Isometheptene is a mild vasoconstrictor marketed as a combination preparation that includes dichloralphenazone, a muscle relaxant, and acetaminophen. It has indirect  $\alpha$ - and  $\beta$ -adrenergic agonist effects as well as minor direct  $\alpha$ -adrenergic agonist effects on the peripheral vasculature.<sup>81</sup> When administered early during a migraine exacerbation, it is as effective as sumatriptan in relieving migraine headache.<sup>32</sup> Cerebral vasoconstriction, intracerebral hemorrhage, and myocardial infarction are reported after therapeutic and excessive isometheptene use.<sup>35,56,65,74</sup> Autonomic dysreflexia, which presented as hypertension, headache, diaphoresis, and flushing, was also reported in a man with spinal cord injury who used isometheptene for treatment of a migraine headache.<sup>87</sup>

Isometheptene-associated vasoconstriction is rare, and reported treatments with calcium channel blockers or nitroglycerin are not routinely recommended.

## CALCITONIN GENE-RELATED PEPTIDE ANTAGONISTS

During migraines, calcitonin gene-related peptide is among the many vasoactive peptides released from activated trigeminal nerves.<sup>37</sup> Calcitonin gene-related peptide is a potent vasodilator<sup>13</sup> and is involved in the transmission of nociceptive signals from cerebral vessels to the central nervous system.<sup>24</sup> Calcitonin gene-related peptide receptors are found in nerve fibers in cerebral and dural vessels and in multiple areas of the central nervous system postulated in migraine genesis—the cerebral cortex, periaqueductal gray, locus coeruleus, dorsal raphe nuclei, solitary tractus nucleus, spinal dorsal horn, dorsal root ganglia, and trigeminal ganglia.<sup>79</sup> Treatment of active migraine with sumatriptan decreased CGRP concentrations to normal.<sup>37</sup>

Several CGRP antagonists were developed unsuccessfully.<sup>71,84</sup> Erenumab-aooe (Aimovig), developed for monthly subcutaneous injection, is a recently FDA-approved human immunoglobulin G2 monoclonal antibody made using recombinant DNA technology with a high affinity for the CGRP receptor and indicated for the prevention of migraines in adults. Approximately 4500 patients comprised of healthy volunteers and patients with migraines had rare adverse reactions at the injection site. Some patients develop neutralizing antibodies. The treatment was well tolerated and the benefits appear modest. No overdoses are reported. Since the xenobiotic is a monoclonal antibody, allergic reactions are a possibility.<sup>42</sup>

## 5HT<sub>1F</sub> Receptor Agonists

Although triptans classically exert their antimigraine effects through 5HT<sub>1B</sub> and 5HT<sub>1D</sub> agonism, naratriptan also has 5HT<sub>1F</sub> agonist effects. 5-Hydroxy-tryptamine<sub>1F</sub> receptors are found on the trigeminal ganglion and the trigeminocervical complex but not on smooth muscles, coronary arteries or cerebral vasculature.<sup>88</sup> Lasmiditan is a 5HT<sub>1F</sub> receptor agonist that decreases plasma protein extravasation at the trigeminal ganglion and inhibited nociceptive transmission from the trigeminocervical complex higher up to the CNS without vasoconstriction of vessels.<sup>59</sup> Reported adverse effects from oral lasmiditan include dizziness, fatigue, nausea, paresthesia, somnolence, vertigo, and sensation of heaviness.<sup>27</sup> Lasmiditan has undergone 2 phase II trials and is undergoing phase III trials currently.

## SUMMARY

- Migraine therapies include many xenobiotics for prophylaxis as well as for abortive therapy. Triptans have supplanted ergots as the primary abortive treatment for patients with migraines.
- Ergots interact with multiple 5-HT, dopamine, and adrenergic receptors, and cause severe vasoconstriction and end organ ischemia.
- It is reasonable to treat ergot- and triptan-induced peripheral ischemia with vasodilators, calcium channel blockers, and heparin anticoagulation.
- Triptans are more selective and interact only with 5-HT<sub>1B/D/F</sub> receptors but also cause peripheral vasoconstriction and end organ ischemia. It is reasonable to treat triptan-induced myocardial ischemia with anticoagulation, nitrates, and coronary angiography for transmural infarctions.

- Triptan use in conjunction with other serotonin-increasing xenobiotics is associated with increased risk of serotonin toxicity.

## THYROID AND ANTITHYROID MEDICATIONS

Nicole C. Bouchard

### HISTORY AND EPIDEMIOLOGY

Long before the thyroid was recognized as a functional endocrine gland, it was believed to serve a cosmetic function, especially in women. Egyptian paintings often emphasize the full and beautiful necks of women with enlarged thyroid glands. Early theories on the physiologic function of the thyroid gland included lubrication of the trachea, diversion of blood flow from the brain, and protection of women from “irritation” and “vexation” from men.<sup>43</sup> Although poorly defined in historical accounts, symptoms resembling hypothyroidism and myxedema that were successfully treated with ground sheep thyroid were described 500 years ago. In the 16th century, Paracelsus described the association between goiter (thyroid gland enlargement) and cretinism.<sup>99</sup> A syndrome of cardiac hyperactivity, goiter, and exophthalmos was first described in 1786.<sup>99</sup> Graves and von Basedow further detailed this syndrome and its relationship to the thyroid gland 50 years later.<sup>43</sup>

In 1891, injection of ground sheep thyroid extract was formally described as a treatment for myxedema.<sup>43</sup> Shortly afterward, oral therapy was determined to be equally effective. Seaweed, which contains large amounts of iodine, was used to treat goiter (hypothyroidism) in Chinese medicine as early as the third century A.D. In 1863, Trousseau fortuitously discovered a treatment for Graves disease when he inadvertently prescribed daily tincture of iodine instead of tincture of digitalis to a tachycardic, thyrotoxic young woman.<sup>111</sup>

Sir Charles R. Harington described the chemical structure and performed the first synthesis of thyroxine (tetraiodothyronine { $T_4$ }) in 1926.<sup>90</sup> Triiodothyronine ( $T_3$ ) was not isolated and synthesized until the 1950s.<sup>43</sup> Prior to this, desiccated thyroid gland from animal sources was commonly used to treat hypothyroidism. Despite becoming essentially obsolete in the modern medical community, unprocessed, desiccated thyroid is easily purchased via the Internet and in health food stores as a thyroid supplement.<sup>104</sup> A pharmaceutical-grade porcine-derived thyroid supplement originally produced by Armour, is still available by prescription from several manufacturers. Unfortunately, the misguided use of both organic and synthetic thyroid supplements as vitality agents, stimulants, and weight-loss aids has become increasingly common. Two epidemics of “hamburger thyrotoxicosis” that occurred in the United States in the mid-1980s secondary to consumption of ground beef contaminated with bovine thyroid gland demonstrated the potential widespread toxicologic sequelae after a community unknowingly ingested thyroid hormone.<sup>46,60</sup>

Today, hypothyroidism and hyperthyroidism are relatively common endocrine disorders. The global incidence of neonatal hypothyroidism is one per 3,000 to 4,500 births. It is estimated that hypothyroidism affects 1% to 5% of US adults. It is more prevalent in whites than in people of Hispanic or African American descent. In the elderly, the prevalence of hypothyroidism increases to 15% by the age of 75 years. Worldwide, iodine deficiency is the leading cause of hypothyroidism. According to US retail pharmaceutical statistics for prescription drugs, levothyroxine (both generic and brand combined;  $T_4$ ) has consistently ranked in the top 5 prescription count, with an average 67 million per year. Because of widespread availability of thyroid replacement therapy, many cases of intentional and unintentional overdoses with thyroid hormone are reported.<sup>71</sup> However, despite the profound effects of thyroid hormones on physiologic homeostasis and the widespread use and access to exogenous thyroid hormone, morbidity and mortality from overdose is very low and clinically significant overdoses with thyroid hormone preparations are uncommon.

### PHARMACOLOGY

#### Physiology

To properly understand the impact of thyroid supplements and antithyroid xenobiotics on the function of the human body, an understanding of thyroid physiology is required. Thyroid function is influenced by the following: (1) the hypothalamus, (2) the pituitary gland, (3) the thyroid gland, and (4) the target organs for the thyroid hormones (Fig. 53–1).

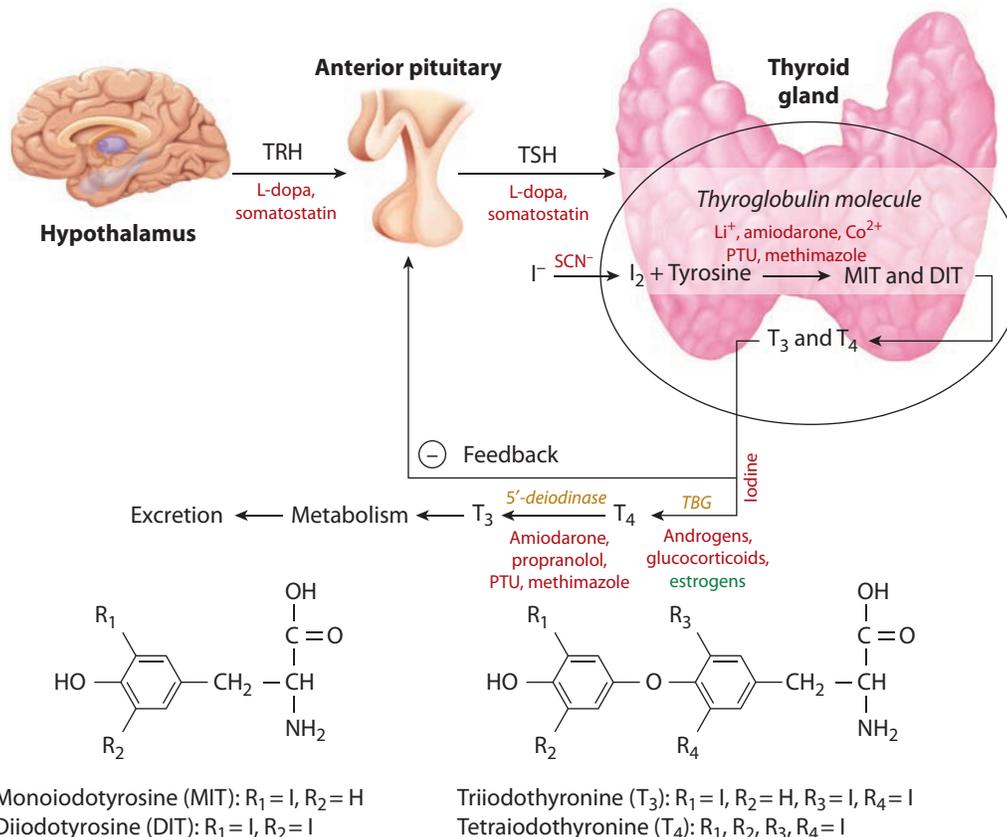

The hypothalamus, viewed by some as the “master gland,” is an intermediate between cerebral centers and the pituitary gland. When the hypothalamus receives specific neurotransmitter stimulation, thyroid-releasing hormone (TRH) is produced, which is then transported through the venous sinusoids to the pituitary gland, which then releases thyroid-stimulating hormone (TSH). Thyroid-stimulating hormone enters the circulation and stimulates the production and release of the thyroid hormones  $T_3$  and  $T_4$  from the thyroid gland. Thyroid physiology exhibits classic autoregulation or “negative biofeedback” of hormonal function. When adequate thyroid hormones are present, they exert an inhibitory effect on the pituitary gland, diminishing production of TSH (Fig. 53–1). Suppression or upregulation of TSH production is a frequently used laboratory marker in the evaluation of hyperthyroidism and hypothyroidism, respectively.

Thyroid hormones are tyrosine molecules with iodine substitutions. Two forms of the hormone are physiologically active:  $T_3$  and  $T_4$  (Table 53–1). Synthesis of thyroid hormones is a multistep process. The follicles of the thyroid gland consist of an epithelial layer of thyroid cells surrounding a proteinaceous colloidal substance containing tyrosine molecules bound to thyroglobulin. After absorption, iodide ( $I^-$ ) is concentrated in thyroid cells by an active transport process called *iodide trapping*. Absorbed  $I^-$  is then oxidized to iodine ( $I_2$ ) by thyroid (iodide) peroxidase within the colloid matrix. Iodine rapidly iodates tyrosine residues to form monoiodotyrosine and diiodotyrosine. These substituted tyrosine molecules then combine to form  $T_3$  and  $T_4$ . The ratio of  $T_3$  to  $T_4$  in thyroglobulin is 1:5. Triiodothyronine and  $T_4$  (thyroxine) ultimately are released into circulation from the thyroglobulin matrix.

Iodide trapping can be inhibited pharmacologically by monovalent anions such as thiocyanate ( $SCN^-$ ), pertechnetate ( $TcO_4^-$ ), and perchlorate ( $ClO_4^-$ ). Thyroid peroxidase is inhibited by high concentrations of intrathyroidal iodide and by thioamide drugs. High intrathyroidal iodide concentrations also inhibit the release of thyroid hormone into circulation (Wolff-Chaikoff effect) (Table 53–2).

Approximately 95% of circulating or peripheral thyroid hormone is  $T_4$ ; the remainder is  $T_3$ . Only 15% of the peripheral  $T_3$  is secreted directly by the thyroid; the balance results from the peripheral (meaning outside the thyroid gland) conversion of  $T_4$  to  $T_3$ . When circulating  $T_4$  enters the cell, it is deiodinated to  $T_3$ . Deiodination of the  $T_4$  molecule occurs by monodeiodination of either the outer ring or the inner ring by 5'-deiodinase or 5-deiodinase, yielding 3,5,3'- $T_3$  and 3,3',5-triiodothyronine (reverse  $T_3$  { $rT_3$ }), respectively.<sup>11</sup> Triiodothyronine has approximately 4 times greater hormonal activity than  $T_4$ , whereas  $rT_3$  is metabolically inactive. Triiodothyronine exerts its effects by binding to thyroid hormone receptors inside the nucleus. This interaction with nuclear receptors regulates gene transcription and protein synthesis, which ultimately increases oxygen consumption and underlies the thermogenic effects of thyroid hormones.

Propranolol, corticosteroids, ipodate (iodinated oral contrast agent), starvation, and severe illness inhibit 5'-deiodinase, which results in decreased production of metabolically active  $T_3$  and preferential monodeiodination to metabolically inactive  $rT_3$ , leading to a syndrome known as “sick

**FIGURE 53-1.** Thyroid hormone synthesis: its control, metabolism, and molecular structures. PTU = propylthiouracil; SCN<sup>-</sup> = thiocyanate; TBG = thyroxine-binding globulin; TRH = thyrotropin-releasing hormone; TSH = thyroid-stimulating hormone; Li<sup>+</sup>, amiodarone, Co<sup>2+</sup>.

euthyroid<sup>m</sup> (Table 53-2). This energy-conserving effect allows attenuation of the thermogenic effects of thyroid hormones in times of physiologic stress.<sup>109</sup>

### T<sub>4</sub> and T<sub>3</sub>

Thyroid supplementation for treatment of hypothyroidism is in widespread use both in human and veterinary medicine. Thyroid hormones historically were derived from animal origin, but now are largely synthetically produced. Desiccated and processed porcine thyroid contains both T<sub>3</sub> and T<sub>4</sub>. Because it is less pharmacologically stable and carries a risk of allergic reaction and thyrotoxicity from T<sub>3</sub>, its use has largely been supplanted by the safer synthetic alternatives. Levothyroxine is the preparation of choice because of its low immunogenicity, 7-day half-life, and easy dosing regimen. It is also available in an intravenous (IV) formulation. Liothyronine (T<sub>3</sub> preparation, available in oral {PO} and IV) and combination T<sub>3</sub>/T<sub>4</sub> preparations available PO. Those synthetic formulations are seldom used clinically because of their short half-lives, high cost, unique therapeutic indication, and increased risk of thyrotoxicosis.

Steady state with regard to suppression of TSH and elevation of T<sub>4</sub> is reached approximately 6 to 8 weeks after initiation of therapy. Doses usually are titrated in increments of 12.5 or 25 mcg/day after 6 weeks based on TSH

measurements. Typical doses for levothyroxine range from 12.5 to 300 mcg/day depending on the patient's age and body weight. Children tend to be dosed by body weight per kilogram and elderly patient dosed between 12.5 and 50 mcg/day because of enhanced sensitivity to thyroxine excess. Different sources suggest varied bioequivalence of Synthroid (T<sub>4</sub>) to generic levothyroxine.<sup>13,25,26,59</sup> As a result, thyroid hormone concentrations and the patient's clinical status should be followed when transitioning between levothyroxine formulations because the switch can present a risk for an adverse drug event.

### PHARMACOKINETICS AND TOXICOKINETICS

Gastrointestinal absorption of exogenous thyroid hormone occurs primarily in the duodenum and ileum. Gastrointestinal absorption is decreased by variations in intestinal flora and binding by certain xenobiotics (Table 53-2). In circulation, T<sub>3</sub> and T<sub>4</sub> both are highly but reversibly bound to plasma proteins—approximately 99.6% and 99.96%, respectively (in nonpregnant adults). Thyroxine-binding globulin binds approximately two-thirds of the circulating thyroid hormones; albumin and other proteins bind the remainder. It is estimated that only 0.4% of T<sub>3</sub> and 0.04% of T<sub>4</sub> exist in the free form. Exogenously derived thyroid hormones exhibit similar binding characteristics when dosed in a physiologic range. The amount of thyroid hormone bound to proteins varies greatly with different physiologic and pharmacologic conditions, for example, increasing in pregnancy<sup>88</sup> and levothyroxine overdose and decreasing in chronic disease. In pregnancy, increases in TBG binding leads to increased production of T<sub>3</sub> and T<sub>4</sub>, resulting in a state of euthyroid hyperthyroxinemia. These changes in protein binding must be evaluated when measuring total thyroid hormone concentrations in the blood (see Diagnostic Testing). Table 53-1 lists some important pharmacokinetic properties of thyroid hormones.

Thyroid hormones undergo their ultimate metabolism peripherally (meaning outside the thyroid gland). Intracellular sequential deiodination accounts for approximately two-thirds of inactivation. Most of the remaining third undergoes hepatic metabolism by glucuronidation or sulfation.

**TABLE 53-1** Pharmacokinetic Properties of Thyroid Hormones

Pharmacokinetic Property	T <sub>3</sub>	T <sub>4</sub>
Oral bioavailability (exogenous), %	95	80
Volume of distribution (L/kg)	40	10
Half-life (days)	1	7
Protein binding (normal adult), %	99.96	99.6
Relative potency	4	1

Xenobiotic	Interaction	Effect
Dopamine, levodopa, somatostatin	Inhibit TRH and TSH synthesis	No clinical hypothyroidism
Iodides (including amiodarone), lithium, aminoglutethimide	Inhibit thyroid hormone synthesis or release	Hypothyroidism
Monovalent anions (SCN <sup>-</sup> , TcO <sub>4</sub> <sup>-</sup> , ClO <sub>4</sub> <sup>-</sup> )	Inhibit iodide uptake to thyroid gland	Hypothyroidism
Estrogens, tamoxifen, heroin, methadone, mitotane	Increase TBG	Altered thyroid hormone transport in serum ↑ Total measured thyroid hormone (vs free hormone)
Androgens, glucocorticoids	Decrease TBG	Altered thyroid hormone transport in serum ↓ Total measured thyroid hormone (vs free hormone)
Salicylates, mefenamic acid, furosemide	Displace T <sub>3</sub> or T <sub>4</sub> from TBG	Transient hyperthyroxinemia
Thioamides (methimazole, propylthiouracil)	Inhibit thyroid peroxidase	Decrease thyroid hormone synthesis
Phenytoin, carbamazepine, phenobarbital, rifampin, rifabutin	Induction of hepatic enzymes	↓ Total thyroid hormone
Iopanoic acid, ipodate, amiodarone, propranolol, corticosteroids, propylthiouracil	Inhibition of 5′-deiodinase	Decrease peripheral conversion of T <sub>4</sub> (↓ T <sub>3</sub> , ↑ rT <sub>3</sub> )
Cholestyramine, colestipol, aluminum hydroxide, sucralfate, ferrous sulfate, some calcium preparations, infant soy formula	Interfere with GI absorption of T <sub>4</sub>	Decreased oral bioavailability of T <sub>4</sub>
Interleukin-α, interleukin-2	Induction of autoimmune thyroid disease	Hyperthyroidism or hypothyroidism

GI = gastrointestinal; TBG = thyroid-binding globulin; TRH = thyroid-releasing hormone; TSH = thyroid-stimulating hormone. Thiocyanate (SCN<sup>-</sup>), pertechnetate (TcO<sub>4</sub><sup>-</sup>), and perchlorate (ClO<sub>4</sub><sup>-</sup>).

Xenobiotics that induce hepatic microsomal metabolism, such as rifampin, phenobarbital, phenytoin, and carbamazepine, increase the metabolic clearance of T<sub>3</sub> and T<sub>4</sub> (Table 53–2).

## **PATHOPHYSIOLOGY**

Thyroid hormones are critical for optimal physiologic growth and function. Thyroid function is the most important determinant of basal metabolic rate. In addition, the thyroid exerts a permissive effect on many hormones, notably catecholamines and insulin.

*Hyperthyroidism* is a condition characterized by excess active thyroid hormone. Most aspects of carbohydrate, protein, and lipid metabolism are increased in the presence of thyroid hormone excess. The disorder is characterized by manifestations of increased metabolism such as hyperthermia, weight loss, diarrhea, heat intolerance, and diaphoresis, along with tachycardia, widened pulse pressure, tremor, anxiety, other behavioral changes, and sometimes tachydysrhythmias such as rapid atrial fibrillation, extrasystoles, and high output congestive heart failure.<sup>32,61,100,101</sup> This constellation of findings, called *thyrotoxicosis*, results from overproduction of the hormone, increased conversion from T<sub>4</sub> to T<sub>3</sub>, or intake of exogenous hormone. Graves disease (diffuse toxic goiter), an autoimmune disorder, is the most common cause of excess thyroid hormone secretion. It accounts for approximately two-thirds of cases and often is accompanied by exophthalmos and

Xenobiotic	Effect	Mechanism
Lithium	Goiter (in 37% of patients) Hypothyroidism (in 5%–15% of patients)	Mechanism unclear
Amiodarone (37% iodine by weight)	1. Hypothyroidism (in 25% of patients) 2. Hyperthyroidism, type 1: in patients with preexisting goiters from low iodine intake 3. Hyperthyroidism, type 2: in patients with previously normal thyroid function	1. Inhibition of 5′-deiodinase 2. Type 1: iodine excess stimulates thyroid hormone production 3. Type 2: causes thyroid inflammation
Propranolol	↓ Peripheral conversion of T <sub>4</sub> to T <sub>3</sub>	Inhibition of 5′-deiodinase
PTU (propylthiouracil) or methimazole	Decreased thyroid hormone synthesis ↓ Peripheral conversion of T <sub>4</sub> to T <sub>3</sub>	Inhibition of thyroid peroxidase Inhibition of 5′-deiodinase
Corticosteroids	↓ Peripheral conversion of T <sub>4</sub> to T <sub>3</sub>	Inhibition of 5′-deiodinase
Iodine	1. Low dose: transient or no effect 2. High doses (>10 mg/day): ↓ thyroid hormone secretion 3. Transient thyrotoxicosis (ie, Jod-Basedow effect) With rapid correction of hypothyroidism from iodine deficiency 4. Delirium 5. Caustic injury [From topical iodine]	1. Transiently stimulates thyroid hormone secretion 2. Inhibition of thyroid hormone synthesis 3. Increases thyroid hormone synthesis 4. Mechanism unclear 5. Direct cytotoxic injury to cells
Iodinated contrast material	1. Rapid ↓ peripheral conversion of T <sub>4</sub> to T <sub>3</sub> (adjunctive treatment in thyroid storm) 2. Prolonged suppression of T <sub>4</sub> to T <sub>3</sub> 3. Causes thyrotoxicosis and thyroid storm 4. Iodide “mumps”	1. Inhibition of 5′-deiodinase 2. Mechanism unclear 3. Mechanism unclear 4. Idiopathic, toxic accumulation of iodide
Radioactive iodine	Treatment of hyperthyroidism, causes hypothyroidism	Uptake into thyroid follicles causes local destruction
Anion inhibitors <sup>a</sup>	↓ Iodine uptake into thyroid follicle, used in iodide-induced hyperthyroidism	Blocks uptake of iodide into the thyroid gland by competitive inhibition

diffusely enlarged, nontender thyroid gland. Toxic multinodular goiter, toxic thyroid adenoma, iodine or amiodarone exposure (which can also cause hypothyroidism; Table 53–3), thyrotoxicosis factitia, and thyroiditis (eg, postpartum, Hashimoto, DeQuervain) are some other etiologies of hyperthyroidism.<sup>41</sup> Severe thyrotoxicosis with significant rapid clinical decompensation is referred to as *thyroid storm* or *thyrotoxic crisis*. Thyroid storm typically occurs when untreated or undertreated hyperthyroidism occurs simultaneously with a physiologic stressor such as trauma, infection, diabetic ketoacidosis, or surgery. In early stages, patients are hyperthermic and markedly tachycardic, tremulous, agitated, or psychotic with nausea, vomiting, and diarrhea. As the disease progresses, stupor, coma, and hypotension ensue. General treatment strategies include early airway control, crystalloid fluid resuscitation, β-adrenergic antagonist administration, parenteral corticosteroids if adrenal insufficiency is suspected, and antithyroid medications such as propylthiouracil and methimazole. The β-adrenergic

antagonist, propranolol, is a mainstay of treatment, as in addition to its desirable effects on tremor, heart rate, and systemic vascular resistance, it decreases peripheral conversion of  $T_4$  to  $T_3$ .<sup>117</sup> Mortality in thyroid storm, even with treatment, can approach 20%.<sup>32,97</sup>

Because plasma catecholamine concentrations are normal or decreased in hyperthyroidism, an increase in sensitivity to catecholamines is thought to be responsible for the increased inotropy and chronotropy produced by thyroid hormones.<sup>20,23,94</sup> Several general mechanisms are proposed for the direct cardiac effects of thyroid hormones, although their relative contributions are uncertain.<sup>5,21,22,55,62,113</sup>

- $T_3$  increases the number of  $\beta$ -adrenergic receptors in various tissues, including cardiac cells.<sup>16</sup> This process occurs via upregulation of  $\beta$ -adrenergic receptor synthesis at the level of the  $\beta$ -adrenergic gene.<sup>6</sup>
- $T_3$  modulates myocyte intracellular signaling mechanisms that lead to increased catecholamine effects. Enhancement of intracellular signaling activity involving protein kinase A, cyclic adenosine monophosphate, G proteins, and increased phosphorylation of thyroid hormone receptor proteins all are implicated to varying degrees.<sup>31,61,92,93,98,107,114</sup>
- Enhancement of myocardial transmembrane and sarcoplasmic reticulum ion channel function, L-type voltage-gated  $Ca^{2+}$  channels, and accelerated  $Ca^{2+}$  entry into the sarcoplasmic reticulum also are suggested.<sup>58,59,81,106</sup> Whether the effects on intracellular signaling represent a direct effect of  $T_3$  on intracellular signaling mediators or  $T_3$ -induced augmentation of the individual  $\beta$ -adrenergic receptor response to catecholamines with a secondary change in postreceptor signaling is unclear.<sup>5</sup>

In addition to these mechanisms,  $T_3$  upregulates synthesis of cardiac thyroid hormone receptors (at TR- $\alpha$  and TR- $\beta$  genes), and the thermogenic effects of thyroid hormones cause decreased systemic vascular resistance, leading to a reflex (and indirect) increase in cardiac output. Comprehensive reviews on this topic explore the more complex cellular aspects of thyroid hormones and their effects on the cardiovascular system.<sup>21,22,61,87</sup>

*Hypothyroidism*, a condition characterized by decreased basal metabolic rate and decreased catecholamine effects, is a common disorder, especially in women and the elderly. Worldwide, dietary iodine deficiency remains the leading cause of hypothyroidism. In certain parts of the world, particularly mountainous regions such as the Andes, Alps, and Himalayas, goitrous hypothyroidism remains endemic. Untreated congenital thyroid deficiency and severe dietary iodine deficiency (goitrous hypothyroidism) in young children result in profound, irreversible mental retardation and dwarfism (also referred to as cretinism). Iodine deficiency is said to be the most common cause of preventable brain damage worldwide. In developed nations, the iodization of table salt has essentially eliminated dietary iodine deficiency as a cause of hypothyroidism leaving autoimmune etiologies as the most common cause, although thyroid function diminishes significantly with age in many patients. Treatment of Graves disease with radioactive iodine typically results in hypothyroidism within one year. Thyroiditis (eg, postpartum, Hashimoto, DeQuervain) is associated with either hypothyroidism or hyperthyroidism as is exposure to certain xenobiotics such as amiodarone and lithium (Table 53–3). Myxedema and myxedema coma are potentially life-threatening emergencies that represent extremes of hypothyroidism. Hypothyroidism is not discussed in more detail in this chapter, except to note that treatment of hypothyroid emergencies, especially with  $T_3$ , can result in thyrotoxic signs and symptoms. Comprehensive reviews of hypothyroidism are available.<sup>103</sup>

## CLINICAL MANIFESTATIONS

Signs and symptoms of toxicity from exogenous thyroid hormone resemble those of catecholamine excess. Pronounced catecholaminelike effects occur in the cardiovascular system, especially tachycardia, tachydysrhythmias (usually atrial fibrillation or flutter), thromboembolism (from both atrial fibrillation and endothelial activation), and high output cardiac failure.<sup>32,61,100,101</sup> Interestingly, although hyperthyroid patients typically are anxious, restless, or agitated, patients with thyroid storm sometimes present with a decreased level of consciousness or even coma.<sup>12,52,66,95,105</sup> Hyperthermia

occurs secondary to the thermogenic effects of thyroid hormones and psychomotor agitation. Hyperthermia can be extreme (ie,  $>106^\circ\text{F}$  [ $>41^\circ\text{C}$ ]). The tachycardia associated with thyrotoxicosis often is disproportionately elevated when compared to the temperature elevation (Chap. 29).

## Acute Toxicity

Acute overdoses with thyroid hormone preparations most commonly occur with oral levothyroxine. Significant ingestions of levothyroxine do not typically manifest clinically until 7 to 10 days after exposure, but rarely can occur as early as 1 to 3 days postingestion.<sup>42,50,69,97,108</sup> The delay of peripheral conversion of  $T_4$  to the metabolically active  $T_3$  and the time required to activate nuclear receptors and protein synthesis account for this clinical latency. By contrast, acute overdoses containing  $T_3$  typically manifest clinically within the first 12 to 24 hours after exposure.<sup>70</sup>

In children, acute thyroxine overdoses almost universally are benign because the ingestions are typically unintentional and of a low dose. Most children remain asymptomatic or develop only mild signs and symptoms. No deaths are reported.<sup>29,36,67,70,71,108,110</sup> In a series of 15 children with unintentional ingestion, only 3 developed mild signs and symptoms within 12 to 48 hours of the exposures which resolved within 24 to 60 hours.<sup>69</sup> Similarly, a case series that involved 41 children (ages 1–5 years) with unintentional exposures to thyroxine (estimated doses ranged from 40 to 800 mcg) found mild signs and symptoms (hyperactive behavior, tachycardia, fever, vomiting, diarrhea, diaphoresis, and flushing) in only 27%. All children had good clinical outcomes. The degree of signs and symptoms did not correlate with the amount ingested or measured serum thyroxine concentrations (measured 1–5 hours postingestion) for most cases in that series (see Diagnostic Testing).<sup>36</sup> Two other series involving 78 and 92 cases of unintentional exposures in children found that mild signs and symptoms developed in only 4 and 8 patients, respectively.<sup>108,115</sup> A report involving an intentional exposure of 9,900 mcg in a 13-year-old boy treated empirically with activated charcoal, dexamethasone, and oral propranolol described only mild tremors and anxiety.<sup>108</sup> A 2.5-year-old boy exposed to an estimated 7,600 mcg and was treated with activated charcoal approximately one hour after exposure and released home. He returned approximately 24 hours later with mild tachycardia and hyperthermia and decrease in appetite. No other treatments were administered. Over the next month, he experienced desquamation of the palms and soles and irritability.<sup>50</sup> Very few cases of severe toxicity in children are reported: one child without a history of a seizure disorder had 2 seizures 7 days after a levothyroxine ingestion (18,000 mcg),<sup>65</sup> another 2-year-old developed thyroid storm with lethargy on postingestion day 5 (estimated ingestion was 6,000 mcg, no activated charcoal was administered, and she was treated with oral propranolol),<sup>74</sup> another child became gravely ill for a 12-hour period (blood pressure, 120/68 mm Hg; pulse, 200 beats/minute; temperature  $104^\circ\text{F}$  [ $40^\circ\text{C}$ ]) 6 hours after ingesting a large amount (3.2 g, or 50 grains) of a desiccated thyroid preparation containing both  $T_3$  and  $T_4$ .<sup>68</sup> All of these children made a full recovery.

Exposures in adults have a wide range of toxicity. Many patients are asymptomatic or mildly symptomatic.<sup>67,72,105</sup> Severe sequelae occur more frequently in adults than in children. Signs and symptoms resemble thyrotoxicosis and, in extreme cases, thyroid storm. Hyperthermia,<sup>42,67,105</sup> dysrhythmias,<sup>7,67,105</sup> and severe agitation<sup>45</sup> are well described. Hemiparesis,<sup>12</sup> muscle weakness,<sup>12,105</sup> seizure,<sup>2</sup> coma,<sup>12,67,105</sup> respiratory failure,<sup>34</sup> sudden death and dysrhythmias,<sup>10</sup> myocardial infarction,<sup>10</sup> cardiac failure,<sup>12</sup> focal myocarditis,<sup>10</sup> rhabdomyolysis with muscle necrosis,<sup>12</sup> delayed palmar desquamation ( $>2$  weeks postingestion),<sup>12,105</sup> acute kidney injury and multiorgan failure,<sup>80</sup> and hematuria<sup>42</sup> are also described. Because patients are expected to be asymptomatic shortly after ingestion and laboratory tests correlate poorly with the degree of signs and symptoms, clinical and laboratory findings early in the course of the ingestion are not reliable indicators of which patients will become ill (see Diagnostic Testing).

## Chronic Toxicity

Following long-term excessive thyroid hormone ingestion, patients can present with thyrotoxicosis or have a more subtle and insidious presentation.

Classically, long-term ingestion of excess thyroid hormone occurs in patients with hypothyroidism, psychiatric disorders, and eating disorders. Persons who ingest thyroid hormones long-term can develop significant weight loss, anxiety, and accelerated osteoporosis.<sup>83</sup> More severe manifestations, such as cardiac dysrhythmias, sinus tachycardia, cardiac failure, and psychosis, also occur. As in patients with hyperthyroidism, intercurrent illness and physiologic stressors can trigger thyroid storm in these patients.

Numerous epidemics of hyperthyroidism and thyrotoxicosis have resulted from the consumption of ground meat containing neck muscle contaminated with thyroid gland.<sup>27,46,60</sup> Investigators in one of these epidemics had 3 volunteers consume a single large portion of “well-cooked” epidemic implicated ground beef that was previously frozen. Although all volunteers remained asymptomatic, the mean serum peak  $T_4$  (8–12 hours postingestion) was elevated approximately 15 mcg/dL, and TSH remained undetectable for 4 to 17 days.<sup>46</sup> The practice of gullet trimming (using larynx muscles for beef) that led to these outbreaks has since been prohibited in US slaughter houses. However, the risk for sporadic cases remains, especially when laryngeal muscles are used or when farmers and hunters butcher their own meat.<sup>88</sup> Until an exogenous source of thyroid hormone is suspected or identified, such patients often are misdiagnosed with painless thyroiditis or thyrotoxicosis factitia.

Thyrotoxicosis factitia is a symptomatic disorder that mimics physiologic disease. It occurs with intentional long-term ingestion of exogenous thyroid hormone. The pattern of ingestion typically is surreptitious and maladaptive. Patients frequently have comorbid psychiatric disorders, such as Munchausen syndrome or eating disorders, or are taking thyroid hormone for secondary gain.<sup>44</sup> Patients with thyrotoxicosis factitia tend to be either health care professionals with access to medications or prescriptions or persons with access to thyroid medications prescribed for relatives, friends, or pets.<sup>37,44,75</sup>

Thyroid hormones remain popular among dieters and athletes who use the hormones as weight-loss aids and as stimulants. Severe consequences can occur. Sudden death was reported in 3 patients suspected of long-term ingestion of thyroid hormone for weight loss and energy enhancement (for which there is a black box warning).<sup>10</sup> In 2002, the heavily promoted Singaporean diet pill (Slim 10) was linked to hepatotoxicity and hyperthyroidism in numerous patients.<sup>46</sup> Investigators found the proprietary herbal preparation was adulterated with significant amounts of the undeclared ingredients  $T_4$ ,  $T_3$  (from thyroid gland extract), and fenfluramine (a drug banned by the US Food and Drug Administration). The medication was promptly withdrawn and the manufacturers convicted under the Singapore Poisons Act.<sup>4</sup> Similar cases were reported from Hong Kong, Japan, and France following ingestion of “slimming pills” containing animal thyroid extract.<sup>57,85,91</sup> Similarly, Redotex, a pharmaceutical Mexican diet supplement that is banned in the United States and contains  $T_3$ , norpseudoephedrine, diazepam, atropine, and a laxative was implicated in toxicity and overdose.<sup>16,28</sup> Unfortunately, thyroid hormone-containing supplements are promoted and are readily available to the general public without a prescription through the Internet and in stores selling nutritional supplements (Chap. 43).<sup>104</sup>

## DIAGNOSTIC TESTING

Traditionally, thyroid testing involved combinations of measurement of total  $T_4$  and some measurement of hormone binding ( $T_3$  uptake). Free  $T_4$  and  $T_3$  are also measured by equilibrium dialysis (free  $T_4$ ), analog assays (ie, competitive analogs of either free  $T_3$  or free  $T_4$  that competitively bind for spaces on the serum-binding proteins), and antibody capture assays (ie, sequential assays that capture a representative portion of the free fraction of thyroid hormone). Assessment of pituitary production of TSH has improved greatly in recent years. Because supersensitive TSH assays can readily detect suppression of TSH production, TSH is now the primary test for screening thyroid function. Suppressed or elevated concentrations of TSH should be reflexively followed up with a free  $T_4$  assay and, if necessary, a free  $T_3$  assay (Table 53–4).

The clinical manifestations of thyrotoxicosis and thyroid storm are well known to occur at normal, low, moderate, and high concentrations of  $T_3$  and

**TABLE 53–4** Diagnostic Tests for Thyroid Hormone and Thyroid Function

Diagnostic Test	Normal Values <sup>a</sup>	Comments
TSH	0.5–4.7 IU/mL	Available assays with respective detection limits: First-generation 1.0 IU/L Second-generation 0.1 IU/L Third-generation 0.01 IU/L
Total $T_4$ by RIA	4.5–12.5 mcg/dL (58–161 nmol/L)	↑ In pregnancy, estrogens, oral contraceptives
Total $T_3$ by RIA	80–200 ng/dL (0.9–2.8 nmol/L)	↑ In pregnancy, estrogens, oral contraceptives
Free $T_4$	8–18 pg/mL (10–23 pmol/L)	↑ In hyperthyroidism, exogenous thyroxine ingestion
Free $T_3$	2.3–4.2 pg/mL (3.5–6.5 pmol/L)	↑ In hyperthyroidism, exogenous thyroid hormone ( $T_3$ or $T_4$ )

<sup>a</sup>Interlaboratory and intersassay variations occur.

RIA = radioimmunoassay; TSH = thyroid-stimulating hormone.

$T_4$ .<sup>15</sup> This lack of correlation between signs and symptoms and serum concentrations is also true for exogenous thyroid hormone ingestion.<sup>9,12,36,42,46,65,70,84,108,115</sup> In a large case series of children with unintentional exposures of thyroxine estimated to be between 40 and 800 mcg, serum  $T_4$  concentrations were drawn in 11 (1–5 hours postingestion). Serum  $T_4$  concentrations were normal in 5 of these children and were slightly elevated in 6 (mean, 16 mcg/dL). In this series, one infant who was estimated to have ingested 4500 mcg had a significantly higher concentration (55 mcg/dL at 4.5 hours) but developed only a transient episode of diaphoresis and a “staring spell” 7 days postingestion. Another child who ingested an estimated 4,200 mcg had a concentration of 12 mcg/dL and developed significant tachycardia and hyperthermia.<sup>38</sup> A young child (estimated ingestion 18,000 mcg levothyroxine) had a serum  $T_4$  concentration of 117 mcg/dL 8 hours postingestion and 38 mcg/dL on day 7, when he was symptomatic.<sup>65</sup> Similar trends were observed for both  $T_3$  and  $T_4$  in 3 other massive levothyroxine ingestions in children.<sup>6,74,108</sup> In an adult with a massive ingestion of levothyroxine (720,000 mcg), serum  $T_4$  concentrations were higher than 30 mcg/dL and free  $T_4$  was above 13 ng/dL (normal range, 0.7–1.86 ng/dL). In this case, TSH remained undetectable until postingestion day 32.<sup>42</sup> Overall, the observed signs and symptoms following thyroid hormone ingestion correlate poorly with the amount ingested or with measured serum  $T_4$  concentrations. Prolonged suppression of TSH is common following ingestion of excess thyroid hormone.

Routine analysis of laboratory thyroid function tests in the setting of acute thyroid hormone overdose likely will not affect management. Analysis of thyroid hormone concentrations is indicated only if confirmation of a suspected ingestion is desired and in massive ingestions when early and severe symptoms may occur. Suppression of TSH and elevated thyroid hormone concentrations with a low serum thyroglobulin concentration help to differentiate between thyrotoxicosis factitia and true endogenous disease.<sup>75</sup>

## MANAGEMENT

Based on the existing literature, conservative management is adequate in most cases of acute unintentional thyroxine ingestions in both adults and children. Most children with acute overdose are managed with home observation and follow-up appointments. In cases in which the acute thyroxine dose is estimated to be greater than 4,000 mcg, patient follow-up by regular telephone contact for 10 days is recommended.<sup>36</sup> Historically, most children with unintentional ingestions were treated with GI decontamination with activated charcoal and/or syrup of ipecac, or by gastric lavage,<sup>36,65,69,71,108</sup> but these procedures (especially emesis and lavage) are probably unnecessary. Based on 2 large series of unintentional exposures in children in which no

toxicity was observed in the clear majority of cases, clinically significant toxicity is not expected with estimated ingestions less than 4,000 mcg.<sup>36,51</sup> Because children almost uniformly develop no more than minor symptoms, activated charcoal administration is recommended only if the ingestion is greater than 5,000 mcg of thyroxine. Aspiration risks are minimal in awake, alert children who are able to protect their airways and take activated charcoal orally, without nasogastric tube placement.<sup>67,115</sup> By extension, adults with acute ingestions greater than 5,000 mcg of thyroxine also should be treated with activated charcoal. Gastric emptying procedures such as orogastric lavage, should be reserved for early presentations with massive thyroxine ingestions (>10,000–50,000 mcg) in suicidal adults or ingestions of preparations containing large amounts of T<sub>3</sub>.<sup>12,42</sup> We recommend that patients with massive ingestions (>10,000–50,000 mcg) or ingestion of T<sub>3</sub>-containing products be admitted for observation in anticipation of developing significant symptoms.<sup>12,42,65,68</sup>

Treatment should be based on the development of toxicity and should include rehydration, airway protection, and control of sympathomimetic symptoms, mental status alterations, and hyperpyrexia.  $\beta$ -Adrenergic antagonism with propranolol is typically used for sympathomimetic symptoms in numerous cases.<sup>9,33,65,84,108,110</sup> Empiric treatment with  $\beta$ -adrenergic antagonists is not recommended. Treatment is only indicated for clinically significant tachycardia, dysrhythmias, and other signs and symptoms of catecholaminergic excess.<sup>33,65,84,108,110</sup>

### Agitation

If sedation is required, parenteral benzodiazepines and barbiturates are recommended. Rapid-acting benzodiazepines, such as midazolam, or diazepam should be used to control severely agitated or symptomatic patients. Phenobarbital should be used as an additional treatment in intubated patients or as an adjunct in patients requiring high doses of parenteral benzodiazepines for sedation because it offers the added theoretical benefit of inducing enhanced hepatic elimination of thyroxine as well as synergy with benzodiazepines (Table 53–2). Because of the general risks of sedation and the lack of evidence regarding the clinical use of enhanced hepatic elimination from phenobarbital, sedation with phenobarbital for the sole purpose of enhanced elimination is not indicated. Sedation with antipsychotics such as haloperidol and droperidol should be avoided because their significant anticholinergic properties can exacerbate thyrotoxic symptoms. In addition, the tendency for this class of drugs to prolong the QT interval and predispose to malignant dysrhythmias is of concern in the already catecholaminergic patient. Antipsychotics should be reserved for medically stable patients with psychiatric behavioral disturbances.

