at atmospheric pressure, prevents delayed deficits in a learning and memory maze model.<sup>202</sup>

Clinical studies of the effectiveness of HBO in preventing neurologic damage from CO are not as convincing as basic science studies would suggest. In uncontrolled human clinical series, the incidence of persistent neuropsychiatric symptoms, including memory impairment, ranged from 12% to 43% in patients treated with 100% oxygen and was as low as 0% to 4% in patients treated with HBO.<sup>82,143,154,157</sup>

Additionally, several controlled clinical trials have evaluated the efficacy of HBO in CO poisoning (Table 122–3). The first randomized study of CO poisoning included more than 300 patients and failed to show a benefit from HBO in patients who had no initial LOC.<sup>174</sup> Unfortunately, seriously ill patients were not randomized to surface pressure oxygen; they received either one or three treatments of HBO. Flaws in the study included significant delays to treatment and the use of suboptimal pressure, 2.0 ATA, well below the greater than 2.5 ATA typically used in positive animal and human studies. A smaller ( $n = 60$ ) controlled study avoided some of these flaws and showed that HBO, at a maximum pressure of 2.8 ATA, decreased delayed neurologic sequelae at 3 to 4 weeks from 23% to 0% in CO-poisoned patients who presented without LOC.<sup>211</sup> However, patients with syncope, a marker of serious poisoning, were excluded. A very small study ( $n = 26$ ) of patients presenting with Glasgow Coma Scale (GCS) scores above 12 after CO poisoning included almost half with LOC.<sup>63</sup> Randomization to HBO versus 100% normobaric oxygen resulted in decreased EEG abnormalities and less reduction in blood flow reactivity to acetazolamide at 3 weeks. Unfortunately, all of these studies failed to definitively study all CO-poisoned patients, including those with syncope or coma.

The first randomized trial to directly address the issue of HBO efficacy in seriously CO-poisoned patients evaluated 191 CO-poisoned patients referred for HBO treatment.<sup>182</sup> Patients were randomized to a minimum of three daily treatments of HBO (2.8 ATA for 60 minutes) or 100% oxygen at 1.0 ATA for 3 days. Although the HBO group had a higher incidence of persistent

Data from Buckley NA, Juurlink DN, Isbister G, et al. Hyperbaric oxygen for carbon monoxide poisoning. *Cochrane Database Syst Rev*. 2011 Apr 13;(4):CD002041 and Penney DG. Carbon Monoxide Poisoning. New York, NY: CRC Press; 2008.

neurologic sequelae at 1 month, there was no significant difference between the two groups; more than two-thirds of each group had persistent problems. This study, although the largest controlled, randomized study to date, suffered from several flaws. Fewer than half of the patients had follow-up at 1 month. Disproportionate numbers of suicide cases (about two-thirds) and drug toxicity (44%), with accompanying neuropsychologic defects, likely confounded finding any beneficial effect from HBO. Finally, HBO treatment was delayed for 6 hours, making it much less likely to be effective.<sup>82,174</sup>

The landmark randomized, double-blind, placebo-controlled study of 152 CO-poisoned patients identified a beneficial effect of HBO.<sup>226</sup> Most of these patients were ill, with a mean initial COHb level of 25% and a 50% incidence of LOC. Patients were all treated within 24 hours of exposure, but the success of the study might be partially attributable to the rapid mean time to treatment of less than 2 hours. Patients received HBO three times at intervals of 6 to 12 hours, each at 2.0 ATA, except for the first hour of the first treatment, which was at 3.0 ATA. Control patients received sham treatments in the HBO chamber with 100% oxygen at 1.0 ATA. At 6 weeks, the HBO group had a 24% incidence of cognitive sequelae versus 46% in the control group. Based on these data, the number of patients needed to treat to prevent one case of cognitive impairment is only five. Critics of this study point out that the neuropsychiatric tests were not significantly different between the groups except for digit span and trail making, and there was no difference in activities of daily living. However, untreated patients had increased self-reported memory problems at 6 weeks (51% vs 28%), and the beneficial effect on cognitive sequelae persisted until 12 months.

A more recent study of 179 patients with transient LOC after CO poisoning showed no benefit from a single HBO treatment.<sup>5</sup> Neurologic recovery at 1 month was approximately 60% regardless of HBO or normobaric oxygen. However, the study was done only at 2.0 ATA, and more than 20% of patients were lost to follow-up. The main effect of HBO is to prevent  $\beta 2$  integrins mediated adherence of neutrophils in the brain; this does not occur in animal studies until at least a pressure of 2.8 ATA is attained.<sup>210</sup>

Based on the strong animal and basic science experience, the positive human studies mentioned earlier, and few adverse effects, it is not surprising that the Underwater and Hyperbaric Medical Society (UHMS) recommends HBO for all CO patients with signs of serious toxicity.<sup>224</sup> With the low risk of this procedure,<sup>181,188</sup> almost 1,500 patients are treated with HBO for CO poisoning in the United States each year.<sup>93</sup> Therefore, we believe that HBO is safe and indicated for serious CO poisoning, even though there is still substantial disagreement in the interpretation of the existing evidence regarding its usefulness.<sup>100,138,232</sup>

### Indications for Hyperbaric Oxygen Therapy

Although the specific recommendations for HBO after acute CO poisoning are listed (Table 122–4), they are not prospectively evaluated. The patients most likely to benefit are those most at risk for persistent or delayed neurologic sequelae, such as those presenting in coma or with a history of syncope.<sup>121</sup> These are likely clinical markers for the episode of hypotension that are necessary for causing neuronal damage from CO-induced ischemic reperfusion injury in animal models.<sup>78,160</sup> However, syncope is neither

a particularly sensitive nor a specific marker for cognitive sequelae. Patients with long exposures, or “soaking” periods, typically longer than 6 hours, are also at greater risk for neurologic sequelae.<sup>13</sup> The presence of a significant metabolic acidosis is a surrogate marker for CO poisoning.<sup>189,216</sup> Patients who present with decreased level of consciousness, a GCS score of less than 9 in one series, had an odds ratio of 7.0 for the development of neurologic sequelae.<sup>170</sup> Although some authors advocate ongoing myocardial ischemia as an indication for HBO, in our experience, these patients usually already meet neurologic criteria for treatment, such as LOC or ongoing mental status changes. Isolated cardiac ischemia, more importantly, deserves immediate proven myocardial salvaging therapy rather than delayed treatment with HBO.

Some authors advocate treating all patients with COHb levels of 40% or greater with HBO. It is reasonable to use a more conservative level of 25% as an indication for HBO.<sup>94</sup> More important than actual level are patient history and examination. Further analysis of data from the most recent controlled trial demonstrates that in patients not treated with HBO, there were no reliable factors (COHb level, LOC, or base excess) for predicting who progressed to cognitive sequelae.<sup>229</sup> A multivariate analysis showed that of all factors (LOC, age, exposure time, and COHb levels), only age of 36 years or older and CO exposure duration of 24 hours or longer were associated with cognitive dysfunction at 6-week follow-up. More problematic is the incidence of cognitive sequelae in patients without those risk factors: 32% in those younger than age 36 years and 36% in those with less than 24 hours of exposure. In conclusion, it appears that there are no completely reliable predictors for screening out patients who will do well without HBO treatment.

Multiple studies attempted to evaluate serum markers after acute CO poisoning that would predict neurologic sequelae. Although COHb confirms exposure, it does not correlate with future outcome, let alone acute symptoms.<sup>90,228</sup> Multiple serum markers, including cytokines, increase after CO poisoning, but their predictive accuracy is unclear.<sup>204</sup> Although impaired mitochondrial cytochrome function and elevated lipid peroxidation are seen in peripheral lymphocytes and monocytes after clinical CO poisoning, they only confirm CO exposure and are too nonspecific to use as predictors of neurologic sequelae.<sup>71</sup>

Therefore, at this time, it is prudent to refer for HBO treatment those patients with the most serious neurologic symptoms, regardless of their COHb level. Such symptoms include coma, seizures, focal neurologic deficits, altered mental status (GCS score <15), and although controversial, LOC. Patients who have had cardiac arrest from CO poisoning and had the return of spontaneous circulation are poor candidates for HBO therapy because virtually all these cases are fatal.<sup>97</sup> In fact, such deaths from CO poisoning are not contraindication to organ donation (Special Considerations: SC12).

Excluding patients from HBO with milder symptoms after CO poisoning is problematic because even they are susceptible to neurocognitive sequelae. One series of 55 patients with mild poisoning as defined by the absence of LOC and maximum measured COHb level less than 15% found that even one-third of these individuals had neurocognitive sequelae up to 12 months after exposure.<sup>35</sup> This was no different than that occurring in the severely poisoned group, although the milder group had a much longer duration of exposure as well as a greater delay to the evaluation of the COHb level. Brain imaging studies confirm that mild exposures, marked by no LOC and COHb levels lower than 15%, result in visible changes.<sup>70,173</sup> Taken to its logical but impractical conclusion, because even apparently mild cases of CO poisoning have poor neurocognitive outcomes, HBO treatment of every CO-exposed patient, regardless of severity, could be justified.

It is still unclear if mild neurologic effects, such as confusion, headache, dizziness, visual blurring, or abnormal mental status testing on initial presentation after CO poisoning, are prognostic for cognitive sequelae, which would necessitate HBO treatment. These effects simply represent CO poisoning, which at COHb levels approaching 10% in volunteers causes temporary impairment of learning and memory.<sup>4</sup> In one prospective clinical trial of CO poisoning, the incidence of cerebellar dysfunction portended a higher incidence of cognitive sequelae (odds ratio, 5.7; 95% confidence interval {CI},

Fetal distress in pregnancy
Equivocal cases with age > 35 years and prolonged exposure ( $\geq$ 24 h).

<sup>a</sup>Patients with these risk factors for cognitive sequelae have the highest potential to benefit from hyperbaric oxygen treatment.

1.7–19.3).<sup>226</sup> Therefore, difficulties with finger-to-nose, heel-to-shin, rapid alternating hand movements, or even ataxia are recommended indications for HBO. Patients with other mild neurologic findings, such as headache, warrant at least several hours of oxygen by nonrebreather facemask until symptoms resolve. If symptoms do not resolve, HBO is recommended; however, any delay to HBO therapy decreases its efficacy.

A more promising method to discern patients who may respond to HBO is based on the genotype, apolipoprotein E, specifically the isoform  $\epsilon 4$ .<sup>106</sup> This particular polymorphism allele is present in up to one-quarter of the population, and it is associated with worse neurologic outcome from trauma and stroke. In the presence of CO poisoning, it is associated with lack of response to HBO for preventing neurocognitive sequelae. Further studies support not treating patients with this particular allele, focusing on those with the potential for response to HBO therapy.

Several professional societies have attempted to develop evidence-based guidelines. The American College of Emergency Physicians stated that no clinical variable predicts patients at risk of cognitive sequelae of likelihood to benefit from HBO.<sup>231</sup> The American College of Emergency Physicians guideline recently stated that it remains unclear if HBO provides any added benefit over normobaric oxygen therapy in preventing long-term neurocognitive sequelae.<sup>232</sup> Similarly, the Cochrane Collaboration review on the use of HBO in CO poisoning concluded that because of so much conflicting data, there is insufficient evidence to support HBO for CO poisoning at this time.<sup>18</sup> The collective odds ratio for protective effect at 4 to 6 weeks with HBO versus normobaric oxygen was 0.78 (95% CI 0.54–1.12) based on a collective experience of 1,361 patients in six studies. The most recent guideline from the UHMS states that CO-poisoned patients should be referred for HBO if they have serious poisoning, such as unconsciousness, whether it is transient or persistent; age 36 years or older; or CO exposure duration of 24 hours or longer, even if intermittent.<sup>224</sup> These guidelines are consistent with the prior studies discussed earlier. The UHMS guidelines also state that many physicians treat when neuropsychologic testing results are abnormal or COHb levels are greater than 25% to 30%.

Some authors recommend selective use of HBO because of cost and difficulties in transport if the primary facility lacks a chamber. However, complications that make such transfers and treatment unsafe are rare.<sup>188</sup> At the present time, we routinely recommend HBO for selected patients poisoned by CO based on the indications in [Table 122–4](#). Fortunately, even without HBO, anywhere from one-third to three-quarters of cases with persistent cognitive sequelae resolve over the subsequent year.<sup>40,226</sup>

### Delayed Administration of Hyperbaric Oxygen

The optimal timing and number of HBO treatments for CO poisoning is unclear. Patients treated later than 6 hours after exposure tend to have worse outcomes in terms of delayed sequelae (30% versus 19%) and mortality (30% versus 14%).<sup>82</sup> This helps explain the failure of one of the first randomized trials on HBO for CO poisoning, which had a mean time to treatment of over 6 hours after poisoning.<sup>182</sup> Meanwhile, HBO treatments delivered within 6 hours after poisoning in patients with LOC after CO seem to almost completely prevent neurologic sequelae.<sup>241</sup> However, patients benefit even if treated later. In the most recent randomized clinical trial showing beneficial effects of HBO, although all patients were treated within 24 hours of exposure, 38% of patients were treated later than 6 hours after exposure. Therefore, it is reasonable to perform HBO, contingent on transport limitations, within 24 hours of presentation for symptomatic acute poisoning.

One case series suggests beneficial effects for HBO used up to 21 days after exposure, even after patients have developed neuropsychologic sequelae.<sup>154</sup> The problem with studies showing HBO benefits days after an acute poisoning or after chronic poisoning is that these cases are all anecdotal and lack control participants. In fact, delayed neurocognitive sequelae frequently resolve within 2 months in patients with mild CO poisoning,<sup>211</sup> and in those with serious CO poisoning who survive to HBO treatment, one-third resolve within 1 year.<sup>226</sup> It is possible that these delayed or chronic cases simply represent the placebo effect of HBO.

### Repeat Treatment with Hyperbaric Oxygen

A randomized clinical trial demonstrated that three HBO treatments within the first 24 hours improved cognitive outcome.<sup>226</sup> Unfortunately, there was no group treated with only one or two HBO sessions in that study. Regardless, it is reasonable to give repeated treatments for patients with persistent symptoms, particularly coma, who do not resolve after their first HBO session. In a pilot study, one HBO treatment was enough to promote almost total mitochondrial cytochrome activity, as measured in peripheral lymphocytes, after CO poisoning.<sup>71</sup> In a nonrandomized retrospective study, CO-poisoned patients who received a second HBO treatment had a reduction in delayed neurologic sequelae from 55% to 18% compared with control participants who had only one treatment.<sup>81</sup>

It is not clear that more HBO treatments are better. A large recent study showed that in seriously poisoned CO patients, two hyperbaric treatments resulted in a worse outcome than one treatment, with complete recovery in 47% versus 68%, respectively.<sup>5</sup> There were serious flaws in that study, including lack of formal neuropsychological testing and the use of only 2.0 ATA of pressure, well below the 3.0 ATA used initially in favorable studies. A recent retrospective nationwide study in Taiwan showed that patients treated for CO poisoning with more than one treatment had lower mortality rates (adjusted hazard ratio of 0.79; 95% CI 0.64–0.95) over the subsequent 4 years, than those receiving only one treatment.<sup>108</sup> With the lack of prospective studies comparing single versus multiple courses of HBO therapy, multiple treatments are not recommended as a routine at this time. The most recent clinical guidelines from the UHMS state that the optimal number of HBO treatments for CO poisoning is unknown and that one should consider reserving multiple treatments for patients who fail to fully recover after one treatment.<sup>224</sup>

### Treatment of Pregnant Patients

The management of CO exposure in the pregnant patient is difficult because of the potential adverse effects of both CO and HBO. A literature review of all CO exposures during pregnancy revealed a high incidence of fetal CNS damage and stillbirth after severe maternal poisonings.<sup>217</sup> A series of three severely symptomatic patients who did not receive HBO had adverse fetal outcomes: two stillbirths and one case of cerebral palsy.<sup>122</sup> There are cases of limb malformations, cranial deformities, and a variety of mental disabilities in children poisoned in utero.<sup>20,139,140</sup> A recent epidemiologic study in Guatemala showed that CO exposure from wood smoke during the third trimester was inversely associated with neuropsychological performance at ages 6 to 7 years when corrected for socioeconomic confounders.<sup>59</sup>

Traditionally, it was thought that fetal hemoglobin had a high affinity for CO. Pregnant ewe studies show a delayed but substantive increase in COHb levels in fetuses, exceeding the level and duration of those in the mothers.<sup>140</sup> Thus, it appeared that fetuses were a sink for CO and could be poisoned at concentrations lower than mothers. However, such data do not apply to humans because in vitro work shows that as opposed to sheep, human fetal hemoglobin actually has less affinity for CO than maternal hemoglobin, at a ratio of 0.8. Under conditions of low oxygenation and high 2,3-BPG, as in serious CO poisoning, the affinity of human fetal hemoglobin starts to approach that of maternal.<sup>229</sup> The more important issue with maternal CO exposure is the precipitous decrease in fetal arterial oxygen content that occurs within minutes at CO concentrations of 3,000 ppm.<sup>77</sup> Therefore, the ensuing hypoxia of the fetus, rather than increase in fetal COHb, is of more concern.

Maternal COHb levels do not accurately reflect fetal hemoglobin or tissue concentrations.<sup>51</sup> In primate studies, a single CO exposure insufficient to cause clinical disease in the mother led to intrauterine hypoxia, fetal brain injury, and an increased rate of fetal death.<sup>76,78</sup> In humans, there are a few cases of fetal demise with maternal levels of COHb less than 10%.<sup>20</sup> However, in that series, some mothers were treated with oxygen before their COHb levels were obtained. Another issue with some of these data is that often the mother was chronically “soaked” with CO, making levels difficult to interpret. Rodent studies show that chronic low-level CO exposure in pregnant mothers may result in permanent cognitive deficits in the subsequent progeny.<sup>57</sup>

Because maternal COHb does not necessarily predict fetal demise, clinicians must direct their attention to maternal manifestations of CO toxicity. Multiple case series demonstrate that pregnant women who present with a normal mental status and no LOC after CO poisoning have excellent outcomes in terms of normal deliveries.<sup>20,122</sup> These infants have no subsequent delay in attaining their developmental milestones. Therefore, it appears that mothers who appear well after acute CO poisoning will have good outcomes with respect to their pregnancies.

The bigger dilemma for clinicians is the approach to treatment of seriously symptomatic CO-poisoned pregnant patients. All patients should receive 100% oxygen by face mask, at least until the mother is asymptomatic. However, CO absorption and elimination are slower in the fetal circulation than in the maternal circulation.<sup>140</sup> A mathematical model predicts that elimination of CO from fetuses takes 3.5 times longer than maternal CO elimination.<sup>103</sup> However, because some of these data are based on sheep fetal hemoglobin kinetics, the optimum time for treatment of the mother cannot be recommended at this time.

Unfortunately, pregnant patients were excluded from all prospective trials documenting the efficacy of HBO. However, treatment of pregnant patients with HBO is not without theoretical risk. Animal studies show conflicting results on the effects of HBO on fetal development. Some studies demonstrate that HBO causes developmental abnormalities in the central nervous, cardiovascular, and pulmonary systems of rodent fetuses. This is in marked contrast to the extensive Russian experience, in which hundreds of pregnant women were treated with HBO, apparently without significant perinatal complications and with improvement in fetal and maternal status for their underlying conditions of toxemia, anemia, and diabetes.<sup>149</sup> There are multiple cases where apparently normal infants are born after their pregnant mothers received HBO for mild CO poisoning. However, less than optimal outcomes have occurred in cases of sicker patients in which the mother has had LOC or presented comatose.<sup>65</sup> A 25-year longitudinal study of 406 pregnant women who received HBO for CO poisoning, with many children followed for up to 6 years of age, showed no psychomotor or growth differences between exposed and unexposed control participants.<sup>222</sup> Thus, it appears that HBO should be safe and have the same efficacy for pregnant patients as in nonpregnant patients. There currently is no scientific validation for an absolute level at which to provide HBO therapy for a pregnant patient with CO exposure. Somewhat arbitrarily, we recommend a threshold for HBO in pregnant patients is a COHb level regardless of symptoms of greater than or equal to 15%. Pregnant patients should not be treated any differently if they meet criteria for HBO described above (Table 122–4). Additional criteria include any signs of fetal distress, such as abnormal fetal heart rate.

### Treatment of Children

It is suggested that children are more sensitive to the effects of CO because of their increased respiratory and metabolic rate.<sup>39</sup> Epidemiologic studies suggest that children become symptomatic at COHb levels less than 10%, which is lower than commonly expected in adults.<sup>121</sup> The other problem is that these younger patients have unusual presentations. Although most children manifest nausea, headache, or lethargy, an isolated seizure or vomiting is sometimes the only manifestation of CO toxicity in an infant or child.<sup>39</sup>

When interpreting COHb levels in infants, clinicians must be aware of two confounding factors. First, many older cooximeters give falsely elevated COHb levels in proportion to the amount of fetal hemoglobin present.<sup>219</sup> Second, CO is produced during breakdown of protoporphyrin to bilirubin. Therefore, infants normally have higher levels of COHb, which are even higher in the presence of kernicterus. Some neonates not exposed to CO have COHb levels approaching 8%.<sup>220</sup> Thus, before it is assumed that an elevated COHb level implies CO poisoning in an infant, the contribution of jaundice and fetal hemoglobin must be evaluated.

There are alternative clinical markers better than COHb for gauging toxicity in children. An elevated lactate concentration was found in 90.1% of

674 pediatric patients admitted for CO poisoning.<sup>54</sup> Many children with elevated troponin concentrations after CO poisoning had normal ECGs or just subtle transitory T-wave changes from repolarization abnormalities.<sup>162</sup> The echocardiogram is abnormal approximately 50% of patients found to have an elevated troponin concentration, usually showing a temporary decrease in left ventricular function and ejection fraction.<sup>162,198</sup>

Although children are more susceptible to acute toxicity with CO, their long-term outcomes appear to be more favorable than for adults. In one series of 2,360 serious CO cases, all cases of delayed neurologic sequelae occurred in adults older than age 30 years.<sup>40</sup> Another series of CO poisoning demonstrated an incidence of delayed neurologic sequelae of 10% to 20% in children after severe CO poisoning.<sup>39</sup> Increased COHb levels (>25%) in adolescents associated with more severe acute symptoms.<sup>127</sup> One retrospective multivariate analysis showed that prolonged LOC requiring ICU care was the only independent risk factor for delayed neurologic sequelae.<sup>36</sup>

This low incidence of DNS in patients treated only with 100% oxygen at normal pressures is used as an argument to avoid HBO. However, their risk of such sequelae exists, and HBO is used successfully to prevent it.<sup>238</sup> In a recent series of 27 hospitalized children for CO poisoning treated with HBO, only 1 child had minor neurologic sequelae (ie, headache and tinnitus).<sup>119</sup> Deaths in children are often directly related to concomitant smoke inhalation.<sup>42</sup> The CoHb half life with surface pressure oxygen is approximately 44 minutes, faster elimination than occurs in adults.<sup>121</sup> Often, children exposed to CO under similar circumstances with a parent, although appearing well, are treated simultaneously with the sick parent, especially if a multiplace chamber is available.

### Novel Neuroprotective Treatments

A variety of neuroprotective therapeutics were tested in animal models. They are targeted primarily at preventing the delayed neurologic sequelae associated with serious CO poisoning. One of the simplest treatments tested is insulin. Hyperglycemia exacerbates neuronal injury from stroke as well as in arrest situations. In CO poisoning of rodents, it is associated with worse neurologic outcome.<sup>138</sup> However, insulin, independent of its glucose-lowering effect, is protective after ischemic insults. In rodent studies, improved neurologic outcome, as measured by locomotor activity, occurs in those with CO poisoning treated with insulin. In light of these findings, it is reasonable to treat documented hyperglycemia with insulin in patients with serious CO poisoning.

Many neuroprotective therapeutics involve blockage of excitatory amino acids that are implicated in neuronal cell death after CO poisoning. Pretreatment of mice with dizocilpine (MK-801), which blocks the action of glutamate at *N*-methyl-D-aspartate receptors, ameliorates learning, memory, and hippocampal deficits with CO poisoning.<sup>113</sup> Ketamine, another glutamate antagonist, decreases the mortality rate of rats poisoned with CO after carotid ligation.<sup>169</sup> Treatment of mice with various glutamate antagonists prevents learning and memory deficits in a model of CO poisoning.<sup>74</sup> Blockage earlier in the immunologic cascade, with a neuronal NO synthase inhibitor also prevented NMDA receptor activation, thus protecting mice from learning deficits after CO poisoning.<sup>207</sup> Further clinical research is needed before recommending any of these antagonists routinely.

One exciting approach is the use of antioxidants, such as dimethyl sulfoxide and disulfiram, that prevent learning and memory deficits when given after CO poisoning in mice.<sup>74</sup> Use of these or related therapeutics, although promising, awaits further animal testing because of potential adverse effects. Likewise, 3-*N*-butylphthalide, a celery seed extract, which has a variety of neuroprotective effects, including improved blood flow, antioxidant, and antiapoptosis effects, was adopted from stroke research. A randomized trial of 185 seriously CO-poisoned patients treated with HBO showed that by adding 3-*N*-butylphthalide 200 mg three times a day orally, neurologic remission improved.<sup>236</sup> Regardless of treatment, both treated and untreated groups showed improvement.

Much of what happens after CO poisoning involves an inflammatory cascade that leads eventually to neurologic sequelae. A recent trial of patients

receiving HBO for CO poisoning were randomized to treatment with 5 and 10 mg/day of dexamethasone versus HBO alone.<sup>235</sup> Both dexamethasone groups showed improved scores on mini mental state examination as well as the National Institute of Health Stroke Scale at 4 weeks after poisoning. This was accompanied by a decrease in myelin basic protein in CSF, confirming the antiinflammatory effect of the drug. Erythropoietin is another potential treatment modality for CO poisoning that also decreases the neuronal inflammatory response.<sup>166</sup> A human trial showed that the addition of recombinant erythropoietin daily for 1 week to HBO decreased the incidence of delayed neurologic sequelae from 30% in the HBO alone to 12%.<sup>165</sup>

Other modalities tested in preventing neuronal damage from CO are not successful. Although hypothermia was associated with good outcomes in uncontrolled human trials,<sup>68,158</sup> controlled animal trials actually show an increased mortality rate.<sup>194</sup> Allopurinol, which prevents the formation of free radicals through xanthine oxidase, inhibits lipid peroxidation in CO poisoning when given before exposure.<sup>202</sup> This strategy is not promising because of the necessity for pretreatment.

## PREVENTION

Early diagnosis prevents much of the morbidity and mortality associated with CO poisoning, especially in unintentional exposures. The increased quality of home CO-detecting devices allows personal intervention in the prevention of exposure.<sup>124</sup> If a patient presents complaining that his or her CO alarm sounded, it is important to realize that the threshold limit for the alarm is set roughly to approximate a COHb level of 10% at worst. Therefore, manufacturers must have their alarms activate within 189 minutes at 70 ppm CO, 50 minutes at 150 ppm, and 15 minutes at 400 ppm (Underwriters Laboratories, UL2034). Alarms are not designed to activate for prolonged exposures below 30 ppm to prevent epidemic alarming during winter thermal inversions in large cities.<sup>11</sup> Government ordinances for obligatory CO alarms could potentially prevent many poisonings, particularly during winter storms.<sup>23,83</sup> Although most serious CO poisonings are associated with the absence of CO alarms, a small proportion of such patients had alarms, suggesting the need for assessing proper functionality after installation.<sup>44</sup>

Routine laboratory screening of ED patients during the winter is not very efficacious in diagnosing unsuspected CO poisoning; the yield is less than 1% for patients tested in whom the diagnosis of CO exposure was already excluded by history. Instead, selecting patients with CO-related complaints, such as headache, dizziness, or nausea, increases the yield to 5% to 11%.<sup>64,193</sup> During the winter, risk factors such as gas heating or symptomatic cohabitants in patients with influenzalike symptoms such as headache, dizziness, or nausea, particularly in the absence of fever, is the most useful method for deciding when to obtain COHb levels for potential patients.

The issue of symptomatic cohabitants is especially important from a preventive standpoint. Alerting other cohabitants to this danger and effecting evacuation prevents needless morbidity and mortality. This is especially critical for multifamily domiciles, such as hotels, that have resulted in dramatic collective exposures and even deaths.<sup>225</sup> Most communities have multiple resources for onsite evaluation. Usually the local fire department or utility company can either check home appliances or measure ambient CO concentrations with portable monitoring equipment. The current workplace standard for ambient CO exposures is 35 ppm averaged over 8 hours with a ceiling limit of 200 ppm (measured over a 15-minute period).<sup>99</sup> Just a 4-hour exposure to 100 ppm of CO may result in COHb level greater than 10% with symptoms.

## SUMMARY

- Unintentional exposures to CO are easily missed or misdiagnosed. Patients with a suspected influenzalike illness should be screened for potential home sources of CO, and symptomatic cohabitants should be alerted.
- Carbon monoxide exposure should be evaluated in patients with unexplained coma, metabolic acidosis, or signs of cardiac ischemia, especially if attempted suicide is suspected.
- Fire victims, in addition to airway complications and potential cyanide and other toxic inhalants may succumb to CO toxicity.

- The mainstay of treatment in CO poisoning is good supportive care with early oxygenation to increase the elimination of COHb.
- Because of the overwhelming clinical successes with HBO and its limited risks, early use of this treatment modality in severe exposures is recommended.
- Discussion with a regional poison control center or hyperbaric facility will help in identifying patients who are most likely to benefit from such treatment.

## HYPERBARIC OXYGEN

Stephen R. Thom

**INTRODUCTION**

Hyperbaric oxygen (HBO) is used therapeutically in poisoning by carbon monoxide (CO) (alone or if complicated by cyanide {CN} poisoning), methylene chloride, hydrogen sulfide (H<sub>2</sub>S), and carbon tetrachloride (CCl<sub>4</sub>). It is also a recognized therapy for air or gas embolism, such as may arise from ingestion of hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>), and for anemia, a functional form of which arises from oxidants that induce methemoglobinemia.

**HISTORY**

Hyperbaric medicine became established as a clinical discipline in the latter half of the 20th century with a focus on treatment of decompression sickness. Utilization of hyperbaric chambers has expanded in the past 60 years with improved understanding of basic mechanisms of action. The first case reports of HBO for documented CO poisoning appeared in 1960,<sup>203</sup> and the consistent application of HBO in CO poisoning began in many centers at that time.<sup>200</sup> The first report presenting statistical evidence of the superiority of HBO compared with normobaric oxygen in CO poisoning, as well as a description of the “late syndrome,” was published in 1969.<sup>76</sup>

**PHARMACOLOGY****Chemistry and Preparation**

Pressures applied while patients are in the hyperbaric chamber usually are 2 to 3 atmospheres absolute (ATA); sea level air pressure equals 1 ATA. Treatments generally last for 1.5 to 8 hours, depending on the indication, and are performed one to three times daily. Monoplace (single-person) chambers usually are compressed with pure oxygen. Multiplace (2–14 patients treated simultaneously) chambers are pressurized with air, and patients breathe pure oxygen through a tight-fitting face mask, a head tent, or an endotracheal tube as clinically indicated.

**Mechanisms of Action**

During treatment, the arterial oxygen tension typically exceeds, 1,500 mm Hg and achieves tissue oxygen tensions of 200 to 400 mm Hg—more than fivefold higher than when breathing air.<sup>214</sup> While one is breathing air under normal environmental conditions, hemoglobin is saturated with oxygen on passage through the pulmonary microvasculature, and the primary effect of HBO is to increase the dissolved oxygen content of plasma. In addition, HBO affects neutrophil adhesion to blood vessels and restores mitochondrial, neutrophil, and immunologic disturbances caused by CO poisoning.

**Pharmacokinetics**

Oxygen inhaled at hyperbaric pressure is rapidly absorbed. Application of each additional atmosphere of pressure while breathing 100% oxygen increases the dissolved oxygen concentration in the plasma by 2.2 mL O<sub>2</sub>/dL (vol%) (Chap. 28). Animal models of focal ischemia suggest that HBO rapidly distributes to target organs to improve penumbral oxygenation.<sup>210</sup> Hyperbaric oxygen increases tissue oxygen concentration and wound oxygen delivery in humans.<sup>182</sup> Regarding pharmaceutical interactions, hyperbaric hyperoxia does not appear to produce appreciable alterations in the pharmacokinetics of pentobarbital, salicylate, or theophylline in canine models<sup>117–119</sup> or gentamicin in healthy human volunteers.<sup>151</sup>

**Pharmacodynamics**

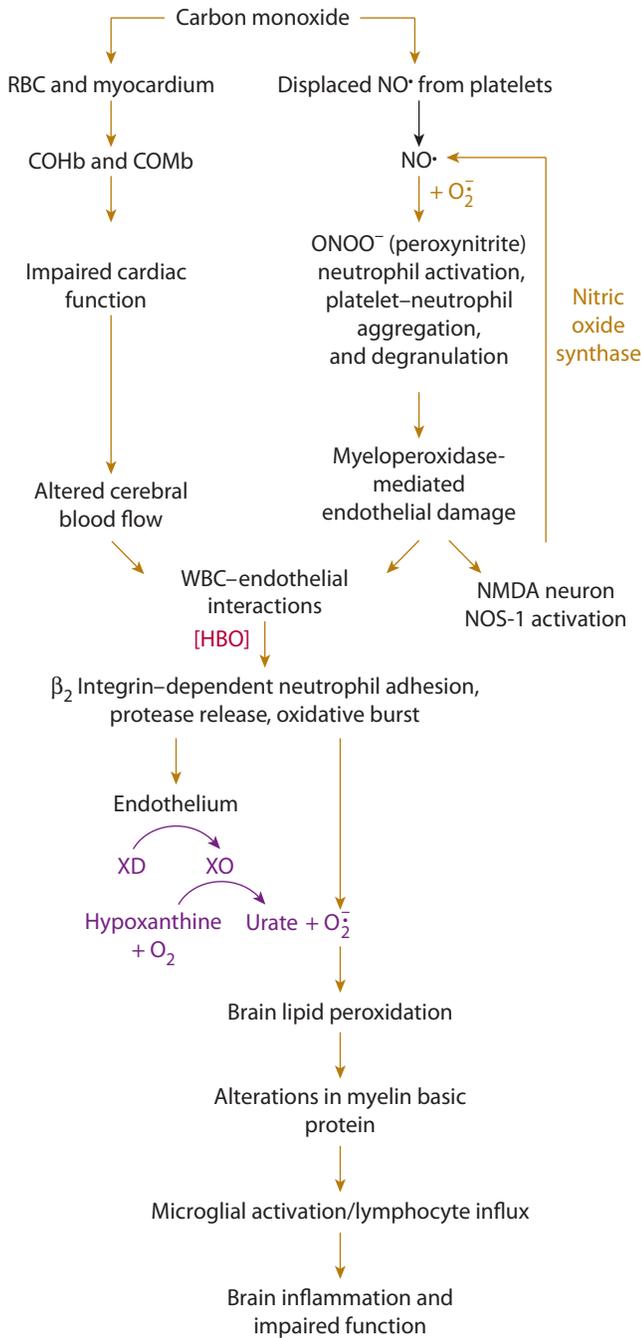

There are transient benefits from HBO for reducing bubble volume in disorders such as air embolism and oxygenating tissues in conditions in

which hemoglobin-based O<sub>2</sub> delivery is impaired. These rather straightforward mechanisms form the basis for using HBO for patients with massive ingestions of H<sub>2</sub>O<sub>2</sub> associated with intravascular gas embolism and for life-threatening poisonings from CN, H<sub>2</sub>S, and exposure to oxidizers causing methemoglobin. Hyperbaric oxygen is also used for CCl<sub>4</sub> poisoning, in which acute application of oxygen and pressure inhibit the cytochrome P450 oxidase system responsible for producing hepatotoxic free radicals.<sup>30,145</sup> Hyperbaric oxygen also has well-described vasoconstriction effects<sup>340,208,228</sup> compared with dynamic CO-associated effects on cerebral vasodilation.<sup>130</sup>

Recent years have shown that benefits persisting beyond the short period when a patient is in a hyperbaric chamber are related to production of reactive oxygen species (ROS) and reactive nitrogen species.<sup>217,218</sup> Reactive species can have positive and negative effects that depend on the concentration of reactant generated and its intracellular localization. Hence, with regard to HBO, as with any xenobiotic, the precise dose defines the risks and benefits of therapy. Because exposure to hyperoxia in typical clinical HBO protocols is rather brief, most studies show that antioxidant defenses are adequate to avoid tissue injuries.<sup>54,55,183,232</sup>

There are at least four separate therapeutic mechanisms supporting the use of O<sub>2</sub> when treating CO poisoning. Administration of supplemental O<sub>2</sub> is a historical cornerstone for treatment based on reducing body burden of carboxyhemoglobin (COHb). Elevated COHb results in tissue hypoxia, and exogenous O<sub>2</sub> both hastens dissociation of CO from hemoglobin and provides enhanced tissue oxygenation directly through the increased PaO<sub>2</sub>. Hyperbaric oxygen causes COHb dissociation to occur at a rate greater than that achievable by breathing 100% O<sub>2</sub> at sea level pressure.<sup>168</sup> Additionally, HBO accelerates restoration of mitochondrial oxidative processes.<sup>28</sup> Among the earliest events observed in both an animal model and in humans with CO poisoning is platelet–neutrophil interactions that mediate intravascular neutrophil activation. These changes precipitate neutrophil adherence to blood vessel walls that initiate vascular changes, leading to a cascade of localized changes in brain that cause neurological dysfunction (Fig. A40–1).<sup>100,219,225</sup> Animal studies indicate that CO-mediated neurologic dysfunction is related to an immune responses to modified myelin basic protein (MBP), impaired neurogenesis associated with diminished production of nerve growth factor, brain-derived neurotrophic factor and neurotrophin-3, and circulating pro-inflammatory microparticles.<sup>33,35,106,167,210</sup> The presence of MBP in cerebrospinal fluid of CO-poisoned patients appears to serve as a predictive marker for the onset and persistence of CO-mediated encephalopathy.<sup>221</sup>

Timely intervention with HBO in animal models causes rapid improvement in cardiovascular status,<sup>60</sup> leads to lower mortality rates,<sup>171</sup> abrogates changes in MBP, and preserves synthesis of nerve growth factors.<sup>35,106,167,210,239</sup> As a late intervention, approximately 1 month after CO poisoning and the onset of delayed neurologic deterioration, mesenchymal stem cell infusion has been explored to restore neuronal integrity when late use of HBO had no benefit.<sup>201</sup> Benefits of HBO are likely based on improved oxygenation and maintenance of mitochondrial function as well as inhibition of neutrophil adhesion. Exposure to 2.8 to 3.0 ATA O<sub>2</sub> for 45 minutes temporarily inhibits neutrophil adherence to endothelium mediated by the activation-dependent β<sub>2</sub>-integrins on the neutrophil membrane in both rodents and humans.<sup>43,107,121,215,226</sup> The ability of HBO to inhibit function of neutrophil β<sub>2</sub>-integrin adhesion molecules in animal models forms the basis for amelioration of encephalopathy resulting from CO poisoning, decompression

**FIGURE A40-1.** The pathway demonstrating concurrent events leading to vascular injury with carbon monoxide poisoning and the sequence of events leading to neurologic injuries. COHb = carboxyhemoglobin; COMb = carboxymyoglobin; NMDA = *N*-methyl-D-aspartate neurons; NO• = nitric oxide; NO<sub>2</sub> = nitrite (major oxidation product of NO•); NOS-1 = neuronal nitric oxide synthase; O<sub>2</sub><sup>•-</sup> = superoxide radical; ONOO<sup>-</sup> = peroxynitrite; RBC = erythrocyte; WBC = leukocyte; XD = xanthine dehydrogenase; XO = xanthine oxidase.

sickness, and smoke-induced lung injury, as well as reperfusion injuries of brain, heart, lung, liver, and skeletal muscle.<sup>8,111,144,211,212,215,229,233,238,254,256,257</sup> Hyperbaric oxygen inhibits neutrophil β<sub>2</sub> integrin expression, but not its expression on other circulating leukocytes that proceeds from reactive nitrogen species generation by type 2 nitric oxide synthase and myeloperoxidase present in neutrophil-specific α-granules. That is, the presence of both enzymes within the same granules is required to generate the requisite reactive agents that inhibit neutrophil adherence. The reaction leads to excessive *S*-nitrosylation of cytoskeletal β actin, which in turn impedes the function of β<sub>2</sub> integrins.<sup>221</sup> This leads to modifications in cytoskeletal regulation of a number of proteins<sup>223,224</sup> without reducing neutrophil viability and functions

such as degranulation and oxidative burst in response to chemoattractants remain intact.<sup>215,223,226</sup> It is important to comment that use of HBO at less than 2.8 ATA, as used in several clinical HBO studies, does not inhibit neutrophil adherence functions.<sup>7,91,127</sup>

**ROLE IN CARBON MONOXIDE POISONING**

Survivors of CO poisoning are faced with potential impairments to cardiac and neurologic functions. Carbon monoxide poisoning causes acute cardiac compromise, including potentially reversible left ventricular dysfunction.<sup>86,129</sup> Survivors appear to exhibit an increased risk for cardiovascular related death in the subsequent 10 years,<sup>88,175</sup> although a study suggests that an excess mortality rate is more closely associated with neurologic and psychological factors.<sup>136</sup> Some patients exhibit acute abnormalities wherein they have impaired consciousness or focal neurologic findings from the time of initial presentation and never recover.<sup>3,49,52,71</sup> Other patients seemingly recover from acute poisoning, but then manifest neurologic or neuropsychiatric abnormalities from 2 days to about 5 weeks after poisoning.<sup>44,57,75,96,140,148,152,161,176,193,196,227,248</sup> Events occurring after a clear or “lucid” interval are termed “subacute” or “delayed” neurologic sequelae. These terms have gained popularity and have some clinical utility, but animal studies suggest neuropathology is more of a continuum. That is, various pathways of injury occur in close proximity, and in some cases, they occur concomitantly.<sup>70,101,149,162,219,220,225</sup>

Since 1960, HBO has been used with increasing frequency for severe CO poisoning because clinical recovery appeared to improve beyond that expected with ambient pressure oxygen therapy. Support for HBO use comes from this experience.<sup>75,76,97,122,147,161,164,181</sup> The clinical efficacy of HBO for acute CO poisoning has been assessed in six prospective, randomized trials published in peer-reviewed journals. Only one clinical trial satisfies all items deemed to be necessary for the highest quality of randomized controlled trials.<sup>248</sup> This double-blinded, placebo-controlled clinical trial involved 152 patients who received treatment with either three sessions of HBO therapy or normobaric O<sub>2</sub> with sham pressurization to maintain blinding. The group treated with HBO had a lower incidence of cognitive sequelae than the group treated with NBO after adjustment for pretreatment cerebellar dysfunction and stratification (odds ratio, 0.45; 95% confidence interval 0.22–0.92; *P* = 0.03).

The only other blinded, prospective, randomized trial was published in 1999, and it involved 191 patients of different severity treated with either daily HBO (2.8 ATA for 60 minutes) with intervening high-flow oxygen for 3 or 6 days versus high flow normobaric oxygen for 3 or 6 days.<sup>188</sup> Additional HBO treatments (up to six daily) were performed in patients without adequate neurologic recovery. The primary outcome measure for this trial was testing performed at completion of treatment (3–6 days) and not from long term follow-up. This study had a high rate of adverse neurologic outcomes in all patients, regardless of treatment assignment. Neurologic sequelae were reported in 74% of HBO-treated patients and in 68% of control participants. No other clinical trial has described this magnitude of neurologic dysfunction. The high incidence may be related to the assessment tool, which could not discern true neurologic impairments from poor test taking related to depression.<sup>189</sup> Suicide attempts with CO represented 69% of cases in this trial. Moreover, 54% of participants were lost to follow-up. Outcomes at 1 month were not reported but were stated to show no difference. Multiple statistical comparisons were reported without apparent planning or the requisite statistical correction. Both treatment arms received continuous supplemental mask O<sub>2</sub> for 3 days between their hyperbaric treatments (both true HBO and “sham”), resulting in greater overall O<sub>2</sub> doses than conventional therapy. Multiple flaws in the design and execution of this study are discussed in the literature, so it is impossible to draw meaningful conclusions from the data.<sup>82,157</sup> Despite these issues, conclusions from this trial were accepted in systematic reviews.<sup>29,252</sup>

Other randomized trials of HBO for CO poisoning were not blinded. The first prospective clinical trial involving HBO therapy did not demonstrate therapeutic benefits.<sup>176</sup> This study was criticized because the authors used

a low (insufficient) oxygen partial pressure (2 ATA) versus the more usual protocols with 2.5 to 3 ATA, an unvalidated questionnaire to assess neurologic function, and because nearly half of the patients received hyperbaric treatments more than 6 hours after they were identified.<sup>27</sup> This 1989 study protocol was repeated again in a more recent trial with no modifications despite the criticisms identified more than a decade earlier. Not surprisingly, the outcome was virtually the same. If study results are expressed on an intention-to-treat basis, patients with transient loss of consciousness had an incidence of neurologic sequelae based on the self-assessment questionnaire of 48%, and those treated with HBO had an incidence of 51%. Patients with initial coma who were treated once with HBO had an incidence of sequelae of 47%; patients who were treated with two HBO treatments had an incidence of sequelae of 60% (not significantly different from any of the other groups).<sup>6</sup>

Hyperbaric oxygen was effective in several other prospective investigations. In a trial involving mildly to moderately poisoned patients, 23% of patients (7 of 30) treated with ambient pressure oxygen developed neurologic sequelae, but no patients (0/30;  $P < 0.05$ ) who were treated with HBO (2.8 ATA) developed sequelae.<sup>227</sup> In another prospective, randomized trial, 26 patients were hospitalized within 2 hours of discovery and were equally divided between two treatment groups: ambient pressure oxygen or 2.5 ATA  $O_2$ .<sup>57</sup> Three weeks later, patients treated with HBO had significantly fewer abnormalities on electroencephalogram, and single-photon emission computed tomography scans showed that cerebral vessels had nearly normal reactivity to carbon dioxide, in contrast to diminished reactivity in patients treated with ambient pressure oxygen.

In conclusion, the efficacy of HBO for acute CO poisoning is supported in animal trials, and studies provide a mechanistic basis for treatment. In this era of evidence-based medicine, a great deal of emphasis has been placed on systematic reviews, which have stressed the need for new studies because of the range in quality of published clinical trials.<sup>29,252</sup> A practice-based recommendation is that HBO should be administered in all cases of serious acute CO poisoning and normobaric 100% oxygen continued until the time of HBO administration is based on existing studies with the best design that most closely address the actual practical handling of patients.<sup>85</sup> We support this opinion, but readers should note that this perspective is not shared by the American College of Emergency Physicians Clinical Policies Subcommittee.<sup>251</sup> In their policy statement, they conclude that published studies are generally inconclusive.

Carbon monoxide-poisoned patients who receive three HBO treatments within 24 hours after presentation manifest approximately half the rate of cognitive sequelae at 6 weeks, 6 months, and 12 months after treatment as those treated with only normobaric oxygen. Risk factors for long-term cognitive impairment in patients not treated with HBO include age older than 36 years, exposure longer than 24 hours, loss of consciousness, and COHb greater than 25%. Recommendations for children can pose special challenges, but in clinical series, there appear to be no marked differences in clinical manifestations compared with those reported in adults.<sup>64,84,114,172</sup> Pregnancy poses another special situation in that CO readily crosses the placenta and may cause fetal distress and fetal death. Hyperbaric oxygen has been administered safely to pregnant women, but there are no prospective studies of efficacy, in CO poisoned women so standard adult guidelines for treatment are reasonable.

One study demonstrates that HBO was only beneficial in reducing neurologic sequelae among patients who do not possess the apolipoprotein  $\epsilon 4$  allele.<sup>93</sup> Because genotype is typically unknown, this report does not alter existing treatment guidelines, but it may become important for future research. Although the basic mechanisms are unknown, it is well established that the apolipoprotein genotype can have profound effects on risk for a variety of neuropathological events.<sup>1,66,150,186</sup> Whether apolipoprotein  $\epsilon 4$  modifies the primary pathophysiological insults of CO or the mechanisms of HBO is currently unknown. As of yet, no objective method is available for staging the severity of CO poisoning, although preliminary reports suggest plasma markers may be used in the future.<sup>220</sup> Psychometric screening tests have not proved reliable because abnormalities during the initial screening do not correlate with development of delayed sequelae.<sup>227</sup>

## ROLE IN METHYLENE CHLORIDE POISONING

Methylene chloride ( $CH_2Cl_2$ ) is an organic solvent used commercially in aerosol sprays, as a solvent in plastics manufacturing, in photographic film production, in food processing as a degreaser, and as a paint stripper (eg, for bathtub refinishing).<sup>41</sup> It is readily absorbed through the skin or by inhalation. Immediate effects of methylene chloride are attributable to the direct depressant actions of this solvent on the central nervous system (CNS) and resulting hypoxia. There are two metabolic pathways involved in its metabolism: an oxidative one mediated by cytochrome P450 enzymes, mainly CYP2E1, that appears to involve a metabolic-switch or two-active site process, and another pathway mediated by glutathione (GSH) that involves mainly glutathione *S*-transferases (GST).<sup>61,206</sup> The P450 pathways generate formyl chloride and CO, with a secondary conjugation of formyl chloride to GSH. The separate GSH-GST pathway involves conjugation of methylene chloride, primarily by metabolism through GST- $\theta$ , to generate  $CO_2$  as well as DNA adducts. These GSH-GST conjugation pathway DNA adducts play a role in late-onset carcinogenesis.<sup>241,242</sup> Acute methylene chloride toxicity has many of the same clinical manifestations as CO poisoning.<sup>202</sup> Production of CO is slow, and peak COHb levels of 10% to 50% are reportedly delayed for 8 hours or more.<sup>39,42,62,109,123,140,141,195,206</sup> Effects that are present after 1 hour or more, particularly if the COHb level is elevated, may be partially caused by CO toxicity. Anecdotal reports of HBO treatment for methylene chloride poisoning report both success and failure, which likely reflect additional confounding because of solvent toxicity.<sup>37,115,180,184,255</sup> Hyperbaric oxygen treatment recommendations, using a standard three treatment protocol, follow those in patients meeting the aforementioned considerations in CO poisoning. Additional treatments in the setting of ongoing CO production and persistent or recurring symptoms will likely necessitate additional treatments as the methylene chloride is mobilized from peripheral stores and undergoes metabolism.<sup>124</sup> Prolonged normobaric 100% oxygen therapy is reasonable in patients with HBO contraindications.<sup>94,177</sup>

## ROLE IN COMBINED CARBON MONOXIDE AND CYANIDE POISONING

Carbon monoxide and CN poisonings can occur concomitantly from smoke inhalation.<sup>4,5,12-15,21,46,51,137,139,155,194,198,244,249</sup> Experimental evidence suggests that they can produce synergistic toxicity.<sup>10,158,165,168,173</sup> Animal studies demonstrate that ambient pressure 100%  $O_2$  can protect against CN toxicity<sup>191</sup> and can enhance CN metabolism to thiocyanate when thiosulfate is used concomitantly.<sup>23</sup> Hyperbaric oxygen also appears to have either direct effects on reducing CN toxicity<sup>50,102,103,127,199,213</sup> or augmenting the effects of other antidotes, including hydroxycobalamin.<sup>34,120,128,191,246</sup> However, animal studies have not uniformly found that HBO improves outcome,<sup>245</sup> and clinical experience regarding CN treatment with HBO is sparse.<sup>3,74,190</sup> In a series of symptomatic smoke inhalation victims with elevated concentrations of both CO and CN who received HBO and treatment for CN involving sodium nitrite and sodium thiosulfate, four of five patients survived without apparent neurologic damage.<sup>89</sup> Clinical case reports in which HBO was used along with standard antidote treatment (sodium nitrite plus sodium thiosulfate) for isolated CN poisonings are equivocal regarding benefit.<sup>74,134,190,230</sup> One case showed dramatic improvement,<sup>230</sup> but another showed none.<sup>134</sup> As one might expect, HBO does not appear to modify blood CN concentrations.<sup>221</sup> Methemoglobin formation with the standard antidote treatment involving nitrite is not thought to generate high enough methemoglobin concentrations to be of concern, but in the setting of concomitant COHb, the additional reduction of oxygen-carrying capacity poses a potential risk.<sup>80,113</sup> Hence, there is a special advantage for hydroxycobalamin use in combined poisonings. Further research in this area is necessary. Because CN is among the most lethal poisons and toxicity is rapid, standard antidotal therapy for isolated CN poisoning is of primary importance. Hyperbaric oxygen is reasonable in any case of dual (CO and CN) poisoning and in CN poisoning when vital signs and mental status do not improve with antidote treatment. Possible use of HBO therapy may change as data on alternative antidotes such as

hydroxycobalamin are investigated. When both interventions are administered immediately after CN poisoning, benefits appear to be additive.<sup>120</sup> Some evidence suggests each offers supportive effects on brain metabolism.<sup>127,128</sup>

### ROLE IN HYDROGEN SULFIDE POISONING

Hydrogen sulfide binds to cytochrome a-a<sub>3</sub>. This is similar to CN, although it is more readily dissociated by O<sub>2</sub>.<sup>207</sup> Clinical manifestations of toxicity are also similar to those of CO and CN.<sup>207</sup> Management of patients with serious H<sub>2</sub>S poisoning principally involves oxygenation and cardiovascular support, as well as consideration of antidotal therapy with sodium nitrite to induce methemoglobinemia.<sup>68,78,81,163</sup> Hyperbaric oxygen is more effective than sodium nitrite in preventing death in animals.<sup>22</sup> Several clinical reports indicate that HBO, sometimes in conjunction with supplemental oxygen and blood pressure support, appears to be beneficial.<sup>7,16,32,79,131,202,250</sup> Relatively late treatment with HBO (eg, over 9 to 10 hours after poisoning) is reported to be beneficial in some<sup>237</sup> but not all cases.<sup>2,204</sup> No definitive data regarding use of HBO for H<sub>2</sub>S poisoning are available, but HBO is reasonable when altered mental status or unstable vital signs persist after standard resuscitation measures.

### ROLE IN OXIDANT-INDUCED METHEMOGLOBINEMIA

Oxidation of ferrous (2<sup>+</sup>) heme to the ferric (3<sup>+</sup>) form renders hemoglobin nonfunctional, and the presence of oxidized hemoglobin varieties causes a left shift of the oxyhemoglobin dissociation curve.<sup>209</sup> Hence, the manifestations of toxicity from acquired methemoglobinemia are usually more severe than those produced by a corresponding degree of anemia. In healthy people, when the fraction of methemoglobin is 10% (approximately 1.5 g/dL), patients generally appear cyanotic but otherwise asymptomatic. With approximately 30% methemoglobin, vague, nonspecific symptoms such as headache, fatigue, dyspnea, tachycardia, and dizziness occur. Unconsciousness is common at levels above 50% and death at 70%. There are numerous anecdotal accounts of clinical improvement with HBO in patients with life-threatening methemoglobinemia.<sup>56,72,73,77,104,126,132,187,243</sup> Ongoing exposure to any oxidants and the potential need for methylene blue to treat methemoglobinemia (Antidotes in Depth: A43) should also be addressed.

### ROLE IN CARBON TETRACHLORIDE POISONING

Experimentally induced CCl<sub>4</sub> hepatotoxicity is diminished by HBO. Mortality rates were decreased in a number of animal studies,<sup>20,31,156,178</sup> and there are also several case reports of patients surviving potentially lethal ingestions with HBO therapy.<sup>125,205,231,258</sup> Because there are no proven antidotes for CCl<sub>4</sub> poisoning, we recommend HBO for patients with confirmed CCl<sub>4</sub> exposures. However, there appears to be a delicate balance between oxidative processes that are therapeutic and those that mediate hepatotoxicity.<sup>24</sup> Therefore, when HBO is being performed, it should ideally be instituted before the onset of liver function abnormalities. More recently, *N*-acetylcysteine (NAC) is effective in limiting liver damage in animals and appears of clinical benefit in humans with massive ingestions.<sup>142,146,234,253</sup> Additive benefit from concomitant use of NAC and HBO was shown in an animal model demonstrating a diminution of toxicity in L-arginine-induced pancreatitis, but there is no experience with CCl<sub>4</sub> poisoning.<sup>166</sup>

### ROLE IN HYDROGEN PEROXIDE INGESTION

Ingestion of concentrated H<sub>2</sub>O<sub>2</sub> solutions (eg, 35%) can result in venous and arterial gas embolism because of liberation of large volumes of O<sub>2</sub>. Exposure to household concentrations of H<sub>2</sub>O<sub>2</sub> (3%) has resulted in symptomatic portal venous air embolism on rare occasion.<sup>143</sup> At standard temperature and pressure, ingestion of 1 mL of household 3% H<sub>2</sub>O<sub>2</sub> liberates approximately 10 mL of oxygen gas; by comparison, each milliliter of 35% H<sub>2</sub>O<sub>2</sub> yields 115 mL of oxygen gas.<sup>159</sup> Symptoms vary with the affected organ. Seizures, alterations in mental status, and strokelike manifestations occur with CNS involvement from arterial emboli. Nausea, vomiting, hematemesis, and abdominal pain occur with gastrointestinal and hepatic venous involvement, and acute obstruction of the portal vein, portal venous hypertension, and bowel edema are described.<sup>45,95,135,170,192</sup> Hyperbaric oxygen is a successful

intervention for portal venous gas and in some cases of impaired consciousness and or focal neurologic findings.<sup>9,65,87,105,143,159,170,179,236</sup> Hyperbaric oxygen reduces the volume of offending gas and improves solubility of gas into tissues and plasma.<sup>170</sup> A history of inadvertent ingestion of concentrated H<sub>2</sub>O<sub>2</sub>, significant signs or symptoms, or radiologic evidence of gas embolism should prompt patient placement in a Trendelenburg, left lateral decubitus position, administration of 100% oxygen and sufficient fluids to sustain perfusion, and consideration for immediate transportation to the nearest hyperbaric facility. Hyperbaric oxygen to treat gas embolism has demonstrated benefit even if delayed beyond 20 hours.<sup>58</sup>

### ADVERSE EFFECTS AND SAFETY ISSUES

Many HBO facilities have equipment and treatment protocols and abilities analogous to those found in an intensive care unit.<sup>110,240,247</sup> The possible capabilities vary, and interventions with HBO should never be undertaken if standard patient support cannot also be achieved. The inherent toxicity of O<sub>2</sub> and potential for injury resulting from elevations of ambient pressure must be addressed whenever HBO is used therapeutically. Preexisting conditions that require evaluation for possible management before initiation of HBO include claustrophobia, sinus congestion, and patients with scarred or non-compliant structures in the middle ear, such as otosclerosis.<sup>112</sup> Middle ear barotrauma is the most common adverse effect of HBO treatment,<sup>39</sup> and it occurs in 1.2% to 7% of patients.<sup>48,174,232</sup> When autoinsufflation fails, puncturing the ear drum or tympanostomy tube placement will resolve the problem. Pneumothorax is a rarely reported complication.<sup>25</sup> Toxicity resulting from O<sub>2</sub> is manifested by injuries to the CNS, lungs, and eyes. Central nervous system O<sub>2</sub> toxicity manifests as a generalized seizure and occurs at an incidence of approximately 1 to 4 per 10,000 patient treatments.<sup>53,88,174</sup> Pulmonary oxygen toxicity typically does not arise when standard treatment protocols are followed.<sup>47,63,90,175</sup> Progressive myopia occurs in some patients undergoing prolonged daily therapy but typically reverses within 6 weeks after treatments are terminated.<sup>138</sup> Nuclear cataracts can form with excessive treatments, exceeding a total of 150 to 200 hours, and they rarely develop with standard treatment protocols.<sup>69,169</sup> Absent onsite hyperbaric capability, the risks of interfacility transportation (eg, clinical decompensation, vehicle crashes) should also factor into decision making.

### PREGNANCY AND LACTATION

Hyperbaric oxygen in pregnant patients presents the additional risks of fetal CNS, ocular, pulmonary, and cardiac toxicity.<sup>11</sup> In CO poisoning, these must be weighed against the potentially devastating fetal outcomes such as spontaneous abortion, intrauterine fetal demise, anatomic malformations, CNS injury, respiratory distress, and neonatal jaundice, which occur even in only mildly symptomatic CO-poisoned mothers.<sup>38,116</sup> For these reasons, COHb thresholds (eg, 15%–20%) for HBO therapy are often set lower for the pregnant patients than for other adults in HBO treatment algorithms. The authors of this text recommend treating a pregnant woman with HBO when COHb levels are greater than or equal to 15%. Normal fetal outcomes have followed HBO, even in the setting of severe maternal toxicity, and significant adverse fetal outcomes have followed normobaric oxygen therapy.<sup>116</sup> A summary of more than 700 Russian patients treated with HBO for various hypoxic states did not find any detrimental HBO effects.<sup>235</sup> Hyperbaric oxygen was used safely in a prospective study of 44 pregnant women poisoned by CO.<sup>59</sup> Multiple other case reports document successful maternal and fetal outcomes in CO-poisoned pregnant patients.<sup>26,67,197</sup> Hyperbaric oxygen was also used successfully in patients with obstetrical procedures complicated by gas embolism.<sup>160</sup> Treatment decisions will ultimately be made on an individual case basis after weighing potential risks and benefits. There are no data regarding the effects of HBO on lactation.

### DOSING AND ADMINISTRATION

Hyperbaric oxygen efficacy is a time- and pressure-dependent phenomenon. Rodent and human studies demonstrate that exposure to 2.8 to 3.0 ATA O<sub>2</sub> for 45 minutes is required to temporarily inhibit neutrophil adherence to

endothelium mediated by the activation-dependent  $\beta_2$ -integrins on the neutrophil membrane and to ameliorate metabolic insults leading to loss of neuronal growth factors.<sup>43,107,121,215,226</sup> Clinical trials using HBO at only 2 ATAs have been unable to demonstrate a benefit of HBO, likely because it is an inadequate dose to achieve biochemical effects on cellular responses as discussed earlier.<sup>6,176</sup> Multiple trials using HBO (2.5 ATA or above) have demonstrated efficacy.<sup>57,148,227,248</sup> One trial using HBO (2.8 ATA) was unable to demonstrate benefit, subject to the previously discussed limitations.<sup>188</sup> If undertaken, HBO therapy (2.5–3.0 ATA, weighted toward the latter) should be provided as early as possible because a mortality benefit is demonstrated if HBO is administered within 6 hours.<sup>76</sup> Clinical trials have initiated therapy within 24 hours of the end of CO exposure.<sup>248</sup> The use of more than one treatment is supported by retrospective and prospective analysis,<sup>75,248</sup> although clinical practice is highly variable in this regard.<sup>35,83</sup>

## FORMULATION AND ACQUISITION

Hyperbaric oxygen therapy is provided in monoplace or multiplace chambers, which are considered class II medical devices. For sites not possessing HBO capacity, various online organizational and professional directories may assist in locating hyperbaric facilities in the absence of preexisting HBO transfer protocols.

## SUMMARY

- Mechanisms of action and efficacy of HBO are complex and remain an area of active investigation. Research findings are provocative because they highlight the fact that traditional assessments of mechanisms for toxicity of some xenobiotics are incomplete.
- Although the efficacy of HBO for acute CO poisoning is supported in animal trials, questions persist on many issues, including patient selection, optimal dose, and session frequency.
- Hyperbaric oxygen is recommended in serious acute CO poisoning, particularly in cases with end-organ manifestations, recognizing highly varied clinical practice scenarios and preferences.
- Further investigation is required to discern cases where clear benefit arises with HBO treatment and to define the constraints that limit its efficacious use.
- Anecdotal evidence supports HBO therapy in  $H_2S$  and  $CCL_4$  poisoning, in oxidant-induced methemoglobinemia, and in  $H_2O_2$  ingestion.

# CYANIDE AND HYDROGEN SULFIDE

Christopher P. Holstege and Mark A. Kirk

<b>Cyanide</b>	
MW	= 26.02 Da
Whole blood	< 1 mcg/mL
	< 38.43 μmol/L
<b>Concentrations</b>	
Airborne	
Immediately fatal	= 270 ppm
Life threatening	= 110 ppm >30 minutes
<b>Hydrogen Sulfide</b>	
MW	= 34.08 Da
Airborne	
Odor threshold	= 0.01–0.3 ppm
Olfactory paralysis	= 100–150 ppm
Immediately fatal	= 1,000 ppm

## CYANIDE POISONING

### History and Epidemiology

Cyanide (CN) exposure is associated with smoke inhalation, laboratory mishaps, industrial incidents, suicide attempts, and criminal activity.<sup>36,106</sup> Cyanide is a chemical group that consists of one atom of carbon bound to one atom of nitrogen by three molecular bonds (C≡N). Inorganic CNs (also known as CN salts) contain CN in the anion form (CN<sup>-</sup>) and are used in industries, such as metallurgy, photographic developing, plastic manufacturing, fumigation, and mining. Common CN salts include sodium CN (NaCN) and potassium cyanide (KCN). Sodium salts react readily with water to form hydrogen cyanide (HCN) gas. Organic compounds that have a cyano group bonded to an alkyl residue are called nitriles. For example, methyl CN is also known as acetonitrile (CH<sub>3</sub>CN). Hydrogen cyanide is a colorless gas at standard temperature and pressure with a reported bitter almond odor. Cyanogen gas, a dimer of CN, reacts with water and breaks down into the CN anion. Cyanogen chloride (CNCl) is a colorless gas that is easily condensed; it is a listed agent by the Chemical Weapons Convention.

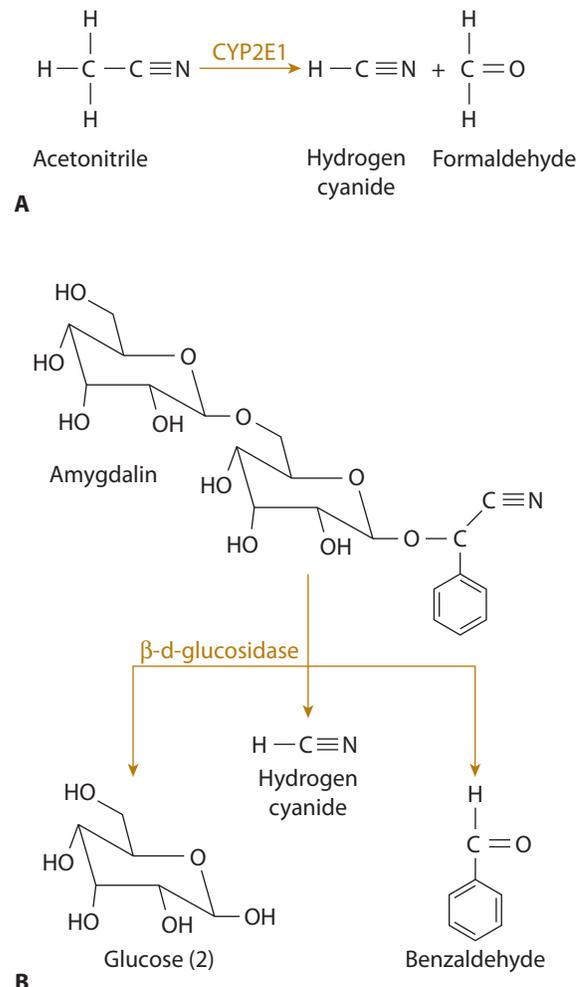

Many plants, such as the *Manihot* spp., *Linum* spp., *Lotus* spp., *Prunus* spp., *Sorghum* spp., and *Phaseolus* spp., contain cyanogenic glycosides.<sup>111</sup> The *Prunus* species consisting of apricots, bitter almond, cherry, and peaches have pitted fruits containing the glucoside amygdalin. When ingested, amygdalin is biotransformed by intestinal β-D-glucosidase to glucose, benzaldehyde, and CN (Fig. 123–1). Laetrile, which contains amygdalin, was inappropriately suggested to have antineoplastic properties despite a lack of evidence to support such claims.<sup>85</sup> When laetrile was administered by intravenous (IV) infusion, amygdalin bypassed the necessary enzymes in the gastrointestinal (GI) tract to liberate CN and did not cause toxicity. However, ingested laetrile causes CN poisoning. Despite data demonstrating its lack of utility in the treatment of cancer, it still is available via the Internet.

Cassava (*Manihot esculenta*) root is a major source of food for millions of people in the tropics. It is a hardy plant that remains in the ground for up to 2 years and needs relatively little water to survive. Because the shelf life of a cassava root is short after it is removed from the stem, cassava root must be processed and sent to market as soon as it is harvested. However, proper processing must occur to assure the food's safety. Processed cassava is called *Gari*. Linamarin (2-hydroxyisobutyronitrile-β-D-glucose) is the major cyanogenic glycoside in cassava roots. It is hydrolyzed to hydrogen CN and acetone in two steps during the processing of cassava roots.<sup>114</sup> Whereas soaking

peeled cassava in water for a single day releases approximately 45% of the cyanogens, soaking for 5 days causes 90% loss. If processing is inefficient, linamarin and cyanohydrin, the immediate product of hydrolysis of linamarin, remain in the food.<sup>92</sup> Consumed linamarin is hydrolyzed to cyanohydrin by β-glucosidases of the microorganisms in the intestines. Cyanohydrin present in the food and formed from linamarin then dissociates spontaneously to CN in the alkaline pH of the small intestines.

Iatrogenic CN poisoning occurs during prolonged or high-dose nitroprusside therapy for the management of hypertension. Each nitroprusside molecule contains five CN molecules, which are slowly released in vivo. If endogenous sulfate stores are depleted, as in the malnourished or postoperative patient, CN accumulates even with therapeutic nitroprusside infusion rates.

In 1782, the Swedish chemist Carl Wilhelm Scheele first isolated hydrogen CN. He reportedly died from the adverse health effects of CN poisoning in 1786. Napoleon III was the first to use HCN in chemical warfare, and it was subsequently used on World War I battlefields. During World War II, hydrocyanic acid pellets (brand name Zyklon B) caused more than one million deaths in Nazi gas chambers at Auschwitz, Buchenwald, and Majdanek.

**FIGURE 123–1.** Biotransformation of cyanogens acetonitrile (A) and amygdalin (B) to cyanide.

In 1978, KCN was used in a mass suicide led by Jim Jones of the People's Temple in Guyana, resulting in 913 deaths. Other notorious suicide cases include Wallace Carothers, Herman Goring, Heinrich Himmler, and Ramon Sampedro. In 1982, seven deaths resulted from consumption of CN-tainted acetaminophen in Chicago that subsequently led to the requirement of tamper-resistant pharmaceutical packaging. Numerous copycat murders subsequently occurred using CN-tainted capsules, with the last high-profile case occurring in 2010 involving an Ohio emergency medicine physician who murdered his wife with a CN-laden calcium capsule.<sup>16</sup> Cyanide is used for illicit euthanasia.<sup>21</sup> Internet websites provide detailed instructions on how to use various available chemicals to produce HCN.<sup>2</sup> The sale of CN is controlled in various countries, but the expansion of the “deep” or “dark” web enables users to purchase CN more easily with use of virtual money such as the “bitcoin.”<sup>79</sup>

The American Association of Poison Control Centers' National Poison Data System reported 1,258 CN exposures from 2011 through 2015 (Chap. 130). One study of poison control center data found that 8.3% of patients with intentional overdoses died, and another 9% developed cardiac arrest but survived; 74% did not receive an antidote, most likely because of the failure of the initial treatment team to recognize the poisoning.<sup>15</sup> The potential for CN poisoning exists after smoke inhalation (ie, recent Kiss nightclub fire in Southern Brazil with more than 200 deaths attributed in part to CN), especially after the combustion of materials such as wool, silk, synthetic rubber, and polyurethane.<sup>45</sup> Ingestion of cyanogenic chemicals (ie, acetonitrile, acrylonitrile, and propionitrile) is another source of CN poisoning.<sup>108</sup> Acetonitrile (C<sub>2</sub>H<sub>3</sub>N) and acrylonitrile (C<sub>3</sub>H<sub>3</sub>N) are themselves nontoxic, but biotransformation via CYP 2E1 liberates CN (Fig. 123-1).<sup>116</sup>

### Pharmacology

The dose of CN required to produce toxicity depends on the form of CN, the duration of exposure, and the route of exposure. However, CN is an extremely potent toxin with even small exposures leading to life-threatening symptoms. For example, an adult oral lethal dose of KCN is approximately 200 mg. An airborne concentration of 270 ppm (mcg/mL) of HCN is immediately fatal, and exposures greater than 110 ppm for more than 30 minutes are generally considered life threatening. The current Occupational Safety and Health Administration (OSHA) permissible exposure limit (PEL) for both HCN and cyanogen is 10 ppm as an 8-hour time-weighted average concentration. The immediately dangerous to life or health value for HCN is 50 ppm.

Acute toxicity occurs through a variety of routes, including inhalation, ingestion, dermal, and parenteral. Hydrogen cyanide readily crosses membranes because it has a low molecular weight (27 Da) and is nonionized. After absorption and dissolution in blood, there exists an equilibrium between the CN anion (CN<sup>-</sup>) and undissociated HCN. Hydrogen cyanide is a weak acid with a pK<sub>a</sub> of 9.21. Therefore, at a physiologic pH of 7.4, it exists primarily as HCN. Rapid diffusion across alveolar membranes followed by direct distribution to target organs accounts for the rapid lethality associated with HCN inhalation.

### Toxicokinetics

Cyanide is eliminated from the body by multiple pathways. The major route for detoxification of CN is the enzymatic conversion to thiocyanate. Two sulfurtransferase enzymes, rhodanese (thiosulfate–CN sulfurtransferase) and β-mercaptopyruvate–CN sulfurtransferase, catalyze this reaction. The primary pathway for metabolism is rhodanese, which is widely distributed throughout the body and has the highest concentration in the liver. This enzyme catalyzes the transfer of a sulfane sulfur from a sulfur donor, such as thiosulfate to CN to form thiocyanate. In acute poisoning, the limiting factor in CN detoxification by rhodanese is the availability of adequate quantities of sulfur donors. The endogenous stores of sulfur are rapidly depleted, and CN metabolism slows. Hence, the efficacy of sodium thiosulfate as an antidote stems from its normalization of the metabolic inactivation of CN. The sulfation of CN is essentially irreversible, and the sulfation product thiocyanate has relatively little inherent toxicity. Thiocyanate is eliminated in urine. A number of minor pathways of metabolism (<15% of total) account for CN

elimination, including conversion to 2-aminothiazoline-4-carboxylic acid, incorporation into the 1-carbon metabolic pool, or in combination with hydroxycobalamin to form cyanocobalamin.

Limited human data regarding the CN elimination half-life are available. Elimination follows first-order kinetics, although it varies widely in reports (range, 1.2–66 hours).<sup>10,49,74</sup> Disparity in values results from the number of samples used to perform calculations and the effects of antidotal treatment. The volume of distribution of the CN anion varies according to species and investigator, with 0.075 L/kg reported in humans.<sup>32</sup>

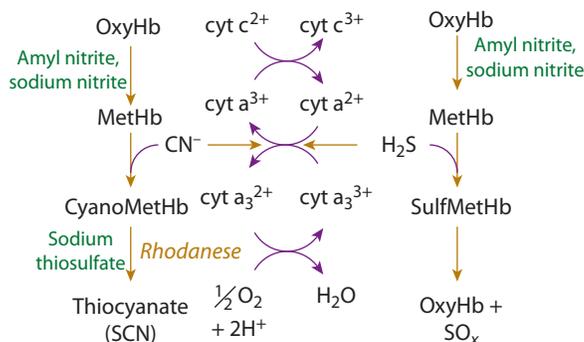

### Pathophysiology

Cyanide is an inhibitor of multiple enzymes, including succinic acid dehydrogenase, superoxide dismutase, carbonic anhydrase, and cytochrome oxidase.<sup>82,88</sup> Cytochrome oxidase is an iron-containing metalloenzyme essential for oxidative phosphorylation and hence aerobic energy production. It functions in the electron transport chain within mitochondria, converting catabolic products of glucose into adenosine triphosphate (ATP). Cyanide induces cellular hypoxia by inhibiting cytochrome oxidase at the cytochrome a<sub>3</sub> portion of the electron transport chain (Fig. 123-2). Hydrogen ions that normally would have combined with oxygen at the terminal end of the chain are no longer incorporated. Thus, despite sufficient oxygen supply, oxygen cannot be used, and ATP molecules are no longer formed. Unincorporated hydrogen ions accumulate, contributing to acidemia.

The lactate concentration increases rapidly following CN poisoning because of failure of aerobic energy metabolism. During aerobic conditions, when the electron transport chain is functional, lactate is converted to pyruvate by mitochondrial lactate dehydrogenase. In this process, lactate donates hydrogen moieties that reduce nicotinamide adenine dinucleotide (NAD<sup>+</sup>) to nicotinamide adenine dinucleotide (NADH). Pyruvate then enters the citric acid cycle, with resulting ATP formation. When cytochrome a<sub>3</sub> within the electron transport chain is inhibited by CN, there is a relative paucity of NAD<sup>+</sup> and predominance of NADH, favoring the reverse reaction, in which pyruvate is converted to lactate.

Cyanide is also a potent neurotoxin. Cyanide exhibits a particular affinity for regions of the brain with high metabolic activity. Central nervous system (CNS) injury occurs via several mechanisms, including impaired oxygen utilization, oxidant stress, and enhanced release of excitatory neurotransmitters. Cranial imaging of survivors of CN poisoning reveals that injury occurs in the most oxygen-sensitive areas of the brains, such as the basal ganglia, cerebellum, and sensorimotor cortex.

Cyanide enhances *N*-methyl-D-aspartate (NMDA) receptor activity and directly activates the NMDA receptor, which increases release of glutamate and inhibits voltage-dependent magnesium blockade of the NMDA receptor. This NMDA receptor stimulation results in Ca<sup>2+</sup> entry into the cytosol of neurons. Cyanide also activates voltage-sensitive calcium channels and mobilizes Ca<sup>2+</sup> from intracellular stores.<sup>61,83,96</sup> As a result, cytosolic Ca<sup>2+</sup> rises and activates a series of biochemical reactions that lead to the generation of reactive oxygen species (ROS) and nitrous oxide.<sup>71,103</sup> These ROS initiate

**FIGURE 123-2.** Pathway of cyanide and hydrogen sulfide toxicity and detoxification. MetHb = methemoglobin; OxyHb = oxyhemoglobin; SulfMetHb = sulfmethemoglobin.

peroxidation of cellular lipids, which, together with CN-induced inhibition of the respiratory chain, adversely affect mitochondrial function, initiating cytochrome c release and execution of apoptosis, necrosis, and subsequent neurodegeneration.<sup>7,95</sup> Experimental studies demonstrate that NMDA inhibitors such as dextrorphan and dizocilpine, antioxidants, and cyclooxygenase inhibitors all protect neurons against CN-induced damage.<sup>58,80,115</sup>

Sulfurtransferase metabolism via rhodanese is crucial for detoxification. However, the aforementioned CN-induced metabolic derangement decreases enzyme detoxification. Decreased ATP and ROS and increased cytosolic Ca<sup>2+</sup> stimulate protein kinase C activity, which in turn inactivates rhodanese.<sup>4</sup>

## Clinical Manifestations

### Acute Exposure to Cyanide

The amount, duration of exposure, route of exposure, and premorbid condition of the individual all influence the time to onset and severity of illness. A critical combination of these factors overwhelms endogenous detoxification pathways, allowing CN to diffusely affect cellular function within the body. No reliable pathognomonic symptom or toxic syndrome is associated with acute CN poisoning.<sup>44,60</sup> The initial clinical effects of acute CN poisoning are nonspecific, generalized, and nondiagnostic, thereby making the correct diagnosis difficult to obtain. Clinical manifestations reflect rapid dysfunction of oxygen sensitive organs, with CNS and cardiovascular findings predominating. The time to onset of symptoms typically is seconds with inhalation of gaseous HCN or IV injection of a water-soluble CN salt and several minutes after ingestion of inorganic CN. The clinical effects of cyanogenic chemicals often are delayed, and the time course varies among individuals (range, 3–24 hours), depending on their rate of biotransformation.<sup>108</sup> Clinically apparent CN toxicity occurs within hours to days of initiating nitroprusside infusion, although concurrent administration of thiosulfate or hydroxocobalamin prevents toxicity (Chap. 61).<sup>102</sup>

Central nervous system signs and symptoms are typical of progressive hypoxia and include headache, anxiety, agitation, confusion, lethargy, non-reactive dilated pupils, seizures, and coma. A centrally mediated tachypnea occurs initially followed by bradypnea and apnea.

Cardiovascular responses to CN are complex. Studies of isolated heart preparations and intact animal models show that the principal cardiac insult is slowing of heart rate and loss of contractile force.<sup>9</sup> Several reflex mechanisms, including catecholamine release and central vasomotor activity, modulate myocardial performance and vascular response in patients with CN poisoning.<sup>72</sup> In laboratory investigations, a brief period of increased inotropy caused by reflex compensatory mechanisms occurs before myocardial depression. Clinically, an initial period of tachycardia and hypertension usually occurs followed by hypotension with reflex tachycardia, but the terminal event is consistently bradycardia and hypotension. Ventricular dysrhythmias are rarely reported.

Pulmonary edema is reported at autopsy.<sup>44</sup> Inhalation of HCN is also associated with mild corrosive injury to the respiratory tract mucosa.

Gastrointestinal toxicity occurs after ingestion of inorganic CN and cyanogens and includes abdominal pain, nausea, and vomiting. These symptoms are caused by hemorrhagic gastritis, which is frequently identified on autopsy, and are thought to be secondary to the corrosive nature of CN salts. However, if death occurs rapidly, this gastritis is not seen at autopsy because development of inflammation occurs over time.<sup>44</sup> After ingestion, a smell of bitter almonds is noted in a few reports but should not be relied on to be emitted from the GI system as health care providers in nearly all case reports published do not mention this finding.<sup>30</sup>

Cutaneous manifestations vary. A cherry red skin color is described as a potential finding as a result of increased venous hemoglobin oxygen saturation, which results from decreased utilization of oxygen at the tissue level. The phenomenon of arterialization of retinal veins is more evident on fundoscopic examination, where veins and arteries appear similar in color. Despite the inference in the name, CN itself does not directly cause cyanosis. The occurrence of cyanosis is most commonly reported in published case reports and is likely caused by cardiovascular collapse and subsequent poor perfusion.<sup>30</sup>

### Delayed Clinical Manifestations of Acute Exposure

Survivors of serious, acute poisoning develop delayed neurologic sequelae. Parkinsonian symptoms, including dystonia, dysarthria, rigidity, and bradykinesia, are most common. Symptoms typically develop over weeks to months, but subtle findings are reported to be present within a few days. Head computed tomography (CT) and magnetic resonance imaging (MRI) consistently reveal basal ganglia damage (globus pallidus, putamen, and hippocampus) with radiologic changes appearing several weeks after onset of symptoms. Whether delayed manifestations result from direct cellular injury or secondary hypoxia is unclear. Extrapyramidal manifestations either progress or resolve. Response to pharmacotherapy with antiparkinsonian drugs is generally disappointing.

### Chronic Exposure to Cyanide

Chronic exposure to CN results in insidious syndromes, including tobacco amblyopia, Konzo, and Leber hereditary optic neuropathy. Tobacco amblyopia is a progressive loss of visual function that occurs almost exclusively in men who smoke cigarettes. Affected smokers have lower serum cyanocobalamin and thiocyanate concentrations than unaffected smoking counterparts, suggesting a reduced ability to detoxify CN. Cessation of smoking and administration of hydroxocobalamin often reverse symptoms. Konzo is associated with the consumption of insufficiently processed “bitter” (cyanogenic) cassava. Neurologic manifestations include spastic paraparesis that is often sudden and symmetrical affecting the legs more than the arms. Malnutrition places individuals at greater risk in part caused by low vitamin B<sub>12</sub> intake.<sup>69</sup> Removal of dietary cassava and institution of vitamin B<sub>12</sub> therapy is the mainstay of prevention and therapy. Leber hereditary neuropathy, a condition of subacute visual failure affecting men, is thought to be caused by mitochondrial DNA mutations exacerbated by exposure to cyanogenic glycosides.<sup>39</sup>

Chronic exposure to CN is associated with thyroid disorders.<sup>1</sup> Thiocyanate is a competitive inhibitor of iodide entry into the thyroid, thereby causing the formation of goiters and the development of hypothyroidism (Chap. 53). Chronic exposure to CN in animals is associated with hydropic degeneration in hepatocytes and epithelial cells of the renal proximal tubules; however, these morphologic lesions are not linked to functional alternations.<sup>105</sup>

### Diagnostic Testing

Because of nonspecific symptoms and delay in laboratory CN confirmation, the clinician must rely on historical circumstances and some initial findings to raise suspicion of CN poisoning and institute therapy (Table 123–1).

Laboratory findings suggestive of CN poisoning reflect the known metabolic abnormalities, which include an increased anion gap metabolic acidosis and elevated lactate concentration. Elevated venous oxygen saturation results from reduced tissue extraction.<sup>63</sup> A venous oxygen saturation above 90% from superior vena cava or pulmonary artery blood indicates decreased oxygen utilization. This finding is not specific for CN and could represent cellular poisoning from other xenobiotics such as carbon monoxide (CO), clenbuterol, hydrogen sulfide (H<sub>2</sub>S), and sodium azide or medical conditions such as sepsis, high-output cardiac syndromes, and left-to-right intracardiac shunts.

Hyperlactatemia is found in numerous critical illnesses and typically is a nonspecific finding. However, a significant association exists between blood CN and serum lactate concentrations.<sup>11,12</sup> Arterial blood gas pH correlates inversely with CN concentration.<sup>12</sup> The finding of a small arterial–venous oxygen difference is also suggestive of CN toxicity.

Cyanide results in nonspecific electrocardiographic findings.<sup>37</sup> Rhythm disturbances such as sinus tachycardia, bradydysrhythmias, atrial fibrillation, ventricular tachycardia, and ventricular fibrillation are all reported, as are elevation or depression of the ST segment, shortened ST segments, and fusion of the T wave into the QRS complex.

A determination of the blood CN concentration will confirm toxicity, but this determination is not available in a sufficiently rapid manner to affect initial treatment. It is clinically not possible to obtain the blood CN concentration at the exact time of the exposure when concentrations would be expected to be at peak. Subsequent later testing would be expected to

**TABLE 123–1 Cyanide Poisoning: Emergency Management Guidelines****When to Suspect Cyanide**

Sudden collapse of laboratory or industrial worker  
 Fire victim with coma or acidemia  
 Suicide with unexplained rapid coma or acidemia  
 Ingestion of artificial nail remover  
 Ingestion of seeds or pits from *Prunus* spp  
 Patient with altered mental status, acidemia, and tachyphylaxis to nitroprusside

**Supportive Care**

Control airway, ventilate, and give 100% oxygen  
 Crystalloids and vasopressors for hypotension  
 Administer sodium bicarbonate; titrate according to ABG and serum  $[\text{HCO}_3^-]$

**Antidotes**

1) Hydroxocobalamin (preferred)

Initial adult dose: 5 g IV over 15 min; pediatric dose 70 mg/kg up to 5 g; to be repeated if necessary

or

2) Cyanide Antidote Kit

Amyl nitrite pearls are included in the kit for prehospital use. For hospital management, sodium nitrite is the preferred methemoglobin inducer and is given in lieu of the pearls.

Give sodium nitrite ( $\text{NaNO}_2$ ) as a 3% solution over 2–4 min IV: Adult dose: 10 mL (300 mg) (Table 123–2 for pediatric dosing)

**Caution:** Monitor blood pressure frequently and treat hypotension by slowing infusion rate and giving crystalloids and vasopressors. Obtain methemoglobin level 30 min after dose; excess methemoglobin formation will cause deterioration during therapy. Withhold nitrites if COHb is suspected to be present.

Give sodium thiosulfate ( $\text{Na}_2\text{S}_2\text{O}_3$ ) as a 25% solution IV:

Adult dose: 50 mL (12.5 g)

Pediatric dose: 1.65 mL/kg up to 50 mL

**Decontamination**

Protect health care provider from contamination  
 Cutaneous: Carefully remove all clothing and flush the skin  
 Ingestion: Oro- or nasogastric lavage and instill 1 g/kg activated charcoal

**Laboratory**

ABG  
 Electrolytes and glucose  
 Blood lactate  
 Whole-blood cyanide concentration (for later confirmation only)

ABG = arterial blood gas; COHb = carboxyhemoglobin; IV = intravenous.

demonstrate lower concentrations depending on the source of exposure. Whole blood or serum can be analyzed, with most reports using whole blood for CN determination. In mammals, including primates, whole-blood concentrations are twice serum concentrations as a result of CN sequestration in red blood cells. Background whole-blood CN concentrations in smokers are higher than in nonsmokers. Coma and respiratory depression are associated with whole-blood concentrations greater than 2.5 mcg/mL, and death is associated with concentrations greater than 3 mcg/mL depending on the timing of the collection relative to the exposure. Serum thiocyanate concentrations are of limited value in assessing patients with acute poisoning because of a lack of correlation with symptoms but are useful in confirming exposure. Depending on the timing of collection, urinary thiocyanate is used as a marker of CN exposure. More recently, a CN metabolite named 2-aminothiazoline-4-carboxylic acid (ACTA) that is not significantly influenced by putrefaction was found to be a reliable biomarker of CN poisoning because of its long-term stability in biological material.<sup>43</sup>

A semiquantitative assay that uses colorimetric paper test strips immediately detect CN. Cyantesmo test strips currently are used by water treatment facilities to detect CN. An investigation of the utility of these strips in

clinical practice found that the test strips incrementally increased to a deep blue color over a progressively longer portion of the test strip with increasing concentrations of CN in the blood.<sup>100</sup> These strips accurately and rapidly detected, in a semiquantifiable manner, CN concentrations greater than 1 mcg/mL.

**Management**

Because CN poisoning is rare, it is easy to overlook the diagnosis unless there is an obvious history of exposure. Thus, the most critical steps in treatment are considering the diagnosis in high-risk situations (Table 123–1) and initiating empiric therapy with 100% oxygen and either hydroxycobalamin or the sodium nitrite and sodium thiosulfate combination. The initial care (Table 123–1) of a CN-poisoned patient begins by directing attention to airway patency, ventilatory support, and oxygenation.

Intravenous access should be rapidly obtained and blood samples sent for kidney function, glucose, and electrolyte determinations. A whole-blood CN concentration should be obtained for later confirmation of exposure. Arterial blood gas analysis and serum lactate concentration will help assess acid–base status. Clinicians should initiate crystalloids and vasopressors for hypotension.

First responders should exercise extreme caution when entering potentially hazardous areas such as chemical plants and laboratories where a previously healthy person is “found down.” Exposure to CN occurs by multiple routes, including ingestion, inhalation, dermal, and parenteral. For patients with inhalation exposure, removal from the area of exposure is critical. Further decontamination is generally unnecessary. Decontamination of a CN-poisoned patient occurs concurrently with initial resuscitation. The health care provider should always be protected from potential dermal contamination by using personal protective devices such as water-impervious gowns, gloves, and eyewear. For patients with cutaneous exposure, remove their clothing, brush any powder off the skin, and flush the skin with water. Particular attention should be given to open wounds because CN is readily absorbed through abraded skin.

Instillation of activated charcoal often is considered by other authors to be ineffective because of low binding of CN (1 g of activated charcoal only adsorbs 35 mg of CN). However, a potentially lethal oral dose of CN (ie, a few hundred milligrams) is within the adsorptive capacity of a typical 1-g/kg dose of activated charcoal. Preexposure activated charcoal administration improved survival in animals given an  $\text{LD}_{100}$  dose of KCN.<sup>75</sup> Based on the potential benefits and minimal risks, we recommend activated charcoal in the patient with an intact protected airway.

Although either hydroxocobalamin or sodium nitrite and sodium thiosulfate combination should be administered as soon as CN poisoning is suspected, hydroxocobalamin is preferred. Hydroxocobalamin is a metalloprotein with a central cobalt atom that complexes CN, forming cyanocobalamin (vitamin  $\text{B}_{12}$ ). Cyanocobalamin is eliminated in the urine or releases the CN moiety at a rate sufficient to allow detoxification by rhodanese. One molecule of hydroxocobalamin binds one molecule of CN, yielding a molecular weight binding ratio of 50:1. The US FDA-approved adult starting dose is 5 g administered by IV infusion over 15 minutes. Depending on the severity of the poisoning and the clinical response, a second dose of 5 g is recommended by IV infusion for a total dose of 10 g. Hydroxocobalamin has few adverse effects, which includes rashes and a transient reddish discoloration of the skin, mucous membranes, and urine. No hemodynamic adverse effects other than a potential mild transient rise of blood pressure are observed.

Although no longer available, the CN antidote kit contained amyl nitrite, sodium nitrite, and sodium thiosulfate. Both thiosulfate and nitrite individually have antidotal efficacy when given alone in animal models of CN poisoning, but they have even greater benefit when they are given in combination.<sup>82</sup> Thiosulfate donates the sulfur atoms necessary for rhodanese-mediated CN biotransformation to thiocyanate. The mechanism of nitrite is less clear. Traditional rationale relies on the ability of nitrite to generate methemoglobin. Because CN has a higher affinity for methemoglobin than for cytochrome  $\text{a}_3$ , cytochrome oxidase function is restored. However, improved hepatic blood flow and nitric oxide (NO) formation are alternative explanations.

**TABLE 123–2 Cyanide Pediatric (<25 kg) Sodium Nitrite Guidelines\***

Hemoglobin (g/dL)	NaNO <sub>2</sub> (mg/kg)	3% NaNO <sub>2</sub> solution (mL/kg)**

Amyl nitrite was packaged within glass pearls that are crushed and intermittently inhaled or intermittently introduced into the ventilator system to initiate methemoglobin formation. The amyl nitrite pearls were reserved for cases in which IV access was delayed or not possible. Intravenous sodium nitrite is preferred and is supplied as a 10-mL volume of 3% solution (300 mg). Adverse effects of nitrites include excessive methemoglobin formation and, because of potent vasodilation, hypotension and tachycardia. Avoiding rapid infusion, monitoring blood pressure, and adhering to dosing guidelines limit adverse effects. Because of the potential for excessive methemoglobinemia during nitrite treatment, pediatric dosing guidelines are available (Table 123–2). Sodium thiosulfate was the second component of the CN antidote kit. It is supplied as 50 mL of 25% solution (12.5 g). It is a substrate for the reaction catalyzed by rhodanese that is essentially irreversible, converting a highly toxic entity to a relatively harmless compound. However, thiocyanate has its own toxicity in the presence of kidney failure, including abdominal pain, vomiting, rash, CNS dysfunction and hypothyroidism with chronically elevated concentrations. Thiosulfate itself is not associated with significant adverse reactions. The pediatric dose of thiosulfate is adjusted for weight. The currently available antidote Nithiodote contains both sodium nitrite and sodium thiosulfate in the same concentrations as were available in the CN antidote kit but no longer provides amyl nitrite.

After acetonitrile exposure, administration of disulfiram is proposed by some authorities as an inhibitor of CYP2E1 to prevent the conversion of acetonitrile to cyanohydrin, thereby preventing significant CN formation but there is not enough data to recommend this therapy currently.<sup>31</sup>

The antidote 4-dimethylaminophenol (4-DMAP), rather than sodium nitrite, is also used as a methemoglobin inducer.<sup>50</sup> It generates methemoglobin more rapidly than sodium nitrite, with peak methemoglobin concentrations at 5 minutes after 4-DMAP rather than 30 minutes after sodium nitrite. The dose of 4-DMAP is 3 mg/kg and is coadministered with thiosulfate. As with sodium nitrite, its major adverse effect is excessive methemoglobin formation and potential for hypotension. Cobalt in the form of dicobalt edetate is used as a CN chelator, and it is associated with significant adverse effects such as hypertension, tachycardia, and angioedema.<sup>81</sup> The cobalamin precursor cobinamide is used both prophylactically and therapeutically to treat experimental CN toxicity, and when given at high enough doses, it has rescued animals from CN induced apnea and coma.<sup>23</sup> Cobinamide is an investigational treatment that has a much greater affinity for CN ion than cobalamin.<sup>27</sup> Dimethyl trisulfide (DMTS) acts as a sulfur donor for rhodanese and has efficacy against CN poisoning in animal models and is being explored for prehospital use in humans. Hyperbaric oxygen (HBO) was considered in the past, but recent evidence suggests no benefit in CN poisoning.<sup>78</sup>

In animal models, the antioxidant vitamins A, C, and E diminish the extent of tissue damage caused by subacute CN intoxication.<sup>90</sup> This is especially important in the tropics, where the majority of dietary staples are cyanophoric crops such as cassava. These therapies have no proven utility in acute poisoning and therefore are not recommended.

Patients who do not survive CN poisoning are suitable organ donors. Heart, liver, kidney, pancreas, cornea, skin, and bone have been successfully transplanted after CN poisoning<sup>38</sup> (Special Considerations: SC12).

## HYDROGEN SULFIDE POISONING

### History and Epidemiology

Hydrogen sulfide exposures are often dramatic and fatal. The American Association of Poison Control Centers' National Poison Data System reported 4,442 exposures from 2011 through 2015 (Chap 130). Only 1,670 of these exposures required evaluation at a health care facility, 573 reported moderate or major effects, and 35 deaths occurred. Most often, serious consequences of H<sub>2</sub>S exposures occur through workplace exposures, but they also occur in environmental disasters and suicides.

Bacterial decomposition of proteins generates H<sub>2</sub>S, and the gas is produced in many industrial activities. Decay of the sulfur-containing products such as fish, sewage, and manure produce H<sub>2</sub>S. Industrial sources include pulp paper mills, heavy-water production, the leather industry, roofing asphalt tanks, vulcanizing of rubber, viscose rayon production, and coke manufacturing from coal.<sup>28</sup> It is a major industrial hazard in oil and gas production, particularly in sour gas fields (natural gas containing sulfur).

Between 1990 and 1999, H<sub>2</sub>S poisoning was associated with the deaths of 18% of US construction workers killed by toxic inhalation.<sup>33</sup> Many died while working in confined spaces such as sewers or sewer manholes. Agricultural workers operating near livestock manure storage tanks are at greatest risk of harm from an inhalation exposure.<sup>14,51</sup> Poisoned workers are “knocked down,” prompting coworkers to attempt a rescue. Numerous case reports describe multiple victims because the would-be rescuers often themselves become victims when they attempt a rescue in an environment having high concentrations of H<sub>2</sub>S.<sup>8,14,33</sup> Studies report that up to 25% of fatalities involve rescuers.<sup>33,40,56</sup> For example, a leaking food waste pipeline in the propeller room of a cruise ship released H<sub>2</sub>S, killing 3 workers attempting to repair the pipe. The emergency response resulted in injury to 18 crew members, including a physician and a nurse rushing into the dangerous environment without personal protective equipment.<sup>3</sup>

Occupational Safety and Health Administration and a variety of occupational organizations such as the American Industrial Hygiene Association, the National Institute of Occupational Safety and Health, the American Shipbuilding Association, and the US Chemical Safety Board recognize the serious dangers of H<sub>2</sub>S exposures in the workplace and continue to promote safety alerts and educational programs.

Natural sources of H<sub>2</sub>S are volcanoes, caves, sulfur springs, and underground deposits of natural gas.<sup>28,99</sup> Hydrogen sulfide is also implicated in several environmental disasters. In 1950, 22 people died, and 320 were hospitalized in Poza Rica, Mexico, when a local natural gas facility inadvertently released H<sub>2</sub>S into the air.<sup>84</sup> Hydrogen sulfide claimed nine lives when a sour gas well failed, releasing a cloud of the poisonous gas into the Denver City, Texas community in 1975.<sup>86</sup> In 2003, a gas drilling incident in southwest China released natural gas and a cloud of H<sub>2</sub>S into a populated area, killing more than 200 people, injuring 9,000, and necessitating the evacuation of more than 40,000.<sup>118</sup>

More recently, a large number of suicides called “chemical suicides” or “detergent suicides” were attributed to mixing common household chemicals such as pesticides or fungicides and toilet bowl cleaners to create H<sub>2</sub>S gas.<sup>70,98</sup> This practice is of concern because the instructions are easily found on Internet sites, precursor chemicals are readily accessible from the cleaning section of many local stores, first responders are at risk of harmful toxic effects from exposure, and the toxic gas can inadvertently expose groups of people in nearby buildings. In Japan, a “chain reaction of suicides” occurred, meaning it escalated nationwide with more than 200 people dead

in the first half of 2008.<sup>70</sup> Information resources on the Internet are implicated for the widespread practice and prompted police to request purging these suicide instructions from Internet sites.<sup>54</sup> In the United States, chemical suicides from H<sub>2</sub>S are likely underreported but rose from 2 in 2008 to 19 in 2010.<sup>98</sup> In as many as 80% of incidents, first responders report exposures after attempted rescue of victims.<sup>98</sup> Suicide victims using this method to harm themselves inadvertently cause injuries and evacuations because of the toxic gas permeating buildings. One incident in Japan caused 90 people to become ill from the toxic gas as it permeated an apartment building, and another resulted in 350 people evacuating a building.<sup>110</sup>

### Pharmacology and Toxicokinetics

Hydrogen sulfide is a colorless gas, more dense than air, with an irritating odor of “rotten eggs.” It is highly lipid soluble, a property that allows easy penetration of biologic membranes. Systemic absorption usually occurs through inhalation, and it is rapidly distributed to tissues.<sup>99</sup>

The tissues most sensitive to H<sub>2</sub>S are those with high oxygen demand. The systemic toxicity of H<sub>2</sub>S results from its potent inhibition of cytochrome oxidase, thereby interrupting oxidative phosphorylation.<sup>28</sup> Hydrogen sulfide binds to the ferric (Fe<sup>3+</sup>) moiety of cytochrome a<sub>3</sub> oxidase complex with a higher affinity than does CN. The resulting inhibition of oxidative phosphorylation produces cellular hypoxia and anaerobic metabolism.<sup>28</sup>

Cytochrome oxidase inhibition is not the sole mechanism of toxicity. Other enzymes are inhibited by H<sub>2</sub>S and contribute to its toxic effects.<sup>99</sup> Besides producing cellular hypoxia, H<sub>2</sub>S alters brain neurotransmitter release and neuronal transmission through potassium channel-mediated hyperpolarization of neurons, NMDA receptor potentiation, and has other neuronal inhibitory mechanisms.<sup>91,99</sup> A proposed mechanism of death is poisoning of the brainstem respiratory center through selective uptake by lipophilic white matter in this region.<sup>117</sup> The olfactory nerve is a specific target of great interest. Not only does the toxic gas cause olfactory nerve paralysis, but it also provides a portal of entry into the CNS because of its direct contact with the brain.<sup>119</sup> It is also cytotoxic through formation of reactive sulfur and oxygen species. It also reacts with iron to fuel the Fenton reaction (Chap. 10), causing free radical injury.<sup>109</sup>

In addition to systemic effects, H<sub>2</sub>S reacts with the moisture on the surface of mucous membranes to produce intense irritation and corrosive injury. The eyes and nasal and respiratory mucous membranes are the tissues most susceptible to direct injury.<sup>76,119</sup> Despite skin irritation, it has little dermal absorption.

Along with NO and CO, researchers recently recognized H<sub>2</sub>S as a signaling molecule of the cardiovascular, renal, inflammatory, and nervous systems, and therefore, they proposed to add H<sub>2</sub>S as the “third endogenous gaseous transmitter.” Mice inhaling a low dose of H<sub>2</sub>S demonstrated a decrease in their metabolic demands, causing them to enter a “suspended animationlike state.”<sup>20</sup> This report propelled researchers into studies probing the biosynthesis, metabolism, and physiological responses of H<sub>2</sub>S in hopes of developing future beneficial therapies to combat the adverse consequences of ischemia-reperfusion injury.<sup>26,34,91</sup> Currently, researchers are pursuing the therapeutic potential for H<sub>2</sub>S donors for diseases such as ischemia-reperfusion injury in acute stroke and ischemic kidney injury, cisplatin nephrotoxicity, atherosclerosis, heart failure, acute and chronic inflammatory diseases, and Parkinson and Alzheimer diseases.<sup>18,26,34</sup> Researchers’ enthusiastic pursuit of a better understanding of H<sub>2</sub>S with an intent to create innovative therapies will likely also benefit our understanding of its mechanisms of toxicity and potentially lead to new treatments for toxic exposures.