### Catecholaminergic Excess and Cardiovascular Symptoms

The principal therapeutic role of  $\beta$ -adrenergic antagonists in hyperthyroidism is for their sympatholytic effects. In addition, propranolol inhibits 5'-deiodinase, thereby decreasing peripheral conversion of T<sub>4</sub> to T<sub>3</sub> (Table 53–2).<sup>117</sup> The clinical significance of decreased peripheral conversion in the setting of overdose is unknown. Propranolol is the most frequently used  $\beta$ -adrenergic antagonist in thyrotoxic patients,<sup>36,42,65,74,84,108,110</sup> and should be used parenterally when signs and symptoms are severe or when rapid control of heart rate is required. Starting doses of 1 to 2 mg IV propranolol every 10 to 15 minutes are recommended. Higher doses have been reported in massive thyroxine overdose, where a patient received 23 mg propranolol IV over one hour on initial presentation, then required an average of 30 mg/day IV for 5 more days.<sup>42</sup> Oral propranolol is recommended for persistent symptoms in patients who are both hemodynamically and medically stable and are not acutely agitated. High oral doses in the range of 20 to 120 mg every 6 hours are usually required. A 2-year-old with thyroid storm after massive levothyroxine overdose was treated with 0.8 mg/kg propranolol PO every 6 hours.<sup>74</sup> Other  $\beta$ -adrenergic antagonists, such as atenolol, nadolol, metoprolol, and esmolol, can be used for signs and symptoms of adrenergic excess, but the evidence for their inhibition of the peripheral conversion of T<sub>4</sub> to T<sub>3</sub> is not established. Continuous electrocardiographic and hemodynamic

monitoring are indicated when parenteral  $\beta$ -adrenergic antagonists are used or when patients require hospitalization.

When nonspecific  $\beta$ -adrenergic antagonists are contraindicated, as in patients with asthma or severe congestive heart failure,  $\beta_1$ -adrenergic receptor selective antagonists (such as atenolol or metoprolol) or calcium channel blockers are recommended. Among calcium channel blockers, diltiazem is the most studied for the management of thyrotoxicosis.<sup>74,94</sup> A double-blind, crossover trial that compared propranolol to diltiazem for thyrotoxic symptoms found that diltiazem was well tolerated and appeared as effective as propranolol.<sup>79</sup> Another study successfully used diltiazem as the sole treatment of cardiovascular signs and symptoms in 11 thyrotoxic patients.<sup>102</sup> Oral doses of 60 to 120 mg diltiazem 3 to 4 times daily or 5 to 10 mg/h parenterally have been used.<sup>79,102</sup> A possible explanation for the efficacy of calcium channel blockers in thyrotoxicosis is that thyroid hormone enhances Ca<sup>2+</sup> uptake by L-type voltage-gated Ca<sup>2+</sup> channels, accelerates Ca<sup>2+</sup> entry into the sarcoplasmic reticulum, and increases cellular Ca<sup>2+</sup> storage capacity.<sup>58,59,81,106</sup> The net effect of these changes is increased inotropy and chronotropy. Calcium channel blockers, particularly diltiazem and verapamil, attenuate these effects. However, the use of parenteral  $\beta$ -adrenergic antagonists in combination with parenteral calcium channel blockers is contraindicated because of the risk for profound hypotension and cardiovascular collapse.<sup>86</sup>

### Hyperthermia

Antipyretics are not recommended for hyperthermia associated with catecholamine excess and thyrotoxic condition. Aspirin, particularly high doses (1.5–3 g/day), should be avoided because it carries a theoretical risk of increased thyrotoxicity from displacement of T<sub>3</sub> and T<sub>4</sub> from thyroxine-binding globulin (Table 53–2). Note, however, that hyperthermia, especially extreme hyperthermia (>106°F {>41°C}), is most likely secondary to psychomotor agitation and excess heat production from the hypermetabolic, catecholaminergic, and thyrotoxic conditions. Extreme hyperthermia is a medical emergency and should be rapidly and aggressively treated with active external cooling with ice baths or other aggressive external cooling measure and with  $\beta$ -adrenergic antagonism, sedation with benzodiazepines and/or barbiturates, and endotracheal intubation with paralysis if necessary (Chap. 29).

### Other Therapies

Bile acid sequestrants, such as cholestyramine and colestipol, and aluminum hydroxide (antacids) and sucralfate bind to exogenous T<sub>4</sub> and decrease GI absorption (Table 53–2). They are used in levothyroxine overdose with possible benefit.<sup>24</sup> Because the evidence supporting their effectiveness is poor, they are not routinely recommended for thyroid hormone overdose.<sup>67</sup>

Oral iodine-containing contrast media is known to decrease peripheral conversion of T<sub>4</sub> to T<sub>3</sub>. Doses of 1 to 2.5 mg/kg iodine PO daily are routinely used for thyroid storm (oral drops commonly referred to as saturated solution potassium iodide {KI or SSKI}). Thioamides, such as propylthiouracil (PTU) and methimazole, and the corticosteroids are thyroid gland inhibitors that are used for treatment of nondrug-related hyperthyroidism. In addition, thioamides inhibit peripheral conversion of T<sub>4</sub> to T<sub>3</sub>. Evidence from limited case reports suggests poor efficacy of both thioamides and corticosteroids in acute overdose (see Thioamides and Iodides).<sup>12,34,67</sup>

Although use of antithyroid drugs such as PTU, corticosteroids, and iodine contrast media in thyroxine overdose has theoretical benefits, these xenobiotics are not validated, potentially harmful, and unlikely to offer additional benefit, or be superior to conventional therapy with activated charcoal,  $\beta$ -adrenergic antagonism, and sedation. These treatments are not recommended as adjunctive therapies for treatment of exogenous thyroxine overdose.

### Extracorporeal Drug Removal

The use of extracorporeal drug removal procedures, such as plasma exchange or plasmapheresis, exchange transfusion (in children), and charcoal hemoperfusion, are reported in extreme cases of thyroid hormone overdose and thyroid storm.<sup>1,12,14,34,47,54,63,67,70,77,80,82,112,116</sup> Overall, results regarding

improvement of clinical condition and plasma clearances of thyroid hormones with these methods are conflicting. The largest series of acute ingestions involved 6 patients who became critically ill after massive thyroxine ingestions of prescribed capsules containing a 1,000-fold concentration excess of thyroxine (dose range, 50,000–125,000 mcg/day for 2–12 days). Charcoal hemoperfusion and plasmapheresis were used in all patients. Plasmapheresis was found to be more effective than hemoperfusion in the extraction of thyroxine. The authors suggest this intervention shortens the duration of thyrotoxicosis. Rebound elevations in plasma concentrations occurred 24 hours later, suggesting redistribution between extravascular and intravascular compartments.<sup>12</sup> This redistribution is expected given the large volume of distribution for thyroid hormones (Table 53–1). It is only reasonable to perform early plasmapheresis in the exceptional situation of a known massive ingestion of thyroid hormone or critically ill patient from thyroid hormone ingestion. The outcomes from most ingestions of thyroid hormone will be favorable with good supportive care, sedation, and  $\beta$ -adrenergic antagonism.

## XENOBIOTICS WITH ANTITHYROID EFFECTS

### Thioamides

Antithyroid drugs are used to decrease the amount of thyroid hormone in hyperthyroidism, most commonly in Graves disease. Thioamides are a group of chemicals with the basic structure of R-SCN. Methimazole and propylthiouracil (PTU) are the 2 principal thioamides used for treatment of hyperthyroidism. Carbimazole, which is bioactivated methimazole, is available in Europe and China. Methimazole and PTU both inhibit the activity of thyroid peroxidase in the thyroid gland.<sup>113</sup> Propylthiouracil has the added effect of inactivating 5'-deiodinase, which decreases the peripheral conversion of  $T_4$  to the metabolically more active  $T_3$ . Because thioamides act primarily by decreasing thyroid hormone synthesis (vs release), a lag time of 3 to 4 weeks may occur before  $T_4$  is depleted. The oral bioavailability of PTU is 50% to 80%. It is rapidly absorbed from the gastrointestinal tract and may undergo first-pass effect by the liver. Although its plasma half-life is only 1.5 hours, its effects are long lasting because of accumulation in the thyroid gland. Propylthiouracil is inactivated by glucuronidation and is renally eliminated. Methimazole is completely absorbed, is concentrated in the thyroid, and is more slowly eliminated than PTU (48 vs 24 hours). We recommend a dose of PTU 100 mg orally every 8 hours. Higher doses may be required and doses in children less than 6 years old usually start at 50 mg/day. Methimazole can be given 30 mg PO daily. Although PTU is 10 times less potent than methimazole, it is more commonly used. The indications for its use are mild to moderate hyperthyroidism.

The 2 thioamides traverse the placenta (methimazole more than PTU) and should not be administered during pregnancy. However, they are minimally secreted in breast milk. Adverse effects occur in 3% to 12% of patients taking thioamides. The most common adverse effect is a maculopapular pruritic rash. Methimazole, PTU, and, to a lesser extent, carbimazole cause immune-mediated, dose-related, and age-related agranulocytosis and neutrophil dyscrasias.<sup>73,78,89</sup> This potentially life-threatening adverse effect is treated by administration of granulocyte colony-stimulating factor.<sup>7</sup> Premature withdrawal of thioamides leads to rebound symptoms and thyrotoxic states.<sup>64</sup>

There are little data regarding overdose with thioamides. A 12-year-old girl with a previous thyroidectomy, who was estimated to have ingested 5,000 to 13,000 mg PTU, developed only a transient decreased  $T_3$  concentration and elevated alkaline phosphatase concentration (7350 mU/mL).<sup>53</sup> The absence of a functioning thyroid gland likely contributed to the benign course in this patient. No other serious sequelae are associated with acute overdose of thioamides.

### Iodides

Prior to the development of thioamides, iodide salt was the principal treatment for hyperthyroidism. Iodides decrease thyroid hormone concentrations by inhibiting formation and release. In thyroid storm, high-dose iodides

(>2 g/day) decrease thyroid hormone release and produce substantial improvements by 2 to 7 days. Common sources of iodides include calcium iodide, sodium iodide, KI (pharmaceutical preparations, iopanoic acid, Lugol solution {iodine + KI solution}, oral drops {saturated solution KI}), and methyl iodide (industrial preparations).

The adverse reaction to long-term ingestion of small or excessive amounts of iodide salts, termed *iodism*, is characterized by cutaneous rash, laryngitis, bronchitis, esophagitis, conjunctivitis, drug fever, metallic taste, "mumps," salivation, headache, and bleeding diathesis. Immune-mediated hypersensitivity signs and symptoms consisting of urticaria, angioedema, eosinophilia, vasculitis, arthralgia, and lymphadenitis, and, rarely, anaphylactoid reactions may occur. Long-term iodide therapy produces goiters, hypothyroidism, and rarely hyperthyroidism. As much as 10 g sodium iodide has been administered IV without development of signs or symptoms of toxicity.

Iodide ( $I^-$ ), unlike iodine ( $I_2$ ), is not caustic (Chaps. 101 and 103). Potassium iodide (KI) is added to table salt to form iodized salt for prevention of goiter. It also is used prophylactically after exposure to large amounts of nuclear fallout to prevent uptake of radioactive iodine into the thyroid gland (Antidotes in Depth: A44) and is the most commonly used iodide for thyroid suppression in hyperthyroidism. "Iodide mumps" is a well-described but rare disorder characterized by severe sialadenitis (or parotitis),<sup>56</sup> allergic vasculitis, and/or conjunctivitis following administration of ionic and nonionic iodine-containing contrast media and oral iodide salts (Table 53–3).<sup>18,19</sup> Although the mechanism remains unclear, it is thought to be idiosyncratic or secondary to iodide accumulation and subsequent inflammation in the ductal systems of the salivary gland. Clinical effects tend to occur within 12 hours and resolve spontaneously within 48 to 72 hours.<sup>18</sup>

Iodides should be avoided in pregnancy because they readily cross the placenta. Severe fetal complications, such as cretinism and death from respiratory failure secondary to obstructive goiter, are reported.<sup>30,48,76</sup> Iodide salts are adsorbed to activated charcoal.

Methyl iodide is a methylating agent used in the chemical and pharmaceutical industry, as a reagent in microscopy, as a catalyst in production of organic lead compounds, as an etching agent, as a component in fire extinguishers, and formerly as a soil fumigant. Inhalational methyl iodide toxicity is associated with early pulmonary congestion, lethargy, and acute kidney injury. It also is associated with delayed cerebellar degeneration, multifocal neuropathies (cranial nerve and spinal), Parkinsonian effects, and late and persistent psychiatric symptoms (months to years).<sup>3,49</sup> Long-term repeated overexposures have led to misdiagnoses such as multiple sclerosis. The toxicity is similar to that of the monohalomethanes (Chap. 108).

## SUMMARY

- Despite the prevalence of thyroid disorders in the general population and the widespread use of levothyroxine, remarkably little morbidity and mortality associated with overdose from thyroid hormones is reported.
- Most children with unintentional exposures can be observed as outpatients for 5 to 10 days.
- Adults with acute intentional ingestions rarely have severe symptoms that require management in an intensive care unit.
- Supportive care with sedation, cooling measures, and  $\beta$ -adrenergic antagonism are adequate in most cases.
- Long-term ingestions tend to produce more severe symptoms as they develop more insidiously or are complicated by thyroid storm.
- Clinicians should suspect exogenous thyroid hormone exposure in patients with thyrotoxicosis and suppressed TSH concentrations.

## D. Antimicrobials

# ANTIBACTERIALS, ANTIFUNGALS, AND ANTIVIRALS

Christine M. Stork

### HISTORY AND EPIDEMIOLOGY

The introduction of penicillin in the 1940s revolutionized the care of patients with infectious diseases. Antimicrobials, including all categories of antibacterials, antifungals, and antivirals, significantly improve the clinical care and outcome of infected patients. Since early in their introduction, the development of antimicrobial-resistant strains of these pathogens has driven an increase in the number of antimicrobials necessary. This, in turn, continues to increase the overall potential for toxicity after use. Fortunately, with most antimicrobials, toxicity due to acute overdose is limited and chronic therapeutic doses are safe.

Most adverse drug events related to antimicrobials occur as a result of iatrogenic complications rather than intentional overdose. The diverse origins of these complications include dosing errors, route administration errors, allergic reactions, adverse drug events, and drug–drug-related interactions. Prevention, in the form of process improvements and information regarding populations at risk for adverse drug events, is continually required to minimize these untoward events. Dosing errors are prominent, particularly in neonates and infants, and those patients with compromised kidney or liver function necessitating care and constant diligence on the part of health care professionals.

Antimicrobials are more commonly associated with allergic reactions than are other pharmaceuticals. The reason is hypothesized to be either a result of their high frequency of use, repeated intermittent prescriptions, or environmental contamination. A complete allergy history is essential to minimize these adverse drug reactions in patients being considered for antimicrobial therapy.

Many adverse drug reactions attributed to antimicrobials are difficult to predict even when given patient and population specific parameters. In some cases, an excipient is found responsible for the adverse event, as is seen after the use of procaine penicillin G (Chap. 46). Antimicrobials are involved in many common and severe drug–drug interactions, primarily through the inhibition of cytochrome and other metabolic enzymes. Patients considered for antimicrobial therapy should be carefully assessed for the use of prescription and nonprescription therapies that are known to be pharmacokinetically or pharmacodynamically affected by the chosen antimicrobial.

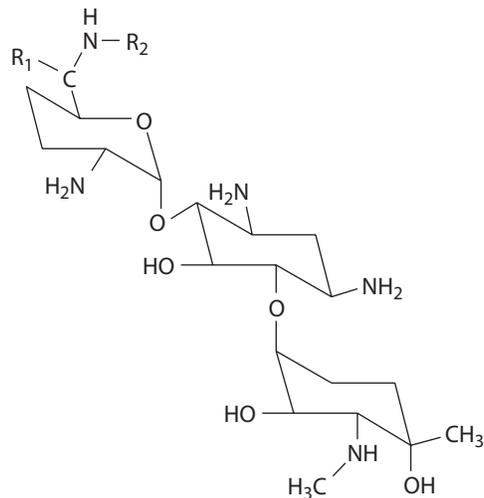

### PHARMACOLOGY AND TOXICOLOGY

Antimicrobial pharmacology is aimed at the destruction of microorganisms through the inhibition of cell cycle reproduction or the altering of a critical function within a microorganism. [Table 54–1](#) lists antimicrobials and their associated mechanisms of activity, toxicologic effects, and related toxicologic mechanisms. Often the mechanisms for toxicologic effects following acute overdose differ from their therapeutic mechanisms.

### ANTIBACTERIALS

#### Aminoglycosides

Aminoglycosides that are in current use in the United States include amikacin, gentamicin, kanamycin, neomycin, paromomycin, streptomycin, and tobramycin. Aminoglycosides are available in parenteral, topical, and ophthalmic forms. Overdoses, almost exclusively the result of dosing errors, are rarely life threatening, and most patients can be safely managed with

Gentamicin C<sub>1</sub>: R<sub>1</sub> = R<sub>2</sub> = CH<sub>3</sub>  
Gentamicin C<sub>2</sub>: R<sub>1</sub> = CH<sub>3</sub>, R<sub>2</sub> = H  
Gentamicin C<sub>1a</sub>: R<sub>1</sub> = R<sub>2</sub> = H

minimal intervention.<sup>28,122</sup> Adverse drug reactions, seen after aminoglycoside use, are generally class based, although subtle differences exist in the potency with which the adverse drug reactions occur ([Table 54–2](#)).

Large intravenous doses of aminoglycosides are both sufficiently safe and effective for use in single daily doses.<sup>5</sup> Rarely, acute aminoglycoside overdose results in nephrotoxicity, ototoxicity, or vestibular toxicity.<sup>117,143</sup> In one reported case, postmortem analysis confirmed a complete loss of hair cells in the inner and outer cochlear (Chap. 25).

Aminoglycosides exacerbate concomitant neuromuscular blockade, particularly at times corresponding to high peak serum aminoglycoside concentrations (Chap. 66).<sup>173</sup> This is caused by inhibiting presynaptic calcium channels, thereby inhibiting the release of acetylcholine from presynaptic nerve terminals. Patients at risk for enhanced neuromuscular blockade include those with abnormal neuromuscular junction function, such as occurs with myasthenia gravis or botulism.

#### Adverse Drug Reactions Associated With Therapeutic Use

Adverse drug reactions, including nephrotoxicity and ototoxicity, correlate most closely with elevated trough serum concentrations than with elevated peak concentrations.<sup>109,152</sup> Less common adverse drug reactions associated with chronic use include electrolyte abnormalities, allergic reactions, hepatotoxicity, anemia, granulocytopenia, thrombocytopenia, eosinophilia, retinal toxicity, reproductive dysfunction, tetany, and psychosis.<sup>113,128,214,228</sup> When aminoglycosides are administered at high doses or during once-daily dosing, sepsislike chills and malaise occur, which are likely due to excipients delivered during the infusion.<sup>51</sup>

#### Nephrotoxicity

The mechanism of nephrotoxicity and ototoxicity is incompletely understood, but involves the formation of reactive oxygen species in the presence of iron. Both the inhibition of mitochondrial respiration resulting in lipid peroxidation and the stimulation of glutamate activated *N*-methyl-D-aspartate

**TABLE 54-1** Antimicrobial Pharmacology and Adverse Effects

Antimicrobial	Antimicrobial Mechanism of Action	Acute Overdose	Chronic Administration
<b>Antibacterial</b>			
Aminoglycosides	Inhibit 30s ribosomal subunit	Neuromuscular blockade—inhibit the release of acetylcholine from presynaptic nerve terminals and acts as an antagonist at acetylcholine receptors	Nephrotoxicity/ototoxicity—form an iron complex that inhibits mitochondrial respiration and causes lipid peroxidation
Penicillins, cephalosporins, and other $\beta$ -lactams	Inhibit cell wall mucopeptide synthesis	Seizures—agonist at picrotoxin-binding site, causing GABA antagonism	Hypersensitivity—immune
Chloramphenicol	Inhibits 50s ribosomal subunit and inhibits protein synthesis in rapidly dividing cells	Cardiovascular collapse	“Gray baby syndrome” Same as mechanism of action
Fluoroquinolones	Inhibit DNA topoisomerase and DNA gyrase; bind to cations ( $Mg^{2+}$ )	Seizures	Not entirely known; bind to cations ( $Mg^{2+}$ ), tendon rupture, hyperglycemia, or hypoglycemia
Linezolid	Inhibits bacterial protein synthesis through inhibition of <i>N</i> -formylmethionyl-tRNA	None clinically relevant	MAOI activity: vasopressor response to tyramine; serotonin toxicity with SSRI and possibly meperidine
Macrolides, lincosamides, and ketolides	Inhibit 50s ribosomal subunit in multiplying cells	Prolong QT interval: blocks delayed rectifier potassium channel, torsade de pointes	Not entirely known; cytotoxic effect; exacerbation of myasthenia gravis
Nitrofurantoin	Bacterial enzymatic inhibitor	Gastritis	Dermatologic, hematologic, pancreatitis, parotitis, hepatitis, crystalluria, pulmonary fibrosis
Sulfonamides	Inhibit paraaminobenzoic acid and/or paraaminoglutamic acid in the synthesis of folic acid	None clinically relevant	Hypersensitivity—metabolite acts as hapten, leading to hemolysis/methemoglobinemia; exposure to UVB causes free radical formation
Tetracycline	Inhibits 30s and 50s ribosomal subunits; binds to aminoacyl transfer RNA	None clinically relevant	Photosensitivity reaction Pregnancy: Discoloration of teeth of offspring
Vancomycin	Inhibits glycopeptidase polymerase in cell wall synthesis	“Red man syndrome”—anaphylactoid	Nephrotoxicity
<b>Antifungal</b>			
Amphotericin B	Binds with ergosterol on cytoplasmic membrane to create pores to facilitate organelle leak	None clinically relevant	Nephrotoxicity—vehicle deoxycholate may be involved; nephrocalcinosis
Triazoles and imidazoles	Increase permeability of cell membranes	None clinically relevant	None clinically relevant

GABA =  $\gamma$ -aminobutyric acid; MAOI = monoamine oxidase inhibitor; SSRI = selective serotonin reuptake inhibitor; UVB = ultraviolet light.

(NMDA) receptors are hypothesized to play a role.<sup>98,238</sup> The incidence of nephrotoxicity with aminoglycoside therapy is estimated at 10% to 25%.<sup>118</sup> Although the aminoglycosides are almost completely excreted prior to biotransformation in the kidney, a small fraction of filtered aminoglycoside is transported by absorptive endocytosis across the apical membrane of proximal tubular cells where it becomes sequestered within lysosomes. As toxicity progresses, lysosomes rupture allowing the sequestered aminoglycoside to bind to and destroy phospholipids contained on brush border membranes in the proximal renal tubule.<sup>9</sup>

**TABLE 54-2** Predominant Manifestations of Aminoglycoside Toxicity

Cochlear	Cochlear and Vestibular		Renal
	Vestibular	Vestibular	
Kanamycin	Amikacin	Streptomycin	Amikacin
Neomycin	Gentamicin		Gentamicin
	Tobramycin		Kanamycin
			Neomycin
			Streptomycin
			Tobramycin

In addition to tubular toxicity renal injury occurs through effects on the glomerulus and vascular system. Acute kidney injury does not generally occur before 7 to 10 days of standard-dose therapy.<sup>141</sup> Because the injury occurs days prior to elevations in serum creatinine concentration, a delay in diagnosis is common.<sup>201</sup> Laboratory abnormalities include granular casts, proteinuria, elevated urinary sodium, and increased fractional excretion of sodium. Usually acute kidney injury (AKI) is reversible. Gentamicin and tobramycin have a higher total incidence of nephrotoxicity compared with netilmicin and amikacin.<sup>118</sup> Risk factors for the development of nephrotoxicity include increasing age, chronic kidney disease (CKD), female sex, previous aminoglycoside therapy, liver dysfunction, large total dose, long duration of therapy, frequent doses, high trough concentrations, the presence of other nephrotoxic xenobiotics, and shock.<sup>9,156</sup> Because the uptake of aminoglycosides into organs is saturable, once-daily high-dose regimens are less problematic than several lesser doses given in a single day.

### Ototoxicity

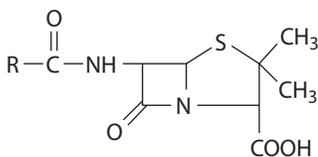

Ototoxicity occurs after acute or prolonged exposure to aminoglycosides (Chap 25).<sup>203</sup> Both cochlear and vestibular dysfunction occur and injury is thought to result from prolonged contact time with sensory hair cells after bioaccumulation in the endolymph and perilymph spaces.<sup>4</sup> Vestibular toxicity, caused by destruction of sensory receptor portions of the inner ear

or destruction of hair cells in the utricle and saccule, occurs in 0.4% to 10% of patients. Symptoms include vertigo or tinnitus. Table 54–2 details the relative characteristic toxicity of various aminoglycosides.

Full-tone audiometric testing first shows high-frequency hearing loss, which subsequently progress in select cases. Given the inability of cochlear hair cells to regenerate, all hearing loss that develops is permanent. After early diagnosis of vestibular dysfunction, select patients improve after discontinuation of the xenobiotic. Simultaneous administration of other ototoxic xenobiotics enhances the ototoxicity of aminoglycosides (Chap. 25).

Withdrawal of the offending xenobiotic is indicated in patients with either nephrotoxicity or ototoxicity caused by an aminoglycoside antibiotic (Chap. 27). Supportive care is the mainstay of therapy. *N*-Acetylcysteine reduced the rate of ototoxicity in patients with end-stage renal failure when given concurrently with aminoglycosides.<sup>124</sup> Experimental treatments in animal models include the use of deferoxamine and glutathione in an attempt to chelate and/or detoxify a reactive intermediate.<sup>167,217</sup> The antibiotic ticarcillin forms a renally eliminated complex with aminoglycosides; however, this is of limited value because in most instances the serum concentration of the aminoglycoside has decreased before any therapeutic measures can be used.<sup>75</sup>

## Penicillins

Penicillin nucleus

Penicillin is derived from the fungus *Penicillium* and many semisynthetic derivatives have found clinical utility. Penicillins, as a class, contain a 6-aminopenicillanic acid nucleus, composed of a  $\beta$ -lactam ring fused to a 5-member thiazolidine ring. Classically available penicillins include penicillin G, penicillin V, and the antistaphylococcal penicillins (nafcillin, oxacillin, and dicloxacillin). Penicillins developed to enhance the spectrum of antibiotic efficacy, particularly against gram-negative bacilli, include the second-generation penicillins (ampicillin, and amoxicillin), third-generation penicillins (ticarcillin), and fourth-generation penicillins (piperacillin). Table 54–1 lists the pharmacologic mechanism of penicillins.

Acute oral overdoses of the various penicillins are usually not life threatening.<sup>222</sup> The most frequent complaints following acute overdose are nausea, vomiting, and diarrhea.

Seizures can occur in persons given large intravenous or cerebral intraventricular doses of penicillins.<sup>114,125,150</sup> More than 50 million units administered intravenously in less than 8 hours is generally required to produce seizures in adults.<sup>206</sup> Penicillin-induced seizures are mediated through binding to the picrotoxin-binding site on the neuronal chloride channel near the  $\gamma$ -aminobutyric acid (GABA)-binding site (Chap. 13).<sup>96</sup> Binding of the penicillin to this site produces an allosteric change in the receptor and prevents GABA from binding, resulting in a relative loss of inhibitory tone.<sup>26</sup> Seizures appear to be related to structure of the beta-lactam ring because penicillin analogs (such as imipenem) also cause seizures, presumably through a similar mechanism.<sup>57</sup>

The treatment of patients who develop penicillin-induced seizures should emphasize benzodiazepines followed by other GABA agonists, if necessary. Patients who receive an intraventricular overdose, where greater than 10,000 units or equivalent is administered, often require cerebrospinal fluid exchange or perfusion to attenuate seizure activity (Special Considerations: SC7).<sup>46,125,154</sup> There are rare reports of hyperkalemia resulting in electrocardiographic abnormalities after the rapid intravenous infusion of potassium penicillin G to patients with CKD and other reports of amoxicillin overdose resulting in frank hematuria and AKI.<sup>36,88</sup>

### Adverse Drug Reactions Associated With Therapeutic Use

Penicillins are associated with a myriad of adverse drug reactions after therapeutic use, the most common of which are allergic in nature.<sup>22</sup>

TABLE 54–3 Classification of Anaphylactic Reactions

Grade	Description
I	Large local contiguous reaction (>15 cm)
II	Pruritus (urticaria) generalized
III	Asthma, angioedema, nausea, vomiting
IV	Airway (asthma, lingual edema, dysphagia, respiratory distress, laryngeal edema) Cardiovascular (hypotension, cardiovascular collapse)

Penicillins are commonly implicated in immune-related reactions such as bone marrow suppression, cholestasis, hemolysis, interstitial nephritis, and vasculitis.<sup>8,86,104,216</sup> Rare reactions include pemphigus after penicillin use and corneal damage after the use of methicillin.<sup>19,248</sup>

### Acute Allergy

Penicillins are the pharmaceuticals most commonly implicated in the development of acute anaphylactic reactions. Anaphylactic reactions are severe, life-threatening, immunoglobulin E (IgE)-mediated immune reactions involving multiple organ systems that typically occur immediately after exposure. Table 54–3 lists the classifications of anaphylactic reactions. Anaphylaxis to penicillin occurs only after IgE antibody formation, which requires prior exposure, although that exposure could be obscure (eg, through consumption of meat from animals fed antibiotics). Life-threatening clinical manifestations include angioedema, tongue and airway edema, bronchospasm, bronchorrhea, dysrhythmias, cardiovascular collapse, and cardiac arrest.<sup>76</sup> The pathophysiology of systemic anaphylaxis is complex and involves multiple pathways. IgE antibodies are cross linked on the surface of mast cells and basophils, resulting in local and systemic release of preformed mediators of an immune response, including leukotrienes,  $C_4$  and  $D_4$ , histamine, eosinophilic chemotactic factor, and other vasoactive substances, such as bradykinin, kallikrein, prostaglandin  $D_2$ , and platelet-activating factor (Fig. 54–1).

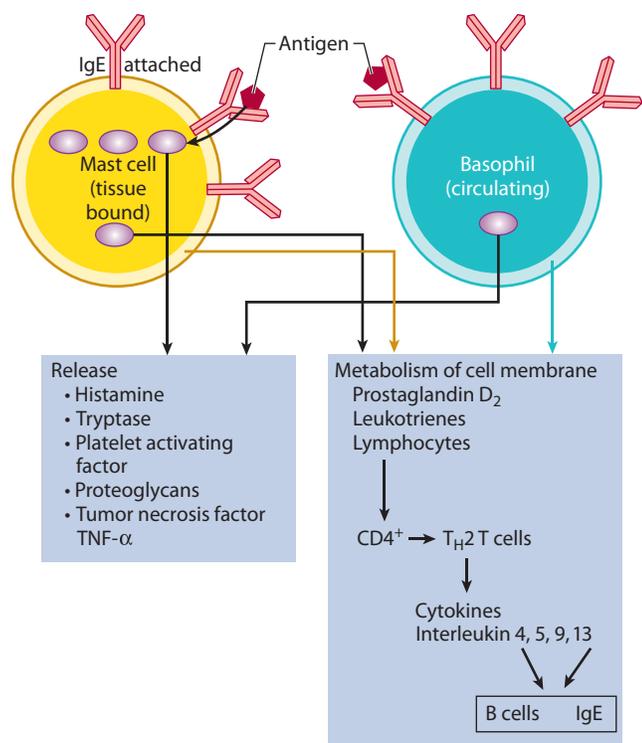

The incidence of penicillin hypersensitivity occurs in 5% of patients, with 1% of penicillin reactions manifesting as anaphylaxis. The risk for a fatal hypersensitivity after penicillin administration is 2 in 100,000 (0.002%) patient exposures.<sup>236</sup> All routes of penicillin administration can result in anaphylaxis; however, it occurs most commonly after intravenous administration.

Treatment is supportive with careful attention to airway, breathing, and circulation. Specific therapy for anaphylaxis is epinephrine 0.01 mg/kg in children (0.3–0.5 mg in adults) given as 1:1,000 (1 mg/mL) dilution intramuscularly (IM) every 5 to 15 minutes.<sup>155,212</sup> Epinephrine bronchodilates and increases cardiac output through  $\beta$ -adrenergic receptor stimulation. In addition,  $\beta$ -adrenergic receptor stimulation results in decreased peripheral vascular tone and decreased mast cell release of mediators. Oxygen, intravenous use of epinephrine (1 mcg/min of 1:100,000 or 1:250,000), intravenous crystalloid, and inhaled  $\beta_2$ -adrenergic agonists are warranted in severe cases, as are corticosteroids.<sup>249</sup> Refractory cases of hypotension may respond to glucagon and methylene blue administration (Antidotes in Depth: A20 and A43).  $H_1$ -receptor antagonists and  $H_2$ -receptor antagonists are useful as second-line therapeutic agents, and can be used to attenuate minor effects such as urticaria or pruritus.

### Amoxicillin-Clavulanic Acid and Drug-Induced Liver Injury (DILI)

The predominant distribution of penicillin-induced hepatotoxicity is cholestatic hepatitis, which typically occurs 1 to 8 weeks after initiation of therapy.<sup>7</sup> The incidence of DILI is estimated at 1 per 2,300 prescriptions and is the most common cause of DILI in the United States and Europe.<sup>25</sup> The mechanism of hepatotoxicity is not clear, but it is hypothesized to be immunoallergic and related to clavulanate, a  $\beta$ -lactamase inhibitor used to prevent the bacterial destruction of  $\beta$ -lactam antimicrobials, or one of its metabolites. Treatment is supportive and clinical findings typically resolve after the discontinuation

## Pathophysiology of Anaphylaxis

<b>Histamine:</b>	<b>Prostaglandin D<sub>2</sub>:</b>	<b>TNF-α</b>
- Pruritis	- Bronchospasm	- Activates neutrophils
- Rhinorrhea	- Vasodilation	- Chemokine synthesis
- Tachycardia		
- Bronchospasm	<b>Leukotrienes:</b>	
- Headache	- Bronchospasm	
- Flushing	- Hypotension	
- Hypotension	- Mucus production	

FIGURE 54-1. Description of systemic anaphylaxis.

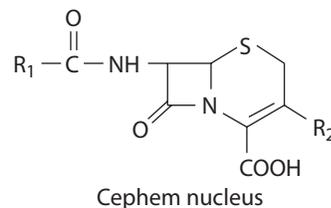

of therapy. However, prolonged hepatitis, ductopenia (vanishing bile duct syndrome), and pancreatitis rarely occur.<sup>53,182</sup> Behavioral disturbances with disorientation, agitation, and visual hallucinations temporally related to use are also reported.<sup>16</sup>

### Hoigne Syndrome and Jarisch–Herxheimer Reaction

The most common adverse drug reactions occurring after administration of large intramuscular or intravenous doses of procaine penicillin G are the Hoigne syndrome and the Jarisch–Herxheimer reaction.<sup>111,148</sup> The Hoigne syndrome is characterized by extreme apprehension and fear, illusions, or hallucinations; both visual and auditory, tachycardia, systolic hypertension, and, occasionally, seizures that begin within minutes of injection.<sup>235</sup> These effects occur in the absence of signs or symptoms of anaphylaxis. Procaine is implicated as the etiology because of the similarity to events that occur after the administration of other local anesthetics known as the so-called caine reaction.<sup>197,208,231</sup> Hoigne syndrome is 6 times more common in men than in women.<sup>211</sup> The reason for this increased prevalence is unclear, but autosomal dominance and influences of prostaglandin and thromboxane A<sub>2</sub> activity occur in this population.<sup>12</sup>

The Jarisch–Herxheimer reaction is a self-limited reaction that develops within a few hours of antibiotic therapy for the treatment of spirochetal diseases such as syphilis or Lyme disease, leptospirosis, and in Q fever. Myalgias, chills, headache, rash, and fever spontaneously resolve within 18 to 24 hours, even with continued antibiotic therapy.<sup>207</sup> The pathogenesis of this reaction is likely either endotoxin induced from the lysed spirochete or cytokine elevation.<sup>177</sup> Antiinflammatory medications and immune modulators such as anti-TNF can be considered, but the optimal treatment is still unclear.

## Cephalosporins

Cephalosporins are semisynthetic derivatives of cephalosporin C produced by the fungus *Acromonium*, previously called *Cephalosporium*. Cephalosporins have a ring structure similar to that of penicillins and are generally divided into first, second, third, fourth, and fifth generations based on their antimicrobial spectrum. First-generation cephalosporins include cefadroxil, cefazolin, and cephalexin. Second-generation cephalosporins include cefaclor, cefditoren, cefotetan, cefoxitin, cefprozil, and cefuroxime. Third-generation cephalosporins include cefdinir, ceftazidime, cefixime, ceftibuten, cefotaxime, ceftriaxone, and cefepime. The fourth-generation cephalosporin is cefepime, and the fifth-generation cephalosporins are ceftaroline and ceftolozane.

Effects occurring after acute overdose of cephalosporins resemble those occurring with penicillins. Some cephalosporins also have epileptogenic potential similar to penicillin.<sup>239</sup> Case reports demonstrate seizures after inadvertent intraventricular administration.<sup>39,131,251</sup> Management of cephalosporin overdose is similar to that of penicillin overdose. Table 54-1 lists the pharmacologic mechanism of cephalosporins.

### Adverse Drug Reactions Associated With Therapeutic Use

Cephalosporins rarely cause an immune-mediated acute hemolytic crisis.<sup>73</sup> Cefaclor is the cephalosporin most commonly reported to cause systemic immune complex hypersensitivity or serum sickness, although this can occur with other cephalosporins.<sup>119,142</sup> Also like penicillins, first-generation cephalosporins are associated with chronic toxicity, including interstitial nephritis and hepatitis.<sup>245</sup> Cefepime is reported to cause reversible coma and seizures.<sup>1,215</sup>

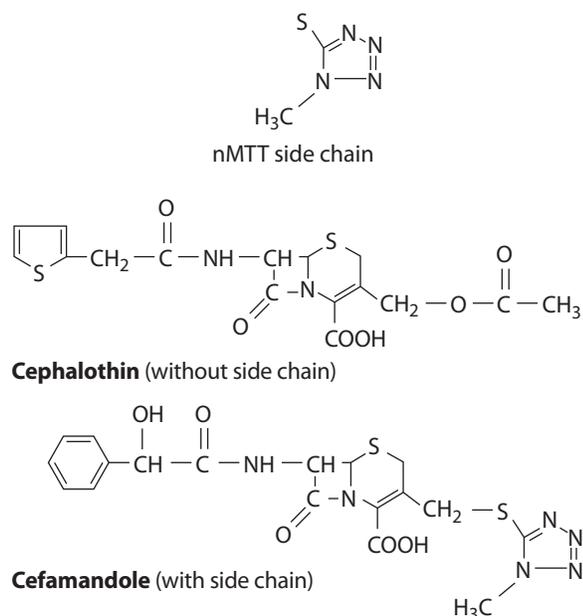

### Cross-Hypersensitivity

The cephalosporins contain a 6-member dihydrothiazine ring instead of the 5-member thiazolidine penicillin ring. The extent of cross-reactivity between penicillins and cephalosporins in an individual patient is largely determined by the type of penicillin allergic response experienced by the patient and the structural similarity of the beta lactam side determinants.<sup>189</sup> The incidence of anaphylaxis to cephalosporins is between 0.0001% and 0.1%, with a threefold increase in patients with previous penicillin allergy.<sup>120</sup> The overall cross-reactivity rate is approximately 1% between penicillin and a first- or second-generation cephalosporin. Cross-reactivity between penicillin and third-, fourth-, or fifth-generation cephalosporins is likely to be negligible because of a dissimilar antigenic side chain.<sup>47</sup> These determinants are quite distinct among cephalosporins, which cause the pattern of cross-hypersensitivity among cephalosporins to be much less well defined than among the penicillins. Caution should be used when considering first- or second-generation cephalosporins in penicillin- or cephalosporin-allergic patients; however, if a risk-to-benefit analysis demonstrates a clear benefit to the patient without equivalent alternatives, the cephalosporin should be given.

### N-Methylthiotetrazole Side-Chain Effects

Cefazolin and cefotetan are the only available cephalosporins containing an N-methylthiotetrazole (nMTT) side chain. As these cephalosporins undergo metabolism, they release free nMTT, which (Fig. 54-2) inhibits the enzyme aldehyde dehydrogenase.<sup>151</sup> In conjunction with ethanol consumption, use of these medications can cause a disulfiramlike reaction (Chaps. 76 and 78).<sup>43</sup>

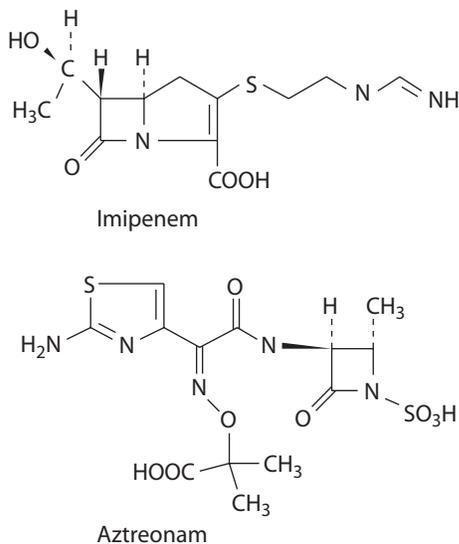

The nMTT side chain is also associated with hypoprothrombinemia, although a causal relationship is controversial.<sup>95</sup> It is thought that nMTT depletes vitamin K–dependent clotting factors by inhibition of vitamin K epoxide reductase.<sup>169</sup> In a study of children one month to one year of age who

**FIGURE 54-2.** Characteristic structures of cephalosporins emphasizing the nMTT side chain. nMTT = *N*-methylthiotetrazole.

were maintained on a prolonged antibiotic regimen, a significant degree of vitamin K depletion was found.<sup>21</sup> Treatment of patients suspected of hypoprothrombinemia caused by these cephalosporins consists of clotting factor replacement, if bleeding is evident, and vitamin K<sub>1</sub> in doses required to reactivate vitamin K cofactors (Chap. 58 and Antidotes in Depth: A17).

### Other $\beta$ -Lactam Antimicrobials

Included in this group are monobactams such as aztreonam and carbapenems such as doripenem, ertapenem, imipenem/cilastatin, and meropenem. **Table 54-1** lists the pharmacologic mechanism of these xenobiotics.

Effects occurring after acute overdose and the management of other  $\beta$ -lactam antimicrobials resemble those occurring after penicillin exposure. Imipenem has epileptogenic potential in both overdose and therapeutic dosing and at a higher risk than other carbapenems.<sup>48</sup>

### Adverse Drug Reactions Associated With Therapeutic Use

The risk factors for developing imipenem-related seizures include central nervous system disease, prior seizure disorder, and abnormal kidney function.<sup>175</sup> The mechanism for seizures is GABA antagonism (similar to the penicillins) in conjunction with enhanced activity of excitatory amino acids.<sup>65,220</sup>

### Cross-Hypersensitivity

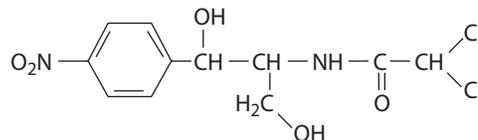

Aztreonam is a monobactam that does not contain the antigenic components required for cross-allergy with penicillins, and generalized cross-allergenicity is not expected.<sup>200</sup> However, aztreonam cross-reacts in vitro with ceftriaxone, thought to be the result of the similarity in their side-chain structure.<sup>174</sup> Skin test–manifested cross-allergenicity has also been noted between imipenem and penicillin, although the clinical incidence of adverse reactions is yet to be determined.<sup>199</sup>

### Trimethoprim–Sulfamethoxazole

Trimethoprim and sulfamethoxazole work in tandem as antibacterials effectively preventing tetrahydrofolic acid synthesis in bacterial cells. Significant toxicity after acute overdose is not expected; however, a myriad of adverse drug reactions occur after chronic therapeutic use. Hyperkalemia can result as a result of the ability of trimethoprim to competitively inhibit sodium channels in the distal nephron, causing impairment in renal potassium excretion. Clinically significant hyperkalemia is reported in patients concurrently on other xenobiotics that increase potassium and among those with CKD.<sup>71,166</sup> Other effects commonly reported after use of trimethoprim/sulfamethoxazole combinations include cutaneous allergic reactions, hematologic disorders, methemoglobinemia, hypoglycemia, rhabdomyolysis, neonatal kernicterus, and psychosis.<sup>157,226</sup>

Trimethoprim also inhibits the renal tubular secretion of creatinine, resulting in an increase in serum creatinine measurement.<sup>66</sup> This effect is thought to be dose related and increases in creatinine ranges from 13% to 35%. The rise in creatinine is independent of glomerular filtration rate and resolves on drug discontinuation.

### Chloramphenicol

Chloramphenicol was originally derived from *Streptomyces venezuelae* and is now synthetically produced. Antimicrobial activity is demonstrated against many gram-positive and gram-negative aerobes and anaerobes.

Chloramphenicol inhibits protein synthesis in rapidly proliferating cells. Metabolic acidosis occurs as a result of the inhibition of mitochondrial enzymes, oxidative phosphorylation, and mitochondrial biogenesis.<sup>246</sup>

**Table 54-1** lists the pharmacologic mechanism of chloramphenicol.

Acute overdose of chloramphenicol commonly causes nausea and vomiting. Infrequently, sudden cardiovascular collapse can occur 5 to 12 hours after acute overdoses. Cardiovascular compromise is more frequent in patients with serum concentrations higher than 50 mcg/mL.<sup>85,159,224</sup> Because tissue concentration measurements are not readily available, all poisoned patients should be closely observed for at least 12 hours after exposure. Orogastric lavage should be used after recent ingestions when the patient has not vomited, and oral or nasogastric activated charcoal 1 g/kg should also be given.

Extracorporeal means of eliminating chloramphenicol are not usually required because of its rapid metabolism. However, hemodialysis, charcoal hemoperfusion, and exchange transfusion in neonates all decrease serum chloramphenicol concentrations. These extracorporeal procedures should be employed in patients presenting early after a life-threatening history of ingestion, particularly if they have severe hepatic or renal dysfunction.<sup>83,153,213,218</sup> Surviving patients should be closely monitored for signs of bone marrow suppression, which is dose dependent.

### Adverse Drug Reactions Associated With Therapeutic Use

Chronic toxicity of chloramphenicol is similar to that which occurs following acute poisoning. The classic description of chronic chloramphenicol toxicity is the “gray baby syndrome.”<sup>159</sup> Children with this syndrome exhibit vomiting, anorexia, respiratory distress, abdominal distension, green stools, lethargy,

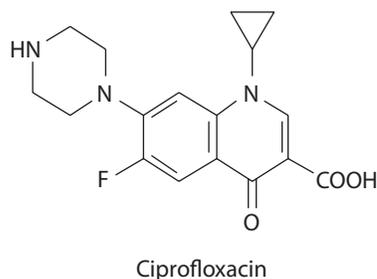

cyanosis, ashen color, metabolic acidosis, hypotension, and cardiovascular collapse.

Approximately 90% of systemic chloramphenicol is metabolized via glucuronyl transferase, forming a glucuronide conjugate. The remainder is excreted renally unchanged. Infants, in particular, are predisposed to the gray baby syndrome because they have a limited capacity to form a glucuronide conjugate of chloramphenicol and, concomitantly, a limited ability to excrete chloramphenicol in the urine.<sup>92,244</sup>

There are 2 types of bone marrow suppression that occur after use of chloramphenicol. The most common type is dose dependent and occurs with high serum concentrations of chloramphenicol.<sup>107,170,205</sup> Clinical manifestations usually occur within several weeks of therapy and include anemia, thrombocytopenia, leukopenia, and, very rarely, aplastic anemia. Bone marrow suppression is generally reversible on discontinuation of therapy. A second type occurs through inhibition of protein synthesis in the mitochondria of marrow cell lines.<sup>161</sup> This type causes the development of aplastic anemia, which is not dose related, generally occurs in susceptible patients within 5 months of treatment and has an approximately 50% mortality rate (Chap. 20).<sup>72,253</sup> The dihydro and nitroso bacterial metabolites of chloramphenicol injure human bone marrow cells through inhibition of myeloid colony growth, inhibition of DNA synthesis, and inhibition of mitochondrial protein synthesis.<sup>115</sup>

Other adverse drug reactions associated with chloramphenicol include peripheral neuropathy, neurologic abnormalities (eg, confusion, delirium), optic neuritis, nonlymphocytic leukemia, and contact dermatitis.<sup>61,126,136,179,210</sup>

## Fluoroquinolones

The fluoroquinolones are a structurally similar, synthetically derived group of antimicrobials that have diverse antimicrobial activities. They include ciprofloxacin, gatifloxacin (ophthalmic only), gemifloxacin, levofloxacin, moxifloxacin, norfloxacin, and ofloxacin. Like other antimicrobials, the fluoroquinolones rarely produce life-threatening effects following acute overdose, and most patients can be safely managed with minimal intervention.<sup>11</sup> **Table 54-1** lists the pharmacologic mechanism of fluoroquinolones.

Rarely, acute overdose of a fluoroquinolone results in AKI or seizures.<sup>129</sup> The mechanism of AKI after fluoroquinolone exposure is controversial. In animals, ciprofloxacin and norfloxacin are nephrotoxic, especially in the setting of neutral or alkaline urine.<sup>63,202</sup> In humans, AKI is reported after both acute and chronic exposure to fluoroquinolones. A hypersensitivity reaction is postulated to explain pathologic changes consistent with interstitial nephritis.<sup>105,185</sup> Treatment includes discontinuation of the fluoroquinolone and supportive care. Improvement in kidney function usually occurs within several days.

Seizures are reported with ciprofloxacin and likely result from the inhibition of GABA or from elevation of neuronal glutamate.<sup>2,58</sup> Other authors postulate that seizures result from the ability of fluoroquinolones to bind efficiently to cations, particularly magnesium. This hypothesis is related to the inhibitory role of magnesium at the excitatory NMDA-gated ion channel (Chap. 13).<sup>65</sup> Treatment is supportive, using benzodiazepines and, if necessary, barbiturates to increase inhibitory tone.

## Adverse Drug Reactions Associated With Therapeutic Use

Several fluoroquinolones are substrates and/or inhibitors of CYP enzymes. This can result in xenobiotic interactions, which are especially important with xenobiotics that have a narrow therapeutic index.

Serious adverse drug reactions related to fluoroquinolone use consist of central nervous system toxicity (as discussed), cardiovascular toxicity, hepatotoxicity, and notable musculoskeletal toxicity.

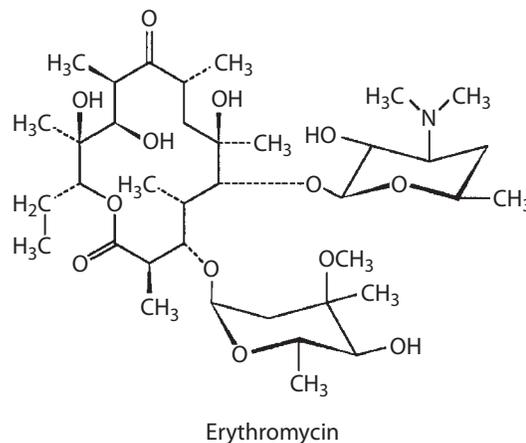

Fluoroquinolones prolong the QT interval, and are reported to result in torsade de pointes.<sup>172</sup> Prolongation is due to the ability of fluoroquinolones to block the rapid component of the delayed rectifier potassium current ( $I_{Kr}$ ). Treatment of patients presenting with QT interval prolongation includes immediate discontinuation of the offending drug and supportive care (Chap. 15).

Fluoroquinolones also rarely result in potentially fatal hepatotoxicity.<sup>138</sup> This adverse effect was most notable with trovafloxacin, which was withdrawn from the US market.

Fluoroquinolones should be used with caution in children and pregnant women because of their potential adverse drug reactions on developing cartilage and bone.<sup>23</sup> There is a higher incidence of bone, joint, tendon, and muscle abnormalities in children treated with a fluoroquinolone versus alternative antibiotic therapy, which persists months after the completion of drug therapy. When followed long-term, however, it was found that these abnormalities are generally reversible. Women who received quinolones during pregnancy had larger babies and more cesarean deliveries because of fetal distress than did controls.<sup>18</sup>

Fluoroquinolones are implicated as a cause of tendon rupture, most commonly the Achilles, which is reported to occur for months to years after the start of treatment as well as after the discontinuation of therapy. An FDA review concluded that because of these risks, these drugs should be reserved for when there is no alternative available.<sup>181</sup> Risk factors include age 60 years or older, concomitant corticosteroid use, AKI or CKD, female sex, and lack of obesity.<sup>132,247</sup> The fluoroquinolone should be discontinued in patients, particularly athletes, who complain of symptoms consistent with painful and swollen tendons.

## Macrolides and Ketolides

The macrolide antimicrobials include various forms of erythromycin (base, ethylsuccinate, gluceptate, lactobionate, stearate), azithromycin, clarithromycin, and fidaxomicin. Ketolides are similar in pharmacology to macrolides; telithromycin is the only available xenobiotic at this time. **Table 54-1** lists the pharmacologic mechanism of macrolides and ketolides.

Acute oral overdoses of macrolide antimicrobials are not life threatening, and symptoms, which are generally confined to the gastrointestinal tract, include nausea, vomiting, and diarrhea. Intravenous overdoses can cause dysrhythmias.<sup>227</sup>

Intravenous and oral therapeutic use of macrolides cause QT interval prolongation and dysrhythmias.<sup>55</sup> The QT interval prolongation seen occurs as a result of blockade of delayed rectifier potassium currents  $I_{Kr}$  (Chaps. 15 and 57).<sup>186</sup> Macrolide-associated oxidative stress to mitochondrial cells subsequently inhibited hERG potassium conductance in rat cardiomyocytes exposed to various macrolides.<sup>195</sup> The relative risk in a large meta-analysis for sudden cardiac death was 2.42, and ventricular

tachydysrhythmia was 2.52, in patients who took macrolides versus those who did not. In children, intravenous overdoses of azithromycin resulted in similar findings.<sup>227</sup>

Although there are no acute overdose data regarding ketolide antimicrobials, effects are expected to be similar to macrolide antimicrobials. Therapeutic use of telithromycin is reported to result in QT interval prolongation, hepatotoxicity, toxic epidermal necrolysis, and anaphylaxis.<sup>37,40</sup>

#### Adverse Events Associated With Interactions With Xenobiotics

Erythromycin is the prototypical macrolide and, as such, has received the most attention with respect to potential and documented xenobiotic interactions. Clarithromycin, erythromycin, and troleandomycin are all potent inhibitors of CYP3A4; azithromycin does not inhibit this enzyme.<sup>64</sup> Erythromycin inhibits CYP enzymes after metabolism to a nitroso intermediate, which then forms an inactive complex with the iron (II) of cytochrome P450. The appendix to Chap. 11 lists substrates for CYP3A4. Clinically significant interactions occur with erythromycin and warfarin, carbamazepine, or cyclosporine.<sup>44,100,178</sup> Inhibition of cisapride metabolism results in increased concentrations of the parent xenobiotic, which is capable of causing prolongation of the QT interval and causing torsade de pointes.<sup>33</sup> Cases of carbamazepine toxicity are documented when combined with the use of erythromycin.<sup>100</sup> Erythromycin also inhibits CYP1A2, producing clinically significant interactions with clozapine, theophylline, and warfarin.<sup>188</sup>

Macrolides interact with the absorption and renal excretion of xenobiotics that are substrates for P-glycoprotein, and they also interfere with the normal gut flora responsible for metabolism. This is hypothesized to be part of the underlying mechanism of cases of macrolide-induced digoxin toxicity, for example (Chap. 62).<sup>168</sup>

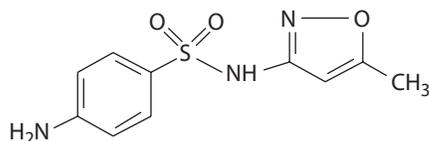

#### End-Organ Effects

The most common toxic effect of macrolides after chronic use is hepatitis, which is hypothesized to be immune mediated.<sup>49</sup> Erythromycin estolate is the macrolide most frequently implicated in causing cholestatic hepatitis.<sup>91,112</sup>

Large doses (>4 g/day) of macrolides are associated with high-frequency sensorineural hearing loss that typically resolves following discontinuation of therapy.<sup>41,135</sup> Renal impairment is noted to be a risk factor.<sup>193,221</sup> Other, rare toxic effects associated with macrolides include cataracts after clarithromycin use in animals and acute pancreatitis in humans.<sup>78,234</sup> Allergy is rare and reported at a rate of 0.4% to 3%.<sup>67</sup> Telithromycin contains a carbamate side chain that is hypothesized to interfere with the normal function of neuronal cholinesterase. It should be used cautiously in patients with myasthenia gravis, particularly patients receiving pyridostigmine because of the risk of cholinergic crisis.<sup>121</sup>

Clindamycin is a lincosamide with structure and clinical effects similar to macrolides'. Clindamycin phosphate is commonly used topically while clindamycin hydrochloride is available intravenously and clindamycin palmitate hydrochloride is available for oral use. Data regarding acute overdose are limited. Neuromuscular blockade is reported after intravenous dosing errors.<sup>3</sup> The most consequential toxicity seen after therapeutic doses is esophageal ulcers, diarrhea, and *Clostridium difficile*-mediated enterocolitis.<sup>186</sup>

#### Sulfonamides

Sulfamethoxazole

Sulfonamides antagonize *para*-aminobenzoic acid or *para*-aminobenzyl glutamic acid, which are required for the biosynthesis of folic acid. Table 54–1 lists the pharmacologic mechanism of sulfonamides. Acute oral overdoses of sulfonamides are usually not life threatening, and symptoms are generally

confined to nausea, although allergy and methemoglobinemia occur rarely.<sup>82</sup> Treatment is similar to acute oral penicillin overdoses.

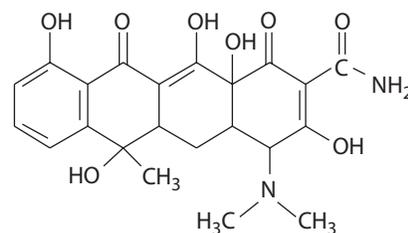

#### Adverse Drug Reactions Associated With Therapeutic Use

The most common adverse drug reactions associated with sulfonamide therapy are nausea and cutaneous hypersensitivity reactions.<sup>89</sup> Hypersensitivity reactions are caused by 2 mechanisms. The first is an IgE-mediated response to the heterocyclic ring at the sulfonamide-N1 position. The more common allergic response occurs 7 to 14 days after initiation of therapy and requires an unsubstituted amine group at the N4 position of the sulfonamide. The incidence of adverse reactions to sulfonamides, including allergy, is increased in HIV-positive patients and is positively correlated to the number of previous opportunistic infections experienced by the patient.<sup>134</sup> This is caused by a reduction in the mechanisms available for detoxification of free radical formation, as cysteine and glutathione concentrations are low in these patients.<sup>241</sup>

Methemoglobinemia and hemolysis occur rarely.<sup>70,162</sup> The mechanism for adverse reactions is not entirely clear. However, when sulfamethoxazole is exposed to ultraviolet B radiation in vitro, free radicals are formed that can participate in the development of tissue peroxidation and hemolysis.<sup>253</sup> This finding is of particular importance in treating patients with glucose-6-phosphate dehydrogenase deficiency associated with decrease in reducing capabilities.<sup>6</sup>

The sulfonamides are associated with many chronic adverse drug reactions. Bone marrow suppression is rare, but the incidence is increased in patients with folic acid or vitamin B<sub>12</sub> deficiency, and in children, pregnant women, alcoholics, dialysis patients, and immunocompromised patients, as well as in patients who are receiving other folate antagonists. Other adverse drug reactions include hypersensitivity pneumonitis, Stevens–Johnson syndrome, toxic epidermal necrolysis, stomatitis, aseptic meningitis, hepatotoxicity, renal injury, and central nervous system toxicity.<sup>29</sup>

#### Tetracyclines

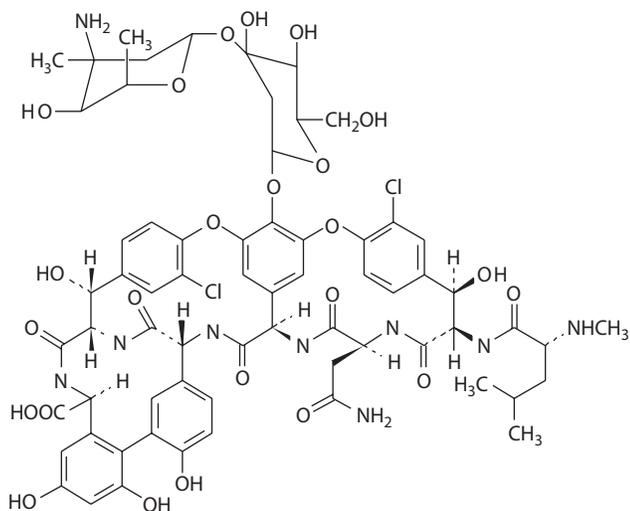

Tetracycline

Tetracyclines are produced by *Streptomyces*. Currently available tetracyclines include demeclocycline, doxycycline, minocycline, and tetracycline. Table 54–1 lists the pharmacologic mechanism of tetracyclines. Significant toxicity after acute overdose of tetracyclines is unlikely. Gastrointestinal effects consisting of nausea, vomiting, and epigastric pain are reported.<sup>42</sup>

#### Adverse Drug Reactions Associated With Therapeutic Use

Tetracycline should not be used in children during the first 6 to 8 years of life or by pregnant women after the 12th week of gestation because of the risk for secondary tooth discoloration in children or fetuses.<sup>196</sup> Tooth discoloration can be effectively mitigated using topical application of carbamide peroxide whitening treatments.<sup>229</sup> Other effects associated with tetracyclines include nephrotoxicity, hepatotoxicity, skin hyperpigmentation in sun-exposed areas, and hypersensitivity reactions.<sup>49,94,110,223</sup> More severe hypersensitivity reactions, vertigo, xenobiotic-induced lupus, and pneumonitis are reported after minocycline use, as are cases of necrotizing vasculitis of the skin and uterine cervix, and lymphadenopathy with eosinophilia.<sup>145,204,209</sup> Demeclocycline rarely causes nephrogenic diabetes insipidus (Chaps. 12 and 27).<sup>50</sup> Degraded tetracycline is reported to result in reversible Fanconi syndrome.<sup>84</sup> Epi-anhydrotetracycline or anhydrotetracycline were likely the causative toxins.

## Vancomycin

Vancomycin

Vancomycin is obtained from cultures of *Nocardia orientalis* and is a tricyclic glycopeptide. Vancomycin is biologically active against numerous gram-positive organisms. Table 54–1 lists the pharmacologic mechanism of vancomycin.

Acute oral overdoses of vancomycin rarely cause significant toxicity and most cases can be treated with supportive care alone. After large iatrogenic, rapidly infused intravenous overdoses, AKI can occur in patients with pre-existing kidney disease because of sustained high serum concentrations. In these patients, multiple doses of activated charcoal and hemodialysis are effective in enhancing clearance.<sup>127,233</sup>

### Adverse Drug Reactions Associated with Therapeutic Use

Rapid infusions of intravenous vancomycin and the subsequent development of the “red man syndrome” occurs through an anaphylactoid (non-IgE-mediated) mechanism.<sup>87</sup> Symptoms include chest pain, dyspnea, pruritus, urticaria, flushing, and angioedema.<sup>190</sup> Spontaneous resolution occurs typically within 15 minutes. Other symptoms attributable to “red man syndrome” include hypotension, cardiovascular collapse, and seizures.<sup>13,164</sup>

The incidence of red man syndrome is approximately 14% when 1 g is given over 10 minutes, and falls dramatically to only 3.4% when given over one hour.<sup>164,171</sup> A trial in 11 healthy persons studied the relationship between intradermal skin hypersensitivity and the development of red man syndrome. Each of the 11 study participants underwent skin testing that was followed one week later by an intravenous dose of vancomycin 15 mg/kg over 60 minutes. Following intravenous vancomycin, all participants developed dermal flare responses and erythema, and 10 of 11 participants developed pruritus within 20 to 45 minutes. After the infusion was terminated, symptoms resolved within 60 minutes.<sup>176</sup>

The signs and symptoms of this syndrome are related to the rise and fall of histamine concentrations.<sup>137,194</sup> Tachyphylaxis occurs in patients given multiple doses of vancomycin.<sup>99,240</sup> Animal models demonstrated a direct myocardial depressant and vasodilatory effect of vancomycin.<sup>62</sup> More serious reactions result when vancomycin is given via intravenous bolus, further supporting a rate-related anaphylactoid mechanism.<sup>20</sup> In rare cases, oral administration of vancomycin can also result in red man syndrome.<sup>17</sup>

Treatment includes increasing the dilution of vancomycin and slowing intravenous administration. Antihistamines are useful as pretreatment, especially prior to the first dose.<sup>180</sup> A placebo-controlled trial in adult patients given 1 g of vancomycin over one hour noted a 47% incidence of reaction without diphenhydramine and a 0% incidence with diphenhydramine.<sup>240</sup>

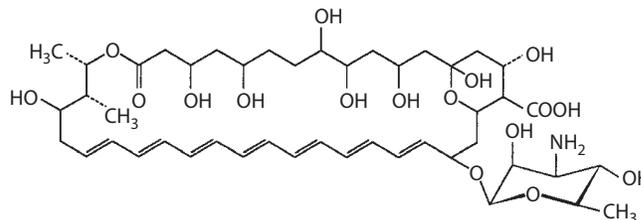

Chronic use of vancomycin results in reversible nephrotoxicity, particularly in patients with prolonged excessive steady-state serum

concentrations.<sup>10,184</sup> Concomitant administration of aminoglycoside antimicrobials increases the risk of nephrotoxicity.<sup>191</sup> Vancomycin also causes, though rarely, thrombocytopenia and neutropenia.<sup>59,69</sup>

## ANTIFUNGALS

Numerous antifungals are available. Toxicity related to the use of antifungals is variable and is based generally on their mechanism of action.

### Amphotericin B

Amphotericin B is a potent antifungal derived from *Streptomyces nodosus*. Amphotericin B is generally fungistatic against fungi that contain sterols in their cell membrane. Table 54–1 lists the pharmacologic mechanism of amphotericin B. Development of lipid and colloidal formulations of amphotericin B attenuate the adverse drug reactions associated with amphotericin B.<sup>97</sup> In these preparations, the amphotericin B is complexed with either a lipid or cholesteryl sulfate. On contact with a fungus, lipases are released to free the complexed amphotericin B, resulting in focused cell death.<sup>102</sup>

There are several case reports of amphotericin B overdose in infants and children. Significant clinical findings include hypokalemia, increased aspartate aminotransferase concentrations, and cardiac complications. Dysrhythmias and cardiac arrest have occurred following doses of 5 to 15 mg/kg of amphotericin B.<sup>35,60,123</sup> Care should be used in the doses of amphotericin B administered according to specific formulation design, as these are not interchangeable. For example, intravenous therapy for fungal infections includes a usual dose of 0.25 to 1 mg/kg/day of amphotericin B or 3 to 4 mg/kg/day of amphotericin B cholesteryl. The potential for significant dosage errors and their sequelae is readily apparent in this comparison.

### Adverse Drug Reactions Associated With Therapeutic Use

Infusion of amphotericin B results in fever, rigors, headache, nausea, vomiting, hypotension, tachycardia, and dyspnea.<sup>146</sup> Slower rates of infusion and lower total daily doses mitigate symptoms of early infusion-related reactions as does pretreatment with diphenhydramine. In addition, acetaminophen, ibuprofen, and hydrocortisone are helpful in alleviating febrile effects.<sup>90,232</sup> Doses greater than 1 mg/kg/day and rapid administration in less than one hour are not recommended. Infusion concentrations of amphotericin B greater than 0.1 mg/mL can result in localized phlebitis. Slower infusion rates, hot packs, and frequent line flushing with dextrose in water is recommended help to alleviate symptoms.

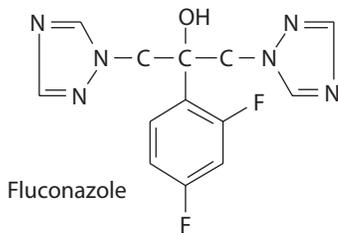

Eighty percent of patients exposed to amphotericin B will sustain some degree of kidney dysfunction (Chap. 27).<sup>45</sup> Initial distal renal tubule damage causes renal artery vasoconstriction, ultimately resulting in azotemia.<sup>79</sup> Studies in animals show depressed renal blood flow and glomerular filtration rate, and increased renal vascular resistance. It is unclear why this occurs, but at this time, renal nerves, angiotensin II, and nitric oxide are excluded as etiologies.<sup>192,198</sup> The toxic effects associated with amphotericin B are likely caused by the deoxycholate vehicle, which accounts for differences seen with the liposomal form.<sup>133,252</sup> After large total doses of amphotericin B, residual decreases in glomerular filtration rate occur even after discontinuation of therapy. This is hypothesized to be the result of nephrocalcinosis. Potassium and magnesium wasting, proteinuria, decreased renal concentrating ability, renal tubular acidosis, and hematuria can also occur (Chaps. 12 and 27).<sup>14,146</sup> Strategies to reduce renal toxicity after

amphotericin B include intravenous saline or magnesium and potassium supplementation.<sup>32,80,101</sup> Liposomal formulations of amphotericin B resulted in fewer patients with breakthrough fungal infections, infusion-related fever, rigors, or nephrotoxicity.<sup>242</sup> However, chest pain is uniquely reported after use of the liposomal preparation.<sup>116</sup>

Other adverse drug reactions reported after treatment with amphotericin B include normochromic, normocytic anemia secondary to decreased erythropoietin release; respiratory insufficiency with infiltrates; and, rarely, dysrhythmias, tinnitus, thrombocytopenia, peripheral neuropathy, and leukopenia.<sup>139,144,146</sup>

Exchange transfusion should be used in neonates and infants after large intravenous overdoses. There is a single case of the successful use of plasmapheresis concurrent with hemodialysis for evolving AKI in a 60-year-old female who had inadvertent administration of amphotericin B deoxycholate 250 mg (4.3 mg/kg) over 2 hours instead of a liposomal product.<sup>243</sup>

### Azole Antifungals: Triazole and Imidazoles

Triazole antifungals include fluconazole, isavuconazonium, itraconazole, posaconazole, terconazole, and voriconazole. Common imidazoles include butoconazole, clotrimazole, econazole, ketoconazole, miconazole, and tioconazole. Triazole antifungals treat an array of fungal pathogens, whereas imidazoles are used almost exclusively in the treatment of superficial mycoses and vaginal candidiasis. Severe toxicity is not expected in the overdose setting. Hepatotoxicity, thrombocytopenia, and neutropenia are uncommon.<sup>30</sup> Rare case reports implicate voriconazole in the development of toxic epidermal necrolysis.<sup>106</sup> Most of the toxic effects noted after the use of these xenobiotics result from their xenobiotic interactions. Fluconazole, itraconazole, ketoconazole, and miconazole competitively inhibit CYP3A4, the isoenzyme system responsible for the metabolism of many xenobiotics. **Table 54-4** lists other organ system manifestations associated with antifungal agents and other antimicrobials.

### ANTIPARASITICS

Antiparasitics such as mebendazole, albendazole, ivermectin, praziquantel, and pyrantel pamoate generally have limited toxicity in overdoses, although significant toxicity can be found after the use of antimalarials for the treatment of malaria (Chap. 55). Common symptoms after therapeutic use are gastrointestinal in nature and include abdominal pain, nausea, vomiting, and diarrhea. A single case of ivermectin-associated hepatic failure has been reported one month after a single dose.<sup>237</sup>

### ANTIVIRALS

Acyclovir, famciclovir, and valacyclovir are generally well tolerated in therapeutic doses and overdoses. Neurotoxicity and, less commonly, AKI are reported after therapeutic use in humans, and similar findings are expected after overdose.<sup>31</sup> The most common neurotoxic complaints include lethargy, confusion, and ataxia.<sup>108</sup> Acute kidney injury occurs as the result of precipitation of acyclovir crystals within the renal tubules with resultant obstructive effects.<sup>230</sup> In 105 dogs ingesting 40 to 2,195 mg/kg, gastrointestinal symptoms were most common, with one dog developing mild creatinine increases.<sup>183</sup> A single case report describes a patient with AKI with crystalluria after ingestion of 30 g of valacyclovir.<sup>187</sup>

**TABLE 54-4** Major Organ System Manifestations Associated With Antimicrobial Toxicity

Antimicrobial	System	Signs/Symptoms/ Laboratory Findings
<b>Antibacterials</b>		
Bacitracin	Immune	Hypersensitivity reactions
Clindamycin	Immune Gastrointestinal Neurologic	Hypersensitivity reactions Nausea, vomiting, diarrhea Dizziness, headache, vertigo
Colistimethate (colistin sulfate)	Renal  Neurologic	Decreased function, acute tubular necrosis Peripheral paresthesias, confusion, coma, seizures, neuromuscular blockade
Metronidazole	Neurologic Gastrointestinal Other	Peripheral neuropathy, seizures Nausea, vomiting Disulfiram reactions
Nitrofurantoin	Gastrointestinal Hepatic Immune  Neurologic	Nausea, vomiting, diarrhea Jaundice Rash, acute and chronic pulmonary hypersensitivity Peripheral neuropathy
Polymyxin B sulfate	Neurologic Renal	Muscle weakness, seizures Azotemia, proteinuria
Selenium sulfide	Cutaneous	Contact dermatitis, alopecia (rare)
Silver sulfadiazine	Cutaneous Hematologic	Contact dermatitis Anemia, aplastic anemia
<b>Antifungals</b>		
Carbol-fuchsin solution (phenol/resorcinol/ fuchsin)	Gastrointestinal	Nausea, vomiting, diarrhea
Gentian violet	Gastrointestinal Immune	Nausea, vomiting, diarrhea Rash (rare)
Griseofulvin	Renal Hepatic Gastrointestinal Immune Other	Proteinuria Increased enzymes Nausea, vomiting, diarrhea Neutropenia Disulfiram reactions, increased porphyrins
Nystatin	Gastrointestinal	Nausea, vomiting, diarrhea
Salicylic acid	Gastrointestinal and dermal	Higher concentrations are caustic
Undecylenic acid and undecylenate salt	Gastrointestinal	Nausea, vomiting, diarrhea

### ANTIMICROBIALS SPECIFIC TO THE TREATMENT OF HIV AND RELATED INFECTIONS

The evaluation and management of patients infected with HIV/AIDS continues to evolve. Medications used to manage this disorder have increased life expectancy as new, more powerful antivirals and xenobiotic combinations become available. Therapeutic for HIV commonly consists of a combination

of xenobiotics from different classes. The current recommendations include highly active antiretroviral therapy (HAART), which involves the use of 2 nucleoside reverse transcriptase inhibitors (NRTI) along with a third antiretroviral drug. Options include an integrase strand transfer inhibitor (INSTI), a non-nucleoside reverse transcriptase inhibitor (NNRTI), a protease inhibitor (PI) with a pharmacokinetic enhancer (cobicistat or ritonavir), or a C-C chemokine receptor type 5 (CCR5) antagonist.<sup>103</sup> The unique mechanisms that each xenobiotic offers aids in inhibiting viral replication and in minimizing xenobiotic resistance. Drug and dosage errors, particularly in infants, are of significant concern and have resulted in iatrogenic overdose.<sup>34,56,140</sup> These drugs also have success in the antiviral treatment of hepatitis C infection.<sup>54</sup> Second-generation

protease inhibitors have revolutionized the care of these patients in that they can be used in combinations that exclude the need for interferon and ribavirin while achieving higher sustained virologic responses.<sup>250</sup> This section focuses on overdoses and major toxic effects from HIV-directed antiviral therapy, as well as from xenobiotics that are specifically used in the management of opportunistic infections. A comprehensive review of these medications and end-organ toxicities is available.<sup>149</sup> Several drug interactions are also possible because of these xenobiotics being substrates for both inducers and inhibitors of several CYP enzymes and P-glycoprotein-associated metabolic systems.<sup>219</sup> Table 54–5 lists the common antimicrobials used to treat HIV-related opportunistic infections, and their common adverse effects.

**TABLE 54–5 Antimicrobials Used to Treat Common Opportunistic Infections, Overdose Effects, and Common Adverse Drug Effects**

Antimicrobial	Opportunistic Infection	Overdose Effects	Common Adverse Drug Effects
Albendazole	Microsporidiosis	No reported cases	Increased AST/ALT, nausea, vomiting, and diarrhea; hematologic (rare), encephalopathy, AKI, rash
Amphotericin B	Aspergillosis Candidiasis Coccidioidomycosis Cryptococcosis Histoplasmosis Leishmaniasis Paracoccidioidomycosis Penicilliosis	Hypokalemia, increased AST, dysrhythmias and cardiac arrest	Infusions related fever, rigors, headache, nausea, vomiting, hypotension, tachycardia, and dyspnea. phlebitis, AKI, potassium and magnesium wasting, proteinuria, decreased renal concentrating ability, RTA, hematuria, anemia, dysrhythmias, tinnitus, thrombocytopenia, peripheral neuropathy, leukopenia
Antimony (pentavalent)	Leishmaniasis	AKI	AKI, multiorgan system failure
Atovaquone	<i>Pneumocystis jiroveci</i> (formerly <i>carinii</i> ) pneumonia (PCP)	No clinical effects	Rashes, anemia, leukopenia, increased AST/ALT
Azithromycin	<i>Mycobacterium avium</i> complex	Nausea, vomiting, diarrhea. Intravenous, dysrhythmias	QT interval prolongation, nausea, vomiting, diarrhea
Clarithromycin	<i>Mycobacterium avium</i> complex	Nausea, vomiting, diarrhea.	QT interval prolongation, nausea, vomiting, diarrhea
Caspofungin	Aspergillosis	No reported cases	Phlebitis, headache, hypokalemia, increased AST/ALT, fever
Clindamycin	<i>Pneumocystis jiroveci</i> (formerly <i>carinii</i> ) pneumonia (PCP) <i>Toxoplasma gondii</i>	Intravenous, neuromuscular blockade	Esophageal ulcers, diarrhea and <i>Clostridium difficile</i> enterocolitis
Dapsone	<i>Pneumocystis jiroveci</i> (formerly <i>carinii</i> ) pneumonia (PCP)	Nausea, vomiting, diarrhea, methemoglobinemia	Bone marrow suppression, hepatitis, rash
Ethambutol	<i>Mycobacterium avium</i> complex	Severe toxicity not expected	Optic neuropathy
Fluconazole	Coccidioidomycosis Histoplasmosis	Severe toxicity not expected	Hepatotoxicity, thrombocytopenia, and neutropenia
Flucytosine	Cryptococcosis	No reported cases	Bone marrow suppression, hepatotoxicity, nausea, vomiting, diarrhea, rash
Foscarnet	Cytomegalovirus	No reported cases	Azotemia, hypocalcemia, and kidney failure (common); anemia, leukopenia, thrombocytopenia, fever, headache, seizures, genital and oral ulcers, fixed-drug eruptions, nausea, vomiting, diarrhea, headaches, seizures, coma, diabetes insipidus, hypophosphatemia, hypokalemia, hypomagnesemia
Fumagillin	Microsporidiosis	No reported cases	Neutropenia, thrombocytopenia
Ganciclovir	Cytomegalovirus	Severe toxicity not expected	Leukopenia, worsening of kidney function; can also cause nausea, vomiting, diarrhea, increased AST/ALT, anemia, thrombocytopenia, headache, dizziness, confusion, seizures
Itraconazole	Histoplasmosis	No reported cases	Hepatotoxicity, thrombocytopenia, and neutropenia
Nitazoxanide	Cryptosporidiosis Microsporidiosis	No reported cases	Hypotension, headache, abdominal pain, nausea, vomiting; may cause green-yellow urine discoloration

(Continued)

**TABLE 54–5** Antimicrobials Used to Treat Common Opportunistic Infections, Overdose Effects, and Common Adverse Drug Effects (Continued)

Antimicrobial	Opportunistic Infection	Overdose Effects	Common Adverse Drug Effects
Paromomycin	Cryptosporidiosis	No reported cases	Ototoxicity, nephrotoxicity, pancreatitis
Pentamidine	<i>Pneumocystis jiroveci</i> (formerly <i>carinii</i> ) pneumonia (PCP)	40 times dosing error in a 17-month-old child resulted in cardiac arrest	Hypoglycemia (early) followed by hyperglycemia, azotemia; can cause hypotension, torsade de pointes, phlebitis, rash, Stevens Johnson syndrome, hypocalcemia, hypokalemia, anorexia, nausea, vomiting, metallic taste, leukopenia, thrombocytopenia
Primaquine	<i>Pneumocystis jiroveci</i> (formerly <i>carinii</i> ) pneumonia (PCP)	No reported cases	Neutropenia, hemolytic anemia, methemoglobinemia, leukocytosis; hypertension
Pyrimethamine	<i>Toxoplasma gondii</i>	No reported cases	Agranulocytosis, aplastic anemia, thrombocytopenia, leukopenia
Rifabutin	<i>Mycobacterium avium</i> complex	High doses (>1 g daily): arthralgia/arthritides	Nausea, vomiting, diarrhea; can cause hepatotoxicity, neutropenia, thrombocytopenia, hypersensitivity reactions
Sulfadiazine	<i>Toxoplasma gondii</i>	AKI and hypoglycemia	Rash, Stevens–Johnson syndrome, toxic epidermal necrolysis, erythema multiforme; headaches, depression, hallucinations, ataxia, tremor, crystalluria, hematuria, proteinuria, and nephrolithiasis
Trimethoprim/sulfamethoxazole	<i>Pneumocystis jiroveci</i> (formerly <i>carinii</i> ) pneumonia (PCP) <i>Toxoplasma gondii</i> Isosporiasis	Severe toxicity not expected	Hyperkalemia, allergy, hematologic disorders, methemoglobinemia, hypoglycemia, rhabdomyolysis, neonatal kernicterus, psychosis
Trimetrexate	<i>Pneumocystis jiroveci</i> (formerly <i>carinii</i> ) pneumonia (PCP)	Severe toxicity not expected; treat similarly to methotrexate (Chap. 51)	Myelosuppression, nausea, vomiting, histaminergic reactions
Valganciclovir	Cytomegalovirus	Severe toxicity not expected; expect to be similar to ganciclovir	Anemia, neutropenia, thrombocytopenia; nausea, vomiting, headache, peripheral neuropathy
Voriconazole	Aspergillosis	Severe toxicity not expected	Hepatotoxicity, thrombocytopenia, and neutropenia, toxic epidermal necrolysis

AKI = acute kidney injury; ALT = alanine aminotransferase; AST = aspartate aminotransferase.

## Specific Antiretroviral Classes

### Nucleoside Analog Reverse Transcriptase Inhibitors

The nucleoside analog reverse transcriptase inhibitors inhibit the reverse transcription of viral RNA into its subsequent DNA through the use of nucleoside analogs. Currently available xenobiotics include abacavir, didanosine (ddI), emtricitabine, lamivudine, stavudine, and zidovudine.

### Acute Overdose Effects

Many intentional overdoses of reverse transcriptase inhibitors occur without major toxicologic effect. The most serious adverse effect anticipated after acute overdose of an NRTI is the development of a metabolic acidosis with elevated lactate concentration, which appears to be more common in women.<sup>52,77,147</sup> After the incorporation of the nucleoside analog into mitochondrial DNA by viral RNA reverse transcriptase enzymes, the faulty DNA results in impaired polymerase gamma activity. This results in decreased production of mitochondrial DNA electron transport proteins, which ultimately inhibits oxidative phosphorylation (Chap. 11). Organ system toxicity follows in addition to the development of acidemia. The reported mortality in patients with NRTI-associated metabolic acidosis associated with elevated lactate is 33% to 57%.<sup>77</sup> Resolution of symptoms in survivors occurs within 1 to 24 weeks. Patients with NRTI-associated acidemia are reported to recover more quickly after the use of cofactors such as thiamine, riboflavin, L-carnitine, vitamin C, and antioxidants.<sup>38</sup> The indications for the use of these xenobiotics are unclear at this time; however, because of the relative lack of toxicity, administration is reasonable.

### Chronic Effects

Development of acidemia is more commonly associated with therapeutic use of reverse transcriptase inhibitors than with acute overdose. The mechanism is likely identical to that described above. Other drug-specific adverse

drug reactions include hematologic toxicity after zidovudine, pancreatitis with didanosine, hypersensitivity after abacavir, and sensory peripheral neuropathy, after stavudine and didanosine.<sup>67,68,93,130,158</sup>

### Nonnucleoside Reverse Transcriptase Inhibitors

The nonnucleoside reverse transcriptase inhibitors bind directly to reverse transcriptase enzymes enabling allosteric inhibition of enzymatic function.<sup>225</sup> Delavirdine, efavirenz, etravirine, nevirapine, and rilpivirine comprise the currently available xenobiotics.

There is a paucity of acute overdose data on these xenobiotics, although they generally appear to have limited toxicity. An adult male with a reported ingestion of 6 g of nevirapine had a sustained laboratory elevation in gamma-glutamyl transferase, but no other reported effects.<sup>74</sup> An infant received a 40 times therapeutic dose of nevirapine with mild neutropenia and metabolic acidosis with elevated lactate concentration.<sup>34</sup> Finally, a 12-year-old child reported an ingestion of 3 g of efavirenz resulting in throat burning, visual impairment, peripheral nervous system abnormalities, and nightmares.<sup>163</sup> Treatment is entirely supportive until more information is available. The nonnucleoside reverse transcriptase inhibitors are also limited in toxicity after chronic use. Use of nevirapine and delavirdine commonly results in hypersensitivity reactions such as rash. Efavirenz is reported to result in dizziness and dysphoria. Otherwise, toxicity can result from the ability of these xenobiotics to either inhibit or enhance CYP isozymes in the metabolism of other xenobiotics.

### Protease Inhibitors

Protease inhibitors inhibit the vital enzyme (protease), which is required for viral replication.<sup>81</sup> Currently available xenobiotics include atazanavir, darunavir, fosamprenavir, indinavir, nelfinavir, ritonavir, saquinavir, and tipranavir.

Data after protease inhibitor overdose are limited. A literature review found diarrhea and hyperlipidemia to be common findings after therapeutic use. Less common were hepatitis, rash, hyperbilirubinemia, paresthesias, and nephrolithiasis.<sup>27</sup> Drug interactions can occur due to almost uniform inhibition of CYP3A-enzymes, and effects on P-glycoprotein along with some having effects and/or substrates for other CYP isoenzymes.<sup>219</sup> A unique finding is an altered fat distribution pattern that, over time, results in lymphodystrophy central obesity, “buffalo hump,” breast enlargement, cushingoid appearance, and peripheral wasting.<sup>81</sup>

### Fusion Inhibitors

This class of xenobiotics interferes with the binding or entry of the HIV virion into the cell.<sup>24</sup> No acute overdose data are available for this class, but after chronic use, hypersensitivity, gastrointestinal complaints, hepatotoxicity, and infusion reactions seem to be of greatest concern.<sup>15,160,165</sup> The currently available drug is enfuvirtide.

### Cellular Chemokine Receptor (Ccr5) Antagonist

These drugs bind to chemokine coreceptors found on CD4 cells, which then ultimately prevents the entry of the HIV virion into the cell. The currently available drug is maraviroc. There is no overdose and adverse events reported; however, maraviroc has a boxed warning due to another CCR5 inhibitor, which was halted in development because of substantial hepatotoxicity.<sup>165</sup>

### Integrase Inhibitor

This class of xenobiotics prevents the activity of the enzyme in HIV to function normally. This enzyme is responsible for the incorporation of the virus into DNA. The currently available xenobiotics are dolutegravir, elvitegravir, and raltegravir. No information is currently available regarding its toxicity after acute overdose. It appears that these xenobiotics are well tolerated at therapeutic doses.

## SUMMARY

- Adverse drug reactions attributable to antimicrobials are largely related to chronic administration, although, rarely, acute severe toxic effects occur after large exposures.
- Acute toxic effects of antimicrobials are far more common following intravenous administration, xenobiotic interactions, or after iatrogenic overdose.
- Vigilance on the part of the health care professionals will prevent the majority of acute toxic manifestations following antimicrobial use.