Inhaled H<sub>2</sub>S enters the systemic circulation where, at physiologic pH, it dissociates into hydrosulfide ions (HS<sup>-</sup>).<sup>18</sup> After dissociation, hydrosulfide ions interact with metalloproteins, disulfide-containing enzymes, and thio dimethyl S transferase. Hydrogen sulfide and dissociation products are then metabolized by multiple enzymes, including mitochondrial sulfide:quinone oxidoreductase, sulfur dioxygenase to form sulfate (SO<sub>4</sub><sup>-4</sup>), and thiosulfate:CN sulfurtransferase (rhodanese) to form thiosulfate (SSO<sub>3</sub><sup>-2</sup>).<sup>18</sup> The most specific marker of H<sub>2</sub>S metabolism is thiosulfate.<sup>18,68</sup> Sulfhemoglobin is not found in significant concentrations in the blood of animals or fatally poisoned humans.<sup>91,94</sup>

TABLE 123–3 Hydrogen Sulfide Poisoning

When to Suspect Hydrogen Sulfide Poisoning	
Rapid loss of consciousness (“knocked down”) and abrupt awakening	
Rapid loss of consciousness (“knocked down”) and apnea	
Rotten egg odor	
Rescue from enclosed space, such as sewer or manure pit	
Multiple victims with sudden death	
Collapse of a previously healthy worker at work site	
Clinical Manifestations	
System	Signs and Symptoms
Cardiovascular	Chest pain, bradycardia, sudden cardiac arrest
Central nervous	Headache, weakness, syncope, convulsions, rapid onset of coma (“knockdown”)
Gastrointestinal	Nausea, vomiting
Ophthalmic	Conjunctivitis
Pulmonary	Dyspnea, cyanosis, crackles, apnea
Metabolic	Metabolic acidosis, elevated serum lactate

### Clinical Manifestations

#### Acute Manifestations

Hydrogen sulfide poisoning should be suspected whenever a person is found unconscious in an enclosed space, especially if the odor of rotten eggs is noted. The primary target organs of hydrogen sulfide poisoning are those of the CNS, cardiac system, and respiratory system. The clinical findings reported in two large series are listed in Table 123–3.<sup>5,24</sup>

Hydrogen sulfide poisoning has a distinct dose response, and the intensity of exposure likely accounts for the diverse clinical findings in the reports. The odor threshold is between 0.01 and 0.3 ppm, and a strong intense odor is noted at 20 to 30 ppm. Mucous membrane and eye irritation occurs at 20 to 100 ppm. Olfactory nerve paralysis occurs at 100 to 150 ppm rapidly extinguishing the ability to perceive the gas odor at higher concentrations. Prolonged exposure occurs when the extinction of odor recognition is misinterpreted as dissipation of the gas. Strong irritation of the upper respiratory tract and eyes and acute respiratory distress syndrome (ARDS) occur at 150 to 300 ppm. At greater than 500 ppm, H<sub>2</sub>S produces systemic effects, including rapid unconsciousness (“knockdown”) and cardiopulmonary arrest. At 1,000 ppm, breathing ceases after one to two breaths.<sup>13,47,99</sup>

Hydrogen sulfide reacts with the moisture on the surface of mucous membranes to produce intense irritation and corrosive injury. Mucous membrane irritation of the eye produces keratoconjunctivitis. If exposure persists, damage to the epithelial cells produces reversible corneal ulcerations (“gas eye”) and, rarely, irreversible corneal scarring.<sup>76,113</sup> The irritant effects on the respiratory tract include rhinitis, bronchitis, and ARDS.<sup>5,24,119</sup>

Neurologic manifestations are common and often are severe. The rapid and deadly onset of clinical effects of H<sub>2</sub>S are termed the “slaughterhouse sledgehammer” effect. In one case series, 75% of 221 patients with acute H<sub>2</sub>S exposure lost consciousness at the time of exposure.<sup>24</sup> If a victim is rapidly removed from the exposure, recovery is often prompt and complete. Because unresponsiveness is rapid, trauma from falls should not be overlooked.<sup>5,41</sup> In a report, 7% of patients experiencing a “knockdown” had associated traumatic injuries.<sup>5</sup>

Hypoxia from respiratory compromise contributes secondarily to neurologic effects.<sup>13,28,47,119</sup> Neurologic outcome is quite variable, ranging from no neurologic impairment to permanent sequelae. Delayed neuropsychiatric sequelae are reported after acute exposures.<sup>87</sup> Most evidence suggests that the early rapid CNS effects are direct neurotoxic effects of H<sub>2</sub>S, but the permanent neurologic sequelae result from hypoxia secondary to respiratory insufficiency.<sup>13,119</sup> Reported neuropsychiatric changes include memory

failure (amnesic syndrome), lack of insight, disorientation, delirium, and dementia.<sup>119</sup> Neurosensory abnormalities include transient hearing impairment, vision loss, and anosmia. Motor symptoms are likely caused by injury to the basal ganglia and result in ataxia, position or intention tremor, and muscle rigidity.<sup>111</sup> Common neuropathologic findings observed on neuroimaging and at autopsy are subcortical white matter demyelination and globus pallidus degeneration.<sup>87</sup>

Animal studies report depressed cardiac contractility producing cardiogenic shock after H<sub>2</sub>S exposures.<sup>52,104</sup> Myocardial hypoxia or direct toxic effects of H<sub>2</sub>S on cardiac tissue causes cardiac dysrhythmias, myocardial ischemia, or myocardial infarction.<sup>46</sup>

### Chronic Manifestations

Most data about chronic low-level exposures to H<sub>2</sub>S come from oil and gas industry workers and sewer workers. Mucous membrane irritation seems to be the most prominent problem in patients with low concentration exposures. Workers report nasal, pharyngeal, and eye irritation; fatigue; headache; dizziness; and poor memory with low-concentration, chronic exposures. The chronic irritating effects of H<sub>2</sub>S is proposed to be the cause of reduced lung volumes observed in sewer workers.<sup>101</sup> Volunteer studies have not demonstrated significant cardiovascular effects after long-term exposure to concentrations less than 10 ppm.<sup>19</sup> The liver, kidneys, and endocrine system are unaffected. No studies demonstrate increased incidences of cancer with low-level exposures.<sup>28</sup>

Rapid loss of consciousness from H<sub>2</sub>S exposure was a well-known and, amazingly, accepted part of the workplace in the gas and oil industry for many years.<sup>57</sup> Some workers experienced repeated “knockdowns,” and these workers reported an increased incidence of respiratory diseases and cognitive deficits. Single or repeated high-concentration exposures resulting in unconsciousness cause serious cognitive dysfunction. As noted above, the acute effects of rapid loss of consciousness are most likely caused by H<sub>2</sub>S neurotoxicity. Although a clear association exists between knockdown and chronic neurologic sequelae, many of the case reports are complicated by associated apnea or hypoxemia from respiratory failure, asphyxia or exposure to other xenobiotics in a confined space, head injury from a fall, or near drowning in liquid manure or sludge.<sup>119</sup> The association of neurotoxic sequelae are less clear with prolonged low-concentration exposures. Case series suggest that low-concentration exposures cause subtle changes that are only measured by the most sensitive neuropsychiatric tests.<sup>73</sup>

Most effects reported to be associated with long-term exposures are nonspecific, and many of the cases have a poorly documented exposure assessment. Epidemiologic data regarding the effects of low-concentration environmental exposures to H<sub>2</sub>S are clouded in populations exposed to complex mixtures of pollutants. Other malodorous sulfur compounds (eg, methyl mercaptan and methyl sulfide) are generated as byproducts of pulp mills. Currently, the association of protracted and low-concentration H<sub>2</sub>S exposure with chronic neurologic sequelae remains controversial and needs further study.<sup>47,48,119</sup>

The strong odor of low concentrations of H<sub>2</sub>S can magnify irritant effects by triggering a strong psychological response.<sup>119</sup> The odor of H<sub>2</sub>S at low concentrations has been the alleged source of mass psychogenic illness cases<sup>42</sup> (Chap. 133). Clinical, epidemiologic, and toxicologic analyses suggested that 943 cases of illness in Jerusalem were caused by the odor of low concentrations of H<sub>2</sub>S gas. Symptoms frequently associated with psychogenic illness include headaches; faintness; dizziness; nausea; chest tightness; dyspnea and tachypnea; eye, nose, and throat irritation; weakness; and extremity numbness.<sup>64</sup> Low concentration exposure to H<sub>2</sub>S produces nonspecific signs and symptoms that could closely mimic psychogenic illness. Attempting to identify true toxicity from a powerful emotional reaction is extremely difficult.<sup>42</sup> Therefore, symptomatic patients must be assessed for toxicity even when mass psychogenic illness is suspected.

### Diagnostic Testing

Only a few inhalation risks are similar to H<sub>2</sub>S in their ability to rapidly “knock down” victims. Some examples include low-oxygen environments

in an enclosed space, HCN, volatile nerve agents, and CO. In H<sub>2</sub>S poisoning, diagnostic testing is of limited value for clinical decision making after acute exposures, confirmation of acute exposures, occupational monitoring, and forensic analysis after fatal accidents. The etiology is often unclear early in the patient’s emergency care and require clinicians to make treatment decisions without confirmatory evidence of poisoning.

Clinicians must base management decisions on history, clinical presentation, and diagnostic tests that infer the presence of H<sub>2</sub>S because no method is available to rapidly and directly measure the gas or its metabolites. Circumstances surrounding the patient’s illness often provide the best evidence for H<sub>2</sub>S poisoning (Table 123–3). At the bedside, the smell of rotten eggs on clothing or emanating from the blood, exhaled air, or gastric secretions suggests H<sub>2</sub>S exposure. In addition, darkening of silver jewelry is a clue to exposure. Paper impregnated with lead acetate changes color when exposed to H<sub>2</sub>S and is used to detect its presence in the patient’s exhaled breath but is not rapidly available.<sup>28</sup>

Specific tests for confirming H<sub>2</sub>S exposure are not readily available in clinical laboratories. Therefore, directly measuring the gas in atmospheric air samples by monitoring devices provides stronger evidence of H<sub>2</sub>S as the causative substance. Epidemiologic data show H<sub>2</sub>S, along with CO and nitrogen (a simple asphyxiant) and oxygen-deficient environments, as some of the most common causes of death and injury from toxic inhalation in confined spaces, especially manholes and sewers.<sup>33</sup> Recognizing confined spaces as extremely hazardous environments, OSHA published the Confined Space Entry Standard to protect workers. It mandates training, rescue procedures, and atmospheric testing before entry, including measuring for the presence of H<sub>2</sub>S. Because of OSHA’s regulations, most emergency response teams are equipped to investigate toxic environments from hazardous materials incidents using a “four-gas detection unit” that measures H<sub>2</sub>S by electrochemical sensors along with measurements for atmospheric oxygen concentration and the presence of explosive gases and CO.<sup>112</sup> In general, the clinician must interpret environmental detection results with caution. Negative results are misleading if toxic gases dissipate before atmospheric air sample collection. False-positive readings occur on field detection devices from interfering gases.<sup>55</sup> Therefore, a positive reading on these devices does not equate to confirmation of that specific gas. Clinical decision making should consider correlation with other circumstantial and clinical data and not rely solely on detection results.

In acute poisoning, readily available diagnostic tests that are biomarkers of H<sub>2</sub>S poisoning are useful but are nonspecific. Arterial blood gas analysis demonstrating acidemia with an associated elevated serum lactate concentration is expected, and oxygen saturation should be normal unless ARDS is present. Hydrogen sulfide H<sub>2</sub>S, like CN, decreases oxygen consumption and is reflected as an elevated mixed venous oxygen measurement. Because sulfhemoglobin (Chap. 124) typically is not generated in patients with H<sub>2</sub>S poisoning, an oxygen saturation gap is not expected.<sup>91,94</sup>

Diagnostic testing for neurologic structure and function show abnormalities for weeks or months in many patients after serious injury from H<sub>2</sub>S. Brain MRI and head CT studies demonstrate structural changes, such as globus pallidus degeneration and subcortical white matter demyelination. Neuropsychological testing demonstrates specific abnormalities in cortical functions, such as concentration, attention, verbal abstraction, and short-term retention. Single-photon emission computed tomography (SPECT)/PET brain scans define neurotoxin-induced lesions that correlate well with clinical neuropsychological testing.<sup>25</sup>

No clinically available biological markers or direct measurements of H<sub>2</sub>S and its metabolites exist; therefore, confirming poisoning is challenging for clinicians, researchers, and forensic specialists.<sup>91</sup> Whole-blood sulfide concentrations greater than 0.05 mg/L are considered abnormal. Reliable measurements are ensured only if the concentration is obtained within 2 hours after the exposure and analyzed immediately.<sup>99</sup>

In acute exposures, blood and urine thiosulfate concentrations reflect exposure.<sup>68</sup> Urinary thiosulfate excretion is used to monitor chronic low-concentration exposure in the workplace. However, one study could not demonstrate a correlation between the degree of exposure and change in

urine thiosulfate from baseline measurements.<sup>35</sup> Another study analyzed the value of blood and urine thiosulfate from data collected in a case series of fatal and nonfatal H<sub>2</sub>S victims.<sup>65,67</sup> Because thiosulfate was detected in the urine but sulfide and thiosulfate were not detected in the blood of nonfatal exposures, this report concluded that thiosulfate in urine is the only indicator to prove H<sub>2</sub>S poisoning in nonfatal cases.

Sulfide concentrations obtained in postmortem investigations are useful but require rapid sample collection because sulfide concentrations rise with tissue decomposition.<sup>99</sup> In the forensic literature, the detection of elevated thiosulfate concentrations is considered a reliable indicator of H<sub>2</sub>S poisoning.<sup>68,77</sup> If death is rapid, urinary thiosulfate concentrations are often not detectable despite blood sulfide and thiosulfate concentrations 10-fold or greater than normal concentrations.<sup>66</sup> At autopsy, a greenish discoloration of the gray matter, viscera, and bronchial secretions is reported.<sup>66,89</sup>

## Management

Clinicians faced with victims of “knockdown” syndrome should search for clues, such as victims’ activities (eg, working at a manure pit), reports of chemicals detected at the scene by first responders, or suggestive clinical signs. The critical decision is whether to administer specific antidotes empirically. The basic aims are to gather as many facts and suggestive clues as possible, weigh the risk benefits for treatment or not, and treat early in the course, all this while meticulous attention to optimal supportive care is required.

The initial treatment (Table 123–4) is immediate removal of the victim from the contaminated area into a fresh air environment. High-flow oxygen should be administered as soon as possible. Optimal supportive care has the greatest influence on the patient’s outcome. Because death from inhalation of H<sub>2</sub>S is rapid a limited number of patients reaching the hospital for treatment are reported in the literature. Most patients experience significant delays before receiving treatment. Therefore, specific treatments and antidotal therapies do not show definitive improvement in patient outcome.

The proposed toxic mechanisms, animal studies, and human case reports suggest that oxygen therapy is beneficial for H<sub>2</sub>S poisoning.<sup>28,97,119</sup>

**TABLE 123–4 Hydrogen Sulfide Poisoning: Emergency Management**

### Supportive care

#### Prehospital

- Attempt rescue only if using appropriate respiratory protection
- Move victim to fresh air
- Administer 100% oxygen
- During extrication, evaluate for traumatic injuries from falls
- Apply ACLS protocols as indicated

#### Emergency department

- Maximize ventilation and oxygenation
- Utilize PEEP or BiPAP for ARDS
- Administer sodium bicarbonate; titrate according to ABG and serum [HCO<sub>3</sub><sup>-</sup>]
- Administer crystalloid and vasopressors for hypotension

### Antidote

- 1) It is reasonable to administer sodium nitrite (3% NaNO<sub>2</sub>) IV over 2–4 min
  - Adult dose: 10 mL (300 mg)
  - Pediatric dose: Table 123–2; if hemoglobin unknown, presume 7 g/dL for dosing

#### Caution:

- Monitor blood pressure frequently
- Obtain methemoglobin level 30 min after dose

#### OR

- 2) It is reasonable to administer hydroxocobalamin
  - Initial adult dose: 5 g IV over 15 min; pediatric dose 70 mg/kg up to 5 g

Proposed mechanisms for the beneficial effects of oxygen are competitive reactivation of oxidative phosphorylation by inhibiting H<sub>2</sub>S–cytochrome binding, enhanced detoxification by catalyzing oxidation of sulfides and sulfur, and improved oxygenation in the presence of ARDS. Studies demonstrate the binding of H<sub>2</sub>S to cytochrome oxidase is readily reversible in the presence of oxygen, and an inverse relationship exists between tissue concentrations of H<sub>2</sub>S and oxygen.<sup>29,91</sup> Increased oxygen concentrations enhance the consumption of H<sub>2</sub>S through metabolic pathways, while oxygen deprivation results in the accumulation of H<sub>2</sub>S in tissue. All patients suspected of H<sub>2</sub>S poisoning should receive supplemental oxygen. In case reports, poisoned patients receiving HBO had favorable clinical outcomes.<sup>6</sup> However, no clinical data are available to suggest HBO is superior to normobaric oxygen for acute poisoning or preventing delayed neurologic sequelae. Unless immediately available, the therapeutic priority is meticulous supportive care with high-flow oxygen therapy over transport to a HBO capable facility.

Recognizing similar toxic mechanisms between H<sub>2</sub>S and CN, the majority of research focuses on antidotes with high binding affinity to metallocompounds, including methemoglobin inducers (ferric iron) and cobalt-containing compounds. Nitrite-induced methemoglobin protects animals from toxicity of H<sub>2</sub>S poisoning in both pre- and postexposure treatment models. Nitrite-generated methemoglobin acts as a scavenger of sulfide. The affinity of H<sub>2</sub>S for methemoglobin is greater than that for cytochrome oxidase. When H<sub>2</sub>S binds to methemoglobin, it forms sulfmethemoglobin.<sup>17</sup> Because H<sub>2</sub>S poisoning is rare, no studies have evaluated the clinical outcomes of patients treated with sodium nitrite. Animal studies suggest that nitrite must be given within minutes of exposure to ensure effectiveness. However, several human case reports showed rapid return of normal sensorium when nitrites were administered soon after exposure.<sup>59,93,107</sup> Sodium nitrite treatment is reasonable to administer to patients with suspected H<sub>2</sub>S poisoning who have altered mental status, coma, hypotension, or dysrhythmias but should be given cautiously because of the potential for nitrite-induced hypotension during the infusion. Sodium thiosulfate is of no benefit in the treatment of H<sub>2</sub>S. Cobalt compounds, actively pursued as effective CN antidotes, have in vitro and in vivo benefits. Improved outcomes, including restoring depressed cardiac contractility, preventing pulseless electrical activity, and increasing survival, are demonstrated in animals administered hydroxocobalamin.<sup>52,109</sup> Cobinamide, a vitamin B<sub>12</sub> analog, is actively being investigated for CN poisoning and showing promise as a novel therapy for H<sub>2</sub>S.<sup>22,62</sup> Studies in rats and sheep suggest beneficial effects of methylene blue administered soon after H<sub>2</sub>S poisoning.<sup>53</sup> Methylene blue administration rapidly restored impaired cardiac contractility and improved neurologic outcomes. The proposed mechanisms for the observed increase in survival of the treated groups included reducing properties, modulating calcium channels, antioxidant effects reducing ROS, and anti-NO effects. Only animal data and case reports are available to guide the use of any of these proposed antidotes.

Treatment of patients with H<sub>2</sub>S poisoning requires optimal supportive care. Beyond supportive care, no definitive evidence of significant clinical benefit exists in humans, and additional research is needed to determine efficacy of specific treatments for H<sub>2</sub>S poisoning. Because H<sub>2</sub>S toxicity is severe and research studies suggest potential benefits of nitrite or hydroxocobalamin therapy, it is reasonable to administer either sodium nitrite or hydroxocobalamin for seriously ill patients exposed to H<sub>2</sub>S. If administered, the best available evidence suggests these therapies should be initiated rapidly to be of any appreciable benefit and only after ensuring optimum supportive care.

## SUMMARY

- Both CN and H<sub>2</sub>S exposures are high-risk xenobiotics.
- There are particular metabolic risks and concerns with regard to exposure to both xenobiotics because they bind specifically to the ferric moiety of the cytochrome a<sub>3</sub> oxidase complex.
- Odor recognition is unreliable and is not a definitive approach to diagnosis.

ACLS = advanced cardiac life support; ABG = arterial blood gas; ARDS = acute respiratory distress syndrome; Hb = hemoglobin; IV = intravenous; PEEP = positive end-expiratory pressure.

- The laboratory evaluation usually is not timely for diagnostic purposes.
- Decontamination, removal from the site of exposure, and oxygen are essential with essential personal protection for responders.
- Hydroxocobalamin is the preferred antidote although sodium nitrite is reasonable in the absence of COHb elevation.

## HYDROXOCOBALAMIN

Mary Ann Howland

## INTRODUCTION

Cyanocobalamin, vitamin B<sub>12</sub>, is formed when hydroxocobalamin combines with cyanide (CN), quickly dropping CN concentrations and improving hemodynamics. Nitrites and sodium thiosulfate were traditionally used to treat patients with CN toxicity. Nitrites have the disadvantage of purposefully inducing methemoglobin, which is dangerous in a patient with coexistent elevated carboxyhemoglobin (COHb) concentrations, such as in fire victims suspected of having CN toxicity. Based on the mechanism of action of sodium thiosulfate, particularly when used alone, sodium thiosulfate is less effective and works less rapidly than hydroxocobalamin. A study in swine did not show a benefit to sodium thiosulfate as sole therapy or show an added benefit to hydroxocobalamin in a model of intravenous (IV) CN toxicity.<sup>7</sup> Separately, hydroxocobalamin is under investigation for the treatment of hemorrhagic shock.<sup>8,9,12</sup>

## HISTORY

The antidotal actions of cobalt as a chelator of CN were recognized as early as 1894.<sup>22,61</sup> Hydroxocobalamin was used as a CN antidote in France for many years, first as a sole agent and then in combination with sodium thiosulfate.<sup>33</sup> Hydroxocobalamin was approved for use in the United States by the Food and Drug Administration (FDA) in December 2006 and is available under the trade name Cyanokit.<sup>21,23</sup>

## PHARMACOLOGY

## Chemistry

The hydroxocobalamin molecule shares structural similarity with porphyrin, with a cobalt ion at its core. The difference between cyanocobalamin (vitamin B<sub>12</sub>) and hydroxocobalamin (vitamin B<sub>12a</sub>) is the replacement of the CN group with an OH group at the active site in the latter.<sup>40,48</sup>

## MECHANISM OF ACTION

In experimental models, hydroxocobalamin is successful in protecting against several minimum lethal doses of CN when an equimolar ratio of hydroxocobalamin to CN was used.<sup>1,16,46,56</sup> The cobalt ion in hydroxocobalamin combines with CN in an equimolar fashion to form nontoxic cyanocobalamin—one mole of hydroxocobalamin binds one mole of CN.<sup>45,46</sup> Thus, given the molecular weights of each, 52 g of hydroxocobalamin is needed to bind 1 g of CN.<sup>33</sup> So, a standard 5 g of hydroxocobalamin would be expected to bind 96 mg of CN. Doing a theoretical calculation and assuming a CN simian volume of distribution of 0.25 L/kg, this would mean, in an 80-kg man, 4.8 mg/L or 4.8 mcg/mL.

An ex vivo study using human skin fibroblasts demonstrated that hydroxocobalamin penetrates intracellularly to form cyanocobalamin.<sup>2</sup> In the setting of CN poisoning, hydroxocobalamin removes CN from the mitochondrial electron transport chain, allowing oxidative metabolism to proceed. Hydroxocobalamin also binds structurally similar nitric oxide (NO), a vasodilator, causing vasoconstriction both in the presence and in the absence of CN. This property contributes to its beneficial effects by increasing systolic and diastolic blood pressure and improving the hemodynamic status of CN-poisoned patients.<sup>12,16,29</sup> Other cobalt chelators, such as dicobalt ethylenediaminetetraacetic acid (EDTA), are used both experimentally and clinically in other countries, but their therapeutic index is narrow, especially in the absence of CN. Additionally, idiosyncratic adverse effects make these compounds less advantageous.<sup>45,61</sup>

## PHARMACOKINETICS AND PHARMACODYNAMICS

Under an FDA Investigational New Drug permit, the first pharmacokinetic study of IV hydroxocobalamin was performed in the United States and published in 1993.<sup>23,24</sup>

Pharmacokinetic studies must be interpreted in light of the fact that elimination of B<sub>12a</sub> from the serum compartment reflects the combination of distribution and elimination, as well as chemical conversion to B<sub>12</sub> in the presence of CN.

Adult volunteers who were heavy smokers were given 5 g of hydroxocobalamin (5%) intravenously. The first four patients received the dose undiluted over 20 minutes.<sup>24</sup> They then received 12.5 g (50 mL of 25% solution) of sodium thiosulfate intravenously infused over 20 minutes. The next 11 patients received the same dose of hydroxocobalamin but diluted with 100 mL water for injection (USP) and infused over 30 minutes. The serum and urine sampling of hydroxocobalamin differed in the two patient groups, yielding somewhat different half-lives (4 versus 1.27 hours). The  $\alpha$  distribution half-life was 0.52 hours in patients administered hydroxocobalamin alone. Peak hydroxocobalamin concentrations averaged 813 mcg/mL (604  $\mu$ mol/L), and volume of distribution ( $V_d$ ) averaged 0.38 L/kg. A mean of 62% of the hydroxocobalamin dose was recovered in the urine in 24 hours. Whole-blood CN concentrations significantly decreased in all participants after receiving hydroxocobalamin. This study was limited by the short collection time for serum hydroxocobalamin concentrations of only 6 hours, making the pharmacokinetic analysis imprecise.<sup>36,37</sup> A pharmacokinetic study in France<sup>33</sup> was conducted in adult victims of smoke inhalation given hydroxocobalamin, 5 g (5%) by IV infusion over 30 minutes, starting within 30 minutes of patient removal from the fire.<sup>36,37</sup> The  $\alpha$  distribution half-life of hydroxocobalamin was 1.86 hours, the elimination half-life of hydroxocobalamin was 26.2 hours

based on sampling up to 6 days, and the  $V_d$  was 0.45 L/kg. The peak serum cyanocobalamin concentration was 287 mcg/mL (212  $\mu$ mol/L). In the one patient who was subsequently determined not exposed to CN, the hydroxocobalamin elimination half-life was 13.6 hours, and the  $V_d$  was 0.23 L/kg. Renal clearance of hydroxocobalamin was 37% in the CN-exposed patients compared with 62% in the unexposed patient.

In another study in France in which 12 fire victims were suspected of having CN poisoning, the patients received IV hydroxocobalamin 5 g in 100 mL sterile water over 30 minutes.<sup>39</sup> Pretreatment and posttreatment CN concentrations and cyanocobalamin concentrations were analyzed. In patients with CN concentrations less than 1.04 mcg/mL (<40  $\mu$ mol/L), a linear relationship existed between the blood CN concentration and the formation of cyanocobalamin. In the three patients with blood CN concentration greater than 1.04 mcg/mL (>40  $\mu$ mol/L), the formation of cyanocobalamin reached a plateau, implying that all the hydroxocobalamin was consumed. When the patient with a blood CN concentration greater than 1.04 mcg/mL (>40  $\mu$ mol/L) received a second 5-g dose of hydroxocobalamin, the cyanocobalamin concentration subsequently rose.<sup>3,39</sup>

The protein binding and tissue distribution of CN, hydroxocobalamin, and cyanocobalamin likely are different.<sup>38</sup> In addition, hydroxocobalamin probably causes redistribution of CN from the intracellular to the intravascular space.<sup>38</sup>

**Cobinamide** is a precursor of cobalamin. Compared with hydroxocobalamin, it is capable of binding two CN molecules versus one, is about five times more water soluble, and has a higher affinity for CN, making the effective dose of cobinamide less than hydroxocobalamin. Intravenous cobinamide was effective in rescuing swine brought to apnea with IV CN and at a dose that was one fifth that of hydroxocobalamin.<sup>12a</sup> In a model of oral CN poisoning in rabbits, oral sodium bicarbonate to raise gastric pH along with either oral aquohydroxocobinamide (water and hydroxyl molecules bound to the cobalt moiety) or oral dinitrocobinamide (two nitrite groups bound to the cobalt moiety) both significantly increased survival time.<sup>18,41</sup> Dinitrocobinamide is also being investigated by the intramuscular route and shows promising results in mice and rabbits.

## ROLE IN CYANIDE TOXICITY

### Animals

The ability of hydroxocobalamin to bind CN and produce beneficial effects on mortality and hemodynamics is demonstrated in many animal species, including rabbits, swine, dogs, and baboons.<sup>34</sup> A study in swine evaluated the effect of hydroxocobalamin plus sodium thiosulfate versus sodium nitrite and sodium thiosulfate in a model using a continuous infusion of CN. There was no difference between the groups with regard to metabolic acidosis with an elevated lactate concentration at times 20 and 40 minutes, cardiac output and pulse rate at 40 minutes, or mortality rate. The mean arterial pressure was higher in the hydroxocobalamin plus sodium thiosulfate group, beginning at 5 minutes and lasting for the entire 40-minute monitoring period.<sup>13</sup> A second CN study in swine done by the same group could not show a benefit to sodium thiosulfate as sole therapy or show an added benefit of sodium thiosulfate to hydroxocobalamin.<sup>11</sup>

### Humans

Many case reports and studies in France document the efficacy of hydroxocobalamin combined with sodium thiosulfate for treatment of CN toxicity.<sup>7,17,28,32</sup> An observational case series reviewed 69 adult smoke inhalation victims suspected of CN poisoning who were treated either at the scene of the fire or in the intensive care unit (ICU).<sup>16</sup> They received a median dose of 5 g of hydroxocobalamin, up to a maximum of 15 g, infused as a 5% solution in sterile water for injection over 15 to 30 minutes. Cardiopulmonary arrest occurred in 15 patients, with a mean blood CN concentration of 123  $\mu$ mol/L (100  $\mu$ mol/L = 2.7 mcg/mL, a fatal concentration if untreated) and a mean COHb of 30%. Two of these patients survived with normal neurologic function. Of 42 patients with confirmed CN concentrations greater than 39  $\mu$ mol/L (1 mcg/mL, a potentially fatal concentration), 28 (67%) survived.

The mortality rate contribution from concomitant COHb toxicity is difficult to determine in this study. Of the 69 patients in this study, 57 also received hyperbaric oxygen, complicating the interpretation of the outcome.<sup>16</sup>

An 8-year retrospective analysis of the use of hydroxocobalamin in the prehospital setting concluded that the risk-to-benefit ratio favors its use in smoke inhalation victims suspected of CN poisoning.<sup>26</sup> Of 72 patients in whom survival status could be determined, 30 (42%) survived. Cyanide blood concentrations were not measured in these patients. Although 21 of the 38 patients found in cardiac arrest had hemodynamic improvement, survival was dismal with only 2 patients ultimately surviving. The neurologic function of those two patients was not described.

Hydroxocobalamin also prevented the rise in CN concentration after nitroprusside infusion compared with patients who only received nitroprusside.<sup>19</sup> Nitroprusside contains 5 CN molecules, which produces CN toxicity if given in too high a dose or for too long a duration. When nitroprusside is administered, the use of concomitant hydroxocobalamin prevents CN accumulation and toxicity in both animal models and in humans.<sup>17,19,62</sup> Sodium thiosulfate also prevents nitroprusside-induced CN toxicity (Antidotes in Depth: A42).

There are currently no studies comparing the nitrite plus sodium thiosulfate regimen with hydroxocobalamin in patients with CN poisoning.<sup>53</sup> There are no studies comparing hydroxocobalamin with or without sodium thiosulfate to sodium thiosulfate alone in smoke inhalation victims presumed to be CN toxic.

The kidneys, heart, and liver of a patient who was declared brain dead after third-degree burns and smoke inhalation after a fire were successfully transplanted into four patients.<sup>27</sup> The victim received 10 g of hydroxocobalamin. Whole-blood CN concentrations were later confirmed to be significantly elevated after administration of hydroxocobalamin.

## ADVERSE EFFECTS AND SAFETY ISSUES

Hydroxocobalamin has a wide therapeutic index.<sup>16,26,60</sup> Large doses were administered to animals with no adverse effects.<sup>45,51,54</sup> The LD<sub>50</sub> (median lethal dose in 50% of test subjects) in mice is 2 g/kg.

Red discoloration of mucous membranes, serum, and urine is expected and lasts from 12 hours to many days after therapy.<sup>16,21,26</sup> Patients should be warned to avoid direct sun exposure while their skin remains red for fear of a photosensitivity reaction.<sup>21</sup> Allergic reactions, including anaphylaxis and angioedema, are reported, but serious allergic reactions are rare.<sup>6,7,17,48</sup> Prior chronic exposure to hydroxocobalamin or cyanocobalamin for treatment of vitamin B<sub>12</sub> deficiency is associated rarely with development of anaphylaxis.<sup>33</sup> A study in 102 healthy volunteers demonstrated that chromaturia is universal, and as the dose increases from 2.5 to 10 g, the incidences of erythema, rash (predominantly acneiform), headache, injection site reaction, nausea, pruritus, chest discomfort, and dysphagia increase.<sup>60</sup> The dermatologic manifestations are quite variable; both immediate in onset or delayed onset with protracted courses occur. Of 102 volunteers randomized to receive hydroxocobalamin, 24 experienced a clinically significant rise in diastolic blood pressures, up to 124 mm Hg. However, only three of them also had clinically significant elevations in systolic blood pressure. These elevations in blood pressure resolved within 4 hours of the end of the infusion. Urinary oxalate crystals were reported in patients receiving hydroxocobalamin whether or not the patient was exposed to CN.<sup>21</sup>

Colorimetric assays are adversely affected because both hydroxocobalamin and cyanocobalamin have an intensely red color. Many clinical chemistry laboratory tests are artificially increased, decreased, or unpredictable.<sup>14,21,52</sup> Hematology tests including hemoglobin, mean corpuscular hemoglobin (MCH), mean corpuscular hemoglobin concentration (MCHC), and basophils are artificially increased.<sup>21</sup> Coagulation tests are unpredictable. Urinalysis tests are usually artificially increased, but pH can also be artificially low with low doses of hydroxocobalamin.<sup>21</sup> An *in vitro* study found statistically significant alterations in serum concentrations of aspartate aminotransferase (AST), total bilirubin, creatinine, magnesium, and iron after hydroxocobalamin administration.<sup>20</sup> Although an *in vitro* study demonstrated a

considerable false increase in COHb concentrations after hydroxocobalamin administration when measured by cooximetry, other authors suggest that the interference is minimal and results in slight overestimates depending on the instrument and the concentration of hydroxocobalamin.<sup>5,30,42</sup> Inconsequential increases of 1% to 5.7% in the COHb level were reported in another study.<sup>30</sup> However, more worrisome is the report of two instances where the COHb levels were falsely low by a factor of 4 to 14 times.<sup>44</sup> An *in vitro* experiment using human blood confirmed a substantial false decrease in the COHb concentration depending on the specific cooximeter.<sup>50</sup>

Because of the inaccuracies in laboratory determinations, blood should be drawn before hydroxocobalamin administration whenever possible. This is particularly important in fire victims when COHb concentrations are necessary for management decisions.

Because of the deep red color of hydroxocobalamin, hemodialysis machines often sound a false “blood leak” alarm depending on the wavelength of light that the optical emitter detects. Nephrologists should be aware of this possibility.<sup>4,21,59</sup>

## PREGNANCY AND LACTATION

Hydroxocobalamin is FDA Pregnancy Category C. Animal studies are insufficient, and there are no controlled trials in pregnant women. Hydroxocobalamin should be used in pregnant women whose CN toxicity is presumed significant. Under these circumstances, the potential benefit to the mother and fetus outweighs the potential undefined risk to the fetus.<sup>55</sup> A pregnant woman in her fourth week of gestation was inadvertently administered 5 g of hydroxocobalamin during a volunteer study. She went on to deliver a normal healthy baby at term.<sup>21</sup>

## DOSING AND ADMINISTRATION

### Cyanide Toxicity

The initial dose of hydroxocobalamin in adults is 5 g. Each vial is reconstituted with 200 mL of 0.9% sodium chloride and administered intravenously over 15 minutes. If 0.9% sodium chloride is unavailable, lactated Ringers solution or dextrose 5% in water may be used. Each vial should be inverted or rocked (not shaken) for 60 seconds before administration. The reconstituted solution should be dark red and free of particulate matter and should be used within 6 hours of reconstitution.<sup>21</sup> A second dose of 5 g should be repeated as clinically necessary and infused over 15 minutes to 2 hours depending on patient status.<sup>21</sup> Although not studied in humans, animal studies and human experiences suggest that a faster rate of administration is free of apparent adverse effects.<sup>10,13,35</sup> Based on isolated case reports and animal studies, intraosseous administration is anticipated to be of comparable efficacy to IV administration.<sup>15,25</sup> In children, a dose of 70 mg/kg of hydroxocobalamin up to the adult dose is recommended.<sup>21</sup>

Sodium thiosulfate is often administered in addition to hydroxocobalamin, but the administration of hydroxocobalamin should always take precedence. The sodium thiosulfate is considered to be additive and was used extensively in conjunction with hydroxocobalamin, but a swine model was unable to show added benefit.<sup>11,31,32,43</sup> Hydroxocobalamin and sodium thiosulfate should not be administered simultaneously through the same IV line because the sodium thiosulfate will inactivate the hydroxocobalamin.<sup>38</sup> The adult dose of sodium thiosulfate is 12.5 g (50 mL of 25% solution) and should be administered intravenously as either a bolus injection or infused over 10 to 30 minutes, depending on the severity of the situation. The dose of sodium thiosulfate in children is 1 mL/kg using a 25% solution (250 mg/kg or approximately 30–40 mL/m<sup>2</sup> of body surface area) not to exceed 50 mL (12.5 g) total dose. The dose should be repeated at half the initial dose if manifestations of CN toxicity persist or reappear.<sup>49,58</sup>

### Nitroprusside-Induced Cyanide Toxicity

Nitroprusside-induced CN toxicity should be treated like CN toxicity from any other cause: stop the nitroprusside dosage and administer hydroxocobalamin according to the doses and precautions listed. The dose of hydroxocobalamin to prevent CN toxicity from the IV infusion of

nitroprusside is not precisely known, but a dose of hydroxocobalamin of 25 mg/h concurrent with nitroprusside administration was sufficient in one study to decrease the red blood cell and serum CN concentrations and to prevent the development of a metabolic acidosis.<sup>62</sup> We recommend continuing the hydroxocobalamin for 10 hours after the discontinuation of the nitroprusside because of a red blood cell CN half-life of 10 hours.<sup>19,62</sup> Hydroxocobalamin should also be used as rescue therapy in the typical dosage. Sodium thiosulfate is used to prevent CN toxicity when mixed with nitroprusside (Antidotes in Depth: A40).

## FORMULATION AND ACQUISITION

Cyanokit contains one 250 mL glass vial containing 5 g of lyophilized dark red hydroxocobalamin crystalline powder for injection.<sup>21</sup> The kit also contains one sterile transfer spike, one sterile IV infusion set, one quick reference guide, and one package insert but no diluent.

## SUMMARY

- Hydroxocobalamin is effective for CN toxicity generated from all routes of exposure. Intravenous hydroxocobalamin is safe in the setting of a fire when COHb is also expected to be present.
- Hydroxocobalamin affects all laboratory tests that are colorimetric, producing falsely elevated or lowered results. Of particular importance is the significantly falsely diminished assay for COHb.
- Hydroxocobalamin causes a red discoloration of the skin and mucous membranes that lasts hours to days.
- Hydroxocobalamin’s deep red color causes many hemodialysis machines to sound a false “blood leak” alarm.

# NITRITES (AMYL AND SODIUM) AND SODIUM THIOSULFATE

Mary Ann Howland

## INTRODUCTION

Sodium nitrite is an effective cyanide (CN) antidote that acts best when administered in a timely fashion and is followed by sodium thiosulfate. The utility of amyl nitrite, a volatile drug available in ampules that can be broken and administered by inhalation while sodium nitrite is being prepared to administer intravenously, is questioned.<sup>39</sup> This combination of sodium nitrite followed by sodium thiosulfate was the only antidote combination available to treat CN toxicity before the US Food and Drug Administration (FDA) approval of hydroxocobalamin in December 2006. Although there has never been a head-to-head study in humans comparing hydroxocobalamin with the combination for the treatment of CN toxicity, the advantages of hydroxocobalamin are that it works quickly and directly to inactivate CN to form cyanocobalamin. In addition, hydroxocobalamin can be administered to patients with impaired oxygen-carrying capacity from elevated concentrations of carboxyhemoglobin (COHb), methemoglobin, or sulfhemoglobin, making it the preferred CN antidote under most circumstances.

## HISTORY

In 1895, Lang reported the efficacy of sodium thiosulfate in detoxifying hydrocyanic acid.<sup>36</sup> The treatment of patients with CN poisoning with methylene blue led to the understanding of the role of methemoglobin in detoxifying CN and the search for better methemoglobin inducers.<sup>22</sup> Experiments in CN-poisoned canines demonstrated the limited role of methylene blue and the efficacy of amyl nitrite, sodium nitrite, and sodium thiosulfate.<sup>12-14</sup> Amyl nitrite administered by inhalation protected canines from up to four minimum lethal doses of sodium CN (a total of 24 mg/kg subcutaneously).<sup>13</sup> In the regimen used, therapy was started within 5 to 7 minutes of exposure and was continued for several hours. The frequency of inhalation was based on clinical response. These experimental results led to the use of inhaled amyl nitrite for patients poisoned by CN. The same authors discovered that intravenous (IV) use of sodium thiosulfate alone protected against three minimum lethal doses of CN in dogs and that the combination of sodium thiosulfate with either inhaled amyl nitrite or IV sodium nitrite protected against 10 to 18 minimum lethal doses, respectively.<sup>12,14</sup>

## PHARMACOLOGY OF THE NITRITES

### Chemistry

The chemical formula for sodium nitrite is  $\text{NaNO}_2$  and for amyl nitrite is  $\text{C}_5\text{H}_{11}\text{NO}_2$ . Sodium nitrite has a molecular weight of 69 Da, and amyl nitrite has a molecular weight of 117 Da. Amyl nitrite is volatile even at low temperatures and is highly flammable.

### Mechanism of Action

Cyanide quickly and reversibly binds to the ferric iron in cytochrome oxidase, inhibiting effective energy production throughout the body. The ferric iron in methemoglobin preferentially combines with CN, producing cyanomethemoglobin. This drives the reaction toward cyanomethemoglobin and liberates CN from cytochrome oxidase. Stroma-free methemoglobin is effective against four minimum lethal doses of CN in rats.<sup>65</sup> Nitrites oxidize the iron in hemoglobin to produce methemoglobin. Because nitrites were accepted antidotes for CN poisoning, for many years, methemoglobin formation was assumed to be their sole mechanism of antidotal action.<sup>43,68</sup> Other, faster methemoglobin inducers, such as 4-dimethylaminophenol and hydroxylamine,

also are effective as CN antidotes.<sup>43,66</sup> The production of methemoglobin by nitrite is slow, but when methylene blue is administered to prevent methemoglobin formation, nitrite remains an effective antidote.<sup>43,51,68</sup> This discovery led to the hypothesis that nitrite-induced vasodilation might be part of the mechanism of action and investigators considered the antidotal actions of other vasodilators. The  $\alpha$ -adrenergic antagonists and ganglionic blockers demonstrated antidotal activity only when administered with sodium thiosulfate.<sup>68</sup> Experimental evidence in hypoxia- or hypotension-induced organ damage suggests that the benefits of nitrites are related to their conversion to nitric oxide (NO), a potent vasodilator. The conversion to NO occurs only in tissues or blood with the lowest oxygen concentrations.<sup>3,17,48,57</sup> Thus, the major mechanism of action of the nitrites is in their ability to produce large exogenous concentrations of NO, which is proposed to displace CN and compete with CN for binding to cytochrome c oxidase.<sup>10,40,55</sup> Pretreatment with a NO scavenger negated the effects of the nitrite.<sup>41,56</sup> Adding support to this theory is a CN poisoned rabbit model in which IV isosorbide dinitrate was comparable to IV sodium nitrite in short-term survival,<sup>38</sup> clinical scores, blood lactate concentrations, and vital signs without changing methemoglobin concentrations (peak methemoglobin of 7.9% with sodium nitrite).<sup>37</sup> When the cytochrome c oxidase is free of CN, the CN can be detoxified by binding to methemoglobin or to thiosulfate.<sup>11</sup>

## PHARMACOLOGY OF SODIUM THIOSULFATE

### Chemistry

The chemical formula of sodium thiosulfate is  $\text{Na}_2\text{S}_2\text{O}_3$ , and the molecular weight is 248 Da. It forms a pentahydrate that is highly water soluble.

### Mechanism of Action

The sulfur atom provided by sodium thiosulfate binds to CN with the help of rhodanese (CN sulfurtransferase) and mercaptopyruvate sulfurtransferase.<sup>14,68,70</sup> Sulfane sulfur (a divalent sulfur bound to one other sulfur) is the only sulfur compound that reacts with CN to produce thiocyanate, which is minimally toxic and renally eliminated. The cationic site on rhodanese is essential to cleaving the sulfur-sulfur bond of thiosulfate and forming a sulfur-rhodanese complex that readily reacts with CN.<sup>69</sup> In animal models in multiple species, sodium thiosulfate protects against several minimum lethal doses of CN.<sup>32,43</sup> The addition of rhodanese increases the efficacy of sodium thiosulfate, but the use of rhodanese is impractical in the clinical setting.<sup>43,70</sup> Rhodanese is probably not solely responsible for sulfur-sulfur bond cleavage because rhodanese is largely a mitochondrial enzyme found in the liver and skeletal muscle. Sodium thiosulfate is a divalent ion that poorly crosses membranes.<sup>19,43,46,68,69</sup> It is also suggested that both mercaptopyruvate sulfurtransferase and rhodanese are involved in the formation of sulfane sulfur in the liver from sodium thiosulfate and that serum albumin then carries the sulfane sulfur from the liver to other organs. When CN is present, albumin delivers this sulfur to CN, forming thiocyanate.<sup>33,68,70</sup>

Thiocyanate is much less toxic than CN and is renally eliminated. Although the production of methemoglobin is therapeutic in CN poisoning, it is also potentially life threatening if nitrites are administered to a patient with impaired oxygen-carrying capacity from elevated concentrations of COHb, methemoglobin, or sulfhemoglobin. Because sodium thiosulfate does not compromise hemoglobin oxygen saturation, it should be used without nitrites in circumstances when the formation of methemoglobin would be

detrimental, as in patients who have elevated levels of COHb or preexistent methemoglobinemia from smoke inhalation, drug exposure, or congenital dysmethemoglobinemias, and when hydroxocobalamin is unavailable. Based on the mechanism of action of sodium thiosulfate, particularly when used alone, it is unlikely to be as effective or work as rapidly as hydroxocobalamin.

Sodium thiosulfate is used prophylactically with nitroprusside (which contains 5 CN ions) to prevent CN toxicity. Sodium thiosulfate is also used to treat calcific uremic arteriopathy (calciophylaxis), theoretically by increasing the solubility of calcium deposits, inducing vasodilation, and acting as a free radical scavenger.<sup>9,45,53,61</sup>

## PHARMACOKINETICS AND PHARMACODYNAMICS OF NITRITES

The pharmacokinetics of sodium nitrite are not established. Most studies were directed at measuring methemoglobin levels rather than nitrite concentrations.<sup>66</sup> In one study, 300 mg of IV sodium nitrite produced peak methemoglobin levels of 10% to 18% in healthy adults and values of 7% when 4 mg/kg was administered.<sup>12,51</sup> Inhalation of crushed amyl nitrite ampules in human volunteers produced insignificant amounts of methemoglobin and caused headache, fatigue, dizziness, and hypotension.<sup>35</sup>

Sodium nitrite administered intramuscularly to dogs was not effective as a CN antidote unless atropine was given as pretreatment.<sup>67</sup> Most likely the rapid reversal of CN-induced bradycardia by atropine facilitated absorption of sodium nitrite, which then was effective.<sup>66,67</sup>

The package insert states that approximately 40% of sodium nitrite is renally eliminated unchanged, and the remainder is metabolized to ammonia and other related molecules.<sup>51</sup>

## PHARMACOKINETICS AND PHARMACODYNAMICS OF SODIUM THIOSULFATE

### Animal Studies

Sodium thiosulfate is a large divalent anion. Canine studies suggest that sodium thiosulfate rapidly distributes into the extracellular space and then slowly into the cell, perhaps with a carrier facilitating entry into the mitochondria.<sup>30,46</sup> When administered before CN, thiosulfate converted more than 50% of the CN to thiocyanate within 3 minutes and increased the endogenous conversion rate more than 30 times.<sup>64</sup> A canine model using continuous IV infusion of CN to induce a respiratory arrest, demonstrated that the IV administration of 500 mg/kg of sodium thiosulfate decreased the serum CN concentration and restored respirations within 3 minutes.<sup>16</sup> Thiosulfate is filtered and secreted in the kidneys. At low serum concentrations, thiosulfate is subsequently reabsorbed, but at high serum concentrations, filtration and secretion predominate.<sup>21,46</sup>

### Human Studies

A volunteer study examined the pharmacokinetics of sodium thiosulfate.<sup>32,46</sup> After injection of 150 mg/kg, the volume of distribution ( $V_d$ ) was 0.15 L/kg, the distribution half-life was 23 minutes, and the elimination half-life was 3 hours. The peak serum thiosulfate concentration rose 100-fold. Approximately 50% of the drug was eliminated in 18 hours, most of that within the first 3 hours, unchanged in the urine. Baseline thiosulfate concentrations were higher in starved patients and children, presumably because of their higher protein metabolism to thiosulfate.<sup>32</sup>

A study of thiosulfate as a cisplatin neutralizer demonstrated a half-life of 80 minutes and that renal clearance accounted for about 30% of the total clearance.<sup>28,60</sup> Oral sodium thiosulfate is poorly absorbed and acts as a laxative.<sup>46</sup>

A pharmacokinetic study was performed in healthy volunteers as well as hemodialysis (HD) patients both on and off HD.<sup>20</sup> Eight grams of sodium thiosulfate was diluted in 50 mL of 0.9% NaCl and infused over 8 minutes. The use of a population pharmacokinetic model revealed a small  $V_d$  (0.226 L/kg), a nonrenal clearance similar to the renal clearance accounting for about 50% of the elimination in both healthy volunteers and HD patients. Total body clearance in the HD patients undergoing HD was double that of the same patients not receiving HD. A one-compartment distribution model was

assumed because of the absence of rebound concentrations after HD ended. Oral bioavailability was only about 8% and was calculated after 5 g of the IV solution was diluted in 100 mL of water and ingested rapidly.

## ROLE OF NITRITES AND SODIUM THIOSULFATE IN CYANIDE TOXICITY

Maximal benefits of sodium nitrite are realized experimentally when sodium nitrite is given prophylactically, but benefits are still evident even when sodium nitrite is administered after CN poisoning. Sodium nitrite is clearly effective soon after administration, even when methemoglobin levels are low. Thus, a target methemoglobin concentration should not be used to determine the correct dose of sodium nitrite, although care must be taken to avoid excessive methemoglobinemia.<sup>34</sup> Administration of sodium nitrite should always be followed by sodium thiosulfate. Sodium thiosulfate donates a sulfur atom, which, with the help of rhodanese (CN sulfurtransferase) and mercaptopyruvate sulfurtransferase, carries sulfane sulfur to bind to CN, producing thiocyanate. Thiocyanate is a much less toxic substance than CN and is renally eliminated.<sup>13</sup>

As early as 1952, the literature reported 16 CN-poisoned patients who survived after administration of nitrites and sodium thiosulfate.<sup>12</sup> Even patients who were unconscious or apneic survived when given timely cardiopulmonary resuscitation and antidotal therapy.<sup>12</sup> Case reports attest to the ability of amyl nitrite, sodium nitrite, and sodium thiosulfate to reverse the effects of CN if they are administered in a timely fashion.<sup>15,24,71</sup> A 34-year-old man who ingested 1 g of potassium CN became comatose within 45 minutes. One hour after ingestion, he arrived in the emergency department, became apneic, and was intubated. His blood pressure was 134/84 mm Hg and pulse was 84 beats/min, and he had fixed and dilated pupils. At 1 hour, 15 minutes, he was given 300 mg of sodium nitrite intravenously over 20 minutes followed by 12.5 g of sodium thiosulfate. Seizure activity that began just before sodium nitrite infusion resolved rapidly, and by the time the sodium thiosulfate was infused, his pupils were reactive, and spontaneous respirations returned.<sup>24</sup>

In another case, a 4-year-old boy ingested 12 50-mg tablets of laetrile (amygdalin) became unresponsive and developed seizures within 90 minutes.<sup>26</sup> Upon arrival at a second hospital, the patient required intubation, had no measurable blood pressure, and had dilated minimally responsive pupils. Arterial blood gas analysis revealed pH, 6.85;  $PCO_2$ , 15 mm Hg; and  $PO_2$ , 169 mm Hg on 100% oxygen with an anion gap of 26 mEq/L. His vital signs improved with intermittent inhalation of amyl nitrite pearls. Six hours after ingestion (and 1 hour, 45 minutes after amyl nitrite administration), sodium nitrite and sodium thiosulfate obtained from another hospital were administered. Within 30 minutes of completion of 5 mL (0.33 mL/kg) 3% sodium nitrite solution by IV infusion, spontaneous respirations returned, and his blood pressure and pulse normalized. Over the next 3 hours, his mental status and acid-base status improved. Fifteen hours after ingestion, he was alert, oriented, and extubated. Elevated whole-blood CN concentrations verified the ingestion.

In the few reported cases of CN ingestion treated solely with sodium thiosulfate, the patients had favorable outcomes.<sup>46</sup> However, before sodium thiosulfate administration, we recommend the use of sodium nitrite or preferably hydroxocobalamin.

A study in swine evaluated the effect of hydroxocobalamin plus sodium thiosulfate versus sodium nitrite and sodium thiosulfate in a model using a continuous infusion of CN. There was no difference between the groups with regard to metabolic acidosis with elevated lactate concentrations at times 20 and 40 minutes, in cardiac output and pulse rate at 40 minutes, or in mortality rate. The mean arterial pressure was higher in the hydroxocobalamin plus sodium thiosulfate group, beginning at 5 minutes and lasting for the entire 40-minute monitoring period.<sup>5</sup> A second study in swine was unable to show a benefit to sodium thiosulfate as the sole therapy or to show an added benefit when combined with hydroxocobalamin after IV CN exposure.<sup>4</sup> All 12 swine in the sodium thiosulfate group died compared with only 1 of 12 in the hydroxocobalamin group.

A study using mice, rabbits, and swine demonstrated that intramuscular injection of sodium nitrite and sodium thiosulfate in doses smaller than those used previously were effective in rescuing the animals.<sup>3</sup> The authors comment that the previous dog experiments were likely ineffective because the IM doses were too big in volume, and the model of IV bolus CN with treatment begun at 2 to 3 minutes later prevented the ability to show an effect.

### ROLE OF SODIUM THIOSULFATE IN NITROPRUSSIDE-INDUCED CYANIDE TOXICITY

Canine experiments reveal that when a nitroprusside (which contains five CN ions) infusion rate is greater than 0.5 mg/kg/h, CN concentrations in the blood rises. Coadministration of sodium thiosulfate with sodium nitroprusside in a 5:1 molar ratio prevents the rise in CN concentration.<sup>29,46</sup> A 70-kg person administered 3 mcg/kg/min would receive 12.6 mg/h (0.042 mmol/h) of nitroprusside. This would require 52.4 mg (0.211 mmol) of sodium thiosulfate per hour to detoxify the CN liberated from nitroprusside. Prolonged infusion or doses in excess of the detoxifying capability of the body leads to thiocyanate or CN toxicity. Adding 0.5 g of sodium thiosulfate to each 50 mg of nitroprusside is effective in most cases.<sup>8,23,27,31,32</sup> An *in vitro* study confirms that the admixture of IV nitroprusside with sodium thiosulfate in a 1:10 ratio is chemically and physically stable at room temperature for up to 48 hours.<sup>58</sup> Although this dose of sodium thiosulfate usually is sufficient to prevent CN toxicity from nitroprusside, thiocyanate can accumulate, especially in critically ill patients and in those with kidney insufficiency.<sup>50</sup> Although thiocyanate is relatively nontoxic compared with CN, it produces dose-dependent tinnitus, miosis, hyperreflexia, and hypothyroidism, especially at serum concentrations greater than 60 mcg/mL.<sup>44</sup> Thiocyanate is hemodialyzable. Nitroprusside-induced CN toxicity should be treated by stopping the nitroprusside and administering standard doses of hydroxocobalamin with or without sodium thiosulfate.

### ROLE OF SODIUM THIOSULFATE IN CALCIFIC UREMIC ARTERIOLOPATHY (CALCIPHYLAXIS)

Calciphylaxis is a rare vascular disease associated with chronic kidney failure that is defined as calcification of the medial layer of arteries, leading to subcutaneous nodules that typically progress to necrotic skin ulcers.<sup>1,2,9,45,53,61</sup> Sodium thiosulfate in a typical dose of 5 to 25 g IV in adults during or after HD (although some patients reported in a recent case series received daily doses) is used to treat this disease.<sup>45,52</sup> Thiosulfate likely increases the water solubility of calcium, leading to enhanced excretion of calcium thiosulfate, which induces vasodilation and acts as a free radical scavenger.<sup>52,53,61</sup> In a uremic rat model, sodium thiosulfate was able to prevent vascular calcifications but also induced a metabolic acidosis and reduced bone strength.<sup>7,54</sup> A patient being treated for calcific uremic arteriopathy developed a severe anion gap metabolic acidosis after each repeated dose of sodium thiosulfate.<sup>59</sup> This was also the case in a patient with chronic kidney disease (not on HD) and calciphylaxis receiving IV 25 g daily of sodium thiosulfate. By day 6, the patient had an anion gap metabolic acidosis that went unnoticed and likely caused two episodes of life-threatening acidemia requiring cardiopulmonary resuscitation on days 8 and 11 until the sodium thiosulfate was recognized as the likely cause.<sup>42</sup>

### ADVERSE EFFECTS AND SAFETY ISSUES: SODIUM THIOSULFATE

The toxicity of sodium thiosulfate is low. The LD<sub>50</sub> (median lethal dose in 50% of test subjects) for animals is approximately 3 to 4 g/kg, with death attributed to metabolic acidosis, elevated serum sodium concentration, and decreased blood pressure and oxygenation.<sup>43</sup> Sodium thiosulfate is hyperosmolar, delivering a significant sodium load, resulting in an osmotic diuretic effect.<sup>46</sup> Administering the infusion over 10 to 30 minutes limits some of these adverse effects.<sup>46</sup> Adverse effects associated with therapeutic doses include hypotension, nausea, vomiting, and prolonged bleeding time (1 to 3 days after a single 12.5-g dose) without changes in other hematologic parameters.<sup>46,51,63</sup>

### ADVERSE EFFECTS AND SAFETY ISSUES: NITRITES

Amyl nitrite and sodium nitrite work in part by inducing methemoglobinemia, but excessive methemoglobinemia is potentially lethal. Therefore, nitrite dosages must be carefully calculated to avoid excessive methemoglobinemia, especially in cases in which other coexisting conditions, such as COHb, sulfhemoglobin, and anemia, might compromise hemoglobin oxygen saturation.<sup>25,49</sup> Children are particularly at risk for medication errors because of dosage miscalculations. A reported death from methemoglobinemia was caused by the administration of an adult dose of sodium nitrite to a 17-month-old child suspected of ingesting a toxic amount of CN.<sup>6</sup>

Nitrites are potent vasodilators, resulting in transient hypotension. Other common adverse effects include headache, tachycardia, palpitations, dysrhythmias, blurred vision, nausea, and vomiting.<sup>12,51,62</sup>

### PREGNANCY AND LACTATION: NITRITES

The nitrites are FDA Pregnancy Category C. There are no adequate studies in pregnant women, and nitrites should only be used in pregnant women when the potential benefit exceeds the potential risk.<sup>51</sup> Hydroxocobalamin would be preferable if available because sodium nitrite has caused fetal death in humans and animals.<sup>51</sup> Fetuses are particularly sensitive to methemoglobinemia with the potential for prenatal hypoxia. High concentrations of nitrites in maternal drinking water have led to teratogenicity.<sup>51</sup>

Hydroxocobalamin is also FDA Pregnancy Category C; however, even with the limited data available, it is the author's impression that it has a lesser risk than nitrite use for a pregnant woman.<sup>18</sup>

It is not known whether nitrites are excreted in breast milk, but the risk is likely to exceed the benefit and is not recommended.

### PREGNANCY AND LACTATION: SODIUM THIOSULFATE

Sodium thiosulfate is FDA Pregnancy Category C. No reports of congenital anomalies in infants born to women exposed to sodium thiosulfate during pregnancy are described.<sup>51</sup> Teratogenic effects were not observed in hamster offspring treated with doses of sodium thiosulfate comparable to those that would be used for CN toxicity. Sodium thiosulfate is recommended in pregnant women when the potential benefit outweighs any potential risk. It is not known whether sodium thiosulfate is excreted in breast milk.

### DOSING AND ADMINISTRATION OF NITRITES AND SODIUM THIOSULFATE

#### Adults

Sodium nitrite 300 mg (10 mL of 3% solution) should be administered intravenously at a rate of 2.5 to 5 mL/min. We recommend repeating sodium nitrite at half the initial dose if manifestations of CN toxicity persist or reappear.<sup>51,62</sup>

The cyanide antidote kit is no longer available. It previously contained amyl nitrite, sodium nitrite, and sodium thiosulfate. Since Nithiodote (sodium nitrite and sodium thiosulfate) took its place and no longer contains amyl nitrite, amyl nitrite is no longer recommended. In situations in which only amyl nitrite is available, one amyl nitrite ampule is broken and held in front of the patient's mouth for 15 seconds on and 15 seconds off. Inhalation of amyl nitrite should be discontinued before sodium nitrite administration. The health care provider should be extremely careful not to inhale the amyl nitrite to prevent lightheadedness and syncope.

Immediately after the completion of the sodium nitrite infusion, 50 mL of 25% solution (12.5 g) sodium thiosulfate should be infused intravenously. The same needle and vein are used, and the dose of the thiosulfate should be repeated at half the initial dose if manifestations of CN toxicity persist or reappear.<sup>62</sup>

In situations in which additional methemoglobin formation would be harmful, as in patients with carbon monoxide poisoning, it is recommended to withhold the nitrite and only administer the IV hydroxocobalamin with or without sodium thiosulfate. Hydroxocobalamin has the advantage of rapidly reversing CN toxicity and is usually considered preferable to the combination of sodium nitrite and sodium thiosulfate. The initial dose of hydroxocobalamin in adults is 5 g IV over 15 minutes with a second dose administered if

warranted.<sup>51</sup> Care must be taken not to administer the hydroxocobalamin and sodium thiosulfate through the same IV line because a physical incompatibility occurs, inactivating the hydroxocobalamin.

## Children

Intravenously infuse 0.2 mL/kg (6 to 8 mL/m<sup>2</sup> body surface area {BSA}) or 6 mg/kg of 3% sodium nitrite solution at a rate of 2.5 to 5 mL/min, not to exceed 10 mL or 300 mg.<sup>17,18</sup> Based on an in vitro calculation, this dose should be safe for a child with a hemoglobin of 7 g/dL in the absence of other factors that could compromise hemoglobin oxygen saturation, such as COHb or sulfhemoglobin.<sup>2</sup> We recommend repeating sodium nitrite at half the initial dose if manifestations of CN toxicity persist or reappear (Table 123–2).<sup>51,62</sup>

The dose of sodium thiosulfate in children is 1 mL/kg using a 25% solution (250 mg/kg or ~30–40 mL/m<sup>2</sup> of BSA) not to exceed 50 mL (12.5 g) total dose immediately after administration of sodium nitrite.<sup>51,63</sup> We recommend repeating sodium thiosulfate at half the initial dose if manifestations of CN toxicity persist or reappear. The same needle and vein should be used.

Amyl nitrite inhalation is administered in children at the same dose and with the same precautions as mentioned for adults.

In situations in which additional formation of methemoglobin would be harmful, as in patients with smoke inhalation from a fire in which unknown toxic gases exist, we recommend withholding the nitrite and administering hydroxocobalamin with or without sodium thiosulfate. In children, a dose of 70 mg/kg of hydroxocobalamin up to the adult dose is recommended.<sup>18</sup>

Care must be taken not to administer the hydroxocobalamin and sodium thiosulfate through the same IV line because physical incompatibility occurs, inactivating the hydroxocobalamin.

## FORMULATION AND ACQUISITION

Sodium nitrite is available in vials containing 300 mg in 10 mL (3% concentration) of water for injection (USP).<sup>62</sup> Sodium thiosulfate is available in 50-mL vials containing 12.5 g in water for injection (USP).<sup>63</sup> Neither vial contains additives or preservatives. In 2011, the FDA approved Nithiodote, a copackaged vial of sodium nitrite (300 mg in 10 mL water for injection) with one vial of sodium thiosulfate (12.5 g in 50 mL of water) for injection.<sup>51</sup>

## SUMMARY

- Intravenous sodium nitrite followed immediately by IV sodium thiosulfate act as CN antidotes.
- Hydroxocobalamin has the advantage of working quickly to reverse CN toxicity and to reduce blood CN concentrations regardless of how they were generated (inhalation, ingestion, or via smoke inhalation from a fire) and is usually preferred over sodium nitrite and thiosulfate.
- The production of methemoglobin by sodium nitrite is both therapeutic in CN poisoning and potentially life threatening if nitrites are administered to a patient with impaired oxygen-carrying capacity from elevated levels of COHb, sulfhemoglobin, or methemoglobin.
- In situations in which additional methemoglobin formation would be harmful, as in patients with carbon monoxide poisoning, the nitrite should be withheld, and IV hydroxocobalamin should be administered.
- Sodium thiosulfate detoxifies CN by forming thiocyanate, which is significantly less toxic than CN and is renally eliminated.
- The action of sodium thiosulfate is slower in onset than hydroxocobalamin or the nitrites.
- Prophylactic administration of sodium thiosulfate in addition to sodium nitroprusside reduces CN toxicity by converting liberated CN to thiocyanate.

## HISTORY AND EPIDEMIOLOGY

Methemoglobinemia is a disorder of the red blood cells (RBCs). Exposure to various xenobiotics can adversely affect the RBC membrane and intracellular metabolism and, interfere with hemoglobin function. Methemoglobin occurs when the iron atom in hemoglobin loses one electron to an oxidant, and the ferrous ( $\text{Fe}^{2+}$ ) or reduced state of iron is transformed into the ferric ( $\text{Fe}^{3+}$ ) or oxidized state. Although methemoglobin is always present at low concentrations in the body, methemoglobinemia is defined herein as an abnormal elevation of the methemoglobin level above 1%. The ubiquity of oxidants, both in the environment and xenobiotics prescribed in the hospital, has increased the number of cases of reported methemoglobinemia.

Methemoglobin was first described by Felix Hoppe-Seyler in 1864.<sup>42</sup> Subsequently, in 1891, a case of transient drug-induced methemoglobinemia was reported.<sup>85</sup> In the late 1930s, methemoglobinemia was recognized as a predictable adverse effect of sulfanilamide use, and methylene blue was recommended for treatment of the ensuing cyanosis.<sup>56,125</sup> Some authors even recommended concurrent use of methylene blue when sulfanilamides were used.<sup>125</sup> Methylene blue was used prophylactically during general surgery to treat an individual with congenital methemoglobinemia.<sup>7,26</sup> In 1948, an enzyme identified as coenzyme I was reported in six patients in two families who had idiopathic methemoglobinemia. The defect in coenzyme I (nicotinamide adenine dinucleotide {NADH} methemoglobin reductase) caused cyanosis in the absence of cardiopulmonary disease and responded to ascorbic acid.<sup>44</sup>

Methemoglobinemia is either hereditary or acquired. The hereditary types are rare and grouped into four types depending on their clinical manifestations. To date there are only several hundred reported cases.<sup>57,115</sup> Although the frequency with which xenobiotic-induced methemoglobinemia occurs is unknown, the American Association of Poison Control Centers' annual data over the past 5 years reports approximately 100 yearly uses of methylene blue as an antidote. These data substantially underestimate the incidence of this poisoning because poison control centers are not notified in most cases (Chap. 130).

Methemoglobinemia is relatively common and generally produces no clinical findings. Cooximetry data collected at two teaching hospitals noted a significant number of elevated methemoglobin levels.<sup>4</sup> Of a total of 5,248 cooximetry tests over 28 months on 1,267 patients, 660 tests revealed methemoglobin levels above 1.5% in 414 patients (some patients had more than one test). Thus, 12.5% of all tests and 19.1% of all patients who had cooximetry performed had an abnormal methemoglobin level. A total of 138 patients with peak methemoglobin levels greater than 2% were identified. The mean peak methemoglobin level was 8.4% (range, 2.1%–60.1%), and the patients ranged from 4 days to 86 years of age.<sup>4</sup>

Benzocaine spray accounted for the most seriously poisoned patients ( $n = 5$ ), with a mean peak methemoglobin level of 43.8% (range, 19.1%–60.1%).<sup>4</sup> Dapsone accounted for the largest number of cases ( $n = 58$ ), with a mean peak of 7.6% (range, 2.1%–34.1%). Of the patients who had elevated methemoglobin levels, 8% had symptomatic methemoglobinemia, and approximately one-third received methylene blue. One fatality and three near fatalities were directly attributed to methemoglobinemia. These data likely represent an underestimation of the true number of cases of methemoglobinemia at these institutions because cooximetry was performed only on physician orders for suspected dyshemoglobinemia, and 25% of cases with levels above 2% were found incidentally when cooximetry was performed in the catheterization laboratory to provide data on oxyhemoglobin and deoxyhemoglobin. In addition, not all patients taking dapsone were tested.<sup>4</sup> Extrapolating these

data throughout the country would suggest under reporting and substantial under recognition of this entity with its potential danger. In a 10-year review of topical anesthetic-induced methemoglobinemia, 33 cases of methemoglobinemia were identified. In approximately 95,000 cases in which anesthetics were used topically to facilitate procedures, the rate of methemoglobinemia was low at 0.035%. However, extrapolated to the number of procedures done nationally, this rate would suggest 3,000 cases per year could be expected.<sup>23</sup> These studies suggest underreporting and substantial underrecognition of this entity with its potential danger. Worth noting was that the location of the procedure was a powerful predictor of outcome. Inpatients who likely were sicker had significantly more methemoglobinemia than their outpatient counterparts.

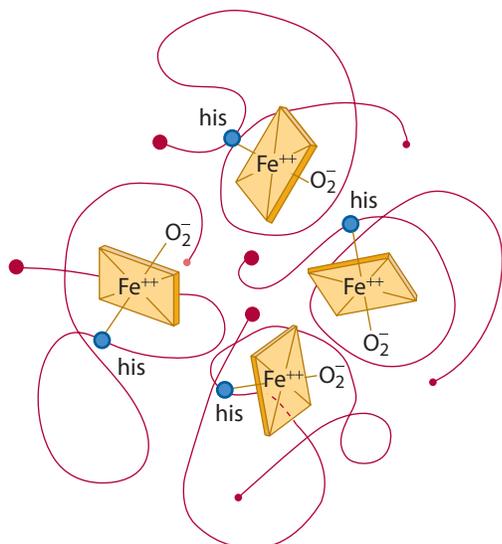

Another study screened a sample of infants younger than 3 months of age who presented to the emergency department with dehydration caused by diarrhea. A small number of patients had elevated levels of methemoglobin.<sup>37</sup> In a large study of children ( $n = 2,089$ ) between the ages of 2 and 5 years old admitted to the hospital for fever, elevated methemoglobin levels were detected in 43% of patients. Levels were assessed using a pulse oximeter calibrated to measure methemoglobin. Vomiting, poor capillary refill, metabolic acidosis with an elevated lactate concentration, severe anemia, and malaria were reported in this population. Higher levels occurred in children who died.<sup>25</sup> Furthermore, the incidence of induced methemoglobinemia in the workplace is poorly documented. A number of reports document several hundred such cases of methemoglobinemia and several more workplace exposures.<sup>15,74,100</sup> Underreporting and underrecognition occur because of the limited symptoms associated with low levels of methemoglobin in most cases. Acute pesticide poisoning leading to methemoglobinemia is common in many parts of the world. In Sri Lanka, a large, multicenter study followed 431 patients with intentional propanil (a herbicide) ingestions and found a 10.7% mortality rate in those with methemoglobinemia.<sup>104</sup> Copper sulfate is another commonly found substance used industrially and as a pesticide that causes both methemoglobinemia and hemolysis.<sup>41,88,113</sup>

Methemoglobin and nitric oxide (NO) are chemically coupled in the RBC. Nitric oxide interacts with oxyhemoglobin and methemoglobin in a complicated and not completely understood fashion. During periods of lowered oxygen delivery to the vascular beds as with acute anemia, NO concentrations fluctuate, and methemoglobin levels rise. Some authors have postulated that this could be an early biomarker of oxidant stress and a predictor of clinical outcome; others suggest that methemoglobin is a mediator of vascular tone.<sup>53,54,119,120</sup>

## HEMOGLOBIN PHYSIOLOGY

Hemoglobin consists of four polypeptide chains noncovalently attracted to each other. Each of these subunits carries one heme molecule deeply within the structure. The polypeptide chain protects the iron moiety of the heme molecule from inappropriate oxidation (Fig. 124–1).

The iron is held in position by six coordination bonds. Four of these bonds are between iron and the nitrogen atoms of the protoporphyrin ring with the fifth and sixth bond sites lying above and below the protoporphyrin plane. The fifth site is occupied by histidine of the polypeptide chain. A variety of hemoglobin mutations are attributable to changes in the amino acid sequence of the polypeptide chain, as with hemoglobin M diseases. This influences this protective “pocket,” allowing easier iron oxidation (Fig. 124–2), or hemoglobin autooxidation. The sixth coordination site is where most of the activity within hemoglobin occurs. Oxygen transport occurs here, and this site is involved with the formation of methemoglobin or carboxyhemoglobin (Fig. 124–3). It

**FIGURE 124-1.** Hemoglobin molecule symbolically represented with its heme center surrounded by the globin portion of the molecule. his = histidine.

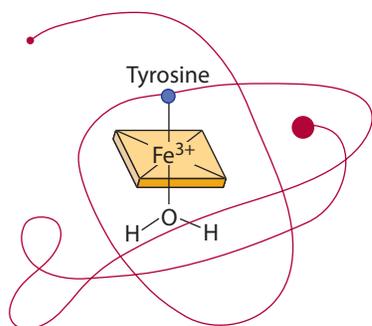

is at this site that an electron is lost to oxidant xenobiotics, transforming iron from its ferrous ( $\text{Fe}^{2+}$ ) to its ferric ( $\text{Fe}^{3+}$ ) state.

Hemoglobin transports an oxygen molecule only when its iron atom is in the reduced ferrous state ( $\text{Fe}^{2+}$ ). During oxygen transport, the iron atom actually transfers an electron to oxygen, thus transporting oxygen as the superoxide charged  $\text{Fe}^{3+}\text{O}_2^-$ . When oxygen is released, the ferrous state is restored, and hemoglobin is ready to accept yet another oxygen molecule. Interestingly, a small percentage of oxygen is released from hemoglobin with its shared electron (forming superoxide,  $\text{O}_2^-$ ), leaving iron oxidized ( $\text{Fe}^{3+}$ ). This sixth coordination site becomes occupied by a water molecule. This abnormal unloading of oxygen contributes to the steady-state level of approximately 1% methemoglobin found in normal individuals.

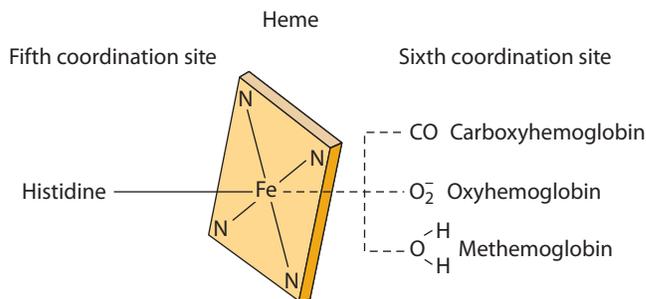

### METHEMOGLOBIN PHYSIOLOGY AND KINETICS

Because of the spontaneous and xenobiotic-induced oxidation of iron, the erythrocyte has multiple mechanisms to maintain its normal low concentration of methemoglobin.<sup>13</sup> All these systems donate an electron to the oxidized iron atom. Because of these effective reducing mechanisms, the half-life of methemoglobin acutely formed as a result of exposure to oxidants is between 1 and 3 hours.<sup>62,84</sup> With continuous exposure to the oxidant, the apparent half-life of methemoglobin is prolonged.

Quantitatively the most important reductive system requires NADH, which is generated in the Embden-Meyerhof glycolytic pathway (Fig. 124-4). Nicotinamide adenine dinucleotide serves as an electron donor, and along with the enzyme NADH methemoglobin reductase, reduces  $\text{Fe}^{3+}$  to  $\text{Fe}^{2+}$ . There are numerous cases of hereditary deficiencies of the enzyme NADH methemoglobin reductase.<sup>57</sup> Individuals who are homozygotes for this enzyme

**FIGURE 124-2.** Hemoglobin M occurs when histidine is replaced by tyrosine in the amino acid sequence of the polypeptide chain. Hemoglobin M is more easily autooxidized (as shown) to methemoglobin.

**FIGURE 124-3.** Heme molecule depicted with its bonding sites. Oxyhemoglobin, carboxyhemoglobin, and methemoglobin all involve the sixth coordination bonding site of iron.

deficiency usually have methemoglobin levels of 10% to 50% under normal conditions without any clinical or xenobiotic stressors. Individuals who are heterozygotes do not ordinarily demonstrate methemoglobinemia except when they are subject to oxidant stress. Additionally, because this enzyme system lacks full activity until approximately 4 months of age, even genetically normal infants are more susceptible than adults to oxidant stress.<sup>3,78,90,127</sup>

Oxidized iron is reduced nonenzymatically using either ascorbic acid or reduced glutathione as electron donors, but this method is slow and quantitatively less important under normal circumstances.

Within the RBC is another enzyme system for reducing oxidized iron that is dependent on the nicotinamide adenine dinucleotide phosphate (NADPH) generated in the hexose monophosphate shunt pathway (Fig. 124-4). Although it is generally accepted that this NADPH-dependent system reduces only a small percentage of methemoglobin under normal circumstances, it plays a more prominent role in maintaining oxidant balance in the cell and is involved in the mechanism of modulating vascular tone during low oxygen delivery to the capillary beds.<sup>54,73,120</sup> Patients with an isolated deficiency of NADPH methemoglobin reductase do not exhibit methemoglobinemia under normal circumstances,<sup>108</sup> perhaps because of the prominence of other cellular protective mechanisms.

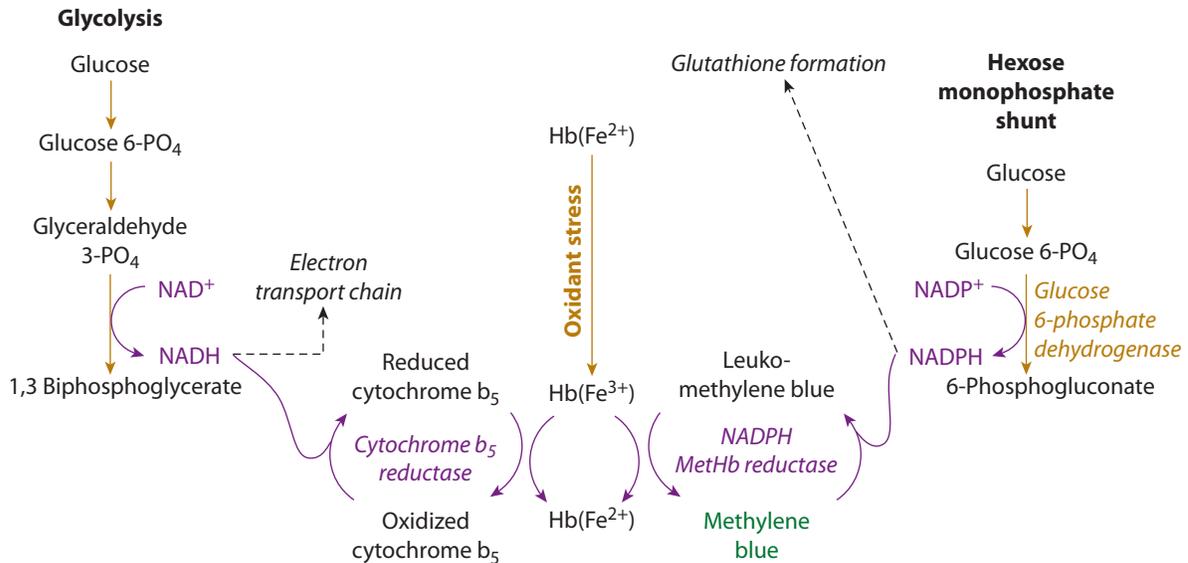

However, when the NADPH methemoglobin reductase system is provided with an exogenous electron carrier, such as methylene blue, this system is accelerated and greatly assists in the reduction of oxidized hemoglobin (Antidotes in Depth: A43).

### XENOBIOTIC-INDUCED METHEMOGLOBINEMIA

Nitrates and nitrites are powerful oxidizers that are two of the most common methemoglobin-forming compounds. Sources of nitrates and nitrites include well water, food, industrial compounds, and pharmaceuticals. Nitrogen-based fertilizers and nitrogenous waste from animal and human sources may contaminate shallow rural wells. Community-based water serves the majority of Americans; however, there are 37 million private wells in the United States. These wells are not tested regularly and some are shallower than appropriate to prevent contamination from fertilizers.<sup>5,21</sup> The contamination of drinking water occurs mainly with nitrates because nitrites are easily oxidized to the highly soluble nitrates in the environment. Furthermore, foods such as cauliflower, carrots, spinach, and broccoli have high nitrate content, as do preservatives in meat products such as hot dogs and sausage.<sup>6</sup>

The reactions of nitrates that occur both in vivo and in vitro are complex and poorly understood. Ingested nitrates are reduced to nitrites by bacteria in the gastrointestinal (GI) tract (especially in infants) and then can be absorbed, ultimately leading to methemoglobin production. However, this conversion is not essential because nitrates themselves can oxidize hemoglobin.<sup>38,55,114</sup> Some question whether well water consumption alone can cause serious methemoglobinemia in the absence of comorbid disease.<sup>34</sup>

In the past, nitrate-contaminated well water was associated with infant fatalities because of methemoglobinemia.<sup>75,83</sup> A number of reports from the midwestern United States demonstrated the problems of poorly constructed shallow wells that permit contamination by surface waters containing chemicals, pesticides, fertilizers, and microorganisms.<sup>86</sup> In several

**FIGURE 124-4.** Role of glycolysis in the Embden-Meyerhof pathway and the role of methylene blue in the reduction of methemoglobin using nicotinamide adenine dinucleotide phosphate (NADPH) generated by the hexose monophosphate shunt. Hb (Fe<sup>3+</sup>) is methemoglobin.

South Dakota studies, 20% to 50% of wells contained both coliform bacteria and water that exceeded the Environmental Protection Agency standards for permissible quantities of nitrogen as nitrates (10 ppm or 10 mg/L).<sup>65</sup> In New York, 419 wells from rural farms demonstrated elevated concentrations of nitrogen compounds, and 15.7% had well water nitrate concentrations higher than 10 mg/L.<sup>43</sup> In Texas, wells that were studied longitudinally showed increasing nitrate contamination.<sup>21</sup> Governmental programs, such as the Private Well Initiative, are aiming to improve drinking water quality throughout the country.<sup>5</sup>

Nitroglycerin (glyceryl trinitrate) and organic nitrates are more effectively absorbed through mucous membranes and intact skin than from the GI tract. Their onset of action is more rapid, and the total effect is much greater, when mucous membrane or cutaneous absorption occurs.<sup>27,62,97</sup> Aromatic amino and nitro compounds indirectly produce methemoglobin.<sup>68</sup> These xenobiotics do not form methemoglobin *in vitro*; therefore, they are assumed to do so by *in vivo* metabolic chemical conversion to some active intermediates.<sup>15,70</sup>

Elevated methemoglobin and carboxyhemoglobin levels are found in victims of fires and automobile exhaust fume poisoning.<sup>12,61,67,79</sup> Heat-induced hemoglobin denaturation in burn patients and the inhalation of oxides of nitrogen from combustion are suggested to be causative factors for methemoglobin formation.

Topical anesthetics are widely used to facilitate multiple procedures and are implicated in the most serious of toxic methemoglobin cases.<sup>1,51</sup> These xenobiotics continue to be a problem despite numerous case studies and recommendations by authors and manufacturers about safe use standards.<sup>28,48,64</sup> Cetacaine spray (14% benzocaine, 2% tetracaine, 2% butylaminobenzoate) and 20% benzocaine sprays commonly produce methemoglobinemia. The dosing recommendations are difficult to comprehend (eg, 0.5-second spray repeat once) and are often ignored. One study showed that the dose is dependent on the residual volume in the canister and the physical orientation of the canister as the spray is being applied.<sup>71</sup>

A review of 52 months of data from the US Food and Drug Administration (FDA) Adverse Event Reporting System demonstrated 132 cases of benzocaine-induced methemoglobinemia. Benzocaine spray was implicated in 107 severe adverse events and two deaths. In 123 cases, the product was a spray. In 69 cases in which the dose was specified, 37 patients received a single spray.<sup>87</sup>

This FDA effort is exclusively based on self-reporting and probably greatly underestimates the extent of the problem.<sup>49</sup> The FDA itself has estimated that approximately 10% of serious events are reported and that some studies show 1% or less serious event reporting.<sup>87</sup>

In one institution, the incidence of benzocaine-induced methemoglobinemia occurring during transesophageal echocardiograms was determined in 28,478 patients over a 90-month period. The incidence was low at 0.067% (1 case per 1,499 patients), with sepsis, anemia, and hospitalization suggested as predisposing factors.<sup>66</sup> During a 32-month period at another institution, an incidence of 0.115% (5 of 4,336) of benzocaine-induced methemoglobinemia was observed.<sup>93</sup> There were no cases of methemoglobinemia in a study of 154 patients receiving lidocaine for bronchoscopy at doses as high as 15 mg/kg. Lidocaine is a much weaker oxidant than benzocaine and is a reasonable substitute in susceptible individuals and is recommended by some authors.<sup>64</sup> In addition to mucosal applications, anesthetics applied topically to skin surfaces produce methemoglobinemia,<sup>22,117</sup> and anesthetics given during delivery to mothers receiving pudendal anesthesia have produced methemoglobinemia in newborns.<sup>121</sup>

Nitric oxide (NO) delivered by inhalation is used to treat persistent pulmonary hypertension of newborns and other cardiopulmonary diseases associated with pulmonary hypertension because it is a potent vasodilator.<sup>105</sup> Despite being a potent oxidant, if NO is used in doses of less than 40 ppm, most patients will maintain methemoglobin levels below 4%.<sup>58,124</sup> Some cases of serious toxicity occurred because of intentional and unintentional overdoses.

Dapsone is implicated as a cause of methemoglobinemia and is used in patients with leprosy and AIDS.<sup>96</sup> Cases of prolonged methemoglobinemia from dapsone ingestion are related to the long half-life of dapsone and the slow conversion to its methemoglobin-forming hydroxylamine metabolites.<sup>30,72</sup> Topical dapsone also produces significant methemoglobinemia.<sup>45,116</sup> Patients receiving dapsone should be carefully monitored for methemoglobinemia.<sup>127</sup> The bladder analgesic phenazopyridine is a commonly reported cause of methemoglobinemia.<sup>24,36,43,89</sup> For this reason, its use should be limited to short periods of time of no more than 3 days and at the lowest dose to improve symptoms. This approach is particularly pertinent in the presence of kidney failure. Predispositions for methemoglobinemia are listed in [Tables 124-1](#) and [124-2](#).

**FIGURE 124-5.** Heinz bodies are particles of denatured hemoglobin, usually attached to the inner surface of the red blood cell membrane. Xenobiotics that result in the oxidative denaturation of hemoglobin in normal (eg, phenylhydrazine) or glucose-6-phosphate dehydrogenase (G6PD) deficient (primaquine) individuals and unstable hemoglobin mutants are prone to develop these bodies. The Heinz bodies are identified when blood is mixed with a supravital stain, notably crystal violet. The Heinz bodies appear as purple inclusions. (Reproduced with permission from Lichtman MA. *Lichtman's Atlas of Hematology*, 1st ed. New York, NY: McGraw-Hill, Inc; 2007.)

or cells with depleted reduced glutathione or NADPH) are thus susceptible to hemolysis. In the presence of methemoglobinemia, reduced glutathione plays a minor role as a reducing agent, but NADPH is necessary for successful antidotal therapy with methylene blue. This codependence on the reducing power of NADPH links these two disorders. Competition for NADPH by oxidized glutathione and exogenously administered methylene blue is postulated to be the cause of methylene blue–induced hemolysis (ie, competitive inhibition of glutathione reduction). Methylene blue itself is an oxidant, but in an assessment of the hemolytic potency of varied drugs, methylene blue in doses of 390 to 780 mg proved to be only a moderate hemolytic agent.<sup>69</sup> The clinical importance of this phenomenon is uncertain. Although it is easier to consider hemolysis and methemoglobin formation as subclasses of disorders of oxidant stress, they are separate clinical entities sharing limited characteristics.

Oxidative damage to erythrocytes occurs at different locations in the two disorders. Hemolysis occurs when oxidants damage the hemoglobin chain acting directly as electron acceptors or through the formation of hydrogen peroxide or other oxidizing free radicals. This results in oxidants forming irreversible bonds with sulfhydryl group of hemoglobin cause denaturation and precipitation of the globin protein to form Heinz bodies within the erythrocyte (Fig. 124-5). Cells with large numbers of Heinz bodies are removed by the reticuloendothelial system, producing hemolysis. Alternatively, a limited number of oxidants can destroy the erythrocyte membrane directly, causing non-Heinz body hemolysis. Methemoglobinemia does not necessarily progress to hemolysis even if untreated.

Numerous cases describe the occurrence of hemolysis after methemoglobinemia. The combined occurrence is reported with dapsone,<sup>30,64</sup> phenazopyridine,<sup>24,36,46,89</sup> amyl nitrite,<sup>17</sup> copper sulfate,<sup>41</sup> and aniline.<sup>65,68</sup> These instances of combined syndromes may represent the incidental toxicity of an oxidizing agent at both locations or may represent the depletion of all cellular defenses against oxidants. Currently, it is not possible to predict when hemolysis will occur after methemoglobinemia with any degree of certainty, and markers of hemolysis should be followed.

## CLINICAL MANIFESTATIONS

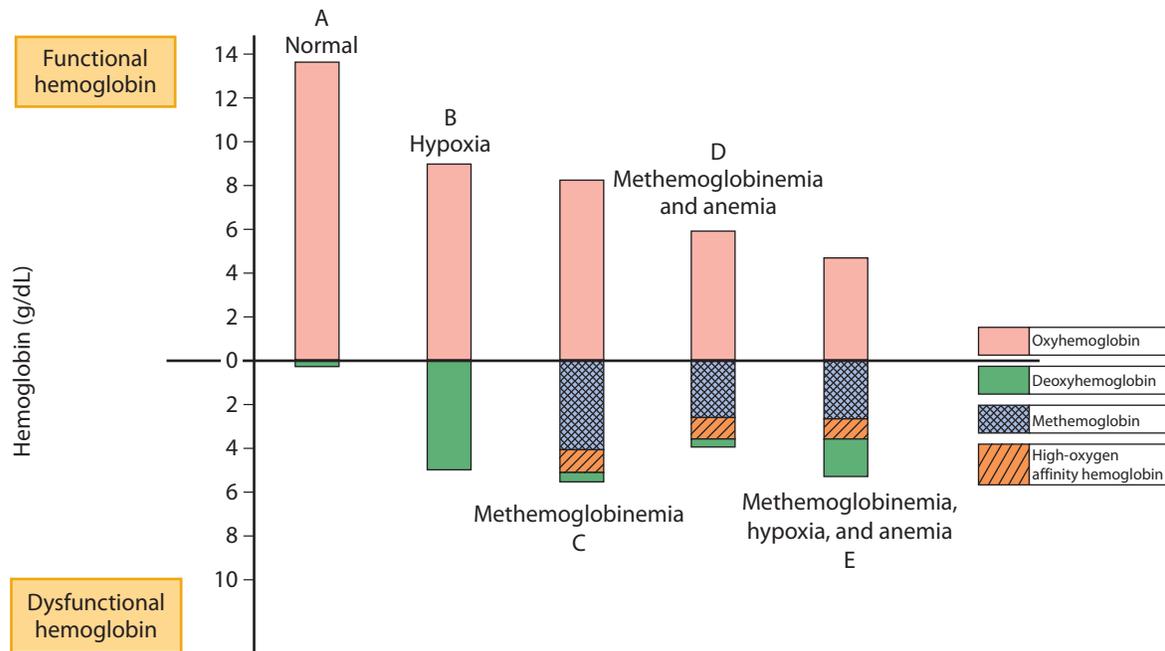

The clinical manifestations of methemoglobinemia are related to impaired oxygen-carrying capacity and delivery to the tissue. The clinical manifestations of acquired methemoglobinemia are usually more severe than those produced by a corresponding degree of anemia. This discordance occurs because methemoglobin not only decreases the available oxygen-carrying capacity but also increases the affinity of the unaltered hemoglobin for oxygen. This shifts the oxygen hemoglobin dissociation curve to the left,

Underlying illness,<sup>37,66,77,93,95</sup> the treatment with xenobiotics for these illnesses,<sup>3,18,70,78,86,94</sup> and the diagnostics and therapeutic modalities<sup>58,85</sup> in patient care all predispose patients to methemoglobinemia. For many individuals, methemoglobin is not caused by one oxidant stressor but rather by a series of stressors that makes methemoglobinemia clinically apparent and potentially predictable.

## METHEMOGLOBINEMIA AND HEMOLYSIS

The enzyme defect responsible for most instances of oxidant-induced hemolysis is glucose-6-phosphate dehydrogenase (G6PD) deficiency. Reviews of hemolysis addressed the confusion regarding the relationship between hemolysis and methemoglobinemia.<sup>10,11,40</sup>

Both hemolysis and methemoglobinemia are caused by oxidant stress, and hemolysis sometimes occurs after episodes of methemoglobinemia.<sup>11,96</sup> Certain protective mechanisms involving NADPH and reduced glutathione nonspecifically reduce the oxidant burden and prevent the development of both disorders. Another source of confusion concerning hemolysis and methemoglobinemia is that reduced glutathione is required to protect against both toxic manifestations. Erythrocytes can withstand hemolytic oxidant damage as long as they can maintain adequate concentrations of reduced glutathione, the principal cellular antioxidant. Glutathione is maintained in its reduced form by using NADPH as its reducing agent. Cells with reduced capacity to produce NADPH (ie, erythrocytes of patients with G6PD deficiency

**FIGURE 124-6.** Clinical manifestations of methemoglobinemia depend on the level of methemoglobin and on host factors such as preexisting disease, anemia, and hypoxemia. Five examples of arterial blood gases and cooximeter analyses are presented. (A) Blood gas from a normal individual with 14 g/dL of hemoglobin. Almost all hemoglobin is saturated with oxygen. (B) Blood gas from a patient with cardiopulmonary disease producing cyanosis in which only 9 g/dL of hemoglobin is capable of oxygen transport. (C) Methemoglobin level of 28% in an otherwise normal individual will reduce hemoglobin available for oxygen transport to less than 9 g/dL (~4 g/dL of methemoglobin and 1.3 g/dL of high oxygen affinity hemoglobin because of the left shift of the oxyhemoglobin dissociation curve). (D) Same degree of methemoglobin as in C but in a patient with a hemoglobin of 10 g/dL. Only 6 g/dL of hemoglobin would be capable of oxygen transport. (E) Methemoglobinemia and anemia to the same degree as D but in a patient with hypoxia.

which further impairs oxygen delivery<sup>29</sup> (Chap. 28). This effect is attributed to the formation of heme compounds intermediate between normal reduced hemoglobin (all four iron atoms are ferrous) and methemoglobin, in which one or more of the iron moieties are in the ferric state.<sup>29</sup> The degree to which this high oxygen affinity hemoglobin reduces oxygen delivery to the tissue from arterial blood is unclear but is clinically significant.<sup>19</sup>

Because the symptoms associated with methemoglobinemia are related to impaired oxygen delivery to the tissues, concurrent diseases such as anemia, congestive heart failure, chronic obstructive pulmonary disease, and pneumonia increase the clinical effects of methemoglobinemia (Fig. 124-6).<sup>31</sup> Predictions of symptoms and recommendations for therapy are based on methemoglobin level in previously healthy individuals with normal total hemoglobin concentrations.

Cyanosis is a consistent physical finding in patients with substantial methemoglobinemia and is caused by the deeply pigmented color of methemoglobin. Cyanosis typically occurs when just 1.5 g/dL of methemoglobin is present. This represents only 10% conversion of hemoglobin to methemoglobin if the baseline hemoglobin is 15 g/dL. By contrast, 5 g/dL of deoxyhemoglobin (which represents 33% of the total hemoglobin concentration) is needed to produce the same degree of cyanosis from hypoxia (Table 124-3). The cyanosis associated with methemoglobinemia is both peripheral and central. Patients often appear in less distress or less ill than patients with the same degree of cyanosis secondary to cardiopulmonary causes.

The symptoms of methemoglobinemia are determined not only by the absolute level of methemoglobin but also by its rates of formation and elimination. A level of methemoglobin that is clinically benign when caused by hereditary defects or maintained chronically likely will produce more severe signs when acutely acquired. Healthy subjects lack the compensatory mechanisms that develop over a lifetime in individuals with hereditary compromise, such as erythrocytosis and increased 2,3-bisphosphoglycerate.

## DIAGNOSTIC TESTING

For an individual in whom methemoglobinemia is suspected, a source for the oxidant stress should be sought. Arterial blood gas sampling usually reveals blood with a characteristic chocolate brown color. However, in patients who

are clinically stable and not in need of an arterial puncture, a venous blood gas will be accurate in demonstrating the methemoglobin level. The arterial  $PO_2$  should be normal, reflecting the adequacy of pulmonary function to

**TABLE 124-3** Signs and Symptoms Typically Associated with Methemoglobin Levels in Healthy Patients with Normal Hemoglobin Concentrations<sup>a</sup>

Methemoglobin Level (%)	Signs and Symptoms
1–3 (normal)	None
3–15	Possibly none Pulse oximeter reads low $SaO_2$ Slate gray cutaneous coloration
15–20	Chocolate brown blood Cyanosis
20–50	Dizziness, syncope Dyspnea Exercise intolerance Fatigue Headache Weakness
50–70	Central nervous system depression Coma Dysrhythmias Metabolic acidosis Seizures Tachypnea
> 70	Death Grave hypoxic symptoms

<sup>a</sup>Associated illness and comorbid diseases produce more severe symptoms at lower levels of methemoglobin.

deliver dissolved oxygen to the blood. However, arterial PO<sub>2</sub> does not directly measure the hemoglobin oxygen saturation (SaO<sub>2</sub>) or oxygen content of the blood. When the partial pressure of oxygen is known and oxyhemoglobin and deoxyhemoglobin are the only species of hemoglobin, oxygen saturation can be calculated accurately from the arterial blood gas. If, however, other dyshemoglobins are present, such as methemoglobin, sulfhemoglobin, or carboxyhemoglobin, then the fractional saturation of the different hemoglobin species must be determined by cooximetry in the laboratory.

The cooximeter is a spectrophotometer that identifies the absorptive characteristics of several hemoglobin species at different wavelengths. Because oxyhemoglobin, deoxyhemoglobin, methemoglobin, and carboxyhemoglobin all have different absorptions at the different measuring points of the cooximeter, their proportions and concentrations can be determined. Some newer cooximeters have an expanded spectrum and are able to measure fetal hemoglobin and sulfhemoglobin.<sup>131</sup>

The pulse oximeter applied to a patient's finger at the bedside was developed to estimate oxygen saturation trends in critically ill patients. Its uses have expanded to measuring hemoglobin, carbon monoxide, methemoglobin, pulsus paradoxus, pulse, and wave form analysis to follow volume loading response in shock states.<sup>59,110</sup> The device takes advantage of the unique absorptive characteristics of oxyhemoglobin and deoxyhemoglobin and the different concentrations of these two hemoglobin species during different phases of the pulse. Each manufacturer has calibrated its oximeter using volunteers breathing progressively increasing hypoxic gas mixtures in the absence of a dyshemoglobinemia.<sup>100,112,123</sup> In other words, the oxygen saturation values displayed on the pulse oximeter are derived independently by each manufacturer, who develops a formula using their own software, hardware and sensor. The manufacturer then compares this value with a set of validation data derived from its own experimental population.

Most pulse oximeters in use today use two different wavelengths to determine O<sub>2</sub> saturation and the manufactures do not provide validation data for situations in which any dyshemoglobin is present. All manufactures disclaim accuracy under such circumstances. Similar to cooximetry, the dual-wavelength pulse oximeter reads absorbance of light at wavelengths of 660 and 940 nm, which are selected to efficiently separate oxyhemoglobin and deoxyhemoglobin. However, methemoglobin absorption at these wavelengths is greater than that of either oxyhemoglobin or deoxyhemoglobin.<sup>8,83</sup> Therefore, when methemoglobin is present, the readings become inaccurate. The degree

of inaccuracy is unique for each brand of instrument and will be influenced by signal quality, skin temperature, refractive error induced by blood cells, and other factors (eg, finger thickness and perfusion).<sup>102</sup> Hemoglobin variants, of which thousands exist, also interfere with pulse oximetry accuracy as well.<sup>122</sup>

In the dog model, the pulse oximeter oxygen saturation (SpO<sub>2</sub>) values decrease with increasing methemoglobin levels. This decrease in SpO<sub>2</sub> is not exactly proportional to the percentage of methemoglobin. However, the pulse oximeter overestimates the level of actual oxygen saturation. For example, in a case in which the methemoglobin level measured in the blood using a cooximeter was 20%, the pulse oximeter indicated an SpO<sub>2</sub> of 90%.<sup>9,118</sup> However, as the methemoglobin concentration approached 30%, the pulse oximeter saturation values decreased to about 85% and then leveled off, regardless of how much higher the methemoglobin level became.<sup>9,118</sup>

From our experience and that of others,<sup>50,101</sup> in humans, much lower levels of oxygen saturation (SpO<sub>2</sub>) than 85% can be displayed by pulse oximetry when methemoglobin levels increase above 30%.<sup>63</sup> These differences result from variations in the way different model pulse oximeters deal with methemoglobin interference and perhaps differences between canine and human hemoglobin.<sup>100,101</sup> Therefore, health care professionals must understand how the particular pulse oximeter measures oxygen saturation when methemoglobin levels are elevated and recognize that cooximetry determination is needed when methemoglobinemia is suspected.

Although the pulse oximeter reading in patients with methemoglobinemia is not as accurate as desired, it remains helpful when it is compared with that of the arterial blood gas: if there is a difference between the *measured* oxyhemoglobin saturation of the pulse oximeter (SaO<sub>2</sub>) and the *calculated* oxyhemoglobin saturation of the arterial blood gas (SpO<sub>2</sub>), then a "saturation gap" exists. The calculated SaO<sub>2</sub> of the blood gas will be greater than the measured SpO<sub>2</sub> if methemoglobin is present (Table 124–4).

Several manufacturers developed pulse oximeters that read multiple wavelengths to identify other hemoglobin species such as methemoglobin, carboxyhemoglobin, and total hemoglobin concentration.<sup>32,33,110,130</sup> Validation studies using human volunteers with these new pulse oximeters suggest that the accuracy for detecting methemoglobin is acceptable.<sup>32,33</sup> Volunteers breathing room air given sodium nitrite at 75% of the recommended cyanide treatment dose developed methemoglobinemia that was detected by the multiwavelength device. There was a spuriously low SpO<sub>2</sub> recorded.<sup>32,33</sup> However, this is not an issue if it alerts the clinician to a potential problem. Certainly,

TABLE 124–4 Hemoglobin Oxygenation Analysis

Measuring Device	Source	What Is Measured	How Data Are Expressed	Benefits	Pitfalls	Insight
Blood gas analyzer	Blood	Partial pressure of dissolved oxygen in whole blood.	PO <sub>2</sub>	Also gives information about pH and PCO <sub>2</sub>	Calculates SaO <sub>2</sub> from the partial pressure of oxygen in blood; inaccurate if forms of Hb other than OxyHb and DeoxyHb are present	An abnormal Hb form may exist if gap exists between ABG and pulse oximeter
Cooximeter	Blood	Directly measures absorptive characteristics of oxyhemoglobin, deoxyhemoglobin, methemoglobin, and carboxyhemoglobin and in some cases other hemoglobins (fetal hemoglobin, sulfhemoglobin) at different wavelength bands in whole blood.	SaO <sub>2</sub> , %MethHb, %CoHb, %OxyHb, %DeoxyHb	Directly measures hemoglobin species	Provides data on hemoglobin only; most instruments will not measure sulfhemoglobin, HbM, and some other forms of Hb	Most accurate method of determining the oxygen content of blood
Pulse oximeter	Monitor sensor on patient	Absorptive characteristics of oxyhemoglobin in pulsatile blood assuming the presence of only OxyHb and DeoxyHb in vivo  Newer pulse oximeters measure methemoglobin.	SpO <sub>2</sub>	Moment-to-moment bedside data	Inaccurate data if interfering substances are present (methemoglobin, sulfhemoglobin, carboxyhemoglobin, methylene blue)	Maximum depression, 75%–85% regardless of how much methemoglobin is present

ABG = arterial blood gas; CoHb, carboxyhemoglobin; DeoxyHb = deoxygenated hemoglobin; Hb = hemoglobin; HbM = hemoglobin M; OxyHb = oxygenated hemoglobin; SaO<sub>2</sub> = hemoglobin oxygen saturation; SpO<sub>2</sub> = pulse oximeter oxygen saturation.

in a situation in which xenobiotics known to produce methemoglobinemia are being used such as in the endoscopy or bronchoscopy suite, these devices are useful to determine changes from baseline in methemoglobin.

Methemoglobin produces a color change that can be observed when a drop of blood is placed on absorbant white paper. In one study when various levels of methemoglobin from 10% to 100% were produced in vitro and a drop of each concentration placed on a white background, a color chart was developed that could reliably be used to predict methemoglobin levels.<sup>111</sup> In situations in which laboratory evaluation is limited, such a bedside test is useful because a determination of the exact methemoglobin level is rarely needed.

## MANAGEMENT

For most patients with mild methemoglobinemia of approximately 10%, no therapy is necessary other than withdrawal of the offending xenobiotic because reduction of the methemoglobin will occur by normal reversion mechanisms (NADH methemoglobin reductase). However, in some patients, even small elevations of methemoglobin are problematic because they suggest the individual is at a point at which further oxidant stress will cause methemoglobin levels to increase.<sup>31,53</sup> An individual receiving dapsone with a small elevation of methemoglobin level will likely be more susceptible to clinically significant methemoglobinemia if challenged with a benzocaine-containing anesthetic or an increase in dapsone dose. In the clinical setting, continued absorption, prolonged half-life, and toxic intermediate metabolites will likely prolong methemoglobinemia. Patients should be examined carefully for signs of physiologic stress related to decreased oxygen delivery to the tissue (Fig. 124-7). Obviously, changes in mental status or ischemic chest pain necessitate immediate treatment, but subtle changes in behavior or inattentiveness are also signs of global hypoxia and should be treated. Patients with abnormal vital signs tachycardia and tachypnea or an elevated lactate concentration thought to be caused by tissue hypoxia or the functional anemia of

methemoglobinemia should be treated more aggressively. A mildly elevated methemoglobin level alone generally is not an adequate indication of need for therapy but when levels exceed 30% treatment is invariably indicated.

The most widely accepted treatment of methemoglobinemia is administration of 1 to 2 mg/kg body weight of methylene blue infused intravenously over 5 minutes. This is usually given as 0.1 to 0.2 mL/kg of 1% solution. The use of a slow 5-minute infusion helps prevent painful local responses from rapid infusion. The painful reaction can also be minimized by flushing the intravenous line rapidly with a bolus of at least 15 to 30 mL of fluid after the infusion. Clinical improvement should be noted within minutes of methylene blue administration. If cyanosis has not disappeared within 30-60 minutes of the infusion, then a second dose is recommended (Fig. 124-7). Methylene blue causes a transient decrease in the pulse oximetry reading because its blue color has excellent absorbance at 660 nm.<sup>74,80</sup>

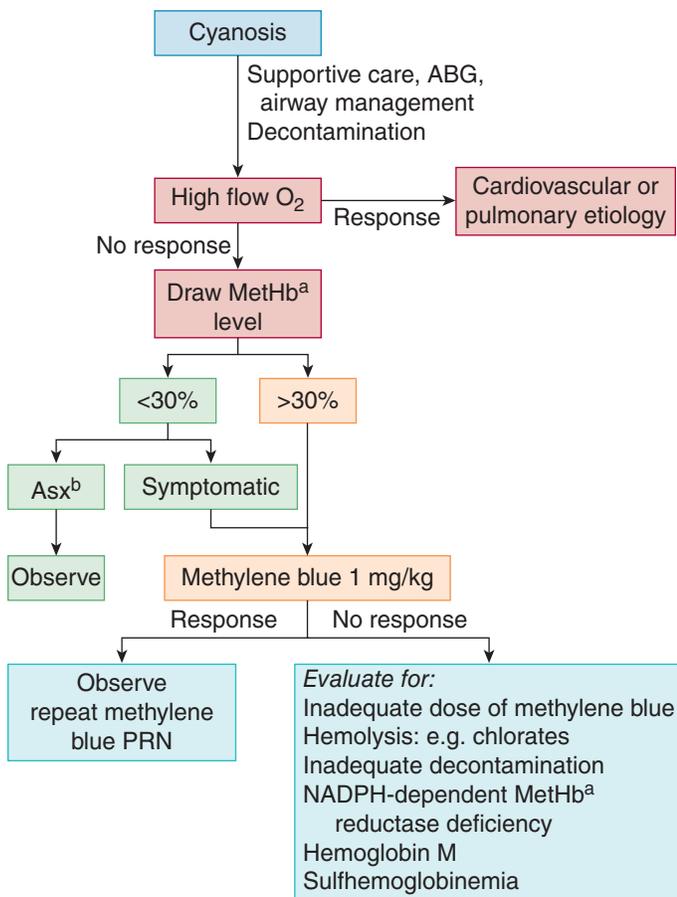

The use of methylene blue in patients with G6PD deficiency is controversial. Deficiency of this enzyme is an estimated 200 million people worldwide. Its incidence in the United States is highest among African Americans (11%),<sup>10</sup> among whom the disease has different degrees of severity. For this reason, G6PD-deficient patients were once excluded from most treatment protocols because methylene blue is a mild oxidant and case reports suggested the toxicity of methylene blue. However, because of the lack of immediate availability of G6PD testing, most patients who need treatment receive methylene blue therapy before their G6PD status is known. Although many patients with G6PD deficiency undoubtedly have been treated unknowingly, few case reports of toxicity are described.

Even the authors of the article most frequently cited as a rationale for withholding methylene blue treatment were unsure whether the methylene blue given to their G6PD-deficient patient produced hemolysis;<sup>106</sup> the dose of methylene blue given to the patient was small, and the patient had taken aniline, which is capable of producing hemolysis. Patients with G6PD deficiency have variable activity of the enzyme and manifest different degrees of disease in response to oxidant stress. For all of these reasons, the judicious use of methylene blue is recommended in most patients with G6PD deficiency and symptomatic methemoglobinemia.