# ANTIMALARIALS

James David Barry

The malaria parasite has caused untold grief throughout human history. The name originated from Italian *mal aria* (bad air) because the ancient Romans believed the disease was caused by the decay in marshes and swamps and was carried by the malodorous “foul” air emanating from these areas.<sup>8</sup> In the 1880s, both the *Plasmodium* protozoa and its mosquito vector were identified.<sup>8</sup> Today, nearly half of the world’s population lives in areas where malaria is endemic. Despite markedly decreased mortality rates over the last 7 years, malaria remains a significant cause of morbidity and mortality worldwide. In 2015, there were 212 million estimated malaria cases, leading to 429,000 deaths.<sup>119</sup> Most of these deaths were from *Plasmodium falciparum* infections of young children and primigravid pregnant women in Africa.<sup>15</sup> Included among those at risk of becoming infected are 50 million travelers from industrialized countries who visit the developing countries each year. Despite using prophylactic medications, an estimated 30,000 of these travelers will acquire malaria.<sup>96</sup>

## MALARIA OVERVIEW

Malaria is an infection of protozoan parasites in the *Plasmodium* genus with a unique life cycle involving the *Anopheles* mosquito as vector. Today malaria is primarily endemic in tropical and subtropical areas worldwide. It was once endemic in temperate areas, including Western Europe and the United States, but economic development and improvements in public health hastened its retreat.<sup>45</sup> Malaria was fully eradicated from the United States between 1947 and 1951 owing in large part to the powerful insecticidal effects of dichloro diphenyl trichloroethane (DDT).<sup>45</sup> The emergence of DDT-resistant *Anopheles* mosquitoes and chloroquine-resistant *Plasmodium* spp has impeded eradication in other parts of the world.<sup>45</sup>

Malaria has a unique life cycle (Fig. 55–1) beginning with inoculation of sporozoites from an infected female *Anopheles* saliva. The sporozoites travel to the liver, where they invade the host’s hepatocytes and undergo asexual division (asexual exoerythrocytic cycle), ultimately causing rupture of the infected hepatocyte (tissue schizont) and release of thousands of merozoites into the bloodstream.<sup>5</sup> The tissue phase is complete at this point with the exception of *Plasmodium vivax* and *Plasmodium ovale*, which can remain dormant in liver cells (hypnozoites), causing recurrent infections years later. The erythrocytic cycle begins when merozoites penetrate erythrocytes (trophozoites), undergoing additional cycles of asexual division (erythrocytic schizont), leading to cell rupture and the release of a new wave of merozoites to infect additional erythrocytes. This erythrocytic cycle is responsible for the clinical manifestations of malaria. Some erythrocytic merozoites differentiate into sexual forms (macrogametocytes {female} and microgametocytes {male}). Ingestion of both sexual forms by the female *Anopheles* during a blood meal allows fertilization and zygote formation in the mosquito midgut epithelium (sporogonic cycle), ultimately leading to rupture of an oocyst and release of sporozoites that migrate to the salivary glands, awaiting injection into another victim.<sup>115</sup>

Six *Plasmodium* spp cause malaria in humans (Table 55–1). The majority of cases worldwide are caused by *P. falciparum* and *P. vivax*, with *P. falciparum* responsible for the overwhelming majority of deaths.<sup>76</sup> Traditional teaching highlights the synchronization of blood parasite cycles causing a somewhat predictable fever periodicity, described as tertian or quartan fever, depending on the causative organism. These classic periodic fevers are rarely observed in Western countries because symptomatic cases are diagnosed earlier than

in the past.<sup>5</sup> The routine use of antipyretics probably also contributes to atypical presentations.

Unlike the other forms of human malaria, *Plasmodium knowlesi* is a true zoonosis, the natural host being macaques (*Macaca* spp) and related monkey species. Natural transmission of a nonhuman *Plasmodium* spp to humans was thought to be rare, but increasing numbers of *P. knowlesi* malarial infections are reported in and around Malaysia, Indonesia, and Southeast Asia, causing scientists to include this parasite as a potential human pathogen.<sup>54</sup>

## ANTIMALARIAL HISTORY

It is somewhat ironic that despite sophisticated drug development methods and advanced technologies of the 21st century, the most widely used old treatments (quinine and its derivatives) and the best new regimens (artemisinins) have both been used for centuries as ancient herbal remedies derived from plants.

The bark of the cinchona tree, the first effective remedy for malaria, was introduced to Europeans more than 350 years ago.<sup>114</sup> The toxicity of its active ingredient, quinine, was noted from the inception of its use. Pharmaceutical advances occurred, funded largely by the US military during World War II, yielding 4-aminoquinolines, 8-aminoquinolines, and novel antifolates. To combat emerging strains of drug-resistant *P. falciparum* that developed during the Vietnam conflict, alternate quinine derivatives (amino alcohols) were developed.<sup>106,114</sup> Other drugs used to treat malaria include the folate inhibitors, selected antibiotics, the sulfonamide sulfadoxine, the tetracyclines, and the macrolides (Chap. 54).

With the introduction of each new drug, resistance developed, particularly in Oceania, Southeast Asia, and Africa.<sup>106,114</sup> In some instances, quinine is again the first-line therapy for malaria.<sup>118</sup> In the past 2 decades, the search for active xenobiotics has returned to a natural product, the Chinese herb qinghaosu. The active metabolite, of which is dihydroartemisinin, is common to all the endoperoxides. These drugs are primarily used as part of an artemisinin-based combination therapy (ACT), which is recommended by the World Health Organization (WHO) as the preferred treatment of malaria in drug-resistant areas.<sup>8,119</sup> With increased leisure travel, a greater number of North Americans are taking prophylactic medications with potential toxicity.

This chapter highlights the toxicity of the most commonly used antimalarials using the structural and mechanistic classification outlined in Table 55–2.

## AMINO ALCOHOLS

### Antimalarial Mechanism

Unlike humans, who eliminate heme through the use of heme oxygenase ultimately producing the bile pigment biliverdin, *Plasmodium* spp convert heme to the nontoxic relatively inert compound hemozoin. Amino alcohols and 4-aminoquinolines concentrate in parasite food vacuoles, where they inhibit the ability of the parasite to detoxify hemozoin, leading to accumulation of toxic heme by-products and parasite death.<sup>89,115</sup> In resistant parasites, these antimalarials fail to concentrate in food vacuoles because of increased drug efflux. This resistance is thought to be conferred through amplification of a transmembrane pump. Interestingly, tricyclic antidepressants, phenothiazines, and calcium channel blockers reverse resistance in experimental models.<sup>89</sup>

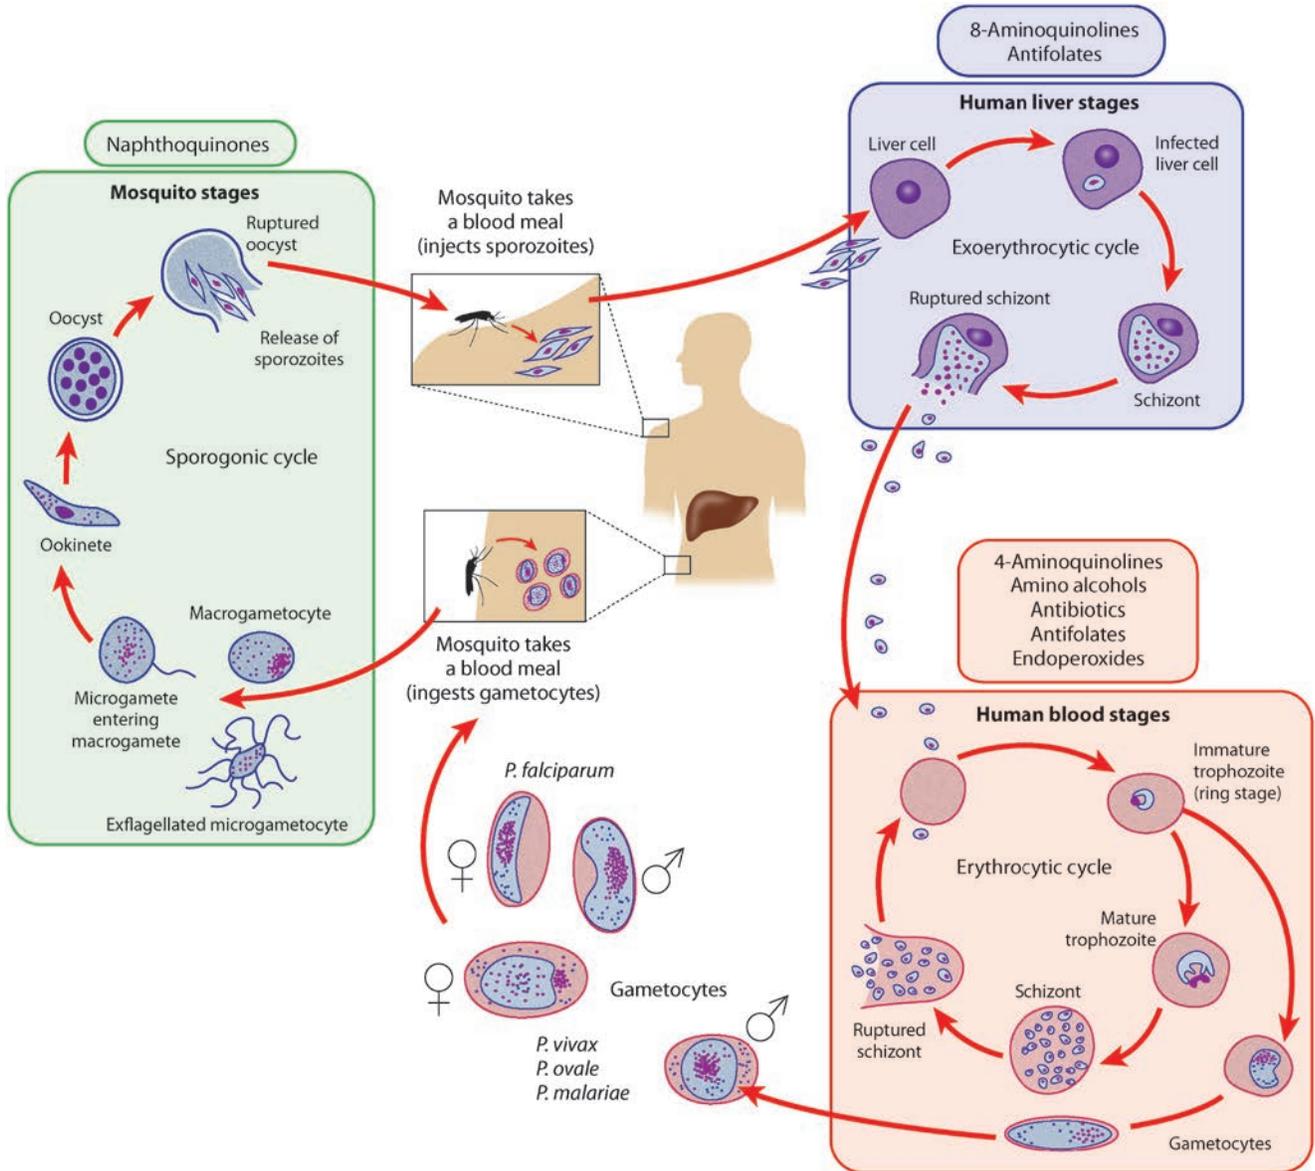

FIGURE 55-1. Life cycle stages during which antimalarials exert their effects.

TABLE 55-1 Plasmodium spp Affecting Humans					
Species	Distribution	Fever Cycle (days)	RBC Preference	Parasitemia	Comments
<i>P. falciparum</i>	Widespread throughout tropics	2 or less (sub-tertian)	All ages	Can be high	Most fatalities
<i>P. knowlesi</i>	Malaysia and neighboring countries	1	All ages	Can be high	Zoonosis (primary host Macaque monkey), severe disease in humans
<i>P. malariae</i>	Worldwide	3–4 (quartan)	Old	Low	Chronic infections, late recrudescence
<i>P. ovale curtisi</i>	Africa	2–3 (tertian)	Young	Low	Relapses/hepatic hypnozoites
<i>P. ovale wallikeri</i>	Africa	2–3 (tertian)	Young	Low	Relapses/hepatic hypnozoites More severe symptoms, increased parasitemia than its <i>R. ovale curtisi</i>
<i>P. vivax</i>	Predominantly Asia	2–3 (tertian)	Young	Low	Relapses/hepatic hypnozoites

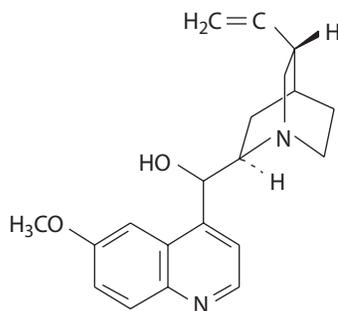

TABLE 55–2 Antimalarial Classification and Mechanisms

Class	Examples	Antimalarial Mechanism	Lifecycle Stage Effect
Amino alcohols	Halofantrine Lumefantrine Mefloquine Quinine	Inhibit heme digestion	Erythrocytic cycle <sup>a</sup>
4-Aminoquinolines	Amodiaquine Chloroquine Hydroxychloroquine Piperaquine	Inhibit heme digestion	Erythrocytic cycle <sup>a</sup>
8-Aminoquinolines	Diethylprimaquine Primaquine	Oxidant stress	Liver stages Hypnozoitocidal
Endoperoxides	Artemether Artesunate Artemisinin Artemisone Dihydroartemisinin	Unknown but oxidant stress likely contributes	Erythrocytic cycle <sup>a</sup>
Antifolates	Cycloguanil Chlorproguanil Dapsone Proguanil Pyrimethamine Trimethoprim	Inhibit dihydrofolate reductase	(All growing stages) Erythrocytic cycle <sup>a</sup> Exoerythrocytic cycle <sup>b</sup>
Antibiotics	Sulfonamides Sulfadoxine  Cyclines Doxycycline Tetracycline  Macrolides Azithromycin Clindamycin	Inhibit dihydropteroate synthetase  Inhibit protein synthesis  Apicoplast disruption	Erythrocytic cycle <sup>a</sup>  Erythrocytic cycle <sup>a</sup>  Erythrocytic cycle <sup>a</sup>
Naphthoquinones	Atovaquone	Inhibit mitochondrial respiration	Mosquito sporogonic cycle <sup>c</sup>

<sup>a</sup>Blood schizonticidal and blood gametocidal. <sup>b</sup>Liver schizonticidal but not effective against hypnozoites.

<sup>c</sup>Altered oocyst development.

## Quinine

The therapeutic benefits of the bark of the cinchona tree have been known for centuries. As early as 1633, cinchona bark was used for its antipyretic and analgesic effects,<sup>75</sup> and in the 1800s, it was used for the treatment of “rebellious palpitations.” Quinine, the primary alkaloid in cinchona bark, was the first effective treatment for malaria. Additionally, because of a reported

curarelike action, quinine is infrequently used as a treatment for muscle cramps. Because of its extremely bitter taste similar to that of heroin, quinine is used as an adulterant in drugs of abuse. Small quantities of quinine can be also found in some tonic waters and bitter lemon drinks.

High doses of quinine and other cinchona alkaloids are oxytocic, potentially leading to abortion or premature labor in pregnant women. Because of this, quinine is occasionally used as an abortifacient (Chap. 19).<sup>77</sup> Chloroquine continues to be used as an abortifacient in some parts of the developing world.<sup>11,90</sup> Neither is safe as an abortifacient because of their narrow toxic-to-therapeutic ratio.

### Pharmacokinetics and Toxicokinetics

See Table 55–3 for the pharmacokinetic properties of quinine. Quinine and quinidine are optical isomers and share similar pharmacologic effects as class IA antidysrhythmics and antimalarials. Both are extensively metabolized in the liver, kidneys, and muscles utilizing cytochrome P450 isoenzymes to a variety of hydroxylated metabolites. As such, quinine could alter the metabolism of other xenobiotics utilizing the same enzyme systems, especially CYP3A4, CYP2D6, and CYP1A2. Quinine is also highly protein bound, primarily to  $\alpha$ -1-acid glycoproteins, providing an additional mode for potential drug–drug interactions. Quinidine’s volume of distribution varies from 0.5 L/kg in patients with congestive heart failure to 2 to 3 L/kg in healthy adults, to 3 to 5 L/kg in patients with cirrhosis.<sup>111</sup> The widely varied volume of distribution between healthy individuals, those with differing levels of parasitemia, and those with various comorbidities, is a shared property of all antimalarials. Quinine undergoes transplacental distribution and is secreted in breast milk.

### Pathophysiology

Quinine overdose affects multiple organ systems through a number of different pathophysiologic mechanisms. Outcomes appear to be most closely related to the degree of cardiovascular dysfunction.<sup>41</sup>

Quinine and quinidine share anti- and prodysrhythmic effects primarily from an inhibiting effect on the cardiac sodium channels and potassium channels (Chaps. 15 and 57).<sup>43</sup> Blockade of the sodium channel in the inactivated state decreases inotropy, slows the rate of depolarization, slows conduction, and increases action potential duration. Inhibition of this rapid inward sodium current is increased at higher heart rates (called *use-dependent blockade*), leading to a rate-dependent widening of the QRS complex.<sup>114,116</sup>

Inhibition of the potassium channels suppresses the repolarizing delayed rectifier potassium current, particularly the rapidly activating component,<sup>116</sup> leading to prolongation of the QT interval. The resultant increase in the effective refractory period is also rate dependent, causing greater repolarization delay at slower heart rates and predisposing to torsade de pointes. As a result, syncope and sudden dysrhythmogenic death occur. This “quinidine syncope”—ventricular dysrhythmias or fibrillation—was identified more than half a century ago as a therapeutic complication.<sup>99</sup> An additional  $\alpha$ -adrenergic antagonist effect contributes to the syncope and hypotension occurring in quinine toxicity. Quinidine possesses antimuscarinic activity in therapeutic dosing.<sup>57</sup>

Inhibition of the adenosine triphosphate (ATP)–sensitive potassium channels of pancreatic  $\beta$  cells results in the release of insulin, similar to the action of sulfonylureas (Chap. 47).<sup>32</sup> Patients at increased risk of quinine-induced hyperinsulinemia include those patients receiving high-dose intravenous (IV) quinine, intentional overdose, and patients with other metabolic stresses (eg, concurrent malaria, pregnancy, malnutrition, and ethanol consumption).<sup>21,107</sup>

The mechanism of quinine-induced ototoxicity appears to be multifactorial. Microstructural lengthening of the outer hair cells of the cochlea and organ of Corti occurs.<sup>48</sup> Additionally, vasoconstriction and local prostaglandin inhibition within the organ of Corti contributes to decreased hearing.<sup>106</sup> Inhibition of the potassium channel also impairs hearing and produces vertigo because it is known that the homozygous absence of gene products that form part of some potassium channels (Jervell and

TABLE 55–3 Pharmacokinetic Properties of Antimalarials

Antimalarial	Bioavailability (%)	Time to Peak (hours) (oral)	Protein Bound (%)	Volume of Distribution (L/kg)	Half-Life	Urinary Excretion (%)	Metabolism	Comments

— = poorly studied or unknown.

Lange-Nielson syndrome) causes deafness and prolonged QT intervals (Chaps. 15 and 25).<sup>105</sup>

Although older theories suggested that quinine caused retinal ischemia, the preponderance of evidence points to a direct toxic effect on the retina, and possibly the optic nerve fibers.<sup>38</sup> Quinine also antagonizes cholinergic neurotransmission in the inner synaptic layer.

Quinine has direct irritant effects on the gastrointestinal (GI) tract and stimulates the brain stem center responsible for nausea and emesis.<sup>114</sup>

### Clinical Manifestations

Quinine overdose typically leads to GI complaints, tinnitus, and visual symptoms within hours, but the time course varies with the formulation ingested, coingestants, patient characteristics, and other case-specific details. Significant overdose is heralded by cardiovascular and central nervous system (CNS) toxicity. Death can occur within hours to days, usually from a combination of shock, ventricular dysrhythmias, respiratory arrest, or acute kidney injury (AKI).

Patients receiving even therapeutic doses often experience a syndrome known as “cinchonism,” which typically includes GI complaints, headache, vasodilation, tinnitus, and decreased hearing acuity.<sup>75,114</sup> Vertigo, syncope, dystonia, tachycardia, diarrhea, and abdominal pain are also described.<sup>49,63</sup>

Quinine toxicity is correlated with total serum concentrations, but only the non–protein-bound portion is likely responsible for toxic effects. However, because free and total quinine concentrations vary widely from person to person,<sup>37</sup> a single quinine concentration does not always correlate with clinical toxicity. In general, serum concentrations greater than 5 mcg/mL cause cinchonism, greater than 10 mcg/mL visual impairment, greater than 15 mcg/mL cardiac dysrhythmias, and greater than 22 mcg/mL death.<sup>4</sup> Similar concentrations in individuals who are severely ill with malaria do not necessarily result in as severe toxicity because an increase in plasma  $\alpha_1$ -acid glycoprotein reduces the free fraction of quinine present.<sup>97,101</sup>

The toxic-to-therapeutic ratio of quinine is very small. It is not surprising that patients taking therapeutic doses frequently develop toxicity because the recommended range of serum quinine concentrations for treatment of *falciparum* malaria is 5 to 15 mcg/mL, well above the concentration reported to cause cinchonism.

The average oral lethal dose of quinine is 8 g, although a dose as small as 1.5 g is reported to cause death.<sup>39,49</sup> Delirium, coma, and seizures are less common, usually occurring only after severe overdoses.<sup>18</sup>

Cardiovascular manifestations of quinine use are related to myocardial drug concentrations. They manifest on the electrocardiogram (ECG) as prolongation of the PR interval, prolongation of the QRS complex, prolongation

of the QT interval, and ST depression with or without T wave inversion. Dysrhythmias and complete heart block are reported.<sup>16</sup> Quinine toxicity can also result in significant hypotension.

Although not commonly reported, mild hyperinsulinemia and resultant hypoglycemia occur in cases of oral quinine overdose. Hypoglycemia with elevated serum insulin concentrations was documented after therapeutic dosing in case reports complicated by severe congestive heart failure and significant ethanol consumption. Hypoglycemia is also noted in healthy patients after overdose. Hypoglycemia is fairly common in patients with severe malaria treated with quinine, occurring in up to 10% of patients and 50% of pregnant women.<sup>107</sup>

Eighth cranial nerve dysfunction results in tinnitus and deafness. The decreased acuity is not usually clinically apparent, although the patient recognizes tinnitus.<sup>95</sup> These findings usually resolve within 48 to 72 hours, and permanent hearing impairment is unlikely.

Ophthalmic presentations include blurred vision, visual field constriction, diplopia, altered color perception, mydriasis, photophobia, scotomata, and sometimes complete blindness.<sup>18,44</sup> The onset of blindness is invariably delayed and usually follows the onset of other manifestations by at least 6 hours. The pupillary dilation that occurs is usually nonreactive and correlates with the severity of visual loss. Funduscopic examination findings are occasionally normal but usually demonstrate extreme arteriolar constriction associated with retinal edema. Normal arteriolar caliber is commonly seen initially, but funduscopic manifestations such as vessel attenuation and disc pallor develop as clinical improvement occurs. Improvement in vision can occur rapidly but is usually slow, occurring over a period of months after a severe toxicity. Initially, improvement occurs centrally and is followed later by improvement in peripheral vision. The pupils occasionally remain dilated even after return to normal vision.<sup>39</sup> Patients with the greatest exposure frequently develop optic atrophy.

Hypokalemia is often described in the setting of quinine poisoning, although the mechanism is unclear. An intracellular shift of potassium rather than a true potassium deficit is the predominant theory behind the hypokalemia associated with chloroquine,<sup>65,69</sup> and the mechanism is assumed to be similar with quinine.

A number of immune-mediated hypersensitivity reactions are described. These are the result of antiquinine or antiquinine-hapten antibodies cross-reacting with a variety of membrane glycoproteins<sup>19,56</sup> dramatically increasing their binding affinity to cell-surface antigens by more than 10,000 times.<sup>40</sup> Asthma and dermatologic manifestations, such as urticaria, photosensitivity dermatitis, cutaneous vasculitis, lichen planus, and angioedema, also occur.<sup>107</sup>

Hematologic manifestations of hypersensitivity include thrombocytopenia (Chap. 20), agranulocytosis, microangiopathic hemolytic anemia, and disseminated intravascular coagulation (DIC), which can lead to jaundice, hemoglobinuria, and AKI.<sup>49,56</sup> Quinine is recognized as a common cause of drug-induced thrombocytopenia and the most common cause of drug-induced thrombotic microangiopathy syndrome (characteristically microangiopathic hemolytic anemia, thrombocytopenia, and acute kidney injury). Hemolysis also occurs in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Severe multisystem hypersensitivity reactions can occur even after minute doses of quinine, such as those in tonic drinks.<sup>40,60</sup> This type of interaction has previously been termed “cocktail purpura.”<sup>75,114</sup>

A hepatitis hypersensitivity reaction, acute respiratory distress syndrome (ARDS), and a sepsislike syndrome are also reported.

### Diagnostic Testing

Urine thin-layer chromatography is sensitive enough to confirm the presence of quinine even after the ingestion of tonic water.<sup>120</sup> Quinine immunoassay techniques are also available. Quantitative serum testing is not rapidly or widely available.

### Management

Patients frequently vomit spontaneously. Emetics should not be used in the absence of vomiting because seizures, dysrhythmias, and hypotension can

occur rapidly. Orogastric lavage is not routinely recommended except for patients with recent, substantial (potentially life-threatening) ingestions with no spontaneous emesis. Activated charcoal effectively adsorbs quinine and additionally decreases serum concentrations by altering enteroenteric circulation<sup>62</sup> but should only be administered in patients with a low risk of aspiration or protected airways.

Expectant treatment should be initiated, including oxygen, cardiac and hemodynamic monitoring, IV fluid resuscitation, and frequent ECG and blood glucose measurements. In general, patients should be monitored until vital signs normalize, mental status improves, and laboratory values stabilize. Variables including the amount ingested, patient comorbidities, and coingestions, highlight the importance of individualized care. Asymptomatic patients with suspected overdose should be monitored for 6 to 12 hours depending on variables as above, before medical clearance.

Extracorporeal membrane oxygenation was used in one case of severe quinidine poisoning with bradydysrhythmias and refractory hypotension to stabilize the cardiovascular system while a quinidine-activated charcoal bezoar was removed and the patient metabolized the remaining quinidine. A similar approach would be reasonable to consider for intractable quinine toxicity.

**Cardiac.** In patients with a conduction delay manifested by a QRS complex of more than 100 milliseconds (ms) we recommend treating with sodium bicarbonate alkalization to achieve a serum pH of 7.45 to 7.50, as would be done in patients with cardiotoxicity associated with cyclic antidepressant overdoses (Antidotes in Depth: A5). Protein binding is increased in the setting of alkalemia, decreasing the cardiotoxic manifestations of quinine. Sodium bicarbonate therapy is successful in case reports<sup>16,41,75</sup> but has not been specifically studied. Since hypertonic sodium bicarbonate will worsen existing hypokalemia, potentially exacerbating the effect of potassium channel blockade.

Potassium supplementation for quinine-induced hypokalemia is controversial because experimental data from the 1960s suggest that hypokalemia is protective against cardiotoxicity and prolongs survival.<sup>20,65,100</sup> Because hypokalemia can also lead to lethal dysrhythmias, supplementation for significant hypokalemia (<3.0 mmol/L) is recommended as a reasonable intervention.

The QT interval should be carefully monitored for prolongation. If necessary, interventions for torsade de pointes, including magnesium administration, potassium supplementation, and overdrive pacing, should be initiated (Chap. 15 and Antidotes in Depth: A16).

Class IA, IC, or III antidysrhythmics and other xenobiotics with sodium channel or potassium channel blocking activity should not be used to treat quinine-overdosed patients because they would be expected to exacerbate quinine-induced conduction disturbances or dysrhythmias. The Class IB antidysrhythmics, such as lidocaine, have been used with reported success,<sup>47</sup> but no clinical trials have been performed (Chap. 57).

Hypotension refractory to IV crystalloid boluses should be treated with vasopressors. In controlled human studies, epinephrine infusions reverse quinidine's antidysrhythmic drug effects and prolongation of the ventricular refractory period in a dose-dependent fashion.<sup>22,74</sup> Although not directly studied, direct-acting vasopressors such as epinephrine, norepinephrine, and phenylephrine are recommended. An intraaortic balloon pump was successfully used for the treatment of refractory hypotension in one case report.<sup>100</sup>

**Hypoglycemia.** A low serum glucose concentration should be supported with an adequate infusion of dextrose. Serum potassium concentration and the QT interval should be monitored during correction and maintenance. Octreotide was successfully used to correct quinine-induced hyperinsulinemia in adult malaria victims.<sup>86</sup> In volunteers, quinine-induced hyperinsulinemia was suppressed within 15 minutes after a 100-mcg intramuscular dose of octreotide (Antidotes in Depth: A9).<sup>85</sup> Octreotide should be used for cases of refractory hypoglycemia in a fashion similar to that recommended in sulfonyleurea toxicity, which is 50 mcg (1 mcg/kg in children) subcutaneously every 6 hours (Chap. 47).

**Ophthalmic.** Fundoscopic examination, visual field examination, and color testing are appropriate bedside diagnostic studies. Electroretinography, electrooculography, visual-evoked potentials, and dark adaptation are helpful in assessing the injury but are not practical because they require equipment that is not portable or readily available in most clinical settings. There is no specific, effective treatment for quinine retinal toxicity.<sup>46</sup> Hyperbaric oxygen was used in 3 patients who recovered vision, but since its role in that recovery was not established, it cannot be routinely recommended at this time.<sup>120</sup>

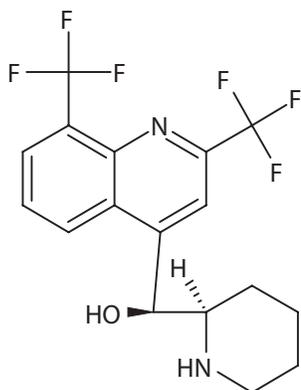

### Enhanced Elimination

The effect of multiple-dose activated charcoal (MDAC) on quinine elimination was studied in an experimental human model and in symptomatic patients.<sup>87</sup> In these patients, MDAC decreased the half-life of quinine from approximately 8 hours to about 4.5 hours and increased clearance by 56%.<sup>92</sup> Although numerous studies show that activated charcoal decreases quinine half-life,<sup>13,62,87</sup> evidence of clinical benefit is lacking. Nevertheless, because ophthalmic, CNS, and cardiovascular toxicity are related to serum concentration, it is prudent to reduce concentrations as quickly as practicable; thus, multiple-dose activated charcoal is recommended unless contraindications exist (Antidotes in Depth: A1).

There is conflicting evidence about a benefit of urinary acidification in enhancing clearance. But because of the increased potential for cardiotoxicity associated with acidification, this technique is never recommended.

Because quinine has a relatively large volume of distribution and is highly protein bound, hemoperfusion, hemodialysis, and exchange transfusion have only a limited effect on drug removal.<sup>13,18,97,114</sup> Although the blood compartment can be cleared with these techniques, total body clearance is only marginally altered. After rapid tissue distribution occurs, there is little impact on the total body burden because of the large volume of distribution and extensive protein binding; thus, extracorporeal methods of drug removal are not routinely recommended.

## Mefloquine

### Pharmacokinetics and Toxicodynamics

See Table 55–3 for the pharmacokinetic properties of mefloquine. Similar to its cousin quinine, mefloquine is hepatically metabolized by cytochrome P450 enzyme systems and excreted primarily in the bile and feces. Some hypothesize that the small, lipophilic structure combined with a long elimination half-life allows mefloquine to easily cross the blood–brain barrier, accumulate in the CNS, and interact with neuronal targets, leading to neurotoxic side effects.<sup>67</sup>

### Clinical Manifestations

Common side effects with prophylactic and therapeutic dosing include nausea, vomiting, and diarrhea. These side effects are noted particularly in the extremes of age and with high therapeutic dosing. Similar findings should be expected in acute overdose.<sup>107,117</sup>

Mefloquine has a mild cardiodepressant effect, less than that of quinine or quinidine, which is not clinically significant in prophylactic dosing or with therapeutic administration. Bradycardia is commonly reported.<sup>24,63,80</sup> With prophylactic use, neither the PR interval nor the QRS complex is prolonged, but QT interval prolongation is reported.<sup>33,63</sup> Reports of torsade de pointes are rare, but the increase in QT interval and risk of torsade de pointes are increased when mefloquine is used concurrently with quinine, chloroquine, or most particularly, with halofantrine.<sup>63,80,81,116</sup> The long half-life of mefloquine means that particular care must be taken with therapeutic use of other antimalarials when breakthrough malaria occurs during mefloquine prophylaxis or within 28 days of mefloquine therapy to avoid potential drug–drug interactions. This risk would be expected to increase with acute overdose, although there is little clinical experience.

Mefloquine is commonly associated with neuropsychiatric side effects. During prophylactic use, 10% to 40% of patients experience insomnia and bizarre or vivid dreams and complain of dizziness, headache, fatigue, mood alteration, and vertigo.<sup>98,113</sup> Only 2% to 10% of these complications necessitate the traveler to seek medical advice or change normal activities.<sup>24</sup> Predisposing factors include a past history of neuropsychiatric disorders, recent prior exposure to mefloquine (within 2 months), previous mefloquine-related neuropsychiatric adverse effects, and previous treatment with psychotropics.<sup>107</sup> Women appear to be more likely than men to experience neuropsychiatric adverse effects.<sup>107,113</sup>

The risk of serious neuropsychiatric adverse effects (convulsions, altered mental status, inability to ambulate due to vertigo, ataxia, or psychosis) during prophylaxis is estimated to be one in 10,600 but is reported to be as high as one in 200 with therapeutic dosing.<sup>31,107</sup> Seizures occur rarely with prophylaxis and therapeutic use. In many of these cases, there is a history of previous seizures, seizures in a first-degree relative, or other seizure risk factors. Other neuropsychiatric symptoms include dysphoria, altered consciousness, encephalopathy, anxiety, depression, giddiness, and agitated delirium with psychosis. Although there is a suggestion that the severity of neuropsychiatric events is dose dependent, there does not seem to be a correlation with serum or tissue concentrations.<sup>56</sup>

The effect of mefloquine on the pancreatic potassium channel is much less than that of quinine, resulting in only a mild increase in insulin secretion.<sup>32,33</sup> Symptomatic hypoglycemia has not been reported as an effect of mefloquine alone in healthy individuals, but has occurred with concomitant use of ethanol and in a severely malnourished patient with acquired immune deficiency syndrome (AIDS).<sup>10,33,63</sup> In overdose, particularly when accompanied by ethanol use or starvation, hypoglycemia can be severe.

Rare events such as hypersensitivity reactions reported with prophylaxis include urticaria, alopecia, erythema multiforme, toxic epidermal necrolysis, myalgias, mouth ulcers, neutropenia, and thrombocytopenia.<sup>81,98,103</sup> It is unclear which, if any, would be significant after overdose. Acute respiratory distress syndrome was linked to therapeutic dosing in one case report.

In therapeutic use, mefloquine is associated with an increased incidence of stillbirth compared with quinine and a group of other antimalarials.<sup>82</sup> Mefloquine was not, however, linked to an increased incidence of abortion, low birth weight, mental retardation, or congenital malformations. The implications of overdose in the absence of malaria are unknown, but fetal monitoring should be instituted.

The consequences of excessive dosing and overdose are not only severe but also prolonged and potentially permanent.

### Management

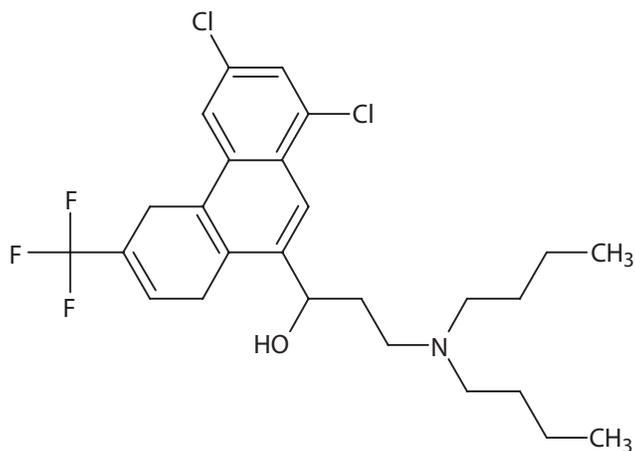

In overdose, treatment is primarily supportive with monitoring for potential adverse effects. Decontamination with activated charcoal is indicated if the patient presents soon after the ingestion. Specific monitoring for ECG abnormalities, hypoglycemia, and liver injury should be provided. Pregnant patients should be followed with fetal monitoring. Because of mefloquine's long half-life and potential for CNS accumulation, observation of asymptomatic patients for at least 24 hours is a reasonable approach. Central nervous

system effects usually resolve within a few days, but persistent, permanent, and delayed-onset CNS effects are reported, so observation for full resolution of CNS effects would not be practical.

In 2 patients with kidney failure who received mefloquine, prophylactic hemodialysis did not remove mefloquine.<sup>28</sup> Given the large volume of distribution and high degree of protein binding of mefloquine, extracorporeal elimination techniques are unlikely to be effective.

In one case report, the severe neuropsychiatric manifestations of mefloquine were reversed with physostigmine, leading the authors to suggest a possible central anticholinergic mechanism. Physostigmine is not recommended as a routine treatment for mefloquine neuropsychiatric side effects.

## Halofantrine

Because of erratic absorption, the potential for lethal cardiotoxicity, and concern for cross resistance with mefloquine, halofantrine is not presently recommended for malaria prophylaxis by the CDC.<sup>6</sup>

## Pharmacokinetics and Toxicodynamics

See Table 55–3 for the pharmacokinetic properties of halofantrine.

## Clinical Manifestations

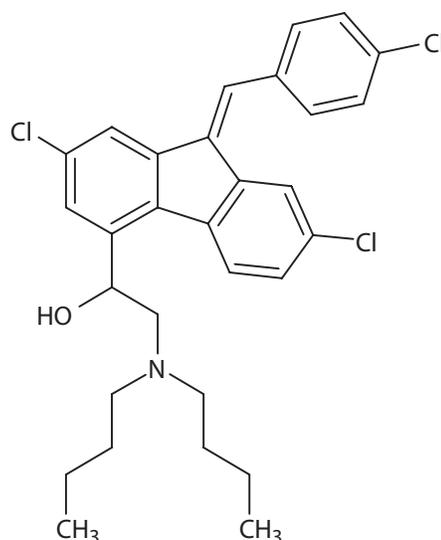

The primary toxicity from therapeutic and suprathreshold doses is prolongation of the QT interval and the risk of torsade de pointes and ventricular fibrillation.<sup>81,109</sup> Palpitations, hypotension, and syncope occur. First-degree atrioventricular (AV) block is common, but bradycardia is rare.<sup>81</sup> Dysrhythmias are also likely in the context of combined overdose or combined or serial therapeutic use with other xenobiotics that cause QT interval prolongation, particularly mefloquine.<sup>55</sup> Because the QT interval duration is directly related to the serum halofantrine concentration, dysrhythmias should be expected in overdose.<sup>24,81,107</sup> Fifty percent of children receiving a therapeutic course of halofantrine will have a QT interval greater than 440 ms.<sup>104</sup>

Other side effects, including nausea, vomiting, diarrhea, abdominal cramps, headache, and lightheadedness, which frequently occur in therapeutic use, are also expected in overdose.<sup>63</sup> Less frequently described side effects include pruritus, myalgias, and rigors. Seizures, minimal liver enzyme abnormalities, and hemolysis are described.<sup>63,73</sup> Whether these manifestations are related to halofantrine or to the underlying malaria is not clear.

## Management

Management of patients with halofantrine overdose should focus on decontamination, supportive care, monitoring for QT interval prolongation, and treatment of any associated dysrhythmias. Based on rare case reports, non-overdose evidence, and known erratic absorption, observation of asymptomatic overdose patients for 24 hours before medical clearance would be a reasonable approach.

## Lumefantrine

Lumefantrine is structurally similar to halofantrine. It is primarily used as a partner drug in the artemisinin-based combination therapy (ACT) artemether plus lumefantrine.

Little toxicity of lumefantrine alone or in combination is reported. Studies do not show QT interval prolongation or evidence of cardiac toxicity related to lumefantrine.<sup>36</sup> Cough and angioedema were described in one case. As in the case of all antimalarials, it is difficult to differentiate drug-related adverse events from those of malaria, comorbid diseases, or other ingested drugs, which confounds the study of potential complications.

## 4-AMINOQUINOLINES

The structurally related compounds chloroquine and amodiaquine were once used extensively for malaria prophylaxis. However, with the development of resistance, they are now used in fewer geographic regions. Amodiaquine is associated with a higher incidence of hepatic toxicity and agranulocytosis. In general, these xenobiotics have low toxicity when used in therapeutic doses. Because of its low toxicity, chloroquine remains the first-line drug for malaria prophylaxis and treatment in areas where *Plasmodium* spp remain sensitive.

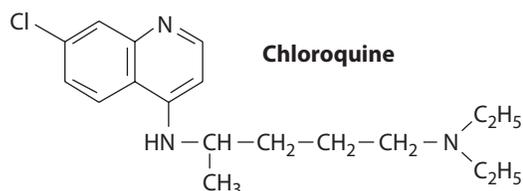

Hydroxychloroquine is similar to chloroquine in therapeutic, pharmacokinetic, and toxicologic properties. The side effect profiles of the 2 are slightly different, favoring chloroquine use for malarial prophylaxis and hydroxychloroquine use as an antiinflammatory.<sup>63,114</sup> Hydroxychloroquine is used in the treatment of rheumatic diseases such as rheumatoid arthritis and lupus erythematosus. In animal studies, chloroquine is 2 to 3 times more toxic than hydroxychloroquine.<sup>52</sup>

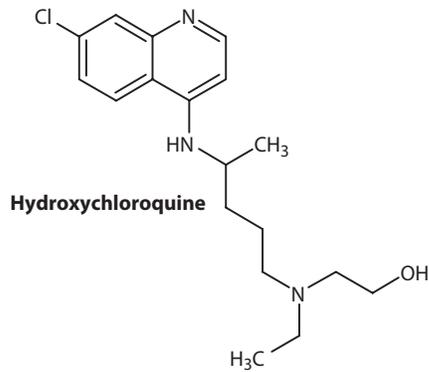

Piperaquine is structurally similar to chloroquine but is primarily used in conjunction with artemisinin compounds as a component of an ACT.

## Antimalarial Mechanism

The 4-aminoquinolines interfere with the digestion of heme and hemozoin formation in a manner similar to that of the amino alcohols.<sup>34</sup>

## Chloroquine and Hydroxychloroquine

### Pharmacokinetics and Toxicodynamics

See Table 55–3 for the pharmacokinetic properties of chloroquine. Oral chloroquine is rapidly and completely absorbed and is ultimately sequestered in many organs, particularly the kidney, liver, lung, and erythrocytes.<sup>17,48</sup>

Chloroquine is slowly distributed from the blood compartment to the larger central compartment, leading to transiently high whole blood concentrations shortly after ingestion.<sup>90,102</sup> It is the initial high blood concentrations that are thought to be responsible for the rapid development of profound cardiorespiratory collapse typical of chloroquine toxicity. These early whole blood chloroquine concentrations correlate with death<sup>27</sup> and are better predictors of cardiovascular symptom severity than serum concentrations.<sup>70</sup> Unfortunately chloroquine concentrations are rarely rapidly available and thus unlikely to be useful for early bedside clinical decision making.

### Pathophysiology

With structural similarity to quinine, the pathophysiologic mechanisms of chloroquine and hydroxychloroquine are also similar. Most notably, sodium and potassium channel blockade are the likely primary mechanisms of cardiovascular toxicity.<sup>116</sup>

Although less common in quinine toxicity, hypokalemia is extremely common in chloroquine overdose. The mechanism appears to be a shift of potassium from the extracellular to the intracellular space and not a true potassium deficit.<sup>65,90,100</sup>

### Clinical Manifestations

Similar to quinine, chloroquine has a narrow toxic-to-therapeutic ratio. Severe chloroquine poisoning is usually associated with ingestions of 5 g or more in adults, systolic blood pressure less than 80 mm Hg, QRS complex duration of more than 120 ms, ventricular fibrillation, hypokalemia, and serum chloroquine concentrations exceeding 25  $\mu\text{mol/L}$  (8 mcg/mL).<sup>26,93</sup> Not surprisingly, suspected ingested doses do not always correlate with blood concentrations,<sup>71</sup> but the suspected ingested dose still remains a potentially helpful historic predictor of the possibility for severe toxicity.

Symptoms usually occur within 1 to 3 hours of ingestion.<sup>93</sup> The range of symptoms associated with chloroquine toxicity is similar to that of quinine, but the frequencies of various manifestations differ, and other features such as cinchonism are uncommon. Nausea, vomiting, diarrhea, and abdominal pain occur less commonly than with quinine.<sup>49,63</sup> In contrast, respiratory depression is common, and apnea, hypotension, and cardiovascular compromise can be precipitous.<sup>49</sup>

The cardiovascular effects of chloroquine and hydroxychloroquine are similar to those of quinine, including QRS complex prolongation, AV block, ST and T wave depression, increased U waves, and QT interval prolongation. Hypotension is more prominent in chloroquine toxicity than with quinine.<sup>49</sup>

Significant hypokalemia in chloroquine toxicity is invariably associated with cardiac manifestations.<sup>49</sup> In fact, the extent of hypokalemia is a good indicator of the severity of chloroquine overdose<sup>26</sup> and mortality rate.<sup>70</sup>

Neurologic manifestations include CNS depression, dizziness, headache, and convulsions.<sup>46</sup> Rarely, dystonic reactions occur. Transient parkinsonism is also reported after excessive dosing.

Ophthalmic manifestations are infrequent in acute chloroquine toxicity and transient in nature.<sup>49,63</sup> More severe and irreversible vision and hearing changes are described in association with the chronic use of chloroquine and hydroxychloroquine as antiinflammatories.<sup>63,78</sup> Myopathy, neuropathy, and cardiomyopathy also occur when used for that purpose.<sup>8</sup> Dermatologic findings and hypersensitivity reactions are similar to those associated with quinine.<sup>33</sup> Likewise, red blood cell (RBC) oxidant stress from chloroquine results in hemolysis in patients with G6PD deficiency (Chap. 20).