If methylene blue treatment fails to significantly reverse methemoglobinemia, other possibilities should be evaluated. The cause of the oxidant stress may not have been identified and adequately removed, allowing for continuing oxidation. In such situations, decontamination of the gut and skin cleansing must be ensured. Additional doses of methylene blue are also indicated. Patients who have sulfhemoglobinemia or who are deficient in NADPH methemoglobin reductase usually will not improve after methylene blue therapy (Antidotes in Depth: A43).

Theoretically, exchange transfusion or hyperbaric oxygen (HBO) would be expected to be beneficial when methylene blue is ineffective. Both interventions are time consuming and costly, but HBO allows the dissolved oxygen time to protect the patient while endogenous methemoglobin reduction occurs. Ascorbic acid is not recommended in the management of acquired methemoglobinemia if methylene blue is available because the rate at which ascorbic acid reduces methemoglobin is considerably slower than the rate of normal intrinsic mechanisms.<sup>14</sup> Methylene blue has no therapeutic benefit in the presence of sulfhemoglobinemia.<sup>98</sup>

Treatment with dapsone deserves special consideration because of its tendency to produce prolonged methemoglobinemia.<sup>20,72</sup> *N*-Hydroxylation of dapsone to its hydroxylamine metabolite by a CYP2C9 and CYP3A4 reaction is mainly responsible for methemoglobin formation in both therapeutic and overdose situations. Both the parent compound and its metabolites are oxidants with long half-lives. Cimetidine is a competitive inhibitor in the cytochrome P450 metabolic pathway and reduces methemoglobin concentrations during therapeutic dosing because less dapsone will be metabolized by the route.<sup>103</sup> In situations of overdose, cimetidine in therapeutic doses will likely exert some protective effects and is reasonable to use with methylene blue. When dapsone is therapeutically indicated but low levels of methemoglobin are found, cimetidine is a reasonable method for reducing oxidant stress.

**FIGURE 124-7.** Toxicologic assessment of a cyanotic patient. <sup>a</sup> = MetHb = methemoglobin; <sup>b</sup> = Asx = asymptomatic.

Additionally, cimetidine dosing may need to be adjusted because of the effects it will have on other medications the patient may be taking.

## SULFHEMOGLOBIN

Sulfhemoglobin is a variant of hemoglobin in which a sulfur atom is incorporated into the heme molecule but is not attached to iron. The exact location of the sulfur atom in the porphyrin ring is unclear. Sulfhemoglobin is a darker pigment than methemoglobin, producing cyanosis when only 0.5 g/dL of blood is affected. The cyanosis produced is similar to that produced by methemoglobinemia. Sulfhemoglobin also reduces the oxygen saturation determined by the pulse oximeter<sup>2,76,82,92</sup> and is characterized in the laboratory by its spectrophotometric appearance and its lack of reaction when cyanide is added to the mixture. Cyanide does not react with sulfhemoglobin but does react with methemoglobin, forming cyanomethemoglobin, which has no adsorption at the spectrums tested. By contrast, the methemoglobin absorption peak will no longer be present after the addition of cyanide, unmasking the sulfhemoglobin as the cause of the abnormal adsorption peak. This technique is not routinely done in clinical laboratories, and the diagnosis often is made based on the patient's failure to improve with methylene blue.<sup>2,76,82,92</sup> In laboratories, isoelectric focusing techniques further define sulfhemoglobin.

Sulfhemoglobin is an extremely stable compound that is eliminated only when RBCs are removed naturally from circulation. Although the oxygen-carrying capacity of hemoglobin is reduced by sulfhemoglobinemia, unlike in methemoglobinemia, there is a decreased affinity for oxygen in the remaining "unaltered" hemoglobin. Therefore, the oxyhemoglobin dissociation curve is shifted to the right. This makes oxygen more available to the tissues. This phenomenon reduces the clinical effect of sulfhemoglobin in the tissues.

Sulfhemoglobin is produced experimentally in vitro by the action of hydrogen sulfide on hemoglobin and was produced in dogs fed elemental sulfur.<sup>98</sup> A number of xenobiotics induce sulfhemoglobin in humans, including acetanilid, phenacetin, nitrates, trinitrotoluene, and sulfur compounds. Most of the xenobiotics that produce methemoglobinemia are reported in various degrees to produce sulfhemoglobinemia. Sulfhemoglobinemia is also recognized in individuals with chronic constipation and in those who abuse laxatives.<sup>98</sup>

Sulfhemoglobinemia usually requires no therapy other than withdrawal of the offending xenobiotic. It appears that patients come to the attention of clinicians earlier because sulfhemoglobinemia produces more cyanosis than does methemoglobinemia. There is no antidote for sulfhemoglobinemia because it results from an irreversible chemical bond that occurs within the hemoglobin molecule. Exchange transfusion would lower the sulfhemoglobin concentration, but this approach usually is unnecessary.

## SUMMARY

- Methemoglobinemia is defined as an abnormal level of methemoglobin above 1%.
- Methemoglobinemia is sometimes caused by an acute, oxidant event that overwhelms the protective mechanisms of the host or more commonly and, importantly, as a final clinical manifestation of multiple oxidant stressors.
- Methemoglobinemia is clinically identified by cyanosis without cardiovascular causes, a normal PO<sub>2</sub> on blood gas analysis, chocolate-colored blood, and elevated methemoglobin level on cooximetry.
- Symptoms are usually milder than the appearance of the cyanosis would suggest and can be as minimal as mild fatigue and exertional dyspnea to seizures and central nervous system (CNS) depression depending on degree and coexisting disease.
- Methylene blue therapy is recommended for symptoms of cardiovascular or respiratory distress, any CNS symptoms or findings, metabolic acidosis and patients with methemoglobin levels above 30%.

- Patients with low methemoglobin levels are under oxidant stress and at risk for more serious methemoglobinemia if oxidant stressors persist or increase in their environment.
- Multiwavelength pulse oximeters are becoming more accurate and should be used routinely to monitor patients undergoing procedures in which oxidants, such as benzocaine and lidocaine, are being used.
- Early detection of oxidant stress using methemoglobin as a marker may help in management of critically ill patients.

## METHYLENE BLUE

Mary Ann Howland

**INTRODUCTION**

Methylene blue is an extremely effective antidote for acquired methemoglobinemia. Methylene blue has other actions, including the inhibition of nitric oxide synthase and guanylyl cyclase and the inhibition of the generation of oxygen free radicals. These actions likely explain the beneficial effects of methylene blue in the treatment of refractory hypotension, hepatopulmonary syndrome, priapism, sepsis, and malaria; the modulation of streptozocin-induced insulin deficiency; the prevention and treatment of ifosfamide-induced encephalopathy; and the reduction of the development of postsurgical peritoneal adhesions.<sup>15,16,21,24,34,44,53,64</sup>

**HISTORY**

Methylene blue was initially recommended as an intestinal and urinary antiseptic and subsequently recognized as a weak antimalarial.<sup>20</sup> In 1933, Williams and Challis successfully used methylene blue for the treatment of aniline-induced methemoglobinemia.<sup>69</sup>

**PHARMACOLOGY****Chemistry**

Methylene blue is tetramethylthionine chloride,<sup>20</sup> a basic thiazine dye with a molecular weight of 319 Da. It is deep blue in the oxidized state and colorless when reduced to leukomethylene blue.

**Mechanisms of Action**

Methylene blue is an oxidizing agent, which, in the presence of nicotinamide adenine dinucleotide phosphate (NADPH) and NADPH methemoglobin reductase, is reduced to leukomethylene blue (Fig. 124-4). Leukomethylene blue effectively reduces methemoglobin to hemoglobin.<sup>9,20,65</sup> Reduction of methemoglobin via this NADPH pathway is limited under normal circumstances. However, in the presence of methylene blue, the role of the NADPH pathway is dramatically increased and becomes the most efficient means of methemoglobin reduction.

More recent attention has focused on the ability of methylene blue to reverse refractory hypotension from many causes, including drug overdose, vasoplegia, and sepsis.<sup>59,63</sup> Methylene blue inhibits nitric oxide synthase and guanylyl cyclase in vascular smooth muscle. This reduces the amount and effect of nitric oxide. Systemic vascular resistance and cardiac output increase, and the sensitivity of adrenergic receptors to sympathomimetics is enhanced.<sup>12,14,27,36,38,68</sup>

**Pharmacokinetics**

The pharmacokinetics of methylene blue were studied in animals and human volunteers after intravenous (IV) and oral administration of 100 mg.<sup>9-11,45</sup> Methylene blue exhibits complex pharmacokinetics, consistent with extensive distribution into deep compartments, followed by a slower terminal elimination, with a half-life of 5.25 hours. Peak concentrations after oral administration in healthy volunteers were reached in 1 to 2 hours, but were only approximately 80 to 90 nmol/L, as opposed to 8,000 to 9,000 nmol/L after IV administration.<sup>45</sup> Experiments in rats indicated that the substantial differences in whole-blood concentrations achieved by these routes of administration results from extensive first-pass organ distribution into the intestinal wall and liver after oral administration.<sup>45</sup> Total urinary excretion at 24 hours accounts for 28.6% of the drug after IV administration compared

to 18.5% after oral administration. In both instances, one-third was in the leukomethylene blue form. A phase 1 bioavailability study in healthy volunteers compared plasma and whole-blood concentrations of total methylene blue after 50 mg IV (dissolved in 10 mL of 0.9% sodium chloride over 9.5 min and followed with 10 mL of 0.9% sodium chloride over 30 seconds) and 500 mg orally as an aqueous liquid.<sup>62</sup> The mean plasma and whole-blood concentrations for 50 mg IV were 748 ng/mL and 1,418 ng/mL compared with the mean plasma and whole-blood concentrations for 500 mg oral of 3,905 ng/mL and 3,957 ng/mL; the times to maximum plasma concentrations were 0.5 hours for IV and 2.2 hours for oral; the time to maximum whole blood concentrations for IV were 0.22 hours and 2.2 hours for oral; the half-lives for plasma were similar for IV and oral at 18.3 hours and 18.5 hours, respectively; and the half-lives for whole blood for IV and oral were 13.6 hours and 14.7 hours, respectively. Interindividual variability was significant. The oral bioavailability of methylene blue ranged from 72% to 84% based on plasma and whole-blood analyses respectively. The mean whole blood to plasma concentration ratio was about 1. The most likely explanation for the discrepancies between this study and earlier studies is the improved sensitivity of the analytical technique.

**Pharmacodynamics**

The onset of action of methylene blue for the reversal of methemoglobin is often within minutes. Maximum effects usually occur by 30 minutes.<sup>22</sup>

**ROLE IN XENOBIOTIC-INDUCED METHEMOGLOBINEMIA**

Methylene blue is indicated in patients with symptomatic methemoglobinemia. This usually occurs at methemoglobin levels greater than 20%, but symptoms often occur at lower levels in anemic patients or those with cardiovascular, pulmonary, or central nervous system compromise.

Historically, sulfanilamide-induced methemoglobinemia was reversed by methylene blue in IV doses of 1 to 2 mg/kg or oral doses of 65 to 130 mg, given every 4 hours.<sup>22,66</sup> With these regimens, a very rapid fall in methemoglobin was accompanied by disappearance of cyanosis. Subsequent investigations confirmed the effectiveness and safety of IV doses of 1 to 2 mg/kg in reversing the methemoglobinemia produced by sulfanilamide,<sup>66</sup> aniline dye,<sup>13</sup> silver nitrate, benzocaine, nitrites, phenazopyridine, and other xenobiotics.<sup>57,61</sup>

The risk-to-benefit ratio of using methylene blue in a patient for methemoglobinemia must always be weighed as with any other xenobiotic. In this case, the benefit of using methylene blue for a patient with significant methemoglobinemia will almost always outweigh the risk of possibly precipitating serotonin toxicity in a patient taking a selective serotonin reuptake inhibitor (SSRI) (refer to Adverse Events).

Methylene blue is ineffective in the treatment of sulfhemoglobinemia (Chap. 124).

**ROLE IN HYPOTENSION**

Hypotension refractory to vasopressors occurs in the setting of sepsis, vasoplegia, and drug ingestion. Methylene blue has successfully reversed the low systemic vascular resistance in a few case studies and case reports.<sup>12,14,27,28,32,35,36,38,47,68</sup> A recent review suggests that although blood pressure responds to methylene blue in distributive shock, a prospective study is needed to establish whether better oxygen delivery and improved survival occur.<sup>26</sup>

## ADVERSE EFFECTS AND SAFETY ISSUES

The most common diverse effects reported in healthy volunteers when administered 2 mg/kg methylene blue were extremity pain, chromaturia, dysgeusia, dizziness, feeling hot, diaphoresis, nausea, skin discoloration, headache, and back pain.<sup>49</sup>

Reports of the paradoxical induction of methemoglobinemia by methylene blue suggest an equilibrium between the direct oxidization of hemoglobin to methemoglobin by methylene blue and its ability (through the NADPH and NADPH methemoglobin reductase pathway and leukomethylene blue production) to reduce methemoglobin to hemoglobin.<sup>45</sup> Methylene blue does not produce methemoglobin at doses of 1 to 2 mg/kg. The equilibrium seems to favor the reducing properties of methylene blue unless excessively large doses of methylene blue are administered<sup>3,19,67</sup> or the NADPH methemoglobin reductase system is abnormal. This equilibrium constant varies substantially, as 20 mg/kg IV in dogs and 65 mg/kg intraperitoneally in rats failed to produce methemoglobinemia.<sup>56</sup> In early studies, 50 to 100 mL of a 1% concentration (500–1,000 mg) of methylene blue was used intravenously in volunteers<sup>39</sup> as well as in the treatment of patients with aniline dye-induced methemoglobinemia.<sup>69</sup> In these studies, methemoglobin concentrations, measured when symptoms were most pronounced, were approximately 1.0 g/dL (0.4%–8.3% of total hemoglobin) and unlikely to be solely responsible for the adverse effects demonstrated. Other consequential adverse effects included shortness of breath, tachypnea, chest discomfort, a burning sensation of the mouth and stomach, initial bluish tinged skin and mucous membranes, paresthesias, restlessness, apprehension, tremors, nausea and vomiting, dysuria, and excitation. Urine and vomitus often appears blue in color. These limited studies led to the recommendation to avoid doses higher than 7 mg/kg.

In high doses, methylene blue induces acute hemolytic anemia independent of the presence of methemoglobinemia.<sup>19,33</sup> In dose-response studies in glucose-6-phosphate dehydrogenase (G6PD) deficient homozygous African-American men, daily oral doses of 390 to 780 mg (5.5–11 mg/kg) of methylene blue produced hemolysis,<sup>31</sup> which was comparable with the results after exposure to 15 mg of primaquine base.<sup>31</sup> Because of the sensitivity of neonates due to the presence of hemoglobin F and diminished NADH reductase increases the risk of hemolysis and therefore the smallest effective dose of methylene blue should be used.<sup>24,30</sup> Because any oxidizing agent can independently induce a Heinz body hemolytic anemia, the specific contribution of methylene blue often is difficult to elucidate.<sup>30</sup>

Because methylene blue is a dye, it will transiently alter pulse oximeter readings.<sup>7</sup> Large doses often interfere with the ability to detect a clinical decrease in cyanosis; therefore, repeat cooximeter measurements and arterial or venous blood gas analysis should be used in conjunction with clinical findings to evaluate improvement. Also because of the dye effects, the bispectral index used to assess depth of anesthesia might also be compromised.<sup>49</sup>

Intraamniotic injection of methylene blue results in a number of adverse effects, including infants born with blue skin (with resultant inaccurate pulse oximetry readings),<sup>43</sup> methemoglobinemia, hemolysis, phototoxic skin reactions,<sup>46</sup> or intestinal obstruction.<sup>7,8,29,33,37,42,50,60</sup> One infant exposed in utero at 5.5 weeks was normal at birth.<sup>29</sup> An excessive dose of enterally administered methylene blue that subsequently leaked into the peritoneum of a premature neonate most likely was responsible for a hemolytic anemia appearing 3 days later.<sup>1</sup>

Methylene blue leads to a bluish-green discoloration of the urine and often causes dysuria.<sup>48</sup> Intravenous methylene blue is irritating and exceedingly painful. It may cause local tissue damage even in the absence of extravasation.<sup>50</sup> Subcutaneous and intrathecal administrations are contraindicated.<sup>50</sup>

Recent reviews reveal an association between an encephalopathy and the use of methylene blue for the staining and localization of parathyroid tumors in women receiving serotonin reuptake inhibitors.<sup>41,55,58</sup> Doses of 3 to 7.5 mg/kg were commonly used for this indication.<sup>55</sup> Five of 132 patients in one review developed one or more of the following: confusion, expressive aphasia, lethargy, and vertigo, which lasted from 2 to 3 days. A second review detailed seven patients with signs and symptoms consistent with serotonin

toxicity. Finally, a review of 31 published case reports in which patients maintained on SSRIs developed an encephalopathy resembling serotonin toxicity associated with the administration of methylene blue before parathyroid gland surgery concluded that caution was warranted.<sup>55</sup> An *in vitro* study documented the ability of methylene blue to competitively bind to monoamine oxidase A, raising the possibility that methylene blue might interact with serotonergic xenobiotics by acting as a monoamine oxidase inhibitor.<sup>51</sup> Two reviews also conclude that methylene blue has the potential to interact with xenobiotics that elevate serotonin to cause serotonin excess and toxicity in situations not involving parathyroid surgery.<sup>18,40</sup> The US Food and Drug Administration recently added a black box warning of the potential serious or fatal serotonin toxicity when methylene blue is given to patients receiving SSRIs, serotonin-norepinephrine reuptake inhibitors, or monoamine oxidase inhibitors.<sup>49</sup>

High doses of methylene blue (7 mg/kg) have the potential to decrease splanchnic blood flow in the setting of septic shock.<sup>28</sup>

One author suggests that methylene blue directly inactivates lactic acid, giving a potentially false impression of improved perfusion.<sup>14</sup> However, this finding needs confirmation.

### Use in Patients with Glucose-6-Phosphate Dehydrogenase Deficiency

Methylene blue is frequently hypothesized to be ineffective in reversing methemoglobinemia in patients with G6PD deficiency<sup>41</sup> because G6PD is essential for generation of NADPH (Chap. 20). Without NADPH, methylene blue cannot reduce methemoglobin. However, G6PD deficiency is an X-linked hereditary deficiency with more than 400 variants. The red blood cells containing the more common G6PD A variant that are found in 11% of African Americans retain 10% residual activity, mostly in young erythrocytes and reticulocytes. By contrast, the enzyme is barely detectable in those of Mediterranean descent who have inherited the defect. Therefore, it is impossible to predict before the use of methylene blue to which persons will or will not respond and to what extent. Currently, it appears that most individuals have adequate G6PD and express deficiency states in relative terms. This variable expression of their deficiency allows an effective response to most oxidant stresses. In addition, in theory, normal cells might convert methylene blue to leukomethylene blue, which might diffuse into G6PD deficient cells and effectively reduce methemoglobin to hemoglobin.<sup>2</sup>

Before assuming that G6PD deficiency is responsible for a continued elevation of methemoglobin levels despite administration of methylene blue, ongoing xenobiotic absorption and continued methemoglobin production must be excluded. On the other hand, when therapeutic doses of methylene blue fail to have an impact on the methemoglobin levels, the possibility of G6PD deficiency should be evaluated, and further doses of methylene blue should not be administered because of the risk of methylene blue-induced hemolysis. In these cases, exchange transfusion and hyperbaric oxygen are potential alternatives for treating methemoglobinemia (Chap. 124).

## PREGNANCY AND LACTATION

Methylene blue was previously listed as a Category X drug in pregnancy. Intraamniotic injection has led to fetal abnormalities, including atresia of the ileum and jejunum, ileal occlusions, hemolytic anemia, hyperbilirubinemia, and methemoglobinemia, and should be avoided. Human data suggest a weak association with developmental toxicity when used orally in the 1970s for treating urinary tract infections in the second and third trimesters.<sup>6</sup>

Intravenous methylene blue should only be used to treat pregnant women with methemoglobinemia when the benefit outweighs the potential risk to the fetus.<sup>49</sup>

There are no data available with regard to use during lactation. However, it is currently recommended to discontinue breastfeeding when methylene blue has been used and not to resume breastfeeding for 8 days after use.<sup>49</sup>

## DOSING AND ADMINISTRATION

The dose of methylene blue is 1 mg/kg given IV over 5 minutes followed immediately by a fluid flush of 15 to 30 mL to minimize local pain. This dose can be repeated in 30 to 60 minutes if necessary based on clinical signs and

symptoms and a consequential methemoglobin level. If there is no effect after two sequential doses of 1 mg/kg, then subsequent dosing should be halted and the diagnosis reexamined or the possibility of severe G6PD deficiency considered. Methylene blue can be diluted in 50 mL of 5% dextrose in water to decrease the risk of local pain. Sodium chloride should not be used for dilution because the chloride may decrease the solubility of the methylene blue.<sup>49</sup> The appropriate dose of methylene blue in obese patients has not been studied. It is reasonable to theorize that because the effects on methemoglobinemia occur in the blood compartment, each dose of methylene blue should be limited to a maximum dose of 100 mg regardless of the weight of a patient. This dose can be repeated if necessary. In neonates, 0.3- to 1-mg/kg doses often are effective.<sup>17,25</sup> The onset of action is rapid, and maximal effects usually occur within 30 minutes.

Subsequent dosing of methylene blue is often required in conjunction with efforts to decontaminate the gastrointestinal tract when there is continued absorption or slow elimination of the xenobiotic producing the methemoglobinemia, such as with dapsone.

Intraosseous administration of 0.3 mL of 1% solution (1 mg/kg) of methylene blue over 3 to 5 minutes into the anterior tibia of a 6-week-old infant was well tolerated.<sup>24,43</sup> The dose of methylene blue for refractory hypotension is not established. Doses of 1 to 3 mg/kg increase systemic vascular resistance and mean arterial pressure and improve tissue oxygenation.<sup>27</sup> Although doses of 7 mg/kg may produce further increases in mean arterial pressure, this result is associated with a decrease in splanchnic blood flow.<sup>28</sup>

Methylene blue should *not* be administered subcutaneously or intrathecally.

## FORMULATION AND ACQUISITION

Methylene blue is available in 10-mL vials of a 1% solution for injection, containing 10 mg/mL (100 mg total in 10 mL) and in a 0.5% solution containing 5 mg/mL (50 mg total in 10 mL).

## SUMMARY

- Methylene blue is an effective reducing agent for patients with acquired methemoglobinemia.
- The onset of action for methylene blue in reversing methemoglobinemia is rapid and its adverse reactions are limited.
- After initial control of methemoglobinemia, subsequent doses of methylene blue often are required when methemoglobin-producing xenobiotics with a long duration of effect, such as dapsone, are ingested.
- Methylene blue is being investigated for use in drug-induced vasoplegic shock.

## HISTORY

Nanotechnology has been serendipitously used by humanity for hundreds of years. Artistically, gold-ruby glass (cranberry glass), present in the Roman Lycurgus cup and later in many church stained glass windows, owes its striking red color and optical properties to gold nanoparticles created when a gold precursor is added to molten silicate glass.<sup>141</sup> Cosmetically, to blacken hair, the Greco-Roman practice of mixing of lead oxide and slaked lime with water created lead sulfite nanocrystals (5 nm), which accumulated in the hair cuticle and cortex.<sup>417</sup> Martiallly, 17th century Damascus steel sword blades owed their high-quality mechanical properties to carbon nanotubes (CNTs) and cementite ( $\text{Fe}_3\text{C}$ ) nanowires found within their structure.<sup>326</sup> Medicinally, specially prepared, “Swarna bhasma,” nanosized colloidal gold, has been used as an antirheumatic, antiasthmatic, and antidiabetic in Indian Ayurvedic practice for centuries.<sup>39</sup> Application of the nanosilver colloidal formation “Collargol” as an antiseptic was reported in 1897.<sup>110</sup>

In 1909, Richard Zsigmondy’s investigations in colloidal chemistry were translated, and his “ultramicroscope” provided resolution to less than 1 micron, to include ultrafine cigarette smoke particles.<sup>460</sup> Langmuir’s detailed experimental work establishing the existence of monatomic films garnered him the Nobel Prize in 1932.<sup>195</sup> In 1959, the physicist Richard Feynman proposed the theoretical framework for “manipulating and controlling things” all the way down to the atomic level.<sup>407</sup> Norio Taniguchi is generally credited with coining the term “nano-technology”—“the processing of separation, consolidation and deformation of materials by one atom or one molecule”—in 1974.<sup>381</sup> The invention of the scanning tunneling microscope in 1981 enabled the visualization of individual atoms and allowed the direct physical manipulation of atomic surfaces.<sup>173</sup> In 1985, Kroto and colleagues reported on a novel, minute crystalline allotropic form of carbon, which had been conceptualized some 15 years previously.<sup>66,188,288</sup> These soccer ball-shaped carbon-60 structures were named “buckminsterfullerenes” after Buckminster Fuller. The discovery of CNTs followed in 1991.<sup>155</sup>

The health and safety of nanotoxicology came to fore during the first consumer recall of a purported nano-based invention.<sup>431</sup> In 2006, the bathroom cleaning product “Magic-Nano” was released in Germany. Within days, more than 110 cases of illness were reported, and several patients were hospitalized with severe respiratory complaints, including acute lung injury. No further episodes of illness occurred after product recall only 3 days after introduction.<sup>168</sup> Although it was ultimately determined that “Magic-Nano” contained no nanoparticles, the incident raised many questions about nanotechnology development, regulation, and health risks.<sup>22,23</sup> More than 1,600 consumer products now incorporate nanotechnology.<sup>388</sup>

## PHYSIOCHEMICAL PRINCIPLES

*Nanotechnology* is defined as the “control and restructuring of matter at the nanoscale, in the size range of approximately 1–100 nanometers, in order to create materials, devices, and systems with fundamentally new properties and functions due to their small structure.”<sup>318</sup> The American Society for Testing and Materials (ASTM) International defines an *ultrafine particle* as a particle ranging in size from approximately 0.001  $\mu\text{m}$  (1 nm; 10 Å) to 0.1  $\mu\text{m}$  (100 nm; 1,000 Å) and a *nanoparticle* as an ultrafine particle with lengths in two or three dimensions greater than 0.001  $\mu\text{m}$  (1 nm; 1,000 Å) and smaller than about 0.1  $\mu\text{m}$  (100 nm; 1,000 Å).<sup>8</sup> Alternatively, *nanoparticles* are described as having three nano-scaled dimensions; *nanofibers* have two nano-scaled dimensions; and *nanoplates* have one nano-scaled dimension.

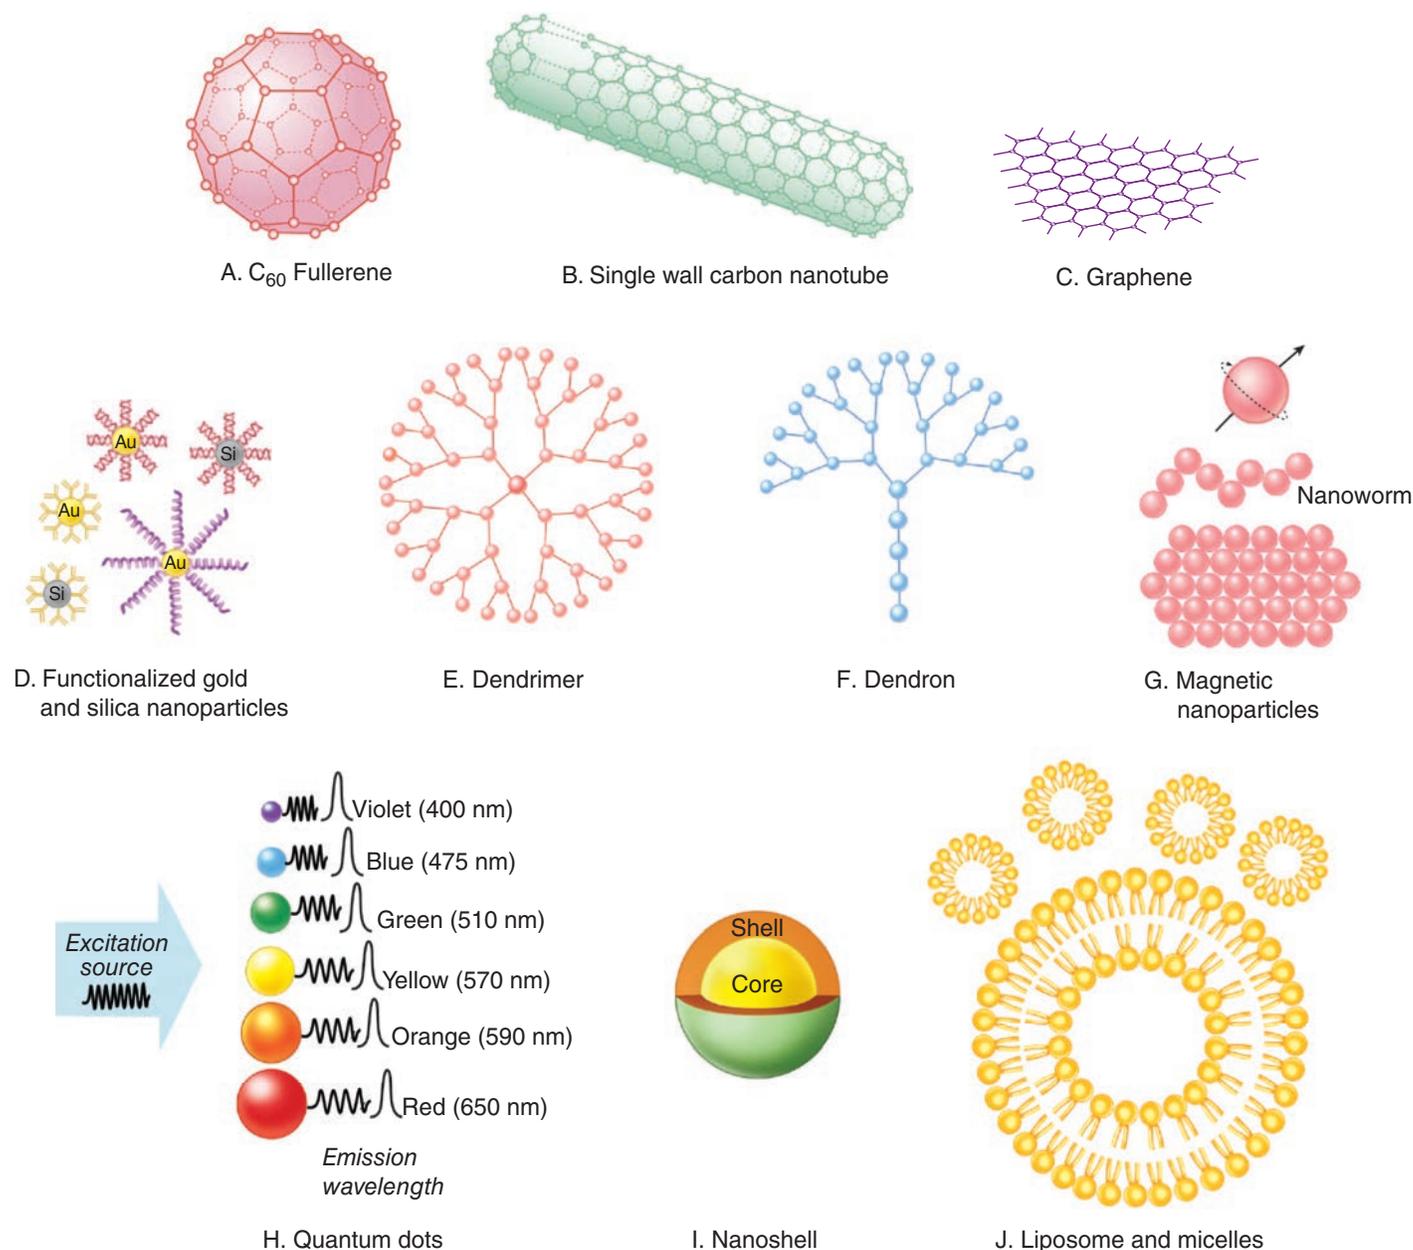

For spherical nanoparticles, as particle diameter decreases, the percentage of molecules on the surface of the nanoparticle increases relative to the total number of molecules. This percentage increases quite steeply below 100 nm.<sup>184</sup>

This provides a large area (high surface to volume ratio) for chemical reactions to occur and for interaction with biologic systems. Furthermore, as particles reach sizes below 100 nm, quantum mechanical principles become manifest, and thus acoustic, diffusion, electrical, magnetic, mechanical, optical, and solubility properties may emerge, which differ from those seen at larger as well as smaller (atomic) scales. Nanoparticles may exist as aggregations (individual particles held together by strong forces) and agglomerations (held together by weak forces such as van der Waals forces and electrostatic and surface tension). The extent of aggregations and agglomerations, particle dispersal, and electrical charge varies, depending on the primary particle constituents and on solvents or media.<sup>35</sup> This imparts additional properties to identical substances even at the nanoparticle level. Whereas  $\text{C}_{60}$  fullerenes are intensely hydrophobic and essentially insoluble in water, colloidal  $\text{C}_{60}$  clusters remain mono-dispersed in water as long as electrostatic repulsions are not disrupted by salts.<sup>35</sup> Single elemental materials can also be engineered with complex architecture (eg, gold and platinum nanostars) to alter catalytic activity.<sup>225</sup>

Nanoparticles may be derived “naturally,” such as those originating from volcanic explosions, fires, ocean spray, sand storms, and soil and sediment weathering and biomineralization processes.<sup>407</sup> “Incidental” nanosized particles are generated as byproducts of processes such as combustion, cooking, munitions discharge, or welding, or even simply rubbing of bulk solids of  $\text{C}_{60}$  between fingertips or glass slides.<sup>72</sup> “Engineered” nanomaterials are intentionally created for research purposes or for manufacture for end-use applications. Nanomaterials and nanoparticles include a vast array of structures, such as coatings, composite nanodevices, dendrimers, fullerenes, graphenes, liposomes, nanocrystals, nanogels, nanofibers (nanorods and hollow nanotubes), nanoshells, nanospheres, conducting nanowires, polymeric micelles, quantum dots (QDs) and quantum rods, and supermagnetic particles (Fig. 125-1). They are composed of materials as diverse as their applications, including carbon, lipids, metals and metal oxides (eg, cadmium, cerium, copper, germanium, gold, iron, silver, selenium, titanium, zinc, and zirconium), nucleic acids, polymers, proteins, and combinations thereof.

## CURRENT AND PROJECTED APPLICATIONS

Nanotechnologies are currently or anticipated to be incorporated into an ever-widening range of disciplines and industries. These include agriculture; automobile components; chemical and materials science (alloys, catalysts, ceramics, coatings, and thin films); defense; electronics; energy capture and storage; environmental sensing and remediation; human and animal food processing; fuel additives; house-cleaning products; paints, flame-retardants, varnishes, and sealants; pharmaceuticals; textiles; and water purification.<sup>318</sup> Specific human and biomedical applications include biomaterials, cosmetic and external products, diagnostics, drug and gene delivery systems, imaging, immune and transplantation sciences, and oncology therapy.<sup>343</sup> Biomaterial products include creation of scaffolds for in vivo or ex vivo growth to support tissue healing, engineering, and regenerative medicine; coatings to minimize immunogenicity, inhibit specific tissues or cell types, and allow macromolecular repair; and implant engineering in prosthetics to control fibrous tissue formation and biointegration, and implant performance.<sup>112,376,385,386</sup> Nanotechnology is radically advancing imaging capability for specific organs, tumors, sentinel lymph nodes, and vasculature. Molecular imaging now permits differentiation of cellular subcompartments, uptake mechanisms, cell architecture, intracellular trafficking, and single proteins and receptors.<sup>15,127,189</sup> Sunscreens, cosmetics, and conditioners have embraced a range of nanotechnologies. Nanoformulations of  $\text{TiO}_2$  and  $\text{ZnO}$ , which the US Food and Drug Administration (FDA) has

**FIGURE 125-1.** Nanoparticles (not to scale). (A) C<sub>60</sub> is a prototypical *fullerene*, or carbon cage, which may enclose additional atoms, ions, or molecular clusters. *Fullerols* (*fullerenols*) use polyhydroxylation at their surface to improve water solubility. (B) *Carbon nanotubes* (CNTs) are single-walled (SWCNTs) or multiple-walled (MWCNTs) cylinders, which are capped at each end and can bundle together into longer and wider agglomerates. (C) *Graphene* consists of a single layer of carbon atoms (ie, a sheet) in a hexagonal lattice. (D) *Gold nanoparticles* and other nanosized noble metals (eg, silver, copper, platinum) have unusual catalytic, optical, electronic, and (photo)thermal properties and can be conjugated to dyes, antibodies, peptides, and oligonucleotides. (E) *Dendrimers* are branched polymers consisting of a central core, an internal branching region, and surface terminal groups; drugs, genes, and imaging agents can be loaded into the inner protected cavities. (F) *Dendrons* are wedge-shaped sections of dendrimers with an accessible reactive group. (G) Magnetic nanoparticles include *superparamagnetic iron oxide* (SPIO) nanoparticles (Fe<sub>2</sub>O<sub>3</sub>, Fe<sub>3</sub>O<sub>4</sub>), pure metals (Fe and Co), and alloys (CoPt<sub>3</sub> and FePt). They are usually surrounded by a shell to minimize agglomeration and chemical reactivity. *Magnetism-engineered iron oxide* (MEIO) nanoparticles can be doped with cobalt, manganese, and nickel to create unique magnetism properties. (H) *Quantum dots* (QDs) and *QRods* (rod-shaped QDs) are semiconductor nanocrystals capable of size-dependent fluorescence with a “tunable” emission spectrum in the 400-nm to 2- $\mu$ m range. Analogous but chemically inert *Cornell dots* (CU or C dots) contain covalently bound fluorescent dyes in a sol–gel-derived silica matrix. (I) *Nanoshells* contain a dielectric silica core surrounded by thin metal gold shell. (J) *Liposomes* and *micelles* are globular vesicles with hydrophobic and hydrophilic zones composed of phospholipids, sphingolipids, and ceramides or other esters or polymers ranging in size from 25 nm to the micron range. Nanoparticles can be further derivatized, chemically modified, or bioengineered with a variety of detection, imaging, or targeting molecules.

permitted in sunscreens since 1999, provide both aesthetic appeal (suntan with transparency, lower viscosity, and improved skin blending) and clinical benefit (more efficient ultraviolet {UV} filtration).<sup>273,431</sup> Wound care is incorporating dressings containing nanocrystalline silver and other delivery systems to improve wound healing through inflammation suppression, upregulation of micronutrients, and antibacterial actions.<sup>260,391,422</sup> Nanotechnology is advancing medical diagnostic capability, detection thresholds, and pathogen sensing, with tagged nanoparticles currently used in commercial genotyping tests and

other assays.<sup>373</sup> Nanoengineering holds the promise of improved pharmacokinetics, solubility, delivery, and targeting of pharmaceuticals, proteins, and genes in a cell-, tissue-, tumor-, or organ-specific manner. New formulations, magnetic drug targeting, thermal ablation, and delivery to incredibly diverse difficult-to-access spaces (eg, intracellular pathogens, tumors, and the central nervous system {CNS}) are being investigated or brought to market.<sup>24,175,351,358,423</sup> Table 125-1 presents selected commercial nanotechnology-based diagnostics, imaging compounds, and therapeutics.

**TABLE 125-1** Selected Commercial Nanotechnology-Based Diagnostics and Therapeutics<sup>a</sup>

<i>Xenobiotic</i>	<i>Proprietary Name</i>	<i>Route</i>	<i>Class or Indication</i>	<i>Nanotechnology Platform</i>
Aminosilane-iron oxide	NanoTherm (EU)	IV	Magnetic tumor thermotherapy	SPIO nanoparticle (aminosilane-coated)
Amphotericin	Abelcet, Amphotec, AmBisome	IV	Antifungal	Liposomal
Aprepitant	Emend	PO	Antiemetic	Nanocrystal
Carmustine	Gliadel	Implant	Chemotherapeutic	Degradable solid copolymer
Certolizumab pegol (TNF antagonist)	Cimzia	SC	Immunosuppressant	Polymer protein conjugate
Cytarabine	Depocyt	IV	Chemotherapeutic	Liposomal
Daunorubicin	DaunoXome	IV	Chemotherapeutic	Liposomal
Denileukin diftitox	Ontak	IV	Chemotherapeutic	Diphtheria toxin-antibody-functionalized nanoparticle
Dominant-negative construct of human cyclin-G1 gene	Rexin-G <sup>b</sup> (Philippines)	IV	Chemotherapeutic	Targeted (collagen binding domain) nanoparticle
Doxorubicin	Doxil, Caelyx, Myocet	IV	Chemotherapeutic	Liposomal
Estradiol	Estrasorb	TD	Menopausal symptoms	Micellar nanoparticle
Estradiol	Elestrin	TD	Menopausal symptoms	Calcium phosphate nanoparticles
Fenofibrate	Tricor, Triglide	PO	Antilipidemic	Nanocrystal
Ferucarbotran	Cliavist, Resovist	IV	MRI contrast agent	SPIO nanoparticle (carboxydextran coated)
Ferumoxide	Feridex, Endorem	IV	MRI contrast agent	SPIO nanoparticle (dextran coated)
Ferumoxsil	GastroMARK, Lumirem	IV	MRI contrast agent	SPIO nanoparticle (siloxane coated)
Ferumoxtran-10	Combidex, Sinerem	IV	MRI contrast agent	SPIO nanoparticle (dextran coated)
Ferumoxytol	Feraheme	IV	Iron deficiency anemia of chronic kidney disease	SPIO nanoparticle (polyglucose sorbitol carboxymethyl ether coated)
Glatiramer acetate (L-glutamic acid polymer with L-alanine, L-lysine and L-tyrosine)	Copaxone	SC	Autoimmune disease mitigation (multiple sclerosis)	Polymeric substances
Gold	Verigene	NA	Molecular diagnostics	Oligonucleotide- or antibody-functionalized nanoparticle
Human GM-CSF gene	Reximmune-C	IV	Chemotherapeutic	Targeted nanoparticle
Inactivated hepatitis A (strain RG-SB) virus particles	Epaxal	IM	Vaccine	Virosome
Inactivated influenza (strains A and B) virus particles	Inflexal V	IM	Vaccine	Virosome
Indomethacin	Indaflex (Mexico)	Topical	Antiinflammatory	Nanoparticle emulsion
Insulin (human rDNA origin)	Exubera (discontinued)	Inhalation	Hypoglycemia	Calcium phosphate nanoparticles
Lanthanum carbonate	Fosrenol	PO	Phosphate reduction	Inorganic nanoparticles
Megesterol acetate	Megace ES	PO	Anorexia, cachexia, AIDS-associated weight loss	Nanocrystal
Morphine sulfate	DepoDur	Epidural	Analgesic	Liposomal
Paclitaxel	Genexol-PM <sup>c</sup>	IV	Chemotherapeutic	Polymeric micelle
Paclitaxel (albumin-bound)	Abraxane	IV	Chemotherapeutic	Protein conjugate
Paliperidone palmitate	Invega Sustenna	IM	Antipsychotic	Nanocrystal
Pegademase bovine (PEG-adenosine deaminase)	Adagen	IM	SCID	Polymer protein conjugate

TABLE 125-1 Selected Commercial Nanotechnology-Based Diagnostics and Therapeutics<sup>a</sup> (Continued)

Xenobiotic	Proprietary Name	Route	Class or Indication	Nanotechnology Platform
Pegaptanib (PEG-anti-VEGF-oligonucleotide)	Macugen	IVit	Aged-related macular degeneration	Polymer protein conjugate
PEG-coated SiO <sub>2</sub>	NA <sup>d</sup>	IV	Oncology diagnostics	Cornell Dots (C dots)
Pegaspargase	Oncaspar	IM, IV	Chemotherapeutic	Polymer protein conjugate
Pegfilgrastim (PEG-G-CSF)	Neulasta	SC	Chemotherapy-induced neutropenia	Polymer protein conjugate
Peginesatide (erythropoietin receptor agonist)	Omontys <sup>e</sup>	IV, SC	Polycythemic	Polymer protein conjugate
Peginterferon alfa-2b	PegIntron	SC	Antiviral (hepatitis C)	Polymer protein conjugate
Peginterferon alfa-2b	Pegasys	SC	Antiviral (hepatitis B/C)	Polymer protein conjugate
Pegloticase	Krystexxa	IV	Antiuricemic	Polymer protein conjugate
Pegvisomant (PEG-human growth hormone analog)	Somavert	SC	Acromegaly	Polymer protein conjugate
Propofol	Diprivan	IV	Anesthetic	Liposome
Sevelamer HCl (crosslinked with epichlorohydrin)	Renagel	PO	Phosphate reduction	Polymeric crosslinked resin
Silver	Acticoat	Topical	Wound healing	Nanoparticle
Sirolimus	Rapamune	PO	Immunosuppressant	Nanocrystal
Titanium dioxide	Numerous	Topical	Ultraviolet-protectant	Nanoparticle
Thymectacin	Theralux	IV	Chemotherapeutic	Nanocrystal
Vincristine	Marqibo	IV	Chemotherapeutic	Liposomal
Verteporfin	Visudyne	IV	Aged-related macular degeneration	Liposomal

<sup>a</sup>No endorsement is implied. <sup>b</sup>US FDA Orphan Drug Approval but not Marketing Approval. <sup>c</sup>South Korean marketing approval. <sup>d</sup>US Food and Drug Administration investigational new drug approval. <sup>e</sup>Voluntary marketing withdrawal.

EU = European Union; G-CSF = granulocyte-colony stimulating factor; GM-CSF = granulocyte-macrophage colony stimulating factor; IND = investigational new drug; IM = intramuscular; IV = intravenous; IVit = intravitreal; MRI = magnetic resonance imaging; NA = not applicable; PEG = polyethylene glycol; PO = oral; SC = subcutaneous; SCID = severe combined immunodeficiency disease; SPIO = superparamagnetic iron oxide; TD = transdermal; TNF = tumor necrosis factor; VEGF = vascular endothelial growth factor; NA = not available.

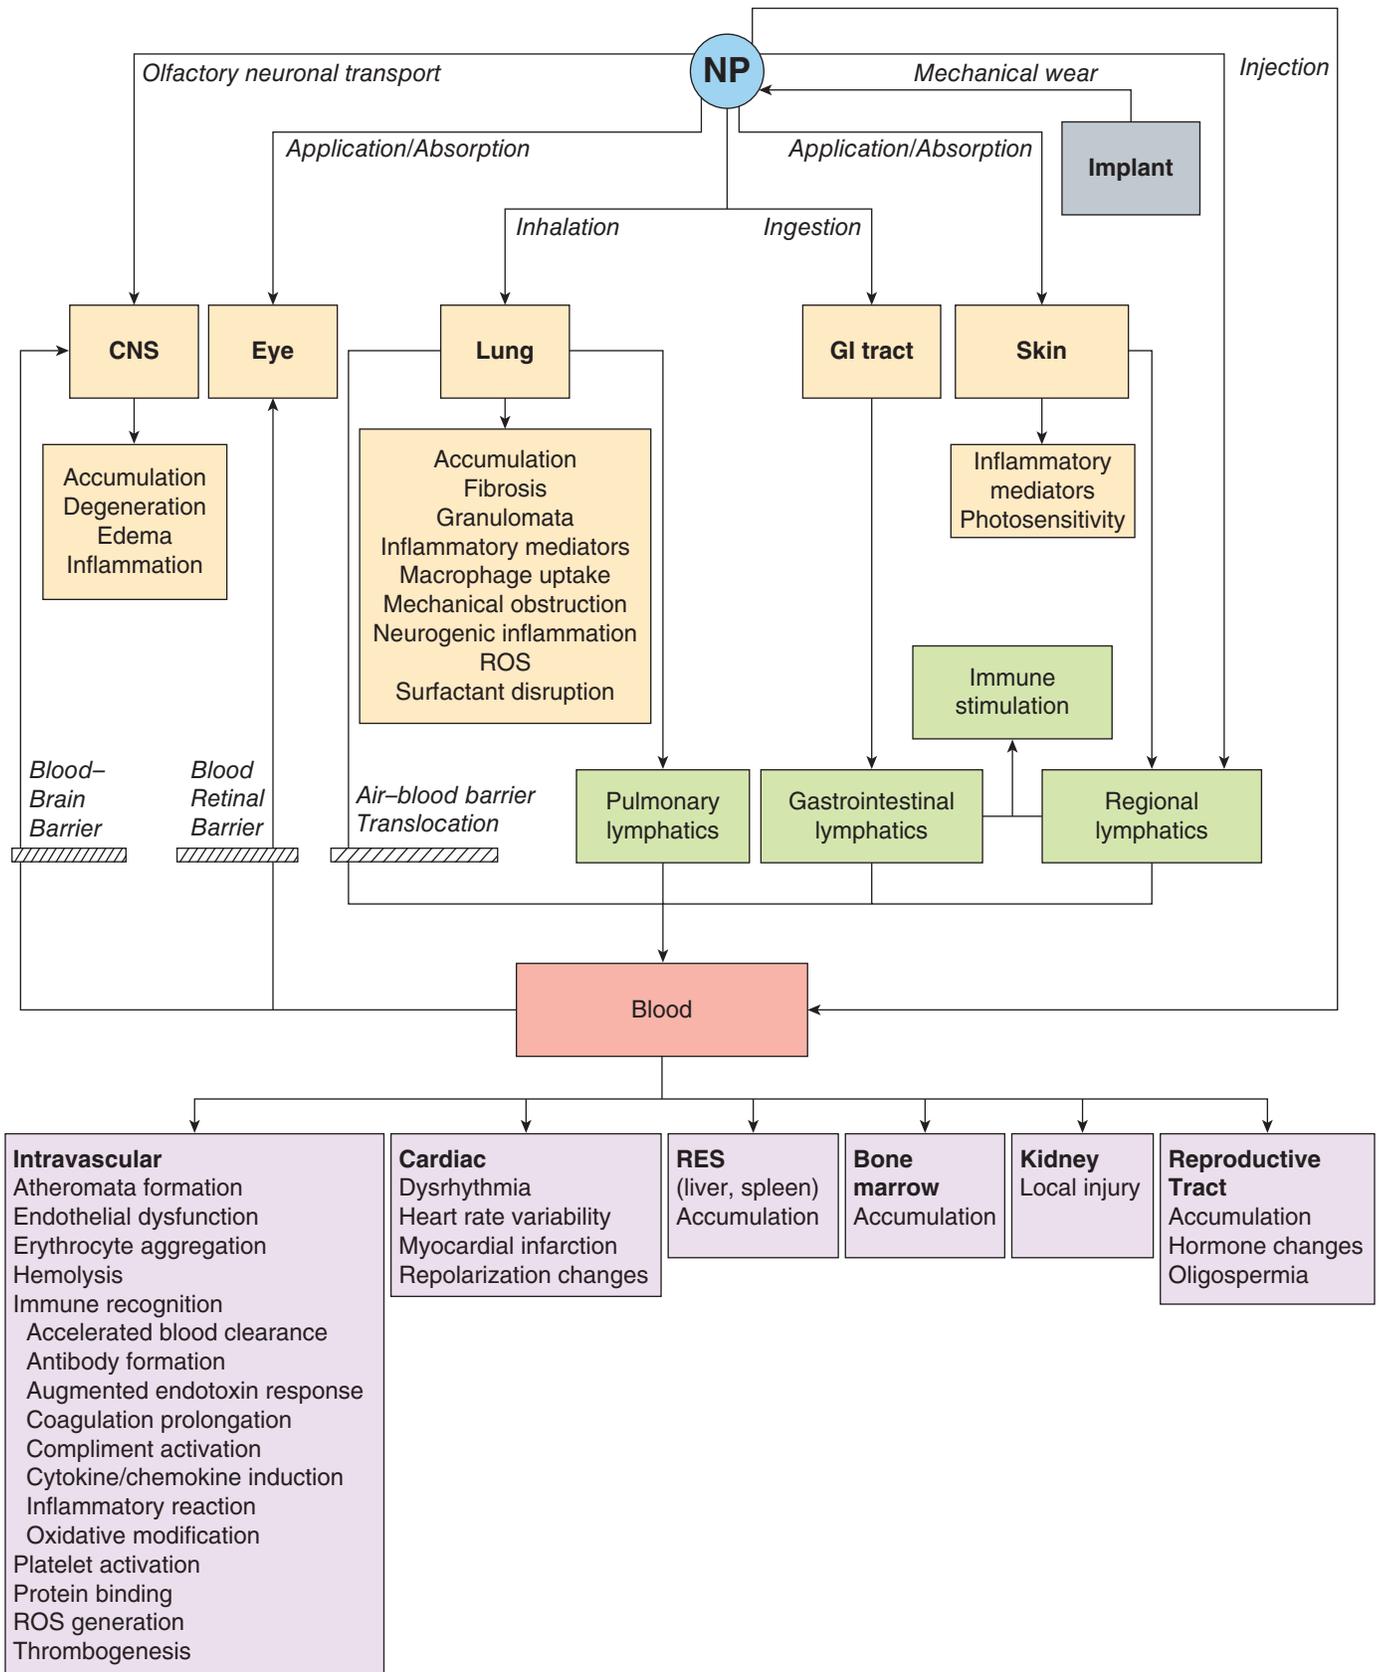

## EXPOSURE AND DISTRIBUTION

Nanoparticle exposure is anticipated through a variety of mechanisms (Fig. 125-2). Exposure might occur through environmental discharge into air, water, or soil during the primary manufacturing process; disposition of industrial or research waste; mixing, weighing, or dumping powders; active cleaning processes or component replacement between production; or engine combustion. Sanding, machining, wearing and weathering, or disposing of nanomaterial-containing products could also liberate nanoparticles. Exposure might also occur during biologic elimination from a primary target or caused by implant or device wear. Nanoparticles can be consumed and then subsequently transformed, sequestered, re-released to the environment, or potentially accumulate in the food web.<sup>32</sup>

### Dermal Exposure

Podoconiosis (endemic nonfilarial, geochemical elephantiasis) is presumed to occur from absorption of various colloid-sized elemental particles in irritant clays (aluminum, silicon, magnesium, iron), which undergo macrophage phagocytosis, induce collagenization of afferent lymphatics, and obliterate them.<sup>70</sup> Thus, transdermal exposure to and disease from certain nanoparticles is assumed established. Nanocompositions in paints and coatings, clothing, transdermal drug delivery devices, topical UV protection products, or proprietary cosmetics are of concern. Nanoparticles can be taken up by human epidermal keratinocytes or cause DNA damage; at issue is whether epidermal penetration to effect such damage actually occurs.<sup>273,337,342</sup> Reviews summarizing studies of TiO<sub>2</sub> and ZnO nanoparticles concluded that

dermal penetration for those substances was unlikely beyond the stratum corneum.<sup>273,274</sup> A study of CeO<sub>2</sub>, silver, and TiO<sub>2</sub> nanoparticles applied to a human skin equivalent model did not demonstrate significant dermal irritability and seemed to confirm the protective effect of the stratum corneum.<sup>245</sup> However, TiO<sub>2</sub> and ZnO nanoparticles (in currently available sunscreens) can reside in the stratum corneum and follicular sink.<sup>405</sup> Solvents or diseased (eg, psoriatic), injured, or mechanically stressed skin might increase dermal penetration.<sup>405</sup> In experiments simulating heavy industrial solvent exposure, toluene, cyclohexane, or chloroform could transport C<sub>60</sub> fullerenes across the stratum corneum into viable epidermis.<sup>437</sup> Epidermal and dermal penetration of a phenylalanine-based fullerene amino acid-derivatized peptide occurred via passive diffusion and was enhanced with skin flexion.<sup>333</sup> Oil-water emulsion base products containing diclofenac sodium released nanoparticles capable of reaching human epidermis.<sup>345</sup> Neutral, anionic, or cationic coated commercially available QDs applied to porcine skin at workday exposure doses could attain the epidermis and dermis.<sup>336</sup> Solid lipid nanoparticles were capable of deep penetration in a perfused human skin flap model compared with conventional liposomes and deformable liposomes.<sup>387</sup> Silver nanoparticles cause focal, microscopic inflammation and edema and localize on the surface and in the upper stratum corneum layers when applied topically for 14 days in pigs.<sup>342</sup> Near-infrared QDs intradermally injected in pigs could be followed to sentinel lymph nodes 1 cm below the skin.<sup>178</sup> Intradermally injected CdSe core-CdS capped-PEG nanoparticles remained in the skin and drained via lymphatic ducts to regional lymph nodes and then accumulated in the liver, kidney, spleen, and hepatic lymph nodes.<sup>131</sup>

**FIGURE 125-2.** Potential mechanisms of nanoparticle exposure, distribution, and systemic toxicity. Accumulation may not be limited to the organ systems depicted. CNS, central nervous system; GI, gastrointestinal; NP, nanoparticle; RES, reticuloendothelial system. ROS, reactive oxygen species.

**Inhalational Exposure**

Nanoparticle aerosols may be generated in manufacturing or research environments. Anthropomorphic ultrafine products are encountered in welding, soldering, cooking fumes, and pollution. As the iron-to-carbon (soot) ratio

increases in diesel combustion, the number and size of self-nucleated metallic nanoparticles and larger agglomeration of metallic and carbon particles increase.<sup>197</sup> Carbon fullerenes can be detected in flaming soot after combustion of various hydrocarbon fuels.<sup>361</sup> Combustion-derived nanoparticles carry

soluble organic compounds, polycyclic aromatic hydrocarbons, and oxidized transition metals on their surfaces.<sup>242</sup> Secondary nanoparticles can form in the atmosphere via gas-to-particle conversions after nucleation and coagulation or condensation.<sup>29</sup> Intermediate particles (>80 nm and <200 nm) may remain suspended in air for days to weeks.<sup>401</sup>

Deposition of inhaled particles is determined by various factors, including diffusion and inertial impaction. In rat nasal passages, computational fluid dynamics models predicted that 3-nm particles deposited mostly in the anterior nose, and larger 30-nm particles distributed throughout the nasal passages.<sup>116</sup> However, nasal deposition of nanoparticles does not necessarily prevent systemic exposure. There were significantly more circulating iridium nanoparticles in blood 24 hours after nose-only inhalation compared with direct intratracheal exposure.<sup>186</sup> At deeper levels, gravity contributes to greater particle deposition of fine particles in the central airways instead of the lung periphery.<sup>69</sup> However, particles of less than 2,500 nm reach the alveoli, transported from the airway duct by convective bulk flow combined with particle motion from sedimentation and diffusion.<sup>147</sup> Alveolar deposition models indicate a saddle-shaped, volume- and rate-sensitive curve, a minimum particle deposition at 50 microns, and peak deposition at 30 nm and 4,000 nm.<sup>59</sup> Consistent with theory, total deposition fraction of ultrafine aerosols in healthy human volunteers increased by as median particle diameter decreased from 100 nm to 40 nm as tidal volume increased, and as respiratory flow rate decreased (longer respiratory and retention time).<sup>160</sup> Deep breathing similarly increased deposition of inhaled 100-cm<sup>3</sup> aerosol boluses of <sup>99m</sup>Tc-radiolabeled carbon ultrafine particles. In shallow breathing, particles deposit with a greater proportion asymmetrically in the left lung, for unclear reasons.<sup>247</sup> Although large particles or those with a high aspect ratio (ie, high length to width ratio) would not be expected to achieve deep lung penetration, “aerodynamic diameter” ( $D_{ae}$ )—defined as the diameter of a sphere of unit density (1 g/cm<sup>3</sup>) with the same terminal settling velocity as the particle itself—actually determines respirability.<sup>86</sup> As  $D_{ae}$  is proportional to the fiber diameter and not to its length, “paradoxical respirability” of high aspect ratio nanoparticles can occur.<sup>86</sup>

Clearance may be affected by mucociliary movement, augmented by macrophages at the alveolar level. Macrophages may move particles toward ciliated epithelium, uptake and store particles, or contribute to transepithelial movement, whereby particles may deposit in the basement membrane or enter the lymphatics or bloodstream.<sup>184,224,278</sup> Translocation demonstrates size- and species-dependence. Iridium particles (2–4 nm) crossed the air-blood barrier to reach secondary target organs to a greater extent than carbon (5–10 nm) particles, and translocation and accumulation was greater with 20-nm iridium aggregates than with 80-nm aggregates.<sup>185</sup> Soluble compounds are generally rapidly absorbed. Nanoparticles may evade effective clearance. Several studies have indicated that 15- to 80-nm particles are inefficiently taken up by macrophages (~20%) but are retained in epithelial cells or interstitium.<sup>278</sup> Prolonged particle pulmonary persistence was seen in one human ultrafine particle inhalation study, accounting for translocation and urinary elimination.<sup>252</sup> In an animal study, at 60 days, 81% of multiwalled carbon nanotubes (MWCNTs) and 36% of ground CNTs administered intratracheally (0.5 mg/rat) could be recovered.<sup>254</sup> In contrast to small particles that transit the visceral pleura, reach the pleural space, and drain into the lymphatic system through chest wall pores (3–8 μm), long nanotubes may travel and embed in the subpleural wall and within subpleural macrophages.<sup>85,335</sup>

### Oral Exposure

Multiple nanoparticulate systems are under evaluation for their ability to enhance solubility, permeability, bioadhesion, bioavailability, and efficacy of poorly absorbed drugs, proteins, and vaccines.<sup>75,304,442</sup> Aerosol deposition in the upper aerodigestive tract could provide matter for subsequent swallowing. Indeed, after pulmonary exposure of rats to CeO<sub>2</sub>, fecal recovery was the highest (71%–90%).<sup>310</sup> Nanoparticles can enter bacteria and living cells, providing a mechanism for food-chain bioaccumulation.<sup>26</sup> Mucus appears to be effective in trapping larger nanoparticles.<sup>310</sup> Nanoparticles can cross either paracellularly (between cells) or transcellularly. Transcellular uptake is thought

primarily to occur at associated lymphoid tissue but may also occur at villi. In general, nanoparticle uptake is enhanced by smaller size and absence of charge.<sup>55,146</sup> Hydrophobicity studies show mixed results (depending on altered permeation through various layers).<sup>176</sup> Similar to skin, inflamed or infected intestinal mucosa can increase permeability and alter experimental results.<sup>193</sup> Nanoparticles can also change intestinal permeability as a result of damage to the integrity of the intestinal barrier.<sup>310</sup> Experimental models have demonstrated that nanoparticles can target (potentially selectively) the gut microbiota and the microbiome, for both beneficial (anti-pathogenic) as well as adverse effects (eg, colitis).<sup>311</sup> Single-walled carbon nanotubes (SWCNTs) ingested by *Drosophila* larvae at concentrations as low as 16 ppm traverse the gut wall, enter the dorsal vessel, and can embed in the central nervous system.<sup>202</sup> Mice exposed to ZnO powder (20 and 120 nm) at 1 to 5 g/kg showed pathological damage in stomach, liver, heart, and spleen, with slightly different patterns of effect.<sup>418</sup> Orally administered TiO<sub>2</sub> large particles (475 nm) are associated with gut-associated lymphoid tissue (GALT) and translocated to systemic organs such as the liver and the spleen (6.5%).<sup>159</sup> Macrophages in human GALT frequently contain multiple microparticles: the food additive TiO<sub>2</sub> (100–200 nm), aluminosilicates (kaolinite illite, mica, smectite or vermiculite) (<100–400 nm), and mixed aluminum-free environmental silicates (100–700 nm in length).<sup>316</sup> These correlated with chronic latent granulomatous inflammation in susceptible individuals. Water-soluble fullerenes had very poor oral absorption in one rat study. Trace amounts that did cross the gastrointestinal barrier demonstrated prolonged retention and the ability to reach brain tissue.<sup>439</sup> Four- and 10-nm diameter colloidal gold particle uptake occurred by persorption through single enterocytes at villi in the proximal ileum, distal ileum, and Peyer’s patch regions of the small intestine.<sup>146</sup> Gold nanoparticles (15 nm) similarly penetrated rat intestine in a separate in vitro experiment.<sup>368</sup> Rats fed silver nanoparticles (~60 nm) showed dose-dependent accumulation kidneys, liver, brain, lungs, and blood; female rats showed more accumulation of silver nanoparticles in all kidney regions.<sup>179</sup>

### Internal Deposition and Degradation

Additional understanding of human–particle interactions proceeds from experience with early colloidal treatments for rheumatoid arthritis, surgical procedures, and implanted devices. Decades ago, it was demonstrated in human and animal models that gold particles of less than 20 nm could spread beyond injected joints to lymph nodes, liver, spleen, and kidneys to induce cellular uptake, mitochondrial damage, and degenerative renal tubular lesions.<sup>372,446</sup> Metallic fragments from surgical diathermy instruments can deposit in urinary tract tissues to induce granulomatous inflammation.<sup>144</sup> Joint replacements and spinal implants can produce particulate wear debris. Dense and loose connective tissue, giant cells, macrophages, and phagocytosed iron and chromium particulate debris have been found surrounding stainless steel spinal implants removed because of late operative site pain.<sup>352</sup> In hip implants, periprosthetic tissue may contain cobalt, chromium, and bone cement wear particles.<sup>42,130</sup> Local particle accumulation leads to a repetitive cycle of macrophage phagocytosis, cell degeneration and death; release of intracellular enzymes and ingested metallic debris; and tissue necrosis.<sup>341</sup> Polyethylene micro-sized wear particles promote osteoclast differentiation, which could contribute to periprosthetic osteolysis.<sup>41</sup> Submicron wear particles (including polyethylene; titanium, alloys of titanium–aluminum–vanadium, cobalt–chromium–molybdenum, and stainless-steel cobalt–chromium–nickel–tungsten; barium sulfate; zirconium oxide; and corrosion products of cobalt–chromium and stainless steel) from patients with failed orthopedic replacements disseminated to the lymph nodes, liver, and spleen.<sup>411</sup> Lymph nodes demonstrated both granulomatous and fibrotic reactions and particle-laden macrophages; elevated serum metal concentrations and granulomatous lesions in the liver and spleen were occasionally found. Rare, severe deterioration can produce massive metallosis and systemic metal toxicity.<sup>283</sup> Metal-on-metal hip resurfacing arthroplasty, large head total hip replacement, and non–metal-on-metal dual modular neck total hip replacement create distinct wear and macrophage, lymphocyte, and eosinophil recruitment patterns, with higher blood levels of Co and Cr ions

in the metal-on-metal groups caused by generation of a higher total metallic particles burden.<sup>438</sup>

### Circulation, Retention, and Elimination

As indicated in the previous sections, circulatory access may occur through intravenous (IV) administration of nanoparticle pharmaceuticals, upper respiratory and pulmonary translocation, intestinal absorption, dermal penetration, or draining lymphatics (Fig. 125–2). In human volunteers, inhaled <sup>99m</sup>Tc-labeled ultrafine carbon particles (<100 nm) reached the blood within 1 minute, peaked between 10 and 20 minutes, and persisted for up to 60 minutes.<sup>270</sup> Both hepatic accumulation and urinary excretion occurred. Gold nanomers (30 nm) can be recovered rapidly in blood platelets of the alveolar capillaries after rat intratracheal injection.<sup>20</sup> Aerosolized gold nanoparticles accumulated in more than 20 rat organs and tissues, particularly the lungs, esophagus, kidneys, aorta, spleen, and heart.<sup>451</sup>

Tight junctions (<2 nm) between endothelial cells preclude most nanoparticle exit from systemic circulation. However, organ-specific endothelial characteristics (hepatic fenestrations and splenic discontinuity), transcytosis, or leak-inducing disease conditions (inflammation and cancer) may allow exit of large particles. Reticuloendothelial system (RES) and renal clearance are particle and coating specific.<sup>182,203</sup> Shielding nanoparticles with neutral compounds or those providing steric repulsion or hindrance is thought to impair opsonization with subsequent RES clearance.<sup>289</sup> Neutral charge may also improve renal elimination of certain dendrimers.<sup>2</sup> Size differences of as little as 2 micrometers may shift elimination from renal to hepatic.<sup>180</sup> Prolonged circulation or tumor-retention times are often the goals of nano-based pharmaceuticals, and a large variety of modifications and delivery systems have been described.

### DETECTION AND DOSE QUANTIFICATION

Previous sampling of generated aerosols generally focused on the average chemical composition and the mass of all deposited particles, with the exception of asbestos, for which the number of fibers with a specific shape and composition is important.<sup>237</sup> Production of engineered nanoparticles frequently results in a distribution of sizes. Dose assessment is complicated by the multiple differences among nanoparticles and ongoing investigation as to the most appropriate metric to measure: bulk amount (total particulate mass), particle burden (number of particles of a certain size), size distribution, total surface area, surface functional groups, delivered or deposited dose (per cell or other biological unit), internalized dose, or an alternative metric. Measurement approaches include various devices to assess particle mass directly (filter collection with analysis, size-selective static sampling, tapered element oscillating microbalance) or indirectly (via various impactor technologies), direct number assessments (via electron microscopy, optical or condensation particle counters, differential mobility analyzing systems, and scanning mobility particle sizers), and surface area.<sup>101,120,217,237,264,265</sup> The chosen method is critical because mass concentration measurements can demonstrate significant variation compared with particle number counts in industrial settings.<sup>101,309</sup>

### TOXICITY Overview

Certain organisms intentionally synthesize nanoparticles (eg, selenium-respiring bacteria, magnetotactic bacteria, gold nanoparticles in alfalfa).<sup>117,198,285</sup> The diverse nature of the substances, compositions, structures, and physical properties involved in nanotechnology limits generalization regarding possible human effects. Multiple reviews have attempted to address the diverse issues surrounding nanoparticle toxicity, and various schemes have been proposed to categorize nanoparticles.<sup>10,94,137,217,224,277,295,363</sup> One older review reported 428 studies documenting adverse effects of 965 unique nanoparticles.<sup>137</sup> Reviews of a single “class” of nanoparticles have documented both adverse and neutral effects. Inference of systemic biological effects in humans is hindered by the *in vitro* nature of many experiments. Differences in experimental methodology, cell line, substance concentration, particle size and

geometry, exposure parameters (route, duration, and frequency), duration of observation, and endpoints or surrogate markers have hindered comparisons. Long-term effects data are lacking. Cell-line specific, organ-specific, and species-specific toxicities remain to be fully characterized.

To address these deficiencies, methodologies are being developed to assess nanotechnology risk in a systematic fashion. Classifying nanoparticles based on the results of multidose-range biological assay profiles (adenosine triphosphate content, reducing equivalents, caspase-mediated apoptosis, and mitochondrial membrane potential) in multiple cell lines has been advocated.<sup>360</sup> Other techniques to evaluate toxicity and biological reactivity of nanoparticles have been reviewed and include cellular proliferation, necrosis, and apoptosis assays; reactive oxygen species (ROS) generation and oxidative stress; activation of proinflammatory signaling or other messenger molecules; genotoxicity and gene expression analysis; and *in vivo* exposure route, short- and long-term effect, tissue localization, biodistribution, and clearance studies.<sup>233,366,374</sup> Studies and models of quantitative structure-activity relationships may take on more importance to profile toxicity as the number of compounds proliferates.<sup>323,428</sup>

Despite the many unknowns, antecedent work within the discipline of particle toxicology has provided extensive epidemiologic and experimental evidence associating airborne pollution particulate matter (PM) with human mortality; cardiovascular, pulmonary, neurologic, and reproductive injury; altered neurocardiac function (decrease heart rate variability and repolarization); and malignancy.<sup>38,77,83,174,300,307,334,412,452</sup> The strength of the association depends on the particle size, type, and the outcome of interest. Similarly, ultrafine particles in home-generated cooking fumes have received attention for their possible role in pulmonary disease, inflammation, and genotoxicity.<sup>244,366,367,415,433</sup> Furthermore, the route of exposure may be disassociated from the primary organ of toxicity. For example, in rats exposed to airborne silver nanoparticles, the most sensitive target organ was the liver.<sup>424</sup>

Genetic or unique susceptibilities to nanoparticles are not well categorized. Preexisting acute or chronic disease (pulmonary disease, cardiac disease, malignancy, infection) or individual genetic variations (resistance to oxidative stress, immune composition, surface or serum proteins) may modify nanoparticle toxicity. For example, after identical ultrafine particle aerosol exposure, patients with chronic obstructive pulmonary disease (COPD) received an increased “dose” (deposition factor, rate, or both) compared with normal participants.<sup>40</sup> Retention of ultrafine particles was similarly higher in patients with COPD than healthy nonsmokers.<sup>252</sup> Patients with preexisting cardiovascular disease or older age show increased susceptibility to concentrated ambient air pollution particles.<sup>77</sup>

Although the following sections generally report “positive” studies to highlight nanotoxicity principles, it is important to acknowledge that many other studies have also produced negative results, and some have challenged the concept of “nano-specific” toxicity.<sup>86</sup> Toxicities identified experimentally must be coupled with an understanding of physicochemical properties (which impact organism and environmental transport) and exposure assessments to appropriately characterize risks.

### Specific Factors Affecting Toxicity

#### Dose

Depending on the nanosubstance, “dose” (particle number or bulk amount) may or may not play a role. Appropriate dose–response curves (linear, supra-linear, biphasic, or threshold) for different toxic effects have not yet been described for most particles.<sup>278</sup> For example, anti-*HER2* antibody-tagged silica-gold nanoshells showed no inherent *in vitro* toxicity to breast adenocarcinoma cells over a range of concentrations and exposure durations.<sup>214</sup> CdSe/ZnS QDs encapsulated in phospholipid block–copolymer micelles injected into *Xenopus* blastospheres were “nontoxic” until doses of  $5 \times 10^9$  nanocrystals per cell produced “abnormalities.”<sup>88</sup> CdSe/ZnS QDs at higher doses (20 nM/L) increased apoptotic cell death and cytokine release.<sup>257</sup> The principal toxicity mechanism changed from intracellular oxidative stress to cadmium ion release as QD concentration increased in another study.<sup>205</sup> Dose-dependent cytotoxicity was seen in human keratinocytes as

SWCNT concentration increased from 0.11 to 10 mcg/mL.<sup>230</sup> Dose- and time-dependent effects were apparent in human peripheral blood lymphocytes exposed to oxidized or pristine MWCNTs.<sup>31</sup> Nano-SiO<sub>2</sub> caused cytotoxicity and induced the apoptotic pathway in dose- and time-dependent manners.<sup>447</sup> In zebrafish embryos, silver nanoparticles induced dose-dependent embryotoxicity and multiple developmental abnormalities.<sup>201</sup> Silver nanowires show dose-dependent cytotoxicity from 1.9 mcg/mL to 1,900 mcg/mL in human laryngeal epithelial and cervical carcinoma cells.<sup>1</sup> Carbon black and fullerene (C<sub>60</sub>) manufactured nanoparticles were genotoxic in vitro and in vivo in a dose-dependent manner.<sup>395</sup>

### Size and Surface Area

Despite a comparable exposure on a mass-for-mass basis, nanoparticle toxicity may diverge significantly from bulk material. This may occur caused by several factors, including increased surface area, chemical reactivity, or ionization; altered absorption profiles; altered cellular interactions; or access to “protected” intracellular spaces. Cobalt-ferrite particles (6 nm) were more cytotoxic and genotoxic than 10- $\mu$ m or 120- $\mu$ m particles.<sup>63</sup> Cytotoxicity of amorphous silica particles increased 33-fold as particle size decreased from 104 nm to 14 nm.<sup>263</sup> Elemental carbon particles (5–10 nm) induced significantly more inflammatory mediators than larger carbon black particles (14 or 51 nm).<sup>17</sup> CoCr nanoparticles generate more superoxide and hydroxyl free radicals and more DNA damage than CoCr microparticles, possibly because of faster dissolving or corrosion within the cell.<sup>293</sup> TiO<sub>2</sub> nanotubes (diameter, 15–30 nm) permitted the best cellular adhesion, migration, viability, and differentiation compared with larger 50-nm nanotubes.<sup>298</sup> CdTe QDs of approximately 2 nm, 4 nm, and 6 nm had over a sixfold difference in inhibition of human hepatoma cell growth.<sup>455</sup> CdTe QDs (2.1 nm) can rapidly enter the nucleus of human macrophages, and gold nanoparticles (1 nm) can penetrate cell and nuclear membranes.<sup>259,398</sup> CdTe QDs (2.2 nm) were more cytotoxic than equally charged, larger QDs (5.2 nm).<sup>218</sup> Nano-tungsten carbide-metallic cobalt particles (~80 nm) generated more hydroxyl radicals induced greater oxidative stress and caused faster cell growth/proliferation than fine (4- $\mu$ m) particles.<sup>79</sup> The toxicity of silver nanoparticles increased as size decreased from 100 nm to 10 nm via multiple mechanisms—cytoplasmic uptake, apoptotic markers, proautophagic proteins, and inflammasome activation all increased.<sup>243</sup> Gold nanoparticles of 1.5 nm were particularly cytotoxic and eliminated stem cell differentiation compared with those that were 4 nm and 14 nm.<sup>353</sup>

### Composition

Toxicity may be primarily related to that of the bulk material. Elemental carbon particles (90 nm) were found to be significantly more toxic than diesel exhaust particles of comparable size (120 nm).<sup>360</sup> Redox-active transition metals may pose a particular hazard.<sup>86</sup> Gold, chrysotile asbestos, Al<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub>, ZrO<sub>2</sub>, and TiO<sub>2</sub> nanoparticles differed in cytotoxicity in murine lung macrophage cells.<sup>370</sup> Quantum dot core materials (cadmium, lead, selenium) can be toxic at relatively low concentrations to the plasma membrane, mitochondrion, and nucleus.<sup>58,139,219</sup> Degradation of coated nanoparticles in the acidic and oxidative conditions of endosomes and lysosomes may result in exposure to inherently toxic core materials or ions. Derivatization or degradation may mitigate or exacerbate toxicity. Functionalization with quaternary amines prevented silica mesoporous nanomaterial-induced cellular injury.<sup>383</sup> Conversely, compared with “pristine” SWCNTs, acid-functionalized SWCNTs blocked cell cycling of murine lung epithelium cells and produced a more pronounced inflammatory response in mouse lungs in vivo.<sup>346</sup> Similarly, oxidized MWCNT were significantly more toxic to human T cells than their “pristine” counterparts or carbon black.<sup>31</sup> Decay of certain water-soluble fullerenes produces daughter compounds with increased toxicity in vivo.<sup>21</sup>

### Contaminants

Contaminants may introduce or mitigate toxicity. “Doping” intentionally introduces impurities to modify the behavior of materials (eg, electrical properties of semiconductors). Similarly, doping can change the electronic, optical, and magnetic properties of nanocrystals.<sup>275</sup> Nitrogen doping of

MWNTs improved biocompatibility and reduced lethality in mice exposed via multiple routes.<sup>47</sup> Nitrogen-doped MWCNTs also proved more biocompatible in *Entamoeba histolytica*.<sup>93</sup>

The manufacturing process may unintentionally instill contamination—atomic or molecular impurities in the nanomaterial structure itself, residual reagents or catalysts, or manufacturing byproducts. Even “purified” SWNT retain significant percentages of cobalt, molybdenum, iron, nickel, yttrium, and zinc.<sup>192,229</sup> Consequentially, nonpurified, iron-rich SWCNTs (26 wt.% of iron) generated hydroxyl radicals and lipid hydroperoxides and depleted glutathione more than “purified” SWCNTs (0.23 wt.% of iron).<sup>165</sup> Purified fullerenes generate significantly less biological oxidative damage and adverse mitochondrial effects than unrefined fullerenes.<sup>18,322</sup> Residual contaminants and impurities of substances used in surface modification of QDs are cytotoxic and genotoxic in vitro.<sup>150</sup> Washing off unbound cetyltrimethylammonium bromide eliminated near total lethality of gold nanoparticles modified with this compound.<sup>65</sup> Single-walled carbon nanohorns, prepared from pure graphite without a metal catalyst, showed no skin irritation, eye irritation, or perioral toxicity.<sup>246</sup> Endotoxin contamination during manufacturing and handling is particularly problematic. Endotoxin contamination may lead to misattribution or mischaracterization of particular nanoparticle's toxicologic or immunologic profile.<sup>82</sup> Conversely, nanoparticles may exacerbate endotoxin-mediated toxicities.<sup>82</sup>

### Coating and Surfactant Materials

Coating materials may shield toxicity of core compounds or alternatively possess inherent toxicity. They can mediate biocompatibility, duration of circulation, and organ- or cell-specific uptake. For example, various densities of electrostatic poly(glutamic acid)-based peptide coatings altered delivery of cationic polymer-plasmid DNA nanoparticles to the liver, spleen, and bone marrow.<sup>140</sup> Quantum dots coated with carboxylic acids, amines, or polyethylene glycol (PEG) increased uptake by human epidermal keratinocytes in that order, with carboxylic acid coated with QDs demonstrating cytotoxicity 24 hours earlier.<sup>337</sup> Nanoparticle cores of 2-diethylamino ethyl methacrylate polymerized with poly(ethylene glycol) dimethacrylate were significantly more toxic to dendritic cells than cores surrounded by a 2-aminoethyl methacrylate shell.<sup>153</sup> Upon inhalation, SiO<sub>2</sub>-coated rutile TiO<sub>2</sub> nanoparticles but not uncoated rutile or anatase or nanosized SiO<sub>2</sub> induced pulmonary neutrophilia and inflammatory markers.<sup>332</sup>

Conversely, covalent materials may reduce toxicity. Dextran coatings decrease iron oxide nanoparticle toxicity (while also mediating superparamagnetic behavior).<sup>359</sup> Carboxylic acid grafting of cobalt-ferrite nanoparticles reduced toxicity by reducing leaching of Co<sup>2+</sup> into solution.<sup>63</sup> Gelatin coating reduced (but did not eliminate) cytotoxicity of CdTe QDs in human acute monocytic leukemia cells.<sup>43</sup> Polyethylene glycol substituted CdSe core/CdS shell QDs were less cytotoxic extracellularly than “bare” QDs.<sup>50</sup> However, some benign coatings can be rendered cytotoxic by air exposure or photodecomposition.<sup>74</sup>

Nanoparticles tend to aggregate due to attractive forces (Van der Waals), and become progressively difficult to re-disperse as size decreases.<sup>317</sup> Single-walled carbon nanotubes agglomerations induced significantly more adverse effects than identical, well-dispersed SWCNTs.<sup>426</sup> Because CNTs are intensely hydrophobic, solvents or surfactant materials are used to disperse them and avoid clumping, although these materials themselves may be cytotoxic.<sup>426</sup> Exposure to protein-rich biological fluids may change the tendency to agglomerate and therefore produce size-dependent effects. Using surfactants to disperse nanoparticles (eg, SWCNTs) can decrease protein adherence and therefore alter biological effect or fate.<sup>90,122</sup>

### Geometry and Architecture

Nanoparticle geometry may modulate toxicity and biological interactions. Previous observations suggested that toxicity might vary with the type of crystalline structure of a given material. For example, asbestos particle shape affects genotoxicity, and inflammatory and mutagenic properties vary by silica type (crystalline or amorphous).<sup>348</sup> Identical concentrations various aluminosilicate zeolite crystals (erionite, mordenite, and synthetic zeolite Y)

of 0.1 to 10 micron size produced variant cytotoxicity and hydroxyl radical generation in rat lung macrophages.<sup>102</sup> Material surface defects are important for ROS generation: amorphous TiO<sub>2</sub> crystals were found to generate significantly more ROS than anatase, mixed anatase and rutile, or rutile crystals.<sup>161</sup> In a separate analysis, nano-TiO<sub>2</sub> (anatase) generates more biological oxidative damage than nano-TiO<sub>2</sub> (rutile),<sup>18</sup> and generally anatase nano-TiO<sub>2</sub> is more photocatalytic than the rutile form.<sup>405</sup>

The findings of more significant toxicity from anatase nano-TiO<sub>2</sub> were reproduced in human mesothelial cells. Compared with rutile forms, anatase forms were actively absorbed into cells and generated ROS and oxidative DNA damage.<sup>142</sup>

A high aspect ratio is thought to contribute to nanoparticle pulmonary toxicity, including penetration of the alveolar wall and visceral pleural.<sup>86,241</sup> Single-walled carbon nanotubes produced pulmonary granulomata and inflammation, but nanoparticle carbon black did not.<sup>18,229,365</sup> “Long” (825 nm) CNTs, which were less easily enveloped by macrophages than their 220-nm counterparts, increased the degree of inflammatory response in rats.<sup>344</sup> Asbestos-like pathology was also seen for “long” MWCNT (nanometer diameter, 15+ μm length) in mice.<sup>312</sup> In mice, single-wall nanohorns showed significantly less toxicity than SWCNTs.<sup>222</sup> Nanofibers and graphene nanoplates with high aspect ratios but low aerodynamic diameter can persist to frustrate macrophage engulfment and contribute to toxicity.<sup>349</sup> However, gold nanorods had significantly less cellular uptake than comparable spherical structures.<sup>56</sup> This geometry dependence was reversed upon PEGylation.<sup>228</sup> Long silver nanowires did not show extensive biopersistence, in part because of their transformation to silver salts, although silver was found in subpleural connective tissue and in adjacent subpleural alveolar spaces and septa.<sup>62</sup>

Attachment by HepG2 cells to micelles with PEG copolymer films varied depending on whether PEG polymer was in a “brush” (anchored at one end) or “mushroom” (anchored at both ends) conformation.<sup>153</sup> Compared with control wafers of the same composition, Fe-Co-Ni nanowires hindered macrophage growth and development.<sup>3</sup> Dendritic clusters consisting of aggregated 60-nm nickel nanoparticles produced higher embryonic toxicity than spherical 30-, 60-, and 100-nm particles of the same material.<sup>157</sup>

Additionally, nanoparticles may adsorb varying layers of surrounding biological proteins or lipids, altering their effective size, shape, and density. Curvature and size of the nanoparticle may affect the extent of this “corona” and influence dynamic interactions with bound proteins such as albumin, apolipoprotein, fibrinogen, and complement, which may effect cell entry or receptor interactions.<sup>221,347</sup> Bioassociation may also change nanomaterial properties. Zinc oxide nanoparticles changed particle size, distribution, and charge in the cell culture media.<sup>421</sup> Single-walled carbon nanotubes adsorbed with serum proteins (primarily albumin) had an antiinflammatory effect, which was lost when surfactant-treated SWCNTs precluded adsorption.<sup>90</sup> The same authors found, in contrast, prevention of protein adsorption to amorphous silica particles reduced toxicity. Compared with traditional cell growth media, copper oxide and titanium dioxide nanoparticles in artificial interstitial fluid displayed increased agglomeration, particle deposition, and ROS, and cytotoxicity in human keratinocytes.<sup>48</sup> Conversely, human plasma protein coronas can reduce formation of reactive oxygen and nitrogen species,<sup>61</sup> and pulmonary surfactant mitigates toxicity of silver nanoparticles by reducing silver dissolution into cytotoxic silver ions.<sup>378</sup> Ingested nanoparticles may take on a biocorona derived from food products (eg, β-lactoglobulin-coated gold nanoparticles coingested with milk).<sup>310</sup>

### Charge

Surface charge (zeta potential, ζP) may significantly alter the physical characteristics of nanoparticles, biological interactions, or effects. Neutral SWCNT aggregate in aqueous solution; introducing a strong negative charge induces dispersal.<sup>346</sup> Negatively charged nanoparticles permeated model pig skin, which excluded positively charged and neutral particles.<sup>181</sup> Increasing surface charge density alters protein absorption; a positive charge promotes electrostatic association with negatively charged serum proteins.<sup>121,140</sup> Charged nanoparticles are recognized as important inducers of complement

activation.<sup>80</sup> Strongly charged particles can also mediate direct membrane damage (hole formation) in the lipid bilayer.<sup>148,149</sup> Positively charged polystyrene nanospheres induced oxidative stress; those with neutral charge did not.<sup>436</sup> Toxic effects of strongly negatively charged acid-functionalized SWCNTs were abrogated by pretreatment with neutrality-inducing L-lysine.<sup>346</sup> Positive charge mediates actin-dependent amorphous silica nanoparticle movement along filopodia and microvilli like structures.<sup>287</sup> Mouse peritoneal macrophages and human hematopoietic monocytic cells show charge-dependent endocytosis—the higher the negative or positive surface charge of albumin particles, the greater the uptake.<sup>331</sup> An overlap of the conduction band energy (E<sub>c</sub>) level of metal oxide nanoparticles with the cellular redox potential (-4.12 to -4.84 eV)—which signifies the permissibility of electron transfers in biological environments—correlated with induction of oxygen radicals, oxidative stress, and inflammation.<sup>453</sup> Also, within lysosomes, positively charged nanoparticles are capable of acting as “proton sponges,” enhancing cytoplasmic delivery and inducing cell death signaling.<sup>336</sup> Metal nanoparticles in mixtures can also change each other’s charge and therefore the associated corona content and composition and cellular uptake.<sup>76</sup>

### pH

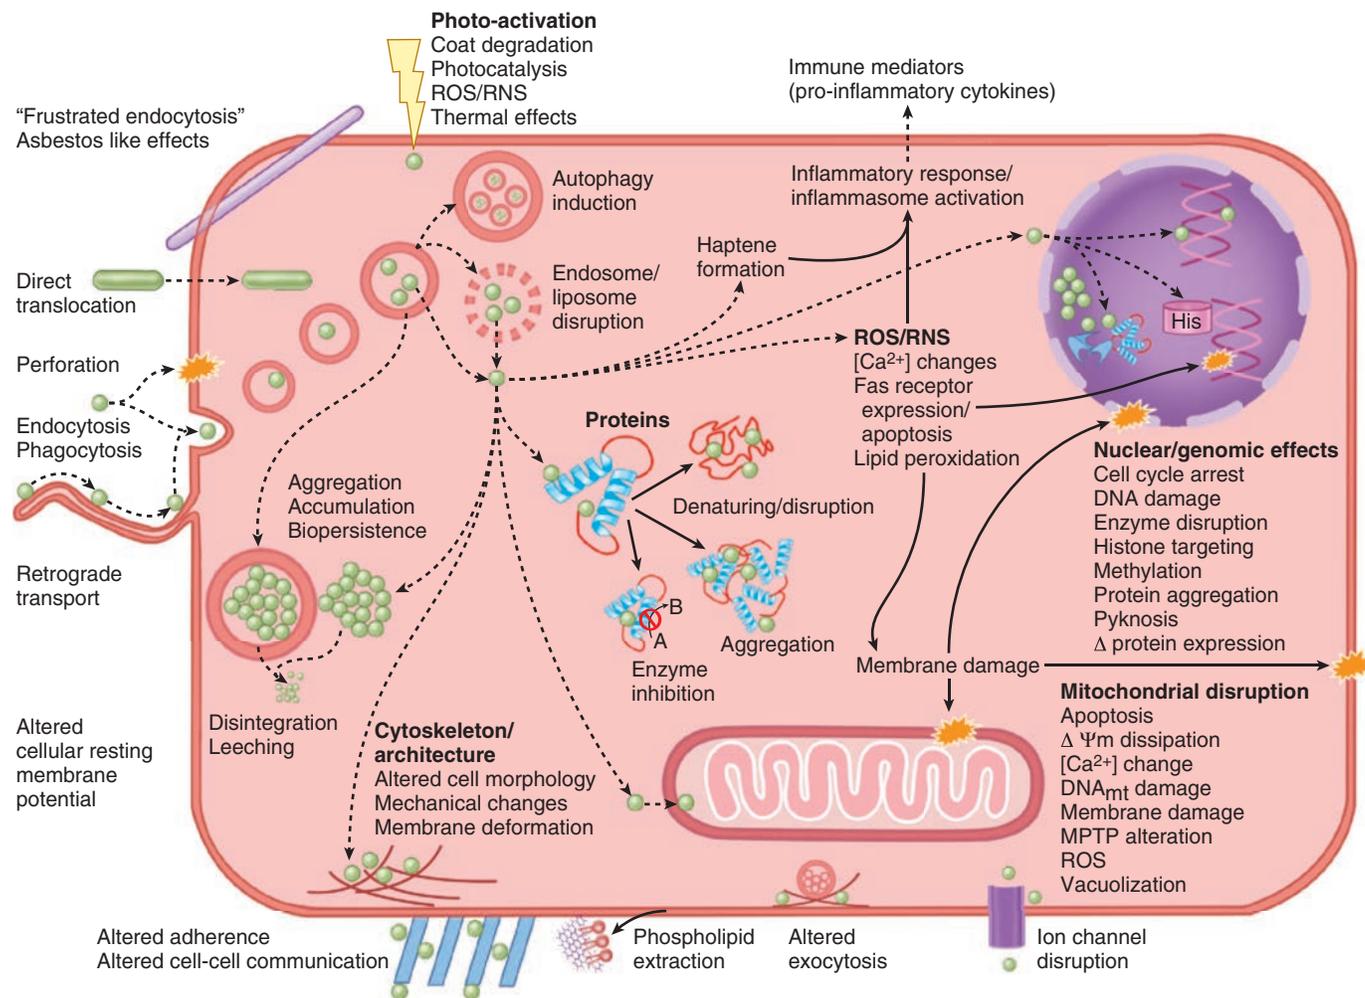

pH can affect toxicity by altering charge, solubility, protective or functional groups, bioavailability, and other mechanisms. As pH was dropped from above 6 to 2, the ζP of citrate-stabilized silver nanoparticles dropped from -50 to neutral and resulted in aggregate formation.<sup>97</sup> pH alters the ζP of both microemulsion (3–5 nm) and hydrothermal (8–10 nm) cerium oxide nanoparticles, which in turn alters protein adsorption and cellular uptake.<sup>299</sup> The significant toxicological difference in mice between 23.5-nm and 17-μm copper particles was judged secondary to stomach retention, with persistent depletion of H<sup>+</sup> ions leading to systemic metabolic alkalosis and generation of ionic copper.<sup>240</sup> CdSe core QDs exposed to low-pH simulated gastric fluid decreased cell viability in vitro, possibly caused by degradation of the ZnS shell and increased solubility of cadmium from shell-free particles.<sup>419</sup> Acidic intracellular organelle localization raises degradation and damage concerns; the inflammatory potential of 15 metal/metal oxide nanoparticle correlated with acidic conditions, hypothesized to be related to elimination of the corona in lysosomes to expose a charged surface.<sup>57</sup> Targeted drug delivery employs intentional engineering of pH-responsive nanoparticles. In the acidic environment of the endosome or lysosome (~pH, 4.5), core-shell particles can swell by almost three times, disrupting these structures and allowing cytosolic entry.<sup>153</sup> Alternatively, at altered pH, certain functional groups can be cleaved, resulting in altered charge and improved QD delivery.<sup>249</sup>

### Cellular Toxicity

At the cellular level, nanoparticle toxicity has been attributed to multiple mechanisms (Fig. 125–3). Oxidative stress, membrane and cytoskeleton structural alterations, cytoplasmic and nuclear protein interactions, energy failure, phototoxicity, autophagy, and genotoxicity have all been described. Nanoparticles may stress cell types differently. This may be due to engineered properties (associated targeting molecules), properties of nanomaterials themselves (size-dependent reticuloendothelial system deposition), or biological processes of target cells (phagocytosis ability, resistance to oxidative stress, cytoskeletal architecture, cell division propensity). Tests in immortalized cell lines may not reflect in vivo findings because of inherent differences in genomic stability or specifically selected traits.

### Uptake

Unintended cellular uptake may contribute to toxicity. Depending on the particle architecture, several mechanisms have been described, including phagocytosis or endocytosis (clathrin-mediated, scavenger receptor-mediated, mannose receptor-mediated, Fcγ receptor-mediated, complement receptor-mediated), potocytosis (caveolin dependent), (macro)pinocytosis, and direct cytoplasmic entry.<sup>81,118,268,296,362,390,408</sup> Various types of ammonium-, acetamido-, fluorescein isocyanate-, and methotrexate/fluorescein isocyanate-functionalized SWCNTs and MWCNTs were internalized by a wide

**FIGURE 125-3.** Potential mechanisms of nanoparticle cellular toxicity.  $\Delta\Psi_m$ , mitochondrial membrane potential,  $DNA_{mt}$ , mitochondrial DNA; His, histone; MPTP, mitochondrial permeability transition pore; RNS, reactive nitrogen species; ROS, reactive oxygen species. Additional mechanisms of toxicity may be induced by nanoparticle contaminants.

range of cell lineages (mammalian, fungal, yeast, and bacterial), some of which lack phagocytic and endocytic capacity, and under conditions that block energy dependent pathways.<sup>183</sup> Dextran-coated superparamagnetic iron oxide (SPIO) nanoparticles are taken up by human monocyte-macrophages and concentrated into lysosomes in a nonsaturable manner.<sup>256</sup> Nonendocytic uptake (eg, 78-nm fluorescent polystyrene microspheres and 25-nm gold particles) provides nonmembrane-bound nanoparticles direct access to intracellular proteins, organelles, and DNA.<sup>119</sup>

Engineered nanoparticles, which are capable of endocytosis, would be expected to translocate to distant sites within the body.<sup>94</sup>

### Oxidative Stress

Oxidative stress with subsequent lipid peroxidation, DNA damage, and apoptotic or necrotic pathway induction is a significant concern. Biological oxidative damage as assessed by the ferric reducing ability of human serum revealed a diverse capacity for oxidative potential among nanoparticles.<sup>18</sup> Nanoparticles may donate electrons directly to molecular oxygen to produce superoxide, participate in redox cycling and Fenton chemistry, and interact with light to alter electron pairs.<sup>32</sup> Metal oxide nanocompounds (eg,  $Co_3O_4$ ,  $Cr_2O_3$ ,  $Ni_2O_3$ ,  $Mn_2O_3$ , and  $CoO$ ) capable of electron transfers are effectively produce oxygen radicals and oxidative stress.<sup>453</sup> Research findings are complicated by differences in generation of ROS under abiotic conditions versus intracellularly.<sup>436</sup> Biological media may also alter ROS generation.<sup>111</sup> In neuroblastoma cells, CdTe QDs induced lipid peroxidation and Fas cell death receptor upregulation, which could be mitigated by capping QDs with *N*-acetylcysteine (NAC).<sup>58</sup> Adult zebrafish raised in solutions containing

silver nanoparticles demonstrated oxidative injury, apoptosis, and cellular stress response (eg, GSH and p53 induction).<sup>60</sup> Fullerenes have shown more conflicting results. Depending on experimental conditions and purity, they may either induce  $O_2^-$  and  $\cdot OH$  or possess antioxidant (and anti-oxidation) activity.<sup>123,440</sup> Single-walled carbon nanotubes and tungsten carbide-cobalt nanoparticles generate ROS and activate pathways leading involved in cytotoxicity and neoplastic transformation.<sup>79,230</sup>

### Organelle and Substructure Damage

Nanoparticles may compromise diverse subcellular components. Mitochondrial reduction capacity (eg, MTT assay) is one of the standard in vitro methods to assess nanoparticle toxicity. Nanoparticles' mitochondrial toxicity includes alterations in mitochondrial calcium levels, dissipation of the mitochondrial membrane potential, lipid membrane destruction, and localization within the mitochondria.<sup>58,219,291,436</sup> Small gold nanoparticles (3 nm) can access the voltage-dependent anion channel (porin) to cross the mitochondrial membrane.<sup>338</sup> Induction of the mitochondrial base excision repair pathway enzymes suggests that MWCNTs can induce mitochondrial DNA damage.<sup>457</sup> PAMAM dendrimers (45 nm) can downregulate mitochondrial DNA-encoded genes involved in the maintenance of mitochondrial membrane potential and caused the release of cytochrome C, triggering apoptosis.<sup>200</sup>

Quantum dots (2.1 nm) have been visualized to localize rapidly (<30 min) and preferentially in the nucleus of human macrophages, mediated by endosomal transport along microtubular tracks.<sup>259</sup>  $Co_3O_4$  nanoparticles (45 nm) readily enter cells and their nucleus in vitro.<sup>294</sup> Single-walled carbon

nanotubes can accumulate in the cell nucleus by crossing the lipid bilayer.<sup>314</sup> Genotoxic consequences of this migration are described later.

Nanoparticles may cause disruption and compromise integrity of biological membranes by such means as hole formation in the lipid bilayer.<sup>148,149</sup> Alteration in cellular adherence, migration, and actin cytoskeleton or microtubule function and structure have been described after exposure to SWCNTs, gold/citrate, TiO<sub>2</sub>, SPIO nanoparticles, and others.<sup>114,125,132,166,305</sup> Calcium-mediated cytoskeletal function (as evidenced by cell stiffening) was altered by ultrafine carbon particles (12 nm, 90 nm) but not by diesel exhaust or urban dust particles.<sup>251</sup> Functional processes may be impaired in the absence of the loss of viability. SiO<sub>2</sub>, TiO<sub>2</sub>, Ag, and Au, alone or functionalized with either positive or negative side chains, altered exocytosis and decreased secretion of chemical messenger molecules.<sup>216,235</sup> Other protein functions may also be altered by nanoparticles. Copper nanoparticle clusters selectively induced unfolding and precipitation of hemoglobin A0 and E, but almost none occurred with hemoglobin A2.<sup>25</sup> Nanoparticulate anatase TiO<sub>2</sub> (5 nm) can directly bind lactate dehydrogenase and induce protein unfolding.<sup>87</sup> C<sub>60</sub> fullerene noncompetitively inhibits glutathione peroxidase in a substrate-specific manner.<sup>158</sup> Although relatively high concentrations were required (250 μM), the C<sub>60</sub> fullerene derivative dendrofullerene selectively inhibited P450 metabolism of progesterone.<sup>109</sup> Graphene nanosheets induce toxicity via numerous mechanisms, including deformation and breaking of peptide α-helix structures and DNA base pairs, direct cutting of cell membranes, and destructive lipid extraction onto the material surface.<sup>456</sup> Modification of protein structures by reactive nanoparticles might also serve as a mechanism for haptene formation and immunoreactivity.