Acute hydroxychloroquine toxicity is similar to chloroquine toxicity.<sup>72</sup> Side effects from therapeutic doses include nausea and abdominal pain; hemolysis in G6PD-deficient patients; and, rarely, retinal damage, sensorineural deafness, and hypoglycemia. Hypersensitivity reactions, including myocarditis and hepatitis, are described.

### Management

Aggressive supportive care is recommended, including oxygen, cardiac and hemodynamic monitoring, and large-bore IV access, and serial blood glucose concentrations. Despite reported rapid absorption, one series reported delayed peak blood concentrations in some patients,<sup>70</sup> opening the possibility of a potential benefit for early GI decontamination methods. Orogastric lavage is recommended for life-threatening ingestions presenting early, but there is little evidence of efficacy. Activated charcoal adsorbs chloroquine well, binding 95% to 99% when administered within 5 minutes of ingestion.<sup>59</sup> The frequent development of precipitous cardiovascular and CNS toxicity should be anticipated before initiating any type of GI decontamination.

Early aggressive management of severe chloroquine toxicity decreases the mortality rate.<sup>93</sup> This includes early endotracheal intubation and mechanical ventilation. Evidence suggests that barbiturates are not desirable for induction in patients with chloroquine overdose. When thiopental was used to facilitate intubation, its use immediately preceded sudden cardiac arrest in 7 of 25 patients after chloroquine overdose.<sup>27</sup> Regardless of induction agent, an adequate  $\text{FiO}_2$ , tidal volume, and ventilatory rate should be ensured.

Although theoretically any direct-acting vasopressor would be beneficial in the setting of hypotension not responsive to fluid resuscitation, epinephrine is the vasopressor most extensively studied and is therefore the vasopressor of choice. High doses of epinephrine were used in the original studies describing the benefits of early mechanical ventilation and the administration of diazepam and epinephrine in chloroquine poisoning.<sup>93,94</sup> The epinephrine doses used in these studies are still recommended today.<sup>93,94</sup> The recommended dose is 0.25 mcg/kg/min, increasing by 0.25 mcg/kg/min until an adequate systolic blood pressure (>90 mm Hg) is achieved.<sup>30,69,93,94</sup> Clinicians should be mindful that high doses of epinephrine could exacerbate preexisting hypokalemia.

The use of diazepam to augment the treatment of dysrhythmias and hypotension is a unique use of this drug. Initial observations with regard to patients with mixed overdoses of chloroquine and diazepam suggested less cardiovascular toxicity and a potential benefit of high-dose diazepam.<sup>27,65</sup> Animal and human studies that followed also showed a potential benefit.<sup>30,93,94</sup> When early mechanical ventilation was combined with the administration of high-dose diazepam and epinephrine in patients severely poisoned by chloroquine, a dramatic improvement in survival compared with historical control participants (91% vs 9% survival) occurred.<sup>93</sup> Studies in moderately poisoned patients failed to show similar benefit,<sup>26</sup> and a rat model failed to show an inotropic effect. Although the definitive study has yet to be done, high-dose diazepam therapy (2 mg/kg IV over 30 minutes followed by 1–2 mg/kg/day for 2–4 days) is recommended for serious toxicity. Diazepam or an equivalent benzodiazepine should also be used to treat seizures and for sedation.

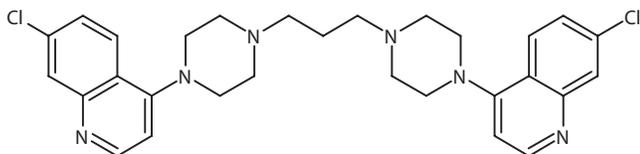

The mechanism for a potential benefit of diazepam is unclear, but multiple theories have been postulated: (1) a central antagonistic effect, (2) an anti-convulsant effect, (3) an antidysrhythmic effect by an electrophysiologic action inverse to chloroquine, (4) a pharmacokinetic interaction between diazepam and chloroquine, and (5) a decrease in chloroquine-induced vasodilation.<sup>65,90,93,94</sup> (Antidotes in Depth: A26).

The use of sodium bicarbonate for correction of QRS complex prolongation is also controversial. Although alkalinization would be expected to counteract the effects of sodium channel blockade, it could also exacerbate preexisting hypokalemia. Although case reports describe the successful use of sodium bicarbonate in conjunction with xenobiotics for massive hydroxychloroquine overdose, no clinical trials have been performed. Before using sodium bicarbonate in the setting of chloroquine toxicity, clinicians should evaluate the overall clinical status of the patient, including the suspected degree of cardiac toxicity and severity of hypokalemia. In the setting of normal potassium, sodium bicarbonate is a reasonable intervention to counteract QRS complex prolongation.

Hypokalemia in the setting of chloroquine overdose correlates with the severity of the toxicity.<sup>26,65</sup> Potassium replacement in this setting is, again, controversial because it has not been shown that potassium supplementation will improve cardiac toxicity. In fact, several reports suggest a possible protective effect of hypokalemia in acute chloroquine toxicity.<sup>26,65,90</sup> This should be balanced against the fact that severe hypokalemia can itself result in lethal dysrhythmias and data suggesting severe hypokalemia (<1.9 mEq/L) is associated with severe, life-threatening ingestion.<sup>24,49,65,102</sup> Hypokalemia could not be directly attributed as the cause of death in most cases, however.<sup>26</sup> Based on the available evidence, potassium replacement for severe hypokalemia would be a reasonable intervention, but it is essential to anticipate rebound hyperkalemia as chloroquine toxicity resolves and redistribution of intracellular potassium occurs. Cases of hyperkalemia-related complications are reported after aggressive potassium supplementation.<sup>52,65</sup>

Because chloroquine and hydroxychloroquine have high volumes of distribution and significant protein binding, enhanced elimination procedures are not beneficial.<sup>17,49</sup> There is limited experience with lipid emulsion therapy in the setting of chloroquine poisoning; thus its use is not recommended (Antidotes in Depth: A23).

### Piperaquine

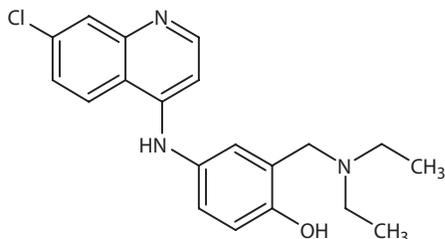

See Table 55-3 for the pharmacokinetic properties of piperaquine.

Piperaquine was used extensively in China and Indonesia as an antimalarial until the development of piperaquine-resistant strains led to the use of better alternatives. Piperaquine has since undergone a rediscovery as a viable combination with artemisinin derivatives in ACT DP (dihydroartemisinin-piperaquine) therapy. Animal studies show piperaquine to be substantially less toxic than chloroquine. Cardiovascular toxicity with piperaquine requires cumulative doses 5 times higher than that of chloroquine. Hepatotoxicity occurs after chronic exposure in animals. In a human study, no significant changes in ECG or in serum glucose concentration, and no postural hypotension occurred after therapeutic doses of DP.

Patients with overdose should be managed with supportive measures and expectant observation, including cardiovascular and CNS monitoring.

### Amodiaquine

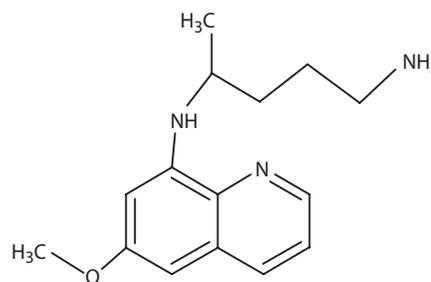

Amodiaquine has pharmacologic properties similar to others in the 4-aminoquinolone family. It is rapidly absorbed from the GI tract and

hepatically metabolized by CYP2C8 into its active antimalarial metabolite, desethylamodiaquine.<sup>118</sup>

Amodiaquine fell out of favor as a prophylactic treatment as a result of serious and sometimes fatal liver and bone marrow toxicity,<sup>107</sup> but is still a component of one of 5 ACTs recommended by the WHO for treatment of active malarial infection. Hypersensitivity reactions (hepatitis and neutropenia) described in prophylactic use are uncommon with therapeutic use.<sup>21,118</sup> Reports of amodiaquine toxicity suggest that involuntary movements, muscle stiffness, dysarthria, syncope, and seizures can occur.<sup>2,49</sup> There is no overdose experience reported. Aggressive symptomatic and supportive care, expectant observation, including cardiovascular and CNS monitoring, should be provided for possible poisoning.

## 8-AMINOQUINOLINES

### Primaquine

Primaquine and its related compounds are the only drugs licensed for the prevention of *P. ovale* and *P. vivax* relapse caused by hepatic hypnozoites (Fig. 55-1). Studies using primaquine in the early 1950s led to the discovery of G6PD deficiency after those with the disease developed hemolysis when administered the drug.<sup>14</sup> Glucose-6-phosphate dehydrogenase deficiency actually offers some protection against malaria because the erythrocytes of those with the disease rupture under the increased oxidative stress of the parasite's metabolism before completion of the erythrocytic cycle. Primaquine is making a resurgence in some countries for *P. falciparum* treatment as a gametocytocide to reduce transmission in campaigns to eradicate malaria from these regions.<sup>50</sup>

### Antimalarial Mechanism

The antimalarial action of primaquine is poorly understood but thought to be related to increasing the oxidative stress of erythrocytes,<sup>115</sup> obstructing proper parasitic development.

### Pharmacokinetics and Toxicodynamics

See Table 55-3 for the pharmacokinetic properties of primaquine. Metabolism is primarily hepatic, using multiple enzyme systems, with CYP2D6 playing a prominent role.<sup>7</sup> The parent compound is metabolized to reactive intermediates that are thought to mediate both its antimalarial and hemolytic effects.

### Pathophysiology

Primaquine blocks sodium channels both in vitro and in animal models.<sup>49,116</sup> Significant cardiovascular toxicity has not been reported, although experience with primaquine overdose is limited primarily to case reports.

The predominant clinical toxicity of primaquine relates to its ability to cause RBC oxidant stress and resultant hemolysis or methemoglobinemia. Methemoglobinemia and hemolysis can occur in normal individuals given high doses as well as those with G6PD deficiency.<sup>63,107</sup>

The major complication of primaquine in therapeutic use is hemolysis in G6PD-deficient individuals.<sup>32</sup> Primaquine is contraindicated in pregnant women because of the risk of methemoglobinemia or hemolysis in the fetus. Reversible bone marrow suppression can occur.

### Clinical Manifestations

Gastrointestinal irritation is common and dose related.

The extent of hemolysis in G6PD-deficient individuals depends on the extent of enzyme activity, those with greater enzyme activity having less severe hemolysis than those with less enzyme activity (Chap. 20). Other variables include the dose of primaquine and comorbid conditions, such as infection, liver disease, and administration of other drugs with hemolytic activity.

Overdose with primaquine is rarely reported, and unintentional overdoses have led to methemoglobinemia requiring IV methylene blue (Chap. 124).<sup>107</sup> Acute liver failure has occurred after unintentional overdose, and fatal hepatotoxicity is described in animal models.<sup>61</sup>

### Management

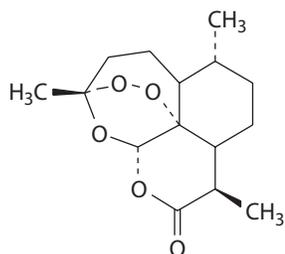

Therapy should be directed at minimizing absorption with appropriate decontamination, and diagnosing then treating significant methemoglobinemia or hemolysis. Because of structural similarities with other quinolone antimalarials and animal model evidence of sodium channel blockade, cardiovascular toxicity should be anticipated with continuous monitoring and resuscitative interventions initiated as needed.

Activated charcoal is a reasonable early intervention (Antidotes in Depth: A1). Methylene blue (Chap. 124 and Antidotes in Depth: A43) is recommended for patients who are symptomatic with methemoglobinemia. Treatment of hemolysis necessitates avoiding further exposure to primaquine and possibly exchange transfusion in severe cases. Adequate hydration should be ensured to protect against hemoglobin-induced acute kidney injury. Urinary alkalinization with sodium bicarbonate is controversial in this setting but is not routinely recommended because it has not been proven to be superior to aggressive sodium chloride 0.9% hydration alone (Antidotes in Depth: A5).

Although no clinical studies have been performed, the large volume of distribution of primaquine makes it an unlikely candidate for benefit from extracorporeal removal.

## ENDOPEROXIDES

### Artemisinin and Derivatives

The medicinal value of natural artemisinin, the active ingredient of *Artemisia annua* (sweet wormwood or qinghao), has been known for thousands of years. Its antimalarial properties were first recognized by Chinese herbalists in A.D. 340, but the primary active component of qinghao, now known as artemisinin, was not isolated until 1974.<sup>8,114</sup> Artemisinin and its semisynthetic derivatives, artesunate, artemether, arteether, and dihydroartemisinin, are the most potent and rapidly acting of all antimalarials. They were introduced in the 1980s in China for the treatment of malaria, and since then millions of doses have been used in Asia and Africa. Because of their extremely short half-lives, the artemisinins are now used in combination with drugs with longer half-lives to delay or prevent the emergence of resistance. Artemisinin-based combination therapies are currently recommended by the WHO for the treatment of uncomplicated malaria<sup>118</sup> but only one has been licensed for use in the United States; artemether and lumefantrine. Five artemisinin-based combination therapies (ACT) are currently recommended by the WHO. These include artemether plus lumefantrine, artesunate plus mefloquine, artesunate plus pyrimethamine-sulfadoxine, artesunate plus amodiaquine, and dihydroartemisinin and piperazine.

### Antimalarial Mechanism

The artemisinins have a unique structure containing a 1,2,4-trioxane ring. The endoperoxide linkage within this ring is cleaved when it comes into

contact with ferrous iron, releasing free radicals that destroy the parasite.<sup>1</sup> Artemisinin is the only known natural product to contain a 1,2,4-trioxane ring, and although chemical synthesis is possible, thus far it has not been financially advantageous.

### Pharmacokinetics and Toxicodynamics

See Table 55-3 for the pharmacokinetic properties of artemisinin. Artemisinin and its derivatives are rapidly metabolized to the primary active metabolite dihydroartemisinin.<sup>68</sup> Similar to its proposed efficacy, the toxicity of artemisinin is thought to be a result of the ability of the trioxane molecular core to form intracellular free radicals, particularly in the presence of heme. In animals, damage to brain stem nuclei is consistently produced after prolonged, high-dose, and parenteral administration.<sup>107</sup> Sustained CNS exposure from slowly absorbed or eliminated artemisinins is considered markedly more neurotoxic than intermittent brief exposure that occurs after oral dosing. Embryonic loss is also observed in animals.

### Clinical Manifestations

In contrast to the experience with animals, the general theme throughout the literature suggests that these drugs have a very low incidence of side effects. This is consistent with the belief that long-term, rather than short-term, peak concentrations are primarily responsible for toxicity.<sup>35</sup> Uncommon side effects include nausea, vomiting, abdominal pain, diarrhea, and dizziness. Few large-scale trials powered to detect rare but possibly significant toxicity have been performed.

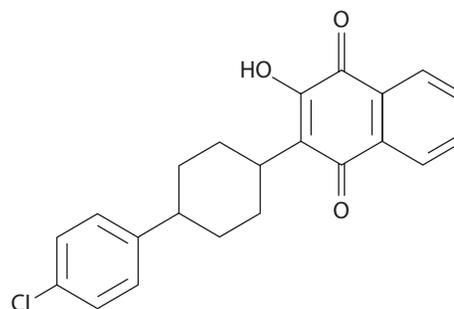

Prospective studies have failed to identify adverse neurologic outcomes.<sup>58,107</sup> Rare reports of adverse CNS effects during therapeutic use suggest the possibility of CNS depression, seizures, or cerebellar symptoms after intentional self-poisoning. In children with cerebral malaria, a higher incidence of seizures and a delay to recovery from coma were noted in a comparison with quinine.<sup>112</sup> No neurologic difference was noted in long-term follow-up. In an artemether-quinine comparative trial of adults with severe malaria, recovery from coma was also prolonged in the artemether group.<sup>110</sup> Rare patients receiving an artemisinin derivative in 2 other studies experienced transient dizziness or cerebellar signs.<sup>88</sup> Most recovered within days. One patient in each study had prolonged symptoms lasting 1 month and 4 months, respectively, but both ultimately recovered.

When serial ECGs were obtained, a small but statistically significant decrease in heart rate was noted coincident with peak drug concentrations.<sup>72</sup> In one therapeutic trial, 7% of adult patients receiving artemether had an asymptomatic QT interval prolongation of at least 25%.<sup>110</sup> Changes in the QRS complex are not reported.

Although uncommon, neutropenia, reticulocytopenia, anemia, eosinophilia, and elevated aminotransferases are reported.<sup>107</sup> Acute ACT overdose is rarely reported outside large population-based studies. Morbidity and mortality of overdose are frequently difficult to differentiate from those of the underlying malarial disease and coingestants.

## NAPHTHOQUINONES

### Atovaquone

Atovaquone is a structural analog of ubiquinone, or coenzyme Q, a mitochondrial protein involved in electron transport.<sup>9</sup> Atovaquone disrupts the protozoal mitochondrial membrane potential, leading to inhibition of several

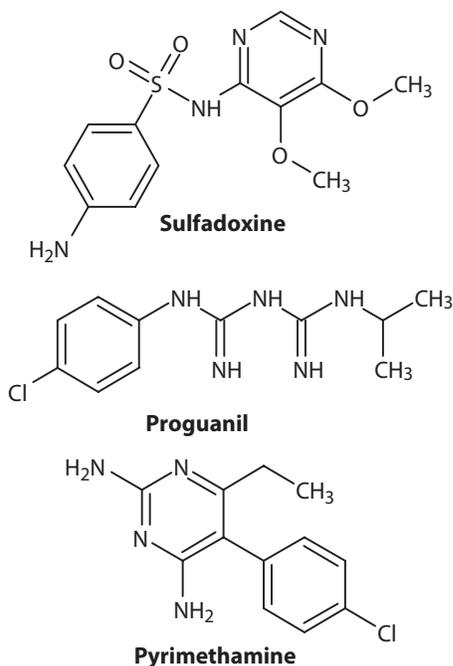

parasite-specific enzymes, ultimately leading to the inhibition of pyrimidine synthesis, which is necessary for protozoal survival and replication. Based on its beneficial side effect profile, the CDC recommends the combination atovaquone–proguanil for treatment of chloroquine-resistant malaria. The price of this combination as well as the variable bioavailability of atovaquone limits its use in less affluent countries.

Atovaquone alone, primarily used to treat *Pneumocystis jiroveci* in patients with AIDS, is relatively well tolerated.<sup>84</sup> Side effects include maculopapular rash, erythema multiforme (rarely), GI complaints, and mild aminotransferase elevations. Three cases of 3- to 42-fold overdose or excess dosing are reported.<sup>25</sup> No symptoms occurred in one case (at 3 times therapeutic serum concentration). Rash occurred in another, and in the third case, methemoglobinemia was attributed to a simultaneous overdose of dapsone.

When used to treat malaria, atovaquone-proguanil side effects include abdominal pain, nausea, vomiting, headache, diarrhea, anorexia, and dizziness.<sup>9</sup> This combination is also associated with elevated aminotransferases<sup>89</sup> and hepatosplenomegaly.<sup>9</sup> Reported overdose has caused little serious toxicity.<sup>107</sup>

Atovaquone is reported to have extensive enterohepatic cycling, with 94% of the drug eliminated in the feces.<sup>9,66</sup> Although there is no evidence, multiple-dose activated charcoal is a reasonable intervention in selected overdose patients.

## ANTIFOLATES AND ANTIBIOTICS

### Antimalarial Mechanism

Proguanil, pyrimethamine, and the antibiotic trimethoprim interfere with malarial folate metabolism by inhibiting dihydrofolate reductase at concentrations far lower than that required to produce comparable inhibition of mammalian enzymes.<sup>114</sup> Dapsone and sulfonamide antibiotics also disrupt malarial folate metabolism, but by inhibiting a different enzymatic reaction—dihydropteroate synthase. Slow onset of action and concerns for the development of resistance have led to the use of these medications in synergistic combinations leading to inhibition of folate metabolism at 2 different sites.

### Pharmacokinetics and Toxicodynamics

See Table 59–3 for the pharmacokinetic properties of pyrimethamine, proguanil, and dapsone.

Proguanil's active metabolite, cycloguanil, is primarily responsible for its antimalarial activity. Both the parent drug and active metabolite share substantial renal excretion, making renal insufficiency a risk factor for toxicity.<sup>51</sup>

Dapsone is chiefly metabolized by CYP2C19 to dapsone hydroxylamine.<sup>108</sup> These hydroxylamine metabolites have a long half-life, partially because of enterohepatic recirculation, and concentrate in erythrocytes leading to oxidant stress resulting in methemoglobinemia and hemolysis. Cimetidine competes for the same CYP enzymes, decreasing methemoglobin levels during therapeutic dapsone dosing<sup>92</sup> presumably by shunting dapsone metabolism to alternate nontoxic pathways.

### Clinical Manifestations

The side effects of proguanil during prophylaxis include nausea, diarrhea, and mouth ulcers.<sup>63</sup> Because of the interference with folate metabolism, megaloblastic anemia is a rare but potential complication. Megaloblastic bone marrow toxicity is reported in patients with chronic kidney disease.<sup>107</sup> Folate supplementation is recommended in pregnancy and CKD to avoid this complication.<sup>31</sup> Rarely, neutropenia, thrombocytopenia, rash, and alopecia are also noted. In a single case report, hypersensitivity hepatitis was described.<sup>31</sup>

Overdose of pyrimethamine alone is rare. In children, it results in nausea, vomiting, a rapid onset of seizures, fever, and tachycardia.<sup>3,49</sup> Blindness, deafness, and developmental delay have followed. It is unclear whether the chronic neurologic deficits described in case reports are attributable to direct toxicity of pyrimethamine on the CNS or to complications of toxicity such as status epilepticus. Chronic high dose use is associated with a megaloblastic anemia and bone marrow suppression, requiring folate replacement.<sup>3</sup>

The sulfonamides, including the sulfone dapsone, have a long history of causing idiosyncratic reactions, including neutropenia, thrombocytopenia, eosinophilic pneumonia, aplastic anemia, neuropathy, and hepatitis.<sup>63,107</sup> Rare occurrence of life-threatening erythema multiforme major and toxic epidermal necrolysis, associated with pyrimethamine–sulfadoxine prophylaxis, has limited the use of this combination.

Acute ingestion of dapsone results in nausea, vomiting, and abdominal pain.<sup>49</sup> After overdose, dapsone produces RBC oxidant stress, leading to methemoglobinemia and, to a much lesser extent, sulfhemoglobinemia through formation of an active metabolite (Chap. 124).<sup>23,64</sup> Hemolysis may be either immediate or delayed. Dapsone, in particular, is known for its tendency to cause prolonged methemoglobinemia. Other symptoms, particularly tachycardia, dyspnea, dizziness, visual hallucinations, seizure, syncope, and coma resulting from end-organ hypoxia, can occur. Additional effects described in overdose include hepatitis and peripheral neuropathy.<sup>49</sup>

### Management

Neural tube defects are associated with the use of folic acid antagonists, thus folate supplementation is reasonable in reproductive age women exposed to these agents. Folinic acid (leucovorin) would be a reasonable intervention after an overdose of proguanil or pyrimethamine (Antidotes in Depth: A12). Other efforts should include supportive care.

After dapsone ingestion, clinically significant methemoglobinemia should be treated with methylene blue (Chap. 124 and Antidotes in Depth: A43). The long half-life of dapsone and its metabolites often make repetitive doses of methylene blue necessary. The patient's clinical status is more important than a single methemoglobin level for determining treatment interventions. There is no antidote for sulfhemoglobinemia, but it constitutes an insignificant portion of total hemoglobin.

Multiple-dose activated charcoal is recommended for patients with a dapsone overdose and no contraindications.<sup>64</sup> Exchange transfusion is a reasonable intervention for patients who fail to respond to methylene blue. Hemodialysis decreased methemoglobinemia concentrations in case reports but subsequent rebound dapsone concentrations were observed.<sup>79</sup> Continuous veno-venous hemofiltration increased dapsone clearance 3-fold in a single case report. These extracorporeal methods of removal are not routinely recommended. Hyperbaric oxygen has been used in case reports as an adjunct to methylene blue in the treatment of methemoglobinemia but is not routinely recommended (Antidotes in Depth: A43).

Cimetidine supplementation is a reasonable intervention after dapsone overdose. Other antioxidants, ascorbic acid and vitamin E, have been used to treat methemoglobinemia<sup>12</sup> but are not routinely recommended because their slow onset of action makes a benefit unlikely.

## FUTURE DIRECTIONS

Shared cytochrome P450 metabolic pathways and genetic polymorphisms are increasingly recognized as contributing factors in drug–drug interactions and toxicity. The clarification of various antimalarial metabolic pathways has led to concern for potential toxicity due to these interactions. The clinical relevance of these interactions is unclear, however. Genetic polymorphism is described in the metabolism of proguanil and dapsone and may be a contributing factor to the hypersensitivity reactions noted with dapsone.<sup>53,91</sup> Table 55–3 highlights the known potentially significant metabolic interactions of antimalarials.

The development of drug resistance and search for treatments with improved efficacy, compliance and side-effect profiles fuels an ongoing pursuit for better antimalarials. Tafenoquinone (WR-238605 or etauine) is an 8-aminoquinoline with greater activity against liver-stage parasites than primaquine. It appears to have fewer side effects than primaquine, less hemolytic toxicity and a longer half-life enabling less frequent dosing that could increase compliance.<sup>29</sup> At the time of this writing, phase III trials of tafenoquinone are ongoing. A number of new ACTs are being studied in different countries, but are not yet recommended by the WHO because of insufficient evidence. These new ACTs include combinations of artesunate and pyronaridine, artemisinin and piperaquine, artemisinin and piperaquine base, artemisinin and naphthoquinone.<sup>118</sup>

Although there is no supporting evidence, one case series discussed eculizumab, a monoclonal antibody targeting the terminal portion of the complement cascade, as a potential therapy for AKI associated with quinine-induced thrombotic microangiopathy.<sup>40</sup> Because the role of complement in quinine-induced thrombotic microangiopathy remains unclear and it deviates from the FDA-approved indication, the use of eculizumab for quinine hypersensitivity is not presently recommended.

The complicated structure and life cycle of malaria protozoa has made the development of an effective malaria vaccine an elusive undertaking. Despite these difficulties, the Malaria Vaccine Technology Roadmap has focused strategic efforts since 2006. The most advanced vaccine in development, RTS,S/AS01, provides modest protection (26%–50%)<sup>42</sup> against *P. falciparum*.<sup>83</sup> Funding for a large-scale implementation pilot using this vaccine is established. Vaccinations in several sub-Saharan African countries began in 2018.

## SUMMARY

- Malaria is a parasitic infection of human erythrocytes caused by protozoan parasites in the *Plasmodium* genus with a unique life cycle involving the *Anopheles* mosquito as the vector. It is primarily endemic in tropical and subtropical areas worldwide.
- The antimalarial properties of quinine have been known for centuries. Therapeutic dosing can result in a unique symptom complex known as “cinchonism.” Significant overdose is heralded by cardiovascular and CNS toxicity.
- The development of resistance has limited the use of chloroquine to specific geographic regions harboring susceptible malarial strains. Rapid development of cardiorespiratory collapse is typical of chloroquine toxicity. Early intubation along with high-dose epinephrine and diazepam are recommended for the treatment of serious chloroquine toxicity.
- Primaquine and dapsone produce significant oxidant stress, resulting in methemoglobinemia and often hemolysis.
- Because of their extremely short half-lives, artemisinins are used in combination with drugs with longer half-lives to delay or prevent the emergence of resistance. Little is known of the acute toxicity after overdose of the newest artemisinin-based medications.

- Understanding antimalarial metabolism and toxicity, creating improved antimalarial medications, and vaccine development are among the many future research efforts under way today.

# ANTITUBERCULOUS MEDICATIONS

Christina H. Hernon and Jeffrey T. Lai

## HISTORY AND EPIDEMIOLOGY

Approximately one-third of the total population of the world, or 2 billion people, are infected with *Mycobacterium tuberculosis*. An estimated 10.4 million new cases of disease are diagnosed annually.<sup>169</sup> In 2010, 1.45 million deaths were reported; of which approximately 0.35 million were attributed to HIV-associated tuberculosis. In 2014, the incidence of TB in the United States was the lowest recorded (9,412 new cases) since the inception of national reporting in 1953, but in 2015, the number increased to 9557, after declining annually for more than 20 years.<sup>25,134</sup> The introduction of isoniazid (INH) into clinical practice in 1952 produced a steady decline in the number of TB cases in the United States over the subsequent 30 years. However, between 1985 and 1991, there was a resurgence in TB cases in the United States resulting primarily from the effects of human immunodeficiency virus (HIV), homelessness, deterioration in the health care infrastructure, and an increase in immigration. With the initiation and implementation of containment strategies, the spread of the infection slowed by aggressive case identification and patient-centered management, including directly observed therapy, social support, housing, and substance abuse treatment. These methods decreased the prevalence rate in the United States and worldwide.<sup>115</sup> In 2006, 20% of *Mycobacterium tuberculosis* isolates were resistant to at least isoniazid and rifampin, called multidrug-resistant tuberculosis (MDR-TB), and 2% were identified as highly resistant extensively drug-resistant tuberculosis (XDR-TB), with resistance to many additional drugs—defined as all fluoroquinolones, and at least one of 3 injectable drugs (capreomycin, kanamycin, and amikacin).<sup>9,24</sup> Between 1993 and 2015, 73 cases of XDR-TB were reported in the United States.<sup>26</sup>

At present, populations that remain at risk for TB include HIV-positive patients, homeless people, people with alcoholism, injection drug users, health care workers, prisoners, prison workers, and Native Americans. In addition, the TB rate in foreign-born persons is nearly 10 times higher than in US-born persons. In the US population, countries of birth generating the highest number of TB cases are Mexico, the Philippines, India, and Vietnam.<sup>9</sup>

The use of multiple drugs in regimens against MDR-TB and XDR-TB results in significant adverse drug effects, approximately 40%, and this increases to approximately 70% in treatment against coinfection with human immunodeficiency virus (HIV). These reactions include hepatotoxicity, peripheral neuropathy, arthralgias, rash, anemia, and require discontinuation of therapy if severe. These effects are greatest in the first weeks of therapy, often are irreversible, and potentially fatal.<sup>97</sup>

## ISONIAZID

### Pharmacology

Isoniazid (INH, or isonicotinic hydrazide) is structurally related to nicotinic acid (niacin, or vitamin B<sub>3</sub>), nicotinamide adenosine dinucleotide (NAD), and pyridoxine (vitamin B<sub>6</sub>) (Fig. 56–1). The pyridine ring is essential for

antituberculous activity. Isoniazid itself does not have direct antibacterial activity. It is a prodrug that undergoes metabolic activation by KatG, a catalase peroxidase in *M. tuberculosis* that produces a highly reactive intermediate,<sup>116,174</sup> which in turn interacts with InhA, a mycobacterial enzyme that functions as an enoyl-acyl carrier protein (enoyl-ACP) reductase.<sup>113,114</sup> Enoyl-ACP reductase InhA is required for the synthesis of very long-chain lipids, mycolic acids (containing between 40 and 60 carbons) that are important components of mycobacterial cell walls.

The activated form of INH is stabilized by the pyridine ring. Enoyl-ACP reductase (InhA) catalyzes the NADH-dependent reduction of the double bonds in the growing fatty acid chain linked to acyl carrier proteins. This INH metabolite enters the binding site of InhA, where it reacts with the reduced form of nicotinamide adenine dinucleotide (NADH).<sup>116</sup> The covalently linked INH-NADH complex remains bound to the active site of InhA, irreversibly inhibiting the enzyme.<sup>95,113</sup>

### Pharmacokinetics

When therapeutic doses of 300 mg are administered orally, INH is rapidly absorbed, reaching peak serum concentrations typically within 2 hours.<sup>75,108,109</sup> Delayed absorption of isoniazid infrequently occurs, with peak concentrations up to 6 hours after ingestion.<sup>5</sup> Isoniazid diffuses into all body fluids with a volume of distribution of approximately 0.6 L/kg and has negligible binding to serum proteins. After the drug penetrates infected tissue, it achieves concentrations well above those generally required for bactericidal activity.<sup>109</sup>

The primary metabolic pathway for INH is via *N*-acetylation via hepatic acrylamine *N*-acetyltransferase type 2 (NAT2) to acetylisoniazid, which undergoes one of the following fates: excretion by the kidney; oxidation to hydroxylamine, a hepatotoxic metabolite via CYP2E1;<sup>171</sup> direct hydrolyzation to hepatotoxic hydrazine; or further metabolism by NAT2 to (somewhat hepatotoxic) acetylhydrazine, which is further metabolized by NAT2 to non-toxic diacetylhydrazine. Hydrazine and (to a lesser extent) acetylhydrazine are oxidized by CYP2E1 to reactive metabolites, which induce oxidative stress or alter lipid metabolism, resulting in hepatic apoptosis or steatosis. The mechanisms and circumstances of hepatotoxicity are not yet clearly elucidated though toxicity is thought to be due to the metabolites and not to isoniazid itself.<sup>162,171</sup> Approximately 75% to 95% of INH is renally eliminated in the form of these hepatic metabolites within 24 hours of administration.<sup>62</sup> *N*-Acetyltransferase-2 (NAT2) exhibits Michaelis-Menten kinetics but is genotypically polymorphic, and the activity of an individual's enzymes is determined by an autosomal dominant inheritance pattern, with homozygous fast acetylators (FF), heterozygous fast acetylators (FS), and homozygous slow acetylators (SS). Patients are distinguishable phenotypically as fast, intermediate, and slow acetylators. Whereas the fast acetylation enzyme is found in 40% to 50% of American whites and African Americans, the fast acetylator enzyme is found in 80% to 90% of Asians and Inuits.<sup>47</sup> These enzymes are distinguishable by the following characteristics: (1) slow acetylators have less presystemic clearance, or first-pass effect, than do fast acetylators; (2) fast acetylators metabolize INH 5 to 6 times faster than slow acetylators; and (3) serum INH concentrations are 30% to 50% lower in fast acetylators than in slow acetylators. The elimination half-life of INH is approximately 70 minutes in fast acetylators and 180 minutes in slow acetylators. Twenty-seven percent of INH is excreted unchanged in urine by slow acetylators compared with 11% excretion in fast acetylators. Slow acetylators are at increased risk of peripheral neuropathy and dose adjustments mitigate this risk.<sup>152</sup> The clearance of INH averages 46 mL/min.<sup>12,164</sup> Additionally, a small portion

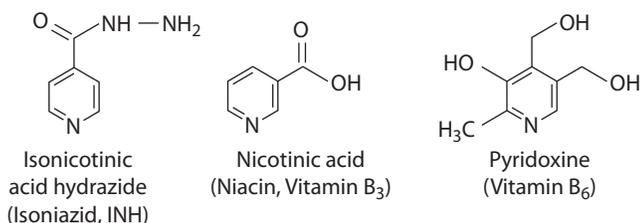

FIGURE 56–1. Isoniazid and related compounds.

of INH is directly hydrolyzed into isonicotinic acid and hydrazine, and this pathway is of greater quantitative significance in slow acetylators than in rapid acetylators. Although both hepatic microsomal oxidation by CYP2E1 of hydrazine or the acetylhydrazine intermediate into reactive intermediates are proposed as causes of INH-related hepatotoxicity, there is no significant association between variations in genetic polymorphisms and hepatotoxicity.<sup>56,101,156,171</sup> There is increasing evidence that hydrazine is directly linked to hepatotoxicity as well as causing hepatotoxicity via an immune-mediated, idiosyncratic mechanism.<sup>96</sup> Lastly, INH nonenzymatically conjugates with certain endogenous metabolites including ketone acids and vitamin B<sub>6</sub> (pyridoxal and pyridoxal 5-phosphate) or enzymatically with NAD<sup>+</sup> via human neutrophil myeloperoxidase. Interruption of homeostasis of bile acids, cholesterol, triglycerides, and free fatty acids is possible with chronic INH therapy, because of CYP2E1-dependent modulation. Fig. 56-2 illustrates the metabolism of INH.

## Pathophysiology

### Mechanism of Toxicity

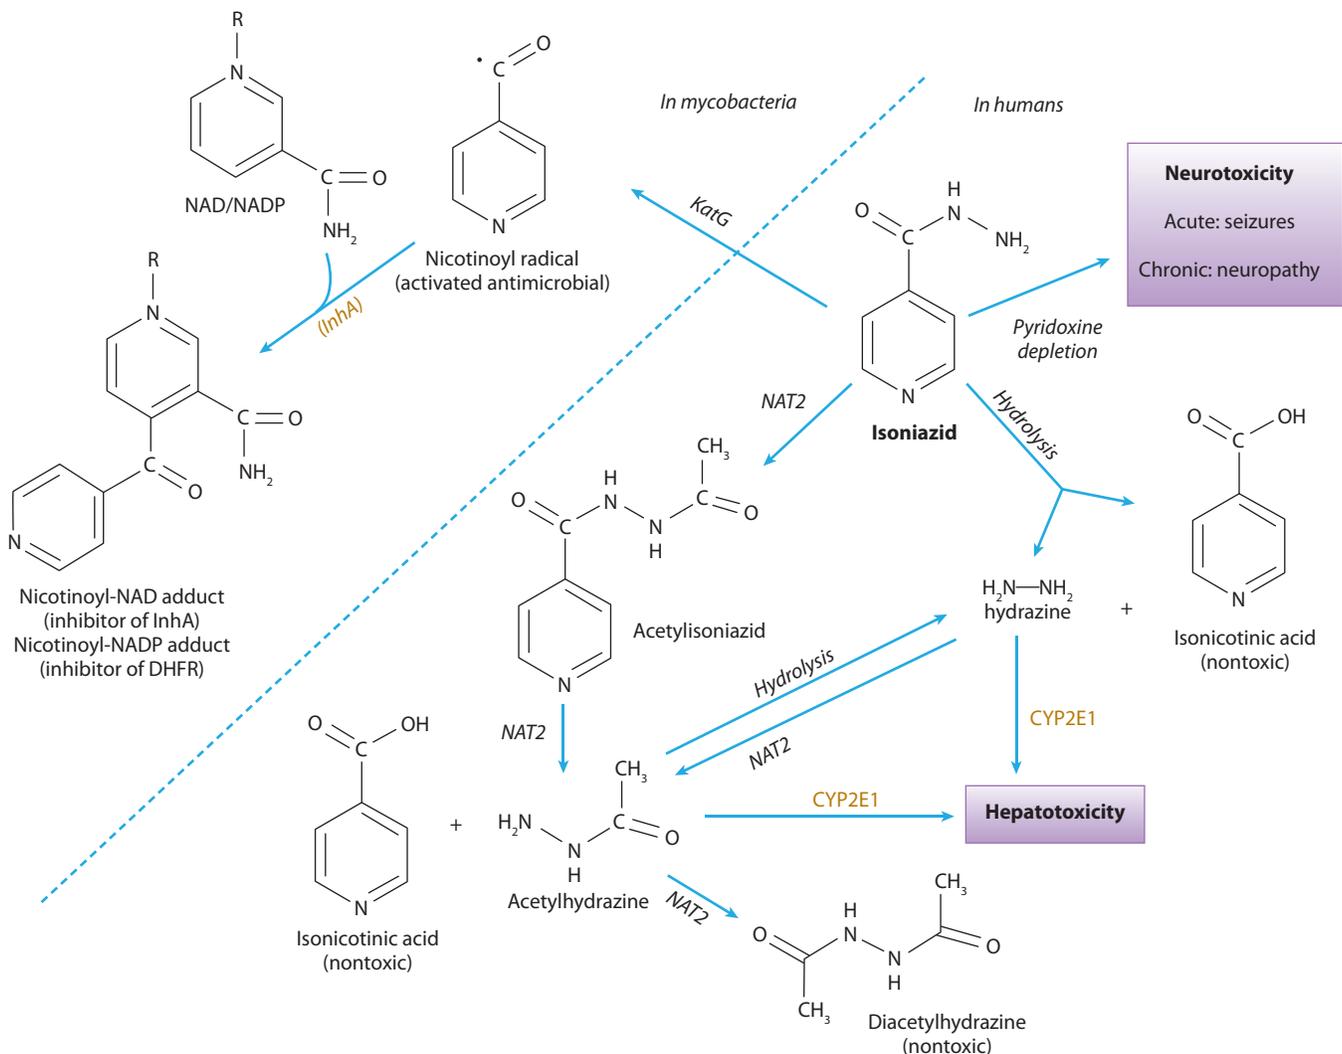

Isoniazid induces a functional pyridoxine deficiency via 2 main mechanisms (Fig. 56-3) and culminates in refractory seizures because of a relative lack of  $\gamma$ -aminobutyric acid (GABA), the primary inhibitory neurotransmitter in the central nervous system, and an excess of glutamate, the primary stimulatory neurotransmitter in the central nervous system (CNS). The GABA-glutamate

pathway establishes an equilibrium between the stimulatory, epileptogenic effects of glutamate against the inhibitory, sedative-hypnotic effects of GABA. Disruption of this homeostasis, with increased glutamate and insufficient GABA, is thought to be the etiology of INH-induced seizures.<sup>73</sup>

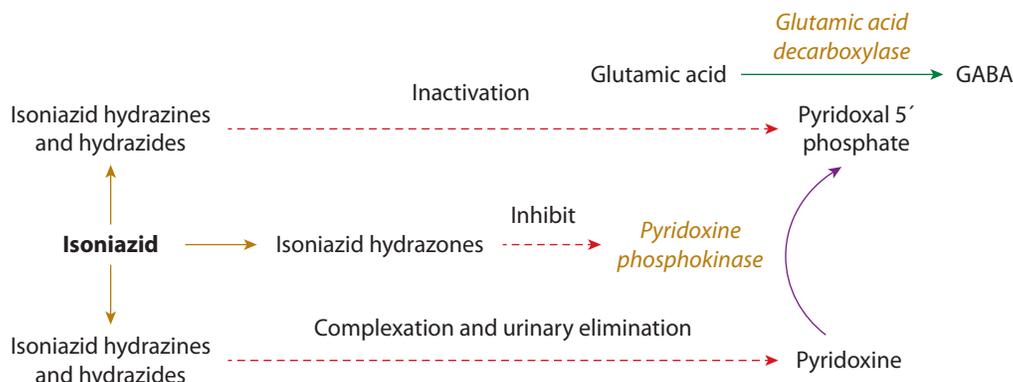

Pyridoxine is converted in vivo to an active form, pyridoxal-5'-phosphate, which serves as an important cofactor in many biotransformation reactions such as transamination, transketolation, and decarboxylation. Isoniazid metabolites inhibit the enzyme pyridoxine phosphokinase, which converts pyridoxine (vitamin B<sub>6</sub>) to its active form, pyridoxal-5'-phosphate, which is a required cofactor for many pyridoxine-dependent enzyme systems in the body, including 2 enzymes that control GABA metabolism.<sup>30,74,99</sup> Glutamic acid decarboxylase (GAD) catalyzes GABA synthesis from glutamate, and GABA aminotransferase degrades the inhibitory neurotransmitter. The inhibitory effects are greater on GAD, which leads to both decreased GABA and elevated glutamate concentrations.<sup>167</sup>

Pyridoxine depletion also decreases catecholamine synthesis and interferes with the synthesis of and/or reacts with NAD<sup>+</sup> to form inactive hydrazine adducts, thereby disrupting cellular reduction/oxidation reactions.

Pyridoxine depletion is further compounded when INH directly reacts with pyridoxal phosphate to produce an inactive hydrazone complex that is renally excreted and thereby increases loss of this required cofactor.<sup>99,164</sup> Urinary excretion of pyridoxine and its metabolites increases with increasing INH dose, reflecting the effect of INH on pyridoxine metabolism.

**FIGURE 56-2.** Metabolism of isoniazid (INH). INH metabolism occurs via enzyme *N*-acetyltransferase type 2 (NAT2), hydrolysis, and further oxidation via CYP2E1 into both nontoxic and hepatotoxic metabolites. Hepatotoxicity is multifactorial and occurs directly via hepatotoxic metabolites and indirectly via induced apoptosis and steatosis. DHFR = dihydrofolate reductase; InhA = mycobacterial enoyl-acyl carrier protein reductase; KatG = mycobacterial catalase peroxidase.

**FIGURE 56-3.** The effect of isoniazid on  $\gamma$ -aminobutyric acid (GABA) synthesis.

Structurally similar chemicals exert similar acute toxic effects. Monomethylhydrazine, a metabolite produced from gyromitrin isolated from the *Gyromitra* spp (“false morel”) mushroom, and the hydrazines used in liquid rocket fuel have a similar mechanism of action (Chap. 117).

### Interactions With Other Drugs and Foods

Drug–drug interactions associated with INH are mediated through alteration of hepatic metabolism of several CYP enzymes. The majority of these interactions are inhibitory, with decreased CYP-mediated transformations, particularly demethylation, oxidation, and hydroxylation (Chap. 11). Clinically relevant adverse effects with elevated concentrations of theophylline (CYP1A2), phenytoin (CYP2C9/CYP2C19), warfarin (CYP2C9/CYP2C19), valproic acid, and carbamazepine (CYP3A4) are caused by decreased hepatic metabolism of these xenobiotics.<sup>42,136,173</sup> The CYP2E1 cytochrome subtype, however, exhibits a complex response to INH called ligand stabilization, in which binding of CYP2E1 initially stabilizes and inhibits its function prior to inducing it. Eventual dissociation of INH from the enzyme active site creates an increased intracellular concentration of CYP2E1 available to metabolize potential substrates. The formation of the acetaminophen (APAP) metabolite responsible for toxicity, NAPQI (*N*-acetyl-*p*-benzoquinoneimine), is catalyzed by CYP2E1. Isoniazid-mediated effects in APAP-induced hepatotoxicity are uncertain because of differences in acetylator status (as described above), variations in CYP2E1 activity, and uncertainty regarding the time induction occurs relative to the time of INH ingestion.<sup>29,78,136</sup>

Ingestion of food decreases the absolute bioavailability of INH and also delays and lowers maximum drug concentration.<sup>122</sup> Additionally, INH interacts with numerous foods.<sup>136</sup> Isoniazid is a weak monoamine oxidase inhibitor; both tyramine reactions to foods (aged cheeses, wines) and serotonin toxicity from meperidine are reported in patients taking INH. Clinical effects include flushing, tachycardia, and hypertension.<sup>41,54,84,147</sup> Furthermore, INH inhibits the enzyme histaminase, leading to exacerbated reactions after the ingestion of histamine in scombrototoxic fish.<sup>68,98,136</sup> **Table 56-1** summarizes additional INH drug and food interactions.

### Pregnancy

Isoniazid is an FDA class C drug (animal studies demonstrate an adverse effect on the fetus, with no adequate human studies; potential benefits may warrant use of the xenobiotic in pregnancy), crosses the placenta, produces umbilical cord serum concentrations comparable to maternal serum concentrations, and is useful in the treatment of tuberculosis in pregnant patients.<sup>15,16,179</sup> Isoniazid daily or twice weekly is the preferred regimen, and coadministration of pyridoxine is strongly recommended.<sup>23</sup>

Mammalian teratogen studies suggest that INH is not a human teratogen, although fetal deformities after acute overdose of INH are reported.<sup>85,164</sup> Administration of INH to pregnant women was not associated with cancer in their offspring. Peak concentration in breast milk occurs approximately one to 3 hours after drug administration and calculated relative infant dose is 1.2% of weight-adjusted maternal dose.<sup>143</sup> Although INH readily and rapidly enters breast milk, breastfeeding during therapy is acceptable.<sup>126,164</sup>

## Clinical Manifestations of Isoniazid Toxicity

### Acute Toxicity

Isoniazid produces the triad of seizures refractory to conventional therapy, severe metabolic acidosis, and coma. These clinical manifestations appear as soon as 30 minutes after ingestion.<sup>66,72,154</sup> The case fatality rate of a single acute ingestion classically is as high as 20%.<sup>17,20</sup> Vomiting, slurred speech, dizziness, and tachycardia typically represent early manifestations of toxicity, though seizures are uncommonly the initial sign of acute overdose.<sup>88</sup> Seizures characteristically occur after the ingestion of greater than 20 mg/kg of INH and invariably occur with ingestions greater than 35 to 40 mg/kg. Patients with underlying seizure disorders are at risk of developing seizures at lower doses, and seizures are reported with initiation of a single therapeutic dose.<sup>17,112</sup> Hyperreflexia or hyporeflexia are an indicator for risk of INH-induced seizures. Consciousness will return between seizures, or status epilepticus occurs.<sup>35,104</sup> Because GABA, the primary inhibitory neurotransmitter, is depleted in acute INH toxicity, seizure activity is often refractory to typical anticonvulsant therapy, persisting until GABA concentrations are restored therapeutically.

Acute INH toxicity is often associated with seizures and an anion gap metabolic acidosis associated with a high serum lactate concentration. Typically, arterial pH ranges between 6.80 and 7.30, although survival in the setting of an arterial pH of 6.49 was reported.<sup>66</sup> Paralyzed animals poisoned with INH do not develop elevated lactate concentrations, a finding that suggests the lactate arises from intense muscular activity associated with seizures.<sup>30,105</sup>

In acute severe INH toxicity, coma as long as 24 to 36 hours is reported, persisting beyond both the termination of seizures and the resolution of acidemia. The cause of coma is unknown.<sup>13,66</sup> Additional sequelae from acute INH toxicity include rhabdomyolysis, acute kidney injury, hyperglycemia, glycosuria, ketonuria, hypotension, and hyperthermia.<sup>6,10,22,106,164,165</sup>

### Chronic Toxicity

Chronic therapeutic INH use is associated with a variety of adverse effects. Overall incidence of adverse reactions to INH is estimated to be 5.4%,<sup>62</sup> the most serious of which is hepatocellular necrosis.<sup>49</sup> Although asymptomatic elevation of aminotransferases is common in the first several months of treatment, the onset of hepatitis uncommonly presents up to one year after starting INH therapy. In 1978, after several deaths among patients receiving INH therapy, the US Public Health Service reported the incidence of clinically evident hepatitis as 1% of those taking INH; of that subgroup, 10% died, for an overall mortality rate of 0.1%.<sup>19,80</sup> Research performed since the resurgence of TB, however, identified a considerably lower rate of hepatotoxicity. Clinically manifest hepatitis occurred in only 11 patients in a population of 11,141 persons receiving INH and close monitoring, yielding an incidence of 0.1%.<sup>103</sup> Additional studies suggest that the death rate from INH hepatotoxicity is only 0.001% (2 of 202,497 treated patients).<sup>125</sup> Hepatotoxicity is associated with chronic overdose, increasing age, comorbid conditions such as malnutrition, and combinations of antituberculous drugs. Overt hepatic failure typically occurs when INH therapy is continued after the onset of hepatocellular

TABLE 56-1 Adverse Reactions and Drug Interactions of Antituberculous Drugs

Drug	Major Adverse Reactions	Drug Interactions Clinical Effect	Monitoring	Comments
Isoniazid (INH)	<i>Acute:</i> seizures, acidosis, coma, hyperthermia, oliguria, anuria <i>Chronic:</i> elevation of aminotransferases, autoimmune hepatitis, arthritis, anemia, hemolysis, eosinophilia, peripheral neuropathy, optic neuritis, vitamin B <sub>6</sub> deficiency (pellagra)	Rifampin, PZA, ethanol: hepatic necrosis Warfarin: increased INR Theophylline: tachycardia, vomiting, seizures, acidosis Phenytoin: increased phenytoin concentrations Carbamazepine: altered mental status Lactose: decreased INH absorption Antacids: decreased INH absorption Red wine/soft cheese: tyramine reaction Fish (scombroid): flushing, pruritus	Hepatic aminotransferases, ANA, CBC	HIV enteropathy may decrease absorption
Rifampin	<i>Acute:</i> diarrhea, periorbital edema <i>Chronic:</i> elevation of aminotransferases, reddish discoloration of body fluids	Protease inhibitors: decreased serum concentration of protease inhibitor Delavirdine: increased HIV resistance Cyclosporine: graft rejection Warfarin: decreased INR Oral contraceptives: ineffective contraception Methadone: opioid withdrawal Phenytoin: higher frequency of seizures Theophylline: decreased theophylline concentrations Verapamil: decreased cardiovascular effect	If administered with HIV antiretrovirals, viral titers should be followed. Hepatic aminotransferases; monitor serum concentrations of drugs (ie, phenytoin, cyclosporine) or clinical markers of efficacy (ie, INR)	Interactions of rifampin with several HIV medications are very poorly described; changes in dosing or dosing interval for both rifampin and antiretroviral drugs are commonly required; teratogenic
Ethambutol	<i>Chronic:</i> optic neuritis, loss of red–green discrimination, loss of peripheral vision		Visual acuity, color discrimination	Contraindicated in children too young for formal ophthalmologic examination
Pyrazinamide (PZA)	<i>Chronic:</i> elevation of aminotransferases, decreased urate excretion	INH: increased rates of hepatotoxicity (when extended courses or high-dose pyrazinamide used)	Hepatic aminotransferases	Courses of therapy of ≤2 months are recommended
Cycloserine	<i>Chronic:</i> depression, paranoia, seizures, megaloblastic anemia	INH: increased frequency of seizures	CBC, psychiatric monitoring	
Ethionamide	<i>Chronic:</i> orthostatic hypotension, depression	Cycloserine: increases CNS effects	Blood pressure, pulse, orthostasis	
<i>para</i> -Aminosalicylic acid	<i>Chronic:</i> malaise, GI upset, elevation of aminotransferases, hypersensitivity reactions, thrombocytopenia		Hepatic aminotransferases, CBC	
Capreomycin	<i>Chronic:</i> hearing loss, tinnitus, proteinuria, sterile abscess at IM injection sites		Audiometry, kidney function tests	

ANA = antinuclear antibodies; CBC = complete blood count; CNS = central nervous system; HIV = human immunodeficiency virus.

injury in both adults and children.<sup>45,46,63,91,142,170</sup> The incidence of hepatitis is 2 to 4 times higher in pregnant women than in nonpregnant women.<sup>52</sup>

Isoniazid-induced hepatitis arises via 2 pathways.<sup>45,172</sup> The first involves an immunologic mechanism resulting in hepatic injury that is thought to be idiopathic.<sup>131,164</sup> The association of hepatitis with lupus erythematosus, hemolytic anemia, thrombocytopenia, arthritis, vasculitis, and polyserositis supports an immunologic process.<sup>128,164</sup> However, symptoms commonly found in autoimmune disorders such as fever, rash, and eosinophilia are usually absent with drug-induced lupus erythematosus, and rechallenge with INH often fails to provoke recurrence of hepatocellular injury.<sup>45,128,172</sup> The second, more common, mechanism involves direct hepatic injury by INH or its metabolites. The metabolites believed most responsible for hepatic injury are acetylhydrazine and hydrazine (Fig. 56-2).<sup>56,101,155</sup>

Peripheral neuropathy and optic neuritis are known adverse drug effects of chronic INH use. The exact pathophysiology of isoniazid-induced neurotoxicity is not known, but is believed to be caused by pyridoxine deficiency aggravated by the formation of pyridoxine-INH hydrazones.<sup>47</sup> Peripheral neuropathy, the most common complication of INH therapy, presents in a

stocking-glove distribution that progresses proximally. Although primarily sensory in nature, myalgias and weakness are also reported.<sup>144</sup> Peripheral neuropathy is generally observed in severely malnourished, alcoholic, uremic, or diabetic patients; it is also associated with slow acetylator status, an effect that leads to increased INH concentrations and, consequently, increased pyridoxine depletion.<sup>59</sup> Optic neuritis is a central neurologic risk of isoniazid therapy which presents as decreased visual acuity, eye pain, and dyschromatopsia. Risk is greater when isoniazid is taken concurrent with other medications such as ethambutol or etanercept. Central scotomata and bitemporal hemianopsia occur on visual field testing in affected patients.<sup>60,72,79</sup> Isoniazid is also associated with such findings of CNS toxicity as ataxia, psychosis, hallucinations, and coma.<sup>2,11,58,124</sup>

### Diagnostic Testing

Acute INH toxicity is a clinical diagnosis that is inferred by history and confirmed by measuring serum INH concentrations.<sup>135</sup> Acute toxicity from INH correlates with serum INH concentration greater than 10 mg/L one hour after ingestion, greater than 3.2 mg/L 2 hours after ingestion, or greater than

0.2 mg/L 6 hours after the ingestion.<sup>104</sup> Because serum INH concentrations are not widely available, clinicians cannot rely on serum concentrations to confirm the diagnosis or initiate therapy. Because of the risk of hepatitis associated with chronic INH use, hepatic aminotransferases should be regularly monitored after therapy is started. In critically ill patients, serum should be assessed for acidemia, kidney function, creatine phosphokinase (CPK), and urine myoglobin, indicating rhabdomyolysis and possible acute kidney injury.

## Management

### Acute Toxicity

The antidote for INH-induced neurologic dysfunction is pyridoxine (Antidotes in Depth: A15). Pyridoxine rapidly terminates seizures, corrects metabolic acidosis, and reverses coma. The efficacy of pyridoxine is correlated with the administered dose; one study identified recurrent seizures in 60% of patients who received no pyridoxine and in 47% of those who received 10% of the ideal pyridoxine dose, and no seizures in patients who received the full dose of pyridoxine.<sup>163</sup> To treat acute toxicity, we recommend that the pyridoxine dose in grams should equal the amount of INH ingested in grams, with a first dose of up to 5 g intravenously in adults. Unknown quantities of ingested INH warrant initial empiric treatment with a pyridoxine dose of no more than 5 g (pediatric dose: 70 mg/kg to a maximum of 5 g). Pyridoxine should be administered at a rate of 1 g every 2 to 3 minutes. When patients have seizures that persist beyond administration of the initial dose, an additional similar dose of pyridoxine is recommended.<sup>7</sup>

Hospital pharmacies typically stock insufficient quantities of intravenous (IV) pyridoxine to treat even a single patient with a large INH ingestion.<sup>127</sup> In the event that IV formulations are unavailable in sufficient quantities, we recommend that pyridoxine tablets are crushed and administered with fluids via a nasogastric tube.<sup>127</sup>

Conventional antiepileptics, although generally used as first line therapy, demonstrate variable effectiveness in terminating INH-induced seizures. Benzodiazepines such as lorazepam or diazepam should be used to potentiate the antidotal efficacy of pyridoxine, particularly if optimal doses of the antidote are unavailable. The benzodiazepines act synergistically with pyridoxine, as well as possessing inherent GABA agonist activity, but they are often ineffective as the sole treatment of acute severe INH poisoning because of their reliance on GABA to exert their activity.<sup>31,32,72,163</sup> Phenytoin has no intrinsic GABAergic effect and is not recommended as therapy for patients with INH-induced seizures.<sup>72,104,121</sup> Barbiturates have potent direct and indirect GABA agonist activity and are expected to be as effective or more effective than the benzodiazepines. However, intubation may be required with use of barbiturates because of greater risk of respiratory depression with this class of antiepileptic. The efficacy of propofol in terminating INH-induced seizures is unstudied in humans, but is reasonable in cases of refractory status epilepticus.

Hemodialysis has clearance rates reported as high as 120 mL/min, but is rarely indicated for initial management of INH toxicity, unless kidney failure is present. In acute overdose, hemodialysis is not routinely recommended to enhance elimination but is reasonable following massive ingestion, when adequate supplies of pyridoxine are not available.<sup>22,146,164</sup>

It is recommended that asymptomatic patients who present to the emergency department within 2 hours of ingestion of toxic amounts of INH receive prophylactic administration of 5 g of oral or IV pyridoxine. This recommendation is based on the observation that INH reaches its peak serum concentration within 2 hours of ingestion of therapeutic doses. Asymptomatic patients should be observed for a 6-hour period for signs of toxicity. Acute toxicity is unlikely to manifest more than 6 hours beyond ingestion.

It is reasonable to perform early gastrointestinal (GI) decontamination by administering activated charcoal enterally by mouth to patients who are awake and able to comply with therapy or via nasogastric tube in intubated patients if no contraindications (which include absent bowel sounds, abdominal pain, abdominal distention).<sup>141</sup> Delayed absorption is uncommon. Late GI decontamination with activated charcoal is not reported to

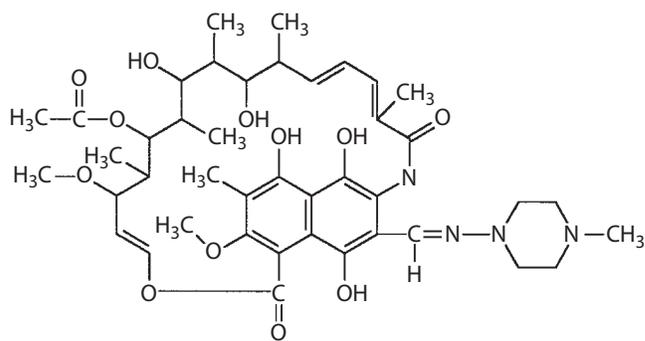

increase survival or decrease toxicity and is not recommended.<sup>133</sup> Orogastric lavage is not routinely recommended, but is reasonable shortly after a large INH ingestion.

### Chronic Toxicity

Hepatitis (defined as aminotransferase concentrations more than 2–3 times baseline) resulting from therapeutic INH administration mandates termination of therapy. After resolution of liver injury, it is appropriate to restart INH treatment, provided aminotransferase concentrations are closely monitored, with reassessment in 6 weeks or any time the patient experiences nausea, vomiting, or abdominal discomfort.<sup>45,142</sup> Pyridoxine does not reverse hepatic injury; consequently, surveillance for and recognition of hepatocellular injury remains essential. Cases of hepatitis refractory to medical therapy, requiring liver transplantation, are reported.<sup>48,67,170</sup> Research is ongoing to identify potential hepatoprotective supplements or medications to reduce INH-associated hepatotoxicity.

Isoniazid produces an axonopathy caused by pyridoxine depletion and manifests as peripheral neuropathies, cerebellar findings, and psychosis. Neurotoxicity is commonly treated with as much as 50 mg/day of oral pyridoxine, although doses as low as 6 mg/day are reportedly effective.<sup>2,11,124,149</sup> Because of its effectiveness in preventing neurologic toxicity, pyridoxine is often used concurrently with INH therapy. Coinfection with TB and HIV causes increased risk of pyridoxine deficiency and peripheral neuropathy with INH therapy, both before and after initiation of antiretroviral therapy, and pyridoxine supplementation should be initiated when peripheral neuropathy is evident.<sup>158</sup>

## RIFAMYCINS

Rifampin

### Pharmacology

Rifamycins are a class of macrocyclic antibiotics derived from actinomycete *Amycolatopsis mediterranei*. Xenobiotics in this class include rifampin (a semisynthetic derivative), rifabutin, and rifapentine, of which the first 2 are most commonly used.<sup>62</sup> Rifampin inhibits the initial steps in RNA chain polymerization through direct binding and formation of a stable drug enzyme complex with RNA polymerase. Disruption of RNA synthesis interrupts transcription and therefore inhibits protein synthesis, leading to cell death. Whereas mycobacterial RNA polymerase is susceptible to rifampin, eukaryotic RNA polymerase is not. High concentrations of rifamycin antibiotics, however, can affect mammalian mitochondrial RNA synthesis, as well as reverse transcriptases and viral DNA-dependent RNA polymerases.<sup>62</sup>

### Pharmacokinetics and Toxicokinetics

When administered orally, rifampin reaches peak serum concentrations in 0.25 to 4 hours; foods, but not antacids, interfere with absorption.<sup>109</sup> Rifampin is secreted into the bile and undergoes enterohepatic recirculation. Although the recirculating antibiotic is deacetylated, the metabolite retains antimicrobial activity. The half-life of rifampin, which is normally 1.5 to 5 hours, increases in the setting of hepatic dysfunction. Additionally, rifampin autoinduces its metabolism to shorten its half-life by approximately 40%. Rifampin is distributed widely into body compartments, and imparts a reddish color

to all body fluids, including the cerebrospinal fluid,<sup>62</sup> and in this setting was erroneously identified as xanthochromia suggesting subarachnoid hemorrhage to the clinician.<sup>72</sup> Because mycobacteria rapidly develop resistance to rifampin, it should not be used as the sole therapy against TB.<sup>62</sup>

In large overdose, elimination half-life is observed within the normal range expected after therapeutic dosing. Transient elevation of bilirubin occurs, and is typically attributed to inhibited hepatic excretion of bilirubin or interference with the bilirubin assay because of the reddish color imparted to all body fluids, including serum.<sup>166</sup> Rifampin therapy carries greater teratogenic risk than other antituberculous therapies, with 4.4% incidence of malformation. Anencephaly, hydrocephalus, and congenital limb abnormality and dislocations are reported.<sup>16,151</sup> Rifampin is associated with hemorrhagic disease of the newborn<sup>16</sup> but is nevertheless compatible with breastfeeding because only minute amounts of rifampin are secreted into breast milk.<sup>16,148</sup>

Rifampin and rifapentine are FDA pregnancy class C, whereas rifabutin is FDA pregnancy class B (animal studies failed to demonstrate risk to the fetus, and no adequate human studies in pregnant women).

### Drug–Drug Interactions

Rifamycins are potent inducers of CYP enzymes, which result in numerous drug interactions (Chap. 11). Of the rifamycins, rifampin has greater activity in inducing CYP3A4 than rifapentine; rifabutin has the least inductive activity of the class.<sup>86</sup> Rifampin also induces CYP1A2, CYP2C9, and CYP2C19.<sup>173</sup> Additionally, the ability of rifampin to induce CYP3A4 is strongly correlated with P-glycoprotein (P-gp) concentrations. P-glycoprotein is a transmembrane protein that functions as a cellular efflux pump of endogenous and exogenous xenobiotics; variations in expression of P-gp significantly affects the bioavailability of many xenobiotics and subsequent drug–drug interactions (Chaps. 9 and 11).<sup>50</sup> Concurrent administration of rifampin thus affects the metabolism of a wide array of drugs such as warfarin, cyclosporine, phenytoin, opioids, and oral contraceptives.<sup>50,138,173</sup> P-glycoprotein induction by rifampin is therefore responsible for a variety of pathophysiologic processes, including insufficient anticoagulation in patients receiving oral anticoagulants, acute graft rejection in transplant patients, graft versus host disease, difficulty controlling phenytoin concentrations, methadone withdrawal, and unplanned pregnancy. Effects arising from CYP3A4 induction begin within 5 to 6 days after rifampin is started and persist for up to 7 days after therapy is stopped.<sup>62</sup>

### Rifamycins and HIV

Coinfection with both TB and HIV is common, causing approximately 4 million deaths per year worldwide. Approximately one-third of all patients with HIV also have TB, and concurrent highly active antiretroviral therapy (HAART) and antituberculous therapy decrease mortality.<sup>161</sup> However, many factors influence the efficacy and feasibility of treating these illnesses. There is decreased absorption of nearly all antituberculous medications in patients with advanced HIV caused by chronic diarrhea, intestinal pathogens, and general malabsorption. Also, there are many drug–drug interactions between antituberculous and HIV medications caused by alterations in absorption, cytochrome enzymes, P-gp transporters, and noncytochrome metabolism.<sup>50,64,73,156</sup> This often creates additive toxicities that compromise efficacy as well as compliance. This is particularly true when combining rifamycins and HIV medications. Toxic manifestations of individual xenobiotics are frequently additive, such as combining nevirapine and rifampin, both of which have risk of skin rash and hepatitis. Caution should be exercised when combining therapies, and individual toxicities should be reviewed to avoid cumulative effects. **Table 56–1** lists common adverse effects and drug–drug interactions.

### Clinical Manifestations

#### Acute Toxicity

The most common side effects of acute rifampin overdose are GI in nature consisting of epigastric pain, nausea, vomiting, and diarrhea.<sup>45,62</sup> The presence of diarrhea distinguishes rifampin ingestion from overdose of other

antituberculous medications. At least 3 reported deaths are described from rifampin or rifampicin ingestion; an autopsy performed on one of these patients demonstrated the presence of pulmonary edema, although no causation was implied.<sup>14,77,111</sup> Other common effects include an anaphylactoid reaction manifested by flushing, urticarial rash, angioedema, and facial and periorbital edema. This occurs in both adults and children.<sup>71</sup> Central nervous system effects of overdose include fatigue, drowsiness, headache, dizziness, ataxia, confusion, and obtundation.<sup>175</sup> Anterior uveitis is occasionally observed, as are neurologic effects consisting of generalized numbness, extremity pain, ataxia, and muscular weakness.<sup>61</sup> Isolated rifamycin overdose infrequently produces serious acute effects.

#### Chronic Toxicity

When rifampin was originally introduced as an antituberculous medication, hepatitis occurred more frequently in patients taking combination therapy with INH than in those taking INH alone. These findings potentially arise from the ability of rifampin to induce cytochromes responsible for INH hepatotoxicity and not from direct hepatic injury by rifampin itself. Liver injury, when attributable to rifampin alone, is predominantly cholestatic, suggesting that clinical surveillance for hepatic injury is important as is regular biochemical monitoring.<sup>45,102</sup> Rifampin alters the metabolism of many other xenobiotics, including INH, pyrazinamide (PZA), and APAP, to increase their potential for hepatotoxicity.<sup>45,102</sup> Although some reports highlight increased compliance and typically mild and transient hepatotoxicity with combined rifampin and PZA treatment for latent TB infection, other recent studies suggest a significant risk of fatal hepatotoxicity, and the Centers for Disease Control and Prevention recommends generally avoiding this combination of drugs.<sup>94</sup>

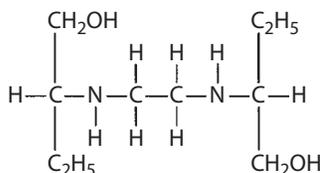

A hypersensitivity reaction that is associated with rifampin therapy presents with an influenzalike syndrome. The antituberculous drug-induced hypersensitivity syndrome, formerly called DRESS syndrome (drug rash with eosinophilia and systemic symptoms), occurs in up to 20% of patients receiving high doses or intermittent (less than twice weekly) dosing and includes fever, chills, myalgias, eosinophilia, hemolytic anemia, thrombocytopenia, or interstitial nephritis (Chap. 17).<sup>21,107</sup> Acute kidney injury is likely related to hypersensitivity, is rarely oliguric, and is usually self-limited; patients usually recover with supportive care, although rechallenge with rifampin should be undertaken only with caution.<sup>107</sup>

The concomitant administration of rifampin and protease inhibitors results in increased rates of arthralgias, uveitis, leukopenia, and skin discoloration. Identical side effects occurred during the simultaneous administration of rifampin and CYP3A4 inhibitors such as clarithromycin, suggesting that toxic effects arise from elevated serum rifampin concentrations.<sup>18</sup> Current recommendations are that rifampin not be given with protease inhibitors, except for ritonavir in rare circumstances. In patients already taking protease inhibitors, rifabutin is recommended in place of rifampin.<sup>110</sup>

#### Diagnostic Testing and Management

Management of patients with acute rifampin overdose is primarily observational and supportive. Stabilization of vital signs is usually adequate, although clinicians should remain vigilant for toxicity from coingestants. Activated charcoal is reasonable, but not routinely recommended. For chronic toxicity, recognition of interactions between rifampin and other xenobiotics is critical. Hepatic function should be monitored because of the ability of rifampin to augment the hepatotoxicity of other xenobiotics. Treatment for hepatic injury involves withholding rifampin therapy and reassessing the appropriateness of other xenobiotics administered to the patient. Influenzalike symptoms and acute kidney injury secondary to rifampin characteristically respond to decreasing the interval between administration of the medication.<sup>107</sup> Although rifampin interacts with protease inhibitors, the utility of therapeutic drug monitoring is uncertain because the correlation of clinical events with serum concentrations of rifampin and antiretroviral drugs is unknown.<sup>18</sup>

## ETHAMBUTOL

### Pharmacology

Ethambutol is bacteriostatic against *Corynebacterium*, *Mycobacterium*, and *Nocardium* (CMN group) bacteria. It is most effective against mycobacteria, specifically *M. tuberculosis* and *Mycobacterium kansasii* as well as some other strains. Although it is a first-line tuberculostatic medication for TB, it is ineffective in monotherapy.<sup>132</sup>

Ethambutol inhibits arabinosyl transferases, interfering with biosynthesis of arabinogalactan and liparabinomannan, thus inhibiting polymerization of arabinose subunits within the arabinoglycan layer of mycobacterial cell walls.<sup>62,77</sup> Specifically, it blocks apical cell wall synthesis, blocking elongation growth but not cell division.<sup>132</sup>

### Pharmacokinetics

Only the D(+) isomer is used therapeutically because the L(-) isomer is the major contributor to optic neuritis, but both enantiomers are bactericidal.<sup>137</sup> Ethambutol is taken up rapidly by growing cells, where bacteriostatic effects appear approximately 24 hours after incorporation by mycobacteria.<sup>62</sup> About 80% of an oral dose is absorbed, but both foods and antacids decrease absorption.<sup>18,62</sup> Maximum serum concentrations are reached within 4 hours of oral administration and are proportional to the dose. Ethambutol is approximately 20% to 30% protein bound and has a half-life of 4 to 6 hours.<sup>62,83</sup> Three-fourths of a standard dose is excreted unchanged in the urine by a combination of glomerular filtration and tubular secretion. Ethambutol clearance decreases with age, and this drug accumulates in patients with impaired glomerular filtration rate (GFR), making adjustments in dosing necessary in patients of advanced age or with kidney disease.<sup>37,62</sup> Increasingly, mutations in the *Mycobacterium embB* gene confer resistance to ethambutol, as high as 14.2%, with acquired resistance reaching nearly 40%.<sup>77</sup>

Ethambutol is FDA pregnancy class C, and is considered safe for use during pregnancy as a first-line medication. Although a 2.2% incidence of congenital abnormalities was identified in women receiving ethambutol therapy, no consistent pattern of abnormalities occurred in their offspring.<sup>16</sup> Although ethambutol is excreted into breast milk in approximately a 1:1 ratio with serum, it is considered to be compatible with breastfeeding.<sup>16</sup>

### Clinical Manifestations and Management

Acute overdose of ethambutol is generally well tolerated, although at least one death is reported.<sup>76</sup> More commonly, nausea, abdominal pain, confusion, visual hallucinations, and optic neuropathy occur after acute ingestions of greater than 10 g.<sup>44</sup> Stabilization of vital signs is recommended, and although GI decontamination with activated charcoal was a hallmark of therapy, it is not routinely recommended. Clinicians must remain vigilant for coingestants, particularly INH. Hemodialysis is not recommended as treatment for multidrug ingestions including ethambutol.<sup>44</sup>

Although peripheral neuropathy and cutaneous reactions occur during chronic therapy, the most significant effect of the therapeutic use of ethambutol is unilateral or bilateral ocular toxicity presenting typically as painless blurring of vision, cecentral scotomas (at and around the blind spot in the central field), and less commonly with decreased perception of color, and loss of peripheral vision. Ethambutol-induced optic neuropathy (EON) is largely dose and duration related and is typically reversible with drug discontinuation.<sup>27,34,157</sup> Optic neuritis develops in approximately 15% of patients receiving 50 mg/kg/day, 5% of patients receiving 25 mg/kg/day, and fewer than 1% of those receiving 15 mg/kg/day.<sup>107</sup> Patients develop ocular toxicity within 2 days of starting ethambutol and as long as 2 years after starting therapy. Age less than 60 years confers significantly greater likelihood

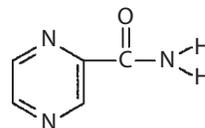

of full recovery with drug discontinuation.<sup>150</sup> The loss of peripheral vision and color discrimination that accompanies the optic neuropathy caused by ethambutol distinguishes this condition from the optic neuropathy secondary to INH.<sup>72,107</sup> Management of chronic toxicity from ethambutol involves cessation of therapy.

Ethambutol is a strong metal chelator, and inactivation of zinc and copper is believed to be related to its induction of retinal cell vacuoles and enlarged lysosomes. This interferes with membrane permeability, causing abnormal cell function and cell death.<sup>34,81</sup> The visual abnormalities induced by ethambutol are similar to those caused by a hereditary condition known as Leber optic neuropathy. Both ethambutol and Leber hereditary optic neuropathy affect oxidative phosphorylation through impairment of mitochondrial function.<sup>33,81</sup> Ethambutol appears to mimic this condition by binding intracellular copper, altering mitochondrial function, and producing neuronal injury.<sup>69,81</sup> Alternatively, alteration in zinc metabolism is believed to cause optic neuritis via progressive degeneration and irreversible neuronal destruction due to chelation of intracellular zinc, inducing vacuolar degeneration in retinal cultures.<sup>34</sup> The effect of this injury is a shift in the threshold for wavelength discrimination without changing the absolute sensitivity of the cone system, which leads to a loss of red-green discrimination.<sup>145</sup>

### Diagnostic Testing and Management

All patients should receive neuroophthalmic testing before ethambutol therapy. The use of visual evoked potentials is especially useful in identifying subclinical optic nerve disease. Furthermore, patients should receive regular visual acuity examinations, and clinicians should encourage patients to report any subjective visual symptoms. The use of ethambutol is relatively contraindicated in children who are unable to comply with an ophthalmic examination.<sup>72,107</sup>

## PYRAZINAMIDE

### Pharmacology and Pharmacokinetics

Pyrazinamide is a structural analog of nicotinamide with a mechanism of action similar to that of INH. Similar to INH, PZA is a prodrug. Pyrazinamide requires deamidation to anionic pyrazinoic acid by pyrazinamidase, an endogenous cytoplasmic bacterial enzyme. In acidic conditions, PZA has enhanced antibacterial function, becoming protonated to the uncharged, active form, 5-hydroxypyrazinoic acid, which enters the cell, accumulates, and kills the bacteria by disruption of mycolic acid biosynthesis. Pyrazinamide is also active at neutral pH under certain conditions of decreased metabolism such as reduced temperature, which will facilitate drug susceptibility testing.<sup>70</sup> Pyrazinamide is effective against both active and dormant bacteria, and its use in antituberculous regimens shortens the course of therapy; however, resistance rapidly develops if it is used as single-agent therapy, and it should therefore only be used with other antituberculous medications.<sup>62</sup> After oral administration, pyrazinamide is rapidly absorbed, with maximum concentrations occurring within 1 to 2 hours of administration, and a half-life of approximately 9 hours. Hepatic metabolism to pyrazinoic acid and 5-hydroxypyrazinoic acid occurs with the metabolites subsequently renally excreted.<sup>62</sup> Drug clearance of PZA increases with continuing therapy, causing decreased serum pyrazinamide concentration within 1 to 2 months.<sup>37</sup> Pyrazinamide is synergistic with rifampin and has the greatest efficacy if administered during the first 2 months of treatment with both INH and rifampin; this regimen effectively shortens the treatment course to only 6 months.<sup>176</sup>

When introduced in the 1950s, PZA was administered in doses of 40 to 50 mg/kg for extended periods of time. The dosages produced clinical hepatitis, with manifestations of highly elevated aminotransferase and bilirubin concentrations. Of patients taking high-dose PZA, elevations in

aminotransferases were identified in 20%, and symptomatic hepatitis was identified in 10%, with a small number of those who developed hepatitis dying from a fulminant hepatic failure. As a result of these findings, PZA was believed to be highly hepatotoxic, and its use was discouraged. The resurgence of multidrug-resistant mycobacteria, however, has forced clinicians to reconsider using PZA. Modern dosing regimens of 30 mg/kg for brief courses of 2 months infrequently produce hepatic injury, with some studies suggesting that addition of PZA to multidrug TB regimens confers no additional risk for hepatotoxicity.<sup>45</sup>

Pyrazinamide is FDA pregnancy class C, but is rarely used in pregnancy because the risk of poorly defined birth defects. There are examples of diagnosed patients diagnosed with tuberculosis in the first trimester (12 weeks) treated with a multidrug regimen including pyrazinamide who carried the pregnancy to term without any apparent complications.<sup>55</sup> Animal studies suggest that PZA has no teratogenicity at therapeutic doses.<sup>1</sup> Pyrazinamide is minimally excreted into breast milk and is presumed safe for breastfeeding.<sup>16</sup>

### Diagnostic Testing

Proper dosing of PZA and short courses of therapy are the 2 most important factors in preventing toxicity. Treatment for hepatotoxicity involves cessation of PZA therapy in conjunction with supportive care.<sup>45</sup> Pyrazinamide inhibits the renal excretion of uric acid, and hyperuricemia results. More than 90% of children treated with short courses developed elevated uric acid concentrations.<sup>130</sup> Most patients, regardless of age, remain asymptomatic and do not develop symptoms of gout. Toxic effects from acute overdose of PZA have not been reported.

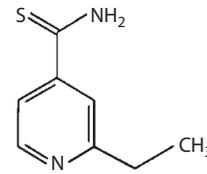

### CYCLOSERINE

Cycloserine, previously avoided because of its adverse effects, is being used increasingly as second-line treatment with other tuberculostatic medications when treatment with primary antituberculous medications (INH, rifampin, ethambutol, and streptomycin) fail or as initial therapy when drug susceptibility testing indicates either MDR-TB or XDR-TB. Cycloserine is a structural analog of alanine and demonstrates inhibition of D-alanine racemase and D-alanine ligase, which are involved in peptidoglycan cell wall synthesis.<sup>65</sup> After oral doses, 70% to 90% of the drug is absorbed, and peak concentrations are reached in 3 to 8 hours. Cycloserine is distributed throughout all tissues and body fluids and easily crosses the blood–brain barrier. Less than 35% of the cycloserine is metabolized, and remaining xenobiotic is excreted unchanged in the urine.<sup>62,178</sup>

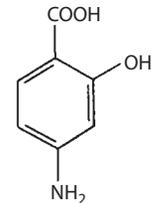

Toxicity is dose dependent and occurs in as many as 50% of patients taking cycloserine. Cycloserine is a partial agonist at the NMDA/glycine receptor, which contributes to neurologic effects such as somnolence, headache, tremor, dysarthria, vertigo, confusion, irritability, and seizures.<sup>65</sup> Psychiatric manifestations include paranoid reactions, depression, and suicidal ideation. Reversible hypersomnolence and asterixis are reported with cycloserine, suggesting reversible thalamic neurotoxicity, which is corroborated by magnetic resonance imaging.<sup>82</sup> Cycloserine is contraindicated in patients with a history of either seizures or depression. Whenever this drug is used, monitoring serum concentrations is recommended. Optimal treatment concentrations are between 20 and 35 mg/dL, and adverse effects are more common above 30 mg/dL. Cycloserine should be introduced slowly to avoid CNS toxicity.<sup>72,107,178</sup> Toxicity usually appears within the first 2 weeks of therapy and ceases upon discontinuation. Potentiation of toxicity due to ethanol consumption has been described. Because cycloserine is renally excreted, patients with impaired GFR are at increased risk of toxicity; it is removed by hemodialysis.<sup>178</sup> Cycloserine is FDA pregnancy class C. Although no teratogenic effects were noted in 3 women exposed to cycloserine during the first trimester of pregnancy, cycloserine is not recommended for use during pregnancy. Cord blood concentrations are approximately 70% of serum concentrations, and no adverse effects occurred in breastfed infants. Consequently, cycloserine is considered to be safe in women who are breastfeeding.<sup>16</sup> Reports of cycloserine overdose are scarce; however, use of peritoneal dialysis was reported in one case of intentional cycloserine ingestion in a woman

who had previously undergone a unilateral nephrectomy, with observation of improvement in CNS effects and effective decrease in serum concentrations of cycloserine.<sup>4</sup> In patients with evidence of CNS toxicity from cycloserine overdose and impaired renal function, it is reasonable to consider extracorporeal drug-removal.

### OTHER ANTITUBERCULOUS MEDICATIONS

Ethionamide

*para*-Aminosalicylic acid

### ETHIONAMIDE

Ethionamide, a congener of INH, is a prodrug converted to its active form, thioamide-S-oxide, by the bacterial cell by a flavoprotein monooxygenase enzyme. Ethionamide-S-oxide is believed to be further metabolized into another cytotoxic metabolite. These mycotoxic intermediary metabolites are thought to have a similar mechanism of action as INH, causing cell death from disruption of mycolic acid biosynthesis.<sup>160</sup> Ethionamide is rapidly absorbed, widely distributed, and crosses the blood–brain barrier. Oral doses yield peak serum concentrations within approximately 3 hours of administration. The half-life is approximately 2 hours. The most common adverse symptoms associated with ethionamide are GI irritation and anorexia. Toxic effects such as orthostatic hypotension, depression, and drowsiness are common. Rash, purpura, and gynecomastia are observed, as are tremor, paresthesias, and olfactory disturbances. It is structurally similar to methimazole, and thyroid dysfunction has occurred in several patients.<sup>93</sup> Approximately 5% of patients receiving ethionamide develop hepatitis. Patients using this medication should be screened intermittently for hepatic injury and thyroid function. Treatment for toxicity involves withholding ethionamide therapy.<sup>62</sup>

Ethionamide is FDA pregnancy class C. Birth defects were observed in 7 of 23 newborns exposed to ethionamide in utero, although a consistent pattern of anomalies was lacking. Data regarding the incidence and safety of breastfeeding while receiving ethionamide also are lacking.<sup>16</sup> Ethionamide is too toxic to be used as first-line therapy, but when needed, it should only be administered with another antituberculous medication because resistance develops rapidly when ethionamide is used alone.<sup>62</sup> Reports of ethionamide overdose are absent from the literature.

### *para*-AMINOSALICYLIC ACID

*para*-Aminosalicylic acid (PAS) is a structural analog of *para*-aminobenzoic acid and appears to be a prodrug, acting as a metabolic precursor that is incorporated into the folate pathway, by dihydropteroate synthase (DHPS) and dihydrofolate synthase (DHFS) to generate a toxic hydroxyl dihydrofolate antimetabolite analog, which then inhibits dihydrofolate reductase (DHFR).<sup>177</sup> This inhibition occurs in mycobacteria but not in other organisms.<sup>62</sup> Despite common adverse effects, PAS is one of the last remaining available drugs effective against XDR-TB.<sup>43</sup> *para*-Aminosalicylic acid is readily absorbed from the gut and is rapidly distributed in all tissues, especially the pleural fluid and caseous material. A population based determination of volume of distribution was 79 L in a study of adult volunteers.<sup>28</sup> *para*-Aminosalicylic acid has a half-life of approximately one hour and is renally excreted. Adverse effects of PAS occur in 10% to 30% of patients and include anorexia, nausea, vomiting, diarrhea, sore throat, and malaise. Between 5% and 10% of patients receiving PAS develop hypersensitivity reactions characterized by high fever, rash, and arthralgias. Hematologic abnormalities of agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, and acute hemolytic anemia are reported.<sup>62</sup> *para*-Aminosalicylic acid was removed by hemodialysis in patients with kidney

failure in small amounts, but is of uncertain clinical use.<sup>90</sup> Adverse effects associated with chronic therapy are typically treated by termination of use. Data regarding the safety of PAS in pregnancy and breastfeeding are lacking.<sup>16</sup> Reports of PAS overdose are absent from the literature.

### Capreomycin

Capreomycin is a cyclic polypeptide currently used more frequently because of its antibacterial activity against MDR-TB and intracellular TB bacilli. Strains of *Mycoplasma* that are resistant to more than one aminoglycoside are characteristically susceptible to this polypeptide. Capreomycin interferes with ribosomes and inhibits protein translation but also appears to act by other mechanisms such as alterations in topoisomerase or the glyoxylate shunt pathway.<sup>53</sup> Because of poor absorption after oral dosing, capreomycin must be administered intramuscularly. Toxicity associated with capreomycin use includes tinnitus, hearing loss, proteinuria, and electrolyte disturbances, although severe acute kidney injury is rare. Risk of toxicity is increased in patients with chronic kidney disease and the elderly.<sup>117</sup> Eosinophilia, leukocytosis, and rashes are described. Pain and sterile abscesses at the site of capreomycin injection are reported.<sup>62</sup> Capreomycin is FDA pregnancy class C. Data are lacking regarding the safety of capreomycin in pregnancy and breastfeeding.<sup>16</sup> Capreomycin overdose is not described.

## BEDAQUILINE

### Pharmacology and Pharmacokinetics

Bedaquiline is a diarylquinoline that received conditional approval in 2012 by the US Food and Drug Administration for the treatment of MDR-TB.<sup>51</sup> It exerts its antituberculous effects via inhibition of mycobacterial ATP synthase.<sup>3</sup> Bedaquiline is relatively slowly absorbed after oral administration, with peak plasma concentrations achieved at 4 to 6 hours.<sup>39,119</sup> Absorption is enhanced approximately 2-fold when bedaquiline is taken with food.<sup>51</sup> Bedaquiline is more than 99% protein bound and has an estimated volume of distribution of 164 L in adults.<sup>159</sup> Bedaquiline is metabolized primarily by CYP3A4 via demethylation to the biologically active *N*-desmethyl bedaquiline, which has 3- to 6-fold lower antimycobacterial activity than its parent compound; CYP2C8 and 2C19 are also implicated in bedaquiline metabolism to a lesser extent.<sup>87</sup> Bedaquiline is primarily excreted in the feces.<sup>36</sup> The terminal half-life for bedaquiline and *N*-desmethyl bedaquiline is estimated to be 5.5 months, likely reflecting prolonged redistribution from tissues.<sup>38</sup> Bedaquiline overdose has not been described. Bedaquiline is FDA pregnancy class B.