Separately, cadmium QDs and other nanoparticles have been found to induce cell death by autophagy (formation and accumulation of QD-containing autophagosomes, followed by lysosome fusion, and degradation of autophagosomes by lysosomes), as opposed to apoptosis.<sup>104</sup> Similarly, carbon nanotubes upregulate autophagy-related genes and autophagosome vacuoles.<sup>399</sup>

### Gene Expression and Genotoxicity

Overwhelming nanoparticle toxicity can induce a cascade of expression of genes involved in apoptotic, autophagocytic, or necrotic pathways. Nanoparticles can also upregulate stress- and inflammation-related genes as well as alter expression of genes involved in the cytoskeleton, trafficking, protein degradation, metabolism, growth and division, and detoxification. As a consequence of direct nuclear entry, nanoparticles can aggregate within the nucleus, bind directly to DNA or chaperone proteins, or induce nuclear membrane damage. Gold clusters (1.4 nm) present in growth media can access and directly associate with the major grooves of DNA to induce complete cell death in multiple carcinoma cell lines at concentrations at which cisplatin is only 10% effective.<sup>291,398,429</sup> Gold nanoparticles can also alter DNA methylation and hydroxymethylation, leading to cell death and failure of stem cell differentiation.<sup>353</sup> As described earlier, graphene nanosheets can deformation and break DNA base pairs.<sup>456</sup> Nanosilver materials similarly bind with *Escherichia coli* genomic DNA.<sup>445</sup> Some QDs can target histones.<sup>259</sup> Other nanoparticles (eg, SiO<sub>2</sub>) can cause clustering of critical enzymes such as topoisomerase I and sequestration of nuclear proteins (histones, splicing factor SC35, nucleolar protein fibrillarin, promyelocytic leukemia body protein and p80 coilin), altering subnuclear architecture.<sup>53</sup> DNA damage also occurs through induction of ROS (compiled by Moller and colleagues<sup>250</sup>). These ROS can affect nuclear DNA mitochondrial DNA differently and can trigger the mitochondria-mediated intrinsic apoptotic pathway.<sup>290</sup>

Nanoparticle damage may be addressed by base repair and other restorative mechanisms or may be so severe that DNA strand breaks, genome duplication or deletion, chromosomal instability, aneuploidy, malignant transformation, and proliferation occur in vitro and in vivo.<sup>154,397,457</sup> Poorly tumorigenic or benign cells can acquire aggressive metastatic capacity when exposed to TiO<sub>2</sub> nanoparticles.<sup>284</sup> Alternatively, premature senescence was recently described using a C<sub>60</sub> carboxylated adduct. Such an ability could be protective as a tumor suppression mechanism or compromise organ systems function.<sup>115</sup>

### Photothermal Toxicity

Nanoparticles containing photoreactive dyes or intrinsic photothermal properties are useful for imaging and attractive for targeted (chemo)therapy. The approved liposomal verteporfin (benzoporphyryrin derivative monoacid ring A) generates <sup>1</sup>O<sub>2</sub> after activation by low-intensity nonthermal laser light (689 nm). This is believed to induce cell death and prevent the loss of visual acuity in patients with subfoveal choroidal neovascularisation.<sup>172</sup> Similarly, dextran-iron oxide nanoparticles linked to a photosensitizer that generates singlet oxygen caused complete cell death when exposed to specific light wavelengths.<sup>239</sup> Nonmetal graphene QDs irradiated with blue light (470 nm) generated ROS, including singlet oxygen, and killed human glioma cells by causing oxidative stress mechanism.<sup>232</sup> C<sub>60</sub>(OH)<sub>22-26</sub>, a water-soluble C<sub>60</sub> derivative under investigation as an antitumor, antibiotic, and drug delivery compound, was only mildly cytotoxic in the dark but was significantly phototoxic to human lens epithelial cells via both type I (free radical) and type II (singlet oxygen) mechanisms under visible light.<sup>427</sup> The concern is that ambient electromagnetic radiation could excite nontherapeutic nanoparticles to generate either ROS or thermal injury. Photolytic conditions have rendered coatings unstable, exposing toxic core metal components.<sup>139</sup> Irradiation of TiO<sub>2</sub>, which can act as a photocatalyst, yields both oxidation and reduction reactions.<sup>113</sup> Gold/citrate nanoparticles (13 nm) were capable of easily crossing human dermal fibroblast membranes and absorbing UV radiation.<sup>305</sup> C<sub>60</sub> fullerenes can generate ROS in the presence of visible light under physiological conditions.<sup>441</sup> The ROS extent depended on C<sub>60</sub> aggregation and associated stabilizing molecules in the aqueous phase.<sup>199</sup> Phototherapy can be harnessed with other modalities for benefit. Laser phototherapy of gold nanostars coated with polyethylene glycol killed primary tumors (photothermal ablation) in mice, but also successfully led to the death of nontargeted distant tumors when anti-programmed death-ligand 1 immunotherapy was administered.<sup>209</sup>

### Miscellaneous Effects

A host of miscellaneous cellular effects are still being characterized. Alterations in cellular resting membrane potential and ion channel functioning by metallic and carbon-based nanoparticles are a particular concern in neuronal tissue.<sup>19,210</sup> Silver nanoparticles caused conformational changes of neuronal voltage-activated sodium currents and produced a hyperpolarizing shift and delayed recovery from inactivation.<sup>211</sup> Quantum dots can provoke intracellular lipid droplet formation caused by accumulation of newly synthesized lipids and downregulation of the β-oxidation of fatty acids.<sup>321</sup> Superparamagnetic iron oxides can generate intracellular gas vesicles.<sup>226</sup> Several nanoparticles have demonstrated ability to stress the endoplasmic reticulum, leading to cell death.<sup>46</sup>

### Organ Systems Toxicity

#### Central Nervous System

A significant concern is nanoparticles' ability to access "protected" spaces: the brain, the eye, and the reproductive tract. Targeted CNS drug delivery and imaging using engineered nanoparticles via IV or noninvasive, intranasal ("nose-to-brain") administration shows diagnostic and therapeutic promise (eg, for dementia, Parkinson disease, and stroke).<sup>106,171</sup> However, unintended CNS access is worrisome, particularly because inhaled nanoparticles must first transit the upper respiratory tract. Translocation of insoluble iridium nanoparticles to brain was eightfold higher with nose only inhalation compared with intratracheal inhalation.<sup>186</sup>

Seventy-five years ago, the intranasal inoculation of small viral (nano) particles (the poliomyelitis virus, 25–30 nm) was shown to produce extensive polio invasion of the olfactory bulbs and lesions extending in a continuous series to the brain stem and beyond.<sup>27,28,151,396</sup> Other small viruses (vesicular stomatitis, herpes simplex, and rabies virus) also access retrograde transport from the olfactory bulb to reach deeper brain structures.<sup>327</sup> Anthropomorphic and engineered nanoparticles also may use this mechanism, with variable efficacy. Nanogold particles injected into rabbit olfactory areas demonstrated a direct connection between the olfactory bulb and the cerebrospinal fluid.<sup>67</sup>

Intranasal instillation of SiO<sub>2</sub>-nanoparticles in rats led to wide distribution, striatal deposition, and a reduction in dopamine activity.<sup>432</sup> In inhalation-exposed rats, ultrafine elemental <sup>13</sup>C particles translocated into axons of the olfactory nerve.<sup>279</sup> Rats exposed to aerosolized gold nanoparticles (20 nm) experienced particle distribution to the olfactory bulb and entorhinal cortex.<sup>451</sup> Rats exposed to poorly soluble manganese oxide ultrafine particles (30 nm) showed olfactory bulb uptake and CNS delivery to the striatum, frontal cortex, and cerebellum.<sup>91</sup> Other animal models demonstrated that cadmium, cobalt, manganese, mercury, nickel, and zinc reach the olfactory bulb when applied intranasally, and neuronal connections carry cobalt, manganese, and zinc into deeper brain structures.<sup>37,143,306,394</sup> Children and dogs exposed to pollution show prefrontal white matter hyperintense lesions, which are associated with significant cognitive deficits in children. Ultrafine PM deposition, vascular pathology, and neuroinflammation were evident in the dogs.<sup>44</sup> Chronic respiratory tract inflammation might further diminish nasal respiratory and olfactory barriers and contribute to brain inflammation.<sup>308</sup>

Circulating nanoparticles may reach the brain. The blood–brain barrier (BBB) might be infiltrated via low-density lipoprotein receptor–mediated transcytosis of nanoparticles with nonspecific apolipoprotein adherence, endocytic processes, paracellular aqueous diffusion, or transcellular lipophilic diffusion.<sup>106,355</sup> Intravenously administered water-soluble fullerene and intraabdominally injected nano-TiO<sub>2</sub> (5 nm, anatase) migrate to brain in experimental models.<sup>106,439</sup> Nanoparticle entry can produce CNS inflammatory changes, inflammatory gene expression, demyelination, oxidative stress, lipid peroxidation, and NO generation; change neurotransmitter concentrations; and alter mitochondrial energy production.<sup>45,91,213,223,357,454</sup> Cyclooxygenase-2, interleukin (IL)-1 $\beta$ , and CD14 upregulation in the olfactory bulb, frontal cortex, substantia nigrae, and vagus nerves and disruption of the BBB associated with PM deposition were reported in patients exposed to high chronic pollution levels.<sup>45</sup> Similarly, IV and intraperitoneal administration in rats of engineered silver, copper, and aluminum nanoparticles disrupted the ventral brain and proximal frontal cortex BBB to produce brain edema.<sup>357</sup>

Nanoparticles can contribute to secondary excitatory neurotoxicity. Intranasal delivery of carbon black (14 nm) increased olfactory bulb excitatory glutamate levels.<sup>393</sup> Similarly, nano-Ag increased spontaneous excitatory postsynaptic currents and network activity.<sup>212</sup> Given the number of CNS and systemic human amyloidoses, a concerning finding was that polymer nanoparticles, QDs, carbon nanotubes, and cerium nanoparticles all greatly enhanced the rate of  $\beta_2$ -microglobulin amyloid fibrillation by decreasing lag time for nucleation.<sup>208</sup> Chronic dietary exposure to TiO<sub>2</sub> nanoparticles in juvenile rainbow trout led to brain accumulation and 50% inhibition of Na<sup>+</sup>, K<sup>+</sup>-ATPase activity, which did not recover after removal from exposure.<sup>325</sup>

### Pulmonary System

The lungs are expected to be the major portal of entry for anthropomorphic nanoparticles and engineered nanoparticles in manufacturing or research settings. Concerns include nanoparticle accumulation and persistent, acute, and chronic inflammation and surfactant disruption. In the bronchial airways, 24-hour retention depends on size fraction, which is negligible for particles greater than 6  $\mu$ m but increases to 80% at 30 nm.<sup>187</sup> In vitro studies show a variety of effects depending on the particle and experimental model. Canine and human alveolar macrophages uptake of elemental carbon particles (5–10 nm) induced lipid mediators AA, PGE<sub>2</sub>, LTB<sub>4</sub>, and 8-isoprostane in a dose-dependent fashion.<sup>17</sup> Single-walled carbon nanotubes activated alveolar macrophages; SWCNTs and C<sub>60</sub> fullerenes disrupted plasma membranes; and SWCNT and MWCNTs effected antigen processing, presentation, and activation of T lymphocytes.<sup>135</sup> In rat alveolar type II and epithelial cells as well as in human bronchial epithelial cells, nanoparticulate carbon black particles (14 nm) induced dose-dependent proliferation via epidermal growth factor receptor (EGF-R) and  $\beta$ 1-integrin membrane receptors, phosphoinositide 3-kinases, and the protein kinase B (Akt) signaling cascade.<sup>409</sup> Cerium oxide nanoparticles can be taken up by human fibroblasts.<sup>207</sup> However, 3-hour exposures to aerosols of this fuel additive, although increasing catalase activity and minimally decreasing glutathione,

did not alter cell viability, ATP content, tumor necrosis factor  $\alpha$  (TNF- $\alpha$ ) production, glutathione peroxidase activity, or superoxide dismutase activity in rat lung slices.<sup>103</sup> Combustion-derived nanoparticles of organic compounds (1–3 nm) were mutagenic in Ames tests.<sup>354</sup> Positive evidence for carcinogenicity of inhaled nanoparticles has been summarized.<sup>330</sup>

All types of carbon nanotubes and nanofibers are considered a respiratory hazard by the National Institute for Occupational Safety and Health (NIOSH).<sup>266</sup> Carbon nanotubes can produce a variety of adverse effects in animal models, including upper airway mechanical blockage, occlusive airway granulomas, macrophage uptake and intermacrophage carbon bridges, abnormal macrophage mitoses, type I pulmonary epithelial cell damage, lymphocytic proliferation, multifocal granulomas, aggregation in alveolar spaces and interstitium, increased inflammatory and oxidative stress biomarkers, fibrinogenic reactions, alveolar wall thickening, bronchiolar epithelial cell hypertrophy, and peribronchial inflammation.<sup>164,192,229,254,266,364,420</sup>

At high doses, mice exposed to MWNTs orally, intraperitoneally, or via nasal installation showed essentially no tissue response, but intratracheal administration showed dose-dependent pulmonary tissue invasion, inflammation and granuloma formation, and death.<sup>47</sup> Mice aspirating 40 mcg of SWCNT and acid-functionalized SWCNTs had significantly higher bronchoalveolar lavage cell counts, polymorphonuclear leukocytes, and cytokines (IL-6, TNF- $\alpha$ , and MIP2).<sup>346</sup> Also of concern are MWCNT retention, persistent inflammation, and asbestos like effects suggested by in vitro and in vivo experiments.<sup>312,335,370</sup> A systematic review of 54 animal studies indicated that carbon nanotubes and nanofibers caused adverse pulmonary effects, including inflammation (44 of 54 studies), granulomas (27 of 54), and pulmonary fibrosis (25 of 54), which were similar to other fibrogenic materials such as silica, asbestos, and ultrafine carbon black.<sup>266</sup> Mice receiving both a known initiator chemical plus inhalation exposure to MWCNT were significantly more likely to develop tumors (90% incidence) and have more tumors than mice receiving the initiator chemical alone, suggesting that MWCNT can increase the risk of cancer in mice exposed to a known carcinogen.<sup>266</sup> Fibrosis and bronchioloalveolar hyperplasia (alveolar bronchiolization) can similarly be induced by inhaled CeO<sub>2</sub>.<sup>350</sup>

Although rats exposed to C<sub>60</sub> fullerenes nanoparticles (55 nm) for 10 days did not have visible of microscopic pathological lesions, particle burden and BAL protein concentrations were elevated.<sup>11</sup> Intratracheally delivered single wall nanohorns generated no inflammatory response, although nanohorns accumulated and persisted.<sup>246</sup> Intratracheal instillation of ultrafine (<200 nm) particles from combusted coal induced a higher degree of neutrophil inflammation and cytokine levels than did the fine or coarse particles.<sup>128</sup> Rats intratracheally instilled with ultrafine carbon black or TiO<sub>2</sub> demonstrated neutrophil recruitment, type II epithelial cell damage, cytotoxicity, impaired macrophage phagocytic ability, and enhanced macrophage sensitivity to chemotactins.<sup>328</sup> A summary of nanosized TiO<sub>2</sub> particle effects concluded that the crystalline form of has the greatest impact on pulmonary responses, and particle surface area, alumina or amorphous silica coating, and shape have lesser influences on toxicity.<sup>224</sup> Nasal instillation resulted in neutrophil recruitment. Alveolar macrophages took up inhaled elemental silver nanoparticles, and deposition in the alveolar wall was noted.<sup>380</sup> Although particles were rapidly cleared from lungs, there was evidence of circulatory spread. Longer term studies showed significant silver lung persistence, chronic macrophage accumulation and alveolar inflammation, and systemic distribution.<sup>377</sup> The severe toxicity of air-generated polytetrafluoroethylene (PTFE fumes) can be reduced by aging, filtering and preexposure, suggesting nanoparticle upregulation of pulmonary inflammatory cytokines and antioxidants.<sup>163</sup>

Pulmonary surfactant provides low surface tension and can identify and bind targets for phagocytosis. Independent of cellular effects, in vitro lung models suggest that nanoparticle deposition may cause pulmonary surfactant dysfunction during the breathing cycle.<sup>169</sup> The collectins (phagocytosis enhancers), human surfactant protein-A and -D, bind double wall carbon nanotubes in a calcium-dependent manner.<sup>340</sup> Diesel exhaust PM can be solubilized and dispersed in the major component of pulmonary surfactant

(dipalmitoyl phosphatidyl choline) and induce genotoxicity in multiple different assays in bacteria and mammals.<sup>340,416</sup>

Humans exposed to nanoparticle-containing welding fumes in a controlled manner immediately increased their IL-6 concentrations in exhaled breath, decreased leukotriene B4 concentrations in nasal lavage samples, and decreased neutrophils and serum IL-8 concentrations the following morning.<sup>78</sup> An early report of uncontrolled workplace exposure to polyacrylate ester nanoparticles and other materials causing retained intracellular nanoparticles, pulmonary inflammation, pulmonary fibrosis, and pleural foreign-body granulomata was criticized for lack of causality and differential diagnosis.<sup>34,369</sup> However, an experimental rat model of polyacrylate/nanosilica nanoparticle exposure reproduced the pulmonary fibrosis and granuloma and pleural and pericardial effusion seen in patients.<sup>458</sup> Also, increased inflammatory and fibrotic biomarkers (IL-1 $\beta$ , IL-6, TNF- $\alpha$ , inflammatory cytokines, and KL-6) were found in nasal lavage-induced sputum and blood serum specimens of workers exposed to MWCNTs.<sup>105</sup> A report of submesothelial deposition of carbon nanoparticles after toner exposure has been criticized for lack of plausibility and causality.<sup>389,425</sup> Nevertheless, office workers increased nine of 11 biomarkers of lipid oxidation after daily visits to a manufacturing plant's nano-TiO<sub>2</sub> production area.<sup>302</sup> Furthermore, nano-TiO<sub>2</sub> production workers demonstrated elevations in all 11 biomarkers of lipid oxidation—malondialdehyde, 4-hydroxy-trans-hexenal, 4-hydroxy-trans-nonenal, 8-isoProstaglandin F2 $\alpha$ , and aldehydes C6-C12.<sup>303</sup> These findings complement evidence of DNA and protein oxidative damage in workers exposed to nano-sized iron oxide.<sup>301</sup> Compared with control participants, workers exposed to carbon nanotubes, nanoparticles of titanium dioxide, silicon dioxide, nanosilver, nanogold, nanoclay, nanoalumina and metal oxides demonstrated increased markers of pulmonary injury at the cellular (Clara cell protein 16) and organ system (lung function test) levels, as well as antioxidant and cardiovascular markers (superoxide dismutase, glutathione peroxidase, vascular cell adhesion molecule, and paraoxonase).<sup>206</sup>

### Cardiovascular and Hematologic Systems

Ultrafine particles can alter human cardiac function (decreasing heart rate variability and repolarization).<sup>77,138,392,413,452</sup> Heart rate variability provides a measure of cardiac autonomic control; a decrease predicts death in patients with prior myocardial infarction.<sup>392</sup> Significant pulmonary inflammation is not a prerequisite, although autonomic reflexes from pulmonary nerve endings may mediate these effects.<sup>124</sup> Jugular vein or femoral artery administration of silver, copper, and aluminum nanoparticles immediately but transiently slows heart rate.<sup>357</sup> Engineered nanoparticles made of flame soot (Printex 90), spark discharge-generated soot, anatase TiO<sub>2</sub>, and SiO<sub>2</sub> induced catecholamine-mediated dose dependent increases in heart rate and dysarrhythmia in Langendorff heart model systems.<sup>371</sup> Human wood smoke exposure increases levels of serum amyloid A (a cardiovascular risk factor) and factor VIII in plasma.<sup>16</sup> Inhaled TiO<sub>2</sub> nanoparticles impair rat coronary arteriole endothelium-dependent vasoreactivity and relaxation, likely caused by microvascular ROS.<sup>196</sup>

Intravascularly, nanoparticle characteristics and concentration determine leukocyte and immune stimulation (detailed in a later section), erythrocyte effects, thrombogenesis, endothelial dysfunction, and atherogenesis. Zinc oxide nanoparticles induced proinflammatory mediators, dyslipidemia, biomarkers of atherosclerosis, and aortic pathological damage in human coronary artery endothelial cell systems and in rats.<sup>444</sup>

Dendrimers can adversely alter human erythrocyte morphology, induce clustering, and provoke significant hemolysis.<sup>84,89</sup> Dendrimer generation, concentration, charge, exposure duration, and material type determine the extent to which this occurs. Intravenously provided diesel exhaust particles aggregate within erythrocytes, decreasing counts.<sup>272</sup> Polycationic (but not neutral or anionic) water-soluble fullerene C<sub>60</sub> derivatives, surfactant stabilized poly(lactic-co-glycolic acid) (PLGA) nanoparticles, and polystyrene nanoparticles all induce significant hemolysis.<sup>30,176,236</sup> The surface silanol groups of silica nanoparticles can induce significant erythrocyte deformation and hemolysis, as can titanium dioxide and silver.<sup>12</sup>

Chitosan-pDNA and uncoated polymer nanoparticles both induce significant hemoagglutination.<sup>140,215</sup>

Engineered and combustion-derived carbon nanoparticles (MWCNTs, SWCNTs, and mixed carbon nanoparticles) stimulated human platelet aggregation, activation of glycoprotein IIb/IIIa, and accelerated the rate of vascular thrombosis in rat carotid arteries.<sup>324</sup> The effect on platelet aggregation was aspirin-resistant but was reduced by low affinity (P2Y12) ADP receptor antagonism. Multiple metal nanoparticles (iron, copper, gold, cadmium sulfide) also induced dose-dependent platelet aggregation through the P2Y12 ADP receptor, an effect was blocked by clopidogrel.<sup>71</sup> Epidemiologic studies support an association between exposure to PM of less than 10 microns and increased risk of deep venous thrombosis.<sup>9</sup> Diesel exhaust particles (20–50 nm) and positively charged polystyrene nanoparticles cause rapid activation of circulating blood platelets and microcirculatory thrombi.<sup>269,271</sup> Healthy volunteers exposed to concentrated ambient air particles increase fibrinogen levels.<sup>126</sup>

Compared with larger particles, ultrafine particles produce larger atherosclerotic lesions, decrease the antiinflammatory effect of high-density lipoprotein, and induce oxidative stress in susceptible animal models.<sup>6</sup> At doses that produced no significant pulmonary inflammatory changes, rats exposed to nano-TiO<sub>2</sub> aerosols display systemic impaired endothelium-dependent arteriolar dilation, outright constriction, and decreases in NO bioavailability by increasing local reactive oxidative and nitrosative species.<sup>276</sup>

### Immune System

Nanoparticle interaction with the immune system is complex: depending on biophysicochemical properties, nanoparticles can stimulate, silence, or elude immune responses.<sup>459</sup> Most concerning is induction of chronic inflammation. Work in murine macrophage cells lines demonstrated that MWCNTs produced a cytotoxic response nearly identical to asbestos.<sup>370</sup> Commercially and academically available MWCNTs induced asbestos like, length-dependent pathology in mice.<sup>312,406</sup> Multiwalled carbon nanotubes can reach the subpleura in mice after a single inhalation exposure to produce mononuclear cell aggregates and subpleural fibrosis.<sup>335</sup> On the other hand, immune suppression may also occur. Fullerene suppression of mast cell-mediated hypersensitivity reactions appears to proceed from endocytosis, endoplasmic reticulum accumulation, intracellular persistence, and inhibition of calcium and ROS generation.<sup>73</sup> Other nanoparticles, such as polyethyleneimines, can induce chronic stress through inflammasome activation, which can promote tumor metastasis.<sup>152</sup>

Particle-specific interactions may yield cellular accumulation, antigen-mediated immune stimulation, inflammatory mediator release, or fibrous or granulomata formation. Mouse granulocyte-macrophage colony formation is now a standard testing methodology for assessing nanoparticle toxicity.<sup>7</sup> Macrophages exposed to Fe-Co-Ni nanowires in vitro increased production of interferon- $\gamma$ , IL-1 $\alpha$ , IL-4, and IL-10.<sup>3</sup> Ultrafine carbon caused macrophages to release<sup>253</sup> lipid mediators arachidonic acid, PGE<sub>2</sub>, LTB<sub>4</sub>, and 8-isoprostane.<sup>17</sup> Subcutaneously implanted “hat-stacked” carbon nanofibers in rats generated fibrous connective tissue formation and macrophage recruitment and ingestion without inflammatory response (necrosis, degeneration, or neutrophil infiltration).<sup>449</sup> Intratracheal exposure to nano-sized nickel and cobalt particles induced rat blood neutrophils to release ROS and reactive nitrogen species.<sup>248</sup>

Human volunteer exposures to concentrated ambient particles (<200 nm) increased inflammatory blood mediators.<sup>129</sup> Intravenous administration of ultrafine diesel exhaust particles promoted monocyte and granulocyte proliferation.<sup>272</sup> Other cell lines can also be induced to release inflammatory mediators. Single-walled carbon nanotubes induced human epidermal cells exposed to release IL-8. Multiwalled carbon nanotube introduced in human neonatal epidermal keratinocytes increased IL-8 and IL-1 $\beta$  release.<sup>429</sup>

Direct immune stimulation can also occur. Fullerenes can induce an IgG response capable of cross-reaction with other fullerenes.<sup>33,51</sup> The degree of induced opsonization by various IgG and complement molecules is thought to explain part of the differences seen in blood clearance and

tissue distribution of nanoparticles.<sup>289</sup> Upon readministration, PEGylated liposomes have accelerated blood clearance caused by IgM binding; this is inhibited by chemotherapeutics that inhibit B-cell proliferation.<sup>156</sup> In the absence of direct immune stimulation, carbon nanotubes can boost immune response as adjuvants.<sup>292</sup> Indeed, pharmaceutical nanoparticles show promises for eliciting polyclonal and monoclonal antibodies to nonimmunogenic haptens as diverse as herbicides, antibiotics, and vitamins.<sup>231</sup> The flip side to this is that nanoparticles contaminated with hydrophobic metal, glass, and polystyrene particulates can stimulate protein aggregation and immunogenicity, as well as exacerbate production of proinflammatory cytokines induced by endotoxin, a separate common contaminant.<sup>82</sup>

Liposome- and polymer-based therapeutic nanomedicines have been compromised by non-IgE mediated hypersensitivity reactions because of complement system activation, which releases C3a and C5a anaphylatoxins.<sup>5</sup> The drug solubilizer Cremophor EL (polyethoxylated castor oil) forms micelles (8–25 nm) at concentrations above 60 mcg/mL and causes its occasionally severe immune reactions presumably caused by complement activation. Carbon nanotubes can activate human complement via both classical and alternative pathways; C1q binds directly to carbon nanotubes.<sup>339</sup> Surface density of coating materials can also alter complement consumption.<sup>4</sup> Certain dendrimers may also strongly activate the complement system.<sup>226</sup> MnFe<sub>2</sub>O<sub>4</sub> magnetic nanoparticles (10-nm diameter) induce severe inflammatory reactions in mice.<sup>191</sup> The importance of characterizing immune cell subset responses is now recognized. Inhaled carbon nanotubes can induce myeloid-derived suppressor cell accumulation in mice, contributing to tumorigenesis.<sup>82</sup> Microcrystalline silica particles induced a strong Th1 response, and carbon black particles and polystyrene particles induced a mixed Th1:Th2 response.<sup>414</sup> PLGA-based nanoparticles did not induce complement consumption, indicating that this action is nanoparticle specific.<sup>49</sup>

### Ocular System

The ocular system is of particular interest because of its immunologic privilege and physiologic characteristics. Therapeutically, nanosuspensions and other constructs show promise for extended release and decreased drug clearance from anterior and posterior ocular structures and diminished systemic drug exposure.<sup>133,320</sup> In vitro studies have shown adverse effects. Silver nanoparticle block the proliferation and migration and inhibit cell survival of bovine retinal endothelial cells.<sup>167</sup> Water-soluble fullerene derivatives are phototoxic to human lens epithelial cells under visible light.<sup>427</sup> Conversely, graphene oxide nanosheets, even when intravitreally injected in rabbits, did not demonstrate significant effects.<sup>443</sup> Conversely, in zebrafish, graphene oxide damaged mitochondria and primarily translocated to the eye, resulting in ocular malformations during embryogenesis.<sup>54</sup> Cerium oxide nanoparticles are reported to offer a protective effect, scavenging reactive oxygen intermediates in rat retina cell culture.<sup>52</sup> In vivo confocal neuroimaging conclusively demonstrated negatively charged nanoparticle-rhodamine formulations injected into rat jugular vein crossed the blood–retinal barrier within 40 minutes.<sup>319</sup> Intravenously administered gold nanoparticles (20 nm) can bypass the blood–retinal barrier to distribute in all retinal layers within 24 hours.<sup>177</sup>

### Reproduction and Development

The reproductive effects of nanoparticles are incompletely characterized. One review concluded that nanoparticles can breach the blood–testis barrier and locate in the testes.<sup>238</sup> Subsequent studies using inhaled fluorescent magnetic nanoparticles (50 nm) and injected gold nanoparticles confirmed testicular distribution and persistence.<sup>13,190</sup> Chronic intratracheal administration of carbon black (14 and 56 nm) showed similar partial vacuolation of the seminiferous tubules and decreased daily sperm production.<sup>450</sup> Silver nanoparticles caused dose-dependent mitochondrial impairment and cytotoxicity in spermatogonia in vitro; aluminum nanoparticles caused apoptosis.<sup>36</sup> Gold nanoparticles can penetrate human sperm cells, resulting in fragmentation and dysmotility.<sup>430</sup> Environmental exposure to relevant concentrations of ZnO, TiO<sub>2</sub>, SiO<sub>2</sub> nanoparticles produced reproductive toxicity

in nematodes, which was correlated with ROS production and attenuated with antioxidants (ascorbate and NAC).<sup>434</sup>

Female reproductive effects are less well described. Oral ZnO nanoparticles achieved lactation and placenta transport and resulted in increased postimplantation loss rate, decreased live births, and zinc accumulation in offspring liver and kidney.<sup>162</sup> In perfused human placenta models, PEGylated gold nanoparticles (10–30 nm) were retained mainly in the trophoblastic cell layer and internalized by trophoblastic cells and did not cross in detectable amounts into the fetal circulation over 6 hours of evaluation.<sup>258</sup> Other nanoparticles—particularly MWCNTs and SWCNTs and TiO<sub>2</sub>-nanoparticles—can cross the placenta to create fetal oxidative stress and inflammation, alter neurodevelopment, alter behavior, and impair learning and memory in offspring in mice and rats.<sup>95</sup> Carbon-based nanomaterials are embryolethal to mice, chickens, and zebrafish, and certain structures such as nanodiamonds impair angiogenesis.<sup>96</sup> Zebrafish embryos exposed to nickel-silica nanomaterials either died or were left with severe malformations or compromised motor function.<sup>227</sup> *Daphnia magna* were unable to reproduce again after exposure during pregnancy to sublethal concentrations of water-stable fullerenes. Less than 10% of daughter daphnids matured after maternal exposure.<sup>382</sup> After exposure to silver nanoparticles (0.1 or 0.5 mg/L for 3 days), nematode offspring decreased by 70%; oxidative stress was the presumed toxicologic mechanism.<sup>329</sup> In the animal model of organogenesis, medaka (rice fish) eggs easily took up 39.4-nm fluorescent particles and concentrated them in the yolk area and gallbladder during embryonic development.<sup>170</sup> Adults demonstrated diffuse uptake into reproductive organs as well as the brain, liver, intestine, gills, and kidney. Medaka fertilized eggs exposed to silver nanoparticles produced a variety of malformations, including systemic edema, hemostasis, and vertebral, finfold, optic, and cardiac abnormalities over the range of concentrations tested (100–1,000 mcg/L).<sup>435</sup> Altered hormone levels and offspring sex ratios seen in some experimental models of nanoparticle exposure suggest endocrine disruption.<sup>220,261</sup>

### Bioaccumulation and Persistence

Nanoparticles can accumulate in certain cells, tissues, or organs to achieve threshold toxicities or leach at a time after the initial exposure. At the cellular level, nanocrystals can be passed to daughter cells upon mammalian cell division.<sup>136,234</sup> Retained fluorescing QDs have been used experimentally to trace *Xenopus* cells from embryo to tadpole stage.<sup>88</sup> Among different fine particles (fiberglass, rock wool, slag wool, asbestos), their biopersistent potential seems to underlie toxic effects.<sup>145</sup> This knowledge drives the concern regarding preliminary studies demonstrating MWCNT persistence, inflammatory induction, and asbestos like pathology.<sup>253,312,335,379</sup> Similarly, the pulmonary biopersistence of aluminum-based nanorods increased with high aspect ratios.<sup>297</sup> Compared with sodium selenite, nano-selenium particles displayed hepatic hyperaccumulation and persistence in fish models, with associated oxidative stress and toxicity.<sup>204</sup> Similarly, uptake, bioconcentration, and alimentary toxicity of TiO<sub>2</sub> nanoparticles were demonstrated in crustaceans.<sup>68</sup> Their transmission and bioaccumulation (by a factor of more than 100% in certain species) up the food chain was also apparent.<sup>448</sup> Nanocrystalline C<sub>60</sub> had a greater propensity to accumulate in *Daphnia magna* fetuses because of their higher lipid fraction (including the egg sac yolk) and correlated with higher mortality.<sup>382</sup> Even short-term oral exposure may lead to reticuloendothelial accumulation in some animal models.<sup>384</sup>

Although desirable for chemotherapeutic applications, prolonged periods of persistence could allow leaching and toxicity of initially protected materials.<sup>423</sup> Bone marrow deposition of nanoparticles<sup>315</sup> could allow for ongoing systemic exposure. Persistence in other compartments could also permit more extensive distribution (eg, translocation from lung tissue). Dextran-coated ultrasmall SPIO particles currently used in clinical trials are retained by human monocytemacrophages for days.<sup>255,256</sup> Quantum dots persisted at least 4 months in mice, and those conjugated to bovine serum albumin or coated with mercaptoundecanoic acid underwent negligible elimination in rats.<sup>14,108</sup> Because of intrinsic resistance to lysosomal degradation, inorganic or metal nanoparticles can have extremely low rates of excretion, resulting in long-term accumulation.<sup>423</sup>

## ADMINISTRATIVE, REGULATORY, AND RESEARCH ISSUES

The 21st Century Nanotechnology Research and Development Act guides US nanotechnology policy.<sup>410</sup> Elements include federal interagency coordination, establishment of national strategic plans for nanotechnology, and triennial review by the National Research Council; establishment of a public database for funded EHS (environmental, health, and safety), educational and societal dimensions, and nanomanufacturing projects; fiscal support for a Nanotechnology Coordination Office; mandates for research in EHS; development of nomenclature and engineered nanoscale standard reference materials standards; development of standards for detection, measurement, monitoring, sampling, and testing of engineered nanoscale materials for EHS impacts; and nanotechnology education. The National Nanotechnology Initiative (NNI) includes 20 federal departments and agencies with administrative, funding, liaison, regulatory, and research and development roles, including the Department of Defense, National Science Foundation, Department of Education, National Institutes of Health, NIOSH, FDA, National Institute of Standards and Technology (NIST), Occupational Safety and Health Administration, Environmental Protection Agency (EPA), United States Department of Agriculture, and others.<sup>64</sup> In its congressionally mandated role to review federal nanotechnology research and development, the National Nanotechnology Advisory Panel provides ongoing recommendations for development of infrastructure, standards and metrics, and EHS risk analysis concurrent with applications research.<sup>318</sup> International regulatory frameworks continue to evolve.<sup>281</sup>

The detailed NNI strategy for EHS research recommends incorporation of many factors in conducting a nanotechnology risk assessment, including nanomaterials synthesis and use; nanomaterial lifecycle stages (from raw materials through disposal or recycling); transport, transformation, secondary contaminants, and abiotic effects; environmental concentrations; exposure of environmental and biologic systems; internal dose; biologic response; and systemic environmental effects.<sup>64,375,405,406,407</sup> Priority needs included the development of nanomaterial detection methods, certified reference materials, standardized physiochemical assessments, and measurement tools; understanding generalizable toxicologic characteristics of nanomaterials in biologic systems; predictive toxicological profiling; identification of environmental, occupational, and other population exposures and health surveillance; and evaluation of risk management approaches to nanomaterials.<sup>64,375</sup> The National Nanotechnology Coordinated Infrastructure (NNCI), which includes 16 sites, is the latest iteration of NSF supported network of US facilities, universities, and partner organizations for nanofabrication and characterization, education and outreach, and exploration of societal and ethical implications of nanotechnology.<sup>282</sup>

### Standards

The NIST is the coordinating agency for instrumentation, metrology, and analytical methods in the United States. Given the broad cross-disciplinary impact of nanomaterials, international standards continue to evolve for nomenclature and terminology, measurements and metrics, reference nanoparticles, toxicity testing and risk assessment tools, and occupational guidelines. The European Centre for Ecotoxicology and Toxicology of Chemicals has proposed a *Decision-Making Framework for the Grouping and Testing of Nanomaterials* (DF4nanoGrouping), which includes three tiers (intrinsic material properties, system-dependent properties and in vitro effects, and in vivo screening) to assign nanomaterials to four main nanoparticles: soluble, biopersistent high aspect ratio, passive, and active nanomaterials.<sup>194</sup> Where available, selected national and international standards relating to these areas are provided in [Table 125–2](#).

### Food, Drug, and Device Safety

The FDA regulates food and color additives, drugs, biologics, devices, blood products, and cosmetics to ensure that they are “safe” and unadulterated. The FDA does not regulate “nanotechnology” *per se* and has forgone even adopting regulatory definitions of “nanotechnology,” “nanomaterial,” “nanoscale,” and related terms.<sup>134,403</sup> Rather, marketing authorization occurs

on a product-by-product basis, with further variation for different product-classes. Although the FDA can require manufacturers to provide necessary information (eg, chemistry, manufacturing, active ingredients, pharmacologic and toxicologic results, and particle size) to support decisions regarding pre-market approval, in evaluating the sponsor “claims,” the FDA may be unaware that nanotechnology is being used, particularly if no nano-related claims are supplied. In general, the FDA has treated nanomaterial ingredients no differently than bulk material ingredients or products. Guidance has been provided for nanotechnology and nanomaterials issues in industry, cosmetics, food substances, animal feed, and dietary supplements.<sup>402–404</sup> Several countries have excluded engineered nanoparticles from food labeled organic.<sup>401</sup>

### Occupational Health and Safety

National Institute for Occupational Safety and Health leads federal agencies in conducting research and providing guidance on the occupational safety and health implications and applications of nanotechnology.<sup>266</sup> National Institute for Occupational Safety and Health has released multiple reports to guide commercial and research entities, including “Approaches to Safe Nanotechnology,”<sup>264</sup> “Building a Safety Program to Protect the Nanotechnology Workforce: A Guide for Small to Medium-Sized Enterprises,”<sup>267</sup> “Filling the Knowledge Gaps for Safe Nanotechnology in the Workplace,”<sup>266</sup> and “General Safe Practices for Working with Engineered Nanomaterials in Research Laboratories.”<sup>265</sup> These publications and others identify potential health concerns (nanoparticle dose, deposition, reactivity, toxicity, translocation, and tumorigenicity) and safety issues (fire, explosion, oxidation, and catalytic potential). Recommendations included epidemiology, surveillance, and background nanoaerosol measurements and particle analysis; personnel exposure sampling and medical surveillance; engineering controls with verification and sufficient ventilation; spill response and emergency preparedness; implementation of risk management programs; and use of filters, respirators, and other proper personal protective equipment.<sup>264,267</sup> To address specific risks associated with carbon nanotubes and nanofibers, OSHA recommends that worker exposure not exceed 1.0 mcg/m<sup>3</sup> elemental carbon as an 8-hour time-weighted average (TWA), based on the NIOSH-proposed occupational recommended exposure limit (REL).<sup>280</sup> OSHA recommends that worker exposure to TiO<sub>2</sub> nanoscale particles not exceed the NIOSH REL of 0.3 mg/m<sup>3</sup>, an order of magnitude less than the NIOSH REL of 2.4 mg/m<sup>3</sup> for fine TiO<sub>2</sub> particles (>100 nm).<sup>280</sup> The REL for soluble silver compounds and silver metal dust is 0.01 mg/m<sup>3</sup>, an order of magnitude less than the threshold limit value for metallic silver (0.1 mg/m<sup>3</sup>) recommended by the American Conference of Governmental Industrial Hygienists (ACGIH). Values for metal fumes may be similarly lower than that for corresponding dusts (eg, a TWA for copper fumes of 0.1 mg/m<sup>3</sup> versus 1 mg/m<sup>3</sup> for copper dusts). The general federal statute limiting “particulates not otherwise regulated” (also known as “inert or nuisance dusts”) to a respirable fraction of 15 millions of particles per cubic foot of air (5 mg/m<sup>3</sup>) would also apply include nanoparticles, although this is suggested to provide inadequate protection.<sup>92,365</sup> National Institute for Occupational Safety and Health anticipates that properly fit, NIOSH-certified respirators in conjunction with respiratory control programs will protect workers from most inhaled nanoparticles.<sup>264,266</sup> Other occupational professional guidance can be found in national and international guidelines and reviews.<sup>262,286</sup>

### Environmental Protection

The EPA is the coordinating federal agency for human nanomaterials environmental research. Nanomaterial applications for environmental remediation and water purification are particularly attractive but require weighing against unintended consequences (eg, nanopollution).<sup>401</sup> Regulation of nanomaterials and the effects of nanotechnology may also come under the EPA’s broad authorities under the Clean Air Act (CAA), Pollution Prevention Act (PPA), Clean Water Act (CWA), Safe Drinking Water Act (SDWA), Federal Insecticides and Rodenticides Act (FIFRA), Comprehensive Environmental Response Compensation and Liability Act (CERCLA), National Environmental Policy Act (NEPA), Resource Conservation and Recovery Act (RCRA),

and Toxic Substances Control Act (TSCA).<sup>401</sup> Under TSCA, new nanomaterials are regarded as “chemical substances” subject to review, and the EPA has required reporting by current or planned manufacturers, processors, and importers of the specific chemical identity, production volume, methods of manufacture and processing, exposure and release information, and available information concerning environmental and health effects of nanoscale

substances.<sup>99,100</sup> The EPA has variously limited use, required personal protective equipment and engineering controls, limited environmental release, and required testing to produce health and environmental effects data. The EPA determined that (nano) silver ion-generating washing machines marketed with bactericidal claims were subject to registration requirements under FIFRA and extended the requirement to copper- and zinc-emitting devices

and ion generators in swimming pools.<sup>98</sup> Under FIFRA, it has fined corporations for making unsubstantiated antimicrobial claims with nano-coating technology.<sup>400</sup>

The ongoing rapid evolution of the discipline will mandate constant updating and assessment of available knowledge. A selected list of organizational resources is provided in Table 125-3.

## SUMMARY

- Nanotechnology and nanotoxicology represent ever-expanding disciplines.
- Toxicity has been demonstrated at the species level, including in humans.
- The special physiochemical properties of nanoparticles can yield non-intuitive biologic effects, which complicate toxicological assessments.
- Documented cellular and organ systems nanotoxicological mechanisms continue to expand.
- Nanoparticle profiles are incomplete. Although surrogate markers of toxicity are suggestive, human risk remains incompletely characterized across lifecycle stages.
- Appropriate research methodologies, in vitro and in vivo models, risk assessment, and workplace and environmental standards await further exploration and consensus.

## CHEMICAL WEAPONS

Jeffrey R. Suchard

## HISTORY AND EPIDEMIOLOGY

The first well-documented intentional use of chemicals as weapons occurred in 423 B.C. when Spartans besieging Athenian cities burned pitch-soaked wood and brimstone to produce sulfurous clouds.<sup>88</sup> Large-scale chemical warfare began in World War I when the Germans released chlorine near Ypres, Belgium, killing hundreds of people and forcing 15,000 troops to retreat.<sup>19,48</sup> Both sides rapidly escalated the use of toxic gases released from cylinders or by artillery shells, including various pulmonary irritants, lacrimators, arsenicals, and cyanides.

The Germans first used sulfur mustard in 1917, again near Ypres, and caused more than 20,000 deaths or injuries.<sup>48</sup> The Allies soon responded in kind. Sulfur mustard was unequaled in its ability to incapacitate opponents, often resulting in temporary blindness.<sup>9</sup> Injuries far outweighed fatalities, diverting manpower and resources to care for the wounded. By the end of the war, chemical weapons caused more than 1.3 million casualties and approximately 90,000 deaths.<sup>19</sup>

Germany began producing nerve agents just before World War II. Tabun was developed in 1936 by Gerhard Schröder when conducting insecticide research for IG Farbenindustrie.<sup>30,78</sup> Sarin was synthesized in 1938.<sup>30</sup> Between 10,000 and 30,000 tons of tabun and 5 to 10 tons of sarin were produced during World War II. Soman was synthesized in 1944, but no large-scale production facilities were developed. When the Allies discovered these chemical weapons at the end of the war, code names were designated based on the order of their development. Tabun was called GA (the letter G standing for German), sarin was GB, and soman was GD.<sup>30</sup>

In 1952, the British synthesized an even more potent nerve agent while searching for a dichlorodiphenyltrichloroethane (DDT) replacement. This substance was given to the United States for military development and was named VX. The Russians developed a similar nerve agent, variably referred to as VR or “Russian VX.”<sup>38</sup> The United States used defoliants and riot control agents in Vietnam and Laos. Iraq used sulfur mustard, tabun, and soman during its war with Iran in the 1980s and may have also used cyanide against the Kurds.<sup>48</sup> More recently, chlorine and sarin were used by government forces in the Syrian civil war, and the Islamic State used sulfur mustard in Syria and Iraq.<sup>87</sup>

Terrorist groups have also used chemical weapons. Sarin was released twice by the Aum Shinrikyo cult in Japan. The first release occurred in Matsumoto in 1994, killing seven and injuring more than 600.<sup>51</sup> A more highly publicized sarin release occurred in the Tokyo subway system in 1995, killing 12 and resulting in more than 5,000 persons seeking medical attention.<sup>75</sup> Cult members have also used VX in assassinations.<sup>50</sup> Chemical weapons are particularly appealing to terrorist groups because the technology and financial outlay required to produce them is much less than for nuclear weapons, and the potential morbidity, mortality, and societal impact remain high (Table 126–1).

Chemical weapons clearly fall within the purview of medical toxicology. Indeed, unlike the diverse xenobiotics widely studied by toxicologists that unintentionally cause poisonings, chemical weapons are specifically designed to kill, injure, or incapacitate. Some compounds generally considered nonlethal, such as tear gas and pepper spray, are therefore also considered chemical weapons. Biologic weapons share some characteristics with chemical weapons (Table 126–2) and are covered in Chap. 127, although the issues common to both chemical and biologic weapons are discussed in this chapter.

This chapter focuses on the acute and long-term clinical effects of exposure to chemical weapons, their mechanisms of toxicity, and the medical treatment of individual casualties based on published human case experience. Many other potential subtopics related to chemical (and biologic)

weapons are not specifically reviewed here, including disaster incident command (Chap. 132), chemical and biological weapon (CBW) agent detection, provision of medical care in a chemically contaminated environment, and evidence accumulated from *in vitro* and *ex vivo* models of chemical weapons poisoning.

## GENERAL CONSIDERATIONS

## Physical Properties

The term *war gas* is generally a misnomer. Sulfur mustard and nerve agents are liquids at normal temperatures and pressures, and many riot-control agents are solids. These weapons are most efficiently dispersed as aerosols, which probably leads to the confusion with gases. Some chemical weapons such as chlorine, phosgene, and hydrogen cyanide are true gases, and although they are generally considered obsolete for battlefield use, they might still be used as improvisational chemical weapons, especially in terrorist attacks.

Liquid chemical weapons have a certain degree of volatility and evaporate into poisonous vapors. Volatility is inversely related to persistence, the tendency to remain in the environment. Persistent chemical weapons, such as mustard or VX, contaminate areas for prolonged periods, denying the opponent free movement and use of contaminated material. The toxic hazard from semipersistent weapons such as sarin and nonpersistent agents such as hydrogen cyanide dissipates more rapidly.

Aerosols, gases, and vapors are highly subject to local atmospheric conditions. Less dispersion occurs with atmospheric inversion layers and in the absence of wind, as typically occurs at night or in the early morning. Enclosed spaces also prevent wind dispersion and simple dilution. Except for hydrogen cyanide, chemical weapon (CW) gases and vapors are all more dense than air and collect in low-lying areas.

As a practical example, in the 1995 sarin release in the Tokyo subway system, photos from the attack show severely affected or deceased victims in very close proximity to mildly affected, ambulatory individuals. The number

TABLE 126–1 Unconventional Weapons: Definitions and Acronyms

Chemical warfare	Intentional use of weapons designed to kill, injure, or incapacitate on the basis of toxic or noxious chemical properties.
Biologic warfare	Intentional use of weapons designed to kill, injure, or incapacitate on the basis of microorganisms or xenobiotics derived from living organisms
Terrorism	The unlawful use of force against persons or property to intimidate or coerce a government, the civilian population, or any segment thereof, in furtherance of political or social objectives.
CW	Chemical warfare, or chemical weapon.
BW	Biological warfare, or biological weapon.
CBW	Chemical and/or biological warfare or weapons.
NBC	Nuclear, biological, and/or chemical; usually in reference to weapons.
CBRNE	Chemical, biological, radiologic, nuclear, and explosive; usually in reference to weapons.
WMD	Weapon of mass destruction; nuclear, radiologic, chemical, or biological weapon intended to produce mass casualties.

**TABLE 126–2** Chemical versus Biological Weapons: Comparison and Contrast<sup>27</sup>

<i>Similarities</i>		
Xenobiotics most effectively dispersed in aerosol or vapor forms		
Delivery systems frequently similar		
Movement of xenobiotics highly subject to wind and weather conditions		
Appropriate personal protective equipment prevents illness		
<i>Differences</i>	<i>Chemical Weapons (CWs)</i>	<i>Biological Weapons (BW)s</i>
Rate at which attack results in illness	Rapid usually minutes to hours	Delayed usually days to weeks
Identifying release	<i>Relatively easy:</i> Rapid clinical effects Possible chemical odor Commercially available chemical detectors	<i>More difficult:</i> Delayed clinical effects Lack of color, odor, or taste Limited development of real-time detectors
Xenobiotic persistence	Variable Liquids semipersistent to persistent Gases nonpersistent	Generally nonpersistent; most BW xenobiotics are degraded by sunlight, heat, or desiccation (exception: anthrax spores)
Victim distribution	Near and downwind from release point	Victims may be widely dispersed by the time disease is apparent
First responders	EMTs, hazard materials teams, firefighters, law enforcement officers	Emergency physicians and nurses, primary care practitioners, infectious disease physicians, epidemiologists, public health officials (but will likely be same as CW if release is identified immediately)
Decontamination	Critically important in most cases	Not needed in delayed presentations; less important for acute exposures
Medical treatment	Antidotes, supportive care	Vaccines, antibiotics, supportive care
Patient isolation	Unnecessary after adequate decontamination	Crucial for easily communicable diseases (eg, smallpox, pneumonic plague); however, many BW agents are not easily transmissible

EMT = emergency medical technician.

of fatalities could have been much higher had sarin been effectively aerosolized instead of being simply allowed to evaporate. Presumably, sarin concentrations decreased so rapidly as distance from the source increased that few victims were significantly exposed. After removal from high-concentration areas, the victims' bodies posed less threat to bystanders because of dilution and improved ventilation. Even so, some health care professionals were secondarily exposed because the victims were not disrobed before entering the hospitals. Up to 46% of hospital staff in areas with poor ventilation reported symptoms consistent with mild acute poisoning, although cholinesterase activities were not reported.<sup>56,57,60</sup> About one-third of rescue workers in the 1994 Matsumoto sarin incident also developed mild toxicity. Rescuers arriving at the scene later were less likely to develop symptoms,<sup>52</sup> suggesting that the vapor dissipated over time.

### Preparation for Chemical and Biological Weapons (CBW) Incidents

A rational medical response to CBW events differs from the common response to isolated toxicologic incidents. Health care professionals must learn about these unconventional weapons and the expected “toxidromes” that they produce.<sup>1</sup> In addition, health care professionals must protect themselves and their facilities first, or ultimately no one will receive care. New medicolegal and ethical considerations will arise in CBW mass casualty events that otherwise infrequently occur. The greatest good for the greatest number of victims may preclude heroic interventions in a few critical patients. Charges of negligence may later arise regarding delays in treatment or failure to diagnose subtle signs of disease even if such actions were unavoidable at the time. Even if physicians become well versed in the appropriate response to CBW incidents, the question remains as to how many will be willing to continue working in the presence of an actual public health disaster.<sup>31</sup> The responses to chemical and biological weapons will also differ, chiefly because of the more immediate nature of the toxic effects of CWs compared with biological weapons<sup>27</sup> (Table 126-2).

Recommendations for sustained health care facility domestic preparedness include improved training to promptly recognize CBW mass casualty events, efforts to protect health care professionals, and establishment of decontamination and triage protocols.<sup>41</sup> Table 126-3 lists some specific recommendations. Several facets of the response to a CBW event are still being refined, such as the optimal choice of personal protective equipment, determining who needs decontamination and by what means, and what is to be done with wastewater produced by mass decontamination.<sup>37,41</sup> On a

**TABLE 126–3** Recommendations for Health Care Facility Response to Chemical and/or Biological Warfare or Weapons Incidents

- Immediate access to personal protective equipment for health care professionals
- Decontamination facilities that can be made operational with minimal delay
- Triage of victims into those able to decontaminate themselves (decreasing the workload for health care providers) and those requiring assistance
- Decontamination facilities permitting simultaneous use by multiple persons and providing some measure of visual privacy
- A brief registration process when patients are assigned numbers and given identically numbered plastic bags to contain and identify their clothing and valuables
- Provision of food, water, and psychological support for staff, who will likely be required to perform for extended periods
- Secondary triage to separate persons requiring immediate medical treatment from those with minor or no apparent injuries who are sent to a holding area for observation
- Providing victims with written information regarding the agent involved, potential short- and long-term effects, recommended treatment, stress reactions, and possible avenues for further assistance
- Careful handling of information released to the media to prevent conflicting or erroneous reports
- Instituting postexposure surveillance

tactical level, communication can be severely impaired by personal protective gear, which points out the need for loudspeakers or other forms of public address.<sup>41,86</sup>

Individual clinicians and hospitals caring for victims of known or suspected CBW incidents should contact their local department of health, which will likely report the incident to outside agencies such as the US Federal Bureau of Investigation and the Centers for Disease Control and Prevention (Table 126-4).

**Decontamination**

Decontamination serves two functions: (1) to prevent further absorption and spread of a noxious substance on a given casualty and (2) to prevent spread to other persons. CWs that are exclusively gases at normal temperatures and pressures such as chlorine, phosgene, or hydrogen cyanide only require removing the victim from the area of exposure. Isolated aerosol or vapor exposures, as from volatilized nerve agents or sulfur mustard, are also terminated by leaving the area and may require no skin decontamination of the victims.<sup>48,76</sup> The experience in Japan with sarin suggests that clothing should be removed from victims of nerve agent vapor exposure and placed in airtight receptacles, such as sealed plastic bags. Some of the secondary exposures to sarin were thought to have occurred as nerve agent that had condensed on the victims' clothing revaporized into the ambient air, and this caution probably holds true also for sulfur mustard vapor exposures. Removal and isolation of vapor-exposed clothing is therefore a recommended part of thorough decontamination to prevent secondary exposures.

Chemical weapons dispersed as liquids present the greatest need for decontamination. Because nerve agents are highly potent and have rapid onset of effects, some victims with significant dermal contamination will not survive to reach medical care.<sup>76</sup> Liquid-contaminated clothing must be removed, and, if able, victims should remove their own clothing to prevent cross-contamination.

Decontamination should be done as soon as practicable to prevent progression of disease and should occur outside of health care facilities to prevent contamination of the working environment and secondary casualties. Decontamination near the incident scene would be ideal in terms of timeliness, although logistically this will not be possible in many situations. Field decontamination before transport will also help to avoid loss of vehicles from being contaminated and taken out of service. Evidence supports the likelihood that contaminated victims will present to health care facilities on their own or be transported for care without decontamination.<sup>37</sup> In mass casualty incidents, decontamination efforts will benefit from separating victims into those who can remove their own clothing and shower themselves with minimal direction and assistance, and the more seriously affected who will require full assistance. The degree of protective gear required by the decontamination personnel cannot be predicted in advance and may be difficult to objectively determine at the time of the incident. Level C personal protective equipment may be sufficient for most hospital settings when the source is defined (eg, receiving and decontamination areas); however, if health care professionals begin to develop clinical effects, level B gear with supplied air would become necessary (Chap. 132).<sup>58</sup> When the source of the

contamination is not yet known, level B gear should be used. Chemically contaminated victims presenting to a health care facility should, if possible, be denied entrance until decontaminated. Patients who have already entered a health care facility and are only later determined to be a contamination hazard present a more difficult problem. If the situation allows, such patients should be taken outside for decontamination before returning and the previous care area cordoned off until any remaining safety hazard is assessed and eliminated.

Nerve agents are hydrolyzed and inactivated by solutions that release chlorine, such as household bleach, or solutions that are sufficiently alkaline. To avoid potential dermal and mucous membrane injury, we recommend a 1:10 dilution of household bleach in water (producing a 0.5% sodium hypochlorite solution) not only for nerve agents but also for sulfur mustard and many biologic agents.<sup>41,46,78</sup> Alternatives include regular soap and water or copious water alone. Rapid washing is more important than the choice of cleaning solution because 15 to 20 minutes is necessary for hypochlorite solutions to inactivate chemical agents.<sup>41</sup> Care should be taken to clean the hair, intertriginous areas, axillae, and groin.<sup>78</sup>

Decontamination after sulfur mustard exposure is more problematic than for nerve agents. First, it is more likely that significantly contaminated victims will survive to reach medical care because they often remain asymptomatic for several hours. In addition, the biochemical damage becomes irreversible long before symptoms develop. Decontamination within 1 to 2 minutes is the only effective means of limiting tissue damage from mustard.<sup>80</sup> However, the actual means of mustard decontamination are identical to those for nerve agents. Victims must be disrobed and thoroughly showered. Dilute hypochlorite solutions (eg, 0.5% sodium hypochlorite, a 1:10 dilution of household bleach) are used to inactivate mustard, but copious water irrigation will also suffice.<sup>48</sup> Symptomatic victims of mustard exposure should still be decontaminated, although it is unlikely to benefit that particular individual it can prevent the spread of mustard to others.<sup>80</sup> Lewisite and phosgene oxime must also be decontaminated quickly, although they produce immediate effects, making it more likely that victims will present promptly when decontamination is most effective.

We recommend water irrigation for riot control weapon exposures because hypochlorite solutions may exacerbate skin lesions.<sup>48</sup> With small numbers of victims, ocular decontamination after lacrimator exposure is ideally performed with topical anesthesia and a specially designed lens that facilitates irrigation. Inadequately decontaminated patients exposed to lacrimators can produce secondary cases among health care professionals, so any contaminated clothing should be removed and bagged.

Significant issues remain regarding decontamination measures. The number of people potentially requiring decontamination may easily outstrip capacity. Incidents with hundreds or thousands of victims will necessitate communal showers, selective decontamination, or both. Decontamination wastewater should ideally be contained and treated, but few facilities have the capability or funds to do this. However, wastewater is a minor issue because with large-scale CWs events, the wastewater represents only a small percentage of the total environmental impact.<sup>41</sup>

**Risk of Exposure**

The actual release of chemical or biologic weapons can be characterized as a low-probability, high-consequence event. Potential sources for civilian exposure include terrorist attacks, inadvertent releases from domestic stockpiles, direct military attacks, and industrial events. Terrorists may sabotage military or industrial stockpiles or directly attack the populace. Experience has shown that physicians are much more likely to encounter hoaxes,<sup>12</sup> isolated cases,<sup>67</sup> or limited incidents with a modest number of casualties.<sup>85</sup> Riot control weapons are exceptions, in that treating riot control weapon and pepper spray victims is a routine occurrence in many urban emergency departments (EDs).

Technical and organizational obstacles decrease the chance of major CBW terrorist events. Obtaining or producing chemical or biologic weapons, although simpler than for nuclear weapons, is only part of the process.

Effective dissemination is difficult if the goal is to maximize casualties. Proper milling of biologics to produce stable, respirable aerosols requires technical sophistication probably only attainable with governmental research support. Low-technology attacks such as food contamination, poisoning of livestock, and enclosed-space weapons dispersal appear more likely to occur than attacks resulting in hundreds, thousands, or millions of casualties. Smaller attacks or merely threatening use of chemical or biologic weapons may be equally consequential from a terrorist's perspective if they exert comparable political influence with significant psychosocial impact.

The chemicals most likely to be used militarily appear to be sulfur mustard and the nerve agents. A "low-tech" terrorist attack could involve the release of toxic industrial chemicals, such as chlorine, phosgene, or ammonia gas, as chemical "agents of opportunity."

### Psychological Effects

Either the threat or the actual use of CBW agents presents unique psychological stressors. Even among trained persons, a CBW-contaminated environment will produce high stress through the necessity of wearing protective gear, potential exposure to weapons, high workload intensity, defensive posture, and interactions with dead and dying patients. Disorders of mood, cognition, and behavior will be common among exposed or potentially exposed victims as a result of the uncertainty, fear, and panic that may accompany a CBW incident, even a hoax. The psychological casualties will probably outnumber victims requiring medical treatment. Civilians without training to recognize the clinical effects of exposure to CWs, which includes some health care professionals, are likely to confuse somatic symptoms with true exposure. Medical resources may easily be overwhelmed unless triage can identify those who will benefit most from appropriate counseling, education, and psychological support. Psychiatrists and other disaster mental health personnel should be enlisted in plans to manage CBW incidents for their expertise in treating anxiety, fear, panic, somatization, and grief.<sup>15</sup>

In Israel during the Gulf War, anxiety-related somatic reactions to missile attacks were reported in 18% to 38% of persons surveyed,<sup>10</sup> and more than 500 people sought medical attention in EDs for anxiety.<sup>64</sup> Among 5,510 people seeking medical attention after the Tokyo subway sarin release, only about 25% were hospitalized.<sup>75</sup> Some of the "victims" presented days or even weeks after the incident, apparently feeling unwell and thinking they were exposed.<sup>57,61</sup> Civilian survivors of chemical attacks in the 1980 to 1988 Iran–Iraq War report increased symptoms of depression, anxiety, and post-traumatic stress disorder compared with those exposed to low-intensity conventional warfare.<sup>24</sup> In one longitudinal study of American Persian Gulf War veterans, 4.6% reported their belief that they were exposed to CBWs, despite the lack of any convincing evidence of deliberate exposures, nor of unintended exposure to any significant levels of CWs. Greater combat stress was associated with a higher incidence in belief in such exposures.<sup>81</sup> Another study reported a 64% incidence in belief of CBW exposure among Gulf War veterans.<sup>8</sup> Reported indicators supporting these beliefs included receiving an alert, having physical symptoms, and being told to use protective gear. Belief in exposure to biologics correlated with having received an alert about chemicals, suggesting that CW alerts can spread misinformation and confusion among recipients.

Uncontrolled release of information will compound terror and increase psychological casualties. Imagine the influx of patients resulting from a news report suggesting that anyone with dizziness or nausea be checked for cholinesterase inhibitor toxicity or that fever and cough indicate infection with anthrax.

### Israeli Experience during the 1990 to 1991 Gulf War

Israel is probably one of the best prepared countries for CBW disasters. In late 1990, the civilian population was supplied with rubber gas masks, atropine syringes, and Fuller's earth decontamination powder.<sup>64</sup> Major Israeli hospitals conduct chemical practice drills every 3 to 5 years.<sup>86</sup> These drills identified several key lessons, including designating specific hospitals for chemical casualties, blocking hospital access to a single guarded entrance

to prevent internal contamination, and extending nurses' authority to initiate treatment by established protocols. The Israeli plan provides two tiers of triage. The first triage occurs outside of the hospital by protected medical personnel who perform only lifesaving interventions, such as intubation, hemorrhage control, and antidotal therapy. Patients are then decontaminated and enter the hospital. Afterward, patients are triaged again according to severity of illness into separate areas where dedicated health care teams provide the appropriate interventions.<sup>69,86</sup>

Thirty-nine ballistic missiles with conventional warheads were launched against Israel from Iraq in early 1991, with only six missiles causing direct casualties. Many more "injuries" resulted from CBW defensive measures and psychological stress than from physical trauma. Of 1,060 injuries reported from EDs during this time period, 234 persons were directly wounded in explosions (most injuries were minor), and there were only two fatalities from trauma.<sup>33,64</sup> More than 200 people presented for medical evaluation after self-injection of atropine, a few requiring admission to the hospital.<sup>3,33,64</sup> About 540 people sought care for acute anxiety reactions. Some suffocated from improperly used gas masks, fell and injured themselves when rushing to rooms sealed against CBW agents, or were poisoned by carbon monoxide in these airtight rooms.<sup>33,64</sup> Increased rates of myocardial infarction and cerebrovascular accidents were also observed.<sup>64</sup> A survey of hospital staff members found that only 42% would report for duty after a CW attack.<sup>70</sup>

### Special Populations

Pregnancy does not appear to be a significant factor in the treatment of women victims of CWs. In the Tokyo subway sarin attack, five victims were identified at one hospital as being pregnant. These women were only mildly affected and were admitted for observation. All had healthy babies, the first one born 3 weeks after the incident.<sup>57,59,61</sup> In Israel, no obstetric complications occurred among women wearing gas masks during labor and delivery.<sup>18,64</sup>

Children differ substantially from adults with regard to CWs effects and decontamination efforts. Children breathe at a lower ground elevation above the ground and at a higher rate than adults. Because nearly all CW gases and vapors are heavier than air, children are exposed to higher concentrations than adults in the same exposure setting and generally exhibit symptoms earlier.<sup>4,66,92</sup> Children are also more susceptible to vesicants and nerve agents than adults with equivalent exposures.<sup>65,92</sup> Children have thinner and more delicate skin, allowing for more systemic absorption and more rapid onset of injury with sulfur mustard. Children have lower activity of endogenous detoxifying enzymes, such as paraoxonase, allowing for greater toxicity with nerve agents. Additionally, children with organic phosphorus compound poisoning less frequently exhibit a muscarinic toxic syndrome than adults and often present with isolated central nervous system (CNS) depression.<sup>65</sup>

Decontamination of children is another feature that requires an age-adjusted approach. Children have a larger surface area-to-mass ratio and are more likely to carry a toxic or fatal dose of a CW on their skin. Most children will need assistance and supervision during decontamination procedures; keeping a mother or other adult guardian with a child should help with both decontamination and thermoregulation.<sup>66</sup>

## NERVE AGENTS

### Physical Characteristics and Toxicity

Nerve agents are extremely potent organic phosphorus compound cholinesterase inhibitors, and are the most toxic of the known CWs (Fig. 126–1).<sup>48</sup> For example, sarin is 1,000-fold more potent in vitro than the pesticide parathion.<sup>76</sup> Aerosol doses of nerve agents causing 50% human mortality (LD<sub>50</sub>) range from 400 mg-minute/m<sup>3</sup> for tabun down to 10 mg-minute/m<sup>3</sup> for VX compared with 2,500 to 5,000 mg-minute/m<sup>3</sup> for hydrogen cyanide. Dermal exposure LD<sub>50</sub>s for these compounds range from 1,700 mg for sarin down to only 6 to 10 mg for VX.<sup>48,76</sup> It is noteworthy that these reported values for toxicity are derived from animal data, limited human exposures, or calculations for previously healthy combatant casualties with offensive use. Data from rats exposed to sarin vapor show that Haber's rule (ie, that the time of exposure to a gas multiplied by the concentration required to cause toxicity is a

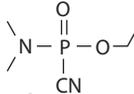

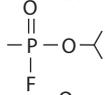

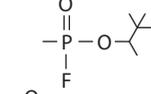

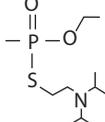

Military Designation	Common Name	Chemical Name	Chemical Structure
GA	Tabun	Ethyl- <i>N,N</i> -dimethylphosphoramidocyanidate	
GB	Sarin	Isopropyl-methylphosphonofluoridate	
GD	Soman	1, 2, 2-Trimethylpropyl-methyl phosphonofluoridate	
VX	–	O-ethyl-S-(2-diisopropylaminoethyl)-methylphosphonothiolate	

FIGURE 126-1. Nerve agents.

constant) does not hold true across all exposure times, with rats surviving slightly higher concentrations than predicted at the shortest (<10 minutes) and the longest exposure (>200 minutes) times.<sup>49</sup>

Pure nerve agents are clear and colorless. Tabun has a faint fruity odor, and soman is variably described as smelling sweet, musty, fruity, spicy, nutty, or like camphor. Most subjects exposed to sarin and VX were unable to describe the odor.<sup>42,76</sup> The G agents tabun (GA), sarin (GB), and soman (GD) are volatile and present a significant vapor hazard. Sarin is the most volatile, only slightly less so than water. VX is an oily liquid with low volatility and higher environmental persistence.<sup>42,48,76</sup> Other G and V nerve weapons have been developed, including cyclosarin (GF) and Russian VX (VR).

### Pathophysiology

The pathophysiology of nerve agents is essentially identical to that from organic phosphorus compound insecticides (Chap. 110), differing only in terms of potency, kinetics, and physical characteristics of the xenobiotics. The resultant toxic syndrome includes muscarinic (salivation, lacrimation, urination, defecation, gastrointestinal [GI] cramping, emesis) and nicotinic (muscle fasciculation, weakness, paralysis) signs, and central effects (loss of consciousness, seizures, respiratory depression).<sup>30,74,78</sup>

### Clinical Effects

Nerve agent vapor exposures produce rapid effects, within seconds to minutes, but the effects from liquid exposure are also delayed as the xenobiotic is absorbed through the skin.<sup>76</sup> Vapor or aerosol exposures have historically been more common, whether through experiments or from unintentional releases in the laboratory<sup>74</sup> or in terrorist attacks.<sup>51,61</sup> Aerosol or vapor exposure initially affects the eyes, nose, and respiratory tract. Miosis is common, resulting from direct contact of the xenobiotic with the eye and may persist for several weeks.<sup>74,78</sup> Other ocular effects include conjunctival injection and blurring and dimming of the vision. Dim vision is often ascribed to pupillary constriction, but central neural mechanisms also play a role.<sup>76</sup> Ciliary spasm produces ocular pain, headache, nausea, and vomiting, often exacerbated by near-vision accommodation.<sup>30</sup> Rhinorrhea, airway secretions, bronchoconstriction, and dyspnea occur with increasing exposures. With a large vapor exposure, one or two breaths may produce loss of consciousness within seconds followed by seizures, paralysis, and apnea within minutes.<sup>46</sup>

In the 1995 Tokyo subway sarin incident, ocular effects were most common after sarin vapor exposure, and patients manifested miosis (89%–99% of symptomatic victims), eye pain, dim vision, and decreased visual acuity.<sup>30,61</sup> Other common complaints were cough, throat tightness, nausea, headache, dizziness, chest discomfort, and abdominal cramping.<sup>44,83</sup> Among 111 patients admitted to one hospital, the most common presenting signs and symptoms were miosis (99%), headache (74.8%), dyspnea (63.1%), nausea (60.4%), eye pain (45%), blurred vision (39.6%), dim vision (37.8%), and weakness (36.9%).<sup>57,61</sup> Excessive secretions were less common

because rhinorrhea occurred in approximately one-quarter of patients admitted to one hospital<sup>61</sup> and in none of 58 patients at another.<sup>83</sup> Secondary exposures occurred among emergency medical technicians and hospital personnel in both the Tokyo<sup>44,56,57</sup> and Matsumoto<sup>51,52</sup> terrorist sarin releases, apparently from evaporation of sarin that condensed on the primary victims' clothing.

Liquid nerve agents permeate ordinary clothing, allowing for percutaneous absorption and rendering the clothing of patients' potential hazards to health care personnel before proper decontamination. Mild dermal exposure produces localized sweating and muscle fasciculations after an asymptomatic period lasting up to 18 hours. Moderate skin exposure produces systemic effects with nausea, vomiting, diarrhea, and generalized weakness. Substantial dermal contamination will produce earlier and more severe effects, often with an abrupt onset. Severe toxicity from any route of exposure causes loss of consciousness, seizures, generalized fasciculations, flaccid paralysis, apnea, and/or incontinence.<sup>48,76,78</sup> Cardiovascular effects are less predictable because either bradycardia (muscarinic) or tachycardia (nicotinic) may occur.<sup>46</sup> In the Tokyo sarin event, tachycardia and hypertension were more common than bradycardia.<sup>55,83</sup> Subtle CNS effects can continue for weeks but typically resolve if no anoxic brain injury occurred.

Long-term effects from nerve agent exposure are mostly limited to psychological sequelae.<sup>72</sup> Neither delayed peripheral neuropathy nor the intermediate syndrome are reliably described in humans exposed to these xenobiotics.<sup>78,79</sup> Follow-up studies from the Japanese sarin incidents show that neuropathy and ataxia, when initially present, resolved within 3 days to 3 months.<sup>91</sup> The main persistent sequela is posttraumatic stress disorder, found in up to 8% of victims.<sup>29,91</sup>

## Treatment of Nerve Agent Exposure

### Decontamination

In some critically ill patients, antidotal treatment will be necessary before or during the decontamination process; but generally, decontamination should occur before other treatment is instituted.

### Atropine

Atropine (Antidotes in Depth: A35) is the standard anticholinergic antidote for the muscarinic effects of nerve agents.<sup>17</sup> Atropine does not reverse nicotinic effects but does have some central effects and will thus assist in halting seizure activity.<sup>30,42,76</sup>

Atropine is administered parenterally, either by the intravenous (IV) or intramuscular (IM) route, and the dose is determined through titration to effect. The standard adult dose determined by the US military is 2 mg, an amount expected to produce substantial benefit in reversing nerve agent toxicity but one that should be tolerated by a healthy unexposed adult unintentionally receiving the drug.<sup>76</sup> We recommend an initial minimum

dose of 2 mg atropine in adults; dosing in children begins at 0.05 mg/kg for mild to moderate symptoms and 0.1 mg/kg for severe symptoms, up to the adult dose.<sup>4</sup> An initial dose of 5 to 6 mg is given for severely poisoned adult patients.<sup>30,76</sup> Repeat doses are given every 2 to 5 minutes until resolution of muscarinic signs of toxicity. Therapeutic endpoints are drying of respiratory secretions and resolution of bronchoconstriction, bradycardia, or seizures (if initially present). Neither reversal of miosis nor development of tachycardia is a reliable marker to guide atropine therapy.<sup>30</sup> The total amount of atropine necessary to treat nerve agent poisoning is often much less than required for organic phosphorus insecticide toxicity of a similar degree. Typically, less than 20 mg is required in the first 24 hours, even in severe cases.<sup>30,76,78</sup> Fewer than 20% of moderately ill patients admitted to one hospital for sarin poisoning in Tokyo required more than 2 mg of atropine.<sup>61</sup> The aforementioned atropine dosing appears to conflict with the experience of an Iranian physician who treated many chemical casualties in the Iran–Iraq War using much higher doses of atropine, starting with 4 mg IV, rapidly titrating by ease of breathing and drying of respiratory secretions, and sometimes giving up to 200 mg. These much higher doses, however, resulted from limited availability of oxime co-antidotal therapy and concern for symptom recurrence during unmonitored victim transport to rearward treatment facilities.<sup>53</sup>

American troops in the 1990 to 1991 Gulf War were issued three MARK I kits for immediate field treatment of nerve agent poisoning. These kits are now also known as NAAKs, for nerve agent antidote kits. Each kit contains two autoinjectors: an AtroPen containing 2 mg of atropine in 0.7-mL diluent and a ComboPen containing 600 mg of pralidoxime chloride (pyridine-2-aldoxime, 2-PAM) in 2 mL of diluent.<sup>76</sup> These autoinjectors permit rapid IM injections of antidote through protective clothing and are given in the lateral thigh.<sup>17</sup> Treatment algorithms guided the number of MARK I kits to administer. In general, conscious casualties not in severe distress self-administer one kit (2 mg of atropine), moderate to severe cases receive three kits (6 mg of atropine) initially, and all receive additional doses as necessary, every 5 to 10 minutes.<sup>17,48,76</sup> A combination atropine (2.1 mg) plus pralidoxime chloride (600 mg) autoinjector is available that gives both drugs with a single injection (Antidotes in Depth: A36).

In a nerve agent mass casualty incident, IV atropine supplies will likely be rapidly depleted from hospital stocks. Alternative sources include atropine from ambulances, ophthalmic and veterinary preparations, or substituting an antimuscarinic such as glycopyrrolate.<sup>30</sup> Facilities expecting large numbers of casualties should store atropine as a bulk powder formulation and rapidly reconstitute it for injection when needed.<sup>20</sup>

### Oximes

Oximes are nucleophilic compounds that reactivate organic phosphorus compound–inhibited cholinesterase enzymes by removing the dialkylphosphoryl moiety. The only oxime approved in the United States by the Food and Drug Administration is 2-PAM, a monopyridinium compound. Other pralidoxime salts are used elsewhere, such as the methanesulfonate salt of pralidoxime (P2S) in the United Kingdom and 2-PAM methiodide in Japan. Other oximes include the bispyridinium compounds trimedoxime (TMB4) and obidoxime (toxogonin) used in other European countries.<sup>42,61,76</sup> Oximes should be given in conjunction with atropine because they are not particularly effective in reversing muscarinic effects when given alone. Oximes are the only available nerve agent antidotes that can reverse the neuromuscular nicotinic effects of fasciculations, weakness, and flaccid paralysis (Antidotes in Depth: A36).

Oximes are effective only if administered before irreversible dealkylation, or “aging,” of the organic phosphorus compound–cholinesterase complex occurs. Soman has an aging half-life of 2 to 6 minutes in humans.<sup>16</sup> It is unlikely that soman-poisoned victims will reach medical care early enough for oxime therapy to be of great benefit. For comparison, tabun has an aging half-life of about 14 hours, sarin 3 to 5 hours, and VX 48 hours.<sup>16</sup> Pralidoxime is effective against sarin and VX in animal studies. It is ineffectual against tabun because of ineffective nucleophilic attack against that particular agent and not because of aging issues. Obidoxime also is effective against sarin but not against tabun.<sup>42</sup>

The bispyridinium Hagedorn (H-series) oximes, particularly HI-6 and HLö-7, are also studied in the context of nerve agent toxicity.<sup>42</sup> HI-6 appears beneficial against soman poisoning (possibly through direct pharmacologic action or reactivation of aged soman-inhibited ChE) but is not very effective against tabun. HLö-7 has reactivating activity for both soman- and tabun-inhibited ChE and may thus represent a universal oxime antidote for nerve agents. Administration of HI-6 and HLö-7 by autoinjector is difficult because they are not stable in aqueous solution.

For more details about pralidoxime administration, dosing, and adverse events, Antidotes in Depth: A36. The ComboPen autoinjector in MARK I kits contains 600 mg of pralidoxime, which produces a maximal therapeutic serum concentration of 6.5 mcg/mL in average human volunteers.<sup>76</sup> However, when possible, pralidoxime is optimally administered intravenously. Repeat pralidoxime dosing or continuous infusions are less likely to be needed for nerve agents than for organic phosphorus compound insecticides because severe effects are shorter lived in properly decontaminated patients.<sup>30</sup>

### Antiepileptics

Severe human nerve agent toxicity rapidly induces convulsions, which persist for a few minutes until the onset of flaccid paralysis. Diazepam is more beneficial than other anticonvulsants and simple  $\gamma$ -aminobutyric acid channel agonists because of its effects on choline transport across the blood–brain barrier and acetylcholine turnover.<sup>42</sup> US military doctrine is to administer 10 mg of diazepam intramuscularly by autoinjector at the onset of severe toxicity whether seizures are present or not. Thus, whenever three MARK I kits are used, a victim is also given diazepam. Additional autoinjectors are given by medical personnel as necessary for seizures.<sup>48</sup> The reason for the IM route of diazepam suggested above is related to timely administration under field conditions. If IV access is feasible, then IV diazepam in 5-mg doses rapidly uptitrated to seizure cessation recommended<sup>42</sup> (Antidotes in Depth: A26). Animal studies suggest that the diazepam dose required to terminate nerve agent seizures may have been underestimated.<sup>45</sup>

Although diazepam is the most well studied benzodiazepine in the treatment of nerve agent toxicity, other medications in the same class such as lorazepam and midazolam have similar or improved beneficial effects in animal studies.<sup>45</sup> Armed service personnel of the United Kingdom are supplied with ComboPens containing atropine sulfate (2 mg); pralidoxime mesylate (P2S; 30 mg); and avizafone (10 mg), a water-soluble prodrug of diazepam.<sup>90</sup>

### Pyridostigmine Pretreatment

The first large-scale use of pyridostigmine as a pretreatment for nerve agent toxicity occurred during Operation Desert Storm in 1991.<sup>34</sup> Whereas pyridostigmine is a carbamate acetylcholinesterase inhibitor that is freely and spontaneously reversible, organic phosphorus compound inhibition is permanent after “aging” occurs. Toxicity from rapidly aging weapons such as soman (GD) can probably not be reversed by standard oxime therapy in realistic clinical situations. Almost paradoxically, then, a carbamate can occupy cholinesterase, blocking access of nerve weapons to the active site, and thereby protect the enzyme from permanent inhibition. After nerve agent exposure, pyridostigmine is rapidly hydrolyzed from acetylcholinesterase and can also be easily displaced by oximes, regenerating functional enzyme. Between 20% and 40% cholinesterase inhibition is desired to protect against nerve weapons.<sup>17</sup> Doses of 60 mg of pyridostigmine bromide reduce cholinesterase activity by 28.4% in healthy individuals. Patients with asthma taking 30-mg doses had a mean 24.3% reduction in cholinesterase activity without significant reductions in respiratory function or in response to inhaled atropine.<sup>62</sup> In animal studies, pyridostigmine confers a benefit against soman and tabun but not against sarin or VX.<sup>17</sup> Also, it must be recognized that pyridostigmine is not an antidote but is instead a pretreatment adjunct that greatly enhances the efficacy of atropine and oxime therapy.<sup>78</sup>

US troops in the 1990 to 1991 Gulf War took 30 mg pyridostigmine bromide orally every 8 hours when under threat of nerve agent attack because of concern for potential exposure specifically to soman, which has a short aging half-life. Pyridostigmine pretreatment is not recommended in the

civilian sector. Cholinergic side effects, mostly GI, were common but rarely required treatment.<sup>34</sup> Israeli soldiers taking the same dose also reported a range of mostly cholinergic symptoms but also a high incidence (71.4%) of dry mouth, which may be more related to environmental and psychological stressors.<sup>71</sup> Nine Israeli patients were hospitalized during the Gulf War for acute intentional pyridostigmine overdoses.<sup>2</sup> All patients recovered fully, including one patient who self-treated with atropine autoinjectors and presented with anticholinergic toxicity and another who had a cardiac arrest, apparently from coingesting 4,000 mg of propranolol.

## VESICANTS

Vesicants are historically designated as “blister agents” because they manifest with blistering of skin and mucous membranes (Fig. 126–2).

### Sulfur Mustard

Sulfur mustard is bis(2-chloroethyl) sulfide, a vesicant alkylating compound similar to nitrogen mustards used in chemotherapy. Nineteenth-century scientists described the compound as smelling like mustard, tasting like garlic, and causing blistering of the skin on contact. The Allies of World War I called it Hun Stoffe (also called “German Stuff”), abbreviated as HS and later as just H. Distilled, nearly pure mustard is designated HD. The French called it Yperite, after the site where it was first used, and the Germans called it LOST after the two chemists who suggested its use as a CW, Lommel and Steinkopf. It was also called “yellow cross” after the markings on German artillery shells filled with mustard.<sup>9,14,80</sup> Sulfur mustard caused over 1 million casualties in World War I<sup>21</sup> and was later used by the Italians and Japanese in the 1930s, by Egypt in the 1960s, and by Iraq in the 1980s.<sup>48</sup> About 100,000 Iranians from both military and civilian backgrounds were exposed to vesicant CWs during the latter years of the Iran–Iraq War (1984–1988), many of whom are still suffering long-term effects.<sup>22</sup> Nonbattlefield exposures also occurred among Baltic Sea fishermen while recovering corroding shells dumped after World War II and to persons unearthing or handling old chemical warfare ordinance.<sup>21,54,67,80</sup>

### Physical Characteristics

Sulfur mustard is a yellow to brown oily liquid with an odor resembling mustard, garlic, or horseradish. Mustard has relatively low volatility and high environmental persistence. Nonetheless, most historical mustard injuries occurred from vapor exposure, a danger that increases in warmer climates. Mustard vapor is 5.4 times denser than air. Mustard freezes at 57°F (13.9°C), so it is sometimes mixed with other substances, including CW agents such as chloropicrin or Lewisite, to lower the freezing point and permit dispersion as a liquid.<sup>14,48,80</sup>

### Pathophysiology

Sulfur mustard toxicity occurs through several mechanisms. First, mustard is an alkylating agent. Mustard spontaneously undergoes intramolecular cyclization to form a highly reactive sulfonium ion that alkylates sulfhydryl (–SH) and amino (–NH<sub>2</sub>) groups.<sup>9,14,48,80</sup> This mechanism is the same as occurs with the nitrogen mustards, first developed as cancer chemotherapy agents in the 1940s.<sup>23</sup> The most important acute manifestation is indirect inhibition

Military Designation	Common Name	Chemical Name	Chemical Structure

L	Lewisite	2-Chlorovinylchloroarsine	
CX	Phosgene oxime	Dichloroformoxime	

FIGURE 126–2. Vesicants.

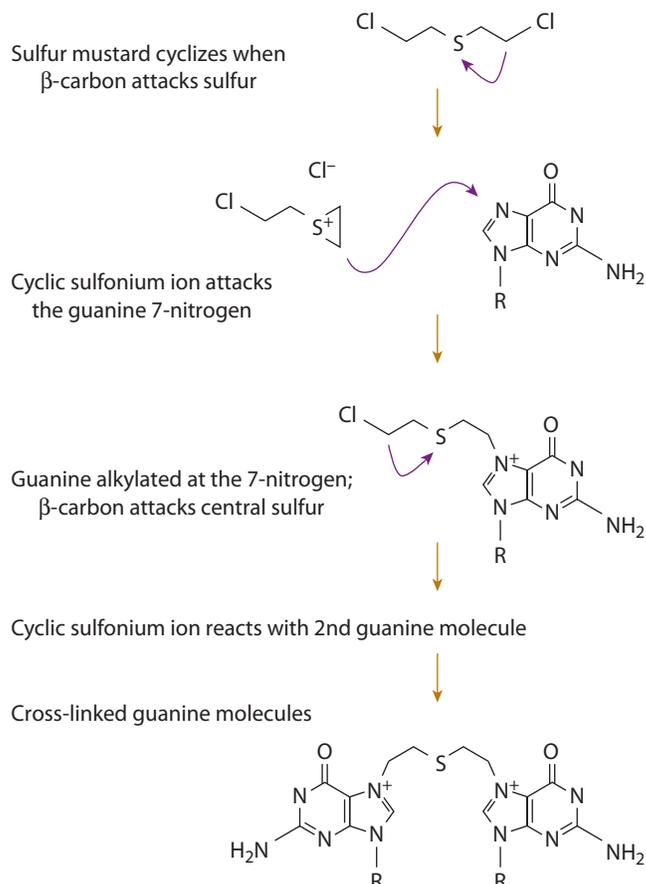

FIGURE 126–3. Mechanism of sulfur mustard toxicity: alkylation and DNA crosslinking.

of glycolysis. Sulfur mustard rapidly alkylates and crosslinks purine bases in nucleic acids (Fig. 126–3). DNA repair mechanisms are activated, including the activation of the enzyme poly(ADP-ribose) polymerase,<sup>43</sup> depleting nicotinamide adenine dinucleotide (NAD<sup>+</sup>), which in turn inhibits glycolysis and ultimately leads to cellular necrosis from adenosine triphosphate depletion.<sup>9</sup> Additional mechanisms are likely involved because the inhibition of glycolysis only partially correlates with the depletion of NAD<sup>+</sup>; sulfur mustard may also inhibit glycolysis directly through undetermined mechanisms.<sup>43</sup> Mustard also depletes glutathione, leading to loss of protection against oxidant stress, dysregulation of calcium homeostasis, and further inactivation of sulfhydryl-containing enzymes.<sup>80</sup> Sulfur mustard is also a weak cholinergic agonist.<sup>48,80</sup>

### Clinical Effects

The organs most commonly affected by mustard are the eyes, skin, and respiratory tract. During World War I, 80% to 90% of American mustard casualties had cutaneous lesions, 86% had ocular involvement, and 75% had airway injury. Iranian soldiers had more airway (95%) and ocular injuries (92%), and 83% had cutaneous lesions, probably because of the more extensive vaporization occurring in the warmer environment.<sup>9,80</sup> Incapacitation is severe in terms of number of lost man-days, time for lesions to heal, and increased risk of infection. In contrast, the mortality rate is rather low. In World War I, only 2% to 3% of British mustard casualties and fewer than 2% of American casualties died. Fatality rates of 3% to 4% were reported from the Iran–Iraq War.<sup>9</sup> Most deaths occur several days after exposure from respiratory failure, secondary bacterial pneumonia, or bone marrow suppression.

Dermal exposure produces dose-related injury. After a latent period of 4 to 12 hours, victims develop erythema that progresses to vesicles or bullae formation and skin necrosis. Warm, moist, and thin skin is at increased risk of mustard injury, in particular the perineum, scrotum, axillae, antecubital fossae, and neck. The vesicle fluid does not contain mustard because all

chemical reactions are complete within a few minutes. If decontamination is not performed immediately after exposure, injury cannot be prevented. However, later decontamination limits the severity of lesions and further spread of the weapon to develop new lesions. Skin exposure to vapor typically results in first- or second-degree burns, although liquid exposure more commonly results in full-thickness burns.<sup>80</sup> Mustard easily penetrates normal clothing and uniforms, and many soldiers received gluteal, perineal, and scrotal burns from sitting on contaminated objects.

Signs and symptoms of ocular and respiratory tract exposures also occur after a latent period of several hours. Ocular effects include pain, miosis, photophobia, lacrimation, blurred vision, blepharospasm, and corneal damage. Permanent blindness is rare, with recovery generally occurring within a few weeks. Inhalation of mustard results in a chemical tracheobronchitis. Hoarseness, cough, sore throat, and chest pressure are common initial complaints. Bronchospasm and obstruction from sloughed membranes occur in more serious cases, but lung parenchymal damage occurs only in the most severe inhalational exposures. Productive cough associated with fever and leukocytosis is common 12 to 24 hours after exposure and represents a sterile bronchitis or pneumonitis. Nausea and vomiting are common within the first few hours. High-dose exposures also cause bone marrow suppression.<sup>9,48,80</sup>

Various long-term sequelae are associated with sulfur mustard. Factory workers chronically exposed to mustard have increased risk of respiratory tract carcinomas, although the carcinogenic risk from battlefield exposures is more controversial.<sup>21,22,79</sup> Respiratory sequelae include chronic bronchitis, emphysema, tracheobronchomalacia, and bronchiolitis obliterans.<sup>22</sup> Some mustard victims also develop a delayed and often recurrent keratitis.<sup>21,73</sup> Chronic dermatologic complications include scarring, pigmentation changes, chronic neuropathic pain, and pruritus.<sup>21,73</sup> Among approximately 34,000 Iranians with confirmed exposure to sulfur mustard during the war with Iraq, chronic pulmonary sequelae were noted in 42.5%, ocular lesions in 39.3%, and dermatologic lesions in 24.5%.<sup>36</sup>

### Treatment

Decontamination is essential in treating the sulfur mustard exposures, even among asymptomatic victims. Further treatment is largely supportive and symptomatic.<sup>9,48,80</sup> Some victims are blinded because of a combination of blepharospasm and corneal edema, which is temporary and completely resolves in most cases. More severe ocular injuries from sulfur mustard are treated with mydriatic and antibiotics drops and applying petroleum jelly to the eyelid edges several times a day.

Several experimental therapies have been proposed for sulfur mustard but are not specifically recommended because of a lack of proven efficacy outside of animal experiments. Antiinflammatory and sulfhydryl-scavenging drugs have shown benefit in animals as prophylactic therapy or if given immediately after exposure.<sup>80</sup> *N*-Acetylcysteine appears to be a promising therapeutic in cell culture and animal studies, although most of the evidence for its use relates to inhalational aerosol exposures to mustard.<sup>7</sup> Neutropenia from bone marrow suppression, however, should be treated with granulocyte colony-stimulating factor.<sup>47</sup>

### Lewisite

Lewisite (2-chlorovinylchloroarsine) was developed as a less persistent alternative to avoid some shortcomings in the use of sulfur mustard in World War I. Lewisite was never used in combat because the first shipment was en route to Europe when the war ended, and it was intentionally destroyed at sea. British anti-Lewisite (BAL, dimercaprol) was developed as a specific antidote and remains in use for chelation of arsenic and other metals.<sup>42,80</sup>

Pure Lewisite is an oily, colorless liquid. Impure preparations are colored from amber to blue-black to black and have the odor of geraniums. Lewisite is more volatile than mustard and is easily hydrolyzed by water and by alkaline aqueous solutions such as sodium hypochlorite. These properties increase safety for offensive battlefield use, but make maintaining a potent vapor concentration difficult.

Lewisite toxicity is similar to that of sulfur mustard, resulting in dermal and mucous membrane damage, with conjunctivitis, airway injury, and vesiculation. An important clinical distinction is that Lewisite is immediately painful, but initial contact with mustard is not. Other differences are faster onset of inflammatory response and healing of lesions from Lewisite, less secondary infection of Lewisite lesions, and less subsequent pigmentation changes.<sup>80</sup> The mechanisms of Lewisite toxicity are not completely known but appear to involve glutathione depletion and arsenical interaction with enzyme sulfhydryl groups. Nevertheless, Lewisite toxicity is qualitatively and quantitatively different from the arsenic it contains. Treatment consists of decontamination with copious water or dilute hypochlorite solution, supportive care, and BAL. British anti-Lewisite is given parenterally for systemic toxicity and is also used topically for dermal or ophthalmic injuries. Alternative metal chelators that may be used as Lewisite antidotes include dimercaptopropane sulfonate and succimer (2,3-dimercaptosuccinic acid).<sup>42</sup> There is inadequate evidence to recommend one chelating drug over another.

### Phosgene Oxime

Although classified as a vesicant, phosgene oxime (dichloroformoxime, or CX) does not cause vesiculation of the skin. CX is more properly an urticant or “nettle” weapon, in that it produces erythema, wheals, and urticaria likened to stinging nettles. Phosgene oxime produces immediate irritation of the skin and mucous membranes. CX has never been used in battle, and little is known about its mechanism or effects on humans.<sup>48,80</sup>

### CYANIDES (CHEMICAL ASPHYXIANTS)

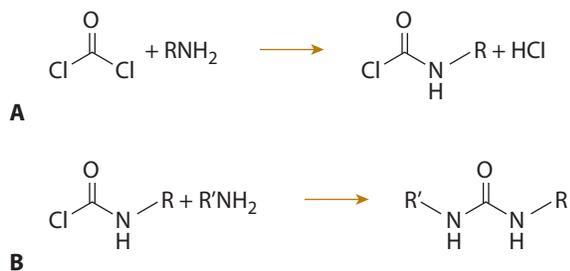

Several cyanides have been used as CWs. Historically, the cyanides were classified as “blood agents” because they are first absorbed and then distributed through the body via blood circulation. During World War I, the French used hydrogen cyanide (HCN) and cyanogen chloride (CNCl), designated as agents AC and CK, respectively, without great success; the Austrians introduced cyanogen bromide (CNBr). Cyanide weapons are relatively ineffective because of rapid dispersion and their “all or nothing” biologic activity. An exposed individual either rapidly succumbs to cyanide toxicity or will rapidly recover with minimal sequelae. Mass casualty events from cyanide CW are reported during the Iran–Iraq War and from Iraq’s suppression of the Kurds.<sup>5,48</sup>

The clinical effects and treatment of cyanide toxicity are covered elsewhere (Chaps. 123 and 126) and do not differ significantly if used as a weapon. Hydrocyanic acid gas persists for only a few minutes in the atmosphere because it is lighter than air and rapidly disperses. Cyanogen chloride additionally causes ophthalmic and respiratory tract irritation and with sufficiently high exposures is reported to produce delayed acute respiratory distress syndrome (ARDS) in victims who are not rapidly killed.<sup>5,48</sup>

### PULMONARY IRRITANTS

Chlorine, phosgene, and diphosgene (DP, trichloromethylchloroformate) were used as war gases in World War I. Chlorine, phosgene, diphosgene, various organohalides, and nitrogen oxides belong to a group of toxic chemicals designated “pulmonary irritants” because they can all induce delayed ARDS from increased alveolar-capillary membrane permeability.<sup>42,48,88</sup> Until chlorine attacks during the Syrian civil war,<sup>87</sup> pulmonary irritants had not been used militarily since 1918. Nevertheless, the risk of chlorine and phosgene exposure remains because of their extensive use in industry and their possible appropriation as terrorist weapons; see Chap. 121 for clinical details because the remainder of this section highlights mass casualty issues regarding these irritant gases.

When released on the battlefield, chlorine forms a yellow-green cloud with a distinct pungent odor detectable at concentrations that are not immediately dangerous. Phosgene is either colorless or seen as a white cloud as a result of atmospheric hydrolysis. Phosgene, which is reported to smell like grass, sweet newly mown hay, corn, or moldy hay, accounted for about 85% of all World War I deaths attributed to CWs.<sup>9,42</sup> Phosgene produces injury by hydrolysis in the lungs to hydrochloric acid and by forming diamides that

**FIGURE 126-4.** Proposed mechanism of phosgene toxicity. (A) Phosgene reacts with amine group to form an amide, releasing hydrochloric acid. (B) A second reaction crosslinks two amine equivalents, forming a diamide.

cross-link cell components (Fig. 126-4). Similar cross-linking reactions occur with hydroxyl and thiol groups. Battlefield exposure triggers cough, chest discomfort, dyspnea, lacrimation, and the peculiar complaint that smoking tobacco produces an objectionable taste. World War I phosgene fatalities were noted to develop a mushroom-shaped efflux of pink foam at their mouths resulting from the acute lung injury. Prolonged observation after phosgene exposure is the rule because some casualties initially appeared well and were discharged, only to return in severe respiratory distress a few hours later.<sup>42,48,88</sup> Exercise appeared to precipitate ARDS in phosgene casualties.<sup>68</sup> For American soldiers in World War I, the average times spent recovering away from the front were 60 days for chlorine and 45.5 days for phosgene.<sup>19</sup>

## RIOT CONTROL AGENTS

Riot control agents (Fig. 126-5) are intentionally nonlethal chemicals that temporarily disable exposed individuals through intense irritation of exposed mucous membranes and skin. These weapons are also known as lacrimators, irritants, harassing agents, human repellents, and tear gas. They are solids at normal temperatures and pressures but are typically dispersed as aerosols or as small solid particles in liquid sprays. Common characteristics include rapid onset of effects within seconds to minutes, relatively brief duration after exposure has ceased and the victim is decontaminated, and a high safety ratio (lethal dose versus effective dose).<sup>42,48,77</sup>

Chloroacetophenone (CN) is the active ingredient in the Chemical Mace brand nonlethal weapon.<sup>82</sup> *o*-Chlorobenzilidene malononitrile (CS) has largely replaced CN because of its higher potency, lower toxicity, and improved chemical stability.<sup>39,77</sup> When used for crowd control, both CN

and CS are disseminated as aerosols or as smoke from incendiary devices. CR (dibenzoxazepine) is a similar weapon with prominent skin irritation. Exposed persons develop burning irritation of the eyes, progressing to conjunctival injection, lacrimation, photophobia, and blepharospasm. Mucous membranes of the upper aerodigestive tracts are frequently also involved. Inhalation causes chest tightness, cough, sneezing, and increased secretions. Dermal exposure causes a burning sensation, erythema, or vesiculation, depending on the dose. Victims generally remove themselves from the offensive environment (which is the primary purpose of their use for “riot control”) and recover within 15 to 30 minutes. Deaths are rare and typically occur from respiratory tract complications in closed-space exposures where exiting the area is impossible.<sup>42,48,77</sup>

The biologic mechanism whereby riot control agents exert their effects is less well described than for other CWs. *o*-Chlorobenzilidene malononitrile (CS) and CN are  $\text{SN}_2$  alkylating agents (versus sulfur mustard, an  $\text{SN}_1$  alkylator) and react with sulfhydryl-containing compounds and enzymes. For instance, CS reacts rapidly with the disulfhydryl form of lipoic acid, a coenzyme for pyruvate decarboxylase. Pain in the absence of tissue injury is likely to be bradykinin mediated.<sup>48</sup>

Personal protective devices dispensing lacrimator substances also cause chemical injuries in the absence of war or civil unrest. Law enforcement agencies and private citizens have access to products containing CS, CN, or (oleoresin capsicum [OC], also known as pepper spray). OC is the essential oil derived from pepper plants (*Capsicum annuum*), which contains capsaicin (trans-8-methyl-*N*-vanillyl-6-noneamide), a naturally occurring lacrimator. Capsaicin activates the TRPV1 receptor, a heat-dependent nociceptor, explaining why exposures are experienced as “hot.”<sup>11</sup> Severe skin injuries,<sup>26</sup> respiratory tract injuries, and fatalities are occasionally reported from exposures to these devices, typically only with prolonged or highly concentrated exposures.

Chloropicrin (PS, trichloronitromethane, or nitrochloroform) is another lacrimator that occasionally causes human toxicity through its use as a broad-spectrum fumigant and soil insecticide, as well as a warning agent associated with structural fumigants such as sulfuryl fluoride.<sup>84</sup> 10-Chloro-5,10-dihydrodiphenarsazine (or diphenylaminechlorarsine {DM}) induces vomiting in addition to irritant effects. Because symptoms are delayed, victims remain in the area, and the likelihood of significant absorption is increased. In addition to upper respiratory and ocular irritation, diphenylaminearsine causes more prolonged systemic effects with headache, malaise, nausea, and vomiting.<sup>48,77</sup>

Military Designation	Common Name	Chemical Name	Chemical Formula
CN	Chemical Mace	1-chloroacetophenone	
CS	Tear gas	<i>o</i> -chlorobenzilidene malononitrile	
CR	Tear gas DBO	dibenzo[ <i>b,f</i> ][1,4]oxazepine	
DM	Adamsite	diphenylaminechlorarsine	
OC	Capsaicin pepper spray	<i>Trans</i> -8-methyl- <i>N</i> -vanillyl-6-noneamide	

**FIGURE 126-5.** Riot control agents.

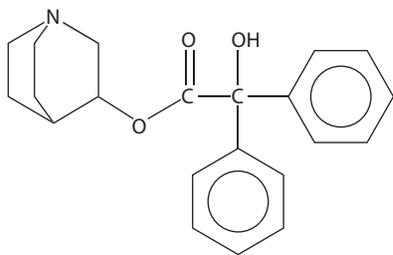

FIGURE 126-6. BZ, 3-quinuclidinyl benzilate (QNB).

The primary treatment for all riot control agents is removal from exposure. Contaminated clothing should be removed and placed in airtight bags to prevent secondary exposures.<sup>39</sup> Skin irrigation with copious cold water should be used for significant dermal exposures.<sup>6,39,40</sup> Symptomatic treatments, such as with topical ophthalmic anesthetics, nebulized bronchodilators, or oral antihistamines and corticosteroids, are indicated for directed therapy in more severely affected victims.<sup>6</sup> Capsaicin-induced dermatitis has been treated variably with immersion in water or oil, vinegar, bleach, lidocaine gel, and topical antacid suspensions.<sup>28,32,82</sup> Cold water produces earlier symptomatic relief, but oil immersion has longer lasting benefits.<sup>32</sup> Given that it is more readily available in most settings, cold water immersion is the treatment of choice.

## INCAPACITATING AGENTS

3-Quinuclidinyl benzilate (BZ or QNB; Fig. 126-6) is an antimuscarinic compound that was developed as an incapacitating CW agent. BZ is 25-fold more potent centrally than atropine, with an  $ID_{50}$  (dose that incapacitates 50% of

those exposed) of about 0.5 mg. Clinical effects are characteristic for anticholinergics, with drowsiness, poor coordination, and slowing of thought processes progressing to delirium. BZ takes at least 1 hour to produce initial manifestations, peaks at 8 hours, continues to incapacitate for 24 hours, and takes 2 to 3 days to fully resolve.<sup>35</sup> During the Balkan Wars of the 1990s, allegations were made that Bosnian Serbs used BZ against civilians, who reported hallucinations associated with attacks by artillery shells emitting smoke.<sup>25</sup> Agent 15 is a similar incapacitating weapon to BZ, reportedly researched by Iraq prior to the Persian Gulf War but not mass produced or used.<sup>12</sup>

Ultrapotent opioids can be used as incapacitating CWs. In 2002, Russian security forces used a fentanyl derivative (carfentanyl or remifentanyl) to end a 3-day standoff with terrorists in a Moscow theater in which Chechen rebels held more than 800 hostages.<sup>63,89</sup> A “gas” was introduced into the theater ventilation system, which quickly subdued the occupants. More than 650 of the hostages were hospitalized, and 128 died. Initial news reports suggested the use of BZ, although the clinical findings were more consistent with a CNS depressant. Within a few days, Russian officials stated that a fentanyl derivative was used and was not expected to cause fatalities. The relatively high case fatality rate could be because of multiple factors, including variability in dose, displacement of oxygen by rapid introduction of gas into the building, failure to adequately notify health care teams and supply them with antidotes, and the poor physical condition of the hostages, coupled with their immobility.

Lysergic acid diethylamide (LSD) has also been investigated as an incapacitating weapon.<sup>35</sup> Although effective at very low doses, battlefield use of LSD is impractical because intoxication will not reliably prevent a soldier from participation in combat.

Table 126-5 describes the various toxic syndromes associated with use of CWs.

TABLE 126-5 Chemical Weapons Toxic Syndromes

Chemical Weapon	Onset	Organ System						
		Eyes	Upper Airways and Mucous Membranes	Lungs	Skin	CNS	GI Tract	Other
<b>Nerve Agents</b>								
Tabun (GA), Sarin (GB), Soman (GD), VX								
Aerosol/vapor (Mild/moderate exposure)	Rapid (seconds–minutes)	Miosis, eye pain, dim or blurred vision	Rhinorrhea, ↑ secretions	Dyspnea, cough, wheezing, bronchorrhea	—	Headache	Nausea, vomiting, abdominal cramps	—
Dermal exposure (mild to moderate exposure)	Delayed (minutes–hours)	—	—	—	Localized sweating	—	—	—
Severe exposure (any route)	As above (by route)	Miosis	↑ Secretions	Apnea	—	Sudden collapse, seizures	Nausea, vomiting, diarrhea, cramping, incontinence	Subjective weakness local muscle fasciculations generalized fasciculations, weakness, flaccid paralysis
<b>Vesicants</b>								
Sulfur mustard (H, HD)	Delayed (hours)	Conjunctivitis, eye pain, blurred vision, blindness (temporary)	Irritation, hoarseness, barky cough, sinus tenderness, tracheobronchitis	(More severe exposures) Productive cough, pseudomembrane formation, airway obstruction	Erythema, vesicles, bullae, necrosis	—	Nausea, vomiting	Bone marrow suppression (in severe exposures)
Lewisite (L)	Immediate irritation	Pain, blepharospasm, conjunctivitis, eyelid edema	(Same as sulfur mustard)	(Same as sulfur mustard)	Erythema, vesicles	—	—	Shock (in severe exposures)

(Continued)

TABLE 126-5 Chemical Weapons Toxic Syndromes (Continued)

Chemical Weapon	Onset	Organ System							
		Eyes	Upper Airways and Mucous Membranes	Lungs	Skin	CNS	GI Tract	Other	
Phosgene oxime (CX)	Delayed vesication Immediate irritation Delayed urticaria	Pain, corneal damage	Irritation	ARDS	Pain, blanching, erythema, urticaria, necrosis	—	—	—	
<b>Toxic Inhalants</b>									
Phosgene (CG)	Immediate Irritation	Irritation	Irritation, stridor (Chlorine)	Dyspnea, cough, ARDS	—	—	—	Chlorine effects more rapid than phosgene	
Chlorine (CL)	Delayed ARDS								
<b>Cyanides</b>									
Hydrogen cyanide (AC)	Rapid (seconds–minutes)	—	—	Hyperpnea and then apnea	—	Anxiety, agitation, sudden collapse, seizures	—	—	
Cyanogen chloride (CK)	Rapid (seconds–minutes)	Irritation	Irritation	Hyperpnea and then apnea	—	Anxiety, agitation, sudden collapse, seizures	—	—	
<b>Riot Control Agents</b>									
Lacrimators (CN, CS) Capsaicin (OC)	Immediate	Pain, lacrimation, blepharospasm, conjunctivitis	Irritation	Cough, chest pain	Burning pain, erythema Vesiculation (severe exposures)	—	Nausea, retching (may occur with CN or CS)	—	
Adamsite (DM)	Rapid (minutes)	Irritation	Irritation, sneezing	Cough, chest pain	—	Headache	Nausea, vomiting, abdominal cramps	—	
<b>Incapacitating Agents</b>									
3-quinuclidinyl benzilate (BZ)	Delayed (hours)	Mydriasis	Dry mouth	—	—	Anticholinergic delirium	—	—	
Ultrapotent opioids	Rapid (seconds–minutes)	Miosis	—	Hypoventilation	—	CNS depression	—	—	

— = not an expected major finding; ARDS = acute respiratory distress syndrome; CN = chloroacetophenone; CNS = central nervous system; CS = *o*-chlorobenzylidene malononitrile; GI = gastrointestinal.

## SUMMARY

- Chemical and biological weapons are appealing to terrorist groups because the impact in terms of death, disability, economic losses, panic, and defensive posture remains high.
- The psychological impact of CBW terrorism will likely exceed that for conventional or nuclear weapons.
- Although the probability of incidents resulting in widespread public health disasters appears low, the consequences are high, and substantial preparations must be made in advance.
- Early decontamination is often critical for victims exposed to CWs.
- Nerve agents are potent organic phosphorus compound acetylcholinesterase inhibitors. Toxicity produces cholinergic toxicity, which is treated with antimuscarinics, primarily atropine, and oximes.
- Vesicant CWs induce blistering of the skin and damage to other tissues in contact, such as the eyes or respiratory tract. Sulfur mustard has no specific antidote, but the arsenic containing Lewisite is treated with BAL, a chelator.
- Exposure to chlorine, phosgene, ammonia and some other gases can produce delayed ARDS. Although used on the battlefield in World War I, it is expected that intentional use of these pulmonary irritant gases is now more likely to occur from their use by terrorists as “agents of opportunity.”

Expertise in dealing with biological weapons (BW) requires specific knowledge from the fields of infectious disease, epidemiology, toxicology, and public health. Biological and chemical weapons share many characteristics in common, including intent of use, some dispersion methods, and initial defense based on adequate personal protective equipment and decontamination (Tables 126–2 and 126–3). However, key differences between biological and chemical weapons involve a greater delay in onset of clinical symptoms after exposure to BWs; that is, the incubation period for most BWs is greater than the latent period for most chemical weapons. Decontamination is less crucial for victims exposed to BWs. Additionally, a few BWs can reproduce in the human host and cause secondary casualties, and disease after exposure to certain BWs can be prevented by the timely administration of prophylactic medications.

Biological weapons may be bacteria, fungi, viruses, or toxins derived from microorganisms. Some fungi are listed as potential BWs; however, none are known to have been developed into weapons to date.<sup>72</sup> Because toxin weapons are not living organisms, some authorities classify them as chemical rather than BWs. For the purpose of discussion in this chapter, toxin weapons derived from microorganisms will be considered BWs. Most of these bacterial BWs exert their effects by elaborating protein toxins.

Many diseases caused by BWs are either infrequently encountered in modern clinical medicine, such as anthrax and plague, or no longer occur naturally, such as smallpox. Therefore, health care personnel require specific training in recognizing and managing biological warfare victims. Potential BWs are categorized by their risk of causing mass casualty outbreaks.<sup>14</sup> The high-risk BWs are more easily disseminated or transmitted and may cause high mortality and potential public health disasters; these BWs include smallpox, anthrax, plague, botulism, tularemia, and several hemorrhagic fever viruses. The moderate-risk BWs include Q fever, brucellosis, the equine encephalitis viruses, ricin, and staphylococcal enterotoxin B, all of which are briefly discussed in this chapter.

## HISTORY

Biological warfare has ancient roots. Missile weapons poisoned with natural toxins were used as early as 18,000 years ago (Chap. 1). Other uses of biological warfare before the modern era relied mainly on poisoning water supplies with natural toxins or spreading naturally occurring epidemic infections to the enemy by hurling infected corpses over battlements or through the intentional transfer of disease-contaminated goods (eg, smallpox blankets).

During World War I, Germany was the only combatant nation with an active BW program; however, by World War II, many nations had BW research programs, including Japan, the Soviet Union, Germany, France, Britain, Canada, and the United States. The Japanese program included field trials with bubonic plague and conducted BW experiments on prisoners of war and civilians.<sup>35</sup> The American program was founded at Camp Detrick, Maryland, in 1942. Fort Detrick, as it is now known, remains the home of the United States Army Medical Research Institute of Infectious Diseases. Anthrax and botulinum toxins were the foci of American BW development during World War II. The British program was established at Porton Down in 1940, but most of the field testing of anthrax occurred on Gruinard Island off the northern coast of Scotland, resulting in long-term soil contamination with anthrax spores.

In London, in 1978, the Bulgarian exile Georgi Markov was assassinated with a tiny metal pellet fired from a gun designed to appear like an umbrella. He was originally thought to have died from sepsis until the pellet was found at autopsy.<sup>23</sup> After the fall of the Soviet Union, government officials

confirmed that the KGB used umbrella guns firing ricin pellets to assassinate Markov and others.

In 1979, an outbreak of human anthrax caused at least 66 fatalities in the Russian city of Sverdlovsk. Autopsies revealed that the deaths were from inhalational anthrax, and epidemiologic investigation demonstrated that almost all the cases occurred downwind from a military facility. These data are consistent only with a release of aerosolized anthrax, which has since been confirmed by Russian authorities.<sup>52</sup>

In the late 1970s and early 1980s, many reports came from Southeast Asia and Afghanistan that Soviet-supported troops were using a BW known as Yellow Rain.<sup>71</sup> Some samples of Yellow Rain were found to contain trichothecene mycotoxins, although controversy remains as to whether this represents intentional biological warfare or was a naturally occurring phenomenon.<sup>63</sup>

During the 1990s, concern arose regarding the use and possible stockpiling of weapons of mass destruction in Iraq.<sup>45</sup> Iraq had an active BW research program, investigating at least five bacteria, one fungus, five viruses, four toxins, and a variety of dispersion methods.<sup>64,74</sup> Thousands of liters of anthrax spores, botulinum toxin, and aflatoxin were produced and weaponized into bombs and as payloads for SCUD missiles.

Biological terrorism and the threat of bioterrorism are now recognized as worldwide, growing public health concerns.<sup>36</sup> In 1984, a large outbreak of salmonellosis was traced to intentional contamination of restaurant salad bars by the Rajneeshee cult in Oregon.<sup>69</sup> The Aum Shinrikyo cult based in Japan investigated the use of cholera and Q fever, unsuccessfully released anthrax spores and botulinum toxin, and even sent members to Africa to obtain the Ebola virus.<sup>56,67</sup> The mere threat of a BW release can terrorize a city, as occurred with several false threats of anthrax spore release in the late 1990s.<sup>13</sup>

In 2001, closely following the September 11, 2001, attack on New York and Washington, DC, a bioterrorist attack occurred in the United States resulting in several cases of inhalational and cutaneous anthrax, with five fatalities. Ricin has also been found in letters and packages and in the possession of would-be terrorists several times, both in the United States and abroad in the post-9/11 era.<sup>62</sup>

## GENERAL CONSIDERATIONS

### Differences Between Biological Weapons Incidents and Naturally Occurring Outbreaks

Because the clinical effects of BWs are often delayed for several days after exposure, it may be difficult to differentiate an occult BW release from a naturally occurring disease outbreak. Several epidemiologic criteria are proposed to aid in such determinations,<sup>55</sup> many of which should be identifiable in a BW incident (Table 127–1).

To avoid early detection, terrorists might choose to release a BW causing endemic infection or a disease that mimics an endemic infection during its season of peak incidence. In some areas of the United States, for example, a few cases of bubonic plague would not attract notice until, perhaps, dozens or hundreds of cases were identified. An outbreak of inhalational anthrax during the influenza season may similarly be hidden among patients with shared early symptoms until an unusually high mortality rate was evident.<sup>19</sup> By the time the BW outbreak was recognized, the perpetrators could dispose of any physical evidence and flee the area. Alternatively, even a single case of smallpox (anywhere in the world) or Ebola virus disease or Congo-Crimean hemorrhagic fever (in nonendemic areas and unassociated with a known outbreak) should raise suspicion of a BW attack.

**TABLE 127-1** Epidemiologic Clues Suggesting Biological Weapon Release

- Large epidemic with unusually high morbidity, mortality, or both
- Epidemic curve (number of cases vs time) showing an “explosion” of cases, reflecting a point source in time rather than insidious onset
- Tight geographic localization of cases, especially downwind of potential release site
- Predominance of respiratory tract symptoms because most BWs are transmitted by aerosol inhalation
- Simultaneous outbreaks of multiple unusual diseases
- Immunosuppressed and elderly persons more susceptible
- Nonendemic infection (“impossible epidemiology”)
- Nonseasonal time for endemic infection
- Organisms with unusual antimicrobial resistance patterns, reflecting BW genetic engineering
- Animal casualties concurrent with disease outbreak
- Absence of normal zoonotic disease host
- Low attack rates among persons incidentally working in areas with filtered air supplies or closed ventilation systems, using HEPA masks, or remaining indoors during outdoor exposures
- Delivery vehicle or munitions discovered
- Law enforcement or military intelligence information
- Claim of BW release by a belligerent force

BW = bioweapon; HEPA = high-efficiency particle absorbing.

### Preparedness

Many BWs initially produce nonspecific symptoms, and diseases that rarely, if ever, occur in clinical practice. Inhalational anthrax and pneumonic plague, for example, could easily be misdiagnosed as influenza or acute bronchitis. Providers in emergency departments and primary care medicine should be educated to recognize the signs, symptoms, and clinical progression of diseases caused by BW.<sup>60</sup> Clear identification, isolation, and aggressive treatment early after exposure within the first 24 to 48 hours are the best and only means of reducing mortality rates and, in the case of smallpox or plague, preventing secondary or tertiary cases.<sup>27</sup>

### Decontamination

Biological weapons are most effective when dispersed by aerosol. Shortly after a known or suspected release of bioaerosols, external decontamination is a relatively minor concern because aerosols sized to reach the lower respiratory tract (<5- $\mu$ m particles) produce little surface contamination. However, simple removal of clothing will eliminate a high proportion of deposited particles, and subsequent showering with soap and water will probably remove 99.99% of any remaining organisms on the skin.<sup>44</sup> Thus, decontamination after BW aerosol exposure, when needed, is achieved through disrobing and showering with soap and water. This can be done onsite or in the victims' homes and away from health care facilities, thereby reducing strain on disaster response manpower and material in multiple-victim exposures.<sup>27,36,44,60</sup> If there is gross, visible evidence of skin exposure to a BW, victims are decontaminated by thorough irrigation, and, if available, sterilizing the skin with a sporicidal and bactericidal solution (eg, 0.5% sodium hypochlorite) and a final water rinse.<sup>44,60</sup> Contaminated clothing should be removed and placed in airtight bags or containers to prevent resuspension in the air. After an occult BW release, victims are identified late after exposure; decontamination will obviously not be helpful and may only serve to delay care.

### BIOLOGICAL WARFARE AGENTS

Starting on September 27, 2001, a 63-year-old Florida man developed malaise, fatigue, fever, chills, anorexia, and diaphoresis. He was admitted to a local hospital on October 2 after presenting with additional complaints of nausea, vomiting, and confusion. Chest radiography showed cardiomegaly, a left perihilar infiltrate, a small left pleural effusion, and a prominent superior mediastinum. Lumbar puncture revealed hemorrhagic meningitis with many gram-positive bacilli. *Bacillus anthracis* was isolated from the

cerebrospinal fluid after only a 7-hour incubation period and from blood cultures within 24 hours. The patient had progressive clinical deterioration and died on hospital day four.<sup>10,42</sup>

On October 4, the US Centers for Disease Control and Prevention (CDC) released a public health message regarding this case, which initially appeared to be an isolated, perhaps naturally occurring sporadic event.<sup>15</sup> Nevertheless, the rarity of inhalational anthrax especially outside of a high-risk occupation, combined with increased suspicion in the wake of the September 11, 2001, attacks led to intense investigation of a potential bioterrorist event. Within days, epidemiologic investigation suggested workplace exposure to anthrax spores, and personnel working in the same building were started on prophylactic ciprofloxacin.<sup>16</sup> On October 12, a case of cutaneous anthrax was reported in New York associated with a suspicious letter opened on September 25.<sup>17</sup> Anthrax cases and environmental contamination were also soon detected in Washington, DC, and in a New Jersey postal facility. The public response to the reports of these serious and fatal cases included misuse and hoarding of antibiotics, purchasing gas masks (often with inappropriate filtering mechanisms for BW), reporting numerous miscellaneous powdery substances, and perpetrating or reporting copycat hoaxes.

By November 7, 2001, a total of 22 cases of anthrax were reported: 10 inhalational and 12 cutaneous.<sup>18</sup> One additional death from inhalational anthrax occurred on November 21, 2001,<sup>4</sup> and a case of cutaneous anthrax also occurred in a laboratory worker analyzing samples obtained during the investigation.<sup>20</sup> In two of the fatal cases, no contact with contaminated letters could be established.<sup>4,54</sup> One infant hospitalized in New York with cutaneous anthrax was initially misdiagnosed as having a brown recluse spider envenomation.<sup>31</sup> The total number of medical victims of anthrax by spring 2002 was 23: 11 cases of inhalational anthrax (with 5 fatalities) and 12 cases of cutaneous anthrax (8 confirmed and 4 suspected).<sup>20</sup>

### Bacteria

#### Anthrax

Anthrax is caused by *Bacillus anthracis*, a gram-positive spore-forming bacillus found in soil worldwide (Figs. 127-1 and 127-2). *B. anthracis* causes disease primarily in herbivorous animals. Human anthrax cases generally occur in farmers, ranchers, and among workers handling contaminated animal carcasses, hides, wool, hair, and bones.<sup>32</sup>

**Clinical manifestations.** A few clinically distinct forms of anthrax occur, depending on the route of exposure. Cutaneous anthrax results from direct inoculation of spores into the skin via abrasions or other wounds and accounts for about 95% of endemic (naturally occurring) human cases. Patients develop a painless red macule that vesiculates, ulcerates, and forms a 1- to 5-cm brown-black dermatonecrotic eschar surrounded by edema.<sup>49</sup> The eschar color gave rise to the name anthrax, from the Greek word *anthrakos*, meaning “coal.” Most skin lesions heal spontaneously, although 10% to 20% of untreated patients progress to septicemia and death. When treated

**FIGURE 127-1.** Anthrax Gram stain.

FIGURE 127-2. Anthrax spores.

with antibiotics cutaneous anthrax rarely results in fatalities. Anthrax is not transmissible among humans.

Gastrointestinal (GI) anthrax results from ingesting insufficiently cooked meat from infected animals. Patients develop nausea, vomiting, fever, abdominal pain, and mucosal ulcers, which can cause GI hemorrhage, perforation, and sepsis. The mortality rate from GI anthrax is at least 50%, even with antibiotic treatment.<sup>32</sup>

Inhalational anthrax results from exposure to aerosolized *B. anthracis* spores. Although this form of anthrax is very rare, it is so closely associated with occupational exposures that it is called “wool-sorter’s disease.” Inhalational anthrax is also likely to be the form that occurs in a BW attack because the anthrax spores would be most effectively disseminated by aerosol. After an incubation period of 1 to 6 days, the patient develops fever, malaise, fatigue, nonproductive cough, and mild chest discomfort, which may be easily mistaken for community-acquired pneumonia.<sup>19</sup> The initial symptoms may briefly improve for 2 to 3 days, or the patient may abruptly progress to severe respiratory distress with dyspnea, diaphoresis, stridor, and cyanosis. Bacteremia; shock; metastatic infection such as meningitis, which occurs in about 50% of cases; and death may follow within 24 to 36 hours. Before the 2001 bioterrorist outbreak, the mortality rate from inhalational anthrax was expected to be nearly 100%, even with antibiotics, after symptoms develop.<sup>30,32</sup> With appropriate antibiotic therapy and supportive care, 5 of 11 patients with inhalational anthrax in 2001 died, and although this is still a high mortality rate, it is less than that previously predicted.<sup>40</sup>

**Pathophysiology.** Inhalational anthrax primarily causes a mediastinitis. Diagnostic imaging typically shows mediastinal widening from enlarged hilar lymph nodes and pleural effusions, although pulmonary parenchymal infiltrates also occur.<sup>40</sup> Inhaled spores are taken up into the lymphatic system, where they germinate and the bacteria reproduce. *B. anthracis* produces three toxins: protective antigen (PA), edema factor, and lethal factor. Protective antigen is so named because antibodies against it protect the individual from the effects of the other two toxins. Protective antigen forms a heptamer that inserts into plasma membranes, facilitating endocytosis of the other two toxins into target cells (Fig. 127-3). Edema factor is a calmodulin-dependent adenylate cyclase. Increased intracellular cyclic adenosine monophosphate (AMP) upsets water homeostasis, leading to massive edema and impaired neutrophil function. Lethal factor is a zinc metalloprotease that stimulates macrophages to release tumor necrosis factor  $\alpha$  and interleukin-1 $\beta$ , contributing to death in systemic anthrax infections.<sup>25</sup> The combination of PA plus edema factor is called *edema toxin*, and PA plus lethal factor is *lethal toxin*.<sup>34</sup>

**Treatment.** The primary antibiotics used to treat anthrax are ciprofloxacin and doxycycline. Although other fluoroquinolones would be expected to have similar activity against anthrax, only the manufacturer of ciprofloxacin applied for and received a US Food and Drug Administration (FDA)–approved

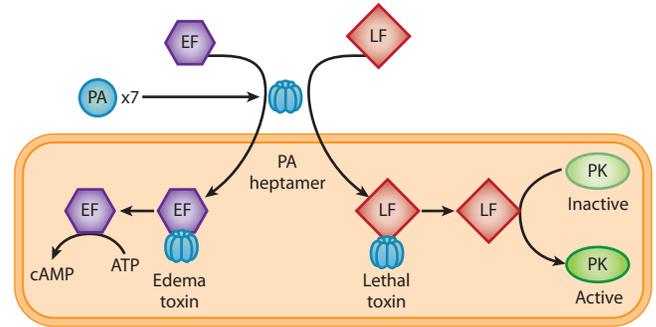

FIGURE 127-3. Model of action of anthrax toxins. Edema factor (EF) and lethal factor (LF) are unable to enter cells until they complex with a protective antigen (PA) heptamer, forming edema toxin and lethal toxin, respectively. When intracellular, release from PA allows EF and LF to exert their intracellular effects. Antibodies against PA confer resistance to the toxic effects of anthrax. ATP = adenosine triphosphate; cAMP = cyclic adenosine monophosphate; PK = protein kinase.

indication for use in this infection. In a mass casualty setting or for post-exposure prophylaxis, adults should receive ciprofloxacin 500 mg orally (PO) every 12 hours. Alternate therapies are doxycycline 100 mg PO every 12 hours or amoxicillin 500 mg PO every 8 hours if the anthrax strain is proven susceptible.<sup>40</sup> The recommended duration of therapy is 60 days, stemming from case experience in Sverdlovsk, where some patients developed disease several weeks (6–7 weeks) after the spore release.<sup>52</sup> Children should also be treated with ciprofloxacin (15 mg/kg; maximum, 500 mg/dose) or amoxicillin (80 mg/kg/d divided every 8 hours; maximum, 500 mg/dose). The relative pediatric contraindication to fluoroquinolones is outweighed by the risk of potentially fatal disease. Cutaneous anthrax is treated with the same drugs and doses as for postexposure prophylaxis.

Inhalational anthrax should be treated initially with intravenous antibiotics. Adults receive ciprofloxacin 400 mg intravenously (IV) or doxycycline 100 mg IV every 12 hours, along with one or two additional antibiotics with in vitro activity against anthrax (eg, rifampin, vancomycin, penicillin, ampicillin, chloramphenicol, imipenem, clindamycin, clarithromycin). Children are given ciprofloxacin 10 mg/kg IV (maximum, 400 mg/dose) or doxycycline 2.2 mg/kg IV (maximum, 100 mg/dose) and additional antibiotics, as indicated earlier.<sup>40</sup> However, in a true mass casualty event, when resources are strained and inpatient care is not available for every victim, oral therapy, as described earlier, may be instituted. When clinically appropriate, oral antibiotic therapy can be substituted for IV forms, with a total treatment duration of 60 days. Some patients in the 2001 outbreak were specifically treated with additional antibiotics that inhibit protein synthesis in attempts to reduce bacterial production of toxins.

Raxibacumab is a human monoclonal antibody that blocks binding of the anthrax PA to its host cell receptor. Raxibacumab is approved for treatment of inhalational anthrax in combination with appropriate antibiotics and prophylaxis when alternate therapies are unavailable or not appropriate.<sup>46</sup> Given the high costs of biological therapies, raxibacumab use is likely to be limited to rare individual cases rather than in mass casualty events.

**Anthrax vaccine.** An effective vaccine against anthrax is available.<sup>33,51,75</sup> In the United States, the Bioport Corporation (formerly Michigan Biologic Products Institute) is licensed by the FDA to produce anthrax vaccine adsorbed (AVA). The vaccine consists of a membrane-sterilized culture filtrate of *B. anthracis* V770-NP1-R, an avirulent, nonencapsulated strain that produces PA, adsorbed to aluminum hydroxide, formulated with benzethonium chloride (preservative) and formaldehyde (stabilizer).<sup>75</sup> In human and animal experiments, the vaccine is highly effective in preventing all forms of anthrax, and the vaccine is recommended for workers in high-risk occupations. As with any vaccine, local reactions to AVA occur in some recipients (up to 20% with mild, local reactions), and self-limited systemic reactions occur more rarely (<1.5%). Women have more frequent injection-site reactions and other adverse events, although this sex difference is also noted

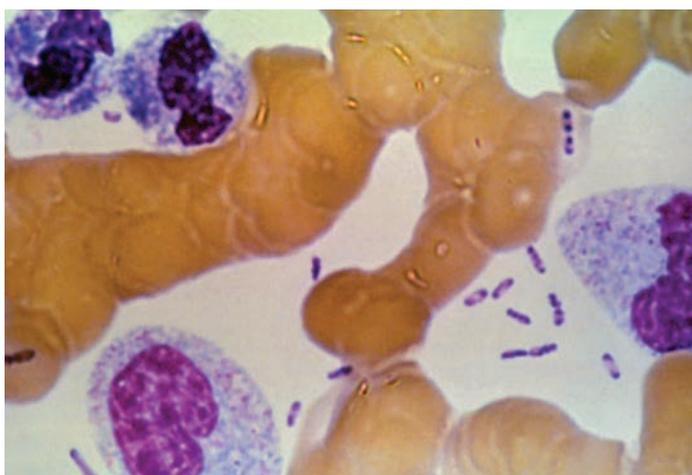

with other common vaccines.<sup>34</sup> Serious adverse events are very rare, with only 22 potentially related cases of serious adverse events from more than 1 million doses administered to US Armed Forces.<sup>33</sup> The dosage schedule for AVA is 0.5 mL subcutaneously at 0, 2, and 4 weeks and 6, 12, and 18 months followed by yearly boosters. Preclinical studies have also been conducted on a human monoclonal antibody against PA, which has been developed as an antitoxin for use in the treatment of inhalational anthrax.

**Lessons from the 2001 Anthrax Bioterrorism Event.** Although the overall number of individuals infected was relatively low, the psychosocioeconomic impact was exceptionally high. Several hundred postal and other facilities were tested for *B. anthracis* spore contamination, and public health authorities recommended antibiotic prophylaxis be initiated for approximately 32,000 persons.<sup>18</sup> Additional indirect costs and effects are more difficult to quantify, including the number of persons self-initiating antibiotic treatment without an evident indication, lost production and wages, environmental and biological sample testing, decontamination efforts, and an international sense of unease.

Published estimates of tens of thousands of deaths from a military-style anthrax attack<sup>43</sup> depend on efficient BW dispersion. The technically easier anthrax letter has clearly proven itself to be a “weapon of mass disruption.” As predicted, the psychological impact far exceeded the actual medical consequences, and events with a modest number of medical patients are probably more likely than true mass casualty BW incidents. On the other hand, prior assumptions regarding the clinical aspects of anthrax were not as reliable. The mortality rate, as noted earlier, of inhalational anthrax was 45%, considerably lower than expected. Presentation with fulminant illness, such as sepsis, still appears to be predictive of a fatal outcome, yet the initial phase of illness does not necessarily lead to death if treated with appropriate antibiotics.<sup>6,42,47</sup> Pleural effusions were the most common radiographic abnormality, rather than a widened mediastinum, and pulmonary parenchymal infiltrates were seen in seven patients despite the belief that pneumonia does not commonly occur with inhalation anthrax.<sup>32,42</sup>

## Plague

*Yersinia pestis* is a Gram-negative bacillus (Fig. 127–4) responsible for more than 200 million human deaths and three major pandemics in recorded history.<sup>49,50</sup> Naturally occurring plague is transmitted by flea vectors from rodent hosts or by respiratory droplets from infected animals or humans. Bubonic plague could result from an intentional release of plague-infested fleas. Plague is a particularly frightening BW because it can be released as an aerosol to cause a fulminant communicable form of the disease for which no effective vaccine exists. Antibiotics must be initiated early after exposure because when symptoms develop, mortality rates are reportedly extremely high.

**FIGURE 127–4.** Dark-stained bipolar ends of *Yersinia pestis* can be seen in this Wright's stain of blood from a patient with plague.

**Clinical presentation.** Plague occurs in three clinical forms: bubonic, septicemic, and pneumonic. Bubonic plague has an incubation period of 2 to 10 days followed by fever, malaise, and painful, enlarged regional lymph nodes called buboes. The inguinal nodes are most commonly affected, presumably because the legs are more prone to flea bites, although cervical or axillary buboes are more common in children.<sup>59</sup> In the United States, 85% to 90% of human plague patients have the bubonic form, 10% to 15% have a primary septicemic form without lymphadenopathy, and about 1% present with pneumonic plague. Secondary septicemia occurs in 23% of patients presenting with bubonic plague.<sup>50</sup> Various skin lesions at the site of inoculation (pustules, vesicles, eschars, or papules) occur in some patients, although the petechiae and ecchymoses that occur in advanced cases may resemble meningococcemia.<sup>49</sup> Distal gangrene occurs from small artery thromboses, explaining why plague pandemics are sometimes called the Black Death. If left untreated, bubonic plague carries a 60% mortality rate.<sup>49</sup>

Pneumonic plague is an infection of the lungs with *Y. pestis*. Between 5% and 15% of bubonic plague patients develop secondary pneumonic plague through septicemic spread of the organism.<sup>50</sup> Primary pneumonic plague occurs from inhalation of infected respiratory droplets or an intentionally disseminated BW aerosol. The incubation period of pneumonic plague is 2 to 3 days after inhalation. The onset of disease is acute and often fulminant. Patients develop fever, malaise, and cough productive of bloody sputum, rapidly progressing to dyspnea, stridor, cyanosis, and cardiorespiratory collapse. Plague pneumonia is almost always fatal unless treatment is begun with 24 hours of symptom onset.<sup>30</sup>

**Diagnosis and treatment.** Plague can be diagnosed by various staining techniques, immunologic studies, or culturing the organism from blood, sputum, or lymph node aspirates. *Yersinia pestis* appears as a gram-positive safety pin–shaped bipolar coccobacillus.<sup>30,59</sup> Chest radiographs in patients with pneumonic plague reveal patchy or consolidated bronchopneumonia. Leukocytosis with a left shift is common, as are markers of low-grade disseminated intravascular coagulation and elevations of unconjugated bilirubin and hepatic aminotransferases.<sup>30</sup>

Antibiotic treatment options are similar to those for anthrax. In a mass casualty setting or for postexposure prophylaxis, treatment should be with doxycycline 100 mg or ciprofloxacin 500 mg PO twice daily for adults. Children should be given doxycycline 2.2 mg/kg or ciprofloxacin 20 mg/kg, up to a maximum of the adult doses. Chloramphenicol 25 mg/kg PO four times daily is an alternative. The durations of treatment are 7 days for post-exposure prophylaxis and 10 days for mass casualty incidents.<sup>39</sup> Patients with pneumonic plague need to be isolated to prevent secondary cases. Respiratory droplet precautions are necessary in pneumonic plague until the patient has received antibiotics for 3 days.<sup>30</sup> In a contained-casualty setting, patients with pneumonic plague should be treated with parenteral streptomycin or gentamicin; alternative antibiotics include doxycycline, ciprofloxacin, and chloramphenicol.<sup>39</sup> A killed whole-cell vaccine effective against bubonic plague is available, but it does not reliably protect against pneumonic plague in animal studies.<sup>49,51</sup>

## Tularemia

*Francisella tularensis* is a small, aerobic, gram-negative coccobacillus weaponized by the United States and probably other countries as well. Tularemia occurs naturally as a zoonotic disease spread by blood-sucking arthropods or by direct contact with infected animal material. Tularemia in humans may occur in ulceroglandular or typhoidal forms, depending on the route of exposure. Ulceroglandular tularemia is more common, occurring after skin or mucous membrane exposure to infected animal blood or tissues. Patients develop a local ulcer with associated lymphadenopathy, fever, chills, headache, and malaise. Typhoidal tularemia presents with fever, prostration, and weight loss without adenopathy. Exposure to aerosolized bacteria, as used in BW, will most likely result in typhoidal tularemia with prominent respiratory symptoms such as a nonproductive cough and substernal chest discomfort. Diagnosing tularemia is often difficult because the organism is hard to isolate by culture and the symptoms are nonspecific.

Chest radiography may demonstrate infiltrates, mediastinal lymphadenopathy, or pleural effusions.<sup>24,28,30,51</sup>

Antibiotic treatment options are similar to those for anthrax and plague. In mass casualty settings or for postexposure prophylaxis, treatment should be doxycycline 100 mg twice daily or ciprofloxacin 500 mg PO twice daily for 14 days for adults. Pediatric dosing for doxycycline is 2.2 mg/kg or ciprofloxacin 15 mg/kg (maximum, adult dose) twice daily. When dealing with a limited number of casualties, the preferred antibiotics are streptomycin 1 g intramuscularly (IM) twice daily or gentamicin 5 mg/kg IM or IV once daily. Alternatives include parenteral doxycycline, chloramphenicol, and ciprofloxacin.<sup>24</sup>

### Brucellosis

Brucellosis could potentially be used as an incapacitating BW because it causes disease with low mortality but significant morbidity. Brucellae (*Brucella melitensis*, *abortus*, *suis*, and *canis*) are small, aerobic, gram-negative coccobacilli that generally cause disease in ruminant livestock. Humans develop brucellosis by ingesting contaminated meat and dairy products or by aerosol transmission from infected animals. The United States weaponized *B. suis*, and other countries are also believed to have developed *Brucella* BWs. Brucellosis commonly presents with nonspecific symptoms such as fever, chills, and malaise, with either an acute or insidious onset. Because brucellae are facultative intracellular organisms that localize in the lung, spleen, liver, central nervous system, bone marrow, and synovium, organ-specific signs and symptoms may occur. The diagnosis is made by serologic methods or culture. Because single-drug treatment often results in relapse, combined therapy is indicated. Patients should be given doxycycline 200 mg/day PO, plus rifampin 600 to 900 mg/day PO for 6 weeks, or doxycycline 200 mg/day PO for 6 weeks, with either streptomycin 15 mg/kg twice daily IM or gentamicin 1.5 mg/kg IM every 8 hours for the first 10 days.<sup>30,38,51</sup>

### Rickettsiae

Features of rickettsiae favoring their use as BW include environmental stability, aerosol transmission, persistence in infected hosts, low infectious dose, and high associated morbidity and mortality. Rickettsiae that have been weaponized include *Coxiella burnetii*, the causative organism of Q fever, and *Rickettsia prowazekii*, the causative organism of louseborne typhus. Release of *R. prowazekii* into a crowded louse-infested population might induce a typhus outbreak with rapid transmission and a high mortality rate.<sup>3</sup>

### Q Fever

Q fever was first described in 1937 and was given its name—Q for “query”—because the causative organism was not then known. Q fever occurs naturally as a self-limited febrile, zoonotic disease contracted from domestic livestock. Q fever is now known to be caused by *Coxiella burnetii*, a unique rickettsialike organism that can persist on inanimate objects for weeks to months and can cause clinical disease with the inhalation of only a single organism. These features are of obvious benefit for use as a potential BW. After a 10- to 40-day incubation period, Q fever manifests as an undifferentiated febrile illness, with headache, fatigue, and myalgias. Patchy pulmonary infiltrates on chest radiography that resemble viral or atypical bacterial pneumonia occur in 50% of cases, although only half of patients have cough, and even fewer have pleuritic chest pain. Uncommon complications include hepatitis, endocarditis, meningitis, encephalitis, and osteomyelitis. Patients are generally not critically ill, and the disease can last as long as 2 weeks. Treatment with antibiotics will shorten the course of acute Q fever and can prevent clinically evident disease when given during the incubation period. Tetracyclines are the mainstay of therapy, and either tetracycline 500 mg PO every 6 hours or doxycycline 100 mg PO every 12 hours should be given for 5 to 7 days.<sup>11,30</sup>

### Viruses

#### Smallpox

Smallpox is caused by the variola virus, a large DNA orthopoxvirus (Fig. 127-5) with a host range limited to humans. Before global World Health Organization (WHO) efforts to eradicate naturally occurring smallpox by immunization, recurrent epidemics were common, and the disease

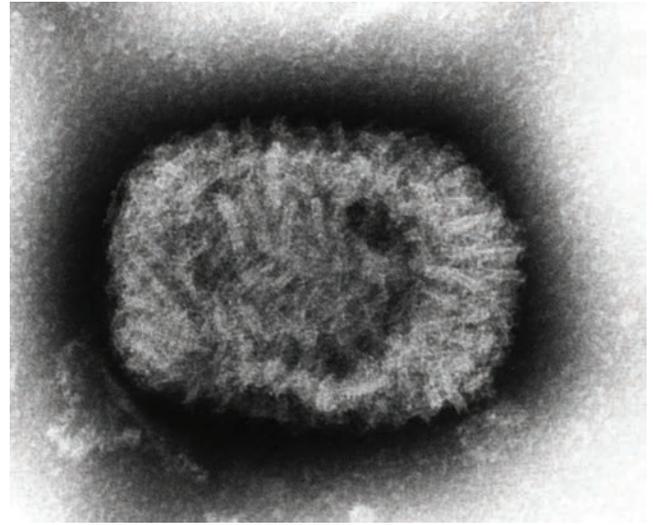

FIGURE 127-5. Variola virus.

carried roughly a 30% fatality rate in unvaccinated populations.<sup>37,48</sup> Smallpox is highly contagious (Fig. 127-6). Outbreaks during the 1960s and 1970s in Europe often resulted in 10 to 20 secondary cases per index case. One German smallpox patient with a cough, isolated in a single room, infected persons on three floors of a hospital.<sup>37</sup> However, the overwhelming majority of secondary infections occur among close family contacts, especially those sleeping in the same room or the same bed.<sup>26</sup>

FIGURE 127-6. Smallpox rash demonstrating non-pruritic, synchronous tense vesicles.

In 1980, the United Nations' WHO certified that smallpox was eradicated and recommended ceasing vaccinations and either destroying or transferring remaining stocks of variola virus to one of two designated biosafety level 4 facilities: the CDC in Atlanta or the Russian State Research Center of Virology and Biotechnology.<sup>9</sup> All remaining known variola stocks were scheduled for destruction in 1999; however, before this was done, a WHO resolution called for a delay based on an Institute of Medicine report concluding that live virus should be retained to develop new antivirals or vaccines to protect against any potential future release of smallpox.<sup>65</sup> The Soviet Union is known to have weaponized smallpox, and other countries are believed to maintain stocks of variola virus. In addition to the known stockpiles of smallpox vaccine, several types of new vaccines are being produced.<sup>57,73</sup> Smallpox vaccination for military personnel was reinstated in 2002 and was made available for some civilians in 2003.<sup>21,22</sup>

**Pathophysiology.** Transmission of smallpox typically occurs through inhalation of droplets or aerosols but may also occur through contaminated fomites. The infectious dose is not known but is probably only a few virions. After a 12- to 14-day incubation period, the patient develops fever, malaise, and prostration with headache and backache. Oropharyngeal lesions appear, shedding virus into the saliva. Two to three days after the onset of fever, a papular rash develops on the face and spreads to the extremities. The fever continues while the rash becomes vesicular and then pustular. Scabs form from the pustules and eventually separate, leaving pitted and hypopigmented scars. Death usually occurs during the second week of the illness. Vaccination before exposure or within 2 to 3 days after exposure provides almost complete protection against smallpox. The disease most likely to be confused with smallpox is chickenpox (varicella). Although the individual lesions of smallpox and varicella are physically indistinguishable, the person infected with smallpox may still be differentiated clinically. The lesions of smallpox should all appear at the same stage of development (synchronous), but chickenpox lesions occur at varying stages (asynchronous). Smallpox lesions tend to be found in a centrifugal distribution (face and distal extremities), but chickenpox lesions are more centripetal, tend to appear first on the trunk and are pruritic.

Two antivirals commercially available in the United States, cidofovir and ribavirin, are effective in vitro against variola.<sup>51</sup> However, current evidence suggests that although cidofovir may prevent smallpox when given within 1 or 2 days of exposure, it is unlikely to be effective after symptoms develop.<sup>37</sup> Even a single case of smallpox should be considered a potential international health emergency and immediately reported to the appropriate public health authorities.

**Smallpox vaccination.** Rapid postexposure vaccination confers excellent protection against smallpox. The smallpox vaccine uses a live vaccinia virus (derived from cowpox vaccine) rather than the actual variola virus that causes smallpox. Although contracting smallpox from the vaccine is impossible, other adverse reactions may occur. The two most serious reactions are postvaccinal encephalitis and progressive vaccinia. Postvaccinal encephalitis occurs in about three cases per million primary vaccinees. Forty percent of cases are fatal, and some survivors are left with permanent neurologic sequelae. Progressive vaccinia can occur in immunosuppressed individuals and is treated with vaccinia immune globulin (VIG) (Fig. 127-7).<sup>73</sup> Another historically common complication of smallpox vaccination was ocular vaccinia, which typically occurred among health care personnel administering vaccine when it was inadvertently placed in the eye. Ocular vaccinia is also treated with VIG. Because smallpox was eradicated before the emergence of HIV, there is limited clinical experience with smallpox vaccination in patients with AIDS who theoretically are at increased risk of progressive vaccinia.<sup>37,48</sup> However, among 10 individuals with undiagnosed HIV at the time of recent smallpox vaccination, none developed complications.<sup>68</sup> Routine vaccination is contraindicated in immunosuppressed people, persons with a history or evidence of eczema and other chronic dermatitis, close household or sexual contacts of patients with these contraindications, and during pregnancy. Because the vaccine is a live virus, it can be transmitted from the vaccinee to

FIGURE 127-7. Progressive vaccinia.

close contacts. Thirty secondary and tertiary cases of vaccinia were reported resulting from recent US military vaccinations.<sup>21</sup> The number of serious adverse events from modern smallpox vaccination is very low;<sup>22</sup> however, rare cardiac complications not reported in previous decades were noted with the recent reinstatement of smallpox vaccination in the early 2000s. More than 1 million military vaccinations given by 2006 resulted in 120 cases of myopericarditis, and 21 cases of myopericarditis occurred among nearly 40,000 civilian vaccine recipients between 2002 and 2003.<sup>57</sup> The number of cardiac ischemic events among vaccinees was not significantly higher than age-matched control participants. After a true exposure to variola, most authorities would agree that the only absolute contraindication to smallpox vaccination is significant impairment of systemic immunity. Concomitant administration of vaccinia immune globulin would be recommended for pregnant women and persons with eczema.<sup>48</sup>

### Viral Hemorrhagic Fevers

Several taxonomically diverse RNA viruses produce acute febrile illnesses characterized by malaise, prostration, and increased vascular permeability that can result in bleeding manifestations in the more severely affected patients. Viral hemorrhagic fevers (VHFs) are all highly infectious by the aerosol route, making them candidates for use as BW. These include the viruses causing Lassa fever, dengue, yellow fever, Crimean-Congo hemorrhagic fever, and the Marburg, Ebola virus, and Hanta viruses. Hanta virus is endemic to North America; occasional natural epidemics of human infection occur, which may initially be difficult to differentiate from a BW release. Clinical features, such as the extent of renal, hepatic, and hematologic involvement, vary according to the specific virus, but they all carry the risk of secondary infection through droplet aerosols. Ribavirin is reasonable for some VHFs, but supportive care is the mainstay of therapy.<sup>7,30,41</sup>

### Viral Encephalitides

Three antigenically related  $\alpha$  viruses of the Togaviridae family pose risks as BWs: western equine encephalitis (WEE), eastern equine encephalitis (EEE), and Venezuelan equine encephalitis (VEE). Birds are the natural reservoir of these viruses, and natural outbreaks occur among equines and humans by mosquito transmission. Eastern equine encephalitis infections are the most severe in humans, with a 50% to 70% fatality rate and high incidence of neurologic sequelae among survivors. Western equine encephalitis is less neurologically invasive, and severe encephalitis from VEE is rare, except in children. Adults infected with VEE usually develop an acute, febrile, incapacitating disease with prolonged recovery. The equine encephalitides have many properties helpful for weaponization, in that they can be produced in large quantities, they are relatively stable and highly infectious to humans as aerosols, and a choice is available between lethal or incapacitating infections.<sup>66</sup>

Venezuelan equine encephalitis is considered the most likely BW threat among the viral encephalitides. After a 1- to 5-day incubation period, victims

experience the sudden onset of malaise, myalgias, prostration, spiking fevers, rigors, severe headache, and photophobia. Nausea, vomiting, cough, sore throat, and diarrhea may follow. This acute phase lasts 24 to 72 hours. Between 0.5% and 4% of patients develop encephalitis, with meningismus, seizures, coma, and paralysis, which carries up to a 20% fatality rate. The diagnosis is usually established clinically, although the virus can sometimes be isolated from serum or from throat swabs, and serologic tests are available. The white blood cell count often shows a striking leukopenia and lymphopenia. Treatment is supportive. Person-to-person transmission can theoretically occur from droplet nuclei. Recovery takes 1 to 2 weeks.<sup>30,66</sup>

### Toxins

Several toxins derived from bacteria, plants, fungi, and algae could theoretically be used as BWs if produced in sufficient quantities. Because of their high potency, only small amounts would be needed to kill or incapacitate exposed victims. Fortunately, obstacles in manufacturing weaponizable amounts limit the number of toxins that are practical for use as BWs. Discussion here is limited to those toxins known or highly suspected to have been weaponized. Toxins themselves are not living organisms and therefore cannot reproduce; for this reason, they are arguably equivalent to chemical weapons. But because toxin weapons are derived from living organisms, they are categorized here as BWs.

### Botulinum Toxin

The United States and some other countries developed botulinum toxin as a potential BW.<sup>1,56,64,74</sup> The two most likely means of using botulinum toxin are by food contamination or by aerosol. Either method would result in the clinical syndrome of botulism (Chap. 38), characterized by multiple bulbar nerve palsies and a symmetric descending paralysis, ending in death from respiratory failure. Inhalational botulism from laboratory incidents has occurred rarely in humans.<sup>53</sup>

### Ricin

Ricin is derived from the castor bean plant (*Ricinus communis*) (Chap. 118) and is the only biological toxin to exist naturally in more than microscopic quantities, comprising 1% to 5% of the beans by weight.<sup>8</sup> Its easy accessibility, relative ease of preparation, and low cost may make ricin an attractive BW for terrorists or poor countries. Although ricin has never been used in battle, it has attracted the attention of domestic extremists and terrorists and was used in some politically motivated assassinations.<sup>2,23,29</sup> Ricin is a glycoprotein lectin (or toxalbumin) composed of two protein chains linked by a disulfide bond. The B chain facilitates cell binding and entry of the A chain into cells. The A chain inhibits protein synthesis, inactivating eukaryotic ribosomes by removing an adenine residue from ribosomal RNA.<sup>2</sup>

Clinical toxicity from ricin will vary depending on the dose and route of exposure. Inhalation of aerosolized ricin results in increased alveolar-capillary permeability and airway necrosis after a latent phase of 4 to 8 hours. Ingestion causes GI hemorrhage with necrosis of the liver, spleen, and kidney. Intramuscular administration produces severe local necrosis with extension into the lymphatics. In the absence of specific immunologic testing, differentiating ricin poisoning from sepsis may be difficult because of the presence of leukocytosis and fever. Vaccination of laboratory animals with an investigational toxoid (a modified toxin that does not cause disease but still induces an antibody response) is protective but is not approved for human use.<sup>29</sup>

### Staphylococcal Enterotoxin B

Staphylococcal enterotoxin B (SEB) is one of several enterotoxins produced by *Staphylococcus aureus*. Staphylococcal enterotoxin B is recognized as a “superantigen” because of its profound activation of the immune system on exposure to even minute quantities. As a BW, SEB could be ingested through contaminated food or water, resulting in acute gastroenteritis identical to classic staphylococcal food poisoning. If inhaled as an aerosol, SEB produces fever, myalgias, and a pneumonitis after a 3- to 12-hour latent period. Staphylococcal enterotoxin B inhalation can be fatal but more often would simply be incapacitating for several days to weeks. Treatment is supportive.<sup>70</sup>

Exposure to SEB among BWs laboratory personnel has occurred, and even trace amounts unintentionally transferred to the face and eyes may cause conjunctivitis and GI symptoms.<sup>61</sup>

### Fungi and Other Fungal Toxins

Fungi may at first appear to be ideal BW, given their relative ease of handling, dissemination, and resistance of spores to physical stressors.<sup>12</sup> The only fungi to be included on lists of microbes with potential use as BWs are *Coccidioides* spp, probably based on the high incidence of symptomatic infection in endemic areas. Nevertheless, the risk of serious disease is low, limiting the utility of *Coccidioides* as an effective weapon.<sup>12,58</sup>

Fungal toxins considered to have potential use as BWs include trichothecene mycotoxins, aflatoxins, and amanita toxins. Although  $\alpha$ -amanitin is extremely potent, water soluble, and heat stable, its use as a weapon would be limited by difficulties in mass production.<sup>58</sup> Aflatoxin would be ineffective on the battlefield because its acute toxicity is uncertain, and the carcinogenic potential is a delayed phenomenon.<sup>5</sup> However, both of these toxins may still be effective as terror agents.

### Trichothecene Mycotoxins

The trichothecene mycotoxins are low-molecular-weight (250–500 Da), nonvolatile compounds produced by filamentous fungi (molds) of various genera, including *Fusarium*, *Myrothecium*, *Phomopsis*, *Trichoderma*, *Tricothecium*, and *Stachybotrys*.<sup>5,71</sup> Trichothecene mycotoxins are unusual among potential BW in that toxicity can occur with exposure to intact skin. Naturally occurring trichothecene toxicity results from ingesting contaminated grains or by inhaling toxin aerosolized from contaminated hay or cotton. Outbreaks of ingested trichothecene toxins result in a clinical syndrome called alimentary toxic aleukia, characterized by gastroenteritis, fevers, chills, bone marrow suppression with granulocytopenia, and secondary sepsis—a syndrome clinically similar to acute radiation poisoning. Survival beyond this stage is characterized by the development of GI and upper airway ulceration and intradermal and mucosal hemorrhage. Trichothecene toxins are potent inhibitors of protein synthesis in eukaryotic cells, producing widespread cytotoxicity, particularly in rapidly proliferating tissues; different trichothecene toxins interfere with initiation, elongation, and termination stages of protein synthesis.<sup>5</sup> Exposure to any mucosal surface results in severe irritation. Dermal exposure can produce inflammatory lesions lasting for 1 to 2 weeks, vesiculation, and, in higher doses, death.<sup>71</sup>

Several reports from the 1970s and 1980s suggested that Soviet-supported forces were using trichothecene mycotoxins, particularly the toxin T-2 (Fig. 127–8), as BW. Aerosol and droplet clouds called Yellow Rain were associated with mass casualty incidents in Southeast Asia.<sup>71</sup> Such incidents would involve multiple routes of exposure, with skin deposition likely being the major site. Early symptoms included nausea, vomiting, weakness, dizziness, and ataxia. Diarrhea would then ensue, at first watery and then becoming bloody. Within 3 to 12 hours, victims would develop dyspnea, cough, chest pain, sore mouths, bleeding gums, epistaxis, and hematemesis. Exposed skin areas would become intensely inflamed, with the appearance of vesicles, bullae, petechiae, ecchymoses, and necrosis.<sup>71</sup>

Nonetheless, evidence that trichothecene mycotoxins were used as BWs was mostly circumstantial. Although T-2 toxin was found in victims’

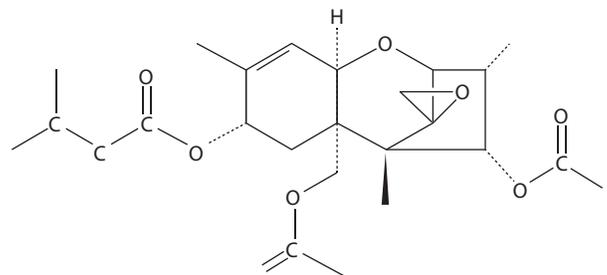

FIGURE 127–8. T-2, a trichothecene mycotoxin.

blood and urine, it was also found in samples from unexposed individuals, probably from baseline ingestion of contaminated foods. Environmental samples containing Yellow Rain droplets were inconsistently found to contain mycotoxins. Eyewitness accounts of Yellow Rain attacks varied widely (including various descriptions of substance's color), and despite the large number of such attacks, no contaminated ordinance or dispersal device was ever recovered.<sup>63</sup> It was also discovered that Yellow Rain droplets were composed mostly of pollen grains. Supporters of the Yellow Rain as BW theory retorted that pollen grains would be an ideal carrier for biotoxins, given that their size is ideal for aerosolization. However, the pollen in Yellow Rain samples did not contain protein, similar to pollen that has been digested by bees. Furthermore, the distribution of pollen species found in Yellow Rain was indistinguishable from the contents of feces of the Asian honeybee, and mass bee defecation resulting in showers of yellow droplets has been observed.<sup>63</sup> The Yellow Rain "bee feces theory" assumes that any mass casualty incidents were from endemic disease outbreaks, other chemical or biological agents not yet identified, or a combination of both.

## SUMMARY

- Many biological weapons (BW) are pathogenic bacteria, viruses, or toxins produced by microorganisms.
- Biological weapons share many features with chemical weapons, including that the most effective method of dispersal to cause mass casualties will be via aerosolization. Disease after exposure to many BWs includes respiratory signs and symptoms.
- Victims of BWs exposure may present in a delayed fashion because of the incubation period of the disease. However, with proper identification of the agent, postexposure prophylaxis with antibiotics or vaccination (or both) is possible.
- With typical universal precautions, ill victims from BWs exposure generally do not pose an infection risk to health care providers and others. Notable exceptions include pneumonic plague, smallpox, and the viral hemorrhagic fevers.

Although the theory of *atomism* originated with the Greeks in the fifth century B.C., it has been only a little more than a century that scientists could describe and measure atoms and the other particles of radiation. Today we use radiation and radionuclides for a vast array of purposes, ranging from mundane household uses such as detecting smoke to powering satellites, treating cancer, and examining the physical properties of individual molecules. Unfortunately, as our knowledge of how to use radiation has expanded, so too has our awareness of radiation as a toxin. Indeed, for three of the last four editions of this text, there has been a significant radiation event that captured the world's attention and demonstrated clearly just how much more we need to know. The particles of radiation, their sources, and the mechanisms by which they pose a health risk are the subjects of the following discussion.

### HISTORICAL EXPOSURES

Soon after x-rays were discovered in 1895, a deepening understanding of radiation and radionuclides led to their wider use and their resulting injuries. In the early days of radiation, exposures were small and of low energy, which nevertheless created injuries for a relatively small number of individuals. Clarence Dally was the first known radiation-induced death in 1904 after repeated exposures to Thomas Edison's early fluoroscopes. By 1927, nearly 100 women employed to create illuminated instrument dials became ill or died after exposure to radium-containing paint. Efforts to protect workers such as those by the British Roentgen Society were hampered by limitations on measurement of radiation despite the development in 1908 of the Geiger counter that could detect but not quantify radiation. Much later in 1984 and again in 1987, lack of proper remediation of closed radiation treatment centers led to scavengers releasing sources of  $^{60}\text{Co}$  and  $^{137}\text{Cs}$ , respectively. In the cobalt incident beginning in Juarez, Mexico, thousands of tiny metal pellets were spilled in a scrapyard and melted with other metals into table legs later shipped throughout Mexico and the United States. In the cesium incident in Goiânia, Brazil, scavengers were fascinated by the bluish glow of the material. Ultimately, 250 individuals were contaminated, 46 patients were treated with a chelator, and 4 died the month after the initial exposure with another dying several years afterward from radiation-induced injuries.

With the advent of the nuclear age, said to have begun with the first detonation of an atomic bomb in New Mexico in July 1945, suddenly the risks of radiation exposure grew to many thousands at once. After the use of the two atomic bombs in Japan at the end of World War II, estimates of dead and injured for both cities were well over 200,000. Most of the deaths were from the bomb blast, but many thousands died from acute radiation syndrome (ARS) and others subsequently from radiation-induced cancers. In addition to the people of those cities who were victims of the bombs, many thousands of military personnel assigned to cleanup tasks or to attend nuclear weapons testing over the following 20 years were also exposed to radiation resulting from nuclear explosions. One relatively well-studied group, the British Nuclear Tests Veterans Association (BNTVA), found that two-thirds of its study group died from neoplasms at ages 50 to 65 years, irrespective of the individual's age at the time of the witnessed explosion.

More recently in the post-nuclear testing era, large radiation incidents occurred at the sites of nuclear reactors. In 1986, the Chernobyl nuclear reactor, built without a hard containment vessel, experienced a series of explosions, releasing an enormous cloud of radioactive material. Thirty-one people died of ARS in the first few weeks after that event, and an unknown number of millions potentially suffered other long-term sequelae in the surrounding geographic area.

On March 11, 2011, a powerful earthquake off the east coast of Japan triggered a destructive tsunami that struck the Fukushima Daiichi nuclear power plant complex, knocking out its own electrical power and disabling the ability to cool its nuclear material. Over the following week, a series of explosions released an amount of radioactive material second only to the Chernobyl incident. Over the intervening time, no conclusive data yet exist describing a change in cancer prevalence, but controversy regarding study methods continues.<sup>14,33,35</sup>

Perhaps one of the most notorious deaths from radiation was that of Alexander Litvinenko, a former Soviet KGB operative who was living in London. On November 1, 2006, shortly after meeting with several men in a public restaurant, Litvinenko experienced nausea and vomiting, prompting a visit to the emergency department (ED). He was treated and released only to return 3 days later for continued vomiting and worsening abdominal pain. Physicians were puzzled by his rapid deterioration, including weight loss, alopecia, hypotension, kidney failure, and leukopenia. He was initially thought to have been poisoned by thallium and later by radioactive thallium. Litvinenko died 22 days later, and it was only after his death that  $^{210}\text{Po}$  was discovered to be the cause, heralding what some consider to be a new era of nuclear terrorism.

In the realm of health care, radiologists of the early 20th century used a thorium-containing contrast called Thorotrast in the initial development of angiography. Unfortunately, this xenobiotic accumulated in hepatic tissue, resulting in malignancies and its eventual discontinuance in 1952 (Fig. 8–25). More recently, the steadily increasing use of computed tomography (CT) has led to increased concerns over their safety and potential for stochastic effects. One retrospective study suggests there is a small but measurably increased risk for certain neoplasms in children after the accumulated radiation dose of several CT scans.<sup>31</sup> This topic is discussed in more detail later.

### PRINCIPLES OF RADIOACTIVITY

Dating from the 15th century, *radiation* remains defined as energy sent out in the form of waves or particles. Although considered by physicists as incomplete, the particle-wave theory remains a useful model by which to understand the toxic aspects of radiation. Despite the *strong nuclear force* that holds the basic building blocks of atoms together, many isotopes are unstable. Various influences such as quantum fluctuations and the *weak nuclear force* can tip the balance toward instability to transform an isotope. This process can be intentional, as with the criticality events in a nuclear reactor or nuclear bomb, but mainly occurs spontaneously in nature as the process called radioactive decay.

#### Radioactive Decay

In 1900, Marie Curie discovered that unstable nuclei decay or transform into more stable nuclei (daughters) via the emission of various particles or energy. Radioactive decay occurs mainly through five nuclear mechanisms: emission of gamma rays, alpha particles, beta particles, or positrons or by capture of an electron. The emission of these various particles makes radioactive decay dangerous because these particles *are* ionizing radiation. Each radioisotope has a specific decay energy signature. That is, the emitted particles from a given radioisotope have known energies, which make identification of radiation sources possible.

The half-life ( $t_{1/2}$ ) is the period of time it takes for a radioisotope to lose half of its radioactivity. Every radioisotope has a characteristic half-life, some lasting millionths of a second and others lasting billions of years. In every

TABLE 128-1 Physical Properties of Radioisotopes

Isotope	Half-Life	Mode of Decay	Decay Energy (MeV)
<b>Radioisotopes of Medicine and Research</b>			
$^2\text{H}$	Stable

EC = electron capture; IT = isomeric transition from upper to lower isomeric state; MeV = megaelectron volts; SF = spontaneous fission.

case, the activities of radioactive isotopes diminish exponentially with time (Table 128-1).

Photons are elementary particles that mediate electromagnetic radiation. Depending on their energy, the radiation has different names ranging from extremely long radio waves to high-energy gamma rays.

X-rays and gamma rays are high-energy photons and are only distinguishable by their source. Gamma radiation is emitted by unstable atomic nuclei via radioactive decay and has a fixed wavelength depending on the energy that formed it. X-rays come from atomic processes outside the nucleus. For example, an x-ray machine generates x-rays by accelerating electrons through a large voltage and colliding them into a metal target. The rapid deceleration of electrons in the target generates x-rays, and in general, the higher the voltage, the greater the energy of the x-rays. Because of their nature, high-energy gamma and x-rays can penetrate several feet of insulating concrete.

Beta particles are electrons. They are emitted during beta decay from an unstable radionuclide. Positrons are positively charged electrons and are also emitted during some decay processes. Electrons have less penetrating ability than gamma radiation but can still pass several centimeters into human skin. Beta particles also cause health problems chiefly through incorporation, or internalization into living organisms.

Alpha particles are helium nuclei (two protons and two neutrons) stripped of their electrons and are emitted during alpha decay. These particles are the most easily shielded of the emitted particles mentioned and can be stopped by a piece of paper, skin, or clothing. Unlike beta particles, alpha particles principally cause health effects only when they are incorporated.

Neutrons are primarily released from nuclear processes, although high-energy photon beams used in radiotherapy can also produce them. The natural decay of radionuclides does not include emission of neutrons, which is mainly a health hazard for workers in a nuclear power facility or victims of a nuclear explosion. Unique among the particles of radioactivity, when neutrons are stopped or captured, they can cause a previously stable atom to become radioactive in a process known as neutron activation.

Cosmic rays complete the group of various kinds of radiation. Cosmic rays are streams of electrons, protons, and alpha particles thought to emanate from stars and supernovas. They rain down on the Earth from all directions only to give up their energy as they strike the nuclei of oxygen and nitrogen in the upper atmosphere of the Earth. By the time they reach the Earth, the energy of cosmic radiation is reduced by several orders of magnitude.

Traveling or living at altitude where the atmosphere naturally shields relatively less cosmic radiation naturally means greater exposure to cosmic rays but in general is not considered a significant threat to humans.

Isotopes and nuclides are very closely related terms, and most experts in the field use them interchangeably. Isotopes are two or more species or variants of a particular chemical element (same number of protons) that have different amounts of neutrons (eg,  $^{123}\text{I}$ ,  $^{125}\text{I}$ ,  $^{127}\text{I}$ ,  $^{131}\text{I}$ ). Nuclide is a more general term that may or may not be isotopes of a given element, such as fissionable nuclides or primordial nuclides. Radioisotopes are isotopes that are radioactive, that is, they spontaneously decay and emit energy. Of the iodine nuclides listed previously,  $^{123}\text{I}$ ,  $^{125}\text{I}$ , and  $^{131}\text{I}$  are radionuclides. The nuclide  $^{127}\text{I}$  is stable (nonradioactive). Finally, radionuclides are simply nuclides that are radioactive.

### Ionizing Radiation versus Nonionizing Radiation

Ionizing radiation refers to any radiation with sufficient energy to disrupt an atom or molecule with which it impacts. In this interaction, an electron is removed, or some other decay process occurs, leaving behind a changed atom. Depending on the specifics of the interaction, the chemical bonds become altered, producing ions or highly reactive free radicals. Hydroxyl free radicals, formed by ionizing water, are responsible for biochemical lesions that are the foundation of radiation toxicity.

The space between collisions of ionizing radiation and their target molecules varies with the particle type and its energy. A charged particle, such as an alpha particle, loses kinetic energy through a series of small energy transfers to other atomic electrons in the target medium, such as tissues. Most of the energy deposition occurs in the *infratrack*, a narrow region around the particle track extending about 10 atomic distances. The energy loss per unit length of particle track is called the linear energy transfer (LET), which is expressed in kiloelectron volts per micrometer (keV/ $\mu\text{m}$ ). Heavy charged particles, such as alpha particles, are referred to as high-LET radiation, and x-rays, gamma rays, and fast electrons are low-LET radiation.

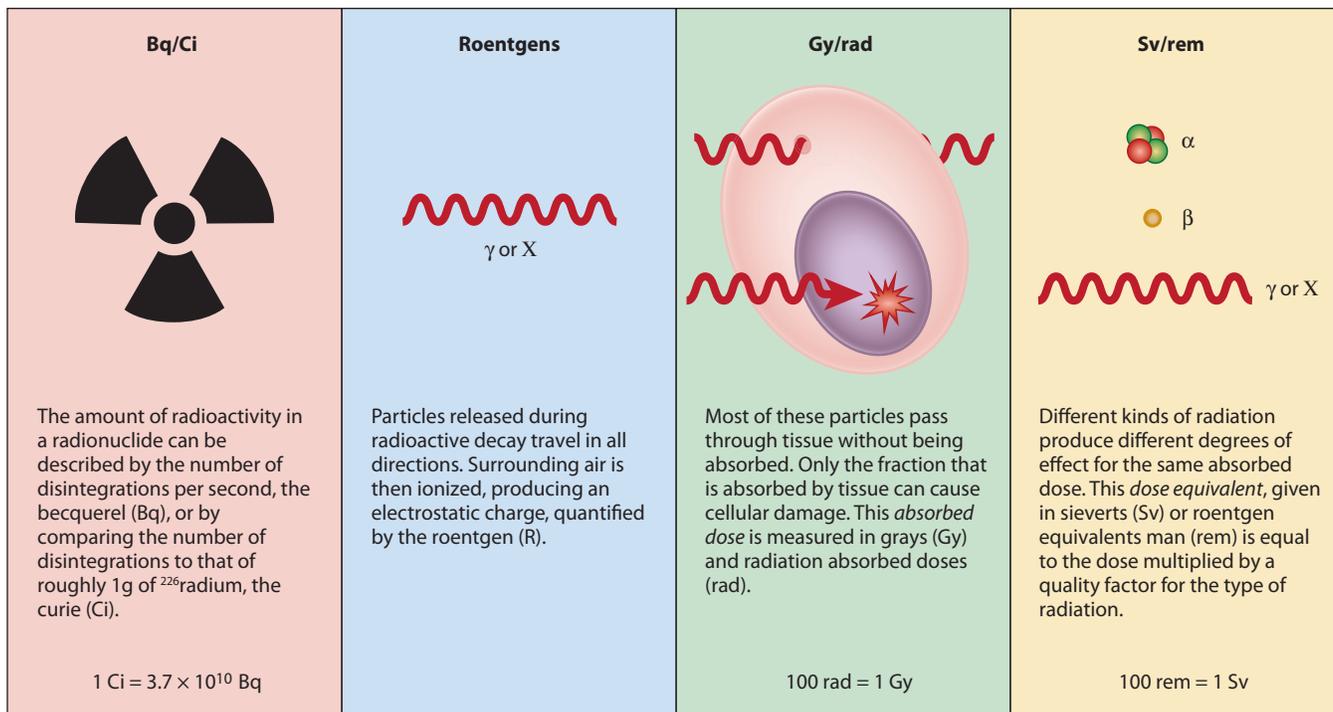

Because of its large size, collisions along the path of an alpha particle are clustered together, impeding its ability to penetrate tissue. By comparison, collisions along the path of gamma rays are spread out, increasing their ability to penetrate tissue. This ability to penetrate tissue and transfer energy accounts for the relative dangers of the forms of radiation and tissue susceptibility.

For a source of radiation to pose a threat to tissue, the ionizing particle must be placed in close proximity to vital components of tissue to inflict damage. High-energy photons penetrate deeply, so they pose a similar risk whether they come from an external source or from an incorporated source. Because alpha particles have much more limited tissue penetration, alpha emitters, radionuclides that radiate these particles, must first be incorporated to pose a threat to tissue. Beta particles similarly have limited tissue penetration and usually are incorporated before damage can occur, although a large external exposure to beta emitters can cause serious cutaneous injury that could be life threatening, as discussed next.

Nonionizing radiation spans a wide spectrum of electromagnetic radiation frequencies. Generally, nonionizing radiation consists of relatively low-energy photons and is used safely in cell phone and television signal transmission, radar, microwaves, and magnetic fields that emanate from high-voltage electricity and metal detectors. Although these are all considered radiation because they each represent energy released from a source, these photons lack the necessary energy required to cause ionization and cellular damage.

### Radiation Units of Measure

The amount of radiation to which an object is exposed, that is, the amount emitted from a source that falls on an object, is given in units called roentgens (R), a term that is now considered obsolete. A roentgen is a unit for measuring the quantity of gamma- or x-radiation by measuring the amount of ionization produced in air. As an example, an individual standing at a given distance from the x-ray-generating tube of a particular x-ray machine is exposed, on the skin, to a particular number of roentgens of x-rays (Fig. 128-1).

**FIGURE 128-1.** The definitions associated with radiation. Both curies and becquerels describe a quantity of radionuclide in terms of the number of disintegrations rather than mass. Roentgens describes the amount of charge per volume of air ionized by either  $\gamma$ - or x-rays, which indirectly quantifies the amount of radiation in the air around a source. Rads and grays (Gy) describe the fraction of radiation that actually interacts with cellular material and potentially causes injury. Roentgen equivalents man (rem) and sieverts (Sv) calculate the effective dose, taking into account the different particles. For example, a 100-keV alpha particle causes more damage to cellular material than a 100-keV beta particle.

Not all radiation to which an individual is exposed poses a risk for cellular damage. Much of the radiation passes through the body and causes no harm. Only the fraction that is absorbed by the tissue has a chance of causing cellular damage. The International System (SI) unit that describes absorbed radiation is the *gray* (Gy), which has replaced the *rad* (radiation-absorbed dose). One Gy equals 100 rad.

To measure the risk of biologic damage regardless of the type of radiation, the effective dose is given in *sievert* (Sv), which has replaced the *rem* (roentgen equivalent man). One Sv equals 100 rem. This calculation, known as *dosimetry*, takes into account the type of exposure (external or internal, partial or total), the particle or particles involved (eg, alpha, beta, gamma), and the radiosensitivity of the organ or organs exposed. The effective dose is calculated according to the following equation:

$$E = D \times W_R \times W_T$$

where  $E$  is the dose in sieverts;  $D$  is the absorbed dose in gray;  $W_R$  is the radiation weighting factor, also called  $Q$ ; and  $W_T$  is the tissue weighting factor indicating the radiosensitivity of each organ.

In 1910, the *curie* (Ci) became the unit describing the amount of radioactivity in a source. One curie equals  $3.7 \times 10^{10}$  disintegrations per second based on the decay of 1 g of radium. The curie was replaced by the SI unit the *becquerel* (Bq) in which 1 Bq is equivalent to 1 disintegration per second. Thus, 1 Ci is equivalent to  $3.7 \times 10^{10}$  Bq. For example, after the Chernobyl incident,  $1.2 \times 10^{19}$  disintegrations per second of radioactive material was released into the atmosphere. By comparison, the radioactive source of <sup>137</sup>Cs in Goiânia contained  $50.9 \times 10^{12}$  Bq ( $13.7 \times 10^5$  mCi) of cesium. A thallium stress test uses  $111 \times 10^6$  Bq (3 mCi) of <sup>201</sup>Tl, and the average indoor concentration of <sup>222</sup>Rn in the United States is 55 Bq/m<sup>3</sup> ( $14.8 \times 10^{-6}$  mCi).

### Protection from Radiation

*Shielding* refers to the process by which one limits the amount of unwanted ionizing radiation in a given setting. Placing a specific material between a radiation source and a target will limit the amount of ionizing radiation that

will interact with the target. When a particle of ionizing radiation is incident on a material, there exists some probability that it will interact with the material and be attenuated. What happens as a result of this interaction depends on several factors, including the type of particle, its energy, and the atomic number of the target material. The photoelectric effect for photons, Bremsstrahlung for beta particles, and elastic scattering for neutrons are several examples of specific interactions. The shielding equation below allows calculation of the efficacy of shielding

$$I = I_0 e^{-\mu x}$$

where  $I$  is the radiation intensity after shielding,  $I_0$  is the radiation intensity before shielding,  $\mu$  is the linear attenuation coefficient, and  $x$  is the thickness material in centimeters. The linear attenuation coefficient is defined as the fraction of photons removed from the radiation field per centimeter of absorber through which it passes. Examples of shielding materials are acrylic, lead, and concrete.

*Distance* is an important safety factor in limiting radiation exposure. Because of their mass and electric charge, alpha and beta particles have a high probability of interacting with matter, such as the atmosphere. The result is that these particles do not travel more than a few centimeters through air and, in general, moving a few feet from the source of this kind of radiation is enough protection by distance. However, x-rays and gamma rays are uncharged and have no rest mass, greatly reducing their probability of interacting with matter, resulting in an unlimited range in space. Photon radiation that is emitted from a point source diverges from that source to cover an increasingly wider area. The intensity of this radiation follows the inverse square law:

$$\frac{I_1}{I_2} = \frac{(r_2)^2}{(r_1)^2},$$

where  $I_1$  is the initial intensity,  $I_2$  is the final intensity,  $r_1$  is the initial distance from the source, and  $r_2$  is the final distance from the source. For example, if

the intensity of radiation 1 m from a source is 1 Gy, its intensity would be 0.11 Gy at 3 m from the source.

*Time of exposure* is another important safety factor in limiting radiation exposure. Obviously, the longer a person is exposed to radiation, the greater the exposure. The US federal and state regulations based on National Council on Radiation Protection and Measurement (NCRP) and US Food and Drug Administration (FDA) recommendations specify the limits of occupational exposure as well as exposure to patients designed to limit the potentially damaging effects of radiation.

### Irradiation, Contamination, and Incorporation

An object is *irradiated* when it is exposed to ionizing radiation. One can be irradiated when handling radioactive isotopes, when undergoing medical diagnostic imaging such as radiography or CT, and during rare exposures to criticality events. These sources of ionizing radiation generate particles that can penetrate tissue well and possibly cause tissue damage. Whole-body irradiation is one in which the entire body is exposed at once. More commonly, shielding devices such as lead aprons and collimation techniques used in radiotherapy limit the amount of exposed tissue to the intended target. The risk of tissue damage depends on the total amount of radiation and the tissue type because different tissue types have their own intrinsic resistance to radiation damage. An irradiated object does not become radioactive itself unless exposed to neutrons, and therefore irradiated individuals pose no risk to others.

The FDA approved irradiation of wheat and flour in 1963. The FDA concluded from 40 years of study that irradiation is a safe and effective process for many foods to control bacteria such as *Escherichia coli*, *Salmonella* spp, and *Campylobacter* spp. Irradiation does not make food radioactive, compromise nutritional quality, or noticeably change the taste, texture, or appearance of food as long as it is applied properly to a suitable product. Organizations that support irradiation of food include the American Medical Association, the Centers for Disease Control and Prevention, and the World Health Organization.

*Contamination* occurs when a radioactive substance covers an object completely or in part. Several examples include a laboratory or industrial worker who unintentionally spills a radionuclide on clothing or skin or a victim of a radiologic dispersing device, a “dirty bomb,” in which a radionuclide is packaged with a conventional explosive and the resultant explosion disperses the radionuclide. In these similar cases, the source of radiation is the nuclide undergoing its normal decay process, and the individual is exposed to particles such as those mentioned in Table 128–1. The risk of tissue damage from the radiation particles is usually quite low, assuming that the contamination is detected and appropriate measures for decontamination are instituted.

*Incorporation* occurs when a radionuclide is taken up by tissue via some route that permits the radionuclide to enter the body. This principle is used in many diagnostic and therapeutic procedures such as a thallium stress test, gallium scan, or thyroid ablation therapy. Depending on the dose and type of radionuclide, incorporation may lead to tissue damage, as was the situation for several people after the event at Goiânia.

### EPIDEMIOLOGY

Everyone is exposed to radiation in one form or another each day (Table 128–2). In the United States, the estimated annual dose equivalent of radiation is now considered to be 6.2 mSv, a number revised sharply upward by the NCRP in 2009.<sup>24</sup> In addition to the naturally occurring sources of radiation in the Earth’s crust that make a significant contribution to our overall radiation exposure, the contribution from human-made sources of radiation, specifically medical exposures, has increased greatly over the past few decades.

Exposures to human-made sources of radiation are not required to be reported to poison control centers in most municipalities. Historically, those that have been reported have not resulted in significant morbidity. The American Association of Poison Control Centers National Poison Data System reports an average of about 300 exposures to radiation over the past 20 years. Of the 231 exposures reported in 2015, 77% were unintentional,

**TABLE 128–2 Annual Estimated Average Effective Dose Equivalent in the United States**

Source	Dose <sup>a</sup>		
	mSv/year	mrem/year	% of Total dose
<b>Natural</b>

mSv = millisieverts; mrem = millirem.

Data from Mettler FA, Bhargavan M, Faulkner K, et al. Radiologic and nuclear medicine studies in the United States and worldwide: frequency, radiation dose, and comparison with other radiation sources—1950–2007. *Radiology*. 2009 Nov;253(2):520–531.

and 8% involved children younger than 6 years of age. There were no deaths reported to poison control centers from exposure to radioisotopes, and only 5 patients experienced a moderate effect, meaning not life threatening (Chap. 130).<sup>28</sup>

### Natural Sources of Radiation

A wide variety of natural sources expose humans on a daily basis to ionizing radiation. Terrestrial sources of radiation originate from radionuclides in the Earth’s crust that move into the air and water. These primordial radionuclides, so named because their physical half-lives are comparable with the age of the Earth, include uranium, actinium, and thorium. Geographic areas vary regarding the content of these radionuclides.

Radon, a radioactive noble gas, accounts for most of the human exposure to radiation from natural sources. This gas, a natural decay product of uranium and thorium, enters homes and other buildings from the building materials themselves or through microscopic cracks in the building’s structures. With a relatively short half-life of 3.82 days, <sup>222</sup>Rn poses a health risk if decay occurs while in the respiratory space and one of its solid daughter isotopes deposits on respiratory tissue. These radon daughters emit alpha particles as they decay and are the principal causes in the associated increased incidence of lung cancer in those exposed to radon. The risk of lung cancer is further increased in heavy smokers who additionally expose their lungs to as much as 200 mSv from <sup>210</sup>Po, a radon daughter that is naturally found in tobacco smoke. The US Environmental Protection Agency (EPA) has recommended household-level intervention when ambient radon concentrations exceed 147 Bq/m<sup>3</sup> (4 pCi/L). Individuals can test their own homes for radon with either short-term (<90 days) or long-term (>90 days) commercially available measurement devices.

The second largest natural source of radiation originates from ingested radionuclides, of which <sup>40</sup>K, a naturally occurring isotope is the most abundant. Potassium is the seventh most abundant element in the earth’s crust, and <sup>40</sup>K represents about 0.012% of this naturally occurring element. With a half-life of 1.3 billion years, <sup>40</sup>K decays via beta emission and electron capture. Because it is part of the environment, the average amount of <sup>40</sup>K in the body is about 3,700 Bq (0.1 μCi), delivering about 0.18 and 0.14 mSv to soft tissue and bone, respectively. The lifetime cancer mortality risk calculated for <sup>40</sup>K is

4 in 100,000 from external exposure compared with one in five from the group predicted to die of cancer from all other causes per the US average.

### Human-Made Sources

The NCRP report no. 160 sharply increased the estimated annual dose of radiation exposure from human-made sources of radiation largely from the steeply rising use of CT (Table 128–3).<sup>29</sup> Evolving contemporaneously with the computer, CT technology has become extremely efficient and available contributing to the estimate that more than 70 million CT scans were performed in the United States during 2005 and 2006 compared with about 3 million scans in 1980, accounting for more than half of the human-made collective dose.<sup>24</sup> Concern over potential cancer risks stemming from this new volume of exposure centers on children in whom doses are higher despite increasing practice to tailor scans to the size of the patient and because their relatively longer lives make children more likely to manifest slowly developing cancers. One retrospective study conducted over 7 years in Great Britain through the National Health Service examined data for more than 175,000 young patients each in two groups with certain leukemias and brain tumors.<sup>2,31</sup> Based on typical machine settings and estimated absorbed doses, this study found an increased relative risk of these cancers resulting from accumulated doses of just a few CT scans. Importantly, this was one of very few studies on this topic that did not rely on extrapolated data from atomic bomb survivors. Perhaps influenced by data like these accompanied by increased availability of other alternative imaging modalities, such as magnetic resonance imaging, several studies report trends of decreasing use of CT for children.<sup>23,30</sup>

Overall use of other non-CT radiologic studies has increased greatly over the past decades as well. Estimates show 377 million radiologic procedures in the United States in 2006, not including more than 500 million dental radiologic examinations, although these examinations are not thought to

contribute significantly to the overall accumulated dose. Nuclear medicine scans, particularly in the field of cardiology diagnostics, increased sharply as well and account for 4% of all radiologic procedures and 26% of the total collective dose.<sup>24</sup>

### Nuclear Occupational Exposure

Estimates of the annual number of workers occupationally exposed to radiation worldwide are several million.<sup>37</sup> On average, the occupations with the highest exposures (about 4 mSv/year) are uranium miners and millers. Overall, as of 1994, the average annual effective dose to monitored workers in the nuclear fuel industry dropped from 4.1 to 1.8 mSv, mainly because of a large decline in underground mining. Despite the many factors that play a role in occupational exposure at more than 1,200 nuclear reactors worldwide, the estimated annual effective dose to measurably exposed workers fell to 2.7 mSv.

*Medical occupational exposure* principally includes physicians, nurses, radiology technologists, and laboratory workers who receive an additional annual effective dose of about 0.5 mSv, which is decreased from about 1 mSv 25 years ago, possibly because of efforts to improved protection practices. Exposures to health care workers were studied in a wide variety of specialties, including cardiology, orthopedics, radiology, urology, and others.<sup>17,39,40</sup> Although each of these fields uses different modalities of radiation that pose different risks to the operator, studies continue to find low overall doses per procedure, suggesting more than 800 procedures would be necessary to approach yearly dose limits.<sup>40</sup> Emergency medicine staff and trauma teams were exposed to higher radiation doses in the past, primarily from holding the cervical spine stable during x-ray studies, but this has largely been replaced by CT. Doses sustained by these staff are well below the upper limits of exposure set by the Nuclear Regulatory Commission (NRC).<sup>11,13</sup> Thus, although the number of CT scans performed continues to rise, the radiation exposure to staff remains low because of collimation and low scatter, as well as proper shielding in properly designed facilities.

Fluoroscopy constitutes less than 10% of all examinations in the United States but remains the largest source of occupational exposure in medicine. Studies of physician exposure to radiation by fluoroscopy used in various procedures, including exploration of the biliary tract, extremity nailing, interventional cardiology, nephrolithotomy, vertebroplasty, and others report, effective doses ranging from 1 to 100  $\mu$ Sv (0.1–10 mrem). Depending on the procedure, doses to the hands, brain, lens of the eye, and thyroid could be much higher placing physicians at greater risk of stochastic effects (see Stochastic versus Deterministic Effects of Radiation) than is suggested by the effective dose.<sup>17,40</sup> Estimated whole-body exposures to these procedures were considered not to exceed the limits established by the Occupational Safety and Health Administration (OSHA) of 50 mSv per year. Although the likelihood of exceeding established radiation limits is low regardless of the procedure and even assuming a reasonable increase in the number of procedures performed, appropriate shielding and safety training are emphasized to minimize the risk of exposure.

Worldwide, nearly 500,000 workers are monitored for exposures during dental radiography, but the annual effective dose averaged over 5 years has declined to 0.05 mSv. Close to 40 million nuclear medicine procedures are performed annually worldwide, but the radiation exposures from this type of procedure are quite small.<sup>24</sup>

*Depleted uranium (DU)* is used by the US military and by several other governments. Uranium ore mined from the earth is about 99% <sup>238</sup>U and 1% <sup>235</sup>U. Enrichment involves separating the isotopes—for example, via high-speed gas centrifuge—so that <sup>235</sup>U can be used as nuclear fuel and the leftover <sup>238</sup>U can be used in munitions. Consequently, although DU is radioactive, it is 40% less so than naturally occurring uranium. External exposure to solid <sup>238</sup>U is considered to be negligible, although currently many studies are investigating the potential link between DU and the incidence of leukemias, other cancers, and birth defects.<sup>1</sup> The Depleted Uranium Follow-Up Program that has surveyed exposed veterans since 1994 has not discovered any consistent, clinically significant differences in uranium-health parameters, which includes hematopoiesis, neuroendocrine, and kidney function.<sup>22</sup>

Coronary angiography				16	1,600

ERCP = endoscopic retrograde cholangiopancreatography; MBq = megabequerel; mCi = millicuries; mSv = millisievert; mrem = millirem.

## EXPOSURE LIMITS

The NRC established the “Standards for Protection against Radiation,” which regulates radiation exposures using a twofold system of dose limitation: doses to individuals shall not exceed limits established by the NRC, and all exposures shall be kept *as low as reasonably achievable* (ALARA). The total effective dose equivalent may not exceed 50 mSv/year to reduce the risk of stochastic effects (see Stochastic versus Deterministic Effects of Radiation). The dose to the fetus of a pregnant radiation worker may not exceed 5 mSv over 9 months and should not substantially exceed 0.5 mSv in any 1 month.

## REGULATION AND REPORTING

The use of ionizing radiation, radiation sources, and the byproducts of nuclear energy are among the most heavily regulated processes worldwide. Regulations for medical use of radiation derive from multiple international and national organizations. Among the international groups are the United Nations Scientific Committee on the Effects of Atomic Radiation (UNSCEAR), the International Commission on Radiological Protection (ICRP), the Biological Effects of Ionizing Radiation (BEIR) Committee, the International Commission on Radiological Units and Measurements (ICRU), the Radiation Effects Research Foundation (RERF), and the International Radiation Protection Association (IRPA). Because international organizations do not have the authority to enforce their recommendations worldwide, most countries have their own regulatory groups that cooperate internationally. In the United States, the NCRP reviews recommendations from the ICRP and makes recommendations. The NCRP issues BEIR reports that have direct standards for ionizing radiation use. For medical imaging standards, recommendations from the NCRP are considered to be guidelines with which all radiology departments must comply. The goal is to foster a radiation protection program that prevents deterministic effects. Additionally, the Conference of Radiation Control Program Directors (CRCPD) suggests state regulations for control of radiation.

National regulatory agencies include the NRC, EPA, OSHA, and FDA. The NRC also runs an Agreement State Program under which the NRC relinquishes to the States portions of its regulatory authority to license and regulate nuclear materials. The US Department of Transportation (DOT) regulates transport of hazardous materials, including radioactive material.

The NRC, the EPA, and many state governments share the responsibility of licensing and regulating radionuclides in the United States. The Oak Ridge Institute for Science and Education’s (ORISE) supports the NRC by maintaining the NRC’s website for Radiation Exposure Information and Reporting System (REIRS) and the database of radiation exposure from NRC licensees (<http://www.reirs.com>). Individual states regulate radioactive substances that occur naturally or are produced by machines, such as linear accelerators or cyclotrons. The EPA oversees the general area of environmental monitoring of radiation. The FDA regulates the design and manufacture of electronic products, inspects diagnostic x-ray equipment, and establishes specific operational standards for x-ray equipment. The NRC regulates medical, academic, and industrial uses of nuclear materials generated by or from a nuclear reactor. The OSHA regulates occupational exposure to radiation and oversees regulations for training programs and “right to know” regulations.

The Oak Ridge Institute for Science and Education’s Radiation Emergency Assistance Center/Training Site (REAC/TS) and the International Atomic Energy Agency (IAEA) both maintain radiation incident registries that track US and foreign radiation incidents. Information for the REAC/TS registries is gathered from many sources, including the WHO Radiation Emergency Medical Preparedness and Assistance (REMPAN), IAEA, state health departments, and medical and health physics literature.

## PATHOPHYSIOLOGY

Ionizing radiation causes damage to tissue by several mechanisms called direct or indirect effects. *Direct effects* are when particles physically damage the DNA in a cell, which can occur at the sugar phosphate backbone, hydrogen bonds, or base molecules. Although any type of radiation can cause this damage, high-LET radiation is more likely to cause direct effects

owing to its greater probability of interacting with DNA. When this kind of damage occurs, a mutation can arise, which may then result in alteration of a germ line, development of a neoplasm, or cell death. The risk of these consequences overall, however, is low because of the relative paucity of DNA within a cell, the even smaller percentage of active DNA within a given cell, and the ability of DNA to repair itself.

Although DNA represents a low-probability target for radiation, the rest of the cell media represents a higher probability target. *Indirect effects* are when radiation impacts a molecule and creates a reactive species, which then chemically reacts with organic molecules in cells altering their structure or function. These radiation-induced ions are unstable, however, and usually convert to free radicals. Water, which is in great abundance within cells, can transform into a hydroxyl radical (OH·) after interaction with incident radiation. The hydroxyl radical diffuses only a short distance through the cell because of its highly reactive nature and itself causes molecular damage. Indirect effects are predominantly caused by low-LET radiation (x-rays, gamma-rays, and fast electrons).

*The bystander effect* refers to cellular damage in unirradiated cells that neighbor irradiated cells. As early as the 1940s, there were reports of inactivation of cells by ionization of the surrounding medium. Recently, the use of a single-particle microbeam (a device that can fire a predefined exact number of alpha particles through a particular cell nucleus) demonstrated that cultured cells that were not hit by radiation showed increased chromosome damage, rearrangement, and rate of death. In one experiment, when 10% of cells on a dish were exposed to two or more alpha particles, the resulting frequency of induced oncogenic transformation was indistinguishable from that when all the cells on the dish were exposed to the same number of alpha particles.<sup>27</sup> Studies demonstrate the bystander effect for proton beams, x-rays, and low-LET radiation.<sup>32,34</sup>

*Genomic instability* is a single mutation followed by a cascade of further mutations altering the fidelity of genomic replication. This modification can be found in cell progeny many generations after irradiation and can have unpredictable outcomes in succeeding generations. Although many hypotheses have been suggested, it appears most likely that the instability is due to irreversible regulatory change in the network of cellular gene products.<sup>12,15,21</sup>

Although any molecule can be damaged in a variety of ways that may lead to cell injury of varying severity, double-stranded breaks in DNA are the type of damage most likely to cause chromosomal aberrations or cell death. The radiosensitivity of the cell is directly related to its rate of proliferation and inversely related to its degree of differentiation.

Thousands of these types of lesions occur daily in the human body. There are several mechanisms by which the body effects its own repair, which forms the basis of fractionated radiation therapy, taking advantage of less efficient repair mechanisms of tumor cells. However, there is evidence that DNA damage induced by radiation is chemically different and more complex from DNA damage that occurs spontaneously, which contributes to a higher rate of mutation than that resulting from spontaneous damage. Dose–response relationships for mutation are approximately linear down to about 25 mGy, the statistical limit of these studies. Although repair mechanisms reduce substantially the radiation risk of mutation, there is no evidence yet that these mechanisms eliminate those risks at low doses, although some question this conclusion.<sup>18</sup>

## STOCHASTIC VERSUS DETERMINISTIC EFFECTS OF RADIATION

The radiation damage just described has two consequential results: it kills cells or it alters cells and causes cancer. Injuries that do not require a threshold limit to be exceeded include mutagenic and carcinogenic changes to individual cells in which DNA is the critical and ultimate target. This is the *stochastic effect* of radiation. Theoretically, there is no dose of radiation too small to have the potential of causing cancer in an exposed individual.

Whereas the stochastic effects of radiation can follow less severe exposures, the *deterministic effects* of radiation usually follow a large whole-body exposure, such as a Chernobyl-type event. In terms of cell death, a relatively large number of cells of an organ system must be killed before an effect becomes clinically evident. This number of killed cells constitutes a threshold

limit that must be exceeded, and this is what is known as the deterministic or nonstochastic effects of radiation.

To illustrate the differences between stochastic and nonstochastic effects, consider a single alpha particle, emitted from  $^{210}\text{Po}$ , which was incorporated after exposure in a radon-contaminated household. Theoretically, if this particle impacts on an active segment of DNA in a patient's respiratory tract, it could give rise to a cancer—the stochastic effect. In contrast, after exposure to the criticality event in Tokaimura, Japan, the most severely injured worker received 17 Sv of neutron and gamma radiation and experienced so much cell death across so many systems in his body that he died well before any injured yet surviving cells could develop into a cancer—the deterministic effect.

## ACUTE RADIATION SYNDROME

The US Army Medical Corps first described ARS in 1946 when victims of the detonations at Hiroshima and Nagasaki were admitted for treatment at Osaka University Hospital.<sup>16</sup> Understanding the features of ARS is essential for managing a patient who is exposed to massive whole-body irradiation, generally considered to be 1 Gy (160 times the average annual exposure) or more. In many cases, a reliable estimate of the radiation dose is difficult, making it more practical to focus on the clinical features of radiation injury and their prognostic utility.

Acute radiation syndrome involves a sequence of events that varies with the severity of the exposure.<sup>41</sup> Generally, more extensive exposures lead to more rapid onset of symptoms and more severe clinical features. Four classic clinical stages are described, which begin with the early prodromal stage of nausea and vomiting. These symptoms begin anywhere from hours to days postexposure. Although the time to onset postexposure is inversely proportional to the dose received, the duration of the prodromal phase is directly proportional to the dose. That is, the greater the dose received, the more rapid the onset of symptoms, and the longer their duration, except in cases in which death follows rapidly. The latent period follows next as an apparent improvement of symptoms, during which time the patient appears to have recovered and has no clinically apparent difficulties. The duration of this stage is inversely related to dose and can last from several days to several weeks. The third stage usually begins in the third to fifth week after exposure and consists of manifest illness described in subsequent paragraphs. If the patient survives this stage, recovery, the fourth stage, is likely but can take weeks to months before it is completed. Those exposed to supralethal amounts of radiation can experience all the phases in a few hours before a rapid death.

These four stages describe the clinical manifestations that can be observed as a result of massive exposure, but the various systems of the body manifest their own injuries, which constitute several subsyndromes. These subsyndromes are not mutually exclusive of one another and often overlap as cell death or damage progresses. Once these subsyndromes are manifest, they often are irreversible.

The cerebrovascular syndrome describes the manifestations of injury to the central nervous system after massive irradiation. This syndrome, after exposure to doses of about 15 to 20 Gy or greater, is characterized by rapid or immediate onset of hyperthermia, ataxia, loss of motor control, apathy, lethargy, cardiovascular shock, and seizures. The mechanism of this injury may be a combination of radiation-induced vascular lesions and free radical-induced neuronal death and cerebral edema.

Despite autopsy evidence of some radiation-induced inflammatory changes to the heart, animal experiments demonstrate that the heart is relatively resistant to high doses of radiation. Cardiovascular shock is more likely because of systemic vascular damage, which can later compound shock resulting from other subsyndromes should the patient survive to that point. A "vascular radiation subsyndrome" might be considered to help explain the hemodynamic changes a patient experiences after a massive dose of radiation.

The pulmonary system is not spared injury from irradiation. Pneumonitis can occur within 1 to 3 months after a dose of 6 to 10 Gy. This can lead to respiratory failure, pulmonary fibrosis, or cor pulmonale months to years later.

The gastrointestinal (GI) syndrome begins after an exposure to about 6 Gy or more when GI mucosal cell injury and death occur. Findings and effects

include anorexia, nausea, vomiting, and diarrhea. As the mucosal lining is sloughed, there is persistent bloody diarrhea, hypersecretion of cellular fluids into the lumen, and a loss of peristalsis, which can progress to abdominal distension and dehydration. Destruction of the mucosal lining allows for colonization by enteric organisms with ensuing sepsis.

The hematologic changes that occur after an exposure to about 1 Gy or greater are called the hematopoietic syndrome. Hematopoietic stem cells are highly radiosensitive, in contrast to the more mature erythrocytes and platelets. Lymphocytes are also radiosensitive and can die quickly from cell lysis after an exposure. This contrasts with granulocytes, which endure radiation better. In addition to stem cell death and white blood cell depletion with immunodeficiency, platelets are consumed in gingival and GI microhemorrhages. The main effect of radiation-induced hematopoietic syndrome is pancytopenia, leading to death from sepsis complicated by hemorrhage. The lymphocyte nadir typically occurs 8 to 30 days postexposure, with higher doses achieving earlier nadir.

The cutaneous syndrome, a local radiation injury, can develop early after exposure or can take years to manifest fully. Target cells include all layers, including the epidermis, hair follicle canals, and subcutaneous tissue. Signs and symptoms include bullae, blisters, hair loss, pruritus, ulceration, and onycholysis. Skin injury ranges from epilation beginning at doses of 3 Gy to moist desquamation at about 15 Gy, to necrosis at greater than 50 Gy.

## DOSE ESTIMATION

As with other medical management in which determining a specific diagnosis is critical to providing appropriate care, determining an accurate dose of radiation exposure is critical to providing the best care for the irradiated patient because increasing radiation exposure will affect different organ systems, call for different therapies, require different levels of monitoring, and assign different prognoses. Indeed, some consider a dose of 1.5 to 2 Gy to be a critical threshold, beyond which some patients could die from their exposure despite treatment, making the determination of whether a patient has received more than this dose an essential feature of the initial assessment.<sup>9,36</sup> Dose estimation is difficult, however, for a number of reasons, such as the absence of a radiation-monitoring device, exposure to radiation of mixed form (eg, gamma and neutron radiation), and partial shielding of various body parts.

*Biodosimetry* is the use of physiological, chemical, or biological markers to reconstruct radiation doses to individuals or populations and assess the probability of developing ARS. Key elements of dose estimation include time to onset of vomiting, lymphocyte depletion kinetics, and chromosomal assays. Today there are numerous tools available on the Internet to assist with dosimetry, including the Biological Assessment Tool available at the Armed Forces Radio-biology Research Institute's website (<https://www.usuhs.edu/afri/biodosimetrytools>), guidelines from the International Atomic Energy Agency, and the Radiation Emergency Medical Management website (<https://www.remm.nlm.gov>).

One early response biodosimetry method was developed by REAC/TS that combines post-incident emesis (which could be a sign of psychological stress) with lymphocyte depletion over the first 24 hours.

$$T = N/L + E,$$

where T is the triage score, N/E is the neutrophil/lymphocyte ratio, and E is whether emesis has occurred. E equals 0 if no emesis and E equals 2 if emesis. Based on cases from the REAC/TS registry, for times longer than 4 hours postevent, if T is greater than 3.7, then the patient is deemed at risk of high dose exposure, that is, greater than 2 Gy, and should receive a more extensive hematological evaluation.

The broad ranges of radiation doses that correlate with lymphocyte count are described in the classic Andrews nomogram of 1965. Again, using historic data from exposed patients, a lymphocyte depletion constant was calculated using the equation

$$L(t) = L_0 e^{-k(D)t}$$

where  $L(t)$  is the lymphocyte count at time  $t$ ,  $L_0$  is the lymphocyte count before the exposure (the population mean taken as  $2.45 \times 10^9$  cells/L),  $K$  is the rate constant for a given dose of radiation, and  $D$  is the dose of radiation. Solving for  $K(D)$  will allow for an accurate estimate of a rapidly delivered, whole-body exposure.

Although there are still other methods of biodosimetry, such as interphase aberrations assessment and electron spin resonance of dental enamel, measurement of chromosomal aberrations has become the gold standard. Introduced in 1966, this technique analyzes the number of dicentric chromosomes that occur after a whole-body exposure to radiation. An exposure to radiation can cause breakage of the DNA molecule in two nonhomologous chromosomes and produce “sticky ends” that recombine end to end. In metaphase, these appear as a single chromosome with two centromeres and are called dicentric. The number of dicentrics in lymphocytes correlates reliably with a given dose of radiation. This assay conforms to International Organization for Standardization (ISO) but suffers from several drawbacks, including reduction of cells for assay in the setting of proliferative cell death, a low mitotic index for irradiated cells, a long time needed for cell cultures to reach metaphase in which dicentrics are measured, and migration of lymphocytes into tissue and the lymphatic system. These complications limit the time available to perform an accurate test as well as make the testing itself a relatively long affair, complicating its potential application to a mass casualty event. The translocation assay uses fluorescence in situ hybridization chromosome-painting technique and is used primarily for estimating doses of historical exposures. Unlike dicentrics, complete translocations persist in cell division and enable dose estimation over years after exposure. In fact, when this technique was used to evaluate the radiation dose experienced by clean-up workers at Chernobyl, the authors concluded that it was likely that recorded doses for these cleanup workers overestimate their average bone marrow doses, perhaps substantially.<sup>19</sup> Another method includes the cytokinesis-block micronucleus (CBMN) assay in which other unstable cell nuclear aberrations form but then disappear over time. This method generates data comparable to dicentric analysis, and when used in a semiautomated fashion, it can greatly improve testing speed.<sup>8</sup> The premature chromosome condensation assay in which chromosomes are stimulated to condense in interphase cells, has been combined experimentally with telomere and centromere staining to reduce greatly the amount of time needed to perform biodosimetry, although this technique is still in an early phase of development.<sup>26</sup> Many of these techniques are not widely available, require incubation times of 48 to 72 hours, and cannot assess for doses greater than 5 Gy.

## CARCINOGENESIS

Radiation was recognized as a carcinogen soon after it was initially discovered in 1895. After decades of research, including animal models, epidemiologic studies, and the lifespan studies of Japanese nuclear bomb survivors, radiation was shown to be a “universal carcinogen” able to induce tumor in nearly every tissue type in nearly every species at all ages. In fact, radiation’s ability to induce cancer is so well established that the past three decades of research have used radiation-induced tumors to focus on DNA damage and repair mechanisms.

Double-stranded breaks are the biologically important lesion for inducing tumors. Although radiation induces point mutations, it also induces deletions, sometimes of an entire gene. Research on transcription-coupled repair, in which the transcribed strands of expressed genes are more rapidly repaired than the rest of the genome, were shown to be repaired most often by an illegitimate recombination process that is error prone, frequently resulting in the loss of heterozygosity, a “double-hit” mutation. This loss of heterozygosity suggests that radiation-induced carcinogenesis would more likely result from inactivation of a tumor suppressor gene than activation of a proto-oncogene.<sup>20</sup>

## COMMONLY ENCOUNTERED RADIONUCLIDES

Most patients who come to medical attention are not exposed to large, whole-body irradiation but rather to small spills in a laboratory or inadvertent exposures from one of many products that are commercially available. With the notable exception of a well-known case of massive americium contamination

in Oak Ridge, Tennessee, and the cesium exposure in Goiânia, Brazil, the vast majority of these types of cases are not reported in the medical literature.

Americium (symbol Am, atomic number 95, and atomic weight 243) was discovered in 1944 in Chicago during the Manhattan Project. Its most stable nuclide, <sup>243</sup>Am, has a half-life of more than 7,500 years, although <sup>241</sup>Am, with a half-life of 470 years, was the first americium isotope to be isolated. It decays by alpha and gamma emission and will accumulate in bone if incorporated. It is used to test machinery integrity, glass thickness, and in smoke detectors (about 0.26 mcg per detector), in which it ionizes the air between two electrodes and generates an electric current that soot impedes, triggering an alarm. Alpha particles from these detectors are easily absorbed within a few centimeters of the surrounding air and pose little risk. One gram of americium dioxide provides enough americium for more than 5,000 smoke detectors. In 1976, a worker at the Hanford Plutonium Finishing Plant suffered a large <sup>241</sup>Am contamination in an explosion at the site. The patient was contaminated with 100 g or 70 MBq (500,000 smoke detectors’ worth) in the explosion. He was treated with long-term pentetic acid (DTPA), and despite some leukopenia from the radiation, he survived for 11 years before dying from unrelated cardiac disease.

Cesium (symbol Cs, atomic number 55, and atomic weight 132) was discovered by Bunsen in 1860. It decays by beta and gamma emissions and tends to follow the potassium cycle in nature. It is used as a radiation source in radiation therapy and as a radionuclide source for atomic clocks. Cesium, the radionuclide of the Goiânia incident, comes in the form of a powder, which would make dispersal relatively easy if used in a dirty bomb. Insoluble Prussian blue is the FDA-approved chelator for patients contaminated with cesium (Antidotes in Depth: A31).

Iodine (symbol I, atomic number 53, and atomic weight 126.9) was discovered by Courtois in 1811. Of the 23 isotopes of iodine, <sup>127</sup>I is the only one that is stable. <sup>129</sup>I and <sup>131</sup>I are fission products that are released into the environment during an event. These isotopes will accumulate in thyroid tissue if incorporated and can cause local damage to thyroid tissue. It is this potential for incorporation that prophylaxis with potassium iodide (KI) is indicated in the event of a large exposure.

Polonium (symbol Po, atomic number 84, and atomic weights range from 192 to 218) was discovered by Marie Curie while she was searching for the cause of radioactivity of pitchblende (uranium ore) and was named after her native country of Poland. Polonium has 27 isotopes, the most isotopes of all the elements and all are radioactive. Polonium is a very rarely occurring natural element, and only 100 mcg is found in a ton of uranium ore. Polonium is chiefly manufactured by bombarding <sup>210</sup>Bi with neutrons in nuclear reactors, and it exhibits several properties that make it extremely dangerous. The short half-life of <sup>210</sup>Po, 138 days, and high specific activity of 4,490 Ci/g means it emits a great deal of high-energy alpha particles (5.3 MeV) that produce 140 W/g. For example, a capsule containing 500 mg of <sup>210</sup>Po reaches a temperature of 932°F (500°C). It also demonstrates a high volatility in which 50% vaporizes in 45 hours at 131°F (55°C) and can contaminate a relatively large area even when left alone. Although only a small fraction of absorbed <sup>210</sup>Po accumulates in tissue, cumulative doses of radiation can lead to organ systems failure and death. Animal data estimate an LD<sub>50</sub> (median lethal dose in 50% of test subjects) of 1.3 MBq/kg and that various mammalian species die within 20 days after an ingestion of 1 to 3 GBq. Because of the extreme specific activity of <sup>210</sup>Po, this corresponds to a dose of about 0.01 mcg/kg. Currently, there are no specific chelating agents for <sup>210</sup>Po. Although there are limited data regarding the effects of <sup>210</sup>Po on humans, Alexander Litvinenko’s death within 22 days of his poisoning with polonium is similar to animal survival data.

Radon (symbol Rn, atomic number 86, and atomic weights range from 204 to 224) was discovered in 1900 by Dorn and is the heaviest noble gas. <sup>222</sup>Radon decays by alpha and gamma emissions. Exposure of radon gas to the pulmonary epithelium is associated with an increased incidence of lung cancer in both uranium miners and in those who dwell in residences with increased concentrations of radon. Damage to bronchial epithelium results from the alpha emissions of radon and radiation from radon daughters that

precipitate as solids and remain in the lungs. Good enclosed space ventilation, abstinence from cigarette smoking, and monitoring of radon concentrations help to minimize this risk.

Technetium (symbol Tc, atomic number 43, and atomic weight 98.9) was discovered in 1937 and was the first element to be produced artificially. Unusual among the lighter elements, Tc has no stable isotopes and is therefore found on earth as a product of spontaneous uranium fission. The majority of technetium is extracted from nuclear fuel rods and is used in nuclear medicine for imaging. <sup>99m</sup>Tc (the *m* is for metastable referring to an intermediate energy state) emits gamma rays that are similar to diagnostic x-rays and easy to detect. <sup>99m</sup>Tc decays to <sup>99</sup>Tc with a half-life of 6 hours, and the half-life of <sup>99</sup>Tc is  $2.1 \times 10^5$  years, allowing it to be easily eliminated before it decays in turn. Most human contact with Tc is in medical scans in which Tc has a biological half-life of about 1 day. There are no reports of adverse effects resulting from overdose with Tc, and no specific therapy is recommended in that event.

Thallium (symbol Tl, atomic number 81, and atomic weight 204) was discovered by Crookes in 1861. <sup>201</sup>Tl is used for cardiac imaging, has a half-life of 73 hours, and decays by electron capture and gamma emission. Pharmaceutical <sup>201</sup>Tl is created in a cyclotron by bombarding thallium with protons creating <sup>201</sup>Pb and is shipped in this form, which decays into <sup>201</sup>Tl. Because the radioactive decay process is continual, it is recommended to administer the <sup>201</sup>Tl close to its *calibration time* to minimize the presence and effects of other radionuclide contaminants. Chelation can be accomplished with Prussian blue (Antidotes in Depth: A31).

Tritium is an isotope of hydrogen whose nucleus contains one proton and two neutrons, and its symbol is <sup>3</sup>H. Tritium decays by beta activity and is used in basic science research as a radioactive label, for luminous dials, and self-powered exit signs, which can contain as much as  $9.3 \times 10^{11}$  Bq (25Ci). Tritium has a half-life of 12.3 years. Tritium emits very weak radiation in the form of 18.6 KeV beta particles, which are easily stopped by thin layers of material, and is safe for glow-in-the-dark watches. Tritium is not absorbed as a hydrogen gas, although, when in contact with oxygen it forms tritiated water, which can be absorbed via inhalation or transdermally. The estimated LD<sub>50</sub> is  $3.7 \times 10^{11}$  Bq (10 Ci) given its extreme specific activity of 9,649 Ci/g. When absorbed as tritiated water, tritium tends to follow the water cycle in humans, providing a whole-body dose if incorporated. However, its biologic half-life is 10 to 12 days, which can be decreased by increasing urine output, greatly limiting its potential toxicity.

## MANAGEMENT

### Initial Assessment and Early Triage

The initial management of patients exposed to radiation will depend on a number of different factors, including the amount of radiation in the exposure and the number of casualties in the event. Small-scale exposures to radiation still require at least a brief evaluation for burns and trauma, depending on the circumstances surrounding the nature of the exposure. Calls to the poison control center from a residence require referral to emergency services for an expert evaluation of the extent of the contamination of the site and appropriate decontamination measures. Exposures in the laboratory or nuclear medicine suites require referral to the radiation safety officer (RSO) in the building for a similar evaluation.

When considering a local incident involving nuclear material, first responders will likely include a hazardous materials team (HAZMAT) and local police and fire departments. Hospitals should involve their RSO, and public officials will involve a state agency such as the State Department of Environmental Protection. As part of its primary mission for the US Department of Energy, REAC/TS offers consultation with anyone on a 24/7 basis on questions regarding radiation exposure. Its emergency phone number is 865-576-1005 (ask for REAC/TS). For large incidents, other federal agencies will be involved led by the Federal Emergency Management Agency. Additional radiation expertise can be provided via the Department of Energy, and if applicable, the Federal Bureau of Investigation will be called to protect against further threats.

In a mass casualty event, established prehospital plans should be followed to provide the best management for the large numbers of variably

injured given that an explosion of potentially catastrophic size also accompanies the radiation exposure. First responders must use universal precautions and should assume that all victims are contaminated; most events will only require C- or D-level protection (Chap. 132). Field triage protocols tailored to the kind of event in question will designate patients as minor, delayed, immediate, or deceased and should not be altered because of radiation exposure.

Preliminary decontamination, including removal of clothing and washing the victim, should be performed before transportation to a medical facility taking care not to contaminate prehospital providers or equipment. Uninjured patients who are contaminated should be relocated upwind of the incident site for further care.

### Initial Emergency Department Management

It is not considered a medical emergency to have been irradiated or contaminated; even highly irradiated patients take days to die, which is why standard protocols regarding trauma and other medical complaints continue to be followed even in mass casualty events. In the event of a radiation incident, there will likely be little warning of these patients arriving, and information will be incomplete. Ideally, the ED is divided into clean and dirty areas where the floor of the dirty area is covered by plastic or butcher's paper. Staff should don surgical scrubs, gowns, surgical caps, masks, booties, and face shields. Two sets of gloves should be worn with the inner set taped to the gown. Tape should also close the back of the gown and trousers to the booties. Dosimeters should be worn at the neck for easy access by the RSO, and staff should be reminded that medical personnel have never received a medically significant acute radiation dose when caring for an exposed patient.

Because of the complex nature of radiation and contamination, it will be necessary to call on the various consultation services, who will likely be a part of the hospital medical response team, that can lend their expertise. These services include burn specialists, dermatologists, nuclear medicine specialists, radiation oncologists, hematologists, toxicologists, and the RSO.

When patients arrive to the ED, it is essential to follow an algorithm that takes into account issues of irradiation or contamination and includes data collection specific to biodosimetry. One such algorithm is the REAC/TS patient treatment algorithm at <https://orise.orau.gov/reacts/infographics/radiation-patient-treatment-algorithm.pdf>. Important patient history includes their location during the incident, duration of the exposure, time interval between exposure and clinical evaluation, occupation of the victim, and whether the patient has had a recent nuclear medicine procedure. Physical examination, in addition to airway, breathing, and circulation, should focus on vital signs, skin (erythema, blisters, desquamation), GI symptoms (abdominal pain and cramping), neurologic findings (ataxia, headache, motor or sensory deficits), and hematologic signs (ecchymoses or petechiae). Vomiting very early after exposure is considered a sign of the central nervous system subsyndrome and is a poor prognostic indicator.

Recommended initial laboratory testing includes baseline complete blood count (CBC) with differential (including an extra sample in a heparinized tube for cytogenetics), serum amylase (increased from specific salivary gland inflammation and degeneration), urinalysis, baseline radiologic assessment of urine, and starting a 24-hour urine collection. Other laboratory tests, if possible, can include blood FLT-3 ligand concentration, blood citrulline, interleukin-6, quantitative granulocyte colony-stimulating factor, and C-reactive protein. Nasal swabs, emesis, and stool should be collected for radiologic monitoring. For patients with persistent vomiting erythema or fever, a repeat CBC with differential is recommended every 4 to 6 hours. If a patient requires surgery, we agree with the Armed Forces Radiobiology Research Institute recommendation that surgery proceed immediately because of the delayed and impaired wound healing associated expected decreases in leukocytes and platelets.

### Decontamination

When a patient is medically stable, decontamination should proceed. Patients who were not decontaminated in the prehospital setting but who

are grossly contaminated should be fairly easily detected as such by a quick evaluation with an appropriate instrument. As a first step, all clothing should be removed gently by cutting and not tearing as is typically done for trauma patients. Rolling supine patients allows contaminated clothes to be carefully gathered and bagged and marked. Bagged clothes and other contaminated articles should be removed from the ED to a site designated by the RSO so as not to present another source of radiation. A portable dosimeter should assist in external decontamination. After clothing removal, remonitor the patient for contamination, paying attention to exposed areas such as hair. Contaminated hair should be washed with soap and water before washing the body to avoid trickle-down contamination. For patients with contaminated wounds, decontamination should prioritize the wound first, then body orifices around the face, and then intact skin. Always wipe gently away from the wound. Irrigate gently to reduce splashing. Care must be taken not to abrade skin by too vigorous scrubbing or shaving of hair. Contaminated nares can be cleared often by having the patient blow his or her nose. Ideally, all irrigating fluids are collected for analysis, but this will be limited by resources and event details. There should be no eating, drinking, or smoking at the scene of decontamination.

For patients with smaller exposures to radionuclides, such as laboratory workers, decontamination is often the only management technique required to limit injury. Portable dosimeters will identify contaminated areas, which should be sealed off to limit spread of exposure, especially if the radionuclide is in gaseous form. As with larger exposures, contaminated clothing must be removed and collected. Contaminated skin must be washed with lukewarm soap and water, repeatedly if needed.

In evaluating an area where a spill of radioactive material has occurred, a judgment must be made regarding the severity of the incident so that appropriate steps are taken. If a major incident has occurred involving large amounts of radioactive material, a large contaminated area, airborne radioactivity, or spread of radiation outside an authorized area, evacuation, notification of the RSO in an institutional setting, and calling local or regional emergency response personnel are recommended. Minor incidents involve small amounts of radioactive material in which the individual knows how to clean the site, has appropriate decontamination material on hand, and can clean the area in a reasonably short time. Several different decontaminating soaps are commercially available from general stores and many scientific suppliers. These soaps come in the form of concentrated detergents, ready-to-use dispensers, or foaming sprays with which a small spill is quickly wiped clean and disposed of in an appropriate container. Most radiation management sources, such as Radiation Emergency Medical Management (REMM) and REAC/TS, recommend a neutral soap or shampoo.