### Adverse Effects

In pooled clinical trials, the most frequently reported adverse effects included nausea, vomiting, headache, arthralgias; additional adverse effects included dizziness, elevated aminotransferases, myalgias, diarrhea, and QT interval prolongation.<sup>51</sup> Notably, one phase 2 clinical trial (C208 Stage 2) revealed an increased number of deaths in the group receiving bedaquiline (10 of 79) as compared to the placebo group (2 of 81) when bedaquiline was added to standard antituberculous regimen.<sup>40</sup> However, there were no sudden deaths reported, no association between plasma concentration of bedaquiline and mortality, and no clear pattern in the causes of death; the reason for the mortality imbalance remains unclear awaiting the results of further safety trials.<sup>40,168</sup>

### Recommended Dosing

The current recommended bedaquiline regimen for treatment of MDR-TB consists of a 2-week loading dose of 400 mg daily, then 200 mg 3 times a week to complete a 24-week course.<sup>51</sup>

### Drug–Drug Interactions

Concomitant administration with rifamycins increases clearance of bedaquiline 5-fold, and significantly decreases serum concentration of bedaquiline; this practice should be avoided pending further evaluation of the safety profile of bedaquiline.<sup>153,168</sup> Similarly, the planned use of bedaquiline in patients who are taking antiretrovirals that are strong CYP3A4 inducers, such as efavirenz, will likely require alteration of the antiretroviral regimen.<sup>168</sup> Bedaquiline should be used with caution in patients who are also taking medications

that inhibit CYP3A4, as these are expected to lead to higher serum concentration of bedaquiline and potential resultant toxicity; there are currently no data regarding appropriate dose adjustments in these situations.<sup>168</sup>

### Monitoring

Monitoring of serum potassium, magnesium and calcium concentrations, as well as aminotransferases (AST and ALT), is recommended at baseline and then monthly thereafter while taking bedaquiline.<sup>168</sup> Because of the dysrhythmogenic effects due to QT interval prolongation, an ECG should be obtained prior to initiation of treatment with bedaquiline, and at weeks 2, 4, 8, 12, and 24 after starting treatment.<sup>168</sup> Monthly ECGs are recommended in patients taking bedaquiline concurrently with other QT interval prolonging xenobiotics.<sup>168</sup>

Reports of overdose are lacking from the medical literature.

## DELAMANID

Delamanid, a nitro-dihydro-imidazo-oxazole derivative, is a new antituberculous medication that received conditional approval in 2014 from the European Medicines Agency and the Japanese drug regulatory authority; it is not currently approved by the FDA.<sup>120</sup> Delamanid is a prodrug and requires activation by mycobacterial nitroreductase Rv3547.<sup>92</sup> It exerts its effects by inhibiting synthesis of methoxymycolic and ketomycolic acids resulting in destabilization of the mycobacterial cell wall; in contrast with INH, it does not inhibit  $\alpha$ -mycolic acid synthesis.<sup>92</sup>

The pharmacologic profile of delamanid has yet to be satisfactorily determined. Delamanid is administered orally, and absorption is enhanced when it is taken with food.<sup>57</sup> It is poorly water soluble, and more than 99% protein bound, with a large  $V_d$  over 2,000 L in adults.<sup>89,123</sup> Its metabolism is complex and shows significant interspecies variation: in humans, the 6-nitro-2,3-dihydro-imidazo-oxazole moiety is cleaved by plasma albumin to form the metabolite DM-6705, which is then degraded by multiple metabolic pathways, primary of which is hydroxylation and subsequent oxidation by CYP3A4.<sup>129,139</sup> Delamanid has a plasma half-life of 38 hours.<sup>57</sup>

Delamanid does not inhibit or induce CYP enzymes *in vitro*; its metabolites demonstrate some inhibition of CYP enzymes but only at concentrations much higher than would be encountered in clinical use.<sup>140</sup>

The recommended delamanid regimen is 100 mg orally twice daily for 24 weeks.<sup>168</sup> Adverse effects reported with delamanid therapy include nausea, vomiting, tinnitus, headache, palpitations, and QT interval prolongation.<sup>57,168</sup> Because of its potential dysrhythmogenic effects due to QT interval prolongation, an ECG should be obtained before initiation of treatment with delamanid, and at weeks 2, 4, 8, 12, and 24 after starting treatment.<sup>168</sup> Monthly ECGs are recommended in patients taking delamanid concurrently with other QT interval prolonging xenobiotics. Delamanid overdose is not described in the literature.

Many other antibiotics and immunomodulators that were overlooked or rejected for the management of TB are increasingly being used as part of multidrug regimens against resistant strains. Discussed more extensively in Chap. 54, these include fluoroquinolones such as ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin, sparfloxacin; macrolides such as clarithromycin, aminoglycosides such as amikacin, streptomycin, kanamycin; interferon, amoxicillin–clavulanate, linezolid, and clofazimine.<sup>100</sup>

Additionally, as the prevalence of drug-resistant tuberculosis continues to increase, one novel strategy that has emerged involves the development of adjunctive therapies to enhance the effectiveness of existing medications.<sup>118</sup> *In vitro* and animal experiments have demonstrated the efficacy of a small molecule transcriptional repressor to enhance the conversion of the prodrug ethionamide to its active metabolite and to reverse acquired ethionamide resistance and clear ethionamide-resistant mycobacterial infection in mice.<sup>8</sup> By developing therapeutics to activate alternate mycobacterial transcription pathways and augment conversion of prodrugs within the target organism, this innovative approach may increase antimycobacterial activity without increasing risk of systemic toxicity to humans and may help to circumvent the mycobacterial enzyme mutations that underlie resistance to many antituberculous medications.

## SUMMARY

- Certain antituberculous medications are potentially fatal in overdose.
- Patients acutely poisoned with INH require immediate and appropriate action to terminate seizures, with the specific antidote pyridoxine, commonly augmented by benzodiazepines.
- Although less common than previously believed, hepatocellular injury resulting from therapeutic dosing of INH requires regularly scheduled, frequent evaluations to prevent fulminant hepatic failure.
- With the increasing prevalence of MDR-TB and XDR-TB strains, antituberculous medications previously avoided or ignored are now being used typically in combination with 2 or more other antituberculous medications. Despite reduced dosages compared with those previously used, significant adverse effects remain a concern.
- Rifampin participates in numerous drug–drug interactions, some involving several antiretroviral therapies. Because antituberculous medications are commonly needed in HIV-infected patients, potential interactions between rifampin and antiretrovirals should remind clinicians to remain vigilant for unanticipated adverse effects.
- Patients receiving ethambutol, pyrazinamide, and other antituberculous medications benefit from careful surveillance for specific adverse effects such as decreased visual acuity, hepatic injury, and psychiatric manifestations. Despite the toxicity of this class of medications, rapid recognition of toxicity is typically responsive to intervention.

## PYRIDOXINE

Mary Ann Howland

**INTRODUCTION**

Pyridoxine (vitamin B<sub>6</sub>), a water-soluble vitamin, is an antidote for overdoses of isonicotinic acid hydrazide (isoniazid, INH), *Gyromitra esculenta* mushrooms, hydrazine, methylated hydrazines, and ethylene glycol. With the exception of ethylene glycol, all of these xenobiotics produce seizures by the competitive inhibition of pyridoxal-5'-phosphate (PLP). Pyridoxine overcomes this inhibition. For ethylene glycol poisoning, it enhances a less toxic metabolic pathway to form benzoic and hippuric acid, instead of oxalic acid.<sup>6</sup> Hydrazine and methylated hydrazines (1,1-dimethylhydrazine, UDMH; monomethylhydrazine, MMH) are used as rocket fuels, and MMH is also found in *G. esculenta* mushrooms.<sup>3</sup>

**HISTORY**

Pyridoxine deficiency, which is characterized by seborrheic dermatitis, cheilosis, stomatitis, and glossitis, was first identified in 1926 but was mistakenly attributed to riboflavin (vitamin B<sub>2</sub>) deficiency (Chap. 44).<sup>32</sup> Ten years later, the deficiency was fully characterized and correctly recognized as a deficiency of vitamin B<sub>6</sub>.<sup>32</sup> A rare genetic abnormality that produces pyridoxine-responsive seizures in newborns was described in 1954.<sup>5</sup>

**PHARMACOLOGY****Chemistry**

The active form of pyridoxine is PLP.<sup>32</sup> The alcohol pyridoxine, the aldehyde pyridoxal, and the aminomethyl pyridoxamine are all naturally occurring, related compounds that are metabolized by the body to its active form PLP.<sup>32</sup> Pyridoxine was chosen by the Council on Pharmacy and Chemistry to represent vitamin B<sub>6</sub>.<sup>32</sup> Pyridoxine hydrochloride was chosen as the commercial preparation because of its stability.<sup>59</sup> Pyritinol is a semi-synthetic pyridoxine analogue of 2 vitamin B<sub>6</sub> compounds linked by a disulfide bridge.

**Mechanism of Action**

Pyridoxal-5'-phosphate is an important cofactor in more than 100 enzymatic reactions, including decarboxylation and transamination of amino acids, and the metabolism of tryptophan to 5-hydroxytryptamine (serotonin) and methionine to cysteine.<sup>24,32</sup> In animals, iatrogenic pyridoxine deficiency produces seizures, resulting from reduced brain concentrations of PLP, glutamic acid decarboxylase, and  $\gamma$ -aminobutyric acid (GABA).<sup>17</sup>

Isoniazid and methylated hydrazines such as MMH interfere with the normal function of pyridoxine as a coenzyme. Isoniazid produces a syndrome resembling vitamin B<sub>6</sub> deficiency, which results in seizures.<sup>47</sup> Specifically, INH and other hydrazides and hydrazines inhibit the enzyme pyridoxine phosphokinase that converts pyridoxine to PLP (Fig. 56-3).<sup>24</sup> In addition, hydrazides directly combine with PLP, causing inactivation through the production of hydrazones that are rapidly excreted by the kidney.<sup>24,59</sup> Isoniazid also impairs lactate conversion to pyruvate.<sup>16</sup> Pyridoxal-5'-phosphate is a coenzyme for L-glutamic acid decarboxylase, which facilitates the synthesis of GABA from L-glutamic acid. Pyridoxal-5'-phosphate is also a necessary cofactor for

serum glutamic-oxaloacetic transaminase (SGOT, also known as aspartate transaminase, AST), which generates L-glutamic acid from  $\alpha$ -ketoglutarate, and for GABA transaminase, which converts GABA to succinic semialdehyde. Animal studies suggest that interference with PLP limits the formation of GABA,<sup>24,54,55</sup> which results in increased glutamic acid, thereby reducing cerebral inhibition and enhancing cerebral excitation, which contributes to the INH- and methylated hydrazine-induced seizures.<sup>44,57</sup> The administration of large doses of pyridoxine overcomes the deficiency.

**Pharmacokinetics**

Pyridoxine is not protein bound, has a volume of distribution of 0.6 L/kg, and easily crosses cell membranes, whereas PLP is nearly entirely plasma protein bound.<sup>59</sup> At extrahepatic sites, pyridoxine is rapidly metabolized to pyridoxal, PLP, and 4-pyridoxic acid, with only 7% excreted unchanged in the urine.<sup>59</sup> After intravenous (IV) infusion of 100 mg of pyridoxine, PLP concentration increases rapidly in serum and in erythrocytes.<sup>59</sup> Pyridoxal-5'-phosphate rises from 37 to 2,183 nmol/L in serum and from undetectable to 5,593 nmol/L in erythrocytes.<sup>59</sup> Oral pyridoxine, in doses of 600 mg, is 50% absorbed within 20 minutes of ingestion by a first-order process, with rapid achievement of peak serum concentrations of pyridoxine, PLP, and pyridoxal.<sup>58</sup> The concentration of PLP appears to be tightly controlled in the serum and related to alkaline phosphatase activity.<sup>25,58</sup> Oral doses of pyridoxine from 10 to 800 mg result in PLP concentrations of 518 to 732 nmol/L at 4 hours after ingestion.<sup>58</sup> Chronic alcoholic patients have lower baseline serum PLP concentrations because acetaldehyde enhances the degradation of PLP in erythrocytes through stimulation of an erythrocyte membrane-bound phosphatase that hydrolyzes phosphate-containing B<sub>6</sub> compounds.<sup>31</sup>

**ROLE IN HYDRAZIDE- AND HYDRAZINE-INDUCED SEIZURES****Animal Studies**

In a canine model of INH-induced toxicity, pyridoxine reduced the severity of seizures, increased the duration of seizure-free periods, and prevented death from a previously determined lethal dose of INH in a dose-dependent fashion.<sup>13,14</sup> Lower molar ratios prevented deaths, and higher molar ratios prevented both deaths and seizures.<sup>14</sup> When used as single treatments for INH-induced seizures, phenobarbital, pentobarbital, phenytoin, ethanol, and diazepam were ineffective in controlling seizures and death, but when combined with pyridoxine, each protected the animals from seizures and death.<sup>13</sup> Other small animal experiments document the effectiveness of pyridoxine against MMH-induced seizures when used without<sup>24,37,50</sup> and with diazepam.<sup>20</sup> Anticonvulsant efficacy is also demonstrated in feline<sup>46</sup> and primate<sup>48</sup> models.

Rat studies with intraperitoneal UDMH also demonstrate the protective effects of pyridoxine, which prevented seizures and death in a model that produced 94% mortality and 100% seizures without pyridoxine.<sup>15</sup> Other studies in dogs and monkeys also demonstrate the effectiveness of pyridoxine in preventing seizures and mortality, and in treating seizures.<sup>4</sup> Intramuscular pyridoxine protected the monkeys from death and stopped the seizures caused by IV exposure to UDMH.

**Human Data**

Clinical experience with pyridoxine for INH overdose in humans demonstrates favorable results.<sup>2,11</sup> Rapid seizure control without morbidity or

mortality was achieved when the ratio in grams of pyridoxine administered to INH ingested ranged from 0.14 to 1.3, although in practice, most patients receive approximately gram-for-gram amounts. In 5 patients, the use of gram-for-gram amounts of pyridoxine resulted in the complete control of seizures and a resolution of the metabolic acidosis.<sup>53</sup> In 8 patients with intentional INH overdoses, basic poison management, intensive supportive care, and a mean dose of 5 g of pyridoxine IV resulted in no fatalities.<sup>8</sup> Seizures were controlled in a 22-month-old boy given 100 mg of IV pyridoxine after an estimated INH ingestion of 5 g.<sup>47</sup> Variable results are reported when lesser amounts of pyridoxine are used.<sup>34</sup> Seizures were reported in 2 patients after ingestion of INH–pyridoxine combination tablets, although the actual amount of pyridoxine ingested was not reported.<sup>49</sup> The failure to provide pyridoxine may result in persistent INH-associated seizures that do not respond to anticonvulsants.<sup>45</sup>

In addition to controlling seizures, administration of pyridoxine also appears to restore consciousness. Two patients, who remained obtunded for as long as 72 hours after the apparent resolution of the seizures, were reported to awaken immediately after 3 to 10 g of IV pyridoxine was administered.<sup>10</sup> A third patient who was lethargic awakened with IV pyridoxine. This suggests that mental status abnormalities associated with INH overdose (and possibly hydrazine overdoses) are responsive to pyridoxine and support repetitive dosing.<sup>11,53</sup> Patients treated with large doses of pyridoxine awaken more rapidly even after experiencing sustained seizure activity or status epilepticus.

Monomethylhydrazine poisoning is encountered in a variety of clinical situations. In the aerospace industry, where MMH is used as a rocket propellant, percutaneous or inhalational poisoning occurs. Ingestion of the false morel mushroom, *G. esculenta*, also produces toxicity when its major toxic compound, gyromitrin, is metabolized to MMH (Chap. 117).<sup>3,19</sup>

The neurologic effects of MMH poisoning are similar to those of INH toxicity and include seizures and respiratory failure.<sup>17</sup> Severe liver damage similar to INH induced hepatotoxicity is also described.<sup>9</sup> As in the case of INH-induced hepatotoxicity, there is no evidence that MMH-induced hepatotoxicity is treated by administration of pyridoxine.<sup>9</sup>

A patient who was exposed to hydrazine became comatose 14 hours later and remained comatose for 60 hours until treated with 25 mg/kg of pyridoxine.<sup>26</sup> A man with an altered consciousness who had ingested an unknown quantity of hydrazine improved after treatment with 10 g of pyridoxine.<sup>23</sup> This improvement occurred over 24 hours and may have been unrelated to pyridoxine therapy. A severe sensory peripheral neuropathy lasting for 6 months developed one week after the overdose and was most likely a result of the hydrazine ingestion and not the pyridoxine. Six patients exposed to an Aerozine-50 (1:1 mixture of hydrazine:UDMH) spill were effectively treated with pyridoxine 200 to 400 mg after developing twitching, clonic movements, hyperactivity, or gastrointestinal symptoms.<sup>20</sup> A patient exposed to UDMH during an explosion developed extensive burns, diverse neurologic manifestations, and electroencephalographic findings that resolved rapidly after the administration of IV pyridoxine.<sup>18</sup>

## ROLE IN ETHYLENE GLYCOL POISONING

Pyridoxal-5'-phosphate is a cofactor in the conversion of glycolic acid to nonoxalate compounds (Chap. 106) (Fig. 106–2). We recommend that patients poisoned with ethylene glycol should receive 100 mg/day of pyridoxine IV in an attempt to shunt metabolism preferentially away from the production of oxalic acid. This approach is supported by an animal model<sup>6</sup> and the study of primary hyperoxaluria,<sup>22</sup> although there are no adequate studies of human ethylene glycol poisoning.<sup>39</sup>

## ADVERSE EFFECTS AND SAFETY ISSUES

Pyridoxal-5'-phosphate is neurotoxic to animals and humans when administered chronically in supraphysiologic doses.<sup>26,28,40</sup> Delayed peripheral neurotoxicity occurred in patients taking daily doses of 200 mg to 6 g of pyridoxine for one month.<sup>38,43,44</sup> Healthy volunteers given 1 or 3 g/day developed a small- and large-fiber distal axonopathy, with sensory findings and quantitative

sensory threshold abnormalities occurring after 1.5 months at the high dose and 4.5 months at the low-dose exposure. When symptoms occurred, the pyridoxine was immediately stopped, but symptoms progressed for 2 to 3 weeks (Chap. 22).<sup>7</sup>

Pyridoxine also induces a sensory neuropathy when massive doses are administered, either as a single dose or over several days.<sup>1,27,52</sup> Ataxia occurred in dogs receiving 1 g/kg of pyridoxine.<sup>52</sup> Larger doses of pyridoxine result in loss of coordination, ataxia, seizures, and death.<sup>48</sup> Death after pyridoxine administration was sometimes delayed for 2 to 3 days.<sup>52</sup>

Two patients treated with 2 g/kg of IV pyridoxine (132 and 183 g, respectively) over 3 days developed severe and disabling sensory neuropathies.<sup>1</sup> One year later, both patients were still unable to walk. Inadequate information is available to determine the maximal single acute nontoxic dose in humans; however, there appears to be a wide margin of safety. Doses of pyridoxine ranging from 70 to 375 mg/kg or doses equivalent to the milligram-per-kilogram historical dose of ingested INH are routinely administered without adverse effects.<sup>29,53</sup>

The 0.5% chlorobutanol preservative in IV pyridoxine equates to doses of 250 to 500 mg of chlorobutanol when 5 and 10 g doses of pyridoxine are administered. Chlorobutanol is a sedative with a long elimination half-life, but doses of 600 mg were given to human volunteers without complication.<sup>12,51</sup> A dose of 5 g IV pyridoxine administered over 5 minutes to 5 healthy volunteers produced a transient minor increase in base deficit without any alteration in the level of consciousness.<sup>30</sup>

## PREGNANCY AND LACTATION

Pyridoxine is Food and Drug Administration pregnancy category A. The recommended daily allowance for pyridoxine in pregnancy is 2.2 mg. Pyridoxine is routinely used in higher milligram doses (10 mg daily or up to 25 mg every 8 hours) for the treatment of hyperemesis gravidarum.<sup>33</sup> Although there has never been a controlled trial in pregnant women of gram doses of pyridoxine, the benefit of using pyridoxine for INH-induced seizures would clearly exceed the theoretical risk to the fetus. Pyridoxine enters breast milk and is considered compatible with breastfeeding when 10–25 mg doses are ingested. However, concentrations of pyridoxine in breast milk after maternal gram doses of pyridoxine are not known and it is reasonable to be concerned for the infant.

## DOSING AND ADMINISTRATION

A safe and effective pyridoxine regimen for INH overdoses in adults is 1 g of pyridoxine for each gram of INH ingested, or 70 mg/kg in a child both to an initial maximum of 5 g.<sup>53</sup> The dose in children is unclear because there are so few children reported in the literature who were treated with IV pyridoxine and the history of ingested amount of INH is unreliable. Extrapolation from canine studies serve as a warning to avoid doses that approach 1 g/kg which risk pyridoxine toxicity. The gram for gram dosing of pyridoxine to INH up to 5 g in an adult or 70 mg/kg in children up to the adult dose is sufficient in the majority of patients.<sup>35</sup> The best way to administer pyridoxine in a patient after an INH overdose is not established. For a patient who is actively seizing, it is reasonable to give pyridoxine by slow IV infusion at approximately 0.5 g/min until the seizures stop or the maximum dose is reached. When the seizures stop, it is reasonable to infuse the remainder of the dose over 4 to 6 hours to maintain pyridoxine availability while the INH is being eliminated.<sup>35</sup> The dose should be repeated if seizures persist or recur or if the patient exhibits mental status depression, which could be an indication of persistent neurotoxicity, nonconvulsive status epilepticus, or a postictal phase. If IV pyridoxine is unavailable, oral pyridoxine should be administered.<sup>42,56</sup>

For hydrazine and methylated hydrazine (ie, MMH, UDMH) poisoning, there is no established dose.<sup>57</sup> Using the same dosage regimen as in the case of INH poisoning is reasonable and appropriate, although it is not tested in humans.

Benzodiazepines and barbiturates are synergistic with pyridoxine and should be used in addition to pyridoxine in rapid escalation to abort INH-induced seizures.

## FORMULATION

Pyridoxine hydrochloride is available parenterally at a concentration of 100 mg/mL with a 1-mL fill in a 2-mL vial with 0.5% chlorobutanol as the preservative and 1.4 mcg/mL aluminum from Frensenius Pharmaceuticals.<sup>41</sup> Thus, a 5-g IV dose of pyridoxine requires fifty 100-mg/mL vials. This is an exception to the rule that appropriate doses of medications rarely require multiple vials and certainly not of this magnitude. This quantity also emphasizes the necessity of maintaining an adequate supply in the emergency department as well as in the pharmacy.<sup>36</sup> Oral pyridoxine is available in many tablet strengths from 10 to 500 mg depending on the manufacturer.

## SUMMARY

- Pyridoxine and a benzodiazepine to achieve synergistic control of INH or MMH poisoning.
- An adequate dose of IV pyridoxine is 70 mg/kg to a maximum of 5 g. It is reasonable to treat recurrent seizures or a persistent depressed metal status with 1 to 2 additional doses and doses approaching 1 g/kg should be avoided.
- Five grams of IV pyridoxine requires administration of fifty 100-mg/mL vials.
- Adequate stocks should be ensured in the emergency department and pharmacy.
- If IV pyridoxine is unavailable, oral pyridoxine should be used.

## ANTIDYSRHYTHMICS

Maryann Mazer-Amirshahi and Lewis S. Nelson

## HISTORY AND EPIDEMIOLOGY

The term *dysrhythmia* encompasses an array of abnormal cardiac rhythms that range in clinical significance from merely annoying to instantly life threatening. The word *arrhythmia* can be defined as a lack of rhythm. Some references state they are synonyms for irregular heartbeat, and others define arrhythmia as irregular heartbeat and dysrhythmia as a disturbance to an otherwise normal rhythm. Throughout the text, we have chosen the term *dysrhythmia*. Antidysrhythmics include all medications that are used to treat any of these various dysrhythmias. The importance of dysrhythmia management in the modern practice of medicine cannot be overstated because dysrhythmias are among the most common causes of preventable sudden cardiac death.<sup>52</sup>

For many years, antidysrhythmics were considered among the most rational of the available cardiac medications. This well-earned reputation related to their high efficacy at reducing the incidence of malignant dysrhythmias. Similarly, they are effective at controlling extrasystoles which cause patient discomfort or anxiety. However, this approach changed dramatically following publication of the Cardiac Arrhythmia Suppression Trials (CAST and CAST II)<sup>28</sup> and more recently with the rise of mechanical interventions, such as ablation therapy and implantable defibrillators. Cardiac Arrhythmia Suppression Trials assessed the ability of three antidysrhythmics to suppress asymptomatic ventricular dysrhythmias considered to be harbingers of sudden death. The original CAST was discontinued in 1989 before completion, when encainide and flecainide, two of the study medications, not only failed to prevent sudden death but actually increased overall mortality. The CAST II noted similar problems with moricizine.<sup>102</sup> It is clear that the enhanced mortality associated with many antidysrhythmics is a result of their pro-dysrhythmogenic effects and that virtually all medications of this group carry such risk. Because most patients with atrial fibrillation do not benefit from rhythm conversion compared with control of the ventricular response rate, the use of antidysrhythmics for this indication is less common but is still useful in some populations.<sup>91</sup>

In addition to the predictable, mechanism-based adverse effect of each medication, unique and often unanticipated effects also occur.<sup>87</sup> Experience with overdose of many of these medications is limited, and management is generally based on the underlying pharmacologic principles, existing case reports, and the experimental literature. This chapter focuses on the medications that serve primarily as antidysrhythmics and, with the exception of lidocaine (found in Chap. 64), have few other medicinal indications. Chap. 15 provides a more detailed description of the electrophysiology of dysrhythmias and a discussion of their genesis. In addition, the toxicities from  $\beta$ -adrenergic antagonists and  $Ca^{2+}$  channel blockers, which have indications in addition to dysrhythmia control, are discussed separately in Chaps. 59 and 60. The toxicology of cardioactive steroids such as digoxin is discussed in Chap. 62.

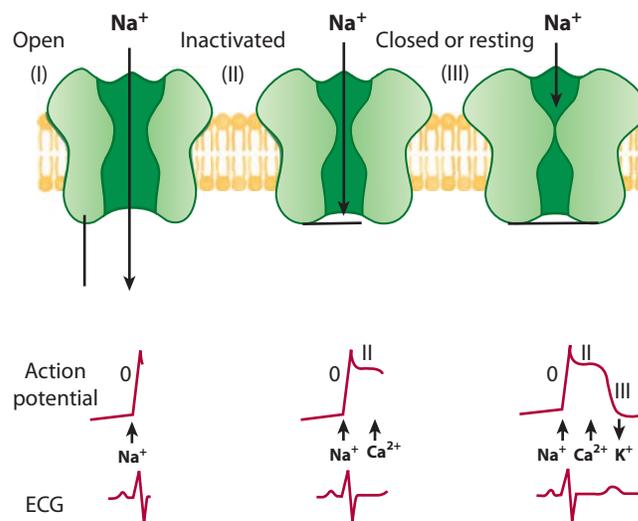

## CLASSIFICATION OF ANTIDYSRHYTHMICS

Despite an incomplete understanding of the underlying mechanisms of dysrhythmia formation, an abundance of antidysrhythmics were developed, each attempting to alter specific electrophysiologic components of the cardiac impulse generating or conducting system.

Antidysrhythmics modify impulse generation and conduction by interacting with various membrane  $Na^+$ ,  $K^+$ , and  $Ca^{2+}$  channels. Generally,

antidysrhythmics manifest electrophysiologic effects either through alteration of the channel pore or, more commonly, by modification of its gating mechanism (Fig. 57-1). Unfortunately, given their exceedingly complex mechanisms of action, the descriptive terms used to explain their molecular actions are not always completely accurate. For example, the description of an antidysrhythmic as a specific “channel blocker,” although representative of the conceptual action of that medication, is inaccurate because in most cases, the molecule does not actually block the channel but rather prevents the channel from opening or closing properly. Furthermore, many of these medications are active nonspecifically at other channels or on other cells, resulting in divergent clinical actions of those similarly classified.

The Vaughan-Williams classification of antidysrhythmics by electrophysiologic properties emphasizes the connection between the basic electrophysiologic actions and the antidysrhythmic effects.<sup>103</sup> Although initially proposed as a descriptive model for electrophysiologic actions and not for clinical effects, the Vaughan-Williams classification is commonly invoked as a user-friendly guide to clinical therapy. A more rational classification would match the electrophysiologic effects of the antidysrhythmics with their molecular interactions on different regions of the various ion channels, such as channel gating and pore conductance.

**FIGURE 57-1.** Sodium channel blockade. On appropriate signal,  $Na^+$  channel activation occurs, at which time the  $Na^+$  channel converts from the resting (III) state to the open state (I). This allows  $Na^+$  influx to initiate phase 0 of the action potential, or cellular depolarization. The  $Na^+$  channels subsequently assume the inactivated state by closure of an inactivation gate; this is a voltage-dependent phenomena and occurs concomitantly with, although more slowly than, channel activation. Cellular depolarization is maintained for a period of time by other ion channels that form the plateau of the action potential. Before reactivating,  $Na^+$  channels must convert back to the resting state, which also occurs in a voltage-gated fashion. Many antidysrhythmics stabilize the inactivated state of the channel and, by slowing conversion to the resting state, prevent its reopening, reducing the excitability of the cell. Because this is a population phenomenon, there are dose-dependent effects on channel blockade; thus, more xenobiotics interfere with more channels. Interestingly, certain xenobiotics, such as ciguatoxin and aconitine, stabilize the open state of the  $Na^+$  channel and produce persistent depolarization. ECG = electrocardiogram.

This discussion of antidysrhythmics uses the Vaughan Williams classification, recognizing its shortcomings.<sup>109</sup> The pharmacokinetic properties of the various medications are summarized in Table 57–1.

## CLASS I ANTIDYSRHYTHMICS

All antidysrhythmics in Vaughan-Williams class I (A, B, and C) alter Na<sup>+</sup> conductance through cardiac voltage-gated, fast inward Na<sup>+</sup> channels (Table 57–1). These xenobiotics bind to the Na<sup>+</sup> channels and slow their recovery from the open or inactivated state to the resting state (Fig. 57–1). This conversion must occur before the channel can reopen and participate in another depolarization. Consequently, as the proportion of

medication-bound Na<sup>+</sup> channels increases, fewer of these channels are capable of reactivation on the arrival of the next depolarizing impulse. As a result, by reducing the excitability of the myocardium, abnormal rhythms are both prevented and terminated.

Blockade of these Na<sup>+</sup> channels slows the rise of phase 0 of the cellular action potential, which correlates with a reduction in the rate of depolarization of the myocardial cell (or V<sub>max</sub>). Similarly, conduction through the myocardium is slowed, producing a measurable prolongation of the QRS complex on the surface electrocardiogram (ECG). Correspondingly, slowed intramyocardial conduction is associated with reduced contractility, manifesting as negative inotropy. Myocardial depression also results from effects

**TABLE 57–1** Antidysrhythmics: Pharmacology, Pharmacokinetics, and Adverse Effects

Antidysrhythmic	Route	Primary Route of Elimination	Elimination Half-Life	Channel Blockade	Volume Distribution L/Kg	Protein Binding (%)	Adverse Effects and Complicating Factors	Other
<b>Class IA</b>								
Disopyramide	PO	Liver, kidney	Variable	Na <sup>+</sup> , (τ = 9 s), K <sup>+</sup> , Ca <sup>2+</sup>	0.59 ± 0.15	35–95 depending on plasma concentration	CHF, negative inotropic effects, anticholinergic, torsade de pointes, heart block, hypoglycemia QRS and QT prolonged	
Procainamide	IV, PO	50%–60% unchanged in kidney; active hepatic metabolite (NAPA)	PA: 3–4 h ↑ CKD NAPA: 6–10 h ↑ CKD	Na <sup>+</sup> (τ = 1.8 s), K <sup>+</sup>	1.9 ± 0.3	16 ± 9	Hypotension (ganglionic blockade), QRS and QT prolonged, fever, SLE-like syndrome, Torsade de pointes	NAPA: active metabolite, renally eliminated, K <sup>+</sup> channel blocker; half-life, 6–10 h A sustained-release PA preparation is available
Quinidine	PO	Liver, kidney, 10%–20% unchanged	6–8 h ↑ liver disease (to >50 h) and CKD (to 9–12 h)	Na <sup>+</sup> (τ = 3 s), K <sup>+</sup> , Ca <sup>2+</sup>	2.7 ± 1.2	87 ± 3	Heart block, sinus node dysfunction QRS and QT prolonged hypotension, hypoglycemia, torsade de pointes, thrombocytopenia, ↑ [digoxin]	
<b>Class IB</b>								
Lidocaine	SC, IV, PO (30% BA)	Liver, active metabolite (MEGX CYP3A4)	Distribution 8 min after bolus Terminal elimination, 2 h	Na <sup>+</sup> (τ = 0.1 s)	1.1 ± 0.4	70 ± 5	Fatigue, agitation, paresthesias, seizures, hallucinations, rarely bundle branch block	Metabolites: GX and MEGX are less potent as Na <sup>+</sup> channel blockers than lidocaine.
Mexiletine	IV, PO	Liver (CYP 2D6)	10–24 h	Na <sup>+</sup> (τ = 0.3 s)	4.9 ± 0.5	63 ± 3	See lidocaine	
Phenytoin	IV, PO	Liver		Na <sup>+</sup> (τ = 0.2 s)	0.64 ± 0.04	89 ± 23	Hypotension and asystole related to IV propylene glycol infusion, nystagmus, ataxia	
Tocainide	IV, PO	Kidney, liver	9–14 h	Na <sup>+</sup> (τ = 0.4 s)	3.0 ± 0.2	10 ± 15	See lidocaine; aplastic anemia, interstitial pneumonia	
<b>Class IC</b>								
Flecainide	IV, PO	Liver (CYP2D6), 75%; kidney, 25%	20 h	Na <sup>+</sup> (τ = 11 s), Ca <sup>2+</sup> , K <sup>+</sup>	4.9 ± 0.4	61 ± 10	Negative inotropic effects, bradycardia, heart block, ventricular fibrillation, ventricular tachycardia, neutropenia QT prolonged	Two major metabolites, one with minor activity, meta-O-dealkylated flecainide; and inactive meta-O-dealkylated lactam of flecainide
Moricizine	PO	Liver	2–4 h	Na <sup>+</sup> (τ = 10 s)	?	95	↑ Mortality after myocardial infarction, bradycardia, CHF, ventricular fibrillation, ventricular tachycardia

Digoxin	IV	(Chap. 62)						
Magnesium Sulfate		(Antidotes in Depth: A16)						

$\tau_{\text{recovery}}$  describes the time it takes for the Na<sup>+</sup> channel to recover from blockade.

ACh = acetylcholine; AV = atrioventricular; BA = bioavailable; BP = blood pressure; CHF = congestive heart failure; CKD = chronic kidney disease; GX = glycine xylidide; IV = intravenous; NAPA = *N*-acetylprocainamide; MEGX = monoethylglycylxylidide; PO = oral; SC = subcutaneous; PA = procainamide.

of reduced intracellular  $\text{Na}^+$  on the  $\text{Na}^+\text{-Ca}^{2+}$  exchange mechanism.<sup>73</sup> This in turn reduces the intracellular  $\text{Ca}^{2+}$  concentration, which is required for adequate contractility.

The differences among class I antidysrhythmics are directly related to their pharmacologic relationships with the  $\text{Na}^+$  channel. However, it is noteworthy that the original subdivision of class I antidysrhythmics was based on clinical observations, not current pharmacologic awareness, accounting for the somewhat illogical ordering of the class I subdivisions.<sup>109</sup> Type IB antidysrhythmics have their highest affinity for inactivated  $\text{Na}^+$  channels. This occurs at the end of depolarization, during early repolarization, and during periods of myocardial ischemia, all situations in which the myocardium is partially depolarized. These xenobiotics also have rapid “on-off” binding kinetics (rapid  $\tau_{\text{recovery}}$ ) and are thus bound only briefly, during late electrical systole, the period during which the  $\text{Na}^+$  channels are predominantly in the inactivated form. They are almost exclusively unbound during electrical diastole, which is the major portion of the cardiac cycle at normal heart rates. However, the degree of binding increases as the heart rate accelerates because the duration of diastole decreases, and the relative proportion of time spent in systole increases; this is termed *use dependence*. Because all IB antidysrhythmics do not bind to activated  $\text{Na}^+$  channels, in therapeutic doses they do not affect the rate of rise of phase 0 of the action potential, or  $V_{\text{max}}$ , and have no effect on the ECG. Alternatively, the class IC antidysrhythmics either act preferentially on activated  $\text{Na}^+$  channels or they release from the  $\text{Na}^+$  channels very slowly (slow  $\tau_{\text{recovery}}$ ) and thus are still bound during the next cardiac cycle. This prolonged channel blockade and reduced channel reactivation results in both greater pharmacologic effects and toxicity, even at slow heart rates. These xenobiotics reduce  $V_{\text{max}}$  and prolong the QRS complex. Class IA antidysrhythmics fall between the other two subclasses.

Although in the Vaughan-Williams classification all class I antidysrhythmics are considered primarily  $\text{Na}^+$  channel blockers, many, particularly those in class IA, have important effects on cardiac  $\text{K}^+$  channels. These channels are critical to maintenance of the cardiac action potential and repolarization of the myocardial cell. Slowing of  $\text{K}^+$  efflux prolongs the duration of the action potential and accounts for the persistence of refractoriness, or the time during which the cell is incapable of redrepolarization. This effect produces QT interval prolongation and predisposes to the triggering of polymorphic ventricular tachycardia (torsade de pointes).<sup>53</sup> Because class IB antidysrhythmics have no effect on myocardial  $\text{K}^+$  channels, they do not alter refractoriness or the QT interval. In fact, class IB antidysrhythmics often reduce the action potential duration, shortening refractoriness. Further discussion of  $\text{K}^+$  channel blockade is found in Chap. 15 and later in the discussion of class III antidysrhythmics.

### Class IA Antidysrhythmics: Procainamide, Quinidine, and Disopyramide

#### Procainamide (Fig. 57–2)

Procainamide is used to suppress either atrial or ventricular tachydysrhythmias. Importantly, procainamide undergoes hepatic biotransformation by acetylation to *N*-acetylprocainamide (NAPA), the rate of which is genetically determined, and rapid acetylators are prone to developing toxicity.<sup>76</sup> Although NAPA lacks the  $\text{Na}^+$  channel–blocking activity of procainamide, it prolongs the action potential duration through blockade of the  $\text{K}^+$  rectifier currents and is independently responsible for the production of cardiac dysrhythmias.<sup>45</sup>

Rapid intravenous (IV) dosing of procainamide is potentially dangerous because its initial volume of distribution is smaller than its final volume of distribution. Because this initial compartment includes the heart, adverse myocardial effects occur unexpectedly. In addition, procainamide exhibits ganglionic-blocking properties, which produce profound hypotension with rapid IV administration. Thus, to prevent toxicity during medication infusion, the IV loading dose is administered by slow infusion with ECG monitoring. Both procainamide and NAPA are renally eliminated and accumulate in patients with chronic kidney disease (CKD).<sup>67</sup>

Although the chronic use of procainamide is commonly accompanied by the development of antinuclear antibodies and infrequently progresses to

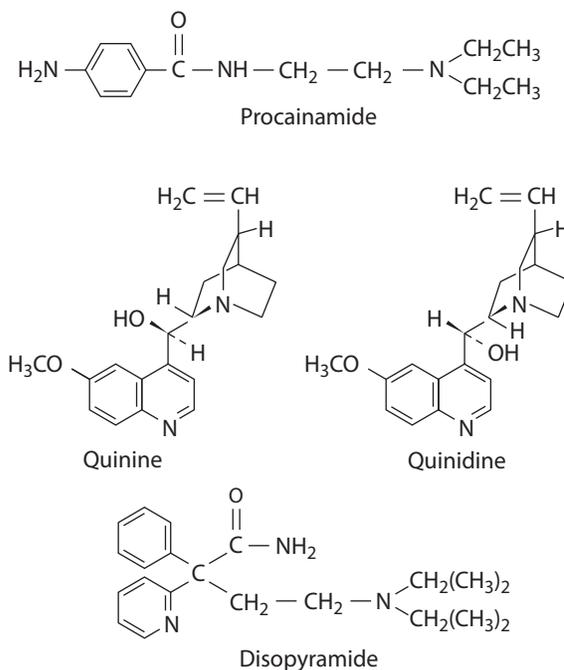

FIGURE 57–2. Structures of class IA antidysrhythmics and quinine.

drug-induced systemic lupus erythematosus,<sup>46</sup> this syndrome is not associated with acute poisoning. Furthermore, NAPA has less propensity than procainamide to produce this syndrome.<sup>45</sup> Other reported adverse effects include seizures and antimuscarinic effects with acute overdose and myopathic pain, hepatitis, thrombocytopenia, and agranulocytosis after long-term use.

Serum procainamide concentrations should be determined as part of therapeutic drug monitoring (therapeutic: 4–12 mcg/mL); NAPA concentrations should also be monitored in patients with CKD (therapeutic: 10–20 mcg/mL). In patients with procainamide overdose, both procainamide and NAPA concentrations should be obtained, although a direct prognostic role is not defined. Because the elimination half-life of procainamide is 3 to 4 hours, which is substantially shorter than that of NAPA (6–10 hours), chronic overdosing typically results in NAPA toxicity.<sup>5</sup> In this situation, the QT interval, a reflection of  $\text{K}^+$  channel blockade, correlates directly and blood pressure correlates inversely with the degree of poisoning. Severe effects usually do not occur until total (procainamide plus NAPA) serum concentrations are greater than 60 mcg/mL. Because of its structural similarity with amphetamine, some patients with procainamide overdose may have a false-positive urine enzyme-multiplied immunoassay test (EMIT) for amphetamines.<sup>110</sup>

#### Quinidine

Quinidine, the *d*-isomer of quinine, is derived from the bark of the cinchona tree. Because it is a weak base, it is typically formulated as the sulfate or gluconate salt. Quinidine undergoes hydroxylation by the liver, and both active and inactive metabolites are renally eliminated.

Quinidine was once widely used for the management of atrial or ventricular dysrhythmias but has largely fallen out of favor because of its adverse effects. Quinidine has substantial cardiotoxicity that includes intraventricular conduction abnormalities and an increased QT interval. “Quinidine syncope,” in which patients on therapeutic doses of quinidine experience paroxysmal, transient loss of consciousness, is almost exclusively a result of torsade de pointes.<sup>51</sup>

Because quinidine shares many pharmacologic properties with quinine (Chap. 55), patients occasionally have cinchonism after either chronic or acute quinidine overdose. This syndrome includes abdominal symptoms, tinnitus, and altered mental status. Quinidine also produces both peripheral and cardiac antimuscarinic effects, which enhance conduction via the atrioventricular (AV) node. Furthermore, as with quinine, quinidine-induced

blockade of  $K^+$  channels in pancreatic islet cells causes uncontrolled insulin release, leading to hypoglycemia. Hypoglycemia occurs more commonly in patients who are critically ill because counterregulatory mechanisms are impaired in this population.<sup>81</sup> The antimuscarinic effects can produce classical anticholinergic findings such as dry mouth and flushed skin.<sup>57</sup>

Serum quinidine concentrations greater than 14 mcg/mL are associated with cardiotoxicity,<sup>57</sup> as evidenced by a 50% increase in either the QRS complex or QT interval. These concentrations have limited utility in clinical management.

### Disopyramide

Disopyramide is more likely than other class IA antidysrhythmics to produce negative inotropy and congestive heart failure. This effect is noted both in patients receiving therapeutic dosing<sup>98</sup> and in those who overdose and is likely related to the blockade of myocardial  $Ca^{2+}$  channels caused by disopyramide.<sup>48</sup> The current use of disopyramide capitalizes on its negative inotropic effects for the treatment of patients with hypertrophic cardiomyopathy who remain symptomatic despite first-line treatment such as  $\beta$ -adrenergic antagonists.<sup>30</sup> The mono-*N*-dealkylated metabolite of disopyramide produces the most pronounced antimuscarinic effects of the class,<sup>57,106</sup> accounting for the occasional, although unproven, use of disopyramide to treat neurocardiogenic syncope.<sup>89</sup> Lethargy, confusion, or hallucinations are prominent in overdose.

Electrophysiologic abnormalities similar to those associated with poisoning from other class IA antidysrhythmics occur, including intraventricular conduction abnormalities, torsade de pointes, and other ventricular dysrhythmias. Disopyramide causes hyperinsulinemic hypoglycemia through its antagonism of  $K^+$  channels in the pancreatic islet cells.<sup>1</sup>

### Management of Class IA Antidysrhythmic Toxicity

Management concentrates on assessment and correction of cardiovascular dysfunction. After airway evaluation and IV line placement, 12-lead ECG and continuous ECG monitoring are of paramount importance. Appropriate gastrointestinal (GI) decontamination is recommended when the patient is sufficiently stabilized. Activated charcoal is recommended for early-presenting patients with a protected airway and an ingestion of a potentially toxic amount of medication. Gastric lavage is reasonable for patients with life-threatening ingestions who present within several hours depending on the severity and probability of retained ingested. Decontamination whole-bowel irrigation is reasonable if a sustained-release preparation is involved (Chap. 5 and Antidotes in Depth: A2).