### Medical Decision Making

Exposure to radiation can lead to a complex spectrum of organ damage that can be difficult and confusing for physicians when creating a treatment plan. Establishment of guidance in the form of a *response category* (RC) helps clarify a medical plan and disposition (Table 128-4). After exposure to radiation, quantitative and semiquantitative criteria should be used to describe different degrees of injury to affected organ systems. Combining descriptions of the patient's severity among categories of hematopoietic, cutaneous, GI, and neurovascular subsyndromes allows assignment of a *grade* of injury. For example, a patient with a third-degree cutaneous injury but only first- or second-degree injuries to the other systems would be given an RC grade of 3, giving the cutaneous injury the greatest weighting because its severity would then carry the worst prognosis. This RC grade then suggests a certain level of care whether ambulatory versus inpatient versus intensive care unit, as well as use of specific treatments such as blood transfusion versus colony-stimulating factors (CSFs) versus bone marrow transplantation. (For specific suggestions, refer to the interactive version of this assessment tool at the REMM's website at <http://www.remm.nlm.gov>.) It is essential to remember that after a mass casualty event, response assets from facilities to medications to personnel may be

diminished significantly and that recommendations using this system can and should be modified in accordance with other recommendations concerning crisis standards of care.<sup>5</sup>

### Medical Management

*Supportive care* quality will determine the extent of the morbidity and mortality. The majority of patients with ARS who succumb usually do so from fluid loss, infection, or bleeding. Irradiated patients require treatment for nausea and vomiting, diarrhea, pain, and fluid and electrolyte losses. Vomiting is thought to occur as a result of serotonin release from damaged gut tissue. The 5-HT<sub>3</sub> antagonists, such as ondansetron and granisetron, are the most effective medications to control vomiting. Prolonged antiemetic treatment is usually not necessary because emesis often resolves within 72 hours. Loperamide, anticholinergics, or aluminum hydroxide are reasonable to treat diarrhea. Mild pain should be managed with acetaminophen, but we recommend against the use of aspirin and nonsteroidal drugs because they exacerbate gastric bleeding. An opioid is recommended for the management of more severe pain.

*Probiotics* is the introduction of selective nonpathogenic strains of *Lactobacillus* and *Bifidobacteria* into the GI tract to suppress the number of pathogens. Experimentally, this technique increased survival in canine and rodent models. Probiotics were used to help care for three men exposed at the incident at Chernobyl, whose survival time was prolonged, although it was not statistically significant when compared, respectively, with case controls. Based on the existing data, it would be reasonable to treat patients who develop diarrhea with probiotics.<sup>4,38</sup>

Intravenous access should be established and maintained with care because these patients are prone to infection. If the patient is expected to become neutropenic and experience a long hospitalization, it would be reasonable to establish central venous access or place a peripherally inserted central catheter to minimize the risk of access-associated infection. Fluid replacement begins with crystalloid solution with the goal of replacing GI losses. The infusion rate will be modified by recorded inputs and outputs and assessment of surface area burns.

Prevention of infection includes attention to several aspects of care. Maintain the patient in a clean environment and institute reverse isolation for patients with at least moderate exposure or when neutrophil counts decline below 1,000/microliter. Prophylactic antibiotics and antifungals are recommended to neutropenic patients, as well as acyclovir or a congener for herpes simplex virus positive patients. If neutropenic patients become febrile we recommend following the Infectious Disease Society of America guidelines for antibiotic choices. It is reasonable to administer broad-spectrum prophylactic antibiotic coverage, including anaerobic coverage for patients with burns.<sup>7,10</sup>

Cutaneous injuries are cared for depending on the nature, location, and extent of the wounds. Care ranges from use of lanolin-free water-based moisturizers to topical steroids to debridement to skin grafting. For patients who develop radiation-induced fibrosis, it is reasonable to treat with pentoxifylline. Surgical consultation or referral to a burn center should be offered early in the clinical course.

*Cytokine therapy* (CSFs) use in radiation-exposed patients is based on demonstrated enhancement of neutrophil recovery in patients with cancer, a perceived benefit in a small number of radiation-incident victims, and several prospective trials using different animal models involving radiation exposure. These last studies demonstrated not only neutrophil recovery but also a survival advantage. The best outcomes were demonstrated when started less than 24 hours postradiation suggesting CSFs should be started as soon as possible for patients exposed to a survivable dose of radiation who are at risk for hematopoietic syndrome, that is, more than 3 Gy. Additionally, it is reasonable to administer cytokines to vulnerable patients at extremes of age, that is, those younger than 12 years and older adults who are exposed to lower threshold doses.<sup>10</sup>

*Use of blood products* is required for patients with significant blood loss or for those experiencing radiation-induced aplasia. This latter complication

**TABLE 128-4** Grading System for Organ System Dysfunction and Response Category for Disposition<sup>e</sup>

Symptom	Degree 1	Degree 2	Degree 3	Degree 4
<b>Neurovascular System</b>				
Anorexia	Able to eat	Decreased	Minimal	Parenteral
Nausea	Mild	Moderate	Severe	Excruciating
Vomiting	1/day	2–5/day	6–10/day	> 10/day
Fatigue	Able to work	Impaired	Assisted ADLs	No ADL
Fever	(<38°C)	(38°–40°C)	(>40°C) <24 hours	(>40°C) >24 hours
Headache	Minimal	Moderate	Severe	Excruciating
Hypotension (BP, mm Hg) (Adult)	>100/70	<100/70	<90/60	<80 systolic
Cognitive deficits	Minor	Moderate	Major	Complete
Neurological deficits	Barely detectable	Easily detectable	Prominent	Life threatening
<b>Hematopoietic System (all counts × 10<sup>6</sup>/L)</b>				
Lymphocytes	1.5–3.5	0.5–1.5	0.25–1	0.1–0.25
Granulocytes	4–9	< 1 <sup>a</sup>	< 0.5 <sup>a</sup>	0–0.5
Platelets	150–350	50–100	0–50	Very low <sup>b</sup>
<b>Gastrointestinal System</b>				
Diarrhea				
Frequency (/day)	2–3	4–6	7–9	≥10
Consistency	Bulky	Loose	Loose	Watery
Bleeding	Occult	Intermittent	Persistent	Large, persistent
Abdominal cramps/pain	Minimal	Moderate	Severe	Excruciating
<b>Cutaneous System</b>				
Erythema	Minimal	<10% BSA	10%–40% BSA	>40% BSA
Edema	Asymptomatic	Symptomatic	Secondary dysfunction	Total dysfunction
Blistering	Rare, sterile	Rare, bloody	Bullae, sterile	Bullae, bloody
Desquamation	Absent	Patchy, dry	Patchy, moist	Confluent, moist
Ulceration or necrosis	Epidermal	Dermal	Subcutaneous	Muscle or bone
Hair loss	Absent	Partial	Partial	Complete
<b>Response Category</b>	1	2	3	4
<b>Triage and Monitoring</b>	Ambulatory	Ambulatory vs. Hospitalized	Hospitalized ICU	Hospitalized Specialized hospitals <sup>c</sup>
		Supportive care Blood products	Blood products CSFs	Blood products CSFs or SCT

<sup>a</sup>An abortive rise in cell counts begins between days 5 and 10, which lasts about 8 to 12 days. Afterward, cell counts decline slowly reaching a nadir around day 20. <sup>b</sup>Cell counts decline faster reaching lower nadir for more severe exposures at about days 22, 16, and 10 for grades 2 to 4. <sup>c</sup>“Specialized hospitals” refers to those with experience in all areas of intensive care medicine, particularly allogenic stem cell transplantation (SCT). ADL = activity of daily living; BP = blood pressure; BSA = body surface area; CSF = colony-stimulating factor; ICU = intensive care unit.

usually begins several weeks after exposure, allowing for time to identify potential donors. Use of leukoreduced and (ironically) irradiated blood products should be the rule to prevent transfusion-associated graft-versus-host disease. This hyperacute complication can be further complicated by its similarity to radiation-induced organ injury, including fever, pancytopenia, rash or desquamation, diarrhea, and hyperbilirubinemia.

Stem cell transplantation (SCT) can be used to treat patients with severe bone marrow injury, but the decision to use this therapy is very complicated. Currently, it is believed that with aggressive supportive care and early use of CSFs, patients only suffering from hematopoietic syndrome may survive a radiation dose of 7 to 8 Gy, but doses greater than 10 Gy are likely to be fatal, providing a narrow window of opportunity even if an appropriate match could be found. Stem cell transplantation use must also account for other factors, including the manner in which the exposed dose was estimated and its accuracy; the presence of other radiation syndromes; and whether other potentially significant concurrent organ injuries, such as burns or acute respiratory distress syndrome, are present because they have historically accounted for 70% of radiation deaths.<sup>7</sup> Over the past 70 years, radiation incidents have

generally produced only small numbers of patients requiring intensive care, the only exceptions being Chernobyl and Goiânia, although with the real threat of terrorism, emergency resources could become severely limited in the face of a large mass casualty event. If conditions were favorable and resources were available, it would be reasonable to attempt SCT in patients with a severe radiation exposure who have an otherwise grave prognosis.

### Management of Internal Contamination

Internal contamination is assessed differently from external doses in that they are not measured but rather are calculated. These calculations are performed by a health physicist on samples such as nasal swabs, urine, or stool to estimate how much activity entered the body. Doses are termed *committed doses* defined as the doses received that last more than 50 years because of the internal deposit of the radionuclide. That is, the radionuclide dose is protracted and remains until it decays or is eliminated via normal kinetic processes. These doses are compared with the annual limits on intake (ALIs) provided by the EPA as a benchmark for medical decision making.

Interpretation of committed doses from contaminated wounds requires special conversion factors provided by the NCRP.

Management of internal contamination is isotope dependent. There are more than 8,000 isotopes, making identification of the particular isotope critical. Although both radioactive decay and biologic elimination contribute to an even shorter effective half-life, medical treatment is directed at one of several categories, including reduction of GI absorption, blocking uptake (as with potassium iodide), isotopic dilution (water for tritium), chemical manipulation (sodium bicarbonate for uranium), excision of shrapnel, and chelation. Both NCRP reports No. 65 and No. 161 provide comprehensive information regarding decorporation of radionuclides; however, for the few isotopes of particular concern for industry, the military, and academic and medical centers, potassium iodide and pentetic acid (DTPA) are the most commonly applicable chelators (Antidotes in Depth: A44 and A45).

## PROGNOSIS

The prognosis of those exposed to radiation varies with the amount of the exposure, the type of medical care received, and the number of casualties in a given exposure scenario. Survival is inversely proportional to the radiation dose absorbed. Even relatively radioresistant cell types can be killed by high amounts of radiation. Historically, the mean lethal dose required to kill 50% of humans at 60 days ( $LD_{50/60}$ ) was about 3.5 Gy without supportive care. The addition of antibiotics and blood products increases that mean to 6 to 7 Gy. This dose is likely to be even higher for those treated early with CSFs in a specialized hospital. Coexisting traumatic injuries or burns will decrease the  $LD_{50/60}$ . An acute dose of 20 Gy or more is considered supralethal. Historically, those who were exposed to greater than 10 Gy died despite care including 20 of 21 workers who were exposed anywhere from 6- to 16-Gy at Chernobyl and one worker at Tokaimura who was exposed to 17 Gy and died 3 months postexposure after requiring highly resource and labor-intensive care, including 10 L of fluid daily and extensive transfusion support.

During a catastrophic radiation incident, resources will likely become depleted to the extent that not all patients who require certain medical treatments to survive will be able to receive them. A consistent and transparent method to allocate scarce resources implemented by senior clinicians within their existing legal and ethical constructs should act to maximize the number of patients to survive, the number of life-years saved, and the individuals' chances to live through each of life's stages. The REMM Scarce Resources Triage Tool is available online for assistance in evaluating a patient's prognosis, in which a patient's injury extent may indicate an expectant prognosis assisting clinicians to help those who may survive instead.<sup>5,6,41</sup>

## CONSIDERATION OF THE DECEASED

Contaminated bodies should be placed in a temporary morgue that is refrigerated. Use of the hospital morgue will lead to contamination there. These bodies *should not* be cremated because this will only redistribute the nuclear material, which is not destroyed by fire. Respect should be paid to the religious beliefs of family members of the deceased for whom cremation is the custom. Reconciling these personal and cultural beliefs necessitates extreme skill emphasizing cultural, religious and scientific understanding.

## PREGNANCY AND RADIATION

When exposure to radiation via medical examination is possible, pregnant women and physicians have exhibited great concern over possible injury to fetuses. In general, radiation effects to an embryo or fetus are dependent on its stage of development and the dose received. The medical decision to perform imaging or a diagnostic procedure that exposes any patient to radiation is always based on a risk-to-benefit analysis with a given patient's situation.

In the normal course of events, uncertainty exists regarding the normal viability of the fertilized ovum in which the estimated baseline risks of birth defects and miscarriage at all stages are 3% and 15%, respectively, for women with normal genetic and reproductive histories. Very early in a pregnancy before implantation, the embryo is in an "all-or-none" period of development in which the greatest risk from radiation is miscarriage but not greater than

baseline risk. Older than this, the fetus is next at greatest risk between 8 to 15 weeks of gestation during which major neuronal migration takes place.

The NCRP considers risk to fetuses to be negligible compared with other risks of pregnancy when the dose to a fetus is less than 50 mGy (5 rad), which corresponds to 50 mSv from x-ray examination, compared with about 6 mSv effective dose from a CT examination of the pelvis. The risk of malformation is increased only at doses above 150 mSv. As mentioned earlier, special attention must be paid to pregnant or potentially pregnant patients when deciding if an examination or procedure involving radiation is considered. Effective doses from various examinations and procedures are known to range from 0.1 mSv from posteroanterior and lateral x-ray examination of the chest to 15 mSv from CT angiography of the chest, to 40.7 mSv from cardiac stress test with <sup>201</sup>Tl. The vast majority of routine diagnostic imaging procedures imparts less than 5 mSv to a fetus, increasing baseline risk by about 0.17%, and so is considered to be of negligible risk, but shared decision making should always balance the potential maternal benefit of the radiologic procedure and the potential risk to the fetus.

## PEDIATRICS AND RADIATION

The use of CT scanning in children has markedly increased over the past 30 years. Estimates include data that, commensurate with the 20-fold increase in use of CT scans in the United States, the use of CT for pediatric patients has increased by about eight times. The reasons for this increase are many, including greater availability, greater use as a primary diagnostic tool, and an increased perception that the risk of being wrong about a diagnosis is high.<sup>3,24</sup> Estimates calculate an increased risk of lifetime mortality rate in the range of 0.04% for a head CT for a young female patient (1 in 2,500) compared with a normal lifetime cancer mortality risk of 20% (1 in 5). This excess relative risk was supported by a large retrospective study of a pediatric population that found increased incidence of certain leukemias and certain brain tumors attributed to CT scans over a 23-year period.<sup>2,31</sup>

Although radiation is considered to be a weak carcinogen and radiographic studies should continue to be ordered in the best interest of the patient, it is likely that the number of scans performed could safely be diminished without compromising care. Reports on this topic commonly include problems with ordering unnecessary multiple CTs, follow-up CT scans, and CT scans that occur simply because of a lack of communication among the patient, health care professional, and technician. These problems, compounded by inappropriate CT protocol for pediatric patients, suggest that the medical community could be more proactive in reducing the health risk of those in our charge.

## SUMMARY

- Ionizing radiation injures humans through the disruption of cellular structure and function that can lead to cell death and or mutagenesis.
- Fortunately, large exposures of radiation to the general population are rare outside of the setting of an armed conflict, and most contaminations that occur are small and easily controlled.
- Recognition of the exposure and thorough decontamination are the critical steps to minimizing the potential toxicity of an exposure.
- Prognosis is based on dose which can be estimated on a number of clinical and laboratory grounds.
- Although consequential, neither contamination nor incorporation should take precedence over the highest priorities of emergency care and urgent surgery.

## POTASSIUM IODIDE

Joseph G. Rella

**INTRODUCTION**

Potassium iodide (KI) is the antidote to radioactive iodine that is released into the atmosphere after a nuclear incident. It is approved as a specific competitive inhibitor of thyroid uptake of radioiodine to reduce the risk of thyroid cancer in susceptible populations. The indications for its use are complex, and initiation and maintenance of therapy require great attention to the details of the circumstances of the exposure to limit harm that would result from either under treatment or overtreatment.

**HISTORY**

Following the study of thyroid cancers in Pacific Islanders who were subjected to fallout from nuclear testing, scientists concluded in 1957 that KI could effectively protect the thyroid from radioactive iodine. The National Council on Radiation Protection and Measurements reported in 1977 that the sudden release of radionuclides, including radioiodine, could affect large numbers of people after a nuclear incident (Fig. A44–1). The following year, the US Food and Drug Administration (FDA) requested the production and storage of KI for the purpose of blocking the effects of radioiodine on the thyroid gland when needed. Although the common terms radioiodine and radioactive iodine are used throughout this text, it is important to note that these are almost exclusively iodide salts containing a radioactive iodine atom rather than molecular iodine that is radioactive. These imprecise terms are retained here for consistency with the medical and lay literature.

**PHARMACOLOGY****Chemistry**

Iodine is a chemical element, symbol “I,” atomic number 53. Its name derives from the Greek *iodēs* meaning violet, owing to the violet color of elemental iodine vapor. Similar to other halogens, iodine occurs mainly as a diatomic molecule  $I_2$ . Although it is considered a relatively rare element, it is the heaviest essential element used widely in biologic functions. Of 37 iodine isotopes, only  $^{127}I$  is stable. The term *iodide* refers to the ion  $I^-$ , which forms inorganic compounds with iodine that is in the oxidation state  $-1$ , such as KI.

**Mechanism of Action**

Neonates, children, and adolescents are particularly susceptible to the toxic effects of radioactive iodine. During the rapid developmental periods for these individuals, there is increasing growth of the thyroid gland, as well as an increase in thyroglobulin and iodothyronine stores. Thyroid tissue also accumulates a larger percentage of exogenously ingested iodide and more efficiently reuses iodine from degraded hormone. This increased activity during human development explains the greater risk for developing thyroid cancer in children compared with adults after exposure to radioactive iodine. During pregnancy, the maternal thyroid gland is stimulated and takes up more iodine compared with in other adults, thus increasing susceptibility in pregnant women to the toxic effects of radioiodine.

Exposure to radioactive iodine occurs via inhalation or via ingestion of contaminated food, as occurred following the Chernobyl incident.

Radioiodine is rapidly absorbed from either the digestive or respiratory tracts. After being incorporated into the thyroid gland, radioiodine exposes thyroid tissue to  $\beta$  and  $\gamma$  emissions, potentially leading to genetic alterations and cancer.<sup>3</sup> This is the stochastic effect of radiation (Chap. 128).

Because the chemical properties of radioactive iodine are unchanged from stable iodine, prophylaxis with KI is effective through the means of isotopic dilution. That is, KI competes with radioactive iodine for the active iodide transport system to reduce the concentration of radioiodine in the serum, making the uptake of radioiodine much less likely, essentially blocking it.

**Evacuation and Food Interdiction**

Potassium iodide is not a panacea for radiation exposure. Even if appropriately used during a release of  $^{131}I$ , KI will not protect against direct radiation exposure or against other radioactive elements that are included in fallout (ie, cesium and strontium). Depending on radiation levels, communities will be evacuated from areas surrounding a nuclear power plant experiencing a release of radioactive material. Evacuation is most effective if implemented before the passage of a radioactive plume, but this should be guided by dose estimates provided by public health authorities.

The FDA and World Health Organization (WHO) both recommend food interdiction and food control as the principal means to limit public exposure to contamination. Contaminated food that is subsequently canned will ultimately pose no risk to the population if it is stored for sufficient time to allow the radioactive iodine to decay completely. The WHO considers food control to be preferable to iodine prophylaxis and the removal of milk from the diet of some populations to be unfortunate but acceptable.<sup>5,20</sup>

**Pharmacokinetics**

Dietary iodide is well absorbed from the small intestine under normal conditions. It distributes selectively into the thyroid gland but also to a lesser extent into salivary glands, choroid plexus, and gastric mucosa. Iodine has a volume of distribution of 0.3 L/kg. During pregnancy and lactation, iodide distribution to the mammary glands and ovaries increases.

Iodide that is not concentrated in the thyroid is excreted 80% in urine and 20% in feces, although additional losses via sweat occur and become an important route of loss in warmer climates. Urine iodide concentrations reflect plasma concentrations and have been used for years as a means to assess dietary iodide intake.

**Pharmacodynamics**

Iodine usually in its ionic form iodide ( $I^-$ ), is an essential nutrient present in humans in minute total body amounts of 15 to 25 mg. Iodine is required for the synthesis of the thyroid hormones L-thyroxine ( $T_4$ ) and L-triiodothyronine ( $T_3$ ), which in turn regulate metabolic processes and determine early growth of most organs, especially the brain. Iodide is actively transported with sodium into thyroid follicular cells, in which it is concentrated 20- to 40-fold compared with its serum concentration. It is then transported into

**FIGURE A44–1.** The decay pathway that describes how  $^{131}I$  is derived from nuclear fuel (whether in a bomb or a reactor) and ultimately decays to stable xenon. s = seconds; m = months; d = days. U = uranium; In = indium; Sn = tin; Sb = antimony; Te = tellurium; Xe = xenon; N = neutron.

the follicular lumen, where it iodinates thyroglobulin to form  $T_4$  and  $T_3$  (Chap. 53). Thyroid hormones are metabolized in hepatic and other peripheral tissues (meaning extrathyroid) by sequential deiodination.

## ROLE IN RADIOACTIVE IODINE EXPOSURE

Studies over the past 50 years demonstrate that radioactive iodine uptake is effectively blocked by KI supplementation.<sup>2,9,18</sup> In nuclear radiology, administration of iodide-containing contrast media can deliver up to 45 times the recommended daily intake of free iodide and delay the uptake of therapeutic iodine-131 ( $^{131}\text{I}$ ) for several weeks.<sup>10,11</sup> Chernobyl remains the largest experience of KI distribution after a release of radioactive material from a nuclear incident from which data and recommendations are derived. After the incident at Chernobyl, the Polish government distributed nearly 18 million doses of KI to the people in its most affected provinces (in addition to food interdiction), but none was distributed to affected areas of Ukraine and Belarus. Studies of these differently treated populations that were exposed to the radioactive plume clearly demonstrated not only a dose–response relationship between radiation dose and the relative risk of thyroid cancer, but also a threefold reduction of this risk through use of KI supplementation.<sup>3,13</sup> Although some controversy exists regarding increased numbers of detected thyroid cancers possibly because of improved screening, other studies demonstrated the actual increased incidence of these tumors and distinguished radiation-induced cancers from sporadic papillary cancers using genetic analysis.<sup>1,6,7,14</sup>

After the Fukushima incident, the Japanese government gave orders to distribute KI at evacuation sites, but this postexposure prophylaxis did not occur.<sup>15</sup> Data on the aftermath of this event continue to be gathered, but as of 2014, there were no confirmed deleterious effects on the thyroid function of children and adolescents from the emitted radioactivity.<sup>19</sup>

## ADVERSE EFFECTS AND SAFETY ISSUES

### Thyroidal Effects

Extensive experience with treating goiter and the use of nutritional supplements in the form of iodized salt demonstrates that both hyper- and hypothyroidism result from supplementation with KI.<sup>12</sup> Specifically, treatment with KI is linked to occasional hyperthyroidism, and iodized salt programs are associated with subsequent hypothyroidism and thyroid autoimmunity. Both the prevalence of goiter and subclinical hypothyroidism increase when iodine intake is chronically high. The Wolff-Chaikoff effect, in which high concentrations of iodine inhibit the synthesis of thyroid hormones, is a grave insult to fetal neurologic development in pregnant women treated with KI, which is why we agree with both the FDA and WHO advice against repeat dosing of KI for pregnant women, if possible.<sup>5,20</sup>

A large study in Poland after the Chernobyl incident investigated the risks and benefits of KI prophylaxis. Of the thousands of men, women, and children who were studied, the vast majority of whom received a single dose of KI, no statistical differences were found between treated and untreated groups when thyroid-stimulating hormone (TSH) concentrations were measured among all populations. Additionally, among adults with thyroid disease, no cases of thyrotoxicosis or exacerbation of preexisting thyroid conditions were found. Although pregnant women were not mentioned *per se*, children born in 1986 and examined in the second and third years of life showed no difference in thyroid status compared with those born after radioiodine had disappeared from the environment. In newborns, 12 of 3,214 treated on the second day of life showed transient decreases in serum free  $T_4$  but had no clinical sequelae.<sup>12</sup> Another systematic review of studies reporting adverse effects of iodine used for thyroid blocking, which also did not mention pregnant women, concluded that KI supplementation seemed not to induce severe adverse effects but that scientifically sound studies of this subject are scarce and provide only weak evidence.<sup>17</sup>

### Extrathyroidal Effects

Many extrathyroidal effects of KI are described. Sialadenitis, or “iodide mumps,” is an inflammation of the salivary glands and appears to be unpredictable. Iododerma is a rare and reversible acneiform eruption related to iodine

ingestion that may result from nonspecific immune stimulation which is similar to bromoderma (Chap. 17).<sup>16</sup> Other reactions reported in association with KI use include gastrointestinal disturbances, fever, and shortness of breath.

Although some reports use imprecise definitions when attributing adverse effects to iodine or iodide-containing medications, “allergy” refers to a specific immune response to target proteins via an immunoglobulin E (IgE) triggered release of cell mediators, such as histamine. There are no studies that demonstrate IgE antibodies to small molecules such as iodine or iodide.

“Allergy” to radiocontrast media is actually an anaphylactoid response to the high osmolarity of these xenobiotics. Anaphylactoid responses manifest by release of similar mediators to anaphylactic response but via non-IgE-mediated pathways. An anaphylactoid response to iodine-containing medications or iodinated contrast materials is predictable in patients with asthma, allergic rhinitis, and food allergies to chocolate, eggs, and milk. Although seafood contains iodide, allergy to fish or shellfish is caused by specific marine proteins and not sensitivity to iodide. Patients manifesting allergic contact dermatitis resulting from iodine-containing cleaning preparations such as povidone–iodine do not react to patch testing with KI. Therefore, when physicians consider the safety of KI dosing in the event of radioactive iodine exposure, reactions to radiocontrast media, seafood, and povidone–iodine should not be interpreted as an allergy to KI. Physicians must also consider that there are inactive ingredients or diluents of the KI formulation as they interpret potential adverse reactions their patients may manifest in response to KI administration.

## PREGNANCY AND LACTATION

Potassium iodide is listed in Pregnancy Category D and readily crosses the placenta and distributes into milk. Both the FDA and WHO support the use of KI for pregnant women when the risk is declared substantial by public health authorities.<sup>5,20</sup>

## DOSING AND ADMINISTRATION

Based on data from Chernobyl regarding estimated doses and cancer risks in exposed children, the WHO in 1999 and the FDA in 2001 provided recommendations for KI supplementation for various populations, depending on their relative risks (Table A44–1).<sup>5,20</sup> These recommendations remain current and are supported in the text.

Adults older than 40 years of age face a near-zero risk of developing thyroid cancer from exposure to radioactive iodine. For this group, the complications from iodide supplementation, such as goiter or Graves’ disease, would likely outweigh any benefit in the setting of relatively mild exposure. However, if public health experts determine that exposure dose is 5 Gy (500 rad) or greater, which is only likely to occur for those living within a 10-mile radius of a nuclear power plant release, KI is recommended.

Adults 18 to 40 years of age are at risk of developing thyroid cancer that is approximately equal to the risks of side effects of a single dose of iodide supplementation, although it should be understood that both risks are very small. The decision to treat should be based on the threshold criteria used as well as the risks of iodide supplementation, such as iodide reactions, or a history of past thyroid disease.

Lactating mothers should take KI when instructed to do so by public health authorities. Potassium iodide is secreted in breast milk and will offer some protection to a neonate, but the risks of treatment are much higher in these patients, requiring greater attention to monitoring, as discussed later.

Pregnant women have increased thyroid uptake of iodide, especially in the first trimester, compared with other adults. Developing fetuses have increased iodide uptake during the second and third trimesters. Because iodide crosses the placenta, fetuses will be exposed to radioactive iodine; thus, supplementation with KI is only recommended at appropriate exposure thresholds.

Children 1 month to 18 years of age are at high risk of thyroid cancer from exposure to radioactive iodine and are at low risk of side effects from supplementation with KI. Therefore, supplementation for children in this age group should begin promptly after official notification of a potential radioactive iodine release.

TABLE A44-1 Threshold Radiation Exposure Doses and Recommended KI Doses for Different Risk Groups

	Predicted Thyroid Exposure (Gy, rad)		KI Dose (mg)	No of 130-mg Tablets	Milliliters of Oral Solution, 65 mg/mL
	Gy	rad			
Adults >40 yr	≥5	≥500	130	1	2
Adults 18–40 yr	≥0.1	≥10	130	1	2
Pregnant or lactating women	≥0.05	≥5	130	1	2
Children and adolescents 3–18 yr	≥0.05	≥5	65	1/2 <sup>a</sup>	1
Children 1 mo to 3 yr	≥0.05	≥5	32	Use KI oral solution <sup>b</sup>	0.5
Birth to 1 mo	≥0.05	≥5	16	Use KI oral solution <sup>b</sup>	0.25

<sup>a</sup>Adolescents approaching adult size (70 kg) should receive a full dose of 130 mg. <sup>b</sup>For smaller, more precise dosing, a potassium iodide (KI) oral solution is available with a dropper marked for 1-mL, 0.5-mL, and 0.25-mL dosing.

Modified with permission from Food and Drug Administration. Guidance. Potassium Iodide as a Thyroid Blocking Agent in Radiation Emergencies. <http://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/ucm080542.pdf>.

Neonates are at significantly increased risk from exposure to radioactive iodine because of a marked increase in uptake of iodide resulting from neonatal body cooling in the immediate postdelivery period. At the same time, neonates are susceptible to functional blocking by overloading with stable iodide. Therefore, when supplementation is indicated, KI should promptly be given to neonates with critical attention to dosing. The WHO recommends the KI solution be available for maternity wards in the precise dosing for newborns. Because the most critical time period for thyroid blockage is within the first postpartum week, dosing neonates who are older than 1 week should be performed at home by dividing, crushing, or suspending tablets in milk, formula, or water.

### Timing of Administration

For full blocking effect, KI should be administered shortly before exposure or as soon as possible afterward. Some models describe the blockade of only 50% of iodide uptake when there is a delay of several hours after an exposure. Depending on the duration and type of risk, administration of KI months after an exposure may also partially reduce thyroid cancer risk.<sup>8,20</sup>

### Daily versus Single Dosing

The protective effect of KI lasts for about 24 hours, so it should be dosed daily depending on the dosing estimates for exposure in children aged 1 month to 18 years in whom an ongoing risk is perceived. Groups in whom a single dose is recommended include pregnant women and neonates, in whom there is a significant risk of causing harm to the fetus related to impaired cognitive development. For lactating women, stable iodide will be delivered to the nursing newborn and may cause functional blocking of iodide uptake by an overload of iodine. Therefore, the FDA recommends that lactating mothers not receive repeated doses except during continuing, severe contamination, which would generally be defined by health officials.

As mentioned previously, Chernobyl is the most significant massive release of radioiodine in history and nearly all human experience and recommendations for this type of exposure derive from this one event. Although distribution of radioiodine was uneven in Poland, the air concentration of radioiodine had decreased fourfold 1 week after the first explosion. Therefore, KI prophylaxis was not repeated. It is perhaps based on this experience that it is generally thought that no more than one or two doses of KI would be needed after release of a single radioactive plume, during which other protective measures such as food interdiction or sheltering measures are implemented. Although the possibility exists that many repeated releases of radioactive gas might require prolonged prophylaxis, repeat dosing for days to weeks will usually be unnecessary.

### Monitoring

Normal thyroid function is critical for proper brain development in a fetus. Just as a fetus and newborn is susceptible to radioiodine uptake, they are also

at risk for development of hypothyroidism from repeat dosing of KI. All neonates who are treated with KI in the first weeks of life should be monitored for changes in TSH, and total T<sub>3</sub> free T<sub>4</sub>. Likewise, when a lactating mother requires repeat doses of KI, the nursing infant should also be monitored for the development of hypothyroidism.

## FORMULATION AND ACQUISITION

Several manufacturers formulate KI and market them as nonprescription, FDA-approved products with a shelf life of 7 years. Longevity studies over many years demonstrate that the active ingredients of KI are very stable. Recognizing that many state and local governments maintain stockpiles of KI for use in the event of a radiation emergency (KI is also a critical part of the US Strategic National Stockpile), the FDA developed guidelines that manufacturers may use to extend the shelf lives of their products in increments of 2 years.<sup>4</sup> Tablets are available in both 130-mg and 65-mg doses, as well as an oral solution in a concentration of 65 mg/mL. Iodide-containing products *not* considered useful as radioiodine protective treatments include iodized salt, seaweed, and tincture of iodine.

## SUMMARY

- Potassium iodide is a safe and effective means of blocking the uptake of <sup>131</sup>I after a nuclear catastrophe.
- Firm reliance on the evaluation of health officials of the risk of exposure is vital because the overall likelihood of exposure to the critical radiation threshold is very low, except for those living within 10 miles of a nuclear reactor.
- Exposed persons should strictly adhere to dosing guidelines to minimize the potential risks of KI dosing, especially in pregnant women and newborn children.
- “Iodine allergy” is not a contraindication to KI administration in the setting of a confirmed release of radioactive iodine.
- Food interdiction and environmental evacuation or avoidance of the radioactive plume are preferable to KI prophylaxis in the event of a potential exposure and may obviate the need for KI completely.

# PENTETIC ACID OR PENTETATE (ZINC OR CALCIUM) TRISODIUM (DTPA)

Joseph G. Rella

## INTRODUCTION

Pentetate zinc trisodium and pentetate calcium trisodium (zinc or calcium diethylenetriaminepentaacetate; Zn-DTPA and Ca-DTPA, respectively) are chelators for certain heavy metals and radionuclides. They are recommended for the treatment of internal contamination with plutonium (Pu), americium (Am), and curium (Cm) that occurs after unintentional exposure to these metals or after exposure resulting from a radiation dispersal device or “dirty bomb.”

## HISTORY

First synthesized in 1954, these chelators were used as investigational therapies to enhance elimination of transuranic elements.<sup>3</sup> Diethylenetriaminepentaacetate is also used for the extraction of metals from soil and as a treatment for iron overload and lead toxicity.<sup>2,9,23</sup> Diethylenetriaminepentaacetate and its derivatives are additionally used to aid with imaging and diagnostics and more recently in chemotherapeutics. Over the past decades, hundreds of human exposures to radionuclides as well as numerous animal studies helped to define the best practices for the use of these chelators, culminating in their approval by the US Food and Drug Administration (FDA) in 2004.

## PHARMACOLOGY

### Chemistry

Pentetic acid is a synthetic polyaminopolycarboxylic acid with a molecular weight of 393 Da. The calcium trisodium salt weighs 497 Da, and the zinc trisodium salt weighs 522 Da. Pentetic acid is water soluble and bonds stoichiometrically with a central metal ion through the formal donation of one or more of its electrons.

### Related Xenobiotics

Several xenobiotics are used in clinical practice to chelate metals. Among these are deferoxamine, dimercaprol (British anti-Lewisite), dimercaptopropane sulfonate, edetate calcium disodium (ethylenediaminetetraacetic acid), penicillamine, Prussian blue, succimer (dimercaptosuccinic acid), and trientine hydrochloride. However, none of these are effective chelators for transuranic metals (elements with atomic numbers greater than 92).

Diethylenetriaminepentaacetate is used to transport gadolinium contrast in magnetic resonance imaging and technetium in nuclear medicine imaging. Other xenobiotics modify the DTPA molecule in conjunction with a monoclonal antibody directed toward specific antigens found on neoplasms, allowing an attached isotope, such as <sup>111</sup>In, to deliver site-directed radiation treatment. These related xenobiotics include tiuxetan, pentetide, and pentetreotide.<sup>18</sup>

### Mechanism of Action

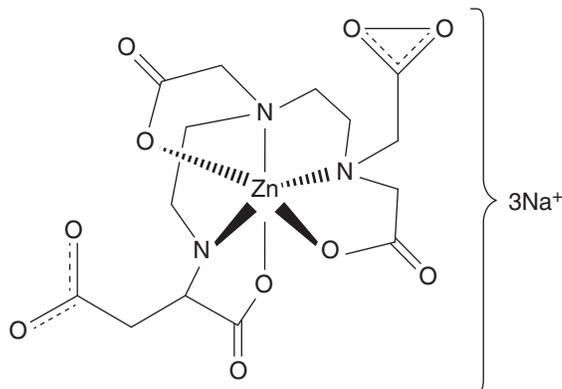

The conjugate base of pentetic acid has a high affinity for metal cations. Pentetic acid wraps itself around the metal forming up to eight bonds, exchanging its calcium or zinc ions for a metal with greater binding capacity (Fig. A45-1). Remaining water soluble, the chelated complex is then excreted by glomerular filtration into the urine. Diethylenetriaminepentaacetate has specific stability constants for the various elements that it chelates, which presumably explains the different binding efficacies of the calcium and zinc salts.

## Pharmacokinetics

Diethylenetriaminepentaacetate is rapidly absorbed via intramuscular, intraperitoneal, and intravenous (IV) routes, but animal studies indicate that DTPA is poorly (< 5%) absorbed by the gastrointestinal (GI) tract. Absorption via the lungs approximates 20% to 30%. Its volume of distribution is small (0.14 L/kg in humans), and it is distributed mainly throughout the extracellular space, although recent data describe a small intracellular activity, particularly in hepatocytes, that explains continued efficacy of delayed protracted treatment. Although some plutonium and americium that is internalized into osteoclasts, bone marrow macrophages, or is still associated with the bone surface is available for chelation by DTPA, that which has been incorporated into the bony mineral matrix is not available for chelation.<sup>7</sup> The plasma half-life is 20 to 60 minutes, although a small fraction is bound to plasma proteins with a half-life of more than 20 hours. Diethylenetriaminepentaacetate undergoes minimal, if any, metabolism. Only a minimal release of acetate is demonstrable, and splitting of ethylene groups has not been detected. Elimination is via glomerular filtration, with more than 95% excreted within 12 hours, and 99% by 24 hours. Although there are no specific data regarding dosing or clearance changes when chelating patients with kidney disease, individuals with kidney disease who receive <sup>99m</sup>Tc-DTPA or Gd-DTPA for imaging purposes demonstrate an increased elimination rate of these chelates with hemodialysis. This suggests that hemodialysis might augment transuranic chelate elimination in contaminated patients with kidney disease, and it would be reasonable to use hemodialysis for these patients.<sup>13,24</sup> Fecal excretion is less than 3%.

## Pharmacodynamics

Diethylenetriaminepentaacetate increases the urinary elimination rate of certain chelated metals. Animal data show that when treatment is begun within 1 hour of internal contamination, Ca-DTPA resulted in 10-fold greater rate of urinary elimination of plutonium compared with Zn-DTPA. The greatest chelating capacity occurred immediately and for the first 24 hours after contamination while the metal was still circulating and available for chelation. After the initial dose of Ca-DTPA, similar rates of elimination of radionuclide resulted from subsequent treatment with either Ca-DTPA or Zn-DTPA, although continued treatment with Ca-DTPA was associated with

**FIGURE A45-1.** Trisodium zinc diethylenetriaminepentaacetate, in which a transuranic element (Am, Pu, Cm) is substituted for Zn forming a stable chelate.

much greater toxicity, as described in the later discussion of adverse effects. Animal studies showed that inhalational Ca-DTPA followed by a month-long regimen of Zn-DTPA reduced lung deposits of aerosolized plutonium to 2% of that compared with untreated animals.<sup>19</sup>

## ROLE IN RADIONUCLIDE CONTAMINATION

Diethylenetriaminepentaacetate is recommended and FDA approved for suspected contamination via inhalation, dermal, or wound exposure from plutonium, americium, and curium, with the goal of mitigating radionuclide incorporation and local tissue irradiation. For inhaled metals, such as might be experienced after an explosion, treatment with nebulized DTPA is recommended. Depending on the chemistry of the metal (eg, uranium concentrates in renal tissue), this irradiation could possibly lead to development of a malignancy later in life. Chelation is reasonable to increase elimination of the radionuclide and decrease cancer risk, although this risk reduction has only been demonstrated in animals. Increased urinary excretion of transuranic elements is a clinically meaningful endpoint for efficacy of DTPA. We recommend against chelation after ingestion of americium, curium, or plutonium, because increased GI absorption will result.

A report published by the Radiation Emergency Assistance Center/Training Site (REAC/TS) reviewed data from 685 transuranic element exposures, most of which were plutonium, curium, and americium. Most of these exposures (63.5%) were by inhalation, typically a breach of a confined area where workers access the radioactive material via arm-length gloves reaching into a protective box. Ages of the exposed ranged from 10 to 64 years of age. From the 18 patients with the most complete urine bioassay data, the average increase in urine elimination of radionuclide was 39 times the baseline rate after the first dose of DTPA.<sup>19</sup> Although older studies using bone ash showed DTPA ineffective at chelating Pu and Am deposited in bone, *in vivo* rat studies show reduced retention of actinides possibly by chelating Pu/Am bound to tissue surfaces, but that this is a very small fraction.<sup>7,8</sup> Historical data concerning contaminated workers at nuclear materials production facilities, which included those who received both prolonged and delayed treatments, demonstrated greatly increased urinary excretion of radioactive material.<sup>1,10-12,20,22</sup>

Although data are limited, we agree with REAC/TS recommendation of DTPA for chelating berkelium, californium, cobalt, einsteinium, europium, indium, iridium, manganese, niobium, promethium, ruthenium, scandium, thorium, and yttrium. Pentetic acid salts are not effective in removing antimony, beryllium, bismuth, gallium, lead, mercury, neptunium, platinum, or uranium. Several reports of workers with wounds contaminated by Pu or Am support the practice of surgical decontamination via debridement to decrease absorption of radioactive material. For patients with a discrete wound in which a radioactive fragment is suspected, surgical removal is recommended in addition to chelation therapy.<sup>1,21</sup>

Diethylenetriaminepentaacetate is neither recommended nor approved for treating patients contaminated with uranium or neptunium for several reasons. Diethylenetriaminepentaacetate mobilizes uranium from tissue stores but does not increase urinary elimination.<sup>5,15</sup> Chelating incorporated neptunium is problematic because it forms extremely stable complexes with transferrin, making it very difficult to decorporate.<sup>6,14</sup>

## ADVERSE EFFECTS AND SAFETY ISSUES

A review of the clinical data by REAC/TS reported the deaths of three patients with severe hemochromatosis who were treated with up to 4 g of Ca-DTPA per day. Three other patients experienced severe symptoms with similar dosing, including obtundation and lethargy, oral mucosal ulceration, stomatitis, dermatitis, and loss of lower extremity sensation. These reactions resolved upon cessation of Ca-DTPA administration. Injury was attributed to zinc depletion–induced impaired DNA synthesis in organs with rapid cell turnover.<sup>19</sup> Caution is advised when treating individuals with severe hemochromatosis.

No serious toxicity is reported among humans after more than 4,500 Ca-DTPA administrations at recommended doses.<sup>3</sup> Reported adverse reactions include nausea, vomiting, diarrhea, chills, fever, pruritus, and muscle

cramps. Transient anosmia was observed in one individual after repeated treatments with Ca-DTPA, also possibly related to zinc depletion, although the specific mechanisms for these adverse reactions remain undefined.

Mice administered 60 times the recommended dose of Ca-DTPA developed severe injuries to kidneys, liver, and the intestines, and deaths occurred.<sup>5</sup> Toxicity was correlated to the total dose and dosing schedule. Fractionated doses increased the mortality rate compared with similar doses given as a single injection. The injuries were believed to result from significant depletion of zinc (Zn) and manganese (Mn) because the same toxicity did not occur when Zn-DTPA was given at the same dose and schedule. These mice data were interpreted to suggest that Zn-DTPA is approximately 30-fold less toxic than Ca-DTPA. Acutely lethal doses of Zn-DTPA were estimated to be 10 g/kg in adult male mice.

## Safety

Because of the renal excretion of the radioactive chelate, the kidneys are exposed to potentially higher doses of radiation than other organs, which theoretically increases the risk of malignancy. Additionally, because urine is radioactive during chelation, there are recommendations to use toilets instead of urinals and to flush several times. Any spilled urine or feces should be cleaned promptly and completely, accompanied by thorough hand washing. Patients being chelated should take special care to dispose of any expectorant or breast milk carefully. After nebulization treatments, patients should be cautioned not to swallow any expectorant.

Radiologically contaminated patients do not generally pose a danger to health care personnel. Universal precautions, including a gown, a mask, gloves, a head cover, and booties, effectively protect workers from contaminated material. Urine, feces, blood, expectorant, and breast milk should be collected and disposed of in a safe manner as arranged by health care providers so as not to become a secondary source of contamination. Ambulances, operating rooms, and dialysis machines may become contaminated after providing care to contaminated patients and should be evaluated for decontamination before providing care for the next patient.

## DOSING AND ADMINISTRATION

If the contamination route is mixed or unknown, then intravenous Ca-DTPA is recommended. The IV dose of Ca-DTPA is 1 g in adults and 14 mg/kg up to the adult dose as a maximum in children younger than 12 years, administered either undiluted over 3 to 4 minutes, or diluted in 100 to 250 mL D<sub>5</sub>W, Ringers lactate, or 0.9% sodium chloride administered over 30 minutes. On the basis of animal studies, it should not be given more slowly.<sup>4</sup> Maintaining normal volume status and frequent voiding should be encouraged to dilute the radioactive chelate and minimize exposure to the bladder. If contamination was solely by inhalation, then we recommend diluting Zn-DTPA 1:1 with sterile water or 0.9% sodium chloride and administering via nebulization.<sup>17</sup>

Although Ca-DTPA is recommended as the initial chelator, Zn-DTPA should be used after the first 24 hours. Animal studies show a 10-fold increased rate of elimination of Pu with Ca-DTPA compared with Zn-DTPA and trace metals, such as zinc, will be severely depleted by continued treatment with Ca-DTPA. After the first 24 hours, Zn-DTPA given daily at the same dose is recommended for continuing therapy because of its sparing effects on the depletion of trace metals and the absence of subsequent liver, kidney, and intestinal injury.

## Timing of Administration and Duration of Therapy

Administration of DTPA should be initiated as soon as possible, preferably within the first hour after contamination and is most effective within the first 24 hours, but remains effective as long as radiocontaminants persist and prior to this sequestration in bone and liver.<sup>16</sup> Historically, about 55% of all patients treated with DTPA received only one dose. The decision to continue therapy should be based on radioassay data. This assessment should include collection of 24-hour urine samples, whole-body or chest counting, and close consultation with the hospital radiation safety officer. Assistance is also available from REAC/TS at 865-576-1005; ask for REAC/TS. Current recommendations are to continue chelation until the deposition of contaminant

is less than 5% of the maximum permissible body burden for each specific contaminant.<sup>3</sup>

If continued therapy is indicated, a regimen of Zn-DTPA is recommended on the subsequent day. Dosing regimens include Zn-DTPA 1 g intravenously daily up to 5 days per week for the first week. If subsequent chelation therapy is indicated, a twice-a-week regimen is recommended until the excretion rate of the contaminant does not increase with Zn-DTPA administration.<sup>16,17</sup> Continued treatment must be coordinated with a radiation safety officer. For all patients, data regarding vital signs, adverse effects, and bioassay studies should be reported to the drug manufacturer and to REAC/TS.

### Monitoring

A complete blood count with differential, blood urea nitrogen, serum electrolytes, and urinalysis, as well as blood and urine radioassays should be obtained before initiating treatment. Daily zinc, manganese, and magnesium monitoring should occur as well as supplementation with zinc. During treatment, repeated blood, urine, and fecal radioassays should be used to monitor elimination.

### Patients with Chronic Kidney Disease

Although dose adjustment is currently recommended for patients with chronic kidney disease, kidney disease will impair chelator-ion complex elimination from the body. Hemodialysis is reasonable to increase the rate of chelator elimination in these patients. Because dialyzed radionuclides will contaminate dialysis fluid, care must be exercised during the procedure as well as while discarding fluid and preparing the machine for subsequent patient use. Consultation with the radiation safety officer (RSO) is recommended to assist with discarding waste material, as well as with the overall chelation treatment of the contaminated patient.

### PREGNANCY AND LACTATION

Calcium-DTPA is listed as FDA Pregnancy Category C based on animal data. Mouse studies involving doses up to 10 times the recommended dose for Ca-DTPA did not produce harmful effects, but doses of greater than 20 times the recommended dose produced teratogenicity and fetal death. Zinc-DTPA is listed as FDA Pregnancy Category B, also based on mouse data. Doses up to 31 times the recommended dose did not impair fertility or harm to fetuses. There are no human pregnancy outcome data from which to draw conclusions regarding the risk of DTPA. Contaminated pregnant women should begin any treatment with Zn-DTPA as opposed to Ca-DTPA because of perceived risks of the latter chelator for adverse reproductive outcome. However, pregnant women with severe internal contamination in which the risk to the mother and fetus is considered to be high, that is, greater than an expected dose of 200 mSv, it would be reasonable to give Ca-DTPA for a first dose in conjunction with mineral supplements that contain zinc. These chelators do not cross the placental barrier.

There are no studies regarding DTPA excretion in breast milk. However, radiocontaminants are excreted in breast milk. Thus, women with known or suspected contamination should not breastfeed until contamination risk is reduced. Likewise, there are no data regarding safety in lactating women, and data regarding the use in children are extrapolated.

### FORMULATION AND ACQUISITION

Diethylenetriaminepentaacetate is available as Ca-DTPA or Zn-DTPA as a sterile solution in 5-mL ampules containing 200 mg/mL (1 g per ampule) for IV use. It should be stored in a cool, dry place with an ambient temperature of between 59°F (15°C) and 86°F (30°C) away from sunlight. Several manufacturers formulate DTPA for IV administration. Five-mL ampules are available singly and in 10 packs. Both chelators are maintained in the US Strategic National Stockpile.

### SUMMARY

- Diethylenetriaminepentaacetate is a safe and effective means of chelating americium, curium, and plutonium in a contaminated patient.
- Rapid consultation with a radiation safety officer is recommended to determine the type and degree of contamination, as well as the need for and duration of any treatment.
- In most cases, Ca-DTPA should be started as soon as possible after a contamination, followed by the use of Zn-DTPA if continued treatment is needed.
- Regular monitoring and supplementation of zinc, magnesium, and manganese during therapy is recommended, although the risk of clinically significant depletion is low at therapeutic doses.
- Hemodialysis can increase renal elimination when chelating contaminated patients with kidney disease, although specific data for this use are limited.

## POISON PREVENTION AND EDUCATION

Lauren Schwartz

Unintentional poisonings are a global health concern. Pesticides, kerosene, household chemicals, and carbon monoxide are common sources of fatal poisonings.<sup>90</sup> According to the World Health Organization (WHO) International Programme on Chemical Safety: Poison Prevention and Management, in 2012, approximately 193,460 people died worldwide from unintentional poisoning, 84% occurring in low- and middle-income countries. Nearly 1 million people die each year as a result of suicide. Approximately 370,000 deaths result from the deliberate ingestion of pesticides. In addition, an estimated 5 million snakebites occur annually, resulting in at least 100,000 deaths. As of June 2016, only 45% of WHO member states had a poison control center (PCC).

Systematic reviews and meta-analysis conducted of poison prevention studies report that poison prevention interventions improve practices. Interventions that distribute home safety equipment along with education are recommended. However, there is a lack of program outcomes demonstrating a reduction of childhood poisoning rates.<sup>1,37,91</sup> This chapter focuses on programs in the United States that aim to prevent unintentional poisonings and improve access to PCC services.

*Healthy People 2020* is a US federal program that outlines the health goals for the nation. These overarching goals are to attain high-quality, longer lives; achieve health equity and eliminate disparities; and create social and physical environments that promote good health and quality of life, healthy development, and healthy behavior across all life stages. Two objectives in the Injury and Violence Prevention section relate to poison prevention. Objective IVP-9 is to reduce poisoning deaths, and Objective IVP-10 is to reduce nonfatal poisonings.<sup>28</sup> Community-based public education programs at PCCs are designed to help meet these public health objectives.

### LEGISLATION AND POISON PREVENTION

Since the first PCC was established in 1953, a number of legislative efforts have improved poison prevention and awareness and reduced the number of unintentional poisonings in children. Public education programs at PCCs have been influenced by these federal measures.<sup>80</sup>

#### National Poison Prevention Week

In 1961, President Kennedy signed Public Law 87-319, designating the third full week of March as National Poison Prevention Week (PPW) to raise awareness of the dangers of unintentional poisonings. Each year, during PPW, PCCs and other organizations across the country create events and activities to promote poison prevention.

#### Child-Resistant Packaging Act

In 1970, the Poison Prevention Packaging Act was passed. This law requires that the Consumer Product Safety Commission mandate the use of child-resistant containers for toxic household xenobiotics. In 1974, oral prescription medications were included in this requirement. A review of mortality data in children younger than 5 years of age showed a significant decrease in deaths after enactment of the child-resistant packaging legislation.<sup>69,80,86</sup>

#### Taste-Aversive Xenobiotics and Poison Prevention

Nontoxic taste-aversive xenobiotics are frequently added to products such as shampoos, cosmetics, cleaning products, automotive products, and rubbing

alcohol to discourage ingestion.<sup>27</sup> This approach is used primarily to prevent poisoning in children, although in the case of rubbing alcohol, adults are also targeted. The most common taste-aversive xenobiotics are the denatonium salts, particularly denatonium benzoate (Bitrex, benzyldiethyl [(2,6-xylylcarbamoyl) methyl] ammonium benzoate), one of the most bitter-tasting xenobiotics known. The bitter taste of denatonium benzoate can be detected at 50 parts per billion (ppb). This aversive xenobiotic is used in concentrations of 6 to 50 parts per million (ppm), typically 6 ppm in cosmetic products and ethanol-containing household products and 30 to 50 ppm in methanol and ethylene glycol.<sup>962</sup> Only limited data are available on the usefulness of taste-aversive xenobiotics for prevention of poisoning. Studies using denatonium benzoate added to liquid detergent and orange juice demonstrate that it can decrease the amount ingested by children.<sup>7,76</sup> However, the degree of taste aversion is not universal. In one study, some children were noted to take more than one sip of denatonium benzoate-containing orange juice.<sup>76</sup> Taste aversion is partially a learned response. Frequently, young children do not find a bitter taste as offensive as do adults.<sup>8</sup> It seems unlikely that taste-aversive xenobiotics will eliminate unintentional ingestions in children because ingestion is required for aversive effects to occur. Taste-aversive xenobiotics are theoretically most beneficial in the prevention of poisoning by toxic and nonaversive xenobiotics, such as ethylene glycol, methanol, paraquat, certain pesticides, acetonitrile, and bromate-containing cosmetics, with which more than one or two sips of the product if ingested can cause significant toxicity. In 1995, in its 1995 Toxic Household Products statute, Oregon became the first state to mandate the addition of an aversive xenobiotic to ethylene glycol- and methanol-containing car products. Unfortunately, analysis of ethylene glycol and methanol exposures before and after the mandate could not demonstrate any difference in children younger than 6 years of age with regard to incidence or severity.<sup>58</sup> Taste-aversive xenobiotics should therefore not be substitutes for other poison prevention modalities.

#### Toll-Free Access to Poison Control Centers

In 2000, the Poison Control Center Enhancement and Awareness Act (PL 106-174) legislated the goal of nationwide access to PCCs. A toll-free number (800-222-1222) was established in 2001 for all US PCCs.<sup>88</sup> Callers are connected to a regional PCC based on the area code and telephone number exchange. **Figure 129-1** displays the national logo incorporated into educational efforts.

#### ROLE OF PUBLIC EDUCATORS IN POISON CONTROL CENTERS

Public educators in PCCs encompass a range of educational backgrounds, including nurses, physicians, pharmacists, health educators, and teachers. The role of PCC public educators is based on social marketing concepts and encompasses two objectives: health promotion to change behavior and marketing of the PCC.<sup>78</sup> Poison control center public education programs teach poison prevention techniques (primary prevention) and raise awareness about available services in case a poisoning occurs (secondary prevention). Education programs use primary or secondary prevention messages or a combination of both. Primary prevention strategies focus on ways to reduce the risk of exposure. Secondary prevention aims to reduce the effect of an exposure through advice of the PCC.<sup>5,30,39,47</sup> Poison control center public

FIGURE 129-1. National toll-free number logo.

educators also provide a range of community-based programs ranging from workshops and health fairs to the production of print materials, videos or DVDs, and awareness campaigns through public service advertising using radio, television, print, and mass transit venues. Social media in health promotion offers an opportunity to further expand the dissemination of health information to diverse audiences through enhanced communication.<sup>56</sup> Poison control center public educators also participate in community health coalitions, working in conjunction with other injury prevention groups such as National Safe Kids, and collaborate with a wide range of community health agencies, substance abuse providers, and others. Caregivers of children younger than age 6 years are often the most important group to reach with education programs. To reach this group, PCC public educators typically work with national programs for families, including Women, Infant and Children (WIC); Head Start; and the Red Cross.

By contrast, individuals older than 65 years of age have not been a priority population for PCC education resources. However, this group is associated with a large number of fatalities reported nationally to PCCs, primarily caused by medication errors.<sup>30</sup> Programs for older adults offer an educational opportunity to reach this high-risk population. Information about medication safety, medication management, and using the PCC as a resource for questions are key messages for PCC public education programs targeting older adults. Collaborative programs with the American Association of Retired Persons (AARP), senior centers, and Departments for the Aging offer an opportunity to provide collaborations focusing on poison prevention and medicine safety programs through educational interventions conducted in senior centers, community agencies, and other groups that serve independently living older adults.

The membership of the American Association of Poison Control Center's Public Education Committee (PEC) includes the PCC public educators from PCCs across the United States and Canada. The mission of the PEC is to provide poison prevention awareness programs in an effort to reduce morbidity and mortality associated with poisoning. Each year, the PEC provides educational sessions at the North American Congress of Clinical Toxicology. Public Education Committee workshops focus on program development, evaluation, grant writing, strategic planning, and other topics of interest to PCC educators.<sup>30</sup>

## NEEDS ASSESSMENTS

To develop successful poison education programs, PCC public educators must first analyze demographic data, call volume rates, cultural and language issues, and barriers to calling a PCC. Geographic information systems (GIS) software offers a way for PCCs to map demographic data. The use of this type of software is increasing in public health and can be applied to PCC efforts. The coordination of data retrieval from various data entry programs and the use of GIS software by PCC staff provides access to call rates by zip codes, counties, census tracts, or congressional districts to be used for

planning programs. Health and social services for the targeted community are also well visualized using GIS maps. Using GIS for population-based programs is recommended for developing social marketing campaigns, health education programs, outreach efforts, and coalition building.<sup>68</sup> The study of geographic areas with low call rates enhances the potential for targeted and focused PCC educational programs.

Focus groups, surveys, and interviews provide useful qualitative methods for PCC public educators to identify the perceptions of parents and caregivers about calling the PCC. Barriers regarding PCC utilization include not knowing the PCC number, preference for calling 9-1-1 rather than the PCC, fear of being reported to child welfare agencies, concerns with regard to confidentiality, language difficulties, lack of in-person contact with health care providers, low self-efficacy, and concerns regarding the cost of the call.<sup>2,5,10,31,35,73,84</sup> Each of these barriers must be considered and creatively addressed when planning new programs for reaching caregivers of young children. In one study, 51% of caregivers interviewed in a low-income urban pediatric clinic said that they would immediately take their children to the emergency department (ED) after a possible poisoning exposure.<sup>71</sup> In a separate study, focus group participants stated they would not call the PCC in the case of a poisoning emergency. Their responses ranking was (1) call the pediatrician, (2) go to the ED, (3) read the label, and (4) call a friend after a poisoning exposure.<sup>31</sup> A focus group with parents provided information to refine a telephone survey concentrating on hazardous household materials and health risks. Feedback from caregivers resulted in a more concise instrument with more targeted questions. In addition, perceptions of the PCC and suggestions for future educational interventions were also gathered from participants.<sup>31</sup> Involving the target audience in the development and testing of information is demonstrated to have improved outcomes when disseminating information.<sup>82</sup>

Follow-up surveys provide a way to analyze factors related to PCC access. English- and Spanish-speaking caregivers in Texas were contacted after an ED visit related to a poisoning exposure in a child. Findings showed that more than half had spoken to PCC staff before the hospital visit. Of those who did not call the PCC, 68% claimed prior knowledge of the PCC yet failed to use it. Significant demographic predictors associated with a failure to call the PCC were being schooled in Mexico and of African American race.<sup>36</sup> Findings from an ethnographic study of 50 Mexican-American mothers with children younger than 5 years of age demonstrated that none had the PCC number in their home.<sup>55</sup>

In person interviews were conducted with parents in the pediatric clinic about poison prevention strategies and awareness of the PCC.<sup>18,22</sup> A pilot study to determine predictors of storage included acculturation, age, gender, and education among Spanish-speaking parents found that less time living in the United States and those with a high school education or less were more likely to store medicines and cleaning products unsafely in the home.<sup>18</sup> Another study conducted with 216 parents and caregivers reported that 80% were aware of the PCC services. However, none knew the 800 number specifically, although many stated they had the number in their home. Of the 42 participants (20% of the sample) unaware of the PCC services, 57% were non-English speakers.<sup>22</sup>

For PCC public educators to plan effective programs with older adults, a needs assessment of the perceived barriers and benefits for this target group related to accessing the PCC is required. Focus groups conducted with older adults show that most do not perceive the PCC as an appropriate service for their concerns but rather as a service for children and parents. Additionally, the participants expressed a very narrow view of what was considered a poison such as bleach and household products. Similar to caregivers of children, older adults repeatedly state that they would call 9-1-1 in an emergency.<sup>11</sup>

## POISON EDUCATION PROGRAMS

More than half of the 2 million annual calls to PCCs nationally involve children younger than 6 years of age (Chap. 130). As a result, programs to teach caregivers about primary and secondary prevention techniques have been the major aim of education efforts. Typically, these programs focus on

**TABLE 129–1** Poison Prevention Tips

- Identify poisons inside and outside the home.
- Keep poisons out of reach of children in a locked cabinet.
- Keep products in their original containers.
- Never keep food and nonfood items together.
- Install carbon monoxide detectors throughout the home.
- Keep plants out of reach of children and pets.
- Use child-resistant containers.
- Post the poison control center number on all telephones and in all cell phones.

teaching poison prevention (Table 129–1) and raising awareness of PCC services. Poison education programs designed to address barriers to accessing the PCC through community interventions are reported in the literature. In one study, parents at two WIC centers reported an increased comfort level with calling the PCC after a video-based intervention.<sup>35</sup> Interventions have demonstrated an increase in knowledge about PCC messages and poison prevention in the study groups.<sup>34,35,37,46</sup>

### Interventions Targeting Health Behavior

Unintentional poisonings can happen even when children are left unattended for a brief period of time (<5 minutes) and a toxic product in use or recently purchased is left within reach of the unattended child.<sup>60</sup> A qualitative study conducted of 65 parents, some whose children had experienced an unintentional poisoning, showed that poison prevention strategies were not consistently implemented in the home. Recommendations included ongoing parent education to reemphasize that “child resistant” is not “childproof” and reinforce safe storage of potentially toxic products, particularly those that are often used.<sup>24</sup> When knowledge and behavior were measured through telephone surveys conducted 3 months after a poison prevention packet was mailed to families of young children who had experienced a poisoning, caregivers were more likely to have the PCC number posted in the home.<sup>35,89</sup>

The ED visit represents an opportunity for poison education programs to work with families to prevent further poisoning exposures.<sup>19</sup> An injury prevention program provided to caregivers of young children after a home injury was effective, particularly regarding retention of poison prevention information and the use of safety devices.<sup>65</sup> A randomized, controlled study measured personalized safety information for parents delivered via computer kiosks in an ED. The intervention group showed significantly higher knowledge of poison storage during follow-up surveys.<sup>25</sup>

The effectiveness of poison prevention education for families who called the PCC after a potential exposure in a young child was also studied. Poison prevention instructions, telephone stickers, and a cabinet lock were sent to the family 1 week after the initial call. Follow-up telephone interviews showed that intervention group recipients reported a higher use of the cabinet lock (59%) and were significantly more likely to post the telephone number for the PCC (78%) than those in the control group who did not receive any poison prevention materials within 2 weeks of the incident.<sup>89</sup>

Poison education programs developed to address caregiver barriers have also been evaluated. An educational video targeting low-income, Spanish-speaking mothers was developed and evaluated. Results showed increased knowledge about the services, staff, and appropriate use of the PCC compared with a control group that attended the regularly scheduled WIC class.<sup>35</sup> Instructor training programs have been designed by a number of PCCs to reach leaders or health educators at community-based organizations to incorporate poison education into their programs for the general population. An evaluation of the “Be Poison Smart” program showed an increase in knowledge and behavior change among service providers after a standardized training session. These reported changes included having the PCC number visibly posted and keeping hazardous products out of reach.<sup>64</sup> Working with community-based services such as WIC presents an opportunity to reach a high-risk population. Pretests and posttests administered to WIC

staff and public health nurses showed increased understanding about poison prevention and increased awareness of PCC services.<sup>66</sup> A randomized trial showed a poison prevention module taught by parenting class instructors in English and Spanish was effective in improving outcomes compared to control group. Follow-up telephone surveys showed increased knowledge about the PCC, participants were more likely to report having the PCC number and behavioral intention to use the PCC.<sup>34</sup>

Community health workers or “promotoras” are involved in health promotion, particularly in hard-to-reach communities. Promotoras are community health educators trained to advocate, promote health, and be culturally aware of the needs of the community they serve.<sup>18</sup> A train-the-trainer model evaluation demonstrated increased knowledge and behavior for teaching healthy homes promotion in the community setting.<sup>48</sup> Home visitors offer an opportunity to bridge the gap between self-report about home safety behavior and direct observation. Safe storage of household products, medicines, and vitamins and posting the PCC number can be addressed through education in the home environment.<sup>45</sup> Focus group participants identified pediatricians as a trusted source of health information for parents.<sup>31,73</sup> The American Academy of Pediatrics (AAP) includes a poison prevention counseling recommendation as part of The Injury Prevention Program (TIPP). The Injury Prevention Program is a safety education program for parents of children newborn through 12 years of age. The TIPP age-related safety sheets include poison prevention advice for parents of children aged 6 to 12 month, 1 to 2 years, and 2 to 4 years.<sup>3</sup> Each safety sheet encourages parents to call the toll-free number for PCCs if the child ingests a potentially poisonous product. It is important that the AAP continues its support for efforts by PCCs to prevent childhood poisonings.<sup>47</sup> In another study, family practitioners and pediatricians were surveyed with respect to poison prevention counseling for parents. Although more than 80% of both groups reported that this was an important topic, family practitioners were less likely than pediatricians to provide poison information during a visit.<sup>23</sup>

Education programs are designed for school-age curricula. The effectiveness of MORE HEALTH, a program to teach kindergarten and third-grade students about poison prevention, was studied.<sup>46</sup> Posttests administered 1 to 2 weeks after the intervention showed increased knowledge in the intervention group of children. Parents of children in the intervention group also self-reported that their homes were more likely to be “poison proofed.”

The current opioid epidemic presents a challenging issue for PCC public educators to address with prevention messages. The increased amount of opioids in homes puts both children and teens at risk for exposures. A survey conducted with adults prescribed opioids in the previous year showed that 32% of respondents with children younger than 6 years old reported safe storage in the home. Only 12% of those with children between 7 and 17 years old in the home reported storing these medicines in a locked place.<sup>50</sup> Key messages for parents and caregivers of young children include using a medicine lock box, never storing liquid methadone in a beverage container, storing opioids in original containers, and calling the PCC regarding safe disposal and in case of any exposure.<sup>74</sup> Key messages for those with older children include education about safe storage and the risks for nonmedical use by their children or other teens visiting the home.<sup>50</sup>

Recommendations have been made to develop programs targeting older adults, particularly about potential problems with medication use and storage.<sup>30,43,77</sup> In one study, interviews were conducted with older adults in the ED to assess knowledge of prescription medications. Patients were taking an average of six prescription medications. As the number of medications per patient increases, the likelihood of not knowing one or more medication also rises. Results show that medication management education programs are needed.<sup>15</sup> There has been a shift in the priority of PCC public educators to develop medicine safety programs for older adults.

### Community-Wide Interventions

A review of pediatric literature focusing on community-based poisoning prevention programs showed that few studies could be found using poisoning rates as the outcome measure. Additional research to measure

community-based poison prevention efforts will be essential to determine the effectiveness of these efforts.<sup>59</sup>

In general, mass mailing of poison information is generally not an effective means to increase call volume for poison exposure or information requests nor is it cost effective.<sup>21,41</sup> Similarly, a distribution of textbook covers with the national logo and PCC information to elementary and secondary schools in low PCC utilization counties was not an effective method for increasing PCC calls.<sup>93</sup> A hospital mailing that combined primary (poison prevention tips) and secondary (telephone stickers) messages was included in an established family health promotion magazine distributed widely in the PCC regional area. This effort resulted in an increased call volume in areas where at least 5% of the residents received the information.<sup>39</sup> In addition, another study result is that overall call volume increased by 11.2% after more than 1 million pieces of literature containing the toll-free number were distributed at sites including EDs, doctor offices, schools, and pharmacies.<sup>40</sup>

An increased number of information calls to the PCC was attributed to a campaign developed to raise community awareness.<sup>79</sup> Media provide a venue for conducting educational activities. Direct mail, radio, television, newspapers, and magazines were incorporated into a media campaign developed to raise awareness in a particular Latino community. A telephone survey conducted before and after the media campaign showed an increase in awareness about the PCC.<sup>2</sup> Although developing this type of program is often costly compared with other educational efforts, the potential audiences are vast. Mass media campaigns are powerful tools used in health promotion and disease prevention efforts.<sup>67</sup> Research shows that a multilevel approach of media campaigns combined with community-based interventions and health education materials influence health behaviors and raise awareness. Additional factors that contribute to successful mass media campaigns include influencing the information environment to maximize exposure, using social marketing strategies, and creating a supportive environment for the target audience to make health changes. Incorporating health education theory and ongoing analyses allow changes midcampaign and assesses outcomes and subsequent media strategies.<sup>67</sup> Radio and television news stations often provide a way to broadcast poison prevention messages during PPW and during periods associated with perceived increased risks to a community.

Social media has become an important venue for expanding health messages and reaching beyond the traditional methods of communication. Although the cost of establishing a social media presence is low, a commitment of staff time and resources are needed to derive the most benefit from these methods of communication.<sup>26,85</sup> There is a need to increase measures of effectiveness of these types of interventions.<sup>38</sup>

The Internet has become a common place for individuals to obtain health information. A survey conducted with parents found that nearly all (98%) used the Internet to search for health information regarding their children. Many used public search engines for obtaining information, raising concerns about reliability and accuracy. Providing education about how to access valid health information is needed.<sup>63</sup> A survey conducted with 21 parents concerning Internet search habits gathered responses to two potential poisoning scenarios; the first one involving a 2-year-old child's exposure to bleach and the other a prescription medicine. Results showed in both scenarios that the parents were most likely to call 9-1-1 in response to the situations. A small number reported that they would be very likely to rely on the Internet. A review of these websites showed that the information presented was often incomplete for poisoning exposures.<sup>32</sup>

## Multicultural Populations

Language and culture must be addressed when planning community-based programs. There is a paucity in the published work of PCC public education work in the United States exploring languages other than English and Spanish. Quantitative and qualitative research examining Latino communities and calls to the PCC have been conducted. The findings from interviews with 206 Latino parents at a WIC site showed that 62% had not heard of the local PCC and 77% did not know that the PCC services were free and offered in Spanish.<sup>84</sup> Two other studies examined the call rates in communities

with significant Latino populations. These areas had lower call rates than comparable areas based on demographic and socioeconomic factors.<sup>16,83</sup> Furthermore, a number of studies demonstrate that Spanish-speaking caregivers are less likely to call the PCC because of concerns including confidentiality and language barriers.<sup>2,5,16,33,55</sup> Poison control center public educators need to provide ongoing information about the PCC services to raise awareness and address the barriers to accessing care. In a study conducted with 100 Mexican-American mothers of children younger than 5 years of age, 32% reported that a doctor or nurse would be the initial contact for health advice. Other sources include friends and family (29%), mother, grandmother, mother-in-law (21%), and spouses (17%). Most of the mothers (81%) acknowledged the use of home remedies to treat their children's illnesses.<sup>52</sup> New immigrant families from Mexico and Latin America are at high risk for poisoning exposures. Poison control center education programs should target populations in communities where the impact has the potential to be consequential.<sup>75</sup> Structured interviews conducted with new immigrant Mexican mothers showed that it was common practice for poisonous products to be stored in alternative containers such as water bottles and other beverage containers. This reflects a common practice in Mexico and other developing countries.<sup>17</sup> PCC public educators should understand the cultural beliefs of the community and ways to discuss poison prevention with new immigrants.

Qualitative research can help to identify cultural issues when planning targeted education efforts. Monolingual Spanish speaking mothers were more likely to report poor storage of household products, plants, and cleaning supplies. They were also less aware of the PCC and more likely to call 9-1-1.<sup>2</sup> Mexican-born mothers of children younger than 5 years of age were interviewed in their homes about poison prevention techniques. Safe storage was clearly a problem in these homes with 64% of homes having bleach stored within reach of children. The presence of multiple families living in the same home further impedes safe storage practices. In this study, families stored all personal products, including medications and household cleansing agents, with them in their bedrooms rather than in common areas such as the bathroom.<sup>55</sup>

Both language and cultural awareness are important within health communication. Health information needs to address both the beliefs and barriers presented with behavior change. The benefits of a culturally aware and bilingual PCC public educator include their ability to provide programs directly to an audience, building trust by recognizing the distinct needs of the community. A lack of bilingual providers was the most significant barrier identified for Spanish-speaking women interviewed about injury prevention techniques.<sup>29</sup> Health education programs including mass media campaigns, designed to accurately reflect the cultural identity—language, beliefs, roles—of the targeted population are more likely to be accepted. Storytelling is also a recommended strategy for health education among many cultures.<sup>53</sup> When asked to provide suggestions for poison prevention education, responses included Spanish radio and video programs as well as brochures that incorporate culturally appropriate values. Incorporating messages into widely recognized media such as telenovelas should also be considered when developing information dissemination channels. Most parents reported interest in learning from PCC staff, doctors, or teachers.<sup>18</sup>

Field testing concepts and materials are important for the development and distribution of appropriate information for multicultural populations. Further work is needed to examine cultural beliefs related to poison prevention and the utilization of the PCC. It is important to address cultural beliefs related to the use of herbal and other complementary medicines.<sup>35</sup> New PCC public education programs are needed to reach multilingual and multicultural communities across the country while also taking into account economic and social needs. Programs are likely to be more successful if individuals trust and view a source as credible, particularly when cultural attitudes and beliefs closely resemble their own.<sup>18,42,53</sup> In addition, "promotoras" or community health workers, should be considered to deliver primary prevention information in the Hispanic community for building relationships with parents and overcoming cultural barriers.<sup>18,48</sup>

## Health Literacy and Numeracy

Health literacy is defined as “the degree to which individuals have the capacity to obtain, process, and understand basic health information and services needed to make appropriate health decisions.”<sup>82</sup> Health literacy encompasses the ability to read, understand, and discuss medical information. Research from the US Department of Education shows that only 12% of US English-speaking adults have proficient health literacy skills.<sup>82</sup> Older adults, Hispanic adults, immigrants, those with less than a high school degree or GED, and lower socioeconomic groups are at highest risk for low health literacy.<sup>44</sup> People with low functional health literacy abilities are less likely to understand written and verbal health information, medicine labels, and appointment information.<sup>44</sup> This type of health information is often written at reading level least 10th grade or higher reading levels.<sup>20</sup> However, 6th grade is the recommended reading level for written medical information. In addition to reading level, use of graphics, font style, color, type size, and layout are important components when developing print material.<sup>20,82</sup> Recommendations for non-print methods for communicating health information include visuals (posters, fotonovelas, pictographs), action-oriented activities (role-play, theater, storytelling), audiovisuals (videos, DVDs), and improving patient–provider communication.<sup>18,20,61,82</sup>

Warning and medication labels are often difficult to understand. The inability to read these warning labels in English presents a barrier for safe storage and safe use of medication and products.<sup>55</sup> Identification of products often includes brand recognition.<sup>54</sup> Instructions for proper use and warnings may not be understood from the label independent of language. A study evaluating 259 first aid and emergency instructions contained on nonpharmaceutical product labels found many provided inaccurate, inconsistent, or no instructions at all regarding potential exposures. More than half (52%) did not include information regarding product ingestion. In addition, only 39% of products recommended contacting the PCC after an exposure. Standardized emergency information with consistent label placement is recommended.<sup>13</sup> To address medication safety issues, particularly with regard to medication labels, a number of studies have evaluated ways to simplify the information provided. New recommendations for standardized prescription medicine labels incorporate four specific time periods (morning, noon, evening, and bedtime) on the container. Patient provider communication is still needed to reinforce understanding of medication regimens.<sup>87</sup> Similarly, recommendations for improving nonprescription medicine labels have been developed, including larger font size, layout, and use of space.<sup>81,92</sup> Consumer testing of nonprescription medicine labels is recommended to ensure patient understanding of the information provided.<sup>81</sup>

The effects of health numeracy as a distinct component of health literacy are presented in the literature.<sup>57,72</sup> Numeracy is an element of health literacy and involves the ability to use numeric information to make effective health decisions in daily life.<sup>4</sup> Numeracy also includes concepts of risk, probability, and the communication of scientific evidence.<sup>57,70,72</sup> Health-related tasks, including measuring medications, scheduling appointments, and refilling prescriptions, rely on applied numeracy skills.<sup>70,72</sup> Managing multiple prescription and nonprescription regimens frequently leads to medication errors.<sup>87</sup> Poison control center public educators should develop interventions that communicate numerical constructs in simplified and understandable ways. Recommendations for techniques to improve understanding of numeric information include simplifying concepts, using plain language design strategies (larger fonts, use of white space, and appropriate visuals), and using “teach-back” patient understanding strategies.<sup>4,82</sup>

## Applying Health Education Principles to Poison Education Programs

Health education involves planning, implementing, and evaluating programs based on theories and models. These models help improve public education interventions for both traditional and social media health promotional approaches.<sup>38,51</sup> There is a need to increase the number of poison educational programs incorporating health education principles. This includes educational efforts designed to reach individuals through community-based programs, mass media, and social media campaigns.

Both the health belief model (HBM) and social cognitive theory (SCT) incorporate the concept of “self-efficacy” and are applicable when designing poison prevention interventions and mass media campaigns. Self-efficacy is the individual’s belief that he or she will be able to accomplish the task requested.<sup>14,20,49,67</sup> Many health educators believe that self-efficacy is necessary to enable behavior change. The SCT suggests that individuals, the environment, and behavior are intimately and inextricably interrelated.<sup>49</sup> The HBM suggests that individuals are more likely to make health behavior changes based on perceived risk susceptibility, severity, potential barriers, and self-efficacy. These decisions are made when actions are seen as potentially more beneficial to the individual than the perceived risks associated with surmounting the current barriers.<sup>14,50</sup>

In one study, the HBM approach was used as a framework for poison prevention and for the assessment of barriers to PCC use. Questions for focus group participants were developed based on the principles of HBM—that is, perceived susceptibility, severity, benefits, barriers, and self-efficacy related to the health action requested. Most of the mothers viewed poisoning as an emergency and believed it was a health concern for their children. Cues to action are also a component of the model and involve discussions about poison prevention or related information. Participants recommended using community-based venues and culturally appropriate information to expand awareness about poison prevention and the PCC.<sup>10</sup>

The HBM and SCT approaches were used to develop the questions for focus groups in both English and Spanish. These questions addressed issues related to poison prevention (severity and susceptibility), the services of the PCC (including barriers), and suggestions for education. Focus group participants suggested the use of modeling to reinforce real-life scenarios in which a mother handles the poisoning emergency with the staff at the PCC with a positive outcome.<sup>33</sup> As a result, a video was developed addressing these ideas. Two poisoning situations in which a mother calls the center are depicted. One involves home management (ingestion of bleach), and the second involves taking the child to the ED (swallowing grandmother’s antihypertensive pill). The video and correlated teaching guides are available in English and Spanish.<sup>35</sup>

It is important to develop questionnaires that will be accepted and understood by the target population. A Spanish language instrument that addresses home safety beliefs using the HBM framework was developed and tested. Low-income, monolingual, Spanish-speaking mothers of children younger than 4 years of age were interviewed about perceived susceptibility, severity, barriers, and self-efficacy factors affecting unintentional home injuries, including poison prevention measures. Barriers identified include literacy skills and access to bilingual health information.<sup>29</sup>

The HBM supports the idea that a “teachable moment” may be the ideal opportunity to present poison prevention interventions.<sup>25,65</sup> People may be more open to health information after a traumatic experience.<sup>12</sup> Events such as an unintentional poisoning exposure may motivate individuals to behavioral change. Applying HBM principles suggests that individuals will make changes in terms of poison prevention when or if they view the severity and susceptibility of a poisoning to be high in the home. Our goal as PCC public educators is to provide efforts using models that have been tested and evaluated for addressing focused community efforts in each population served by the PCC.

## SUMMARY

- Poison control center public educators’ efforts must encompass needs assessments, program development, implementation, and evaluation.
- Focus groups with caregivers of young children conducted across the country have consistently identified barriers to calling PCCs. These include calling 9-1-1, fear of being reported to child welfare agencies, and lack of confidence in handling poisoning emergencies.
- Using health education theories and models, programs should be developed that address these barriers and encourage caregivers to use the services of the PCC appropriately.
- Education programs focusing on the needs of older adults and promoting the use of the PCC as a resource for medicine safety should be designed and evaluated.

- A multilevel approach for health communication is needed for poison public education programs.
- Culture, health literacy, health numeracy, and language needs of target populations are important considerations when planning poison education programs.

## POISON CONTROL CENTERS AND POISON EPIDEMIOLOGY

Mark K. Su and Robert S. Hoffman

### HISTORY

In 1950, the American Academy of Pediatrics (AAP) created a Committee on Accident Prevention to explore methods to reduce injuries in young children. A subsequent survey by that committee demonstrated that injuries resulting from unintentional poisoning were a significant cause of childhood morbidity. At the same time, there was a realization that a source of reliable information on the active ingredients of common household xenobiotics was lacking and that there were few accepted methods for treating poisoned patients. In response to this void, the first poison control center (PCC) was created in Chicago in 1953.<sup>114</sup> Although initially designed to provide information to health care providers, both the popularity and the success of this center stimulated a PCC movement, which rapidly spread across the country. The myriad of new PCCs not only offered product content information to health care providers but also began to offer first aid and prevention information to members of the community.

In the past 60 years, countless achievements have been realized by a relatively small group of remarkably altruistic individuals. Throughout this time, poison services have remained free to the public, highlighting their essential role in the American public health system. Many of the legislative and educational accomplishments that are chronicled in Chap. 1 have directly reduced the incidence and severity of poisoning in children.<sup>34,109,128</sup> Concurrently, the number, configuration, and specific role of PCCs has shifted in response to public and professional needs.<sup>54,86</sup>

Modern regional PCCs are staffed by highly trained and certified health professionals who are assisted by extensive information systems. Support is provided by 24-hour access to board-certified medical toxicologists and consultants from diverse medical disciplines, the natural sciences, and industry. The American PCC is charged with seven major objectives:

- Maintaining and interpreting a database of xenobiotics
- Providing information and advice to the public and to health professionals
- Collecting epidemiologic data on the incidence and severity of poisoning
- Integrating epidemiologic data as part of the public health surveillance system
- Preventing unnecessary hospitalizations after exposure and thereby cutting health care costs
- Educating health care professionals on the diagnosis and treatment of poisoning
- Contributing to the science of toxicology

In the past, PCCs were evaluated based on the number of incoming calls and measures of community awareness. Current emphasis should be placed on evaluating health outcomes such as intensive care unit (ICU) admissions, length of stay in hospitals, and total health care expenditures. One crucial test of the utility of modern PCCs will be their ability to help reverse the US current trend of increased adult deaths from pharmaceutical poisoning largely driven by prescription opioids.<sup>50,72</sup> This chapter explores some of the critical roles of US poison control centers and attempts to offer a vision of the future. An overview of the composition of PCCs worldwide can be found elsewhere.<sup>107</sup> Unique issues facing PCCs in other countries are discussed in Chap. 136.

### MAINTAINING AND INTERPRETING A DATABASE OF XENOBIOTICS

The first toxicology database created in the United States was a set of cumbersome 5" × 8" index cards produced in the 1950s by the US National Clearinghouse of Poison Control Centers.<sup>114</sup> When it grew to include more

than 16,000 cards, the sheer volume of space required to store this information, and the extensive time necessary to manually search these cards created the necessity of a central repository, such as a PCC. As available information grew, a rapid expansion of information technology occurred, and the unwieldy index card database was privatized and transformed into microfiche. Although this resource was physically smaller, specialized equipment was required, and a search was still time consuming. Numerous encyclopedic and clinical textbooks were written to supplement the database and provide resources for the office or the bedside. With the growth of the computer age and the Internet, the computer product known as POISINDEX was established to replace the microfiche format as the major source of data on the contents of innumerable household and industrial products, drugs, and plant and animal xenobiotics. POISINDEX also provides uniform management strategies for many potentially toxic exposures. Over the years, several proprietary competitors to POISINDEX, such as TOXINZ and TOXBASE, have gained recognition as valuable tools. Additionally, open source programs such as WIKITOX provide free information to both clinicians and members of the public.

With this evolution of information technology, PCCs are no longer perceived as the sole guardians of toxicology information. Although these services are still essential for the public at large and for professionals who are away from their computers or smartphones, a predictable decline in PCC use has paralleled this growth in availability of information. A 1991 study in Utah demonstrated that 82.6% of emergency physicians who had POISINDEX available in their institutions no longer routinely consulted the PCC.<sup>29</sup> A similar 1994 New York State study suggested that 76% of physicians who had POISINDEX in their emergency departments (EDs) perceived that its availability decreased their own use of their PCC.<sup>130</sup>

An initial analysis might suggest that this is an acceptable trend for health care professionals in that it both allows physicians to respond more rapidly to patient needs and for PCCs to be more available to those individuals, especially non-health care professionals, who do not have access to this information system. In fact, one model demonstrated that an integrated voice response system effectively reduced human interactions for medication identification by more than half at one PCC.<sup>80</sup> By extension, it might be suggested that both the public and health care providers can easily access the same information as certified specialists in poison information, making the human interaction nearly obsolete. However, this practice of "not calling" not only undermines the efforts of PCCs to gather epidemiologic data (see later) but also creates a knowledge gap. In other words, the interpretation of the data is as essential (or more essential) than the data itself. For example, some commonly used sources of toxicology information such as the *Physicians' Desk Reference* and material safety data sheets occasionally provide information that is inaccurate, potentially misleading, or severely limited.<sup>21,60,97</sup> Likewise, reviews of drug interaction programs designed for mobile devices demonstrate significant variability between individual programs and inferiority compared with larger online resources.<sup>5,41,105,108</sup> Although the POISINDEX routinely provides more accurate information regarding overdose, it is only updated quarterly and cannot be expected to adapt to ongoing epidemiologic trends such as regional variations in substance use.

The best source for essential new information is skilled professionals who specialize in poisoning. Also, because most databases are designed to provide information about known entities, they perform poorly when dealing with unknown and unclear scenarios, especially long and complex differential diagnoses. For example, consider the case of a clinician caring for a lethargic child whose only medication is Zantac syrup. After other causes

of altered mental status are excluded, the clinician considers drug toxicity. Consultation with standard references suggests that altered consciousness would not be expected with use of this medication. However, a certified specialist in poison information at a regional PCC recognizes the potential for drug error, has the physician review the syrup bottle in question, and then calls the pharmacy where the drug was provided. The certified specialist in poison information learns that although the prescription was written for Zantac (ranitidine), the bottle actually contains Zyrtec syrup (cetirizine), which could account for the child's symptoms.

Thus, although originally designed as providers of information, PCCs are valued consultants. They provide content information and interpretation of clinical material, leading to the implementation of appropriate management strategies. This goal can only be achieved through rigorous training and certification and recertification criteria designed to provide valued up-to-date interactions with health care professionals. Access to computer programs may be deceptively inaccurate or superficial compared with a thoughtful human analysis. Computers do not recognize anxiety, inappropriate questions, and other subtle issues that can only be appreciated with human interactions.

Another illustrative example of the value of PCCs can be drawn from the use of flumazenil for benzodiazepine overdose (Chap. 72 and Antidotes in Depth: A25). Although it is easily determined that flumazenil is the antidote for benzodiazepine overdoses, many subtle characteristics of the patient or the overdose often contraindicate its use. A prospective study determined that when flumazenil was used before consultation with the PCC, contraindications to its administration were present in 10 of 14 (71%) cases, resulting in one serious adverse event.<sup>24</sup> In the study mentioned earlier, although physicians with access to the POISINDEX were less likely to call the PCC, 86.7% still thought that using the PCC to gain access to a medical toxicologist was a valued resource.<sup>29</sup> Many PCCs are linked with centers for poison treatment, which are health care facilities that can provide both bedside consultation and unique diagnostic and therapeutic interventions for a subset of patients with severe or complex poisoning.<sup>1</sup> The benefits of consultation are discussed later under Health Care Savings.

## PROVIDING INFORMATION AND ADVICE TO THE PUBLIC AND TO HEALTH PROFESSIONALS

Poison Control Centers in the United States interact with the public and health professionals over 2.5 million times annually.<sup>94</sup> Although the financial value of these interactions will be discussed in the next section, two major limitations to the success of PCCs are highlighted in the literature. The first, which should be intuitively obvious, stems from the fact that PCCs are remote from the patient and can therefore only make decisions based on the information provided to them. Although certified specialists in poison information are highly skilled and use a variety of communication styles to obtain the most accurate information,<sup>110</sup> the quality of the information impacts on the utility of their recommendations. The greatest concern here is over estimation of dose. In a 3.5-year study of all children referred by a PCC to a health care facility for determination of either a methanol or an ethylene glycol concentration because of a history of exposure, only 21 of 102 had measurable concentrations.<sup>64</sup> Although this has serious limitations on the interpretation of PCC data,<sup>68</sup> the implications for clinical care are even greater. Likewise, a human volunteer study demonstrated that adults are totally incapable of determining residual volumes in containers or describing the actual volume of semiquantitative descriptors such as "a small mouthful" or "a gulp."<sup>67</sup> Because critical decisions are made based on the history of ingestion or amount ingested, a clear challenge for PCCs is to develop methods to improve the accuracy of this information. Sharing digital imagery is one useful method of assisting caregivers with determination of residual container volumes.

The second challenge involves the gap that exists between recommendations that are made by PCCs and those that are accepted. Two papers highlight this concern. In a 7-year analysis of PCC recommendations for the administration of high-dose insulin and dextrose therapy, the recommended

treatment was actually administered only 50% of the time.<sup>53</sup> Similarly, in a 5.5-year study of calcium channel blocker and  $\beta$ -adrenergic antagonist overdoses at a different PCC, high-dose insulin and dextrose therapy was only started in 42% of cases when it was recommended.<sup>45</sup> Because this therapy is considered effective and potentially lifesaving (Antidotes in Depth: A21), PCCs need to evaluate the reasons these recommendations are not accepted and explore methods to improve communication with providers. Similarly, patient compliance with PCCs' recommendations is unknown. Patients may call PCCs directly to request assistance after an exposure occurs. However, because of inaccurate data collection (ie, patient names, telephone numbers), patient outcomes are often unknown because of insufficient follow-up.

## COLLECTING POISON EPIDEMIOLOGY DATA

In 2007, the Centers for Disease Control and Prevention (CDC) reported that poisoning fatality surpassed both motor vehicle crashes and firearms to become the leading cause of injury-related fatalities.<sup>7</sup> This trend has continued and is largely influenced by an epidemic of prescription opioid abuse.<sup>72</sup> Understanding the evolving trends in poisoning is essential to the development of enhanced surveillance, prevention, and education programs designed to reduce unintentional poisoning. Although data can be analyzed from numerous sources such as death certificates, hospital discharge coding records, and PCCs, it is essential to recognize the biases that are inherent in each of these reports. Because not all significant poisonings result in either hospitalization or fatality, data from PCCs appear to offer a unique perspective.

Unfortunately, the term "poisoning" is often defined differently and therefore is a confusing term. In this text, "poisoning" is used to denote any exposure to any xenobiotic (drug, toxin, chemical, or naturally occurring substance) that results in injury. Yet the data collected and disseminated by PCCs are defined by the term "exposures."<sup>15-20,93-96</sup> Potential xenobiotic exposures are inevitable given their ubiquity. However, many exposures are of no toxicologic consequence because of the properties of the xenobiotic involved, the magnitude or duration of the exposure, or the uncertainties regarding whether an actual exposure has occurred; therefore, data collected by PCCs represent a limited and ill-defined measure of poisoning.

The situation is further confounded by multiple biases that are introduced by the actual reporting process, which, first and foremost, is voluntary and passive. Because the majority of calls concern self-reported data that originate from the home setting and are never subsequently confirmed, a significant percentage of the data generated to date likely actually represents only potential or possible exposures, which then introduce large statistical errors into the database. This is highlighted by the 21 of 102 children who tested positive for a toxic alcohol discussed earlier.<sup>64</sup> Even though only those 21 children were definitively exposed and potentially poisoned, all 102 were entered into the database as exposures. If these figures are representative of the rest of the data set, they suggest that an actual ingestion does not occur in the vast majority of reported unintentional exposures in children. Also, current events, hoaxes, and media awareness campaigns all influence self-reporting rates.<sup>87</sup> Furthermore, to report a possible exposure, a caller must have a telephone, probably speak English, and have some degree of health literacy and numeracy.<sup>85,127</sup> Although telecommunications devices for hearing impaired individuals and translation services exist, they are rarely used in communications with PCCs. Enhancement of technology to facilitate the accurate exchange of information between certified specialists in poison information and either hearing impaired callers or those who do not speak English is essential to enhance outreach to special populations and those with limited English proficiency and ultimately the success of PCCs. Although text messaging is an interesting option, preliminary data suggest that encounters are too slow and complicated to be productive.<sup>111</sup> Another potential source of PCC notification would be to entertain more active reporting systems automatically triggered directly by hospital laboratory values. Theoretically, with the advent of sophisticated electronic medical record (EMR) systems, PCCs could be sent automatic notifications of patients exposed to xenobiotics. The implementation of this type of system is not currently widespread due to heterogeneity of the EMRs and potential

issues with maintaining patient privacy and Health Insurance Portability and Accountability Act (HIPAA) compliance.

Under the present passive system, when hospitals report exposures to the PCC, a comparison of the hospital chart with the PCC record shows good agreement, demonstrating an accurate exchange of information.<sup>70</sup> Unfortunately, a reporting bias similar to that described earlier is well recognized regarding professional use of PCCs and is called the *Pollyanna phenomenon*.<sup>61</sup> For example, when examining New York City Poison Control Center Data from 2011 to 2014, reports of novel psychoactive substances were noted to increase, largely driven by the recent surge in synthetic cannabinoid receptor agonists.<sup>103</sup> Over time, reporting significantly dropped, possibly because of either effective public health interventions or decreased drug supply. In a similar case, during the spring of 1995, PCCs in the northeast United States began to receive numerous reports of severe psychomotor agitation and other manifestations of anticholinergic syndrome in heroin users. In the initial phase of the epidemic, most of the callers requested assistance in establishing a diagnosis and determining possible etiologies and raised questions regarding treatment with physostigmine.<sup>62</sup> Although the epidemic continued for many months, after the media announced that the heroin supply was tainted with scopolamine and clinicians became familiar with the indications and administration of physostigmine, call volume decreased. Stated simply, health care professionals are less likely to call the PCCs regarding issues with which they are familiar, are of little clinical consequence, or are not recognized as being related to a poison. Thus, a bias is introduced that results in a relative overreporting of new and serious events and a relative underreporting of the familiar or very common, unrecognized poisoning and exposures or poisonings that are apparently inconsequential. Numerous comparisons support this contention. Investigators who rely on published data from PCCs as a sole source of epidemiologic information demonstrate a failure to understand the complexity of poisoning data and the aforementioned consequential limitations of PCC-derived data.

### Fatal Poisoning

A 4-year study compared deaths from poisoning reported to the Rhode Island medical examiner with those reported to the area PCC.<sup>83</sup> Not surprisingly, the medical examiner reported many more deaths: 369 compared with 45 reported by the PCC. Although the majority of the cases not reported to the PCC were victims who died at home or were pronounced dead on arrival to the hospital or those in whom poisoning was not suspected until the postmortem analysis, 79 patients who subsequently became unreported fatalities were actually admitted to the hospital with a suspected poisoning. In 10 of these cases, the authors concluded that a toxicology consultation might have altered the outcome. Examples of interventions that, if recommended and performed, might have resulted in a more favorable outcome included the proper use of antidotes such as naloxone, *N*-acetylcysteine for acetaminophen poisoning, the cyanide antidote kit, sodium bicarbonate for a cyclic antidepressant overdose, hyperbaric oxygen for carbon monoxide poisoning, hemoperfusion for a theophylline overdose, and hemodialysis for a lithium overdose.

Likewise, when medical examiner data were analyzed in Massachusetts, more than 47% of poison fatalities were not reported to the PCC.<sup>118</sup> A California study evaluating 358 poisoning fatalities reported to the medical examiner showed that only 10 PCC fatalities were reported over a similar time period, demonstrating an even more consequential reporting gap.<sup>9</sup> Again in this study, whereas the majority of underreporting occurred in prehospital deaths (68%), only 5 of 113 hospitalized patients who ultimately died were reported to the PCC. Additionally, a cross-sectional comparison of national mortality data with PCC data for agricultural chemical poisoning demonstrated a similar trend of underreporting to PCCs of seriously poisoned admitted patients who became fatalities.<sup>77</sup> Furthermore, when data for an entire year from the National Center for Health Statistics (NCHS) were compared with the same year of data from the American Association of Poison Control Centers (AAPCC), it was apparent that the AAPCC data captured only about 5% of annual poison fatalities.<sup>69</sup>

More recent analyses highlight a remarkable trend. When 11 states evaluated trends in poison-related mortality rates from 1990 to 2001, an average increase of 145% was noted.<sup>66</sup> A more comprehensive investigation of the National Vital Statistics System (NVSS) accessed via the CDC's Web-based Injury Statistics Query and Reporting System (WISQARS) database demonstrated a 5.5% increase in injury related mortality from 1999 to 2004. The mortality rate from poisoning accounted for 62% of the increase in unintentional injury, 28% of the increase in suicide, 81% of the increase in death from undetermined intent, and more than 50% of the total increase in injury-related mortality.<sup>104</sup> Since 1999, the age-adjusted drug poisoning death rate has increased from 6.1 per 100,000 to 16.3 per 100,000 in 2015.<sup>31</sup> Although the vast majority of poisoning fatalities occur in adults, a review of the entire 2010 AAPCC database only found 74 reported fatalities in children.<sup>25</sup> Focusing on PCC data alone would produce the erroneous assumption that poisoning-related fatalities were not a significant public health concern. In actuality, poisoning is a significant concern considering that other programs designed to reduce deaths from motor vehicle crashes and firearms have been largely successful; however, decades have gone by without a major intervention targeting poison-related fatality.

It is logical to assume that similar disparities exist regarding the reporting of nonfatal poisonings. The resultant gap in public health data needs to be addressed through improved definitions, epidemiology, reporting, and analysis of poison-related data systems. This inequity has developed through a long-standing tradition of PCCs to focus attention and concentrate on the largely benign exposures in children. The emphasis needs to be redirected toward seriously ill poisoning, ICU utilization, and other markers of actual poisoning rather than health care utilization for benign events.

### Nonfatal Poisoning

An outreach study in Massachusetts determined that hospitals geographically close to a PCC reported their cases almost twice as often as hospitals remotely located (46% versus 27% of total cases).<sup>32</sup> Additionally, the authors noted that private physicians were less likely to report cases than residents in training. A 1-year retrospective review demonstrated that only 26% (123 of 470) of poisoned patients who were treated in a particular ED were reported to the PCC.<sup>63</sup> Interestingly, only 3% of inhalational exposures were reported compared with 95% of cyclic antidepressant ingestions. The authors also noted, as suggested earlier, that reporting decreased when comparable exposures occurred over a short period of time. Finally, in the physician survey study cited earlier, physicians reported that they would “almost never” contact the PCC for asymptomatic exposures (62.9%), chronic toxicity (50.4%), or simply to assist in establishing a reliable database (90.2%).<sup>29</sup> This statement is most likely accurate even in jurisdictions where reporting of all or select exposures is incorporated into public health laws.

### Occupational Exposures

Xenobiotic exposure occurs commonly in the workplace. As a result of the long-recognized association between occupational exposure and illness, a number of federal and state government-funded agencies, such as the National Institute for Occupational Safety and Health (NIOSH), Occupational Safety and Health Act (OSHA), and the Agency for Toxic Substances and Disease Registry (ATSDR), exist to prevent occupational illness, educate the public, and collect data on exposures to occupational xenobiotics. Legislation provides for mandatory reporting in some instances and offers workers job protection for voluntary reporting. Poison control centers also provide information on occupational exposures and collect data. Again, there are discrepancies between the poison information data and the data collected by governmental agencies. A 6-month survey in California noted that only 15.9% of the occupational cases reported to the PCC were captured by a state occupational reporting system.<sup>11</sup> The most common occupational toxicologic illness—dermatitis—was even further underrepresented in these cases. A follow-up study by the same authors demonstrated that more than one-third of calls came directly from the individual worker, 70% of whom were unaware of the link between their occupation and their symptoms.<sup>10</sup>

Although these data suggest that PCCs can provide substantial assistance after occupational exposures, one author expressed concern, noting in a follow-up study that the PCC failed to provide an adequate epidemiologic assessment because an average of 12 other people per workplace who were also potentially exposed in addition to the index case were not identified.<sup>13</sup> A 1999 survey of PCCs concluded that “responses to work-related calls are inadequate” and suggested that written protocols might be helpful.<sup>14</sup>

### Adverse Drug Events and Xenobiotic Errors

Although the actual numbers of adverse drug events (ADEs) are a source of controversy, data suggest that a striking number occur each year in the United States, with many resulting in death.<sup>22,35,81</sup> The ease of 24-hour telephone access, combined with the ability to consult with a health professional, make PCCs ideal resources for reporting of ADEs.<sup>38</sup> Yet more than 76% of physicians surveyed stated that they would “almost never” contact the PCC regarding ADEs.<sup>29</sup> Moreover, 30 of 56 (53.6%) PCCs surveyed stated that they had not submitted any of their ADE data to the FDA Med-Watch program.<sup>35</sup> Many of the other centers reported only partial compliance with the MedWatch system.<sup>35</sup>

Prescription drug errors are another source of potential poisoning. Retrospective review of PCC data suggests that many of these errors are reported. In one report, the PCC provided valuable feedback to pharmacists and physicians about these errors. Ideally, reporting to the state board of pharmacy would ensure that proper surveillance and counseling continue. The PCC is ideally suited to perform this function.<sup>116</sup> Unfortunately, although pharmacists are ideally positioned to identify prescribing errors, data suggest that pharmacist utilization of PCCs is poor.<sup>2</sup>

### Drugs of Abuse

Poison control centers also collect data on exposures to drugs of abuse and misuse. These data consist largely of calls for information from the concerned public and reports of overdose requiring health care intervention. Although ethanol, tobacco, and caffeine are the most common xenobiotics used in society, these cases are rarely reflected in PCC data, with the exception of unintentional exposures in children. In fact, because most substance abuse does not result in immediate interactions with the health care system, other databases such as the National Institute of Drug Abuse (NIDA) Household Survey (now referred to as the Monitoring the Future Study) might better reflect substance abuse trends. Yet even this database has significant limitations.<sup>8,58</sup> Because PCCs are more focused on immediate health care effects of exposures, it could be argued that only cases in which health care interaction is required are of value in the database. Because PCCs collect data in real time, they are ideally positioned to track emerging trends and report sentinel events. Examples include PCC experiences with trends in opioid abuse among teenagers,<sup>55,123</sup> bath salts,<sup>98</sup> synthetic cannabinoid receptor agonists,<sup>98,102</sup> and tainted cocaine.<sup>124</sup>

### Grossly Underreported Xenobiotics

As discussed earlier, there is little doubt that ethanol and tobacco are the most common xenobiotics intentionally used and misused in our society. Although their toxicologic manifestations are acute and severe at times, chronic subclinical poisoning often goes unnoticed for many years. Similarly, based on the 2007 to 2010 National Health and Nutritional Exam Survey, approximately 500,000 American children have lead concentrations above 5 mcg/dL.<sup>30</sup> We must remain cognizant of these large-scale exposures when we read that plants, cleaning products, and cosmetics comprise the most common exposures to xenobiotics;<sup>132</sup> rather, these are the most commonly “reported” exposures.

## INTEGRATING EPIDEMIOLOGIC DATA AS PART OF THE PUBLIC HEALTH SURVEILLANCE SYSTEM

With the current limitations of the PCC data, it should be clear that neither the numerator nor the denominator of the actual number of poisonings is easily appreciated. However, analysis of these data for trends has some utility because the inherent biases involved in PCC reporting are probably consistent over many years. Increasingly, PCC data are being used as part of

surveillance and prediction models,<sup>51,132</sup> often that extend beyond poisoning to other public health concerns.<sup>117</sup> Rapid reporting in collaboration with the CDC highlights an essential partnership.<sup>42,59,98</sup> Efforts should be directed to encourage reporting to PCCs by such enhanced access methods as web-based forms for passive reporting, a direct interface between laboratory and hospital databases that actively transmits data to PCCs and linkages to other agencies that collect reports of poisoning such as state and local health departments and medical examiners. Additional resources should be directed at improved case definitions (distinguishing asymptomatic exposure from poisoning) and integration with other essential databases such as MedWatch, NVSS, and NCHS.

Despite its limitations, PCC data have significant utility. It is often an exposure rather than an actual poisoning that provides the impetus for contact with health care. For exposures that are unlikely to be consequential, the PCC can intervene to prevent potentially harmful attempts at home and costly unnecessary visits to health care providers. Interaction with parents at a time of perceived crisis also provides a “teachable moment” (Chap. 129) that may help prevent a more consequential exposure in the future. For exposures that result in poisoning, the period of time immediately after exposure is an ideal moment to initiate first aid measures designed to prevent or lessen the severity of poisoning. For these reasons, the cost, benefits, and efficacy of PCCs, especially regarding home calls, must be measured in terms of exposures and not poisonings.

### HEALTH CARE SAVINGS

When visits to pediatric EDs for acute poisoning were analyzed, one study demonstrated that 95% of parents had not contacted the PCC before coming to the hospital, and 64% of these children required no hospital services.<sup>33</sup> In contrast, when parents called the PCC first, fewer than 1% sought emergency services afterward. When 589 callers to one PCC were surveyed, 464 (79%) respondents stated that they would have used the emergency care system if the PCC were unavailable.<sup>74</sup> In a similar study, 36% of callers would have selected a more costly alternative if the PCC were unavailable.<sup>12</sup> Likewise, when primary care providers were surveyed, more than 80% said that they would activate 9-1-1 if there were no PCC.<sup>3</sup> Poison control center data confirm that approximately 75% of reported exposures that originate outside of health care facilities can be safely managed onsite with limited telephone follow-up. Suggesting simple techniques or reassurance can successfully reduce hospital visits for patients who typically call PCCs for what only represents a potential exposure. The use of established protocols, especially for unintentional exposures in children, reduces ED referral rates and unnecessary hospital charges.<sup>65,122</sup> Unfortunately, this approach is not demonstrated to be beneficial for adults.

Limited data suggest that direct bedside consultation and care help reduce length of hospital stay and health care costs.<sup>40</sup> Yet although PCCs operate remotely, in one assessment, consultation with a PCC reduced length of stay by nearly 3 days.<sup>126</sup> Similarly, when the PCC was consulted for patients already in the hospital, length of stay and costs were reduced by 1.9 days and nearly \$5,000, respectively.<sup>23</sup> This experience has been replicated outside the United States, where PCC consultation resulted in a decreased length of stay of more than 3 days.<sup>56</sup>

The national average cost to the PCC for a single human exposure call is on the order of \$35.<sup>134</sup> A federally funded study concluded that in one year, PCCs reduced the number of patients who were treated but not hospitalized by 350,000 and reduced hospitalizations by an additional 40,000 patients, for a cost savings over more than \$3 million.<sup>92</sup> Each call to a PCC prevented at least \$175 in subsequent medical costs, providing strong theoretical evidence to support the cost efficacy of PCCs. In fact, two natural experiments support these calculations: In 1988, Louisiana closed its state-sponsored PCC. During the year that followed, the cost of emergency medical services (EMS) for poisoning in Louisiana increased by more than \$1.4 million. This additional expenditure represented a greater than threefold increase above the operating cost of that center.<sup>76</sup> Similarly, because of financial disputes in California, direct access to the San Francisco PCC was

electronically restricted for one major county, with a recording referring callers instead to the 9-1-1 system for assistance.<sup>106</sup> The result of each blocked call resulted in increased health care costs by approximately \$33. Moreover, these calculations cannot account for the unmeasured benefits to society from PCC interventions that reduce waiting times for ambulance availability and hospital treatments because of lower volumes, money saved by the prevention or reduction of injury from early intervention or lives saved by enhancing access to or use of the health care system for seriously poisoned patients. In El Paso, Texas, cooperation between EMS and the PCC was able to reduce ambulance dispatches by 1750 over 5 years.<sup>4</sup> Overall estimates place the rate of return for PCC funding between 11 and 36:1.<sup>71,119</sup> A similar study done in Southern California showed that when the PCC was notified before EMS dispatch, \$486,595 and \$183,279 were saved in charges and payments, respectively.<sup>82</sup>

However, many barriers prevent a person from calling a PCC, including lack of familiarity with its available services, intellectual and cultural factors, language difficulties, and confidentiality concerns<sup>39,75,85,127</sup> (Chap. 129). Epidemiologic studies demonstrate that areas of increased population density with high percentages of minority inhabitants have lower utilization of PCC services.<sup>125</sup> Additional barriers include the absence of caregiver comfort with the extensive personal contact provided by the health care system and a concern regarding implications of child abuse or neglect when reporting to agencies such as PCC, many of which have governmental ties.<sup>115</sup> Data demonstrate that public educators can help overcome some of these barriers.<sup>120</sup> One good example of an effort to overcome reporting barriers was the institution of a single national toll-free number for poisoning (800-222-1222). Although it is clear that this intervention improved access and increased total calls to the PCC,<sup>79</sup> it has yet to be determined if this has altered the patterns of use (Fig. 129-1).

In terms of alternative ways for PCCs to obtain data on poisoning exposures and assist the public, the use of the internet and mobile devices are being explored. The online platform webPOISONCONTROL was studied as an alternative for the public to obtain emergency advice regarding potential toxic exposures.<sup>84</sup> After using this online platform, user comments suggested advantages, such as not having to call the PCC and overall convenience. Disadvantages included relatively limited guidance and no human interaction for opportunities to ask questions. Thus, although automated online platforms show potential, this study points toward a need for both human interaction and the need to expand communication channels with the public for increased convenience. Another method of PCC contact for the public that is being investigated is the use of texting or chatting. These are alternative methods of communication that have become extremely popular, especially among millennials. Although only a few PCCs currently use texting or chatting, this option is worthy of further investigation as the number of calls to PCCs continues to decrease and other techniques of public engagement become necessary.<sup>121</sup>

## PROVIDING EDUCATION FOR THE PUBLIC AND HEALTH PROFESSIONALS

Poison control center staff work closely with physicians, community health educators, community support groups, and parent-teacher associations to develop poison prevention activities.<sup>88</sup> Table 130-1 lists common strategies advocated to prevent poisoning. Poison control centers are also actively involved in enhancing training programs for paramedics,<sup>52</sup> medical students,<sup>73</sup> pharmacy students,<sup>44</sup> and resident physicians<sup>44,100,131</sup> and are an integral part of postgraduate training programs in medical toxicology.

As stated previously, there is an inherent risk in both enhanced public and professional education programs. Currently, the decreased telephone use of a PCC could be both the result of a decrease in the incidence of exposure or poisoning or an enhanced understanding of the prevention, diagnosis, and treatment of poisoning. Although education should never be viewed as detrimental, programs must include an emphasis on the continued use of PCCs to ensure access to current information in a rapidly changing discipline. In actuality, as a result of the ongoing analysis of incoming

**TABLE 130-1 Common Strategies Advocated to Help Prevent Poisoning**

All xenobiotics should be kept in their original containers. Food and drink containers should never be used for transfer of a xenobiotic.
Never store xenobiotics in unlocked cabinets under the sink. Apply locks to medicine cabinets that are within the reach of a child.
In the absence of a lock, the more toxic xenobiotics should be stored on the highest shelves.
Xenobiotics should never be left in the unlocked glove compartment of the family car.
Parents should buy or accept medication only if it is in a child-resistant container.
Medication should be considered as medicine, not a plaything and certainly not candy.
Adults should not take their medications in front of children:
This will limit exposure to drug-taking role models that may become objects of imitative behavior.
Unused portions of prescription medications should be discarded, or returned to a pharmacy.
Activated charcoal should be readily available in the home for use if directed by a certified specialist in poison information or clinician. (Particularly for those living in remote areas.)
Children who have ingested a poison will do so again within a year, these children should receive an enhanced level of supervision.
Turn on the light in the room and wear glasses (if appropriate) when taking medications.

calls, the knowledge base has the potential to change as rapidly as the calls are reported. This is far more rapid than can occur in any published literature or electronic database. Thus, additional emphasis should be applied to routine use of the PCC as a public health tool to improve the accuracy of epidemiologic data. Reporting of rare or suspected events can serve as sentinel efforts that help identify consequential adverse drug opportunities long before normal postmarketing surveillance tools identify areas of concern.

On the other hand, outreach programs that advise the public to access free services for inconsequential events would easily overwhelm an already stressed system of responding to incoming calls by demanding an immediate response to the less serious calls in an appropriate time frame. Public education and public health must both be considered to ensure that PCCs are staffed with the appropriate number of skilled individuals to respond not only to daily events but also to address surges in calls that would result from actual epidemics or responses to media announcements. Increasing calls to demonstrate increased use offers no public health advantage if the use is inappropriate or if seriously ill or potentially ill callers lose access to timely responses.

## DEVELOPMENT OF FUTURE PUBLIC HEALTH INITIATIVES

The initial public health efforts of PCCs focused on attempts to alter product concentration and to enhance product labeling and packaging. These beneficial endeavors should continue and must evolve. However, current events have also increased PCC activities in preparedness for mass gatherings and disasters resulting from radiologic, biological, and chemical terrorism.<sup>57,78</sup> Additional links with governmental agencies such as the CDC have expanded the role of the PCC in community health. As an example, national PCC data from the National Poison Data System (NPDS) shows that PCC data of exposures related to influenza like illness (ILI) is highly correlated with CDC ILI data.<sup>6</sup> Furthermore, the need for 24-hour rapid access to centralized information, existing data entry and retrieval systems, and links to experts in medical toxicology and emergency medicine helps to place PCCs in critical roles in both local and national initiatives. Important contributions have included development of triage and treatment protocols,<sup>26-28,36,37,43,48,65,89-91,99,101,112,113,129,133</sup> assessments of antidote supplies,<sup>47-49</sup> and disaster preparedness.<sup>46</sup> Table 130-2 summarizes initiatives that require creation or enhancement to improve poisoning epidemiology data. Many of these are discussed extensively in a report from the Institute of Medicine. Lastly, increased awareness of the essential public health role of PCCs by the lay public and policy makers must be accomplished in order to maintain the political and financial support necessary to ensure PCC quality, innovativeness, responsiveness to societal needs and viability.

**TABLE 130–2** Goals for Improving Poisoning Epidemiology Data

Identify and remove barriers to reporting.  
 Create multiple methods of reporting:  
   Telephone, fax, web based, or e-mail  
 Simplify communications devices for hearing impaired individuals.  
 Allow rapid access to translation services.  
 Enhance awareness of the public health role of poison control centers.  
 Enhance education of caregivers and health care professionals.  
 Establish public health legislation requiring professional reporting of exposures.  
 Distinguish possible exposures from actual exposures to improve the integrity of the database.  
 Create a category for unconfirmed exposures in the database and encourage its use.  
 Divide confirmed exposures by certainty:  
   Confirmed by history  
   Confirmed by physical examination  
   Confirmed by quantitative and qualitative laboratory analysis  
 Integrate the AAPCC database with other databases (eg, the ICD and “E” code systems) and use a standardized data collection instrument.  
 Automatically interact with hospital and commercial laboratories.  
 Uplink pharmacy ADE reports, hospital discharges, public health department reports (similarly available with lead screening programs), fire departments and hazardous materials responders, industry workplace exposures, death certificates, and drug abuse monitoring systems.  
 Provide real-time analysis of incoming data.  
 Enhance the speed of data collection and reporting.  
 Analyze data as it is reported to identify emerging trends.  
 Mandate the use of accepted epidemiologic and statistical analyses of data.  
 Provide rapid and regular feedback to primary reporters.  
 Issue timely analyses and reports.

ADE = adverse drug event; AAPCC = American Association of Poison Control Centers; ICD = International Statistical Classification of Diseases and Related Health Problems.

## SUMMARY

- Public education efforts help reduce the likelihood of exposure.
- Provision of basic management advice helps to diminish the consequences of a poisoning after an exposure has occurred.
- Reassurance and proper basic management help to curtail unnecessary concern, travel, and use of expensive health care.
- Interactions with health care professionals streamline the care of poisoned patients saving hospital days and health care expenditures.
- Collaboration with public health authorities identify, inform, and help mitigate the consequences of ongoing toxicologic events.
- Data on exposures have been effectively used to create legislation to further limit poisoning by altering contents or improving packaging or labeling.

# 131

# PRINCIPLES OF OCCUPATIONAL TOXICOLOGY: DIAGNOSIS AND CONTROL

Peter H. Wald

Three workers engaged in the production of mercuric acetate (Chap. 95) were admitted to the hospital within 22 calendar days of each other, 30, 48, and 5 days, respectively, after their last working day. The workers served the same reactor in which elemental mercury was oxidized by peroxide to mercuric oxide and mercuric acetate was formed by the reaction of mercuric oxide with acetic acid. They all presented with neurologic findings, including ataxia, dysarthria, tremor, deteriorating vision, and cerebellar signs. The first 2 workers had rapidly progressive downhill courses to coma that ended in death. The diagnosis of mercury vapor intoxication of the first 2 patients was established 21 and 16 days after their admission, when the third worker was admitted and hospitals were informed about their exposure. Blood mercury concentrations in all 3 patients were approximately 2,000 mcg/L with low urine mercury concentrations. All patients were chelated with penicillamine without any noticeable effect. Organic mercury probably was formed as an unintended byproduct of this reaction. In this reaction, methyl mercury acetate, which is 5.4 times more volatile than mercury vapor, could have been formed. The incorrect diagnosis of mercury vapor exposure in these cases was established even though (1) the observed signs of a rapid irreversible clinical course, ataxia, dysarthria, and constriction of visual fields are rarely present in mercury vapor poisoning and are characteristic of organic mercury poisoning; (2) the degree of deterioration after removal from exposure further implicated organic mercury, not mercury vapor; (3) blood mercury concentrations were in the range associated with severe poisoning in the Iraq methyl mercury epidemic; (4) patients had little response to treatment with penicillamine, the opposite of what is expected with mercury vapor; and (5) the blood-to-urinary mercury concentration ratios were high, but this ratio usually is less than 0.5 in mercury vapor toxicity or in workers exposed to mercury vapor. The other important facet of these cases is the public health implications of this sentinel health event. Three employees in this workplace were affected by this exposure. Further investigation of the workplace revealed that no other workers were affected but also that there were no changing facilities so employees wore their work clothes home. Investigation of their homes revealed elevated environmental mercury concentrations and elevated blood mercury concentrations in family members. Here, an occupational exposure became an environmental exposure for the community.

Many important problems are associated with the diagnosis and treatment of occupational and environmentally caused diseases, including (1) the ability to correctly establish the diagnosis as originating from an exposure, (2) the ability to correctly treat the condition, and (3) the ability to correctly act on any public health issues related to the exposure. The following discussion instructs clinicians on how to assemble adequate information to achieve the appropriate diagnosis and treatment.

## TAKING AN OCCUPATIONAL HISTORY

Because time spent at work is a large percentage of many people's day, the occupational health history should be a routine part of the medical history. This is especially true of patients who present to health care with potential xenobiotic exposures. The history should include several brief survey questions. Positive responses then lead to a more detailed occupational and environmental history, which is composed of 3 elements: present work, past work, and nonoccupational exposures.

### The Brief Occupational Survey

The following 3 questions should be incorporated into the occupational survey:

- Exactly what kind of work do you do?

- Are you exposed to any physical (radiation, noise, extremes of temperature or pressure), chemical (liquids, fumes, vapors, dusts, or mists), or biologic hazards at work (Table 131-1)?
- Are your symptoms related in any way to starting or being away from work? For example, do the symptoms start when you arrive at work at the beginning of the day or week or when you work at a specific location or during a specific process at work?

### Present Work

Collected data on a person's present job reveal what his or her present exposures may be, which can help formulate the differential diagnosis for the

**TABLE 131-1** Hazard Classes, Hazard Types, and Several Common Examples Found in the Workplace

Hazard Class	Hazard Type	Examples
Physical hazards	Human-machine interfaces	Repetitive motion Lifting Vibration Mechanical trauma, electric shock
	Physical environment	Temperature Pressure Long or rotating shifts
	Energy	Ionizing radiation: x-ray, ultraviolet Nonionizing radiation: infrared, microwave, magnetic fields Lasers Noise
Chemical hazards	Solvents	Aliphatics, alicyclics, aromatics, alcohols, ketones, ethers, aldehydes, acetates, peroxides, halogenated and nitrogen containing compounds
	Metals	Lead, mercury, cadmium
	Gases	Combustion products, irritants, simple and chemical asphyxiants, oxygen-deficient environments
	Dusts	Organic (wood) and inorganic (asbestos or silica), nano-materials
	Pesticides	Organic chlorine, organic phosphorus, carbamate
	Epoxy resins and polymer systems	Toluene diisocyanate, phthalates
Biologic hazards	Bacteria	<i>Bacillus anthracis</i> , <i>Legionella pneumophila</i> , <i>Borrelia burgdorferi</i>
	Viruses	Hepatitis, HIV, Hantavirus
	Mycobacteria	<i>Mycobacterium tuberculosis</i>
	Rickettsia and Chlamydia	<i>Chlamydia psittaci</i> , <i>Coxiella burnetii</i>
	Fungi	<i>Histoplasma capsulatum</i> , <i>Coccidioides immitis</i>
	Parasites	<i>Echinococcus</i> spp, <i>Plasmodium</i> spp, <i>Toxoplasma gondii</i>
	Envenomations	Arthropod, marine, snake
	Allergens	Enzymes, animals, dusts, insects, latex, plant pollen dusts

**TABLE 131–2** Components of an Occupational Health History

Current work history
Specifics of the job
Employer's name
Type of industry
Duration of employment
Employment location, hours, and shift changes
Description of work process
Unusual activities of the job that are occasional (eg, maintenance)
Adjacent work processes
Employee health, safety, or union contact if available; otherwise manager or supervisor
Hazardous exposures (Table 132–1)
Possible health effects
Suspicious health problems
Temporality of symptoms
Specific distribution of symptoms (rash, paresthesias)
Affected coworkers
Presence or absence of known risk factors (smoking, alcohol)
Workplace sampling and monitoring
Individual or area air monitoring
Surface sampling
Biologic monitoring
Medical surveillance records
Exposure controls
Administrative controls
Process engineering controls
Enclosure
Shielding
Ventilation
Electrical and mechanically controlled interlocks
Personal protective equipment
Respirators
Protective clothing
Earplugs, glasses, gloves, face shields, head and foot protection
Work history (prior)
Review current work history for all past employment
Nonoccupational exposures
Secondary employment
Hobbies
Outdoor activities
Residential exposures
Community contamination
Habits: tobacco, alcohol, other xenobiotics

employee's complaints. These data should be systematically collected by focusing on 4 areas: specifics of the job, hazardous exposures, health effects, and monitoring and control measures (Table 131–2).

### Specifics of the Job

It is not sufficient simply to inquire what the patient does for a living. Similar to health care professionals, workers in other industries have their own jargon. When asked for a job title, a patient may respond with a title that has meaning only in his or her trade. Even if the job title is recognizable, it may not provide any useful information and, in fact, may be misleading. A secretary working in a small plastics manufacturing plant has potential occupational exposures that are quite different from a secretary who works for a law firm.

The important specific information requested should include the name of the employer, type of industry, duration and location of employment,

hours and shift changes, process description (including unusual occasional activities), and adjacent processes. The employer should be able to provide information about materials used at the plant. However, clinicians should always obtain the patient's permission before calling the employer. A patient may be fired or otherwise discriminated against (despite legal protections) for suggesting that health problems are work related.

For patients in whom exposures are expected, it is important to question more closely to learn precisely what happens in the patient's immediate work environment because nearby work processes may contribute other exposures. If possible, the patient should be asked for a diagram of the work area. The patient also should be questioned about job process changes. A previously safe job may have been changed to a potentially dangerous job without a change in the patient's job title.

The patient should describe exactly what he or she does on any given day and for how long. Unusual and nonroutine tasks, such as those performed during overtime, maintenance, or in an emergency, should also be described. The primary job may not involve xenobiotics, but the patient may nevertheless perform tasks that entail unprotected exposure to a toxic xenobiotic.

### Hazardous Exposures

The names or types of all xenobiotics to which the patient may be exposed are important in determining potential adverse effects and any relationship to the patient's complaints. It is important to elicit any recent changes in suppliers of these products because even a slight change in the formulation of a xenobiotic may cause adverse effects in an individual who previously had no problems working with that xenobiotic. This information should be obtained from the material safety data sheet (MSDS), an important but not universally reliable source of information. In addition to adverse health effects, the MSDS contains information on chemical reactivity, safety precautions, and other data. As an initial step, the MSDS should be requested and reviewed; however, information provided on health effects should be confirmed using other resources. Four major concerns result from relying solely on the MSDS: (1) some MSDS forms are excellent, but others are incomplete and inadequate; (2) components of a product that are regarded as "trade secrets" do not have to be revealed; (3) components that have important health effects (eg, solvent or solid carriers of the "active ingredients") are often grouped together under "inert ingredients" without being specifically named; and (4) process intermediates or unintended byproducts of a manufacturing process are often not identified. However, if a xenobiotic is believed to be related to a health effect, manufacturers are required to release to a physician all information, including trade secrets and inert components.

Exposures to physical and biologic xenobiotics can be elicited during the review of job processes. Most patients know what they are, or have been, exposed to, even if they do not know the exact name of the xenobiotics or its medical effects.

### Health Effects

Significant occupational exposures usually cause medical effects, although some do so only after a substantial latency period. Key areas of inquiry include suspicious health problems, temporality of symptoms, and affected coworkers. These data, combined with workplace monitoring and sampling data, may help in determining whether the patient is experiencing a work-related illness (Table 131–3). Patients may suspect that their illness or complaint is work related, especially when symptoms occur at the workplace and improve or disappear over the weekend or during a vacation. Specific distribution of findings, such as a rash in a bilateral glove pattern, is supportive of an occupational cause. Coworkers with similar complaints (not necessarily of the same severity) should raise suspicion that a workplace exposure is responsible for a particular symptom complex. Diseases such as lung cancer or hepatitis, which occur in the absence of known risk factors such as smoking and alcohol, must be epidemiologically investigated.

**TABLE 131–3** Evidence Supporting Work-Relatedness of Occupational Disease

Known or documented exposure to a causative xenobiotic
Symptoms consistent with suspected workplace exposure
Suggestive or diagnostic physical signs
Similar problems in coworkers or workers in related occupations
Temporal relationship of complaints related to work
Confirmatory environmental or biologic monitoring data
Scientific biologic plausibility
Absence of a nonoccupational etiology
Resistance to maximum medical treatment because employee continues to be exposed at work

### Workplace Sampling, Monitoring, and Control

Control of workplace hazards begins with an industrial hygiene monitoring program. Employers are required to give results of both area and individual sampling to employees, and these results are potentially valuable to associate presenting symptoms to a workplace exposure. A medical surveillance program that includes periodic spirometry and respiratory questionnaires usually indicates that the patient works with a potential respiratory toxin. A medical surveillance program that includes biologic monitoring for a specific xenobiotic may also provide an immediate clue to the cause of the patient's complaints. Finally, if the patient knows exactly what he or she is working with, the physician can usually quickly determine whether any of the xenobiotics are compatible with the patient's complaints. Many companies do not perform routine industrial hygiene monitoring or medical surveillance. Individuals who become sick or ill at work are often sent to local emergency departments (EDs). In such situations, emergency physicians will need to perform the type of time-consuming, detailed occupational history outlined here or be able to consult or refer immediately to appropriate physicians or clinics.

Portions of [Table 131–2](#) and the following section on Evaluation and Control of Workplace Hazards detail the types of controls typically used in workplaces. It is important to determine whether the workplace uses any of the listed control measures. The existence of control measures usually indicates that the employer recognizes and has attempted to deal with a hazardous exposure.

### PAST WORK

It is important not to limit the occupational history to the patient's current workplace and job. Many occupational diseases (asbestosis is the classic example) have long latency periods between xenobiotic exposure and initial development of clinical symptoms. In addition, patients may have been exposed to xenobiotics at work that make them more sensitive to other environmental xenobiotics. For example, someone who developed asthma secondary to a previous workplace exposure may have asthma attacks on exposure to simple irritants in the current workplace. When taking an in-depth occupational history, issues that may be relevant to the current work history as well as for each previous job should be explored.

### Nonoccupational Exposures

Workers may be exposed to toxic xenobiotics in the course of pursuing secondary employment, hobbies such as using lead solder for stained glass or electronics or outdoor activities in contaminated or industrial areas. Residential exposures, such as those from gas and wood stoves, chemically treated furniture and fabrics, and pest control, are also relevant. It is important to ask patients about these potential exposures before focusing entirely on exposures in their primary place of employment. This obviously includes relevant issues from the social history, such as tobacco, alcohol, and both licit and illicit drug use.

## EVALUATION AND CONTROL OF WORKPLACE HAZARDS

### Initial Workplace Evaluation

The Occupational Safety and Health Administration (OSHA) places legal responsibility for providing a safe and healthy workplace on the employer.

The rationale for this placement of responsibility is that the employer is in the best position to make any modifications necessary to prevent additional work-related illness and injury. The physician will likely need to initiate a dialogue with a patient's employer to promote preventive action but should do so only with the patient's informed consent. The initial treating physician should also refer the patient to an occupational medicine specialist who is specifically trained to manage work-related exposures and diseases and initiate prevention programs.

It is important for the health care provider to identify an individual with an appropriate administrative role, such as someone in the company's medical department, the patient's supervisor, the plant's safety officer, or the shop manager. If management is willing, a plant walk-through inspection can provide unique insight and information usually unavailable in an office setting. A walk-through by an occupational medicine specialist makes it easier to understand the work environment, identify safety and health hazards, assess control measures, and recognize opportunities for prevention. It also facilitates a good working relationship with key personnel in management and labor. The physician, who cares for a number of patients who work in the plant or who provides health services to the workers through the company or labor union, should be invited to participate in the walk-through. Assistance with plant inspections can be obtained from occupational health specialists, such as occupational physicians or industrial hygienists.

### Industrial Hygiene Sampling and Monitoring

Equipment is available to measure airborne concentrations of toxic xenobiotics, noise levels, radiation levels, temperature, and humidity. Employees can be fitted with pumps and other devices to measure individual exposure concentrations at the breathing zone, where, depending on what controls are used, concentrations may vary from those in the general work area. These results then can be compared with OSHA standards and other available standards to help determine the extent of the hazard and to formulate a control plan. The Occupational and Safety Health Act requires that employers monitor the concentrations of only a few specific hazards, including arsenic, asbestos, benzene, cadmium, chromium, cotton dust, ethylene oxide, formaldehyde, lead, noise, and vinyl chloride. A complete listing of all xenobiotics is available in the OSHA standard *29 CFR 1910 Part Z—Toxic and Hazardous Substances* ([http://www.osha.gov/pls/oshaweb/owastand.display\\_standard\\_group?p\\_toc\\_level=1&p\\_part\\_number=1910](http://www.osha.gov/pls/oshaweb/owastand.display_standard_group?p_toc_level=1&p_part_number=1910)). In addition, monitoring is required for certain tasks such as hazardous waste operations or entering a confined space that may have an oxygen-deficient atmosphere. Ongoing sampling of the remaining estimated 60,000 xenobiotics used in the workplace is not required. Where industrial hygiene sampling is performed, OSHA's medical access standard gives any exposed worker or his or her representative the right to review and copy all sampling data.

### Control of Workplace Exposures

Control of exposures in the workplace has traditionally relied on a hierarchy of methods to protect workers. The preferred solution is complete elimination of the exposure by substitution. When substitution is not possible, the next preferred method consists of shielding for workers to reduce their exposure. The least favored method is personal protective equipment (PPE), which requires a positive action from the worker.

### Engineering Controls

Health and safety professionals prefer—and OSHA regulations require when feasible—the use of engineering controls to reduce worker exposure to hazardous xenobiotics. These controls intercept hazards at their source or in the workplace atmosphere before they reach the worker. Engineering controls include redesign or modification of process or equipment to reduce hazardous emissions; isolation of a process through enclosure or shielding; and automation of an operation; and installation of exhaust systems that remove hazardous dusts, fumes, and vapors. Local exhaust systems, such as hoods, are preferable to general dilution ventilation because the former removes contaminants closer to their source and at relatively high rates.

Engineering controls have several advantages over control measures focused on the worker. Properly installed and maintained engineering controls are reliable and consistent, and their effectiveness does not depend on human supervision or interaction. They can simultaneously limit exposure through several routes, such as inhalation and skin absorption. In addition, engineering controls do not place a burden on the worker or interfere with worker comfort or safety.

### Work Practices

Work practices are procedures that the worker can follow to limit exposure to hazardous xenobiotics. Examples are the use of high-powered vacuum cleaners instead of compressed air cleaning and pouring techniques that direct hazardous xenobiotics away from the worker. Although not as effective as engineering controls, work practice can be a useful component of an overall hazard control program.

### Administrative Controls

Administrative controls reduce the duration of exposure for any individual worker or reduce the total number of workers exposed to a hazardous xenobiotic. Examples are rotating workers into and out of hazardous areas so that no single worker is exposed full time and specific scheduling of procedures likely to generate high concentrations of xenobiotics, such as cleaning or maintenance activities, occurs during nights or weekends. Administrative controls sometimes have the side effect of exposing more workers, albeit at lower doses that limit exposures below action levels.

### Personal Protective Equipment

Personal protective equipment, such as respirators, earplugs, gloves, and hard hats, is the least effective but most commonly used control method. Personal protective equipment is the only viable protection strategy when other controls are not practical but can also be used as an additional layer of protection in the presence of engineering controls. Some employers favor PPE over the institution of more costly engineering and administrative controls. Programs that use PPE should have additional Industrial Safety and Hygiene staff or resources to ensure the programs are properly designed and administered.

Respirators and other forms of PPE often are hot, uncomfortable, and awkward to wear and make it difficult for workers to breathe, speak, or hear, depending on the equipment involved. Consequently, workers often remove or only intermittently use the protection. Respirators place extra stress on the heart and the lungs. Both respirators and earplugs limit conversation and therefore present a safety hazard in themselves.

Because PPE does not stop a hazard from entering the environment, the worker is entirely vulnerable to exposure if the equipment fails. In addition, generally only one route of exposure is protected. For example, the commonly used half-mask respirator still leaves the skin and eyes exposed.

Choosing the right piece of PPE is difficult and depends on the nature and extent of the hazard. For example, each type of respirator is rated for the amount of protection it provides; as expected, the cost of a respirator increases with its protection factor. Use of the wrong type of respirator will leave the worker insufficiently protected.

Half-mask respirator cartridges are available in various colors that are coded to the xenobiotic filtered out of the breathing environment. If the wrong cartridge is used, the worker is unprotected from the hazardous contaminant. To be effective, a respirator must be meticulously “fit” to the individual worker. Failure to achieve a proper seal negates the usefulness of respirators. High cheekbones, dentures, scars, perspiration, talking, head movements, and facial hair can prevent a proper seal. These factors often are ignored or overlooked by an employer who adopts a “one-size-fits-all” policy.

Even if each employee is provided the proper respirator, the respiratory protection program may not be effective. The Occupational Safety and Health Act requires that employers institute a program of proper fit testing, cleaning, maintenance, and storage of respirators, which can be at least as costly as the institution of engineering controls.

In some instances, use of PPE may be unavoidable. An employer may need to control a hazardous exposure through a combination of measures, such as engineering controls and PPE. Ideally, the employer is using PPE as a control of last resort and in strict compliance with OSHA standards.

### Worker Education and Training

Regardless of the control measures used, workers and supervisors must be educated in the recognition and control of workplace hazards and the prevention of work-related illness and injury. The OSHA Hazard Communication Standard (Table 131–4) requires that employers train workers in ways to detect the presence or release of hazardous xenobiotics, their physical and health hazards, methods of protection against the hazards, and proper emergency procedures, as well as how to read the labeling system and how to read and use an MSDS.

With the passage of federal, state, and local right-to-know laws, many consulting companies now offer hazard communication training. These programs are of uneven quality. Those that tend to focus on acute hazards, ignore chronic effects, and emphasize PPE over other control measures are less effective in both training workers to recognize hazards and ultimately controlling hazardous workplace exposures.

### Medical Monitoring

Together with industrial hygiene monitoring, exposure control, and worker education, a medical monitoring program forms the foundation of an effective occupational disease prevention regimen. However, medical monitoring is fraught with technical and ethical pitfalls (Table 131–5). Medical monitoring encompasses both medical screening and medical surveillance.

*Medical screening* refers to the cross-sectional testing of a population of workers for evidence of excessive exposure or early stages of disease, regardless of relationship to work, that potentially influences the ability to tolerate or perform work.

Preemployment and preplacement physical examinations are another type of medical screening that are often favored by employers. The Americans with Disabilities Act (ADA) and the newer ADA Amendments Act of 2008 (ADAAA) (Table 131–4) regulate the timing, scope, content, and use of these examinations and the information gathered. Comprehensive resources for information on the ADA are available at <http://www.adata.org>. The ADA prohibits “preemployment” medical examinations and inquiries. After a job offer is made, “preplacement” examinations and inquiries can be conducted to determine whether an applicant can perform a job safely and effectively. The physician evaluates the individual’s medical history, current symptoms, and physical laboratory findings to determine whether he or she currently has the physical or mental capacity necessary to perform the essential functions of the job and whether the individual can do so without posing a “direct threat” to the health or safety of him- or herself or others. This threat must be more than theoretical and cannot be based on some future time; the threat must be concrete and relatively immediate.

Few tests and few conditions are good predictors of either the capacity to perform a task or increased susceptibility to a particular exposure. Many workers and their advocates view preplacement examinations as a way for employers to choose the “fittest” worker and to avoid their legally mandated obligation to provide a safe and healthy workplace for all workers. This is not true for most employers. Physicians asked by an employer to perform preplacement examinations should be sure that each component of the examination relates to the actual job the individual is being hired to perform and the actual risks he or she will encounter on the job. Both the law and sound occupational medical practice dictate that the employer’s attention and efforts be directed toward redesign of the job and its hazards so that it is safe and healthy for all workers to perform.

*Medical surveillance* refers to the ongoing evaluation, by means of periodic examinations, of high-risk individuals or potentially exposed workers to detect early pathophysiologic changes indicative of significant exposure. The Occupational Safety and Health Act requires little in the way of medical surveillance, although several OSHA standards require employers to institute

**TABLE 131–4** Government Agencies and Their Important Regulatory Authority of the Workplace—A Timeline

Regulation	Agency	Authority
Occupational Safety and Health Act (1970)	Department of Labor	<p>Congress passed the Occupational Safety and Health Act and created the Occupational Safety and Health Administration (OSHA) to ensure worker and workplace safety. The goal was to make sure employers provide their workers a place of employment free from recognized hazards to safety and health, such as exposure to toxic xenobiotics, excessive noise levels, mechanical dangers, heat or cold stress, and unsanitary conditions.</p> <p>To establish standards for workplace health and safety, the Act also created the National Institute for Occupational Safety and Health (NIOSH) as the research institution for the Occupational Safety and Health Administration. Part 1910.1200 of OSHA established the Hazard Communication Standard (HazCom). The purpose of this section is to ensure that the hazards of all xenobiotics produced or imported are evaluated and that information concerning their hazards is transmitted to employers and employees. This transmittal of information is to be accomplished by means of comprehensive hazard communication programs, which are to include container labeling and other forms of warning, material safety data sheets, and employee training.</p>
Resource Conservation and Recovery Act (RCRA, 1976)	Environmental Protection Agency (EPA)	<p>RCRA (commonly pronounced “rick-rah”) gave the EPA the authority to control hazardous waste from “cradle to grave.” This includes the generation, transportation, treatment, storage, and disposal of hazardous waste. RCRA also set forth a framework for the management of nonhazardous wastes. The 1986 amendments to RCRA enabled the EPA to address environmental problems that could result from underground tanks storing petroleum and other hazardous xenobiotics. RCRA focuses only on active and future facilities and does not address abandoned or historic sites (see CERCLA).</p>
Hazardous and Solid Waste Amendments (HSWA, 1984)		<p>HSWA (commonly pronounced “hiss-wa”), the Federal Hazardous and Solid Waste Amendments, are the 1984 amendments to RCRA that required the phasing out of land disposal of hazardous waste. Some of the other mandates of this strict law include increased enforcement authority for the EPA, more stringent hazardous waste management standards, and a comprehensive underground storage tank program.</p>
Toxic Substances Control Act (TSCA, 1976)	EPA	<p>TSCA was enacted by Congress to give the EPA the ability to track the 75,000 industrial xenobiotics currently produced or imported into the United States. The EPA repeatedly screens these xenobiotics and can require reporting or testing of those that may pose an environmental or human health hazard. The EPA can ban the manufacture and import of xenobiotics that pose an unreasonable risk.</p> <p>Reporting requirements include (1) premanufacturing notification for new xenobiotics, (2) allegation of significant adverse reactions, (3) reporting of health and safety studies, and (4) notification of suspicion of substantial risk to health.</p>
Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, 1980)	EPA	<p>CERCLA, commonly known as the Superfund Act, was enacted by Congress on December 11, 1980. This law created a tax on the chemical and petroleum industries and provided broad federal authority to respond directly to releases or threatened releases of hazardous xenobiotics that may endanger public health or the environment. Over 5 years, \$1.6 billion was collected, and the tax went to a trust fund for cleaning up abandoned or uncontrolled hazardous waste sites. CERCLA (1) established prohibitions and requirements concerning closed and abandoned hazardous waste sites, (2) provided for liability of persons responsible for releases of hazardous waste at these sites, and (3) established a trust fund to provide for cleanup when no responsible party could be identified.</p> <p>The law authorizes 2 types of response actions: (1) short-term removals, in which actions may be taken to address releases or threatened releases requiring prompt response, and (2) long-term remedial response actions that permanently and significantly reduce the dangers associated with releases or threats of releases of hazardous xenobiotics that are serious but not immediately life threatening. These actions can be conducted only at sites listed on the EPA’s National Priorities List (NPL).</p>
Superfund Amendments and Reauthorization Act (SARA, 1986)	EPA	<p>SARA reflected the EPA’s experience in administering the complex Superfund program during its first 6 years and made several important changes and additions to the program. SARA (1) stressed the importance of permanent remedies and innovative treatment technologies in cleaning up hazardous waste sites, (2) required Superfund actions to consider the standards and requirements found in other state and federal environmental laws and regulations, (3) provided new enforcement authorities and settlement tools, (4) increased state involvement in every phase of the Superfund, (5) increased the focus on human health problems posed by hazardous waste sites, (6) encouraged greater citizen participation in making decisions on how sites should be cleaned up, and (7) increased the size of the trust fund to \$8.5 billion. SARA also required the EPA to revise the Hazard Ranking System (HRS) to ensure that it accurately assessed the relative degree of risk to human health and the environment posed by uncontrolled hazardous waste sites that may be placed on the NPL. Emergency Planning and Community Right-to-Know Act (EPCRA), also known as Title III of SARA, was enacted by Congress as the national legislation on community safety. This law was designated to help local communities protect public health, safety, and the environment from xenobiotic hazards. The law requires manufacturers to report the amount of toxic xenobiotics released each year (Toxic Release Inventory {TRI}).</p> <p>To implement EPCRA, Congress required each state to appoint a State Emergency Response Commission (SERC). The SERCs were required to divide their states into Emergency Planning Districts and to name a Local Emergency Planning Committee (LEPC) for each district.</p>
Americans with Disabilities Act (ADA, 1990) and the ADA Amendments Act of 2008 (ADAAA)	Department of Labor	<p>The ADA was enacted by Congress to establish clear and comprehensive prohibition of discrimination on the basis of disability. The act specifically covers discrimination in the areas of (1) employment, (2) public services, (3) public accommodations and services operated by private entities, and (4) telecommunications. The ADAAA reaffirms Congress’ initial intent of the 1990 law to (1) broadly define “disability,” (2) use the definition of “handicapped individual” under the Rehabilitation Act of 1973 and (3) state that mitigating measures (eg, insulin for diabetes) shall not be a factor when determining whether an impairment substantially limits a major life activity. The final regulations for the Act were published in the Federal Register in March 2011. <a href="http://www.eeoc.gov/laws/regulations/adaaa_fact_sheet.cfm">http://www.eeoc.gov/laws/regulations/adaaa_fact_sheet.cfm</a>.</p>

**TABLE 131–5 Ethical Code of Conduct****Occupational and environmental health professionals have an obligation to:**

- Promote a safe and healthy workplace environment.
- Uphold ethical standards.
- Avoid discrimination.
- Maintain professional competence.
- Protect patient confidentiality.
- Advise and report significant individual and population health while respecting confidentiality.
- Directly address and disclose conflict of interest issues.

Data from American College of Occupational and Environmental Medicine. Code of Ethics: 2010. <http://www.acoem.org/codeofconduct.aspx>.

medical surveillance programs, for example, for workers exposed to asbestos, arsenic, cadmium, chromium, vinyl chloride, lead, and ethylene oxide. Depending on the potential exposure, medical surveillance may include a history and physical examination, chest radiography, pulmonary function tests, blood and urine tests, and other laboratory evaluations.

A medical surveillance program may also include biologic monitoring, the purpose of which is not to identify the occurrence of disease but to measure the uptake or presence of a particular xenobiotic or its metabolites in body fluids or organs. Ideally, this occurs before any pathophysiologic damage occurs. Consequently, biologic monitoring is potentially a primary preventive measure. For example, several volatile organic compounds, such as benzene and toluene, if inhaled or absorbed through the skin, produce metabolites that can be measured in urine.

Biologic monitoring has some advantages over air monitoring because biologic monitoring measures the *actual* absorption of a xenobiotic by the body as opposed to ambient concentrations in the workplace. The amount of a chemical absorbed may not be closely correlated to ambient xenobiotics for several reasons, including differences in individual work habits, use and effectiveness of PPE, dermal absorption of xenobiotics unrelated to their concentration in the air, and nonoccupational exposures.

Biologic monitoring, however, has several significant limitations. For most xenobiotics, there are no standards of “normal” or “safe” concentrations against which results can be compared. The timing of specimen collection is critical because different xenobiotics have different biologic half-lives. The storage and handling of specimens and interpretation of results are vulnerable to error. Nevertheless, if carefully designed and implemented, biologic monitoring can be a useful complement to a comprehensive industrial hygiene program.

With the exception of biologic monitoring, medical monitoring programs identify disease processes already underway and therefore are, at best, a form of secondary prevention. If workers are identified as having higher than acceptable exposures, they should be removed from exposure with continuing pay while their internal concentrations decline and while the employer investigates any potential breakdown in the workplace controls. To be an effective preventive measure, these programs must be coordinated with environmental monitoring programs that identify the nature, source, and extent of workplace hazards; implementation of engineering controls and other measures that control hazards as close as possible to the source; and worker education programs that, at a minimum, inform workers of exposures, their effects, and proper control measures.

## ETHICAL ISSUES

Physicians delivering occupational medicine services are required to fulfil many often-conflicting roles, including caring for individual employees, protection of groups of employees, ensuring a safe workplace, carrying out mandated regulatory examinations, and confirming the effectiveness of workplace hazard controls. The physician’s first role is to do good for the patient or population he or she charged with protecting. [Table 131–5](#) outlines the 7 critical behaviors required for ethical practice

as adopted by the American College of Occupational and Environmental Medicine Medical monitoring programs<sup>1</sup> and preplacement examinations discussed earlier raise issues of doctor–patient confidentiality. Other potential conflicts include access to employee medical records, which should be available only to the corporate medical or first aid department and not to the personnel office and general management. Unless required by statute, employers should never be told the results of history, physical, or diagnostic examinations unless the patient gives his or her written consent. The examining physician need only inform the employer that an individual is or is not capable of performing a particular job with or without specified restrictions. The physician should not disclose diagnostic information about medical conditions. The complex roles of occupational medicine physicians and medical toxicology consultants also require the fulfillment of several additional obligations, which are detailed next.

### Obligations of the Health Care Provider to the Individual Patient, Coworkers, Employer, Government, and Community

Occupational diseases and injuries are, in principle, preventable. Physicians who diagnose a work-related disease or injury have an opportunity and an ethical obligation to participate in the identification and control of workplace hazards and the prevention of further occupational illness and injury. Physicians can choose from a range of possible follow-up measures, the goals of which are to prevent recurrence or worsening of the disease or injury in the patient and to prevent the development of disease or injury in other potentially exposed workers. Some of these activities may necessitate contact with occupational medicine physicians, medical toxicologists, industrial hygienists, lawyers, journalists, government officials, management personnel, and union officials.

### Obligations to the Patient

#### Inform the Patient That the Illness May Be Work Related

When the workplace is determined to be a factor in the etiology or aggravation of the patient’s illness, this fact and its implications should be discussed with the patient. It should never be assumed that the patient is fully aware of the health risks associated with any workplace exposure. The worker should be provided information regarding the nature of workplace hazards, their health risks, preventive measures, and recommendations regarding continued exposure.

#### Suggest How the Patient Can Reduce the Exposure

In some cases, the patient should take steps to reduce exposure. Helpful adjustments in work habits include using a respirator or other PPE provided by the employer; using workplace shower and dressing or change rooms to avoid carrying xenobiotics from the workplace to the home; and avoiding ingestion of workplace xenobiotics by careful hand washing before eating or smoking and by taking lunch, coffee, and smoking breaks away from the work station. Obviously, these recommendations assume that the employer provides the appropriate equipment and facilities, which is not always the case. The most effective hazard control measures require significant commitment by, and cooperation from, the employer.

#### Suggest That the Patient Remove Him- or Herself From the Exposure

The employer may be willing to transfer the patient to a location away from the offending hazard. This may result in a reduction in pay, seniority, or other benefits, which may be compensable under workers’ compensation. The employment provisions of the ADA require employers to make “reasonable accommodations” for both work- and non-work-related disabilities. Nevertheless, the employer may not be able to accommodate the patient. The patient should be counseled carefully, and other options should be explored.

#### Advise the Patient to Notify the Employer

Patients who are experiencing a work-related illness may be entitled to workers’ compensation benefits, Social Security disability, or other government-sponsored benefit programs. In addition, they may have a valid claim against

the manufacturer of a xenobiotic, a defective product, or another third party. The degree of disability necessary to bring a successful claim varies.

After a patient is informed that he or she has a work-related illness, strict time limits are set in motion, and failure to meet them can preclude the patient from successfully filing a claim or receiving needed benefits. The patient should be advised to provide written notice immediately to his or her employer of a work-related illness (supported by a physician's letter) and to seek advice about statutes of limitations and other requirements. This information is generally available from the State Workers' Compensation Board and is usually required to be provided to the employee by the employer. If a union is available at the workplace, it may be able to advise and assist the patient.

### Obligations to Coworkers

A patient with a work-related illness should be advised to inform his or her coworkers about the condition. If the patient belongs to a union, he or she should inform the union representative. If there is no union, the patient may contact OSHA or discuss the situation with the employer.

If the patient is a union member and agrees, the physician can contact the union, which may assist in hazard investigation, identify and warn other workers potentially affected by the hazard, and engage with the employer to take corrective action. The union can help the patient obtain any available benefits.

State based Committees on Occupational Safety and Health (COSH) are coalitions of labor, health, legal professionals, and community and environmental activists working to prevent job-related illnesses and injuries. These groups provide education and technical assistance nationwide on a range of topics, including the health effects of specific hazards, control measures, how to use government agencies, and the legal rights of disabled workers.

### Obligations to Notify the Government

Some states have laws that require direct physician reporting of occupational disease. In addition to the federal agencies specifically empowered to protect worker health and safety, physicians may contact the state or local health department, which may initiate action or refer the problem to one of the federal agencies. Many states also require physicians to report any occupational injury or illness to the workers' compensation carrier.

### Obligation to Notify the Employer

When treating a patient with an occupational injury or illness, health care providers often are required to report to government agencies, health departments, or insurance carriers. As part of that reporting process, the employer should also be notified. When there is imminent danger to coworkers or the public health, the employer should be contacted to correct the exposure situation.

### Obligation to Inform Colleagues and the Public

On occasion, an individual primary care physician or specialist is the first person to suspect a link between a workplace exposure and a serious health problem. This discovery is often referred to as a "sentinel health event." Armed with an increased index of suspicion and the occupational history, the physician will be able to alert workers and companies and prevent the occurrence of a major health problem. Even if the physician chooses not to be involved in subsequent investigation or research, it is important that information about suspected problems and hazards be made available to researchers, workers and employers in similar industrial settings, government agencies, health care professionals.

## INFORMATION RESOURCES

Health care professionals require information on industrial toxins in a number of situations, ranging from caring for an acutely ill patient in an ED, when information must be obtained quickly, to caring for a patient with chronic symptoms that may reflect an occupational disease. However, the use of information resources depends on the proper identification of the xenobiotic in question. If the xenobiotic, its generic name, and ingredients are not known, diagnostic and treatment become more difficult.

The practitioner should take a logical approach to seeking information about industrial xenobiotics. First, the xenobiotic must be identified by its generic name. This can be done by reviewing the MSDS or by contacting poison control centers (PCCs), the employer, manufacturer, unions, or government agencies. Material Safety Datasheets also are available by searching online. A good starting point to find MSDSs on the Internet is <http://www.ilpi.com/MSDS/index.html>, but typing "MSDS" into any online search engine yields a number of sites offering data sheets.

### Poison Control Centers

Regional PCCs are able to provide assistance even when the exact chemical name is unknown because information on xenobiotics and their management are cross-referenced by trade name and manufacturer. Moreover, specialists in poison information can usually suggest additional resources. Most PCCs have computerized listings of poisons that are updated regularly. The best-known system is POISINDEX (Truven Health Analytics, Ann Arbor, MI). Subscribers to this system receive quarterly updates of an alphabetically organized listing of approximately 500,000 industrial and nonindustrial xenobiotics. The system includes trade names, the components, and the concentrations, when available, of each xenobiotic listed. These elements are then cross-referenced to management protocols. The name of the manufacturer is also listed and often includes emergency contact numbers if additional information is required.

### Employers and Manufacturers

Many state and federal laws require manufacturers to generate, retain, and disclose information that may help physicians care for persons with work-related health problems. Scientific information, exposure data, information on health effects, and collected medical data are included in the types of information that must be retained.

The Chemical Transportation Emergency Center (CHEMTREC; 800-424-9300; <http://www.chemtrec.com>), sponsored by the Chemical Manufacturers Association, has as its primary responsibility providing information to health care practitioners responding to hazardous spills. However, it also provides information on commercial products found in patients' workplaces. Employers are required to furnish this information to employees in the form of MSDSs.

### Workers' Compensation Insurance Carriers

Smaller companies often lack internal health and safety staffs. Workers' compensation or company risk insurance carriers may have valuable information about exposures and controls in the workplace. As a service to their clients, carriers often do walk-throughs and hazards evaluations for clients that lack these resources and suggest appropriate engineering controls. Health care professionals can contact the carrier directly to see what additional information is available.

### Regulatory Agencies

The Occupational Safety and Health Act requires chemical manufacturers to create an MSDS for each chemical they produce, and employers who use chemicals must retain the MSDSs in the workplace. Required information includes xenobiotic and common names; physical, safety, and health hazard data; exposure limits; precautions for safe handling and use; generally applicable control measures; and emergency and first aid procedures. The OSHA Hazard Communication Standard requires individual employers to provide employees with information on the xenobiotics used in their workplaces. A call to the plant manager, foreperson, or safety officer may be all that is necessary to determine the name of the xenobiotic in question. Employers may be able to provide information on exposure concentrations in the patient's work environment. In addition, company medical departments (where they exist) may have results of medical testing performed on the patient.

There is an important point to reiterate about MSDSs: health care providers should not rely on these sheets as the sole source of information. The MSDSs are created by the chemical manufacturers as they generate scientific

and health data during the course of seeking approval from the Environmental Protection Agency (EPA) to manufacture xenobiotics, and they are not a complete product evaluation. In addition, Section 8(c) of the Toxic Substances Control Act (TSCA) requires chemical manufacturers to report records of significant adverse reactions to human health or the environment. When contacting chemical manufacturers, physicians should ask to speak with a toxicologist, chemist, or someone in the products information department.

## Unions

When available, labor unions can be excellent sources of information on xenobiotic exposures. At the local level, union officers, health and safety committee members, and shop stewards may be able to provide MSDSs, exposure data, medical and epidemiologic information, and reports of incidents or cases of interest in a particular plant. The health and safety department of the American Federation of Labor and Congress of Industrial Organizations (<http://www.aflcio.org/Issues/Job-Safety>) in Washington, DC, can provide information on occupational health and safety activities and advice on which member unions may be of specific help. At the international level, unions often have well-trained health and safety professionals who may provide or suggest sources of helpful information (<http://www.ilo.org/global/topics/safety-and-health-at-work/lang-en/index.htm>). In addition, some cities and states (<http://www.nycosh.org>) have a coalition of occupational safety and health groups that may provide information about other known exposed or affected workers.

## Government Agencies

A myriad of agencies have some regulatory authority over manufacturing and services industries. These agencies and their important regulatory authority are listed in [Table 131-4](#).

The Occupational Safety and Health Act of the U.S. Department of Labor (<http://www.osha.gov>) is responsible for setting and enforcing workplace health and safety standards. It is empowered to investigate occupational health and safety complaints and can inspect work sites and levy fines for violations of its standards. In approximately half of the 50 states, the OSHA program is implemented by a state agency. Individual workers, their representatives (unions), or their physicians can file a complaint with the state or federal OSHA program and request an inspection. The clinician may file a complaint with OSHA concerning a hazardous working condition at any time through the OSHA web site at [https://www.osha.gov/workers/file\\_complaint.html](https://www.osha.gov/workers/file_complaint.html). Last accessed July 10, 2018. In an emergency, such as reporting an imminent life threatening situation, contact OSHA immediately using the toll free number 800-321-OSHA (6742) or TTY 877-889-5627. The Occupational Safety and Health Act regulations protect workers from discrimination and punishment by their employer, who may be angered by their filing a complaint.

Some state OSHA agencies have separate enforcement and consultation arms. Thus, companies can request assistance from the occupational health specialists in the consultation branch without fear of reprisal from the enforcement branch. Health care workers should be familiar with the functions of their state agency and workers' rights under the law.

The National Institute for Occupational Safety and Health (NIOSH) of the U.S. Department of Health and Human Services is part of the Centers for Disease Control and Prevention (<http://www.cdc.gov/niosh>). The National Institute for Occupational Safety and Health is not a regulatory agency and is responsible for researching the causes of occupational disease and injury and methods for their prevention and control, evaluating workplace conditions, recommending exposure limits to OSHA for standard setting, and training occupational health and safety professionals. It is empowered to conduct onsite evaluations of health hazards in response to requests from employee representatives or employers. After conducting these evaluations, NIOSH investigators immediately contact OSHA, the employees, and the employer if they find that the workers are in imminent danger.

As part of the process of recommending exposure standards to OSHA, NIOSH develops comprehensive documents that critically evaluate all available scientific data on particular xenobiotics. These "criteria documents"

review the chemical's properties, production methods, uses, and workers at risk as well as studies of exposure effects in humans and animals. Methods of screening, surveillance, and control are presented. The agency periodically issues technical reports and special occupational hazard reviews of specific occupations. In conjunction with OSHA, NIOSH develops and disseminates health hazard alerts to inform employers, employees, and health care professionals of serious health effects of particular xenobiotics.

The EPA (<http://www.epa.gov>) is charged with protecting the land, air, and water of the nation. The agency administers a number of laws designed to preserve the public health and environment, one of which is the TSCA. This act authorizes the EPA to collect information on xenobiotic risks from manufacturers and processors and to review information on new xenobiotics and new uses of xenobiotics before they are manufactured. Unless designated a trade secret, this information is subject to disclosure and therefore is available. The TSCA assistance office may be most useful when resource materials and government documents contain no information about the xenobiotics or processes in question.

The National Toxicology Program (<http://ntp.niehs.nih.gov>) is a federal program established in 1978 to develop scientific information on exposure to xenobiotics. The Agency for Toxic Substances and Disease Registry (ATSDR; <http://www.atsdr.cdc.gov>) was created by Congress in the Comprehensive Environmental Response, Compensation and Liability Act of 1980 (also known as Superfund Act) to implement the health-related sections of laws that protect the public from hazardous wastes and environmental spills of hazardous substances. In 1986, the Superfund Amendments and Reauthorization Act made amendments to the initial enabling legislation of 1980 and broadened the responsibilities of the ATSDR in the areas of health assessment, toxicologic databases, information dissemination, and medical education. One of its offices, the Division of Health Assessment and Consultation, provides emergency response for toxic and environmental disasters, consults in public health emergencies, assesses hazardous waste sites, provides technical assistance to agencies and organizations, and estimates health risks to humans from exposure to hazardous xenobiotics. The program areas in which ATSDR operates include health assessments, toxicologic profiles, emergency response, and exposure and disease registries.

## Online Databases

Printed material often is adequate for determining the adverse health effects of xenobiotic exposures, but some resources may be unavailable to physicians, and textbook publications usually lag 2 years or more behind new information. As a result, current findings and reports may be missed if the practitioner relies solely on printed material. The National Library of Medicine (<http://www.nlm.nih.gov>) sponsors Internet searching of both Medline (PubMed: <http://www.ncbi.nlm.nih.gov/pubmed>) and a number of databases in the Toxicology Data Network (TOXNET; <http://www.toxnet.nlm.nih.gov>) that are very useful for finding information about industrial xenobiotics. Additional databases are available for searching on the OSHA, NIOSH, EPA, and ATSDR web sites.

## SUMMARY

- Industrial, workplace, and environmental exposures represent a different kind of challenge to primary care and emergency physicians.
- Patients often present with diagnostic dilemmas or with common symptoms that do not respond to the usual medical treatment. The challenge for nonoccupational health professionals is to correctly establish and treat the condition.
- The basic approach to all patients emphasizes additional questions integrated into the medical history and access to printed and electronic information resources that are not part of the usual patient evaluation.
- Exposures to occupational and environmental xenobiotics have public health implications.
- Physicians who make the diagnosis of an occupationally or environmentally related disease have an obligation to prevent further injury, protect the Public Health and follow ethical standards.

# HAZARDOUS MATERIALS INCIDENT RESPONSE

Brandy Ferguson and Bradley J. Kaufman

A disaster is typically classified in 2 categories: hazards and threats. Hazards are naturally occurring events, such as blizzards, tornadoes, and flooding. A threat is a human-made event, such as a bombing attack or release of a bio-hazardous agent. Response to an incident must be tailored to the hazard or threat. Whether faced with an earthquake or a hazardous material, incident response must be rapid, effective, and orderly. This chapter focuses on the identification, management, and response to hazardous materials incidents.

According to the US Department of Transportation, a hazardous material is any item or agent that has the potential to cause harm to humans, animals, or the environment, either by itself or through interaction with other agents.<sup>46</sup> These agents can be chemical, radiologic, or biological; moreover, the chemical agents are xenobiotics that can exist in the solid, liquid, or gaseous form.

A hazmat incident can be the result of an unplanned or uncontrolled release of or exposure to a hazardous material. Although there are no specific requirements for an event to be considered a hazardous materials incident, typically, there must be the potential for many people or a large area to be affected. This factor differentiates such an event from the majority of xenobiotic exposures that affect only one person.

In addition, a single event could provide exposure to multiple xenobiotics. Each incident, and the response, is unique, and the response required for chemical, biologic, or radiologic agents might differ substantially. For instance, an event in which a biologic agent is released in a densely populated space, such as a concert or sporting event, will likely result in a different response compared with the identical xenobiotic being released in an area with low population density, such as a small town. Emergency managers and health care professionals must consider all possibilities and adjust the incident response based on the specific xenobiotics involved, the route of the exposure, and other variables (eg, time, location, and weather conditions). This chapter discusses the basic principles used for a confined and quickly identifiable hazardous materials incident.

In general, a hazardous materials incident response focuses on the care of patients exposed to xenobiotics in the prehospital setting, prepares for multiple casualties, and emphasizes patient decontamination while at the same time trying to prevent exposure and contamination of first responders and health care professionals.

Every emergency response has the potential to involve hazardous materials, and first responders must always consider this as they approach an incident. For example, an apparently simple motor vehicle crash can release gasoline into the environment, or a train derailment may result in the release of an unknown xenobiotic from a transport container. In the prehospital setting, early identification of a hazardous material event can be difficult, but it is vital to collect as much information as possible to achieve an adequate and efficient response.

## DISASTER MANAGEMENT AND RESPONSE

Local resources and agencies provide initial disaster management preparedness and response. Police, fire, and emergency medical services (EMS) provide initial response for an event. If necessary, local agencies can escalate response to the county, state, or federal level. The US Federal Emergency Management Agency (FEMA) within the US Department of Homeland Security is the lead federal agency for emergency management in the United States.

According to FEMA, disaster management contains 4 phases: (1) mitigation, (2) preparedness, (3) response, and (4) recovery. Mitigation measures are

plans and efforts that attempt to prevent and reduce or eliminate the effects of a potential hazard from becoming a disaster. A hazard-vulnerability analysis (HVA) determines the hazards or threats most likely to have an impact on a facility. Vulnerability measures weaknesses within a system, and risk determines how much is at stake for a facility. Risk can be calculated using the following equation:

$$\text{Risk} = (\text{Likelihood of occurrence}) \times (\text{Impact of occurrence})$$

An emergency manager at a facility can use these calculations from an HVA to stratify susceptibilities in preparation for disaster mitigation.

Preparedness involves creating action plans to be initiated when a disaster occurs, as well as testing plans with mock exercises and run-throughs. Preplanning is critical to limit damage from an event, and well-developed and tested action plans are necessary for a successful incident response.

The response phase includes the mobilization of appropriate resources and the coordinated management of the incident. A hazardous materials incident response must include the containment of the xenobiotic followed by neutralization, removal, or both. Typically, a response includes multiple trained professionals from various agencies, often including EMS, fire departments, police departments, the Environmental Protection Agency (EPA), the local office of emergency management, and other first responder emergency services personnel. Major hazardous materials events, especially those considered purposeful or the result of a terrorist act, may have responders from multiple federal, state, and local agencies, each with equipment and vehicles, and hundreds of personnel at the scene. These events can be chaotic until control and coordination are achieved. The recovery phase occurs after the immediate needs and threats to human life are addressed in the response phase and entail the restoration of property, infrastructure, and the environment.

Limiting the loss of life is dependent on all responding agencies and personnel working efficiently and effectively together. The coordination of federal, state, and local governments is mandated by the National Incident Management System (NIMS).<sup>10,35</sup> The National Incident Management System uses a systematic approach designed to allow agencies to work together and manage incident response. The National Incident Management System provides for an incident command system (ICS) to be used during a disaster response. Interoperability and compatibility among on-scene assets are dictated by the ICS, which consists of an organizational hierarchy and defines the necessary management components of the overall incident, including mechanisms necessary for controlling personnel, operations, and communications.

The ICS is a standardized, on-scene, all-hazards approach to incident management. The goal of the ICS is to enable a coordinated response among agencies and jurisdictions. It provides a common organizational structure and integrates equipment personnel, facilities, procedures, and communication. During a response, an incident commander (IC) is responsible for managing the incident, establishing objectives, and implementing tactics. Four subsections report to the IC: operations, planning, logistics, and finance and administration. The operations section controls the organizational efforts to reach incident management objectives and directs resources. The planning section supports the incident action planning process, collects and analyzes information, and tracks resources. The logistics section arranges for resources and services, and the finance and administration section monitors costs related to the incident. Each section has an integral role in providing efficient and effective incident response.

Medical professionals are a necessary part of all hazardous materials incident responses because patient assessment and treatment are typically the highest priority. However, as with all mass casualty events, medical

professionals, even those with advanced training, must not spontaneously respond to the location of the event.<sup>30</sup> Unsolicited medical personnel at the scene of a hazardous materials incident, although well intentioned, may actually harm the coordinated response and interfere with operational efforts.

The plan for mobilization, management, and use of volunteer medical personnel at the scene of a disaster should be created in advance, especially for events that might reasonably be expected to require resources. Unsolicited medical professionals lack the training and equipment needed to work within a multiagency coordinated operation. Furthermore, they often function outside the organized ICS and most likely lack or are unaware of the necessary personal protective equipment (PPE). By definition, these environments are hazardous; moreover, freelance medical personnel have the potential to become patients themselves, thereby adding to the burden of on-scene rescuers. For instance, although a patient affected by a specific hazardous material may have the same physical findings and treatment indications at the scene or at the hospital, the differences in location often require variation in the medical decision making and patient care. Disaster plans incorporate the use of local medical assets such as hospitals and clinics. Therefore, communities are best served if medical providers respond to their respective institutions during an incident.

## RESPONSE COMPONENTS

After the identification of a release of a hazardous material, there must be a notification to emergency response personnel. Typically, someone witnesses the incident, such as a motor vehicle crash in which a tanker trailer is breached, or some resultant effects of the release, such as a fire. The individual activates the emergency response system by calling 9-1-1. Alternatively, an automated detector may activate an emergency response to a hazardous materials incident even before there are easily observable results of the release.

Initially, first responders are often not aware that an incident involves hazardous materials. For instance, a responder to an unconscious patient may be unaware that the cause of the medical emergency was a chemical exposure. First responders must consider that every incident may have a hazardous materials etiology. Awaiting confirmation or exclusion of the presence of a hazardous material can be challenging for responders because they must weigh the possibility of contamination with the urge to treat a critically ill patient. It is important that emergency responders remain vigilant for such situations in care of the patients and themselves.

Extensive knowledge, training, and judgment are requirements for all emergency personnel, especially those responding to a hazardous material incident. They must follow basic response paradigms. Personnel should approach the scene from uphill and upwind if possible. Personnel should not immediately rush to the scene because the rescuer may become an additional victim. Establishment of a perimeter is essential to scene security to prevent uncontaminated individuals from becoming exposed. First responders and prehospital personnel must also consider other aspects of incident response, including the need for escalation to other emergency response agencies, weather and wind conditions, terrain, confinement of the release, intentionality, and the need for rapid rescue and evacuation of casualties. The identification of material, establishment of containment or safety zones, wearing of PPE, decontamination, and medical management of patients are discussed later.

## Identification of Hazardous Materials

If the identity of the xenobiotic(s) is known before arrival at the scene, research can begin with review of the physical, chemical, and toxicologic properties of the xenobiotic. If the xenobiotic is not known before arrival at the scene, efforts to obtain this information should begin as soon as safely possible.

Identification of the specific xenobiotic(s) involved is of the highest priority because many of the response components depend on the properties and potential health effects of the xenobiotic itself. Whether the incident involves a mode of transportation (eg, a railcar) or is at a fixed location (eg, a factory

or medical facility), all available information must be used toward material identification. This information can be gleaned from placards, container labels, shipping documents, material safety data sheets (MSDSs), detector devices, personnel at the scene, patients' signs and symptoms, and odors at the scene (eg, the rotten egg smell of hydrogen sulfide).

Because many hazardous materials are transported via railcar or road-trailer, emergency response personnel must always maintain a high index of suspicion when responding to a transportation incident. In the United States, first responders are required to be familiar with the use of the *Emergency Response Guidebook*, which is an aid for quickly identifying the hazards of the material(s) involved in a transportation incident.<sup>46</sup>

Hazardous materials may be categorized in various ways and are often grouped by their harm-causing property. For instance, hazardous materials may be classified as radioactive, flammable, explosive, asphyxiating, pathogenic, and biohazardous. Xenobiotics most commonly encountered at hazardous materials incidents vary from one locale to another and are predominately determined by the major local industries.<sup>49,50</sup> For example, pesticides are the most commonly encountered class of hazardous materials in Fresno County, California, where the major industry is agribusiness. Although most hazardous materials incidents involve only one hazardous material, more than one xenobiotic may be encountered at an incident. One study described 107 hazardous materials incidents involving a total of 156 materials.<sup>50</sup>

For consequential hazardous materials, the vast majority are caused by gases, vapors, or aerosols. In one study, 4 of the 5 most commonly encountered individual chemicals were ammonia, phosphine, sulfur oxides, and hydrogen sulfide.<sup>9</sup> Because they do not adhere to skin, gases do not contaminate people secondarily. Therefore, patients exposed to gases generally do not require decontamination. Inhalation is the most common route of exposure at hazardous materials incidents and was the route of exposure at 73%, accounting for 76% of the exposed patients described in one study.<sup>8,9</sup>

Because the number of hazardous materials is large, it is efficient to group hazardous materials according to their toxicologic characteristics. The International Hazard Classification System (IHCS) is the most commonly used system (*Table 132-1*).<sup>46,49</sup> Individual hazardous materials studies commonly use their own classification systems, which emphasize the toxicodynamic effects of hazardous materials (eg, systemic asphyxiants), highlighting individual chemicals (eg, ammonia or chlorine) or general classes of chemicals (eg, acids, bases, or volatile organic compounds).<sup>8,9</sup>

## Chemical Names and Numbers

Chemical compounds may be known by several names, including the chemical, common, generic, or brand (proprietary) name.<sup>56</sup> In a hazardous material response, a chemical may be the sole substance or one of several compounds in a mixture. The Chemical Abstracts Service (CAS) of the American Chemical Society numbers chemicals in order to overcome the confusion regarding multiple names for a single chemical. The CAS assigns a unique CAS registry number (CAS#) to atoms, molecules, and mixtures. For example, the CAS# of methanol is 67-56-1.<sup>35,36</sup> These numbers provide a unique identification system for chemicals and a means for crosschecking chemical names. Identifying a chemical by name and CAS# is critical because one must be as specific as possible about the hazardous material in question. Trade or brand names can be misleading and should not be used in isolation. The SDS describing a product usually lists the chemical name, the CAS#, and the brand name.<sup>29</sup>

## Vehicular Placarding: United Nations Numbers, North American Numbers, and Product Identification Numbers

Xenobiotics in each hazard class of the IHCS (*Table 132-1*) are assigned 4-digit identification numbers, which are known as United Nations, North American, or Product Identification Numbers, and are displayed on characteristic vehicular placards. This system is used by the US Department of Transportation in the *Emergency Response Guidebook*.<sup>46</sup> The IHCS assigns a xenobiotic to a hazard class based on its most dangerous physical characteristic, such as explosiveness or flammability. Other potential hazards

**TABLE 132-1** International Hazard Classification System**Class 1: Explosives**

Division 1.1: Mass explosion hazard

Division 1.2: Projection hazard

Division 1.3: Predominantly a fire hazard

Division 1.4: No significant blast hazard

Division 1.5: Very insensitive explosives

Division 1.6: Extremely insensitive detonating articles

**Class 2: Gases**

Division 2.1: Flammable gases

Division 2.2: Nonflammable compressed gases

Division 2.3: Poisonous gases

Division 2.4: Corrosive gases (Canada)

**Class 3: Flammable or Combustible Liquids****Class 4: Flammable Solids**

Division 4.1: Flammable solid

Division 4.2: Spontaneously combustible materials

Division 4.3: Dangerous when wet materials

**Class 5: Oxidizers and Organic Peroxides**

Division 5.1: Oxidizers

Division 5.2: Organic peroxides

**Class 6: Poisonous Materials and Infectious Substances**

system in an attempt to harmonize an approach to classification and labeling. The Globally Harmonized System of Classification and Labelling of Chemicals classifies substances and mixtures by their health, environmental, and physical hazards.

CHEMTREC is a service of the Chemical Manufacturers Association providing continuous essential chemical information with regard to shippers, products, and manufacturers. CHEMTREC is available at 800-424-9300 or at <http://www.chemtrec.org>. Details of an incident are relayed to the shipping or manufacturing 24-hour emergency contact, and they are linked to hazardous materials incident responders. Technical data are available on handling the substance(s) involved, including the physical characteristics, transportation, and disposal.

A regional poison control center is a valuable source of medically relevant information. Other information sources include local and state health departments, the American Conference of Governmental and Industrial Hygienists, the Occupational Safety and Health Administration (OSHA), National Institutes of Occupational Safety and Health (NIOSH), the Agency for Toxic Substances and Disease Registry, and the Centers for Disease Control and Prevention.<sup>1-3,36-38</sup>

Exact identification may not always be possible. Hazardous materials responders may be able to classify the hazardous material into one of several major toxicologic classes by identifying a hazardous material toxidrome, allowing providers to reasonably treat patients while protecting themselves and others. For example, it is helpful to recognize irritation of the mucous membranes and upper airway caused by a highly water-soluble irritant gas (Chap. 121) or signs of cholinergic excess caused by organic phosphorus compounds or carbamate poisoning (Chaps. 3 and 110).

Although the exact identity of the hazardous material is usually not known, the physical state of the material (eg, solid, liquid, or gas) may be. Airborne xenobiotics can potentially harm many more victims because of their rapid distribution and ambient nature. Airborne xenobiotics include not only gases and vapors but also the liquid suspensions (eg, fog, aerosols, and mists) and solid suspensions (eg, smoke, fumes, dusts) (Chaps. 28 and 121).

### Exposure and Contamination

It is important to note that emergency personnel and equipment can become contaminated at hazardous materials incidents. For example, in one study, a crashed exterminator truck leaked organic phosphorus pesticide onto the street. An ambulance that was responding to the initial call for a motor vehicle crash was contaminated after driving through a puddle of the pesticide.

*Primary contamination* is contamination of people or equipment caused by direct contact with the initial release of a hazardous material by direct contact at its source of release. Primary contamination occurs whether the hazardous material is a solid, a liquid, or a gas. *Secondary contamination* is contamination of health care personnel or equipment caused by direct contact with a patient or equipment covered with adherent solids or liquids removed from the source of the hazardous material spill. For instance, if a hazardous material remains on a victim (external) or within a victim (internal) or on the body surface or clothing, the person will continue to be exposed and to potentially expose others to the substance until decontamination occurs. If such a patient arrives at a health care facility and is not decontaminated, the hospital and health care providers are at risk for secondary contamination.

Health care professionals should work with hazardous materials personnel to determine whether the hazardous material presents a significant risk of secondary contamination and whether decontamination of the skin and mucous membranes is necessary. Secondary contamination generally occurs only with solids or liquids, but as noted later, some "gaseous" xenobiotics are actually suspended liquids or solids. In general, patients or equipment covered with adherent solid or liquid hazardous materials, including chemical, biological, or radiologic agents, should be decontaminated before transportation to prevent downstream contamination of health care professionals and equipment.<sup>12,20-22,49,50,53</sup>

of a xenobiotic, such as its ability to cause cancer or birth defects, are not considered. This system provides very little guidance in treating poisonings caused by hazardous materials.

### National Fire Protection Association 704 System for Fixed Facility Placarding

Fixed facilities, such as hospitals and laboratories, use a placarding system that is different from the vehicular placarding system. The National Fire Protection Association (NFPA) 704 system is used at most fixed facilities.<sup>31</sup> The NFPA system uses a diamond-shaped sign that is divided into 4 color-coded quadrants: red, yellow, white, and blue. This system gives incident responders information about the flammability, reactivity, and health effects, as well as other information, such as the water reactivity, oxidizing activity, or radioactivity.

The red quadrant on top indicates flammability; the blue quadrant on the left indicates health hazard; the yellow quadrant on the right indicates reactivity; and the white quadrant on the bottom is for other information, such as OXY for an oxidizing product, W for a xenobiotic that has unusual reactivity with water, and the standard radioactive symbol for radioactive substances. Numbers in the red, blue, and yellow quadrants indicate the degree of hazard: numbers range from 0, which is minimal, to 4, which is severe, and indicate specific levels of hazard. For instance, NFPA 704 defines divinyl benzene with the following values: blue 1 (can cause significant irritation), red 2 (must be moderately heated or exposed to relatively high temperatures before ignition can occur), and yellow 2 (readily undergoes violent chemical changes at elevated temperatures and pressures).

Similar to all placarding systems, this one also has limitations. It does not name the specific hazardous substances in the facility and gives no information about the quantities or locations of the materials.

### United Nations

Recognizing that the transport of chemicals often occurs across international boundaries and labels and MSDSs often have different information in different countries, the United Nations developed a chemical classification

In terms of cutaneous decontamination, exceptions can exist such as a diaphoretic patient exposed to a highly water-soluble irritant gas (eg, ammonia), which dissolves in sweat. In this case, the primary purpose of decontamination is to prevent or treat the patient's chemical burns caused by caustic action of aqueous ammonium hydroxide on perspiring skin while assuring prevention of secondary contamination of rescuers.

Aerosols are airborne xenobiotics, not gases. Aerosols are suspensions of solids or liquids in air, such as solid dusts or liquid mists, that can cover victims with these adherent solids or liquids, which cause secondary contamination. These patients require decontamination to prevent secondary contamination.

### Hazardous Materials Site Operations

Limiting dispersion of the hazardous material is critical to prevent further consequences. The physical state of a material determines how it will spread through the environment and gives clues to the potential route(s) of exposure. Unless moved by physical means such as wind, ventilation systems, or people, solids usually stay in one area. Solids can cause exposures by inhalation of dusts, by ingestion, or rarely by absorption through skin and mucous membranes. Solids that undergo sublimation, changing directly from a solid into a gas without passing through the liquid state, can give off vapors that may cause airborne exposure. Only 2 commonly encountered solids sublime, dry ice (CO<sub>2</sub>) and naphthalene. A vapor is defined as a gaseous dispersion of the molecules of a substance that is normally a liquid or a solid at standard temperature and pressure (STP), that is, 32°F (0°C = 273°K) and 1 atm (760 torr = 760 mm Hg = 14.7 psi). Uncontained liquids will spread over surfaces and flow downhill. Liquids that evaporate create a vapor hazard.

The vapor pressure (VP) is useful to estimate whether enough of a solid or liquid will be released in the gaseous state to pose an inhalation risk. Vapor pressure is defined essentially as the quantity of the gaseous state overlying an evaporating liquid or a subliming solid. The lower the VP, the less likely the xenobiotics will volatilize and generate a respirable gas. Conversely, the higher the VP of a chemical, the more likely it will volatilize or generate a respirable gas. Water has a VP of approximately 20 mm Hg at 70°F (21°C), and acetone has a VP of 250 mm Hg at the same temperature. Therefore, acetone evaporates more rapidly than water and poses more of an inhalation risk. Standard reference texts (eg, *NIOSH Pocket Guide to Chemical Hazards and the Merck Index*) list VPs for commonly encountered chemicals.<sup>36,37,46</sup>

### Hazardous Materials Scene Control Zones

Scene management is a fundamental feature of hazardous materials incident response. It is almost always necessary to isolate the scene, deny access to the public and the media, and limit access to emergency response personnel to prevent unnecessary contamination. Three control zones are established around a scene and are described by “temperature,” “color,” or “explanatory terminology” (Table 132–2 and Fig. 132–1). NIOSH, the US EPA, and most US prehospital and hospital health care professionals use the temperature terminology system.<sup>37</sup>

The *hot zone* is the area immediately surrounding a hazardous materials incident. It extends far enough to prevent the primary contamination of people and materials outside this zone. In general, evacuation, but no decontamination or patient care, is carried out in this zone. This is because rescuers are generally hazardous materials technicians who wear level A or

B suits that severely limit their visibility and dexterity. In specific situations, antidotes, such as nerve agents, are administered via autoinjectors.

The *warm zone* is the area surrounding the hot zone and contains the decontamination or access corridor, where victims and the hazardous materials entry team members and their equipment are decontaminated. It includes 2 control points for the access corridor. Many consider initiating therapy at this stage, particularly for chemical weapons, events when multiple casualties are involved as stated earlier. However, with these rare exceptions, medical care should be initiated only after the patient exits into the cold zone.

The *cold zone* is the area beyond the warm zone. Contaminated victims and hazardous materials responders should be decontaminated before entering this area from the warm zone. This is the area where resources are assembled to support the hazardous materials emergency response. The incident command center is usually located in the cold zone, and there is greater ability to provide patient care there. Care provided in this zone includes the primary survey and resuscitation with management of airway (with cervical spine control), breathing, circulation, disability, and exposure with evaluation for toxicity and trauma (ABCDE). Definitive care also includes antidotal treatment for specific poisonings.

### Personal Protective Equipment

A critical goal of hazardous materials emergency responders is protecting themselves and the public. Safeguarding hazardous materials responders includes wearing appropriate PPE to prevent exposure to the hazard and prevent injury to the wearer from incorrect use of or malfunction of the PPE equipment.

Donning PPE poses significant health hazards for the provider, including loss of cooling by evaporation, heat stress, physical stress, psychological stress, impaired vision, impaired mobility, and impaired communication. Because of these risks, individuals involved in hazardous materials emergency response must be properly trained regarding the appropriate use, decontamination, maintenance, and storage of PPE. This training includes instruction regarding the risk of permeation, penetration, and degradation of PPE. Personal protective equipment with a self-contained breathing apparatus (SCBA) with a fixed supply of air significantly limits the amount of time the wearer can operate in the hot zone, usually about 20 minutes.

### Levels of Protection

The EPA defines 4 levels of protection for PPE: levels A (greatest protection) through D (least protection). The different levels of PPE are designed to provide a choice of PPE, depending on the hazards at a specific hazardous materials incident (Table 132–3).<sup>26,38</sup>

*Level A* provides the highest level of both respiratory and skin (clothing) protection and provides vapor protection to the respiratory tract, mucous membranes, and skin. This level of PPE is airtight and fully encapsulating, and the breathing apparatus must be worn under the suit.

*Level B* provides the highest level of respiratory protection and skin splash protection by using chemical-resistant clothing. It does not provide skin vapor protection but does provide respiratory tract vapor protection. Some hospitals have specially trained health care professionals who wear level B PPE when decontaminating patients presenting to the hospital. However, the majority of hospitals are training their frontline emergency department (ED) health care professionals to wear level C PPE when decontaminating contaminated patients who present to the hospital.

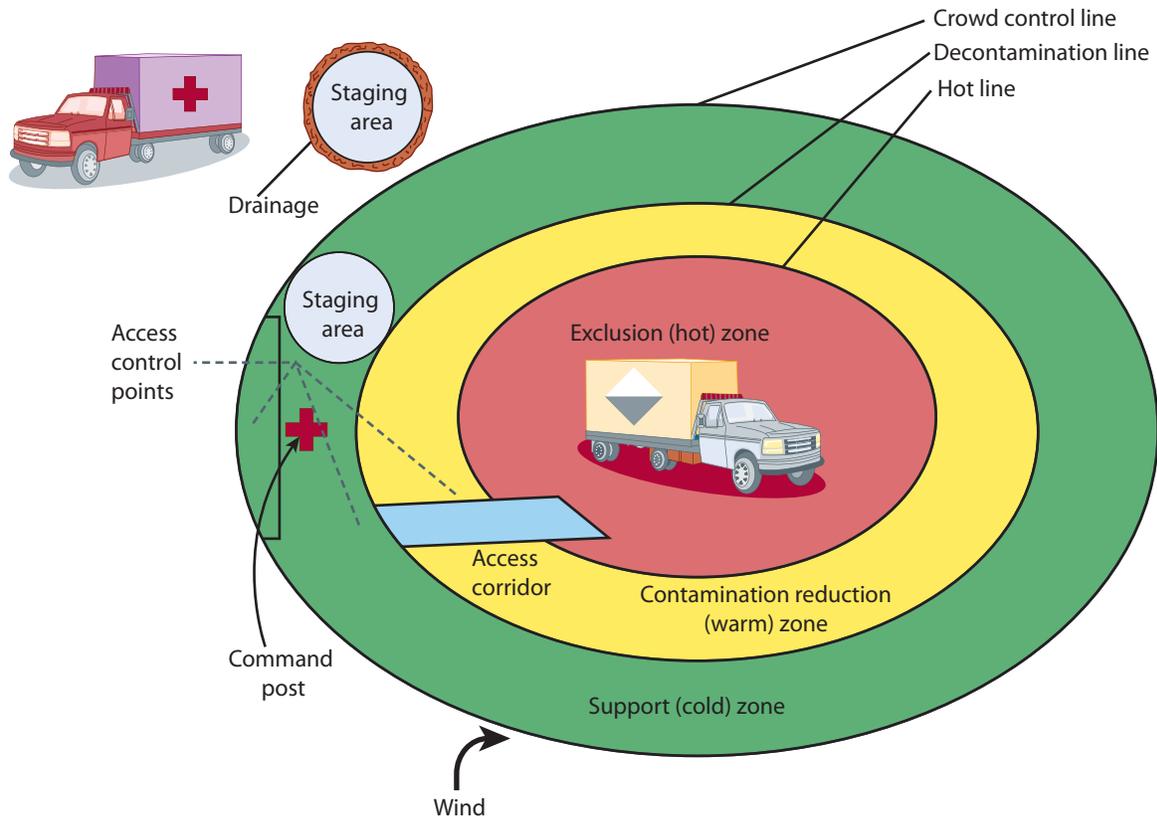

*Level C* protection should be used when the type of airborne xenobiotic is known, its concentration can be measured, the criteria for using air-purifying respirators (APRs) are met, and skin and eye exposures are unlikely. Level C provides skin splash protection, the same as level B; however, level C has a lower level of respiratory protection than levels A and B.

*Level D* is basically a regular work uniform. It should not be worn when significant chemical respiratory or skin hazards exist. It provides no respiratory protection and minimal skin protection. Level D was specifically developed to show *what not to wear* for chemical protection.

TABLE 132–2 Nomenclatures of the Hazardous Materials Control Zones

Temperature Terminology System <sup>a</sup>	Color Terminology System	Explanatory Terminology System
Hot zone	Red zone	Exclusion or restricted zone
Warm zone	Yellow zone	Decontamination or contamination reduction zone
Cold zone	Green zone	Support zone

<sup>a</sup>Data from the National Institutes of Occupational Safety and Health and the Environmental Protection Agency.

**FIGURE 132-1.** National Institutes of Occupational Safety and Health/Occupational Safety and Health Administration recommended hazardous materials control zones.

**Personal Protective Equipment Respiratory Protection**

Personnel must be fit tested before using any respirator. A tiny space between the edge of the respirator and the face of the hazardous materials responder could permit exposure to an airborne hazard. Contact lenses cannot be worn with any respiratory protective equipment. Corrective eyeglass lenses must be mounted inside the facemask of the PPE. The only exception to these general rules is the use of hooded level C powered air purifying respirators (PAPRs) that do not require fit testing and allow individuals to wear their own eyeglasses within the hooded PAPR. This is the reason that most US hospitals prefer hooded PAPRs for their ED personnel who must decontaminate patients.

Level A PPE (Fig. 132-2) mandates the use of a SCBA. A SCBA is composed of a face piece connected by a hose to a compressed air source.

An open-circuit, positive-pressure SCBA is used most often in emergency response and provides clean air from a cylinder to the face piece of the wearer, who exhales into the atmosphere. Thus, a higher air pressure is maintained inside the face piece than outside. This affords the SCBA wearer the highest level of protection against airborne hazards because any leakage will force air out of the face piece and not allow airborne hazards to enter against the higher pressure within the face piece. Disadvantages of the SCBA include its bulkiness and heaviness and a limited time period of respiratory protection because of the limited amount of air in the tank.

A supplied-air respirator (SAR) may be used in level B PPE and differs from SCBA in that air is supplied through a line that is connected to a source

Level <sup>a</sup>	Protects Skin and Eyes From			Protects Respiratory System From	
	Select Vapors and Aerosols	Gases, Vapors, and Aerosols	Oxygen-Deficient Atmospheres	Liquids and Solids	Gases and Vapors
D					
C	+			+	
B	+		+	+	+
A	+	+	+	+	+

<sup>a</sup>Level A is a self-contained breathing apparatus (SCBA) worn under a vapor-protective, fully encapsulated, airtight, chemical-resistant suit. Level B is a positive-pressure supplied-air respirator with an escape SCBA worn under a hooded, splash-protective, chemical-resistant suit. Level C is an air-purifying respirator worn with a hooded, splash-protective, chemical-resistant suit. Level D is regular work clothing (offers no protection).

**FIGURE 132-2.** Individuals wearing level B PPE. (Reproduced with permission from the Occupational Safety and Health Administration.)

located away from the contaminated area. Only positive-pressure SARs are recommended for hazardous materials use. One major advantage of SARs over SCBA is that they allow an individual to work for a longer period. However, a hazardous materials worker must stay connected to the SAR and cannot leave the contaminated area by a different exit.

An APR may be used in level C PPE and allows breathing of ambient air after inhalation through a specific purifying canister or filter. There are 3 basic types of APRs: chemical cartridge, disposable, and powered air (PAPR). Although APRs afford the wearer increased mobility, their use is only acceptable when there is sufficient oxygen in the ambient air. The chemical cartridges or canisters purify the air by filtration, adsorption, or absorption. Filters may also be used in combination with cartridges to provide increased protection from particulates such as asbestos. Powered devices reduce the work of breathing, which can significantly limit an individual's performance while wearing PPE.

### Decontamination

One of the most important and essential aspects of hazardous materials response is decontamination of patients. Not only does decontamination reduce the health consequences for the patient (by reducing absorption or exposure time), but it also prevents secondary contamination. Decontamination of equipment, the environment, and the entire area (ie, hot zone) is necessary but is secondary in priority to the decontamination of victims.

An estimated 75% to 90% of contaminants can be removed simply by removing clothing and garments. Subsequent decontamination is most commonly accomplished by using water to copiously irrigate the skin of a patient, thereby physically washing off, diluting, or hydrolyzing the xenobiotic. However, the water solubility of a xenobiotic must be considered to determine whether water alone is sufficient for skin decontamination or whether a detergent is needed. The general rule regarding solubility is that "like dissolves like." In other words, a polar solvent, such as water, will dissolve polar substances such as salts. For example, the herbicide paraquat is actually a salt, paraquat dichloride, that is miscible in water. Therefore, if skin is contaminated with paraquat, copious water irrigation is sufficient for skin decontamination. A mild liquid detergent is acceptable but is not necessary. On the other hand, a nonpolar solvent, such as toluene, is not water soluble and is immiscible. Therefore, if skin is contaminated with toluene, water irrigation alone will be insufficient for decontamination, and mild liquid detergent is necessary. Furthermore, copious water is often not available at the site, thereby requiring rescuers to ration the supply and minimize irrigation using the least amount of water necessary. Some solid chemical contaminants react with water and cause an increased hazard. Providers should use care with chemical contaminants because some solid contaminants react with water and create an increased hazard. Some xenobiotics are better removed mechanically by physically wiping it from the skin while avoiding smearing the xenobiotic or abrading the skin. Some contaminants may be chemically "inactivated" by applying another chemical, such as a 0.5% hypochlorite solution (see extensive discussion in Special Considerations: SC2).

All exposed skin, including the skin folds, axillae, genital area, and feet, should be decontaminated. Lukewarm water should be used with gentle water pressure to reduce the risk of hypothermia. Water should be applied systematically from head to toe while the airway is protected.

Exposed, symptomatic eyes should be continuously irrigated with water throughout the patient contact, including transport, if possible. Remember to check for and remove contact lenses.

Removal of internal contamination is often much more problematic. In some cases, specific antidotes are administered to enhance elimination or inactivate the hazardous material. For instance, Prussian blue can trap radioactive cesium in the intestine so that it can be eliminated from the body in the stool rather than be reabsorbed.

### Scene Triage

Victim decontamination and movement from a scene requires an organized methodology for categorization of medical severity. The most common

triage method used is the Simple Triage and Rapid Treatment (START) system, although many others exist. This system follows a simple algorithm that allows for a color categorization based upon respiration, perfusion, and mental status: immediate (red), delayed (yellow), walking wounded or minor (green), and deceased or expectant (black). Victims may be initially triaged in the contaminated zone and then retriaged after decontamination. Prehospital providers receive training in START triage and transport patients to a hospital facility according to triage destination. Scene security is an important aspect of scene triage. The decontamination areas must be properly secured by responders (eg, police, EMS) to ensure secure and efficient decontamination of patients. The IC, along with other sections of the ICS, can develop tactics and plans to ensure scene safety.

## HAZARDOUS MATERIALS INCIDENT RESPONSE RULES AND STANDARDS

Occupational Safety and Health Administration and the NFPA have developed rules and guidelines, respectively, regarding hazardous materials incident response. Occupational Safety and Health Administration rules are mandated as law and must be followed. Meeting NFPA guidelines will ensure OSHA compliance.<sup>24,31-34,38,41,45,46</sup>

The Superfund Amendments and Reauthorization Act of 1986 (SARA) required OSHA to develop and implement standards to protect employees responding to hazardous materials emergencies. This resulted in the *Hazardous Waste Operations and Emergency Response* standard, 29 CFR 1910.120, or HAZWOPER.<sup>47</sup>

NFPA 471, *Recommended Practice for Responding to Hazardous Materials Incidents*, outlines the following tactical objectives: incident response planning, communication procedures, response levels, site safety, control zones, PPE, incident mitigation, decontamination, and medical monitoring.<sup>32</sup>

NFPA 472, *Standard on Professional Competence of Responders to Hazardous Materials Incidents*, helps define the minimum skills, knowledge, and standards for training outlined in HAZWOPER for 3 types of responders.<sup>33</sup>

### Prehospital Hazardous Materials Emergency Response Team Composition, Organization, and Responsibilities

#### First Responder at the Awareness Level

First responders at the awareness level could be first on the scene at an emergency incident involving hazardous material. They are expected to recognize the presence of hazardous materials, protect themselves, secure the area, and call for better-trained personnel. They must take a safe position and keep other people from entering the area. They must recognize that the level of mitigation exceeds their training and call for a hazardous materials response team. Most basic curricula of emergency medical technicians include this level of first responder training.

#### First Responder at the Operational Level

These individuals are trained in all competencies of the awareness level and are additionally trained to protect nearby persons, the environment, and exposed property from the effects of hazardous materials releases. Operational level certified individuals are expected to assume a defensive posture, control the release from a safe distance, and keep the hazardous material from spreading. Operational level individuals are trained on the following aspects of material containment: absorption of liquids, containment of the spill, vapor suppression, and vapor dispersion. They do not operate within the hot zone.

#### Hazardous Materials Technician

Hazardous materials technicians respond to hazardous materials releases, or potential releases, for the purpose of controlling the release. They are trained in the use of chemical-resistant suits, air-monitoring equipment, mitigation techniques, and the interpretation of physical properties of hazardous materials. Technicians are capable of containing an incident, making safe entry into a hazardous environment, determining the appropriate course of action, victim rescue, and cleaning up or neutralizing the incident to return

property to a safe and usable status, if possible. These individuals are trained to operate within the hot zone to mitigate the incident. This certification level includes knowledge of hazardous material chemistry, air-monitoring equipment, tools used within the hot zone, and more.

Each of these providers must work in conjunction to ensure effective and efficient incident response, treatment of individuals, scene control, and patient transport to nearby health care facilities.

## Advanced Hazardous Materials Components

### Advanced Hazardous Materials Providers

Paramedics are trained in the recognition of signs and symptoms caused by exposure to hazardous materials and the delivery of antidotal therapy to victims of hazardous materials poisonings.<sup>24</sup>

The inclusion of such training into a hazardous materials response team is beneficial, not only for the needs of the public but also to protect hazardous materials technicians who make entry into hazardous atmospheres. Ideally, entry into hazardous atmospheres should not be performed until appropriately trained paramedics are on the scene with resuscitative equipment in place, including a drug box containing essential antidotes for specific hazardous materials.<sup>24</sup>

### Patient Care Responsibilities of the Prehospital Decontamination Team and the Hazardous Materials Entry Team

Hazardous material incident responders should identify the entry and exit areas by controlling points for the access corridor (decontamination corridor) from the hot zone, through the warm zone, to the cold zone (Fig. 132–1). This corridor should be upwind, uphill, and upstream from the hot zone, if possible. Hazardous materials technician entry team members should remove victims from the contaminated hot zone and deliver patients to the inner control point of the access (decontamination) corridor. Hazardous materials decontamination team members decontaminate patients in the decontamination (access) corridor of the contamination reduction (warm zone).<sup>11,14,18,19,24,27,28,43</sup>

The primary responsibility of the prehospital hazardous materials sector is the protection of the hazardous materials entry team personnel. This is accomplished by researching and recording clinically pertinent information about the hazardous material, remaining available on scene for medical treatment, and assessing individuals before entry into and on exit from a hazardous environment.<sup>24</sup> Documentation of each assessment should be recorded on a prepared form and compared with the exclusion criteria defined by NFPA 471.<sup>24,32</sup>

In some systems, the hazardous materials entry team may include specialized providers who have the ability to provide lifesaving patient care within the hot zone. The ability to perform triage or cardiopulmonary resuscitation or to provide any medical care is greatly limited by the PPE being worn. Therefore, only immediately lifesaving procedures should be considered, such as intubation or antidote administration. In one study, health care professionals were observed performing tasks (laryngotracheal mask placement versus endotracheal intubation, and intravenous cannula insertion versus interosseous needle insertion) with and without CBRN (chemical–biological–radiologic–nuclear) PPE. This study observed 64 clinicians and found that procedure times were slower for endotracheal intubation and intravenous cannula placement, skills requiring more dexterity.

### Patient Care Responsibilities of Emergency Medical Services Providers at Hazardous Materials Incidents

Emergency medical services providers who are not part of the hazardous materials team should report to the incident staging area and await direction from the IC. They should approach the site from upwind, uphill, and upstream, if possible.

Emergency medical services providers should remain in the cold zone until properly protected hazardous materials incident responders arrive, decontaminate, and deliver patients to them for further triage and treatment. Emergency medical services providers should evaluate each patient,

triage as appropriate, and move the patient to the appropriate casualty collection point or rapidly transport to the hospital. Exposed victims who are initially asymptomatic should continue to be observed and reassessed for the delayed development of symptoms, and the EMS provider should be prepared to upgrade or downgrade the triage category for the patient. All EMS systems should have protocols in place that direct operations at hazardous materials scenes. Ideally, EMS response for an event with involve direct communication with the EMS medical director or medical control; this physician will assist with coordination of appropriate care with the hospital, regional poison control centers, and toxicologists.

Transportation of patients from the hazardous materials incident is ultimately under the control of the IC but is usually delegated to the pre-hospital hazardous materials medical sector and EMS providers. Patients with skin contamination should be transported from the hazardous materials site without being properly decontaminated. Before transportation, EMS should notify the receiving hospital of the number of victims being transported and their toxicologic history, patient assessments, and treatment rendered.

### Hospital Responsibilities for Hazardous Materials Victims

Ideally, local or regional ED physicians and personnel will receive advanced notification about a hazardous materials incident before any victims arrive at the hospital. This notification to the hospital should occur as early in the event as possible to allow for maximum preparation time. The notification should include, if known, information regarding the event, hazardous materials involved, number and condition of casualties to be transported to the hospital, and estimated time of arrival, as well as information regarding the decontamination completed. Assistance of a poison control center and a medical toxicologist is generally recommended.

Victims may leave an incident scene and subsequently present to a hospital. The hospital must have a preestablished protocol (eg, mass casualty with decontamination response plan) by which hospital response teams will decontaminate patients who arrive at the hospital if not previously decontaminated or if field decontamination is believed to be insufficient.<sup>7,15–17,23,25,40,42,44,48,51,52</sup> Patients who require skin decontamination should be denied entry to the ED until they are decontaminated by an appropriately trained and equipped hazardous materials response team. Again, patient treatment should not be initiated until the patient is in the cold zone. The emergency physician will determine when the patient is safe to enter the ED after carefully assessing the risks and benefits to the decontaminated patient, the other patients in the ED, and the ED health care personnel.

## SUMMARY

- Hazardous materials incident response is an integrated, interdisciplinary approach involving prehospital, hospital, poison control center, and public health professionals.
- Most exposures are inhalational, which can be a gas, solid, small suspended particles, or liquid aerosols.
- Prehospital and hospital health care professionals must use appropriate PPE when caring for contaminated patients.
- Decontamination is critical to alter xenobiotic absorption for patients and to prevent secondary contamination of downstream health care professionals and equipment.
- The general principles of toxicology apply regardless of whether a patient is at a hazardous materials incident in a prehospital or hospital setting. Although patient care resources vary among these treatment settings, the fundamental principles of patient care remain the same. All patients should receive a primary survey and resuscitation, emphasizing airway, breathing, and circulation.

# RISK ASSESSMENT AND RISK COMMUNICATION

Charles A. McKay

All health care professionals confront questions involving risk on a daily basis. In the area of toxicology, these questions take many forms. An anxious parent with questions about a child's potentially toxic exposure, an urgent consultation for a critically ill patient in the emergency department or intensive care unit, a request to interpret a laboratory test, media requests for information about environmental public health issues, a response to a hazardous materials incident, and biopreparedness education all involve directed communication of information and recommendations. Toxicologists and Certified Specialists in Poison Information (CSPIs) must establish rapport and provide information, instructions, and when appropriate, reassurance, typically by telephone or in short face-to-face interactions. For CSPIs, attribution of a patient's symptoms to one or more potential exposures is further complicated by the absence of visual clues usually available during a clinical evaluation. In addition, the true reason or concern for a call is often difficult to discern, given limited time and incomplete information transfer. Cultural issues also impact perception and communication. All of these situations require a knowledgeable, compassionate, and well-reasoned response to toxicologic concerns.

This chapter focuses on 2 particular components of this response: risk assessment and risk communication. The underlying principles apply equally to individual calls to poison control centers (PCCs), educational outreach to the public and medical professionals, occupational and environmental exposure evaluations, and supportive roles with other public health agencies in terrorism preparedness, environmental public health tracking programs, and research.

## RISK ASSESSMENT

In the context of this text, risk assessment is the process of determining the likelihood of toxicity for an individual or group after a perceived exposure to some substance, generally referred to as a xenobiotic. It involves determining the nature and extent of the exposure (ie, xenobiotic, dose, duration, route) and its specific clinical effects, defining an exposure pathway, and assessing the likelihood of effects from a given situation. When available, a published body of knowledge should be applied to some components of risk characterization or assessment. An overview and a number of tools are available through the websites of the US Environmental Protection Agency (EPA) and the Agency for Toxic Substances and Disease Registry (ATSDR) of the Centers for Disease Control and Prevention (CDC).<sup>1,12</sup> However, any given risk assessment is hampered by incomplete information. The exact xenobiotic or mixture, whether there was an actual exposure or just proximity to the xenobiotic (completion of an exposure pathway), the exact dose, and unpredictable features such as host factors (underlying medical conditions or genetic polymorphisms) that could modify the response to a potential exposure, are all potential contributors of uncertainty. Unfortunately, those conducting a risk assessment are affected by their own biases and assumptions in the interpretation of their results, as are the people to whom a risk assessment is communicated. The emotional response to being "poisoned" makes evaluation and attribution even more difficult.

A good example of the practical difficulties involved in a risk assessment is evident from a published description of mass psychogenic illness.<sup>22</sup> In this incident, many individuals at a school complained of odor-triggered non-specific symptoms such as dizziness, nausea, and palpitations. Symptoms spread, even occurring in some individuals after removal from the building, in a so-called line of sight transmission with no evident dose-response pattern. Extensive testing identified the possibility of potential odor sources, such as dry floor drain traps. However, there was no actual release documented,

and a plausible scenario that would account for significant symptoms could not be identified. When people returned to the school days later, symptoms recurred, again in the absence of documented exposure to any inciting chemical. The extent of investigation of these events is often profound, highlighting the difficulty in appropriate use of potentially unlimited laboratory technology. Yet a complete risk assessment is frequently elusive: our ability to assess a "no-risk" situation is limited. As noted in the letters to the editor of the journal in which the case was published, one can always criticize the methods or conclusions in this and "subsequent and comparable" outbreaks in businesses, hospitals, and mass gatherings.<sup>4,19,30,34</sup>

The fear-arousal cycle that triggers a multitude of "medically unexplained symptoms" precipitates the "maladaptive thoughts, feelings, and behaviors" that characterize "somatic symptom disorder" as described in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM 5) should, in theory, respond to a properly communicated risk assessment. However, any uncertainty will hinder this response. However, any uncertainty will hinder this response. It is stated that "the absence of evidence of harm" is not the same as "the evidence of absence of harm." Both of these positions potentially converge in the face of continued research, data, and debate toward the dichotomous choices of "evidence of harm" or "evidence of safety." Unfortunately, this goal of a refined and improved risk assessment based on accumulating knowledge is polarized in debate and policy as 2 opposing principles: the *Kehoe principle* and the *precautionary principle*. The Kehoe principle is best summarized as "prove something is harmful before excluding a product with known benefits because of concern about potential, unproven future adverse effects." A common example of the use of this principle is the continued marketing of a xenobiotic after another member of the class was removed because of safety issues. More intense scrutiny is indicated, but a class-wide medication recall without evidence of some level of harm by an individual therapeutic drug is very rare. This principle was misused in the past to minimize known risks attributable to environmental lead pollution to delay removal of lead additives from gasoline.<sup>33</sup> Critics of the Kehoe principle suggest that waiting for evidence of harm from a substance results in costly or irreparable damage.

The alternative precautionary principle is often summarized as "where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason to postpone cost effective measures to prevent environmental degradation."<sup>27,40</sup> Critics of the precautionary principle often cite the uncertainty of the "threat" and the lack of attention to the "cost" component of the principle, complaining that devotees stifle economic growth and prosperity with unfounded fears rather than reasoned consideration of known data. This principle is commonly extended to potentially harmful situations other than the environment. A common criticism of the precautionary principle is the degree to which alternative actions are evaluated for safety. As an example, concern about thimerosal safety (as a vaccine preservative and source of ethylmercury exposure) in young children led many parents to forego childhood vaccinations. Vaccine manufacturers removed the thimerosal preservative from most routine childhood vaccines. Although this process was accelerated by the theoretical—and, ultimately, unfounded—concerns regarding this source of mercury exposure in young children, the cost of delayed or omitted vaccination was a number of real and preventable serious infectious diseases that occurred, including hepatitis B and measles.<sup>6-8,14</sup>

Although the Kehoe and precautionary principles originated as policy approaches to public health issues, they underlie the automatic or subconscious biases that each individual brings to his or her own personal risk assessment or tolerance. A framework of belief systems and assumptions about life,

**TABLE 133–1** Components of Risk Assessment**Hazard Identification**

Name and amount of suspected xenobiotic (or general use category if the xenobiotic is unknown)

**Exposure Pathway**

Proposed route of exposure

Consistency with the nature of the xenobiotic (eg, water-soluble liquid)

**Modifying Factors**

Environmental factors that would influence systemic availability of the xenobiotic

Patient characteristics (susceptibility or resistance factors), such as:

Chronic medical conditions

Possible xenobiotic–drug or other interactions

Genetically determined receptor physiology (eg, potassium channel or *HERG* mutations predisposing to long QT syndrome)

Genetic polymorphisms in hepatic or other metabolic pathways

**Toxicity Assessment**

Compare and contrast organ or systemic effects expected from the particular xenobiotic with existing symptoms

Evaluate both deterministic effects (dose dependent: usually acute or chronic organ injury) and stochastic effects (multifactorial, probabilistic: predominantly carcinogenesis and developmental or transgenerational impact)

justice, and eternity determine the response to uncertain situations.<sup>3,13,17</sup> These underlying worldviews should be considered when discussing risk with an individual and explicitly recognized and addressed in a formal risk assessment. The essential components of a risk assessment for a chemical exposure are listed in [Table 133–1](#).

## DIFFERENTIATING PUBLIC HEALTH FROM INDIVIDUAL RISK ASSESSMENT

It is difficult to translate public health risk assessment done for populations by the EPA or other regulatory or advisory organizations to the individual level. Simplistically, the iterative process of adjusting known noncancer adverse exposure outcome limits in an animal model (eg, lowest observed adverse effect level {LOAEL} or no observed effect level {NOEL}) to a safe level of exposure for all humans (including so-called sensitive subpopulations) is arbitrarily set at repetitive multiplicative factors of 10 for each of these extrapolations unless experimental data support a lower multiplier. These are called “uncertainty factors” and are used in the absence of specific information about human exposure to identify a conservative human “safe dose.” Thus, a “safe dose” is determined as 0.001 times the animal model LOAEL, reflecting a 10-fold reduction in dose for extrapolation from LOAEL to NOEL, another 10-fold reduction for extrapolation from animal to human, and another 10-fold reduction for potentially “sensitive” human populations. These “uncertainty factors” are actually safety factors for the adverse effect of interest. When individuals exceed these limits, they remain protected by very robust safety factors, and are not—as it is often portrayed—exposing themselves to a defined harm. The dietary guidelines for fish consumption (also known as “fish health advisories”) are a good example. Based on concern about exposure to methylmercury and polychlorinated biphenyls, these dietary recommendations rely on epidemiologic studies that suggest subtle neuropsychiatric abnormalities in maternal–fetal pairs (in at least some populations) from levels of fish consumption 10 to 100 times that of the “usual” American diet. Clinical mercury toxicity requires still higher levels of consumption. Although it seems reasonable (precautionary) for pregnant women to limit their intake of certain fish species containing high organic mercury levels, it is inappropriate to avoid fish and the nutrients contained therein because of a misplaced fear of mercury exposure. Furthermore, these risk assessments do not apply to nonpregnant women, children, or men, although they are often generalized to all humans.<sup>2</sup>

The public health modeling concept for cancer health effects risk assessment is even more complex and often misunderstood. In this setting, modeling assumes a linear, no-threshold carcinogenic effect from exposure to a given xenobiotic. Cancer risks from exceedingly small exposures are extrapolated from data in cancer-prone animal models with exposures so large that they are only likely in the experimental setting. This experimental construct ignores the moderating impact of incremental dosing of small amounts over a protracted period of time and potential metabolic and self-repair mechanisms in humans. This aspect of injury surveillance and repair is based on the presence of “cellular chaperones” exemplified by heat-shock protein research.<sup>25</sup> This hormesis effect is modeled as a “U-shaped” dose–response curve whereby low dose exposures are protective against toxicity. Although demonstrated for a number of hazards and exposure settings, hormesis remains controversial as a general concept applicable to risk assessment.<sup>5,21</sup> Even more controversial is the modeling characteristic for “endocrine-disruptors.” These xenobiotics have estrogen receptor and other endocrine gland (eg, thyroid) potential interactions during critical pre- and perinatal timeframes, resulting in the potential for adverse effects at low concentrations, although the relevance of reports to actual human exposures is often unclear.<sup>35,40</sup> Modeling of the quantitative or population impact of this “inverted U” dose–response curve is further complicated by confounders, the potential for contradictory effects in different sexes and exposure timeframes; as well as the difficulty of attributing a cancer cause to a single xenobiotic or exposure. It is very difficult to communicate an acceptable cancer risk to a community, even when using the simple linear, no threshold model. The “acceptable risk” in regulatory modeling is a calculation of “one excess cancer in a population of 1 million exposed individuals.” Although a limitation of this model is explicit in the footnote that this estimate represents “a plausible upper bound estimate of risk at low dose where true risk is often lower, including zero,”<sup>15</sup> this important caveat is rarely communicated, resulting in the common response by individuals that “an extra cancer is acceptable for you, but not when it is my child.”

As this brief review of the principles of regulatory approaches to non-cancer and cancer effects demonstrates, risk assessment is often imprecise. Risk characterization for the individual should avoid unfamiliar statistical concepts, aiming instead to communicate the likelihood of significant risk for the exposure actually experienced. The CDC codifies this approach for a community using such escalating terms as “no public health concern,” “public health concern,” “public health threat,” and “immediate risk.” Although there is debate about the general use of these terms in isolation (without explicit explanations), a similar approach with an individual would summarize the risk assessment using the phrases “safe,” “no adverse effects are expected,” “may be of concern—we will need to do some follow-up testing,” and “this might be (or is) a problem—let’s do the following studies or treatments.”

## RISK COMMUNICATION

Risk communication consists of an exchange of facts and opinions that allow an individual or a group to make an informed decision regarding a course of action or treatment. Practically, risk communication is a way of translating incomplete knowledge so that individuals can achieve informed decision-making. During a one-on-one interaction with a poisoned individual and his or her family or a caller to the PCC, there is a need to gain the fullest attention or cooperation of the individual. After this occurs, the discussion is usually focused on the risks and benefits of various treatment options (eg, gastrointestinal decontamination) or possible diagnostic modalities (eg, observation versus neuroimaging versus antidote administration). The group dynamics of environmental exposure risk communication at a public meeting are very different. Federal agencies that interact with communities in “Superfund” sites (eg, the EPA and the ATSDR) promulgate principles and practical recommendations for risk communication in this setting. [Table 133–2](#) summarizes general principles of risk communication.

Although some of these recommendations are more applicable to longer term deliberations and interactions, much of the individual communication done by the PCC and medical toxicologists succeeds or fails based on

**TABLE 133–2** Principles of Risk Communication<sup>9</sup> and Applicability to the Poison Control Center

Principle	Applications
Accept and involve the individual as a partner.	The caller must be involved to obtain the best information possible.
Plan carefully and evaluate your efforts.	There is a very short time to establish rapport with the caller; do not increase the caller's anxiety by asking irrelevant questions or arguing. Monitor your tone; ask for repetition of key information or recommendations.
Listen to the individual's specific concerns.	Why did the person call? Was it for information, treatment recommendations, or reassurance? Make sure the underlying reason for the call is addressed.
Be honest, frank, and open.	If there is uncertainty or there are unknowns, indicate that uncertainty while providing a workable plan.
Work with other credible sources.	Involve medical toxicology backup and other consultants, particularly for questions regarding chronic exposure or effects.
Meet the needs of the media.	If calls involve media notification or contact, make sure the critical information is stated frequently, provide a human context, and avoid sensationalism.
Speak clearly and compassionately.	Remember that the caller was concerned enough to initiate the contact; make sure the call is completed with a clear plan; provide follow-up appropriate to the situation.

these same principles (Table 133–2). Lacking the opportunity for repeated interactions over time to identify and discuss assumptions and biases, toxicologists need to establish credibility, listen to concerns and empathetically respond, admit areas of insufficient knowledge, and commit to follow-up interactions to convey effectively a risk characterization for an individual based on the available knowledge and experience. The scientific terms, rationale, and any extrapolation from modeling (eg, animal data or case series) should be conveyed in an understandable manner to show that appropriate safety factors are incorporated into areas of uncertainty as a risk-diminishing step. The toxicologist should also emphasize that a precautionary action or even taking no action, results in consequences; these need to be evaluated in the total decision-making process. The patient or audience should leave the interaction with a clear understanding of the difference between a short-term risk of symptoms that will resolve or result in serious illness and the degree of certainty about the potential for a long-term consequence.

Multiple examples of the difficulties inherent in risk communication exist. The need to balance rapid, lifesaving response in a disaster with the need for respiratory and skin protection for the responders is a component of every chemical emergency or mass casualty incident. Poor risk communication commonly occurs when the experience and expectations of a community are at odds with the message delivered by an “expert.” This dissonance was demonstrated in the messaging surrounding 2 recent public health incidents, both problematic based on sensory clues: public water quality in Flint Michigan and the Elk River West Virginia spill of 4-methylcyclohexane methanol. Initial statements that underplayed the water quality issues in Flint flew in the face of grossly discolored and heavily sedimented water. Although the lead leached from the old water pipes was not the cause of the discoloration, this was not reassuring to disenfranchised residents.<sup>11,23</sup> In West Virginia, residents were told that the water was safe to drink and that concentrations of the contaminant were below detectable concentrations; however, because the odor threshold was below the analytical threshold limit of detection, the water had a noticeable smell.<sup>29</sup>

These examples demonstrate the mistrust and difficulties often present in public health emergencies. Even though no significant acute health effects are attributable to either event, simmering concerns about legacy issues (eg, “chemical alley” in West Virginia) and expressed concern about the long-term consequences of low-level lead exposure in Flint and similarly affected communities (in the absence of measurements early in the crisis) highlight issues of environmental justice and public trust, best characterized as “outrage” (see later).

Effective risk communication must therefore address several questions. The appropriate process is to first obtain the best information available regarding the identification of the xenobiotic and the nature of the exposure and then convey the following:

- Likely **magnitude** of the risk: This includes information on the process by which the person would be exposed (ie, the exposure pathway), such as airborne inhalation or drinking water delivery via a contaminated ground water plume and dose–response, such as: “Does the reported exposure to a particular xenobiotic (amount and duration) approach the exposure amounts reported to cause symptoms?”
- The **urgency** of the risk must also be conveyed along with practical recommendations for simple actions consistent with the level of urgency.
- The **applicability** of a risk characterization also needs to be addressed. Are the animal data applicable to humans? Is the exposure something of concern for an individual?
- **Uncertainties** of the risk assessment: This should include a “worst-case scenario” approach to unknown exposures or uncertainties in the quantity of an absorbed dose. The need for continued observation or follow-up for clinical changes would be expressed here. Individual risk tolerance varies greatly. The same information will be interpreted differently by risk-averse versus risk-tolerant people. A variety of comparisons or communication techniques are used to provide an adequate characterization of risk. It is important to remember that the public and even medical professionals have limited ability to understand and incorporate data that rely on numbers and statistics. This health numeracy limitation is even more prevalent than is limited health literacy (Chap. 129).<sup>36</sup>
- **Management options:** In addition to follow-up and repeated evaluations by a medical toxicologist, the range of choices, associated with their relative benefits or risks, should be presented to the individual or group of individuals. A summary recommendation or opinion from the presenter should emphasize specific steps people can take to decrease exposure or potential toxicity if indicated by the level of risk. This last step is important because uncertainty significantly impacts the ability of an individual to take appropriate action. People should not leave the meeting or interaction with the impression that “no one knows what is going on or what we should do.”

## APPLICATION OF RISK ASSESSMENT AND COMMUNICATION PRINCIPLES TO TOXICOLOGY

Many home-initiated PCC calls concern nontoxic or minimally toxic xenobiotics potentially ingested by children;<sup>31</sup> however, the common problem of incomplete documentation of the ingestion (unwitnessed ingestions, lack of diagnostic testing) raises the possibility of undertriage of any given call based on misplaced confidence that relies on prior experience. It is generally assumed that the sheer volume of calls provides some reassurance regarding the accuracy of our risk assessment of these xenobiotics, but we should remain cautious in our interpretation of PCC data (Chap. 130).<sup>6,20,35</sup> Given these uncertainties, even calls about nontoxic xenobiotics require communication between the caller and CSPI beyond simple substance identification. The importance of risk assessment and communication principles is demonstrated in the joint position statement<sup>28</sup> on the prehospital management of “minimally toxic substances” crafted by the American Association of Poison Control Centers (AAPCC), the American Academy of Clinical Toxicology

(AACT), and the American College of Medical Toxicology (ACMT). According to the position statement, a CSPI can make a risk assessment that an exposure is benign or minimally toxic only if the following characteristics are true:<sup>28</sup>

- “The information specialist has confidence in the accuracy of the history obtained and the ability to communicate effectively with the caller.”
- “The information specialist has confidence in the identity of the product(s) or substance(s) and a reasonable estimation of the maximum amount involved in the exposure.”
- “The risks of adverse reactions or expected effects are acceptable to both the information specialist and the caller based on available medical literature and clinical experience.”
- “The exposure does not require a health care referral because the worst potential effects are benign and self-limited.”

The position statement further notes that patient disposition decisions can be altered by many additional factors, including intent, environment, presence of symptoms (possibly unrelated to the xenobiotic in question), and ongoing review of current recommendations in the face of more data.<sup>28</sup> These points emphasize both the dependence of the CSPI on information derived from the caller and his or her confidence in the level of comprehension of the caller. The caller should understand that his or her exposed child is safe; the expert toxicology communication with the caller should alleviate concern—the extent and detail of the assessment process is guided by the caller’s risk tolerance. Toxicologists have developed a number of Web-based consumer tools, attempting to provide simple information outside of direct patient-to-expert consultation. Their utility will depend on the success of implementing these principles.

In the case of a symptomatic patient or a hospital- or physician-initiated contact to a PCC or medical toxicologist, the caller should expect more than just xenobiotic-related information; he or she also expects knowledge and expertise that will provide reassurance or direction for improving the patient’s health status. However, merely relaying information regarding the diagnosis, course, and predicted outcome is insufficient. There is often another underlying reason for the call, such as anxiety, uncertainty, or misinformation established through previous experiences or knowledge base. A sense of guilt frequently underlies a parent’s call for an inadvertent exposure occurring when a child was unsupervised. A health care professional may have had significant difficulties in the management of a previously poisoned patient. If these issues are not addressed, then the caller will continue seeking reassurance by repeated calls to the PCC or by seeking additional input from other sources, such as family, friends, primary physicians, other health care providers. Any variance in the information obtained from these sources will likely be construed as inconsistencies among supposed experts rather than differences in emphasis with regard to the same information, leading to further uncertainty for the caller. Of further concern, the Internet has become a common source of second opinion for health care. Although many sites are useful, there is no quality control or filter to sort good information from bad or even harmful advice.<sup>16</sup> Table 133–3 lists some barriers to effective risk assessment and communication.

TABLE 133–3 Factors That Affect Appropriate Risk Assessment and Effective Risk Communication <sup>13</sup>	
Nature of previous encounters with poison control center or health care field	
Lack of prior patient–health care professional relationship	
Incomplete or inadequate response to a prior question	
The provision of information contrary to “popular understanding,” cultural background, or media representation	
Loss of credibility	
Lack of appreciation of individual or cultural differences in the perception of risk or the applicability of data	
Incomplete or limited comprehension of scientific or statistical principles	

## INTERPRETING PUBLIC HEALTH CONCERNS FOR THE INDIVIDUAL

Medical toxicologists and CSPIs frequently encounter callers or individuals at community events or interact with the media regarding public health–related issues, such as heavy metal exposures involving mercury, lead, or arsenic or concerns about “toxic mold,” plasticizers, and other environmental xenobiotics. Often these people are concerned that their symptoms or future personal or family health will be adversely impacted by such exposures. Such supposed exposures are usually poorly documented, sometimes also driven by popular media descriptions or litigation, and the risk is virtually impossible to ascertain during a short telephone or personal interaction. In these situations, the individual is best served by referral to a primary care physician with toxicology consultation or directly to a medical toxicology clinic. The data and perceptions can be completely reviewed and a more appropriate risk assessment communicated in those settings. These interactions are very difficult because they are often emotionally and politically charged.<sup>32</sup>

In general, the communication of and response to information depend on a preexisting worldview and prevailing circumstances. The same possible outcome will be perceived as more or less severe depending on factors other than the nature of the outcome itself. Several authors characterized the perceived tolerance to different risks, stratified by features such as familiarity and personal control<sup>13,41</sup> (Table 133–4). The emotional response of individuals confronted with these risks is sometimes characterized as “outrage.” One communications specialist posited that “risk = hazard + outrage.”<sup>38</sup> He characterizes situations in which there is a significant hazard but little outrage as requiring “precaution advocacy,” essentially informing the relevant parties of the need for more action or involvement to reduce risk. On the other end of the spectrum is a situation with little hazard but significant outrage, which requires “outrage management” to address fear or anger that is dissociated from the actual hazard posed by the situation. The greater the degree of familiarity with the particular exposure situation and the greater the voluntary nature of the exposure, the less fear or outrage will be expressed for a given adverse outcome, whether this is an appropriate response or not. Although not necessarily applicable to the initial “fight-or-flight” response to an emergency, these concepts are certainly applicable to the aftermath of these events. Of note, although risk communicators use analogies to place exposures into a context familiar to their audience, one must be careful to avoid equating voluntary and involuntary risk assumption or equating those exposures or risks assumed by one segment of the population unequally. An example of this is the use of a smoking risk analogy when talking to a nonsmoker.

Risk communication is very important in the setting of preparedness for terrorism. Although a great deal of attention and money is directed to improvement of public health infrastructure, reporting and surveillance mechanisms, and response to perceived and actual terrorist acts, less attention has been directed to the process of communicating risk to the individual.<sup>10,26</sup> Although some countries practice public health emergency

TABLE 133–4 Factors That Alter the Acceptability of Perceived Risk <sup>13</sup>	
More Acceptable	Less Acceptable
Natural	Human made
Associated with a trusted source	Not associated with a trusted source
Familiar	Unfamiliar
Voluntary	Involuntary
Potentially beneficial	Limited or absent potential benefit
Statistical (low harm likelihood)	Catastrophic (high harm likelihood)
Fairly distributed or shared by all	Unfairly distributed (“injustice”)
Affects adults	Affects children

drills regularly, the United States has concentrated on development of organizational structures and lines of authority, with attention to the importance of outcome-based exercises only recently emphasized.

Maintaining readiness for catastrophic terrorist events (or natural occurrences such as pandemic influenza or storm-related flooding) should use the same risk assessment and communication techniques appropriate for other urgent public health matters. Unfortunately, many factors affect the characterization of risk other than the facts. The importance of presentation style, perception, or the role of the communicator's own biases is exemplified by these 2 composite articles describing the same events:

**Event Description 1:** *Unknown assailants have infiltrated the mail delivery system, resulting in severe illness and deaths of children, healthy adults, and elderly people throughout the country. The initial symptoms can be nonspecific but rapidly progress to death if treatment is not begun early. The medical community routinely fails to diagnose the conditions early, and the government has no system in place to detect this threat after it occurs. The long-ignored public health system is not prepared to deal with the huge burden of preventing illness in those who may have been or will be exposed. Anyone who receives regular mail may be at risk. Tens of thousands of our citizens are taking prophylactic antibiotics "just in case." If you receive any unusual packages or see collections of powder that do not have an obvious explanation, call the police. If you develop a fever, cough, chest pain, or unusual rash, which may not be painful, seek medical attention at once. Tune in to your local news station for more information on this burgeoning threat to our nation's security.*

**Event Description 2:** *A small number of individuals in isolated exposure settings have developed illnesses after bioterrorism events. Most people have survived these exposures, particularly with early and proper medical care. The government has developed a case definition, and medical experts have disseminated information to assist the medical community and public in the early recognition of symptoms and signs that are consistent with this exposure. Prophylactic treatment within days of exposure of those in high-risk professions, such as mail handlers at major postal sorting facilities, prevents illness. Unfortunately, there have been a large number of hoaxes and false alarms about possible terrorist events and a lot of understandable fear in the community about nonspecific symptoms. For more information, contact your local health department or obtain information from frequently updated reliable web sites, such as the CDC's Web site.*

Both of these paragraphs describe the 2001 anthrax bioterrorism events within the United States, during which a total of 22 people become ill, of whom 5 died from anthrax exposure. The first communication suggests that everyone is at risk and the situation is dire; the communication in the second paragraph is that the risk is isolated (a single individual died who was not in what was recognized as an at-risk setting from the 7 identified mailings), and there is a plan and process being developed to respond to the threat. Whereas the first is sensationalistic, imparting a helpless victim role to the reader, the second provides a framework in which to assess personal risk and access sources of reliable information. Both types of reports were prevalent after the 2001 anthrax attacks. Which report seems more complete, accurate, or useful is determined by the assumptions and perspectives of the reader in addition to the message the author wishes to deliver or response desired. Some would say that communicating a high degree of risk is important to gain the attention of the reader and to ensure that no one ignores a warning. However, the lack of a risk perspective prevents the reader from placing this information in context with the myriad other risk communication messages conveyed on a daily basis. In general, risk communication messages that do not provide a context or comparison to generally familiar activities or risks are more prone to misinterpretation or misapplication. "White powder" events continue throughout the country on a regular basis, but the development of systematic evaluation steps and education by organizations such as the United States Postal Inspection

Service in conjunction with automated environmental sampling at mail handling facilities have decreased the fear of a toxic exposure in this setting. As biopreparedness moves from public health infrastructure development and surveillance improvement to planning and response drills, appropriate message development and risk communication to the public needs continued emphasis.

Informing the public of scientific issues related to complex toxicology principles and risk-to-benefit analysis is also a nonemergency component of risk communication. Clinicians do this every day when interpreting laboratory findings for their patients, as discussed elsewhere in the text (Chaps. 7, 86, and 93). The "press release" examples provided below highlight 2 opposing positions on the recent controversy regarding the herbicide glyphosate (Chap. 109).<sup>18</sup> Read these paragraphs from the perspective of a concerned, but scientifically uninformed parent or school administrator:

**Hypothetical Press Release 1:** *The pesticide in most prevalent use today is a carcinogen. In 2015, the highly respected International Agency for Research on Cancer (IARC) designated glyphosate as a probable human carcinogen, one step away from being labeled a known human carcinogen. Based on evaluation of studies involving cell-based models and experimental animals, as well as human data, the designation puts an end to the longstanding industry claims of low toxicity. Steps should be taken to remove this toxic chemical from the environment and to eliminate exposure, particularly to children on school grounds.*

**Hypothetical Press Release 2:** *Glyphosate and its commercial formulations (consisting of the active herbicide and solvents and surfactants added to help it gain and maintain access to plants) have a long history of use throughout the world. They have an excellent safety profile when used as directed. This safety profile is attributable to the dissimilarity between targeted plant and human cell structure. Suicidal ingestions of large amounts of glyphosate formulations can result in fatality, but this is caused by a severe pulmonary reaction to aspirated detergents in the product. A number of organizations in various countries have evaluated decades of data and concluded that glyphosate is unlikely to be a carcinogen. In 2015, a 17-member working group of the international Agency for Research on Cancer (IARC) decided that the weight of evidence supported a probable human carcinogen designation. This anomalous result relied on statistical reevaluation of existing animal experimental data, focusing on lymphomas and rare hemangiosarcomas and human epidemiologic studies. The IARC designation is controversial, considering the likelihood of publication and recall bias in animal and human retrospective studies, respectively. In particular, questions persist regarding the human applicability of cancer-prone animal models at cytotoxic daily doses orders of magnitude in excess of human exposure. These issues speak to the differences between internal and external validity and impact the confidence scientists have in statistical analysis of existing data.*

The first statement is direct and identifies a specific action as a desired endpoint. Unfortunately, it mixes "toxicity" and "cancer-causing" without distinguishing the vast difference between these 2 concepts in both dose amount, duration, and mechanism. It makes categorical statements and implies a level of certainty (eg, "human data") without mentioning all the limitations that are involved (eg, bias, extrapolating from experimental models and retrospective epidemiologic assessments). In addition, it implies a progression or proximity in the cancer categories by the false "one step away" analogy. Although short, it is misleading to the point of being false.

The second statement is longer and provides more background and context for the process of decision making or designation, but it concludes without an action step or relevant answer to the implicit question: "Am I at risk?" In addition, for a lay public audience, the statement is much too complex, does not use plain language, and assumes knowledge that is unlikely to be present (eg, regarding specific cancer types, the nature and definitions of bias and editorial process, and the meaning of such concepts as "cytotoxicity"). A shorter statement that removes both the parenthetical partial explanation

about mechanism of action and the disconnected statement about suicidal ingestions could be summarized as:

**Hypothetical Press Release 2a:** *Glyphosate is a weed killer with a long history of safe use throughout the world in the ongoing effort to minimize crop stress and maximize food production. A number of organizations in various countries have evaluated decades of data and concluded that glyphosate is unlikely to be a carcinogen. In 2015, a 17-member working group of the international Agency for Research on Cancer (IARC) reviewed the same published studies and decided that the weight of evidence supported a “probable human carcinogen” designation. The IARC decision is controversial. Many cell-based or experimental animal studies use exposure conditions much more extreme than any usual human exposure, and it is always difficult to sort out the real cause in studies that ask people to recall the nature of daily exposures when evaluating the cause of an illness (this is called “recall bias”). These issues impact scientists’ confidence in the application of studies and statistical analysis. An ongoing prospective study has not identified any increased risk of cancer in people who use glyphosate very regularly, which should be even more reassuring to the vast majority of the population who have infrequent or no use of glyphosate.*

Although still lengthy, the last statement provides cautionary remarks that frame the decision-making process. Critics would argue that it is too simplified and omits mention of “low-level exposure” for “susceptible populations” or “susceptible periods of human development.” However, the obvious difference in scientific rationale for the first and last example of hypothetical press releases should at least allow a thoughtful conversation in the latter case. It is left to the reader to determine how best to work with media representatives to further this type of risk communication.

## SUMMARY

- High-quality risk assessment and effective risk communication are the hallmarks of a successful interaction between the public and PCCs and between a toxicologist and an individual patient, the media, or the public health community.
- A toxicologist’s job is to obtain the best information possible regarding potential exposures and then convey that information in an understandable fashion with a detailed risk characterization of the hazard, likelihood of a completed exposure pathway (thus, the likelihood of an actual exposure), possible health effects, and treatment options.
- It is important to clarify the difference between public health standards and individual health risks, with an understanding of the many psychosocial issues that influence perception.
- Information should be provided in a context that allows the individual to prioritize his or her response based on a factual and balanced presentation with respect to his or her health literacy and health numeracy.

## CASE STUDY 14

**History** A 27-year-old man with a past medical history of opioid dependence who is currently on methadone maintenance therapy was brought into the hospital for a routine medical clearance before arraignment. The patient complained of chest pain and had an electrocardiogram (ECG) that showed ST-segment elevation; however, compared with a prior ECG, it was unchanged (Fig. CS14-1). The patient was admitted for observation.

While he was in the emergency department (ED), the patient developed nausea, vomiting, diarrhea, and abdominal discomfort; he was given 4 mg of intravenous ondansetron. The patient then complained of persistent abdominal discomfort and stated that he was in opioid withdrawal. He was then given 10 mg of methadone intramuscularly. Shortly thereafter, the patient was found unresponsive, he was attached to a cardiac monitor, and the following rhythm (Fig. CS14-2) was obtained:

**Physical Examination** The patient was pulseless and unresponsive on the

stretcher. Active cardiopulmonary resuscitation was in progress.

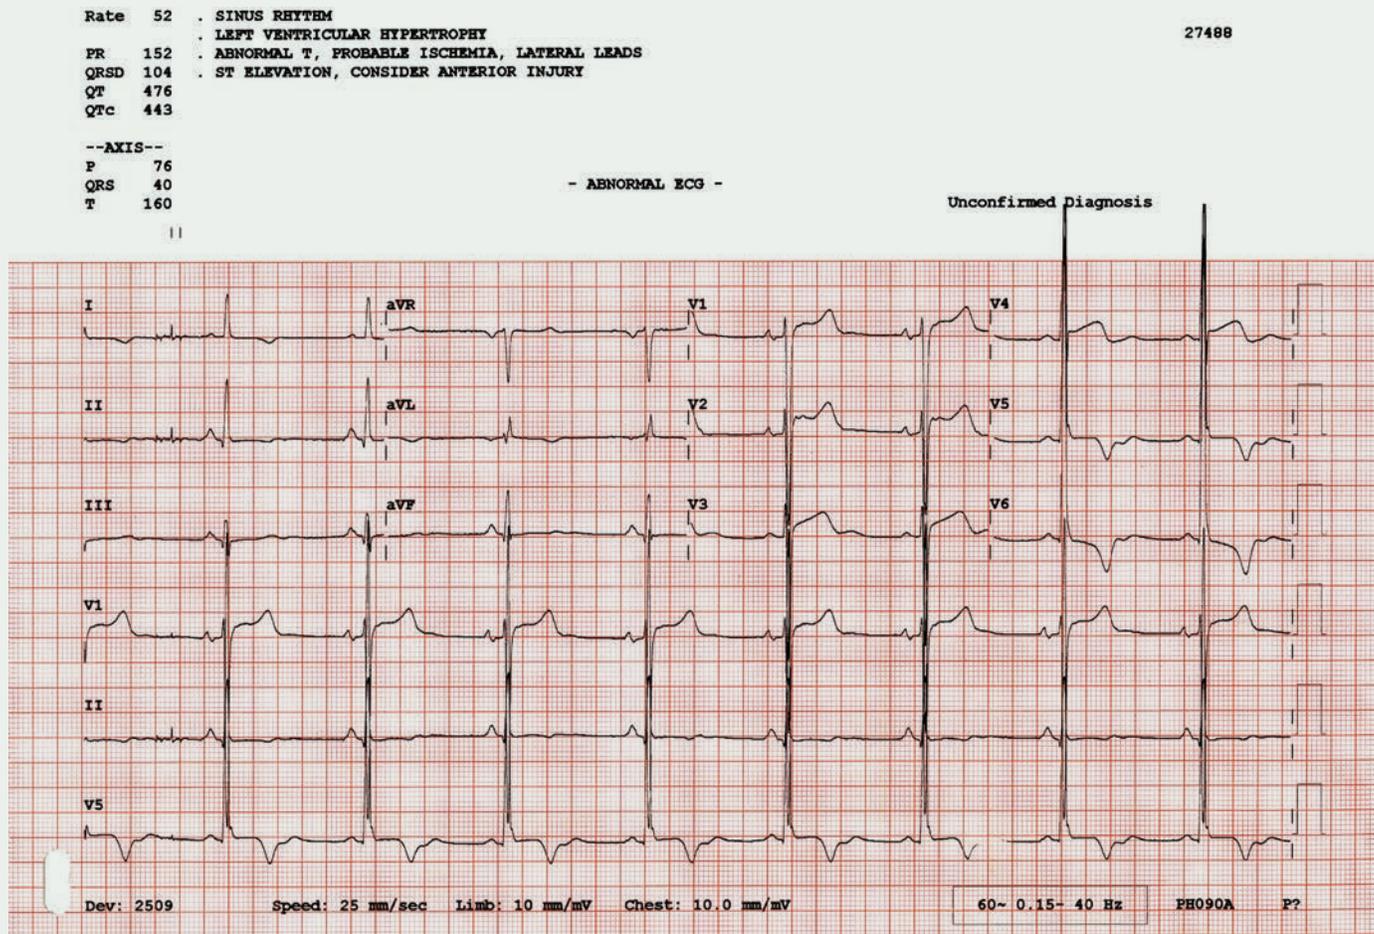

**Initial Management** The patient was immediately defibrillated. The patient had return of spontaneous circulation, and then 2 g of magnesium sulfate was administered intravenously. The patient was started on an isoproterenol infusion and is admitted to the critical care unit. An ECG performed after return of spontaneous circulation is shown in Fig. CS14-3.

### What Is the Differential Diagnosis?

The patient developed a pulseless rhythm. During this episode, the rhythm strip demonstrated torsade de pointes. Upon evaluation of the postdefibrillation ECG, the patient's QT interval was prolonged. The differential diagnosis for a prolonged QT interval is extensive (Chap. 15). Electrolyte abnormalities, specifically hypokalemia, hypocalcemia, and hypomagnesemia, are common causes of a prolonged QT interval that are easily treatable (Chap. 12).

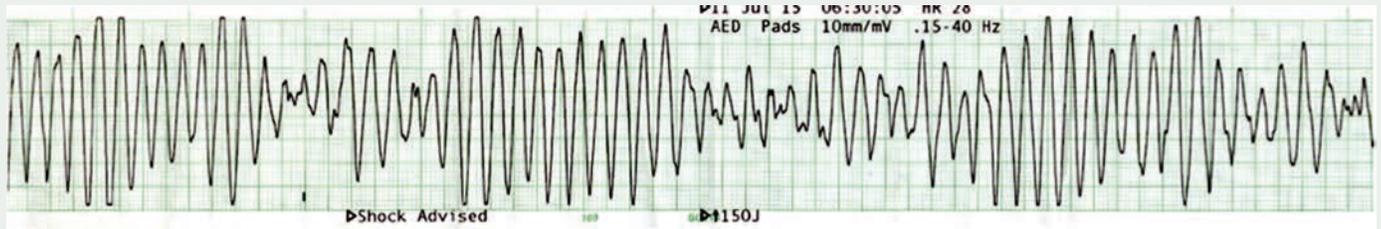

Although there are hereditary causes of a prolonged QT interval, these are quite rare. The most common cause of a prolonged QT interval is usually medication related and results from potassium channel blockade. The list of medications that prolong the QT interval is quite extensive and includes many common classes; for example, they can be chemotherapeutics, such as arsenic trioxide, antibiotics such as clarithromycin, antidepressants such as citalopram, or anti-psychotics such as droperidol and haloperidol. Reviewing the potential for drugs to prolong the QT interval on a website, such as Crediblemeds.org, and also checking for drug interactions should be part of the routine care of patients.

Methadone predictably leads to QT interval prolongation (Chap. 36). The risk of developing a prolonged QT interval is related to the dose of the methadone; the higher the dose taken, the higher the risk. The risk of developing torsade de pointes is additive; as other medication are added,

**FIGURE CS14-1.** This 27-year-old man was on chronic methadone therapy. His initial electrocardiogram shows a sinus bradycardia.

## CASE STUDY 14 (CONTINUED)

**FIGURE CS14-2.** A 27-year-old man who chronically received methadone was given 10 mg of methadone intramuscularly for opioid withdrawal and 4 mg of ondansetron for nausea and vomiting. Shortly thereafter he developed torsade de pointes.

the QT interval prolongs, increasing the risk of developing torsade de pointes. Methadone is a particular concern; in addition to the prolonged QT interval, it also leads to a bradycardia, which further increases the risk of torsade de pointes.

Ondansetron, a 5HT<sub>3</sub> antagonist that is used commonly in EDs, also prolongs the QT interval. This demonstrates that even a medication that is used several times a day should be checked for an interaction with any other xenobiotic the patient is taking (Chap. 134).

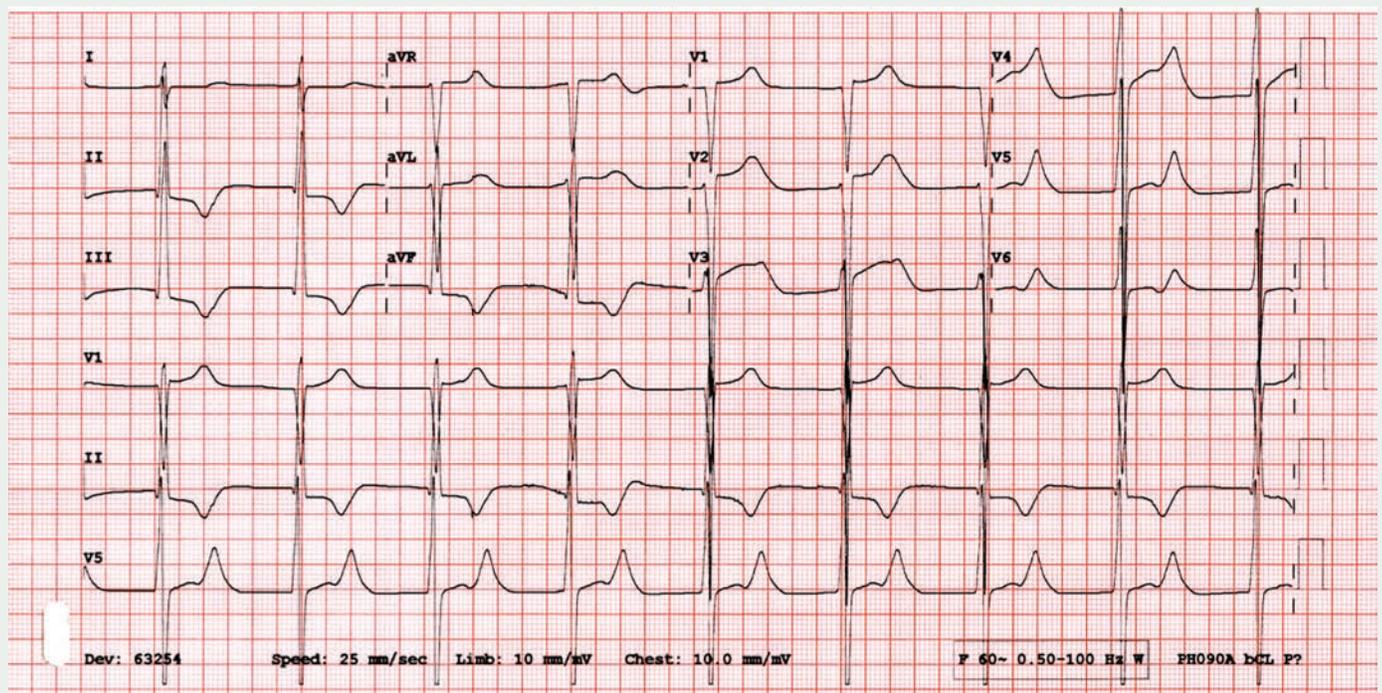

### What Clinical and Laboratory Analyses Further Assist in Identifying Causes of the Patient's Presentation?

The most important tests in evaluating

patients who have loss of consciousness are vital signs, pulse oximetry, and an ECG. Measuring the QRS complex and QT interval is incredibly important in evaluating the poisoned patient in these circumstances. Serum electrolytes should be checked, specifically, the sodium, potassium, magnesium, and calcium, to evaluate for easily reversible causes of a prolonged QT interval. Often, however, the cause of a prolonged QT interval is best uncovered by performing a thorough history and medication reconciliation.

**Further Diagnosis and Treatment** The ECG after defibrillation was found to have a markedly prolonged QT interval of 640 ms (Fig. CS14-3). In addition to the prolonged

QT interval, the patient had hypokalemia from his persistent vomiting. The co-administration of ondansetron and methadone, drugs known to cause prolongation of the QT interval, in the setting of hypokalemia was synergistic, leading to torsade de pointes. The most important treatment of torsade de pointes is prevention for which magnesium sulfate was administered. He was administered isoproterenol intravenously to increase the heart rate in the intensive care unit, and he had no further episodes of torsade de pointes. The patient's QT interval narrowed after discontinuation of methadone and ondansetron, and he was transitioned to buprenorphine for his opioid dependence.

**FIGURE CS14-3.** A postdefibrillation electrocardiogram of the same 27-year-old man demonstrates a sinus bradycardia and a prolonged QT interval. This was likely caused by a combination of the methadone therapy treatment with, ondansetron, and the hypokalemia that resulted from vomiting.

# MEDICATION SAFETY AND ADVERSE DRUG EVENTS

Brenna M. Farmer

## HISTORY AND EPIDEMIOLOGY

Patient safety is of great interest to many stakeholders—patients, regulatory and accreditation bodies, hospital and health system administrators, and health care professionals. Interest has expanded since the publication of the Institute of Medicine’s 1999 report on medical errors and measures necessary to ensure a safer health care system. Its subsequent report in 2001 focus on quality with one aim, to avoid injury to patients and redesign health care, so that safety is a property of the system.<sup>49,53</sup> A 2006 report focused specifically on reducing medication errors and adverse drug effects.<sup>51</sup> These reports and others reveal that medications errors represent up to 25% of all medical errors.<sup>55</sup> Many health care institutions address medication safety through their pharmacy and therapeutics (also commonly called drug and formulary), medication safety, patient safety, and quality improvement committees. **Table 134–1** shows a timeline of some important developments in medication safety.

Studies of medical errors, including those involving medications, are of a highly variable quality and usefulness. This occurs in large part because of diverse populations, variable definitions, and multiple study acquisition and analysis methodologies. Despite these differences, studies consistently establish that medical errors cause thousands of deaths each year. Medical errors are a leading cause of death in the United States, with estimates of 251,000 deaths per year. This number is likely an underestimate given how “cause of death” uses ICD 10 codes, on death certificates and does not

capture human or system errors.<sup>78</sup> Previous studies estimated that 44,000 to 180,000 people die each year of medical errors<sup>53,71</sup> and of these injuries 60% are probably preventable.<sup>16</sup> With preventable health care harm as a leading cause of death in the United States, the National Patient Safety Foundation has labeled medical error as a public health crisis.<sup>90</sup>

Approximately 9.5 million patients experienced an adverse drug event (ADE) from 2008 to 2011 according to a large retrospective analysis of the Healthcare Cost and Utilization Project’s National Inpatient data set. Previous reports estimated that more than 1.5 million preventable ADEs occur each year.<sup>51</sup> An ADE is an untoward event or outcome associated with the therapeutic use of a drug. The definition of ADEs includes medication errors as well as adverse drug reactions and drug interactions. A medication error is “any preventable event that may cause or lead to inappropriate medication use or patient harm while the medication is in the control of the health care professional, patient, or consumer.”<sup>89</sup> An adverse drug reaction is a sign or symptom related to use of a medication that results in unpleasant effects when an error has not occurred.

The cost of a single ADE is estimated to be \$1,800 to \$5,000 at academic and community hospitals.<sup>11,22,23,47</sup> Similarly, length of stay increased from 1.8 to 3 days when an ADE occurred.<sup>47,100</sup> Other studies estimated that the annual cost of ADE morbidity and mortality was greater than \$77 to \$177 billion in the ambulatory care setting,<sup>33,56</sup> \$2 billion in hospitals,<sup>11,23</sup> and \$4 billion in nursing homes.<sup>15</sup> These costs exclude legal or other costs that accrue to the patient or their families.

**TABLE 134–1** Critical Events in the Evolution of Medication Safety

1820	United States Pharmacopeia (USP) is established in Washington, DC
1906	The Pure Food and Drugs Act is passed by Congress
1927	The Bureau of Chemistry is re-formed into Food, Drug, and Insecticide Administration and the Bureau of Chemistry and Soils
1930	The Food, Drug, and Insecticide Administration was renamed the Food and Drug Administration (FDA)
1962	Kefauver-Harris Drug Amendments passed to ensure drug efficacy and greater drug safety President Kennedy proclaims the Consumer Bill of Rights, which includes the right to safety, right to be informed, and right to choose
1963	Representatives from FDA, USP, American Medical Association (AMA), and American Pharmacists Association form the US Adopted Names Council to establish drug nomenclature
1968	The FDA is placed in the Public Health Service after reorganization of the federal government health programs
1970	The FDA requires the first patient package insert
1975	The Institute of Safe Medication Practices’s (ISMP) work officially begins with a continuing column in <i>Hospital Pharmacy</i>
1987	The first ISMP list of dangerous drug abbreviations is printed in <i>Nursing ’87</i>
1989	Agency for Health Care Policy and Research (AHCPR) is established as an agency in the Public Health Service in the Department of Health and Human Services
1991	Institute for Healthcare Improvement is founded as a not-for-profit organization to aid in improvement of health care quality USP and ISMP create Medication Error Reporting Program (MERP)
1993	A consolidation of several adverse reaction reporting systems is launched as MedWatch, the FDA voluntary reporting system for problems associated with medical products
1996	The National Coordinating Council for Medication Error Reporting and Prevention (NCC MERP) is formed
1997	National Patient Safety Foundation is established with patient safety as its sole purpose ISMP founds a subsidiary, Medical Error Recognition and Revision Strategies (Med. E.R.R.S.), to work with drug companies to predict problems with names, labels, and packaging
1998	USP launches MEDMARX, an Internet-accessible medication errors reporting system for hospitals Founding members of The Leapfrog Group meet to discuss ways to purchase health care to influence its quality and affordability ISMP publishes a list of high alert medications
1999	The Institute of Medicine (IOM) Report <i>To Err Is Human: Building a Safer Health System</i> <sup>82</sup> is published The Leapfrog Group founding members establish the reduction of preventable medical errors as their initial focus The National Quality Forum is created as the President’s Advisory Commission on Consumer Protection and Quality in the Health Care Industry Agency for Health Care Policy and Research is renamed Agency for Healthcare Research and Quality
2006	IOM Report <i>Preventing Medication Errors</i> <sup>83</sup> is published
2007	USP and Quantros, a company that collects data on health care quality, patient safety and accreditation, partner to run MEDMARX

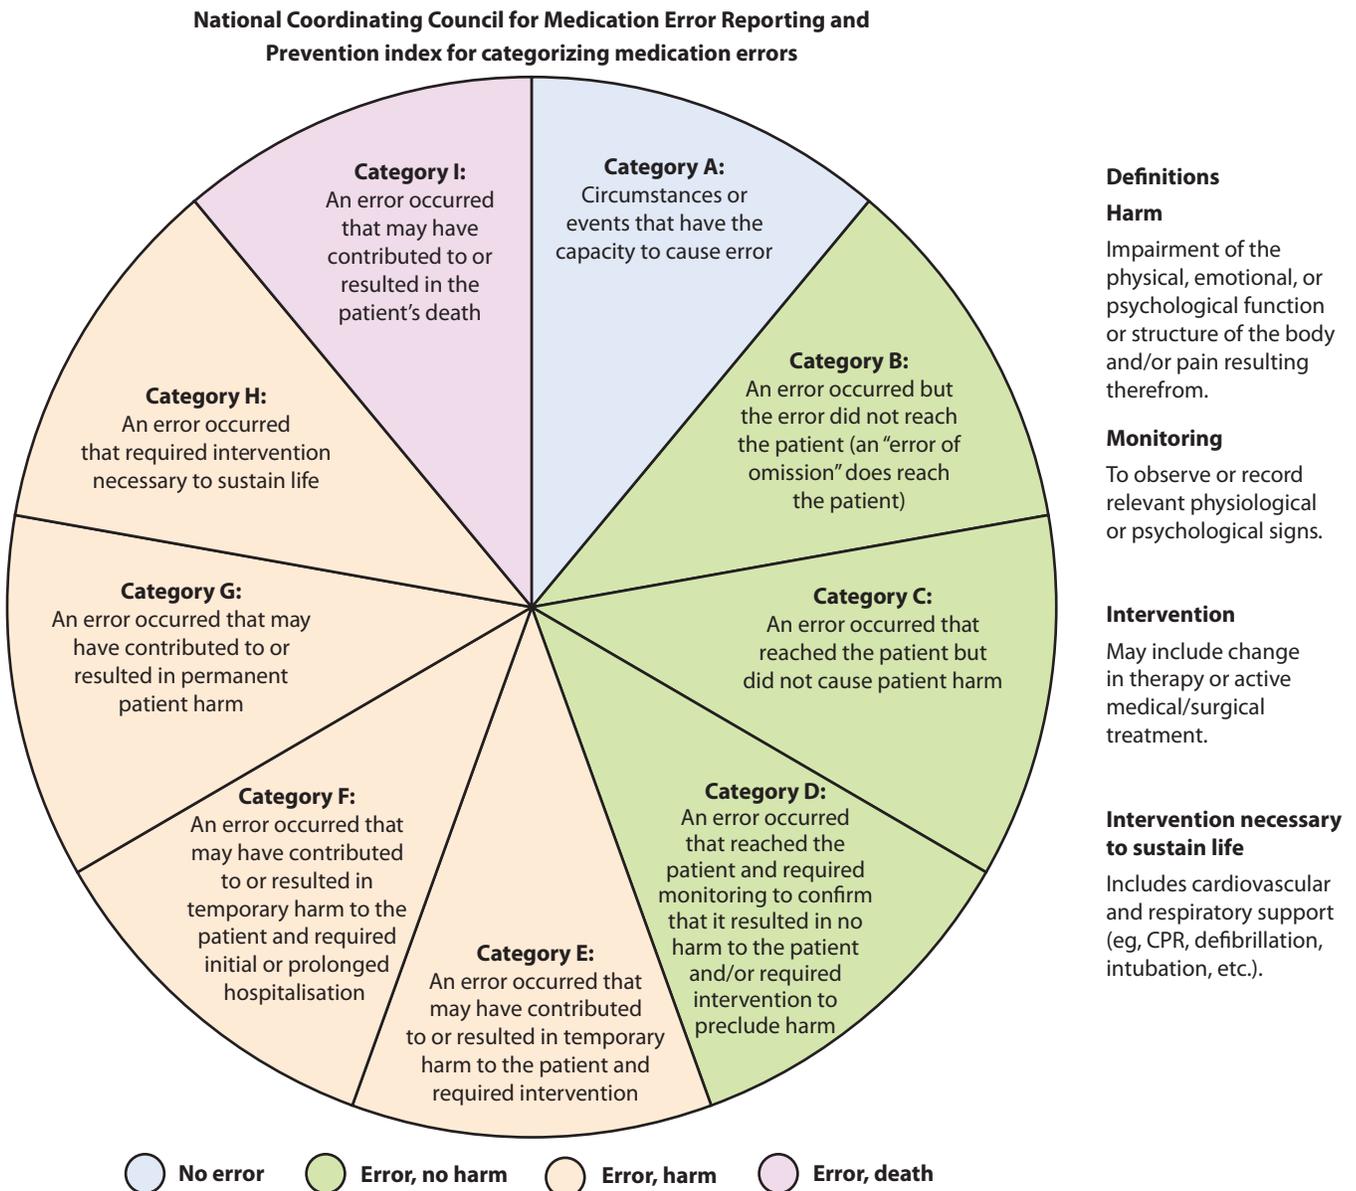

**Morbidity and Mortality From Medication Errors and ADEs**

Although medication errors are the most common cause of iatrogenic patient injury, less than 2% result in injuries. Poison Control Centers take calls every day for unintentional therapeutic errors related to medications. In 2015, 12.7% of all human exposure calls to poison control were for therapeutic errors.<sup>88</sup> Adverse drug events and medication errors with serious effects lead to 3.1% to 6.2% of all hospital admissions.<sup>69</sup> Nevertheless, the incidence of ADEs in hospitalized patients is estimated to range from 2% to 20%,<sup>22</sup> resulting in 7,000 deaths annually in the United States.<sup>53</sup> A retrospective review of hospital death certificates by ICD 9 and ICD 10 codes from 1983 to 2004 revealed an increase of 361% in fatal medication errors and a 33% increase in deaths from ADEs occurring in a patient's home.<sup>98</sup> The hospital death certificate review also revealed an increase in fatal medication errors 32 times higher when prescription medications were combined with ethanol and or illicit xenobiotics.<sup>98</sup> According to voluntary MedWatch reports to the US Food and Drug Administration (FDA), 17% of reported ADEs were associated with death, 7% were associated with permanent disability, and many others had serious complications. Women and elderly patients were at the highest risk.<sup>85</sup>

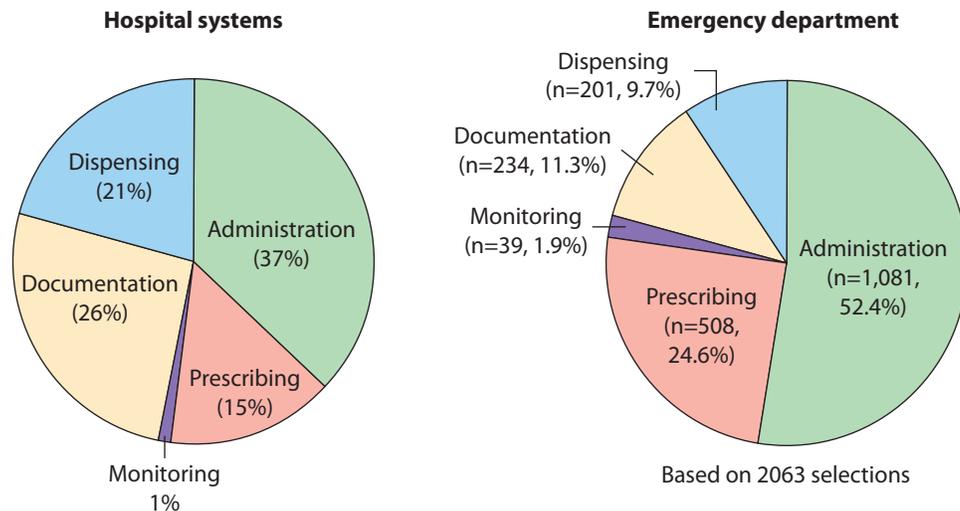

Adverse drug events lead to many emergency department (ED) visits and hospitalizations. In one study, 2.5% of all ED visits, for unintentional injuries, are for ADEs and these ADEs make up 6.7% of unintentional injury hospitalizations from the ED.<sup>20</sup> In this study, individuals greater than 65 years of age were at higher risk of unintentional injury and hospitalization.<sup>20</sup> In another study, 59% of ED patients had a medication error occur and 37% of those patients had the error reach them. Factors increasing these errors were boarding patient status, number of medication orders, and number of medications administered.<sup>95</sup> The most recent study of ED visits showed that 27% of ED visits for ADEs lead to hospitalization and reiterated that elderly patients were most at risk.<sup>111</sup>

**National Coordinating Council for Medication Error Reporting and Prevention Taxonomy**

A useful medication error taxonomy, developed by the National Coordinating Council for Medication Error Reporting and Prevention (NCC MERP), classifies medication errors according to severity of outcome (Fig. 134-1).<sup>89</sup> Importantly, the categories of least severity (A and B) describe circumstances

**FIGURE 134-1.** Diagram showing National Coordinating Council for Medication Error Reporting and Prevention categories of medication errors, ranging from fatal to errors with no impact on patient care. (© 2001 National Coordinating Council for Medication Error Reporting and Prevention. All rights reserved.)

**FIGURE 134-2.** Diagram showing MEDMARX data for (A) hospital systems and (B) specifically for the Emergency Department. (Adapted with permission from United States Pharmacopeial Convention, www.usp.org.)

or events in which the potential to cause error exists, or the error occurs but does not affect the patient. These “near misses” are so frequent that they serve as a critical source of information related to systems problems and education about medication error, but are typically underreported and underappreciated. In one study of 154,816 errors reported by hospitals and health systems to MEDMARX from 1999 to 2001, most of the errors were in category C (47%) and resulted in no patient injury, whereas there were 19 errors in category I, contributing to or resulting in patient death, comprising 0.01%.<sup>105</sup> See Fig. 134-2 for a comparison of errors in the inpatient versus the ED setting based on the NCC MERP classification.

**Medications Involved**

The US FDA reports suggest that opioid analgesics and immune modulators are the most common medications in which errors resulted in death.<sup>85</sup> The medications most frequently involved in errors and ADEs reported to MEDMARX were insulin, anticoagulants, morphine, and potassium chloride.<sup>105</sup> These are considered high-alert medications according to the sentinel event alert system of The Joint Commission. Another retrospective review suggests that corticosteroids, chemotherapeutics, anticoagulants, nonsteroidal antiinflammatory drugs, and opioids are the most common medications associated with ADEs.<sup>100</sup> Identifying characteristics of high-risk medications include low therapeutic index, pharmacokinetic interactions, inherent undesirable effects, newly approved or “off-label” use, and direct-to-consumer promotion.<sup>12</sup> Table 134-2 lists medications/medication classes commonly reported.

**The Medication Process**

The Medication Process comprises the 5 stages in the sequence of ordering a medication to its delivery to the patient: prescribing, transcribing, dispensing, administering, and monitoring.<sup>7</sup> For patients discharged from care, follow-up adds a sixth stage.<sup>28</sup> Each stage yields multiple steps. The potential for error is high, increasing exponentially as the number of steps and their complexity increase. Table 134-3 describes typical errors that occur at each stage in the process, along with prevention strategies.

The greatest number of errors resulting in preventable ADEs (medication errors) occurs at the prescribing stage.<sup>8</sup> In a study of serious medication errors, 39% occurred at prescribing, 12% at transcribing, 11% at dispensing, and 38% at administering.<sup>72</sup> In one study of 17,808 inpatient and ED medication orders, 6.2% of orders written involved a prescribing error and 30% of these were likely to harm the patient if they were not discovered.<sup>14</sup> Another prospective study suggested that up to 43.8% of medication orders on hospital wards had a prescribing error discovered by ward-based pharmacists, independent of the level of prescriber experience.<sup>108</sup> In the ED, most errors occurred in either the prescribing or administering phase.<sup>95</sup>

Transcribing errors usually involve poor communication due to illegible handwriting, the use of trailing zeroes, or inappropriate abbreviations. Poor handwriting also leads to confusion, particularly with regard to look-alike and sound-alike medications.<sup>96</sup> All information, whether printed, spoken, or otherwise communicated, must be transmitted in a clear, unambiguous, and timely fashion with avoidance of abbreviations. In its 2004 National Patient Safety Goals, The Joint Commission developed a minimum list of 5 sets of dangerous abbreviations, acronyms, and symbols that should not be used, and proposed preferred terms.<sup>115</sup> The Institute for Safe Medication Practices (ISMP) published a more comprehensive list that is updated periodically.<sup>54</sup> By not using these abbreviations, the hope is that communication will be improved and that there will be no misinterpretation of poor physician handwriting.

Dispensing errors are most commonly due to substitution and labeling errors.<sup>109</sup> Errors at the stage of administering medications include incorrect drug, incorrect dose, incorrect route, and a drug given to the wrong patient. Computerized provider order entry (CPOE) was introduced to improve the medication process from prescribing to administering, but has introduced new problems. See the *Information Technology* section for further discussion.

**TABLE 134-2 Medications or Medication Classes Commonly Responsible for Medication Errors**

Acetaminophen	Corticosteroids
Albuterol	Electrolyte replacement
Antibiotics	Potassium chloride
Amoxicillin	Fluid replacement therapies
Cefazolin	Furosemide
Cephalexin	Nonsteroidal antiinflammatory drugs
Levofloxacin	Opioids
Penicillin	Fentanyl
Vancomycin	Meperidine
Anticoagulants	Methadone
Heparin	Morphine
Warfarin	Opioid-acetaminophen combinations
Antidiabetics and Hypoglycemics	Oxycodone
Aspirin	Sedatives
Cardiovascular	Benzodiazepines
Clopidogrel	
Digoxin	
Inotropes	
Vasopressors	
Chemotherapeutics	

**TABLE 134–3** Errors Based on Medication Process Stage and Error-Reducing Strategies

<b>Monitoring</b>	<p>Potent medications</p> <p>Parenteral administration</p> <p>Emergent procedures</p> <p>Complex procedures</p>	<p>Ensure adequate personnel</p> <p>Clearly defined protocols and guidelines:</p> <ul style="list-style-type: none"> <li>Procedural sedation</li> <li>Rapid sequence ventilation</li> </ul> <p>Adequate monitoring time following drug administration</p>	<p>Decision support tools</p> <ul style="list-style-type: none"> <li>Drug concentration monitoring</li> <li>Other laboratory monitoring</li> <li>Other vital sign monitoring</li> </ul>		
<b>Follow-up</b>	<p>Patients leaving the hospital or health care facility, and especially medicated patients</p>	<p>Medication reconciliation</p> <p>Paper discharge instructions</p> <p>Written information regarding new medications</p> <p>Advise of required follow-up</p> <p>Consider medication effects if a patient is driving</p> <p>Pill counting devices</p> <p>Medications organizing systems</p>			

Monitoring and discharging with follow-up are associated with fewer errors. These phases involve attention to liver and kidney function, checking medication concentrations, and attention to and evaluation of drug interactions and pharmacokinetic interactions.<sup>28</sup> Monitoring must be an ongoing process that begins when the patient receives the medication, regardless of where the patient is in the health care system, and continues as long as the individual continues to have the medication prescribed. In the acute stages of treatment, such as in the hospital or ED, the process is especially important and requires optimal 3-way linkage between the pharmacy, laboratory, and physician.<sup>106</sup> This process must be maintained throughout the individual's continued relationship with the health care system. In the outpatient setting, providers must be aware of signs and symptoms related to adverse drug effects while they are monitoring and following up patients. In a study of 661 patients in 4 primary care practices, patient reports of medication side effects to their physicians led to changed therapies in 76% of cases. A failure to identify medication-related symptoms and change therapy resulted in 21% ameliorable and 2% preventable ADEs. Ameliorable ADEs were defined as those in which "the severity or duration could have been reduced substantially had different actions been taken."<sup>122</sup>

### SPECIAL AT-RISK POPULATIONS

Important medication safety issues exist for children and older adults, a problem that is exacerbated by their underrepresentation or exclusion from clinical trials. It is estimated, for example, that only a third of the medications used to treat children are adequately tested in this population.<sup>25</sup> Similar concerns apply to medications used in older adults and those individuals with specific underlying medical conditions that would have excluded them from trials.<sup>48</sup>

### Pediatric Considerations

Adverse events involving medications in children occur from the prenatal period through maturation. Errors occur in all settings: the home, ambulatory care, prehospital setting with emergency medical services (EMS), ED, hospital floor, pediatric intensive care unit (PICU), and neonatal intensive care unit (NICU), and by all caregivers. Approximately 1 in 6.4 pediatric orders results in an error that reaches the child.<sup>80</sup> Because of the greater need for dose calculations to allow for weight-based dosing, dose-related errors are more likely to occur in children.<sup>58</sup> Errors also occur in the home environment with nonprescription medications, but the true incidence is unknown. In one survey, the errors associated with home antipyretic use were estimated at almost 50%.<sup>81</sup> These errors were typically associated with underdosing, which is generally of little immediate harm.<sup>104</sup> In the ambulatory care setting, the incidence is unknown but one study identified "numerous" errors in prescription writing in a pediatric clinic.<sup>120</sup> An EMS study determined that 43% of paramedics knew cases in which a dosing error occurred.<sup>44</sup> In the ED, the error rate was estimated at 10% of all pediatric charts.<sup>63</sup> There is an increased risk of errors in children cared for in nonacademic or rural EDs compared with academic or pediatric EDs.<sup>61</sup> A retrospective chart review of 177 pediatric charts in 4 rural EDs identified 84 different medication errors in 69 of the 135 patients who received medications. The outcomes of these errors were in NCC MERP categories A to D (Fig. 134–1).<sup>79</sup> A study of 18 pediatric EDs' voluntary event/incident reporting data showed that 19% of all incidents were related to medication events. A total of 94% were medication errors and 6% were ADRs. Errors included using incorrect weights, duplicate dosing, and miscalculations. Human factors contributed to 84% of the medication errors in this study.<sup>110</sup> See the Factors Affecting Human Performance section for further discussion.

Hospitalized children experience up to 3 times the rate of medication errors and potential ADEs as do adults.<sup>59</sup> The incidence of medication errors of hospitalized children is estimated at about 6% for all orders written; the majority (74%) of these occur at the prescribing stage and approximately 20% are classified as potentially harmful based on a 4-point Likert-type scale developed by the investigators.<sup>37</sup> Pharmacists based on pediatric hospital wards discovered that 5.9% of orders contained a prescribing error and were

able to intervene through the order entry system.<sup>30</sup> Generally, children in the intensive care unit are at higher risk for errors compared to adults and hospitalized children not in the ICU, presumably reflecting the increased complexity of disease and the medications used.<sup>61</sup> Incorrect dosing, especially with the intravenous route, is the most commonly reported error. Dosing of antimicrobials and intravenous fluids are the most common medications involved.<sup>29,35,59</sup> Errors and discrepancies found in hospital discharge instructions, with lack of complete medication reconciliation, also lead to patient harm (Chap. 31).<sup>57</sup>

### Geriatric Considerations

Medication errors in older adults also occur throughout the health care continuum: in the home, ambulatory care, nursing homes, assisted-living setting, and in the hospital (Chap. 32). Adults older than 65 years of age have a relative risk of 2.37 for drug complications and 4.12 for medication errors compared to adult patients younger than 65 years of age.<sup>16</sup> The incidence of medication error at home with nonprescription medications is unknown but, for reasons outlined below, would be expected to exceed that of the younger adult population. Using a variety of methodologies, ADEs were evaluated for a 12-month period in a multispecialty ambulatory care practice in a cohort of 27,617 Medicare enrollees, equivalent to more than 30,000 person-years of observation. Extrapolating their findings, to the estimated 38 million Medicare enrollees (those ≥65 years), would predict nearly 2 million ADEs annually, of which more than 25% would be considered preventable and about 180,000 fatal or life threatening.<sup>43</sup> One study estimates that there are about 265,802 ED visits in patients older than 65 years of age for ADEs, and 99,628 of these patients require admission to the hospital. In the same study, patients older than 80 years constituted half of those admitted to the hospital. Medications or classes of medications involved in two-thirds of the hospitalizations were diabetic and antithrombotic medications.<sup>18</sup> A more recent study estimates that 34.5% of all ED visits for ADEs were in patients older than 65 years and were more likely to be hospitalized than other age groups. The medications involved were anticoagulants, antidiabetics, hypoglycemics, and opioids.<sup>111</sup>

There are more than 1.5 million nursing home residents in the United States. The average such resident uses 6 different medications, and 20% use 10 or more.<sup>13</sup> Extrapolating the findings of a study of 18 community-based nursing homes in Massachusetts over a 1 year period predicts 350,000 ADEs annually, more than one-half of which would be preventable.<sup>42</sup> Fatal or life-threatening ADEs would represent 20,000 of these predicted events of which 80% would be preventable. Approximately one million other seniors live in assisted-living facilities, and are vulnerable to medication errors for a variety of reasons, including inadequate physician support, inadequately trained staff, and staffing shortages. Adverse drug events cause 10.5% of hospital admissions for geriatric patients and are the most common type of adverse event occurring in hospitalized elderly patients.<sup>72,124</sup> These medications result in nearly 50% of ADE-related visits to the ED but are only prescribed during 9.4% of outpatient visits.<sup>19</sup>

Addressing these issues is becoming ever more important as the US Census Bureau predicts a rise of 62 million in the number of Americans 65 years of age or older by the year 2025 and a 68% increase in the 85 years of age or older population that are at an even higher risk.<sup>6</sup> Advancing age brings with it several important considerations from the point of view of medication safety. Medical comorbidity increases with age, and therefore an increasing likelihood of receiving multiple medications. With more medications, the number of potential errors and interactions increases. Frailty and cognitive decline in older adults result in errors following self-administration. Alterations in medication absorption, metabolism, distribution, and elimination may all affect the efficacy of the medication (Chaps. 9 and 32).

Beers and STOPP/START criteria are methods to determine appropriate medication prescribing for geriatric patients.<sup>3,92</sup> These criteria identify inappropriate prescribing due to increased risk of adverse events with some focus on renal clearance and drug interactions.<sup>3,92</sup> Both criteria have

limitations as geriatric patients are underrepresented in clinical drug trials, the recommendations are not individualized and medications on the lists are appropriate for certain conditions such as intravenous diphenhydramine for allergic reactions. The updated Beers list includes conditions when a medication is appropriate for use in the elderly to address this limitation.<sup>3</sup> Additional limitations include that the lists do not include every medication that should be avoided and these lists have not been shown to change morbidity, mortality, or cost.<sup>99</sup> The prevalence of inappropriate medication use in older adults is estimated to be in the 12% to 40% range.<sup>113</sup> One in 5 prescriptions given to elderly individuals are considered inappropriate based on Beers criteria, with diphenhydramine and amitriptyline being the most common medications prescribed inappropriately.<sup>93</sup> Older adult patients medicated with benzodiazepines, for example, have a 4-fold increase in falls (Chap. 32).

## RESPONSE TO MEDICATION ERROR

One of the leading causes of medication errors is human performance deficit. See the Factors Affecting Human Performance section later. Almost invariably a human action will precede the ADE, and this temporal contiguity of action and consequence typically generates a tendency to blame someone. In most cases, the blame will fall on the last person to have contact with the patient. In recent years, however, a consensus emerged that blaming people for errors is counterproductive. The number of ADEs that result from egregious behavior is very small, and more often than not an explanation for the fault will be found within the system that allowed the error to occur. Attempts to understand the nature of these faults, and to correct them, while being sensitive to the potential for unintended consequences, is the most appropriate response. Several processes can be used to respond to errors or system-problems. These include root cause analysis, clinical incident analysis, failure mode and effect analysis, and Lean Six Sigma (LSS).

*Root cause analysis* (RCA), a term originally used to investigate major industrial events, is a technique that provides a structured, process-oriented analysis of sentinel events. The Joint Commission in accredited hospitals mandated its use in 1997. It is a time-consuming process requiring multidisciplinary teams with specialized training, and is subject to bias and methodologic limitations.<sup>118</sup> Nevertheless, a judiciously conducted RCA provides insight into systemic failures underlying the ADE, and identify areas that require change. An alternative approach, a clinical incident analysis protocol, was developed that more appropriately shifts the emphasis from the individual to the system.<sup>117</sup> The clinical incident analysis protocol utilizes 7 factors as the basis for an investigation. Some organizations developed a hybrid combining these 2 approaches. Both RCA and clinical incident analysis are conducted retrospectively, and therefore subject to retrospective bias.

An alternative approach is failure mode and effect analysis (FMEA), which proactively attempts to identify potential errors and to initiate preventive measures. A multidisciplinary group is utilized in the FMEA approach to identify a process or subprocess that needs analysis, to identify the steps of the process and determine the risk/likelihood/severity of failure of each step. Once this phase is accomplished, the team prioritizes a high-risk step and conducts an RCA to make recommendations on redesigning the step. The establishment modifications are analyzed in their performance to determine change and decrease in risk. This process is designed as a quality control and assurance to protect the proceedings from legal investigation.<sup>4</sup>

Other processes are being introduced into the health care industry to improve quality of care and safety and reduce costs. Two such approaches are Lean and Six Sigma, sometimes used together as LSS. Both were initially described in the Toyota Production System and adapted to health care. Define, measure, analyze, improve, and control are all steps related to LSS. It involves defining the process that needs evaluation, determining how to measure the process, analyzing the data collected based on the determined measures, forming an improvement plan based on the

analysis, and putting a new process in place with the goals of developing a lasting culture regarding the newly improved process with elimination of waste.<sup>1,126</sup> Each of these steps has principles to guide the use of LSS. The Agency for Healthcare Research and Quality has specific forms to aid health care facilities when adopting these approaches to safety and improvement.<sup>70</sup>

## REDUCING ERRORS

To reduce medication errors, each health care system should simplify, standardize, and stratify processes and communication. The medication process should be carefully automated with computer order entry and bar coding as extensively as the system will permit. Although these information technology solutions will aid the medication process, nothing is perfect and each change introduces new potential problems. See the Information Technology section later. Limitations of attention and vigilance should be understood and the reporting of errors in a nonpunitive environment should be encouraged.<sup>72</sup> Improving information access, error proofing, reducing reliance on memory, enhanced training, and the use of buffers or redundancy in an attempt to prevent errors should also be encouraged.<sup>71</sup> Each time a medication is given, the focus should be “right drug, right dose, right route, right patient, at the right time.”

In 2003, the American Academy of Pediatrics Committees on Drugs and on Hospital Care developed a position statement regarding the reduction of medication errors in children. The recommendations can be adapted to all hospital settings and to patients of all ages. These recommendations include appropriate staffing, utilization of the resources in the pharmacy, standardization of hospital equipment and protocols, and the development of a nonpunitive, barrier-free system to report and easily track errors.<sup>114</sup> Other more recent groups also encourage reduction of medication errors and participation in medication safety. The American College of Medical Toxicology encourages medical toxicologists to use their expertise and training to aid health care systems in reduction of errors and other pharmacy and therapeutics issues.<sup>2</sup>

For older adults, prescribers should review medication indications and avoid age bias. Polypharmacy should be limited, with medications prescribed only as necessary. Dosing should be adjusted as needed based on renal and hepatic function as well as drug interactions. Medication review by pharmacists aid in decreasing the use of potentially inappropriate medications and in decreasing the number of medications prescribed (polypharmacy).<sup>83</sup> In the hospital, outside of the ED and emergent situations, pharmacists ought to review all medication orders, when available, and verify the medication as appropriate prior to it being dispensed. Pharmacists can also aid in medication reconciliation at transitions of care and upon hospital discharge to prevent complications of polypharmacy.<sup>40,65</sup>

## FACTORS AFFECTING HUMAN PERFORMANCE

Human factors lead to many medication errors. In fact, it is not surprising that human performance deficits are the primary causes of medication errors in such an extremely complex medical environment. A performance deficit means that the individual making the error had the prerequisite knowledge to avoid the error but failed to do so. Performance deficits originate from cognitive failings because of interruptions, distractions, inexperience, or simple overloading. These cognitive errors are discussed below. Other variables contribute to performance deficit, including many ergonomic issues such as workload, resource limitations, and staff shortages. This environment is both burdened and enriched by many inherited properties. Human factors and ergonomics theory draws on a variety of disciplines, including industrial engineering, industrial psychology, cognitive psychology, and information technology. Much should be done to optimize the interface between humans and the work environment and to ensure that systems operate more efficiently. As a general principle, it is preferable if the dominant purpose in designing medical devices and processes is they fit human users, and not forcing the converse. [Table 134–4](#) lists some of the more common human performance deficits. Such errors often manifest as simple slips of action, or

**TABLE 134–4** Common Factors That Adversely Affect Human Performance<sup>27,105</sup>

Attentional capture
Diminished motivation/morale
Distractions
Fatigue
Fragmentation, transitions of care
Inadequate resource availability (Resource Availability Continuous Quality Improvement Trade-Off)
Increased work acuity/cognitive load
Inexperience
Interruptions
Poor workplace ergonomics
Sleep deprivation/debt

execution failures, arising from distraction by something other than the task at hand.<sup>101</sup> Vigilance is better maintained in individuals who are well rested and working without interruption or distraction in a well-designed environment. Fewer medication errors occur in optimally designed environments.<sup>72</sup>

Human performance deficits such as diminished memory, sleep deprivation, depression, and distractions contribute to errors. Resident physician mood and lack of sleep are also factors in performance deficits. Depressed residents made 6.2 times as many medication errors as nondepressed residents.<sup>34</sup> Sleep deprivation and improper supervision were highlighted initially after the Libby Zion case, in which a patient on phenelzine developed fatal serotonin toxicity following the administration of meperidine by a sleep-deprived and inadequately supervised intern. Interns working a traditional schedule of call every third night with extended work shifts (36 hours) made 35.9% more serious medical errors than those with the current reduced work schedule.<sup>66</sup> In particular, there were 20.8% more serious medication errors during the older work schedules compared with the current reduced hour schedule.<sup>66</sup> In 2008, an Institute of Medicine study addressed resident work hours and patient safety. This report recommended residents be provided with designated sleep time during each day and rest periods each week in order to decrease the risk of fatigue-related medical errors.<sup>52</sup> However, work schedules may not have as much effect on medical errors as once thought. A new study reviewed 2 different work schedules for surgery residents. It found that there was no difference in types of medical errors with a restrictive (standard work schedule based on regulatory guidelines) versus less-restrictive work schedule.<sup>5</sup>

A particularly important goal for human performance deficit is the reduction of cognitive load and distractions. Many medication errors originate from cognitive performance deficits. In the ED, increased cognitive load such as related to increased number of boarding patients, increased number of medication orders, and increased number of medications to be administered all lead to increased medication errors.<sup>95</sup> Further efforts must be directed at strategies to reduce cognitive failure. The adoption of some very simple strategies based on human factors engineering principles will reduce error, such as simplification of the number of steps involved, reducing reliance on memory, applying cognitive forcing strategies,<sup>27</sup> and using cognitive aids. Research into reducing distractions during medication administration focused on adapting principles from the airline industry, “the sterile cockpit principle.”<sup>36</sup> This principle limits interruptions and distractions that could interfere with proper performance of a critical task or tasks. In the airline industry, the use of this principle occurs during takeoff, taxi, and landing. In medication administration, this principle involves the use of “do not disturb” signs or vests worn by the nurse administering medications, no conversations to disrupt the medication nurse during this important task, and the other nurses on the unit answering phone calls or patient/family questions. This approach reduces medication administration errors by improving human performance.<sup>36,102</sup> One particularly useful aid to reduce cognitive

load is the color-coded Broselow-Luten system, for pediatric medication dosing.<sup>76</sup> This approach has the potential for further development to improve the safety of nonprescription medications and other potentially dangerous products used in the home.

Another factor that contributes to errors is the assignment of a new role to a provider such as asking physicians to dispense or administer medications. Pharmacists are the only professional group formally trained and experienced in dispensing medication, and not surprisingly, their presence is associated with a lower medication-dispensing error rate.<sup>64,74</sup> Nurses administer medications because they receive such training and the administration should be restricted to them except during specific circumstances such as procedural sedation.<sup>28</sup>

## KNOWLEDGE DEFICITS

The 2 most common factors contributing to prescribing errors are related to knowledge deficits. These deficits include lack of knowledge about the medication and about the patient.<sup>72,75</sup> Knowledge deficits are likely due to the number of new medications, dosage formulations, and indications. With the large number of medications prescribed and the continuing and frequent release of new medications, it is difficult to know all of the relevant clinical pharmacology of each medication, including interactions, side effects, and contraindications. Decision support, most commonly in electronic format, should be contemporaneously available to health care professionals to assist in decreasing prescribing errors.<sup>96</sup> However, electronic pharmacopeias, as a form of decision support, have errors and omit warnings, such as discussed with extended-release or long-acting opioids.<sup>67</sup> These tools also need updating by manufacturers for new prescribing information and warnings before prescribers can download and use the update.

Knowledge deficits also affect dosing calculations and drug ordering. This is related in part to the lack of formal medical school education regarding the medication process. Only 10% of medical students answered dose calculation questions correctly in one study.<sup>123</sup> However, students in their final year of training performed much better than students.<sup>123</sup> It is unclear where, when, and how the students obtained the knowledge in the higher years. Specific training is needed in both of these areas of calculation and order writing. Improvements are demonstrated following a short educational intervention,<sup>91</sup> but it is unclear how long this knowledge is retained. Generally, there appears to be a tacit assumption that these skills will be acquired during clinical training, but this study suggested that this knowledge is not acquired independently and that specific training is indicated.

The prevailing emphasis in physician training is on knowledge acquisition. Less time is spent inculcating critical thinking skills and/or teaching reasoning, the assumption being made that these are passively acquired during the process of training. Although this is partially true, it does not exclude opportunities to improve these cognitive faculties by direct intervention.<sup>26</sup>

## COMMUNICATION

Improved team communication should result in fewer medication errors. Orders should be written clearly, or CPOE (discussed in detail in the Information Technology section) should be used. Orders should optimally include the indications for the medication. Both generic and trade names should be included in orders so that confusion with look-alike/sound-alike medications is avoided. Abbreviations should have limited use and trailing zeros should be eliminated. Verbal orders should be used sparingly due to the high risk of sound-alike medications and confusion with dosing.<sup>96</sup> If a verbal order is necessary, then it should be restated immediately to the ordering clinician to ensure that it is correct and restated from the physician to the nurse in a “closed loop” communication process.

Communication theory should receive more emphasis in health care training. Good communication skills both within and among disciplines and especially between practitioners and their patients will limit errors. As patients are admitted, transferred within, and discharged from health

care facilities, it is essential that precise communication as to what medications, their strengths, doses, and purpose the patient is receiving occur. Any changes that have occurred must be accurately recorded. The medication reconciliation process was adopted by The Joint Commission in 2005 and continues to be an important National Patient Safety Goal. As with other aspects of patient safety, these issues should be formally introduced into the education curriculum. Studies show that pharmacists are an integral part of optimal medication reconciliation.<sup>40,65</sup> Although medication reconciliation may decrease errors in medication histories, it has not been studied for ADEs and few studies link it to decreased health care usage. Efforts to improve documentation of medication reconciliation rather than improved safety efforts are likely the result of the regulatory mandate from the Joint Commission.<sup>96</sup>

## INFORMATION TECHNOLOGY

Information technology (IT) in health care has been ponderously slow to develop compared with its use in other organizations, but it is now gathering momentum and has obvious potential to improve patient safety.<sup>9,50</sup> One study estimates that adoption of health IT led to a 22% reduction of adverse drug events with the use of CPOE, decision support, electronic medication administration records, and use of barcode medication reconciliation from 2010 to 2013.<sup>38</sup> However, as considerable gains are made, new technology also introduces new types of errors.<sup>21,125</sup> The US Pharmacopeia announced in 2004 that nearly 20% of 235,159 medication errors reported to MEDMARX involved computerization or automation.<sup>105</sup> One study evaluating CPOE in a tertiary care hospital found that the system actually facilitated a wide variety of medication error risks.<sup>44</sup> Another study conducted by the Pennsylvania Patient Safety Authority found that CPOE facilitated 50% of the medication errors found during a 6-month study period.<sup>68</sup> Common errors associated with order entry include wrong medication selection and input of incorrect data (patient weight, creatinine clearance).<sup>116</sup> Another study identified 24 different types of failures associated with CPOE but suggested that many could be easily corrected, in particular by concentrating on organizational factors.<sup>62</sup> However, more detailed insights offer why process-supporting IT systems fail.<sup>121</sup> Much of the data involved in the medication process are relatively straightforward, amenable to rapid and efficient processing, including crosschecking with patient medication history and evaluating for medication interactions (an example of decision support). A study reviewing 28 trials of point-of-care decision support report showed a 4.2% improvement in patient care with a trend toward better improvement in care when a response was required from prescriber.<sup>112</sup>

Past studies demonstrate that computerized order entry with decision support reduces the incidence of serious medication errors by 50% to 55% once the transitional instability has passed.<sup>10,77</sup> This approach mainly reduces errors at the prescribing stage of the medication process and, while likely to prevent 80% of prescribing errors that led to no patient harm, the errors most likely to cause patient harm is not as amenable to reduction as these errors are related to dispensing, administering, or monitoring.<sup>14</sup>

In high-risk populations, CPOE reduces medication errors. In children, CPOE with substantive decision support reduced ADEs (including medication errors) and potential ADEs in an inpatient pediatrics ward.<sup>45</sup> It also decreased the rate of nonintercepted medication errors by 7% although there was no change in the rate of patient harm.<sup>59,119</sup> In the NICU, CPOE eliminated all calculation errors as decision support included an automatic dosage calculator.<sup>24</sup> However, these decision support systems cannot improve human errors as a result of entering incorrect weights, incorrect units of weight (kilograms versus pounds), or medications entered on the wrong patient.<sup>116</sup> In geriatric medication errors, CPOE resulted in less potentially inappropriate medication prescribing through decision alerts, which led to a pharmacist call to the prescriber that offered alternative choices of medications if possible.<sup>84</sup> Decision support in CPOE also leads to too many alerts when orders are placed, causing alert fatigue and resulting in providers entering an answer to proceed past (or “blow-by”) the alert without reading or comprehending the alert. A study reviewing an alert about critical

drug–drug interactions with warfarin found that only 19% of providers and 9.7% of pharmacists responding appropriately to the alert and changed the medication order.<sup>82</sup> There is a commercially available software screening system to identify outlier prescribing errors not identified with other clinical decision support tools in CPOE. The outlier alerts would identify high dose, contraindications, and medications never prescribed to specific populations.<sup>107</sup>

Unit dose dispensing systems, usually in association with CPOE and barcoding of medications, reduced monthly errors from 5 to none in an inpatient setting.<sup>39</sup> The package sent from pharmacy is prepared to administer to a specific patient at the appropriate dose, eliminating the need for the nurse to draw up medications resulting in fewer errors. Other dispensing systems, like automated dispensing cabinets (ADCs), are also linked to CPOE, barcoding, and allow for a pharmacist to verify correct drug, correct dose, patient allergies, and use of the medication prior to a drug being dispensed from the cabinet. These ADCs can decrease dispensing errors. However, errors occur when using ADCs. One such problem, “drug override,” occurs, particularly in an emergency situation or as a work-around. This allows a drug to be dispensed prior to pharmacist verification. Another error, look-alike medication errors, occurs because of the small screens on the ADCs. Errors also occur when the ADCs are stocked such that an incorrect drug is placed in an incorrect bin of the ADC.<sup>41</sup>

Use of barcoding for dispensing and administration of medication ensures that the correct drug is given to the intended patient at the dose intended. Barcoding significantly decreased the relative risk of targeted, preventable ADEs by 47% to 50% in an NICU.<sup>87</sup> The risk of opioid-related ADEs were also reduced when barcode medication administration was implemented.<sup>86</sup> This technique decreases the amount of time nurses spend administering medications in the ICU, allowing them to reallocate that time to other direct patient care activities.<sup>31</sup> As with all technology, new problems arise with the implementation of barcoding and can lead to errors. Such problems range from inability of the scanner to read the barcode on the medication or on the patient identification band, downtime processes, mismatch of barcodes due to new manufacturer barcode, or new or aging scanners, and many more.<sup>32</sup> For a summary of Information Technology, see [Table 134-3](#).

## SERVICE-BASED CLINICAL PHARMACISTS

Clinical pharmacists are now employed in high-risk areas such as the ICUs, the pediatrics services, and EDs to identify and prevent medication errors. In one ICU study, the input of a clinical pharmacist during rounds saved an estimated \$270,000 annually in costs of rehospitalization due to ADEs.<sup>74</sup> The involvement of a clinical pharmacist in work rounds of an adult ICU reduced preventable ADEs by 66%.<sup>74</sup> The introduction of clinical pharmacists in pediatric services is credited with a 94% reduction of potential ADEs and medication errors.<sup>59</sup> In particular, the addition of pharmacists in the PICUs reduced the serious medication error rate by 80%.<sup>60</sup> Another study showed that pharmacists in 3 EDs identified 2,200 interventions with an estimated savings of \$488,000. This savings came from lower-cost medications, reduced length of stay, and fewer readmissions.<sup>103</sup> Similarly a pharmacist reduced the error rate by 67% from 16 errors per 100 medication orders in the control group (without a pharmacist) to 5 errors per 100 medication orders in the intervention group (pharmacist present in the ED).<sup>17</sup> A recent study suggests that the availability of ED pharmacists has even more impact on reducing errors by their assistance for questions, discussion, and consultation rather than in the review of medication orders.<sup>94</sup> And, as previously discussed, hospital pharmacists are able to improve medication reconciliation across the continuum of care for patients.<sup>65</sup>

However, fiscal restrictions will inevitably mitigate against the expansion of service pharmacists as cost–benefit arguments will be applied. An unintended consequence of having a clinical pharmacist present is that nurses, residents, and attending physicians can defer to them and consequently spend less time developing and maintaining their own skills for off-hour periods when such help may not be available.

## ROLE OF THE TOXICOLOGIST

Clinical and medical toxicologists are in a unique position to investigate causes and help decrease the incidence of both medication errors and ADEs in the institutions where they work. With their specialized knowledge and training in pharmacology, poisoning, and clinical medicine, both physicians and pharmacists with advanced training in toxicology also aid in the prediction, identification, and management of ADEs. Medical toxicologists should optimally be involved in Pharmacy and Therapeutics and Medication Safety committees (or related efforts) at their institutions. They should educate and collaborate with the providers at their hospitals with regard to means to reduce errors and encourage diligent reporting of medication errors to the hospital and the national databases such as MedWatch at the FDA. They should also encourage drug manufacturers to be diligent in alerting physicians with regard to identified problems.<sup>2</sup>

## SUMMARY

- Medications are the principal commerce of modern medicine, and medication safety is of paramount importance to health care systems. The delivery of medications safely to patients is a complex process and is particularly important in pediatrics and geriatrics.
- Health care professionals should be aware of the reasons errors occur and how they are prevented in order to improve patient and medication safety.
- Information technology holds promise for significant improvement in medication safety. Focus should be on CPOE, barcoding, unit dose dispensing, avoidance of look-alike/sound-alike medications, and education.
- Use of clinical pharmacists and updated electronic-based literature should be encouraged.
- Communication and nonpunitive local and national reporting must be encouraged in order to learn from errors.
- Patient safety requires a collaborative effort particularly with the medication manufacturer, but also with federal regulation authorities, independent research organizations, error theorists, hospital administrators and managers, information technologists, nurses, cognitive psychologists, human factors ergonomists, and chronobiologists and all of the health care professionals involved in patient care.
- Clinical and medical toxicologists have a significant role in medication safety.

# DRUG DEVELOPMENT, ADVERSE DRUG EVENTS, AND POSTMARKETING SURVEILLANCE

Louis R. Cantilena\*

This chapter will focus on drug-induced diseases that occur as expected or unexpected adverse drug events (ADEs), as a drug–drug interaction or an ADE causing an untoward drug–disease interaction. Also included in this chapter is a brief overview of the drug development process in the United States and specific aspects of the process that relate to the development of antidotes. In addition, a discussion of an approach to the diagnosis of drug-induced disease, monitoring of drug safety postapproval, and the suggested role for the clinical and medical toxicologists in the discovery, reporting, and prevention of ADEs.

Adverse drug events are defined as untoward effects or outcomes associated with use of any dose of a drug whereas an adverse drug reaction refers to harm from a therapeutic dose. In this chapter, the word “drug” will be used for a pharmaceutical product and includes prescription and nonprescription medications, and dietary supplements.

In the United States, all new prescription and nonprescription medications must be shown to be both safe and effective in order to achieve approval by the US Food and Drug Administration (FDA), a prerequisite for marketing and sale. Dietary supplements fall outside of this legal requirement (Chap. 43) and are regulated under the Dietary Supplement Health and Education Act of 1994 (DSHEA).

## HISTORY OF THE US DRUG APPROVAL PROCESS

The evolution of drug product regulation in the United States has for the most part, been reactionary; that is, most drug regulations were created in response to medicine-related disasters at various times in our history. Prior to 1900, there was no requirement for a drug or medical device manufacturer to demonstrate that the product actually worked (efficacy), was safe when used as directed, or was made to be within precise manufacturing specifications. In addition, no laws existed that required labeled claims on marketed drug products to be proven valid. Any product could be sold as a company desired and it was left to the consumer or health care professional to determine if the products actually worked and were safe. Initiation of medicinal product regulation and the overall evolution of the US drug law and regulations are closely linked to specific medical product disasters that occurred during the 20th century in the United States. Relatively recent changes in US drug approval law further changed drug review timelines and FDA prioritization of drug application reviews. Most recently, specific incentives to encourage the development of new antimicrobials and novel therapeutics that impart a significant improvement in the effectiveness or safety of drug treatment compared to existing or the current standard of care for the condition have been included in provisions of the FDA authorization legislation.<sup>28</sup> These incentives include extended patent protection or a shortened FDA review timetable that comes with priority review designation.

Examples of the pre-1900—or preregulation—marketed products include aspirin containing heroin sold as cough syrup and wine with cocaine to enhance sales of the alcoholic beverage. There was no legal requirement for systematic testing of products to determine content or the presence of possible adulterants in product formulations. **The Pure Food and Drug Act of 1906** required pharmaceutical manufacturers to meet a standard for the concentration and purity of the drugs they marketed. However, the burden of proof was on the FDA to show that the drug was incorrectly labeled or that

the advertising or label was false or misleading. To a large extent this is the current regulatory state for dietary supplements.

**The Food, Drug, and Cosmetic Act of 1938** resulted from a tragedy in which more than 100 patients (mostly children) died from poisoning by an excipient used in an oral solution of sulfanilamide, an antibiotic. The Massengil pharmaceutical company added the solvent diethylene glycol to the formulation in an attempt to improve the palatability of a pediatric formulation of a sulfanilamide. Diethylene glycol is a sweet-tasting, but nephrotoxic and neurotoxic hydrocarbon (Special Considerations: SC9). Only after almost a full year of marketing were cases of kidney failure and death reported in sufficient numbers to alert authorities to the extremely toxic nature of the product. The Food, Drug, and Cosmetic Act of 1938 was the result of this medical product disaster and accomplished the following:

- Required companies to list the ingredients on each product label
- Required companies to provide the known risks concerning use of the product to physicians or pharmacists
- Made illegal the misbranding of food or medical products
- For the first time, required companies to test their products for safety before being sold.
- Drugs already marketed before 1938 were exempt from the requirement (Chap. 1).

The Kefauver-Harris Amendments to the Food and Drug Act of 1962 resulted from a drug approval disaster that occurred in Europe and not in the United States. An application in the early 1960s for the approval of thalidomide, a sedative-hypnotic already marketed in Europe at the time, was submitted to the FDA for review and approval. The sedative-hypnotic had a rapid onset and short duration of action, did not affect ventilation, did not cause a morning-after effect, and was inexpensive. Dr Frances Kelsey, a medical officer at the FDA, delayed approval by asking the sponsor to clarify several issues in the reportedly poorly organized new drug application (NDA). In the interim, an unusual teratogenic effect, phocomelia, or limb misdevelopment, was linked to the use of thalidomide in Europe. Congressional hearings on the “almost” approval for marketing in the United States resulted in the **Kefauver-Harris Act of 1962**, which required a drug manufacturer or sponsor to do the following:

- File an investigational new drug (IND) application prior to initiating a clinical study with a drug in humans
- Demonstrate that the drug was effective for the condition that it was being marketed to treat
- Provide adequate directions for safe usage of the drug

The act was not retroactive and drugs that were already on the market were exempt from these new requirements. However, the Waxman-Hatch Act of 1983, among other things, incentivized companies to establish evidence in support of actual indications for an exempt drug. The effects of this incentivization were demonstrated when a small pharmaceutical company studied the use of colchicine in gout, which the company applied for, and subsequently received exclusivity, leading to a 50-fold increase in the price of this ancient drug.<sup>17</sup>

Subsequent US food and drug laws that have primarily affected FDA review and approval of products include the following:

- **The Orphan Drug Act of 1983:** The act provides financial incentives to drug manufacturers to develop drugs for the treatment of rare diseases and conditions.<sup>19</sup> A rare disease is defined as one in which there are

\*Dr. Cantilena completed work on the chapter shortly before his tragic death.

fewer than 200,000 affected persons in the United States, or one affecting more people, but in which the cost of drug development is likely to exceed any potential sales of the drug. Overall, the Orphan Drug Act has been very successful. As of early 2016, there were 596 approved orphan drugs in the United States, treating approximately 200 rare diseases. In 2016 alone, 9 orphan drugs were approved, which represents 41% of all drugs approved by the FDA in that year. Drug approval via orphan drug designation is incorporated for the approval of antidotes for poisoning. For example, 2 chelators, insoluble Prussian blue and pentetate calcium trisodium, were approved under orphan drug regulations in 2003 and 2004, respectively, for the treatment of exposure to radioactive heavy metals (Antidotes in Depth: A31 and A45). The level of evidence required for efficacy for orphan approval is similar to that required for non-orphan agents but often the type of evidence incorporated in approval decisions is diverse because of the rarity of the respective conditions and/or the ethical barriers to conducting a prospective study. Particularly applicable to the practice of medical toxicology, especially involving making the diagnosis of drug-induced disease, is the fact that the safety database for orphan pathway–approved drugs at the time of product approval is significantly less than that for standard NDAs. The relevance of that is that fewer human exposures, or exposure of the drug candidate to only healthy volunteers, prior to approval could result in the inability to detect less commonly occurring ADEs before marketing. When this occurs, the FDA can require specific postmarketing studies and/or registries of patients who are given the drug therapeutically.

- **The Prescription Drug User Fee Act (PDUFA) of 1992:** The Act requires that manufacturers pay user fees to the FDA for NDAs and regulatory supplements to enable the FDA to hire additional reviewers and accelerate the review process. This Act, which has undergone several revisions (the latest in 2017, covering the FDA until 2022), was originally considered by some to be controversial because of the new working relationships created between industry and regulators, and the concern that it may lead to compromises that are not in the best interest of public health.
- Based on the number of safety-related drug withdrawals from the US market, there does not appear to be evidence of a negative effect of public health safety since the enactment of the PDUFA legislations. An early comparison of review times over the first 4 PDUFA authorizations did not find a substantial improvement in FDA review times.<sup>12</sup> Compared with European Medicines Agency (EMA) and Health Canada—the analogous agencies to FDA in those regions—the FDA already had, and has maintained, significantly shorter review times over the past decade.<sup>12</sup> A more recent review shows that FDA has maintained its advantage for regular reviews submitted through 2010, over the European Medicines Agency (EMA) and the Swissmedic agency.<sup>11</sup> Additionally, although some believe that the shorter review times for FDA approval appear to be associated with an increased likelihood of drug withdrawal and black box label modification of the drug label postapproval,<sup>46</sup> others do not concur.<sup>11</sup> The debate on this issue intensified during the controversy involving the cyclooxygenase-2 (COX-2) inhibitor antiinflammatory drugs. This widely publicized withdrawal and press coverage of the related litigation resulted in congressional hearings on the review practices and monitoring of drug safety by the FDA. The legislation evolved to attempt to provide FDA with regulatory authority, adequate funding, and to encourage scientific exchange between the FDA and sponsors of drug products during the drug development process with the goal of improved quality and efficiency of the development process. The sixth reauthorization of the FDA covering the period of 2018 (PDUFA VI, also known as the 21st Century Cures Act, to 2022) was signed into law in late 2016 and is further discussed later in this section.
- **The Dietary Supplement Health and Education Act (DSHEA amendment) of 1994:** The Act removed from FDA the authority to require proof of safety or efficacy prior to marketing of products considered dietary supplements (including herbal remedies). Only when

the manufacturer of a product makes a specific health claim, such as “treats congestive heart failure,” does the FDA have premarketing approval authority. That is, the use of structure or function claims, such as “supports heart function,” obviates the need for FDA approval. Furthermore, rather than placing the burden of proof on the manufacturers for safety and efficacy of a product, the FDA is required to determine that a product is unsafe to prevent sale and distribution in the United States. Few dietary supplements have reached the benchmark of premarketing rigorous proof of efficacy and safety of their product.

- **The FDA Modernization Act of 1997:** In addition to reauthorizing the FDA, this bill put in place mechanisms to improved communication and collaboration between FDA and pharmaceutical sponsors, enhancing label information for practitioners and consumers, as well as allowing FDA to utilize an accelerated drug approval process for the treatment of life-threatening illnesses such as AIDS and cancer if the drug has the potential to address medical needs unmet by currently available drugs. Many of the accelerated drug approvals rely on efficacy results derived from surrogate markers linked to the ultimate indication for the drug. For example, the protease inhibitors were approved on the accelerated track for the treatment of AIDS based on their demonstrated ability to reduce HIV viral load in preapproval clinical studies. Although practical and ultimately useful, subsequent legislation such as the Food and Drug Administration Safety and Innovation Act (FDASIA) refined this process to ensure that confirmatory clinical studies were, in fact, completed in a timely manner by a sponsor of a product approved under the accelerated process.
- **The Animal Efficacy Rule (Animal Rule) in 2002:** The FDA enacted a regulation that allows sponsors to reach approval of some products based on safety testing in humans and efficacy testing in animals.<sup>18</sup> This rule is intended to allow FDA to approve products for serious or life-threatening conditions caused by exposure to lethal or permanently disabling toxic biologic, chemical, radiologic, or nuclear substances. For the indications of treatment of chemical, biologic, or radiologic mass poisonings, such as could be expected in a terrorist attack, testing for efficacy would not be possible for obvious ethical or, in the event of an infectious outbreak, for logistical reasons. The Animal Rule allows the sponsor to establish product efficacy in a validated animal model and then provide human safety data, preapproval in healthy human volunteers. The human safety data would obviously involve administration of therapeutic dosages of the chemical/biologic/radiologic drug in the absence of the poisoning. The sponsor would also be expected to perform a field study post approval, in the event that the indicated exposure occurs naturally for an infectious disease or during an attack.
- **The Pediatric Research Equity Act of 2003:** The Act requires manufacturers to study drugs being submitted for approval for a claimed indication in children. The FDA provides incentives such as patent extension and marketing exclusivity for performing these evaluations. As a result, more data from children are being provided to guide therapeutic use of medications in this patient group, at the expense of allowances for marketing exclusivity to those manufacturers who provide such data.<sup>19</sup>
- **The Food and Drug Administration Amendments Act (FDAAA) of 2007:** This act increased FDA responsibilities and authorizations primarily aimed at improving product safety.<sup>2</sup> Specified deadlines for drug application reviews were added as well as the creation of a priority for FDA review based on indication and potential benefit of the candidate drug for a disease population. Four of the provisions of FDAAA reauthorize past legislation: PDUFA, the Medical Device User Fee Amendments of 2007 (MDUFA), the Pediatric Research Equity Act of 2007 (PREA), and the Best Pharmaceuticals for Children Act of 2007 (BPCA). The Food and Drug Administration Amendments Act gives authorization to FDA to require postmarketing studies, primarily of drug safety, including surveillance and clinical trials, as well as the requirement that sponsors incorporate Risk Evaluation and Mitigation Strategies (REMS) in their

proposed marketing activities as a prerequisite for product approval. Risk Evaluation and Mitigation Strategies are a mechanism to allow FDA to require proactive risk surveillance for newly approved products or those in which significant safety signals are detected. The elements of REMS vary considerably among products, and may be applied to both safety concerns and the potential for misuse, as in the case of prescription opioids.<sup>26,49</sup>

Within this FDA reauthorization was a mandate to take the initial steps to set up an active surveillance system utilizing health care claims databases to detect post-approval signals of ADEs. This was called the Mini-Sentinel Pilot Program, which aimed to establish contractual and organizational relationships that could lead to an effective active drug safety surveillance system. The Sentinel program is further discussed below.

The Food and Drug Administration Amendments Act also included a requirement for FDA to ensure that clinical trial information is provided to the National Institute of Health's [www.ClinicalTrials.gov](http://www.ClinicalTrials.gov) web site. Initially there was poor overall compliance with reporting and a significant time lag before most trials were reported into the system.<sup>38</sup> A more recent analysis of [ClinicalTrials.gov](http://ClinicalTrials.gov) data, examining the trials completed from 2008 through August, 2012 continues to show poor overall reporting compliance. Industry-funded clinical trials, with FDA oversight demonstrated higher reporting compliance and a shorter time lag compared to NIH-funded, academic studies.<sup>1</sup>

Drug shortages, which have been present for decades, reached crisis levels in 2010. The reasons are multifactorial, but coincide with a time when an empowered FDA began enforcing high manufacturing standards at production sites around the nation and the world.<sup>25</sup> Although some of the concerns leading to plant closure were not associated with patient harm, the proactive stance primarily affected generic drug manufacturers,<sup>7</sup> initially mainly those producing oncology drugs that were unable or unwilling to respond to standard regulations. The shortage of important drugs had significant medical and ethical consequences including delays in care and medication errors. Furthermore, economic consequences of the use of more expensive (and potentially less effective) alternative drugs and development of a “gray” market led to higher costs.<sup>44</sup> Some health systems turned to compounding pharmacies, which were largely unregulated. As this practice grew, new concerns such as interstate transport of compounded medications and safety risks from lax oversight became prominent.<sup>13</sup> This came to light with the highly publicized fungal meningitis outbreak at a compounding facility in Massachusetts ultimately resulting in 64 deaths and significant injury to more than 700 patients given intrathecal corticosteroids that were prepared in this facility.<sup>5</sup>

- **The FDASIA again reauthorized PDUFA (then PDUFA V) in 2012:**<sup>42</sup> This law included 2 noteworthy new FDA responsibilities and authorizations: the establishment of a user fee requirement for generic drugs and for biosimilar (generic-like) biologic products similar to what is called the innovator product for drugs, and a new category of drug application designation called the “breakthrough therapy” designation. The breakthrough designation allows FDA to collaboratively assist drug developers in an expedited review and approval process of a product application when there is preliminary clinical evidence that shows the drug may be a substantial improvement over existing therapies for treatment of patients with serious or life-threatening diseases.<sup>44</sup> Other new initiatives include an active effort to include patient groups representative of the affected populations in the overall FDA review processes and some yet to be determined measures to enhance the safety of the drug supply chain. This act allowed FDA to better regulate foreign drug manufacturing facilities to help alleviate shortages, and to require pharmaceutical companies to make the FDA aware of impending drug shortages. In addition, the provisions of the BCPA and PREA were made permanent.
- **PDUFA VI, also known as the 21st Century Cures Act:** The sixth reauthorization of the FDA covering the period of 2018 to 2022 was signed into law in 2016. Some areas that will likely be emphasized with the

implementation of PDUFA VI include early and further communication between FDA review staff and drug sponsors on priority reviews as well as further development and emphasis on postmarketing drug safety systems and reporting requirements for sponsors. In addition, expanding and making the FDA Sentinel system (see below) for medical product safety surveillance fully operational will likely be brought forward during PDUFA VI, beginning in 2018.

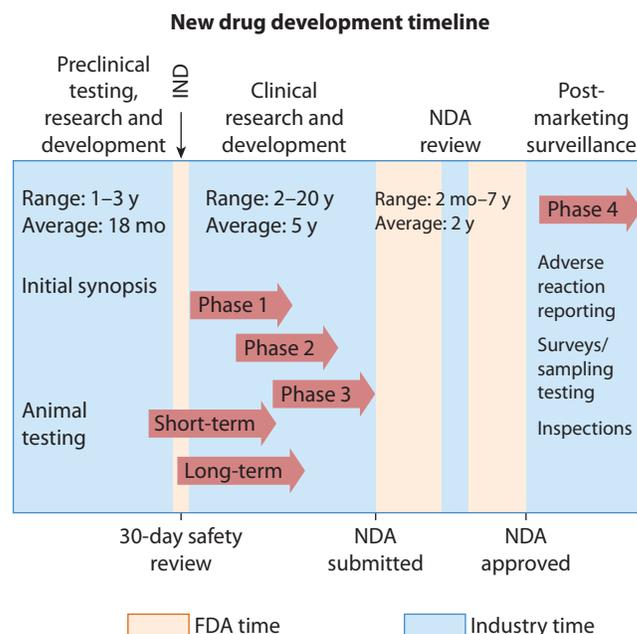

A complete listing of FDA regulatory milestones and drug law history of the FDA is found on the FDA website.<sup>17</sup>

## THE DRUG DEVELOPMENT PROCESS

Figure 135–1 is a schematic overview of the process for drug development of a new molecular entity (NME). The process begins with the preclinical evaluation of the candidate drug. During this evaluation, preclinical toxicologic testing is performed in more than one animal species, and other testing includes product stability, assurance that good manufacturing methods are being followed, drug purity, and potential carcinogenicity. Exposure–response relationships for efficacy and nonclinical safety in animal models as well as in vitro receptor binding or surrogate marker effects are often determined at this phase of the evaluation. Generally, for small-molecule (ie, nonbiologic) drugs, the metabolism of the drug in animal and in vitro human systems is determined. Following this preclinical testing, the sponsor submits an IND application to the FDA for approval to initiate human testing. This application contains all relevant data concerning animal and in vitro toxicology testing, product manufacturing and purity, and the clinical protocol for using the drug in the initial human investigation. Within 30 days, the FDA must review the IND application and either allow the proposed human study to proceed or inform the sponsor that additional data or preclinical (eg, animal) study is required before clinical testing of the candidate drug can begin.

The clinical study of new candidate drugs is divided into 4 basic phases.

Phase 1 clinical testing involves a relatively small number of participants with the primary aim of determining the safety and toxicity of the drug. In addition, phase 1 studies will also determine the human pharmacokinetics and metabolism of the drug. Phase 1 studies are normally conducted in 20 to 100 healthy volunteer participants, with the notable exception of phase 1 studies for cancer chemotherapeutics, which enroll only patients with cancer.

**FIGURE 135–1.** Schematic representation of new drug development. FDA = US Food and Drug Administration; IND = Investigational New Drug; NDA = New Drug Application. (Reproduced with permission from U.S. Food and Drug Administration. U.S. Department of Health and Human Services. [www.fda.gov](http://www.fda.gov).)

Phase 2 clinical testing is designed to determine the potential efficacy of the drug candidate in humans, usually at varying levels of exposure to the drug candidate. In this phase, approximately 100 to 300 participants are usually studied. In phase 2 clinical trials, participants generally have the diseases for which the drug is intended or are capable of demonstrating the appropriate, validated, biologic surrogate marker to indicate a meaningful response to the drug. An example of this would be when a drug intended for early treatment of acute coronary syndrome is tested to show that it can inhibit *in vivo* platelet function after oral dosing in human study participants. In addition to confirming that the drug has the desired effect on the disease state or target disease marker, this phase explores the exposure–response relationships of the candidate drug and metabolites to observed effects in patients. Once the exposure–response relationships are identified, dose selection for phase 3 studies is determined, which is another goal of the phase 2 program. In general, phase 2a studies enroll patients with a mild, or early, form of the disease to limit potential confounding factors that exist in more severe or advanced stages of the disease process. Phase 2b studies, in general, focus on patients with a more advanced disease condition, and with the knowledge derived from phase 2a, test doses of the drug candidate that are likely to produce a range of exposures that will further define the target patient exposure of the drug for the phase 3 studies.

Phase 3 clinical drug studies usually involve large-scale clinical trials in the actual, or close-to-the actual patient population for whom the drug is intended. Typically, this phase of drug development will involve testing a treatment cohort versus a control treatment of several hundred to several thousand patients who have the target disease, depending on both the prevalence of the disease and effectiveness of the drug. In some cases, an active comparator is used instead of placebo or in addition to placebo in a 3-arm study depending on the indication. The primary goal of phase 3 studies is to determine the safety and efficacy of the candidate drug in a patient population close to the actual intended patient population in question, under conditions similar to the anticipated medical use. At the completion of phase 3, an NDA or, in the case of a biologic product, a Biologics License Application (BLA) (request for approval to market) is submitted to the FDA. A drug candidate completing phases 1, 2, and 3 can thus be approved for marketing after study in only 2,000 to 4,000 patients. In the setting of a fast-track approval or under the Orphan Drug regulations, substantially fewer patients will receive the drug before its approval for marketing. The relatively small number of human exposures to a new chemical or biologic entity prior to approval for marketing is an important factor that limits the sensitivity of the drug approval process to detect uncommon ADEs.

Toward the end of the review cycle of an NDA, the FDA often seeks the external advice of its constituted advisory committees prior to their approval decision, especially in the setting of an uncertain risk–benefit profile of a drug candidate. Food and Drug Administration advisory committees are generally organized by therapeutic areas and are composed of medical professionals, primarily from academia, as well as biostatisticians, a patient representative, a consumer representative, and in some cases, a nonvoting industry representative. These same advisory committees also convene to consider postapproval safety or efficacy data when FDA is considering an important change to a drug label or another postapproval regulatory action. Generally, the FDA prepares questions for the committee members and provides an FDA briefing document containing a detailed data analysis and background of the issue from the FDA perspective as well as a briefing document prepared by the drug sponsor containing corresponding information from its viewpoint. Committee members comment and vote on the FDA questions during the proceedings. For a new drug approval, one question generally includes a yes or no answer as to whether the committee member believes that the drug can be marketed with an adequate risk–benefit profile. The advisory committee vote is technically nonbinding for the FDA, but the FDA generally follows the advice of the committee. An issue of concern is the fact that some members of FDA advisory committees with perceived conflicts of interest (COI) are granted waivers by FDA to participate in the proceedings.<sup>32</sup> The appearance of conflict of interest on an advisory committee can have

a significant impact on the drug approval process, and the FDA has begun to decrease the number of committee member waivers granted. To limit potential conflicts of interest, the FDA implements a rigorous financial COI screening procedure to limit negative perception of the process. The potential unintended consequence of the elimination or minimization of waivers for committee members to participate in a meeting is that, for some highly specialized medical indications, there are few experts in the country with in-depth knowledge of the condition who may have worked on a study that is being used in the NDA, thus limiting the essential experience and expertise of the committee.

After the NDA or BLA review process and, at times, following an advisory committee meeting about the application, the FDA may issue an approval for marketing the new drug or biological agent. There are certain NDA or BLA applications to FDA that qualify for expedited regulatory pathways such as accelerated approval where conditional approval is granted with the expectation that confirmatory evidence (eg, postapproval clinical trial) will be forthcoming within a specific time. In this case, should the confirmatory trial be unsuccessful, FDA approval is withdrawn. Normal approval for marketing of a drug or biologic agent, granted by the FDA, however, marks the transition point between phase 3 and phase 4 of drug development as discussed separately below.

### Phase 4 of the Drug Development Is the Postmarketing Surveillance