For patients who have widening of the QRS complex duration, bolus administration of IV hypertonic sodium bicarbonate is recommended (Antidotes in Depth: A5). Depolarization is accelerated, and the QRS complex duration is reduced by enhancing rapid  $Na^+$  ion influx through the myocardial  $Na^+$  channels.<sup>10</sup> However, hypokalemia from the use of sodium bicarbonate may further prolong the QT interval, requiring careful

monitoring of the serum  $K^+$  and ECG. Class IA antidysrhythmic-induced hypotension is treated primarily with rapid infusion of 0.9% NaCl to expand intravascular volume and to simultaneously increase myocardial contractility by enhancing the Starling force. Hypotension in the setting of QRS complex prolongation responds favorably to hypertonic sodium bicarbonate, which enhances inotropy by both accelerating depolarization and raising intravascular volume. In refractory cases, dobutamine or a catecholamine such as epinephrine or norepinephrine is recommended based on the assessment of the hemodynamic requirements for inotropy versus pressor effect. Epinephrine, by analogy with chloroquine and tricyclic antidepressants, may be superior to norepinephrine.<sup>21,58</sup> Extracorporeal life support can improve hemodynamics, but their use has not been systematically evaluated, but use in patients with standards indications, if readily available, seems reasonable. Because disopyramide also blocks  $Ca^{2+}$  channels,  $Ca^{2+}$  administration is reportedly beneficial,<sup>2</sup> and although evidence to support this antidotal effect is lacking, it is reasonable to administer in appropriate doses. Glucagon effectively reversed myocardial depression in canine models, but it has not been evaluated in humans because such its use remains experimental at this time.<sup>75</sup>

We recommend treating patients with stable ventricular dysrhythmias occurring in the setting of class IA antidysrhythmic poisoning with hypertonic sodium bicarbonate or lidocaine. Although it seems counterintuitive to administer another class I antidysrhythmic to a patient already poisoned by a class I antidysrhythmic, there is sound theoretical and experimental literature to support the use of lidocaine in this setting.<sup>111</sup> Because lidocaine is a class IB antidysrhythmic with rapid on-off receptor kinetics, it displaces the "slower" class IA antidysrhythmic from the binding site on the  $Na^+$  channel, effectively reducing channel blockade. Sodium bicarbonate enhances conduction through the myocardium, promoting spontaneous termination of the ventricular dysrhythmia.<sup>34</sup> Magnesium sulfate and overdrive pacing can prevent recurrent torsade de pointes after initial spontaneous resolution or defibrillation. Medications that must be avoided in treating patients with dysrhythmias associated with class IA poisoning include other class IA and IC antidysrhythmics, as well as the  $\beta$ -adrenergic antagonists and  $Ca^{2+}$  channel blockers, all of which exacerbate conduction abnormalities or produce hypotension.

The roles of activated charcoal hemoperfusion, hemofiltration, and continuous arteriovenous hemodiafiltration are inadequately defined, but these are reasonable and appropriate means to remove NAPA.<sup>67</sup> There is not sufficient clinical evidence to support the use of hemodialysis or hemoperfusion for quinidine or disopyramide poisoning.<sup>1,43</sup>

### Class IB Antidysrhythmics: Lidocaine, Tocainide, Mexiletine, and Moricizine

#### Lidocaine (Fig. 57-3)

Lidocaine is an aminoacyl amide that is a synthetic derivative of cocaine. Its predominant clinical uses are as a local anesthetic and, for mechanically

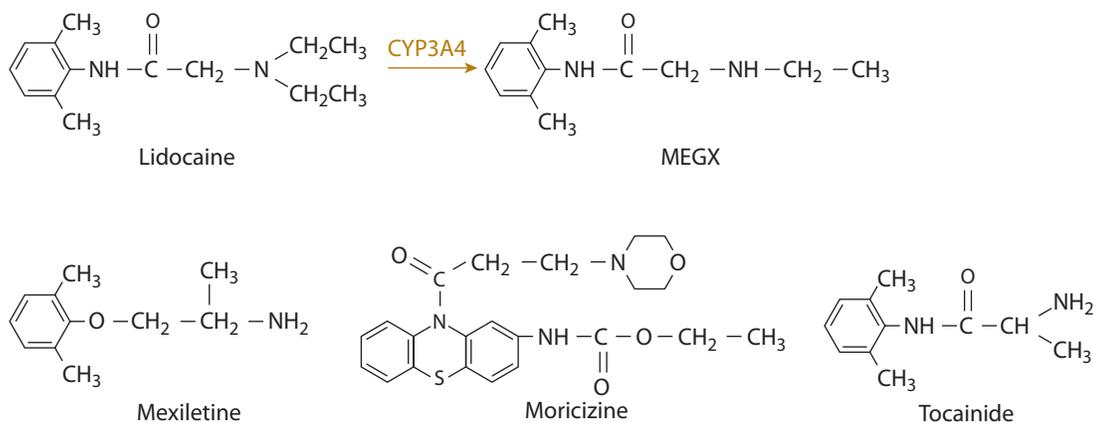

FIGURE 57-3. Structures of the class IB antidysrhythmics lidocaine (and metabolite monoethylglycylxylidide {MEGX}), tocainide, mexiletine, and moricizine.

similar reasons, to control ventricular dysrhythmias. The high frequency of lidocaine-related medication errors relates in part to its wide use in the past as well as the availability of “amps” of varying quantities, designed for specific uses such as preparation of IV infusions or for local anesthesia.<sup>54</sup> Many of the current cases of lidocaine toxicity result from its use in liposuction, discussed later. Lidocaine prevents myocardial reentry and subsequent dysrhythmias (Chap. 15) by preferentially suppressing conduction in compromised tissue.<sup>99</sup> After an IV bolus, lidocaine rapidly enters the central nervous system (CNS) but quickly redistributes into the peripheral tissue with a distribution half-life of approximately 8 minutes.<sup>11</sup> Lidocaine is 95% dealkylated by hepatic CYP3A4 to an active metabolite, monoethylglycylxylidide (MEGX) and, subsequently, to the inactive glycine xylidide (GX). Glycine xylidide is further metabolized to monoethylglycine and xylidide. Monoethylglycylxylidide, although less potent as a Na<sup>+</sup> channel blocker than lidocaine, bioaccumulates because of its substantially longer half-life.<sup>8</sup>

Patients with massive lidocaine exposures develop both CNS and cardiovascular effects, generally in that order. Because of its rapid entry into the CNS, acute lidocaine poisoning typically produces CNS dysfunction, with paresthesias or convulsion, as the initial manifestation.<sup>33,86,95</sup> Concomitant respiratory arrest generally occurs. Shortly after the CNS effects, depression in the intrinsic cardiac pacemakers leads to sinus arrest, AV block, intraventricular conduction delay, hypotension, or cardiac arrest. If the patient is supported through this period, the xenobiotics rapidly distributes away from the heart, and spontaneous cardiac function returns.

Acute lidocaine toxicity is generally related to excessive or inappropriate parenteral therapeutic dosing. Common settings include inadvertent IV or intraarterial administration instead of the intended route and excessive subcutaneous administration during laceration repair or other procedures.<sup>105</sup> Acute lidocaine toxicity is reported with topical tracheal application of lidocaine used for bronchoscopy,<sup>113</sup> during circumcision,<sup>86</sup> and during ureteral application during ureteroscopic stone extraction.<sup>78</sup> The typical CNS manifestations of submassive lidocaine poisoning include drowsiness, weakness, a sensation of “drifting away,” euphoria, diplopia, decreased hearing, paresthesias, muscle fasciculations, and seizures. The more severe of these effects develop when serum lidocaine concentrations exceed 5 mcg/mL and are often preceded by paresthesias or somnolence. Any of these symptoms should, therefore, prompt the clinician to examine the patient’s medication administration history or medication-infusion rate. Apnea and seizures, as well as hypotonia in neonates, are reported to result from submassive acute lidocaine toxicity.<sup>85</sup>

A related form of toxicity and death results from subcutaneous and adipose administration of lidocaine during tumescent liposuction.<sup>83</sup> In this technique, a large volume of dilute lidocaine is used to distend subcutaneous fat before liposuction.<sup>9</sup> Although in some reports, the cause of death was controversial,<sup>82</sup> postmortem lidocaine concentrations were commonly elevated, and it is likely that lidocaine metabolites were also involved in the adverse events.<sup>55</sup> Interestingly, proponents of this procedure suggest that lidocaine doses up to a maximum of 55 mg/kg are safe,<sup>9</sup> but the conventional recommended limit for subcutaneous lidocaine with epinephrine is only 5 to 7 mg/kg. Of significant concern is that the recommended doses used for liposuction procedures do not consider the ability of lidocaine to saturate the CYP3A4 enzymes. When saturation occurs, elimination lags behind absorption, and lidocaine toxicity results.

Numerous publications unequivocally demonstrate the toxicity associated with orally administered lidocaine despite its poor bioavailability.<sup>20,115</sup> Some of the toxicity is attributed to MEGX. Because of the relatively high concentration of viscous lidocaine (typically 4%), this preparation is over-represented in reports of oral lidocaine poisoning.<sup>115</sup> As little as 15 mL of 2% viscous lidocaine in a 3-year-old child (estimate, 300 mg or 21.4 mg/kg/dose) is reported to cause seizures.

Chronic lidocaine toxicity most commonly occurs as a result of therapeutic misadventure in patients on lidocaine infusions, generally in a critical care unit. Toxicity after appropriate dosing is most likely to occur in patients with reduced hepatic blood flow as occurs with congestive heart failure,

liver disease, or concomitant therapy with CYP3A4 and CYP1A2 inhibitors (Chap. 11).<sup>104</sup> Adverse reactions to lidocaine also increase with advancing age, decreasing body weight, and increasing infusion rate. Chronic lidocaine toxicity occurs in 6% to 15% of patients receiving infusions at 3 mg/min for several days.<sup>93</sup> Partly for this reason, lidocaine is no longer routinely used to prevent dysrhythmias in the immediate postmyocardial infarction period. The clearance of lidocaine falls after approximately 24 hours of the start of an infusion, and this effect may be caused by competition for hepatic metabolism between lidocaine and its metabolites.

### Mexiletine

Mexiletine, originally developed as an anorectic, was found to have anti-dysrhythmic, local anesthetic, and anticonvulsant activity.<sup>17</sup> It is currently available in oral form for the management of ventricular dysrhythmias and is used for the management of chronic neuropathic pain. Its chemical structure and electrophysiologic properties are similar to those of lidocaine. Mexiletine, a base, is absorbed in the small intestine; therefore, its absorption is increased when the gastric contents are alkalinized. Congestive heart failure and cirrhosis, as well as therapy with cimetidine or disulfiram, decrease the clearance of mexiletine.<sup>62</sup> Its metabolism, predominantly through CYP2D6, is accelerated by concomitant use of phenobarbital, rifampin, and phenytoin.

Adverse effects with therapeutic dosing are primarily neurologic and are similar to those that occur with lidocaine. The few reported cases of mexiletine overdose describe prominent cardiovascular effects such as complete heart block, torsade de pointes, and asystole.<sup>23,37</sup> Neurotoxicity resulting from overdose includes self-limited seizures, generally in the setting of cardiotoxicity. Moreover, a single case report described a patient with mexiletine poisoning who experienced status epilepticus without any hemodynamic or ECG abnormalities.<sup>72</sup> Mexiletine is reported to produce a false-positive result on the amphetamine immunoassay of the urine.<sup>23,59</sup>

### Moricizine

Moricizine possesses the general qualities of class I antidysrhythmics but is difficult to specifically subclassify because it has properties that place it in both classes IB or IC.<sup>22</sup> Historically, it is discussed as a class IB antidysrhythmic, as it is here. The parent medication undergoes extensive and rapid metabolism. Dose-related lengthening of PR interval and QRS complex are expected, as are hemiblocks, bundle blocks, and sustained ventricular tachydysrhythmias. Experience in the setting of myocardial infarction during CAST II suggests that it is a pro-dysrhythmic.<sup>102</sup> Clinical experience with overdose is limited but is expected to be similar to that of other class I antidysrhythmics.

### Management of Class IB Antidysrhythmic Toxicity

The focus of the initial management for IV lidocaine-induced cardiac arrest is continuous cardiopulmonary resuscitation to allow lidocaine to redistribute away from the heart. Apart from this setting, management of hemodynamic compromise includes fluid replacement and other conventional strategies. Catecholamine administration is recommended for the management of resistant hypotension, and if refractory toxicity persists, insertion of an intraaortic balloon assist pump or cardiac bypass.<sup>39</sup> Cardiopulmonary bypass, which does not directly enhance elimination, maintains hepatic perfusion, thereby allowing the lidocaine to be metabolized.<sup>39</sup> When bradydysrhythmias do not respond to atropine, chronotrope such as norepinephrine or isoproterenol is recommended. External pacing or insertion of a transvenous pacemaker is reportedly successful in some instances, but the myocardium is often refractory to electrical capture. Lidocaine-induced seizures, and those related to lidocaine analogs, are generally brief in nature and do not require specific therapy. For patients requiring treatment, an IV benzodiazepine is recommended; rarely, a barbiturate is required. Similarly, although IV lipid emulsion is often described as useful for the resuscitation of patients with life-threatening local anesthetic overdose (local anesthetic systemic toxicity) its use for lidocaine poisoned patients is limited to case reports and likely unnecessary given the rapid time course of recovery. As such, lipid emulsion is not recommended for lidocaine poisoning except in

cases of severe and prolonged toxicity that are refractory to other therapies.<sup>49</sup> Lipid emulsion was used in the successful resuscitation from cardiac arrest after local infiltration of lidocaine for an incision and drainage procedure.<sup>105</sup> It was also used to reverse the CNS toxicity of lidocaine used for local anesthesia during procedures (Antidotes in Depth: A23).<sup>63</sup> Enhanced elimination techniques are limited after IV poisoning because of the rapid time course of poisoning.

After oral poisoning by a class IB antidysrhythmic, activated charcoal is recommended. Lidocaine and its metabolites are not well cleared by hemodialysis,<sup>27</sup> and there are no adequate data to support the use of extracorporeal removal for mexiletine or moricizine. There is one case report of a patient with a large oral mexiletine overdose who was successfully treated with hemodialysis, but how to apply this more broadly remains unclear.<sup>4</sup>

## Class IC Antidysrhythmics: Flecainide and Propafenone

### Flecainide

Flecainide, a derivative of procainamide, is orally administered to maintain sinus rhythm in patients with structurally normal hearts who have atrial fibrillation or supraventricular tachycardia.<sup>100</sup> Kidney disease, medication interactions, and congestive heart failure all decrease the clearance of flecainide and its active metabolite. Additionally, alkaluria reduces its clearance, presumably by enhanced tubular reuptake of nonionized flecainide. Therapeutic doses produce left ventricular dysfunction with worsening congestive heart failure. This is presumably a result of the negative inotropic effect of flecainide, which itself relates to its antagonistic effects on Ca<sup>2+</sup> channels. Furthermore, sudden dysrhythmic death occurs, particularly in patients with underlying ischemic heart disease.<sup>100</sup>

Flecainide toxicity is associated with an increase in QRS complex duration, prolongation of the PR interval, and prolongation of the QT interval. The duration of the QRS complex has significant prognostic value: a QRS duration of 200 ms or greater is predictive of the need for mechanical circulatory support.<sup>108</sup> The expected consequences of these electrophysiologic disturbances include bradycardia, premature ventricular contractions, and ventricular fibrillation. Occasionally, supraventricular tachycardia can present with a bizarre axis and is often mistaken for ventricular tachycardia, which results in inappropriate treatment.<sup>108</sup> The combination of marked QRS complex and PR interval changes, associated with minimal QT interval prolongation, is characteristic of flecainide toxicity and contrasts with those described with other antidysrhythmics.

### Propafenone

Propafenone bears a structural resemblance to propranolol,<sup>36</sup> as well as similar qualitative, but not quantitative, electrophysiologic properties.<sup>32</sup> Propafenone blocks fast inward Na<sup>+</sup> channels, is a weak  $\beta$ -adrenergic antagonist, and is an L-type Ca<sup>2+</sup> channel blocker.<sup>32</sup> Its long half-life allows the accumulation of propafenone, particularly in patients with the slow metabolizer pharmacogenetic variant of CYP2D6 or those exposed to xenobiotics that inhibit this enzyme.<sup>64</sup> Propafenone overdose produces sinus bradycardia, ventricular dysrhythmias, and negative inotropy. The ECG often shows a right bundle branch block pattern, first-degree AV block, and prolongation of the QT interval. Generalized seizures have occurred.<sup>77</sup>

### Management of Class IC Antidysrhythmic Toxicity

Management concentrates on assessment and correction of cardiovascular dysfunction. After airway evaluation and IV line placement, 12-lead ECG and continuous ECG monitoring are of paramount importance. Appropriate GI decontamination is recommended when the patient is sufficiently stabilized. Activated charcoal is recommended for early-presenting patients with a protected airway and an ingestion of a potentially toxic amount of medication. Gastric lavage is reasonable for patients with life-threatening ingestions who present within several hours depending on the severity and probability of retained ingested. Decontamination should also include whole-bowel irrigation are recommended if a sustained-release preparation is involved (Chap. 5 and Antidotes in Depth: A2).

Standard management strategies for hypotension, such as fluid resuscitation, and for seizures, with benzodiazepines as well as careful attention to maintaining the airway as indicated. Additionally, therapy for hypotension and the ECG manifestations of class IC poisoning include IV hypertonic sodium bicarbonate to overcome the Na<sup>+</sup> channel blockade.<sup>60</sup> The utility of calcium salts for the treatment of propafenone toxicity is undefined. Several reports of overdose in humans verify QRS complex narrowing in response to hypertonic sodium bicarbonate administration on flecainide<sup>12,50,66</sup> and propafenone.<sup>77</sup> The renal elimination of flecainide is reduced by urinary alkalization, suggesting that sodium chloride, in equimolar doses, is superior to sodium bicarbonate; however, the routine attempt to enhance urinary clearance with saline is not supported by evidence and is not recommended.<sup>70</sup> The administration of other class IC or IA antidysrhythmics is contraindicated because of their additive blockade of the Na<sup>+</sup> channel. Similarly, the administration of phenytoin to a child with propafenone poisoning was associated with a prolongation of the QRS complex, which initially responded to sodium bicarbonate, but the patient subsequently developed bradyasystolic arrest.<sup>69</sup> However, amiodarone was successful in the setting of flecainide-induced ventricular fibrillation refractory to other therapy.<sup>96</sup> As with  $\beta$ -adrenergic antagonists, an animal model and human case reports suggest that hyperinulinemic euglycemic therapy is beneficial after propafenone poisoning.<sup>7,116</sup> In patients with refractory bradycardia, pacing should be attempted with the caveat that the efficacy of an external or internal pacemaker may be limited because of the xenobiotic-induced increased electrical pacing threshold of the ventricle. Successful therapy with cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO) is reported and is recommended in patients with severe toxicity when available.<sup>6,13,25</sup> Intravenous fat emulsion therapy was reportedly successful in two patients with severe flecainide poisoning<sup>29</sup> and in propafenone poisoning.<sup>7,107</sup> Although the safety and efficacy of lipid emulsion therapy in this setting remains undefined, it is reasonable for those who are seriously ill, deteriorating, and refractory to conventional therapy.

Extracorporeal removal is not expected to be beneficial for patients with flecainide poisoning. Although hemodialysis was successful in removing propafenone after overdose, additional studies are needed to determine its clinical benefit.<sup>14</sup> It is not recommended at this time.

## CLASS III ANTIDYSRHYTHMICS

### Amiodarone, Dofetilide, Dronedaron, and Ibutilide

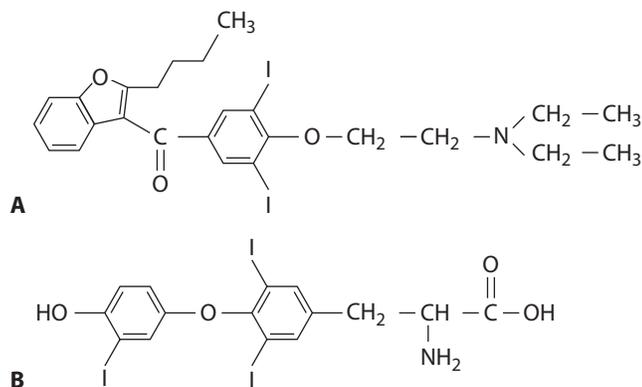

The class III antidysrhythmics prevent and terminate reentrant dysrhythmias by prolonging the action potential duration and effective refractory period without slowing conduction velocity during phase 0 or 1 of the action potential. This effect on the action potential is generally caused by blockade of the rapidly activating component of the delayed rectifier K<sup>+</sup> current, which is responsible for repolarization.

The class III antidysrhythmics in use today prolong repolarization of both the atria and ventricles. Thus, common ECG effects at therapeutic doses include prolongation of the PR and QT intervals and abnormal T and U waves. Chap. 15 contains a detailed discussion of the pharmacologic mechanisms of class III antidysrhythmics. Also, Chaps. 16 and 59 discuss sotalol.

### Amiodarone and Dronedaron

Amiodarone (Fig. 57–4) is an iodinated benzofuran derivative that is structurally similar to both thyroxine and procainamide. Forty percent of its molecular weight is iodine. Dronedaron is an analog of amiodarone that does not contain iodine.<sup>60</sup> The 2015 revision of the Advanced Cardiovascular Life Support guidelines places significant emphasis on the early IV administration of amiodarone for ventricular dysrhythmias. Both medications are used primarily to terminate or prevent atrial fibrillation, and although dronedaron is less effective and has safety issues,<sup>24</sup> it is not associated with many of the potentially severe adverse effects of amiodarone.<sup>92</sup>

Although amiodarone and dronedaron have multiple pharmacologic effects, their efficacy is primarily the result of their class III antidysrhythmic effects. They also have weak  $\alpha$ - and  $\beta$ -adrenergic antagonist activity and can

**FIGURE 57-4.** Structures of amiodarone (**A**) compared with triiodothyronine (**B**). Note that amiodarone is nearly 40% iodine by weight.

block both L-type  $\text{Ca}^{2+}$  channels and inactivated  $\text{Na}^+$  channels. Amiodarone is slowly absorbed by the oral route and concentrates in the liver, lung, and adipose tissue. It has a very long elimination half-life, measured in weeks, and steady-state pharmacokinetics do not occur until after 1 month of use. Dronedrone has a half-life of about 24 hours and a smaller volume of distribution.

The ECG effects of amiodarone differ based on the route of medication administration. Therapeutic oral doses prolong the PR and QT intervals but do not alter the QRS complex. Intravenous dosing prolongs the PR interval but has few other ECG manifestations. Ventricular dysrhythmias and sinus bradycardia are the most serious cardiac complications of therapeutic doses of amiodarone. Ventricular tachycardia reported to be resistant to cardioversion and pharmacologic interventions occur<sup>35</sup> but are surprisingly uncommon given the frequency and extent to which the QT interval prolongation occurs. The ability of amiodarone to compete for P-glycoprotein is responsible for several drug interactions, including elevated digoxin and cyclosporin concentrations and enhanced anticoagulation effectiveness of warfarin<sup>61</sup> (Chap. 9).

The diverse complications associated with long-term amiodarone therapy do not occur after short-term IV use. Chronic therapy with oral amiodarone causes substantial pulmonary, thyroid, corneal, hepatic, and cutaneous toxicity caused by bioaccumulation in these organs. Dronedrone rarely causes hepatic or pulmonary toxicity.<sup>26</sup> Many of these effects appear to be dose related, but because of the wide range of bioavailabilities and metabolic patterns among different patients, as well as the overlap between therapeutic and toxic serum concentrations, therapeutic drug monitoring is of limited benefit.<sup>41</sup> Pneumonitis, the most consequential extracardiac adverse effect, occurs in up to 5% of patients taking the xenobiotic therapeutically. Amiodarone pneumonitis rarely develops within days of initiating therapy but typically occurs only after years of therapy. Its occurrence appears to be dose related: a daily dose of greater than 400 mg is a risk factor, and pneumonitis is rare in those taking less than 200 mg daily. Focusing on using the minimal effective dose has reduced the incidence of pneumonitis.<sup>31</sup> Oxygen supplementation speeds the development of pneumonitis, which explains the initial belief that patients with chronic lung disease are at increased risk for amiodarone pneumonitis. Manifestations of pneumonitis include dyspnea, cough, hemoptysis, crackles, hypoxia, and radiographic changes.<sup>18</sup> A chest computed tomography scan is the most helpful initial diagnostic test for pneumonitis but is not useful for monitoring purposes, which is often done with diffusing capacity of carbon monoxide.<sup>41</sup> Bronchoalveolar lavage typically reveals interstitial pneumonitis with many macrophages and a characteristic finely vacuolated foamy cytoplasm, but confirmation of the diagnosis requires open lung biopsy.

Thyroid dysfunction, either amiodarone-induced thyrotoxicosis (AIT) or amiodarone-induced hypothyroidism (AIH), occurs in approximately 4% of patients.<sup>19</sup> Amiodarone-induced hypothyroidism is more common than AIT when iodine intake is sufficient.<sup>41</sup> Amiodarone-induced hypothyroidism is

likely caused by an exaggerated Wolff-Chaikoff effect, in which iodine—in this case from amiodarone—inhibits the organification and release of thyroid hormone. Amiodarone-induced thyrotoxicosis appears to exist in two distinct forms: type I AIT, which occurs in patients with abnormal thyroid glands and iodine-induced excessive thyroid hormone synthesis and release, and type II AIT, in which destructive thyroiditis leads to release of thyroid hormone from the damaged follicular cells. The relative prevalence of the two forms of AIT is unknown. Amiodarone also reduces the effect of thyroid hormone on peripheral tissue. The diagnosis is confirmed with standard thyroid function testing (thyroid-stimulating hormone, total triiodothyronine and free thyroxine<sup>101</sup> (Chap. 53).

Corneal microdeposits are extremely common during chronic therapy and leads to vision loss.<sup>68</sup> Abnormal elevation of hepatic enzymes occurs in more than 30% of those on long-term therapy, and the hepatotoxicity progresses to cirrhosis. Periodic monitoring of aminotransferases is recommended.<sup>41</sup> Hepatotoxicity has occurred after initial loading of amiodarone.<sup>84</sup> Slate-gray or bluish discoloration of the skin is common, particularly in sun-exposed portions of the body.<sup>88</sup>

### Dofetilide

Dofetilide is approved for conversion of atrial fibrillation or atrial flutter to a normal sinus rhythm. Dofetilide increases the effective refractory period more substantially in atrial tissue than in ventricular fibers, accounting for this clinical indication.<sup>90</sup> Dofetilide has no known effect on  $\text{Ca}^{2+}$  or  $\text{Na}^+$  channels, nor does it result in  $\beta$ -adrenergic antagonism. Dofetilide increases the QT interval but does not change either the PR interval or QRS complex in humans. Heart rate and blood pressure are also not appreciably affected.

Although limited data are available, the expected and reported adverse cardiac events include ventricular tachycardia, particularly torsade de pointes.<sup>112</sup> The approximate incidence of torsade de pointes in patients receiving high therapeutic doses of the medication is 3%.<sup>3</sup> For this reason, the US Food and Drug Administration has in place strict requirements for the use of dofetilide, such as an individualized dose initiation algorithm and mandatory hospitalization for initial therapy.<sup>56</sup>

Overdose data reported by the manufacturer include two cases. One patient reportedly ingested 28 capsules and experienced no events, but a second patient inadvertently received two supratherapeutic doses 1 hour apart and experienced fatal ventricular fibrillation.<sup>80</sup> A 33-year-old man ingested 5 mg (20 capsules) and developed QT interval prolongation within 1 hour of ingestion but had no dysrhythmia during his 4-day hospital stay.<sup>16</sup> One patient with a 90-fold intentional overdose experienced nonsustained ventricular tachycardia, frequent multifocal premature ventricular contractions, and ventricular bigeminy, which were successfully treated with potassium and magnesium.<sup>47</sup>

### Ibutilide

Ibutilide is an antidysrhythmic with predominant class III activity used for the rapid conversion of atrial fibrillation and flutter to normal sinus rhythm. Because of its extensive first-pass metabolism, ibutilide can only be administered parenterally. Its metabolic pathways are not well understood but do not involve the isoenzymes CYP3A4 or CYP2D6. Pharmacokinetic data thus far do not indicate that age, sex, hepatic, or CKD necessitates adjustment of recommended dosage of ibutilide. In addition to its effects on the delayed rectifier current, ibutilide activates a slow inward  $\text{Na}^+$  current.<sup>71</sup>

Ibutilide increases the QT interval and causes torsade de pointes, especially in patients with congenital long-QT syndrome and in women.<sup>42</sup> Although ibutilide enhances the efficacy of transthoracic cardioversion for atrial fibrillation, its use in patients with ejection fractions below 20% is associated with an increased incidence of sustained polymorphic ventricular tachycardia. Acute kidney injury, including biopsy-identified crystals, is reported in association with ibutilide cardioversion, but a causal relationship is not yet definitive.<sup>38</sup> Acute overdose information, only available in limited form (four patients) through the manufacturer, suggests that ventricular dysrhythmias and high-degree AV conduction abnormalities should be expected.<sup>79</sup>

### Management of Class III Antidysrhythmic Toxicity

Treatment experience with class III antidysrhythmic overdose is limited. Isoproterenol, magnesium sulfate, and overdrive pacing can prevent recurrent torsade de pointes after initial spontaneous resolution or defibrillation. However, prolonged therapy may be required for amiodarone overdose because of the long half-life of drug.<sup>94</sup> Administration of class IB antidysrhythmics or propranolol for the control of monomorphic ventricular tachycardia cannot be recommended on theoretical grounds. Paradoxically, amiodarone may reduce the risk of torsade de pointes associated with the other class III antidysrhythmics.<sup>97</sup> This effect is likely mediated by the beneficial effects of amiodarone on the dispersion of myocardial repolarization and its Ca<sup>2+</sup> channel-blocking activity.

Oral activated charcoal is recommended if patients present shortly after overdose. Hemodialysis is not expected to be beneficial in general, either because of extensive protein binding or because of large volumes of distribution (Table 57-1). A neonate survived cardiovascular collapse with the use of ECMO after an iatrogenic IV amiodarone overdose.<sup>44</sup> Although the benefit versus risk profile of this intervention is undefined, it is reasonable to implement ECMO if it is available or reasonably attainable through transfer. Lipid emulsion sequesters amiodarone and is demonstrated to be beneficial in swine models.<sup>114</sup> It is only reasonable administered to patients with severe amiodarone poisoning refractory to standard resuscitative efforts. However, when amiodarone is used as a treatment for poisoning by another xenobiotic, lipid emulsion therapy will reduce the effectiveness of the amiodarone because of subsequent sequestration.<sup>74</sup>

### ANTIDYSRHYTHMICS-UNCLASSIFIED

Adenosine, a nucleoside found in all cells, is released from myocardial cells under physiologic and pathophysiologic conditions. It is administered as a rapid IV bolus to terminate reentrant supraventricular tachycardia. The effects of adenosine are mediated by its interaction with specific G protein-coupled adenosine (A<sub>1</sub>) receptors that activate acetylcholine-sensitive outward K<sup>+</sup> current in the atrium, sinus nodes, and AV nodes. The resultant hyperpolarization reduces the rate of cellular firing. Adenosine also reduces the Ca<sup>2+</sup> currents, and its antidysrhythmic activity results from its effect in increasing AV nodal refractoriness and from inhibiting delayed afterdepolarizations elicited by sympathetic stimulation.<sup>65</sup>

Adverse effects of adenosine administration are very common and include transient asystole, dyspnea, chest tightness, flushing, hypotension, and atrial fibrillation. Although bronchospasm occurs after pulmonary vascular administration, it is not reported after routine IV use. Dyspnea, and probably chest tightness, is related to adenosine stimulation of the pulmonary vagal C fibers.<sup>15</sup> Fortunately, most of the adverse effects of adenosine are transient because of its rapid metabolism to inosine by both extracellular and intracellular deaminases. The clinical effects are potentiated by dipyridamole, an adenosine uptake inhibitor,<sup>40</sup> and by denervation hypersensitivity in cardiac transplant recipients. Methylxanthines block adenosine receptors (Chap. 63). In this setting, larger-than-usual doses of adenosine are required to produce an antidysrhythmic effect. Overdose of adenosine is not reported. Treatment is supportive because of the rapid elimination of the medication.

Digoxin, a cardioactive steroid, is often considered a member of this class. A complete discussion of digoxin can be found in Chap. 62.

Magnesium ion is occasionally included in this class as well because of its ability to prevent the development of recurrent torsade de pointes. A complete discussion of magnesium sulfate can be found in Antidotes in Depth: A16.

### SUMMARY

- In the overdose setting, the class IA, B, and C antidysrhythmics all produce Na<sup>+</sup> channel blockade, which can induce profound wide-complex cardiac dysrhythmias and morbidity if not treated judiciously.
- The class IC antidysrhythmics are considerably more toxic than the other class I antidysrhythmics, although even the class IB antidysrhythmics are lethal in overdose. Dysrhythmias are their primary toxicologic effect.

- The class III antidysrhythmics in overdose cause malignant dysrhythmias, particularly torsade de pointes. Amiodarone has many noncardiac effects, particularly pneumonitis and thyroid effects, which limit its therapeutic usefulness.
- Proper management of both adverse effects and overdose can be accomplished only by understanding the pharmacokinetics and toxicokinetics of these medications.

## MAGNESIUM

Silas W. Smith

**INTRODUCTION**

Although magnesium is a divalent cation like other metals, we will refer to it as magnesium in this text. It is an essential cofactor in more than 350 enzyme reactions in cardiac, neurologic, neuromuscular, and endocrine processes, as well as in basic energy, structural, nucleic acid, and signal transduction pathways.<sup>107,136</sup> Hypomagnesemia results in nausea, vomiting, weakness, muscle spasms, neurologic and muscular excitation (tremor, hyperreflexia, and tetany), and cardiac dysrhythmias. Hypermagnesemia produces cardiovascular effects, including conduction disturbances, hypotension, and cardiac arrest; respiratory depression; gastrointestinal (GI) complaints of nausea, vomiting, and thirst; and neuromuscular sequelae, including weakness, paralysis, and central nervous system (CNS) depression.<sup>4,77,131</sup> Magnesium as chloride, citrate, hydroxide, oxide or sulfate is used to repair xenobiotic-associated hypomagnesemia and as an adjunctive treatment for cardiovascular toxins, fluoride toxicity, pesticide poisoning, and alcohol use disorders.

**HISTORY**

In 1679, Nehemiah Grew described the process of obtaining the eponymous salts in the springs of Epsom through evaporation, which he later published in 1695 to be magnesium sulfate ( $\text{MgSO}_4$ ).<sup>105</sup> Later as an antidote,  $\text{MgSO}_4$  was used as a therapy for tetanus in 1906.<sup>63</sup> In 1923,  $\text{MgSO}_4$  was introduced to treat the convulsions of nephritis in children, which was later extended to the advanced chronic nephritis in adults.<sup>131</sup> On the basis of reports in 1925 and 1926,  $\text{MgSO}_4$  came into common practice for the prevention and control of seizures in severe toxemia of pregnancy; its use for this indication was “grandfathered” by the US Food and Drug Administration (FDA).<sup>20</sup> The cardiac utility of  $\text{MgSO}_4$  was demonstrated in 1935 and 1943 as therapy to suppress “paroxysmal tachycardia.”<sup>13,139</sup> Magnesium sulfate also continues in use as a uterine tocolytic, a bronchodilator a migraine therapy and as a nutritional adjunct to prevent hypomagnesemia in hyperalimentation.

**PHARMACOLOGY****Chemistry and Preparation**

Magnesium has the atomic number 12, with a molecular weight of 24.3 Da. Despite having a smaller atomic radius than calcium, magnesium binds water tighter, with two hydration shells, leading to a radius 400 times larger than its dehydrated form.<sup>64</sup> This property underlies its calcium antagonism, despite similar chemical reactivity and charge.<sup>64</sup> For clinical use, magnesium is prepared as a salt, typically in combination with chloride, citrate, hydroxide oxide, or sulfate. Magnesium as  $\text{MgSO}_4$  is typically formulated in its heptahydrate form  $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$ , with a molecular weight of 120.38 Da alone and 246.47 when accounting for water. It occurs as colorless crystals or white powder, which is freely soluble in water.

**Related Agents**

The use of magnesium as an oral saline cathartic (eg, magnesium citrate, magnesium hydroxide, and  $\text{MgSO}_4$ ) is discussed in Antidotes in Depth: A2.

**Pharmacokinetics**

Magnesium is the fourth most common plasma cation after sodium, potassium, and calcium but follows potassium as the second most prevalent intracellular cation.<sup>37</sup> Adults contain approximately 1 mole (21–28 g)

of magnesium; homeostasis balances intestinal absorption and renal excretion.<sup>107</sup> A normal serum magnesium concentration is 1.5 to 2.0 mEq/L (1.7–2.4 mg/dL; 0.7–1 mmol/L).<sup>16</sup> Magnesium is approximately 30% to 40% protein bound.<sup>16,82</sup> Extracellular magnesium represents only 1% of the body's total stores, with the remaining magnesium found in bone (~60%), muscle (~20%), and soft tissues (~19%). Serum values do not always accurately reflect tissue concentrations and can be normal despite intracellular deficiency.<sup>37</sup> This discrepancy was assessed by determining retained magnesium in response to an intravenous (IV) load: those retaining more than 30% of an 800-mg load of IV magnesium were considered magnesium depleted; those retaining less than 20% were replete.<sup>120</sup> Magnesium is not metabolized, but only ionized magnesium is physiologically active. After being absorbed, magnesium is eliminated by the kidney and occurs at a rate proportional to the plasma concentration and glomerular filtration. As kidney function declines, compensatory decreases in tubular resorption occur; however, in end-stage kidney disease, limited magnesium excretion can lead to hypermagnesemia.<sup>136</sup>

Pharmacokinetic studies of  $\text{MgSO}_4$  typically have involved pregnant women with preeclampsia. After a 4-g loading dose followed by a 1-g/h continuous maintenance infusion, serum magnesium concentrations approximately doubled from 0.74 to 0.85 mmol/L to 1.48 to 1.70 mmol/L at 30 minutes and remained constant for at least 24 hours.<sup>91</sup> When a 4-g loading dose is followed by a 2-g/h continuous maintenance infusion, magnesium concentrations reach 1.73 to 2.25 mmol/L.<sup>91</sup> After IV  $\text{MgSO}_4$  administration, the apparent volume of distribution ( $V_d$ ) increases rapidly and becomes constant within 2 hours in healthy nonpregnant individuals but may not become constant for up to 4 hours in pregnant women.<sup>21</sup> Given intramuscularly,  $[\text{MgSO}_4]$  does not peak until 90 to 120 minutes followed by a slow decline back to baseline concentrations over 4 to 8 hours, unless repeated intramuscular (IM) magnesium is provided at 4 hours.<sup>21,82,91</sup>

**Pharmacodynamics and Mechanisms of Action**

The critical roles and functions of magnesium are more completely reviewed in Chap. 12. Selected key magnesium actions provide the physiologic basis for antidotal strategies. Adenosine triphosphate (ATP) avidly binds and requires magnesium to participate in enzymatic reactions.<sup>103</sup> Separately, magnesium acts as a calcium channel blocker. In the heart, this produces negative inotropy in isolated preparations. However it results in positive inotropy in healthy human volunteers, presumably because of decreased systemic and pulmonary arterial vascular resistance.<sup>37,103</sup> Additionally, limiting calcium outflow from the sarcoplasmic reticulum and restricting outward potassium movement appear to underlie the role of magnesium in reduction of sinus node rate firing, increased atrioventricular (AV) node refractoriness, and suppression of ectopy.<sup>37,103</sup> The role of magnesium in calcium channel blocker, activation of adenylate cyclase, and increased production of endothelial vasodilator prostacyclin and cyclic adenosine monophosphate (cAMP) lead to vascular relaxation in peripheral and intracranial blood vessels.<sup>6,12,128</sup> In the pulmonary system, the inhibitory actions of magnesium on smooth muscle lead to a weak bronchodilating effect.<sup>58</sup>

In the nervous system, the glutamate *N*-methyl-D-aspartate (NMDA) receptor mediates excitatory neurotransmission. The NMDA receptor undergoes voltage-dependent blockade following magnesium administration with a high permeability for calcium in those receptors expressing

NR1 and NR2 although not NR3 subunits.<sup>18</sup> Magnesium used as an NMDA antagonist has demonstrated neuroprotective and antinociceptive effects in clinical trials.<sup>3,133</sup> Magnesium competitively blocks presynaptic calcium entry to decrease or abolish acetylcholine release at motor endplates and postsynaptically decreases sensitivity to acetylcholine.<sup>48,77</sup> Magnesium similarly blocks N- (and L-) type calcium channels to inhibit catecholamine release from adrenergic nerves.<sup>110</sup> Effective serum concentrations for the prevention or treatment of eclamptic seizures range from 4 to 7 mEq/L (2.0–3.5 mmol/L).<sup>91</sup>

### ROLE IN XENOBIOTIC-INDUCED HYPOMAGNESEMIA

Table 12–10 lists common xenobiotic causes of hypomagnesemia. These include xenobiotics that cause GI or renal losses (laxatives, alcohol, and diuretics), chemotherapeutics (cisplatin, human epidermal growth factor receptor antagonists), antimicrobials (aminoglycosides, amphotericin B, pentamidine), immunosuppressants (cyclosporine and tacrolimus), and proton pump inhibitors. In animal models, magnesium administration is additionally protective against cisplatin-induced nephrotoxicity while improving chemotherapeutic efficacy.<sup>78,104</sup> Receptor activator of nuclear factor  $\kappa$ -B ligand (RANKL) inhibitors used to treat osteoporosis and bone metastases also place patients at risk for hypomagnesemia.<sup>79</sup> The choice of oral or IV repletion should depend on the degree of hypomagnesemia and the clinical scenario, with IV treatment used for severe cases.

### ROLE IN POISONING BY CARDIAC TOXINS

Digoxin inhibits the magnesium-dependent sodium-potassium adenosine triphosphatase ( $\text{Na}^+\text{-K}^+\text{-ATPase}$ ). Antidotal use of  $\text{MgSO}_4$  in cardiovascular poisoning dates back to 1935, when it was used to mitigate digoxin-associated dysrhythmias in 15 patients.<sup>139</sup> In 1950, Szekeley reported that 3 to 4 g of  $\text{MgSO}_4$  interrupted digoxin-associated bidirectional tachycardia or extrasystolic bigeminy in six patients.<sup>115</sup> In controlled studies of cardioactive steroids toxicity in dogs<sup>71,126</sup> and monkeys,<sup>127</sup> cardiotoxicity (ie, ventricular dysrhythmias and death) was significantly more pronounced and occurred at lower concentrations in magnesium-deficient animals. In another dog experiment,  $\text{MgSO}_4$  reversed cardioactive steroids-induced myocardial potassium egress (a measure of sodium- $\text{Na}^+\text{-K}^+\text{-ATPase}$  inhibition).<sup>89</sup> In humans,  $\text{MgSO}_4$  abolished digoxin-associated extrasystoles in all but 1 of 14 patients.<sup>42</sup> Magnesium sulfate eliminated digoxin-associated tachydysrhythmias in all 7 patients who were also determined to have decreased intracellular [magnesium] despite normal serum [magnesium] and [digoxin].<sup>25</sup>

In seven patients taking digoxin for chronic Chagasic cardiomyopathy, all of those with magnesium deficiency as determined by muscle biopsy had cardiac dysrhythmias (eg, ventricular tachycardia {VT}, AV dissociation), some despite normal serum magnesium.<sup>17</sup> Twenty-one hospitalized patients with low intracellular magnesium concentrations as determined by monocyte analysis or serum hypomagnesemia, experienced classic digoxin toxicity (eg, ventricular tachycardia, multiple premature or multifocal ventricular beats, supraventricular tachycardia with AV nodal block) at relatively low serum digoxin concentrations (three of 2 nmol/L).<sup>135</sup> Three of 21 patients with digoxin toxicity had low intracellular magnesium concentrations but normal serum concentrations. In human case reports, magnesium has stabilized refractory digoxin-associated ventricular dysrhythmias when digoxin-specific antibody fragments were unavailable.<sup>46,68</sup> Magnesium augmented the efficacy of Digifab in reversing marinobufagenin-induced  $\text{Na}^+\text{-K}^+\text{-ATPase}$  inhibition in humans with pregnancy-induced hypertension and elevated marinobufagenin concentrations, providing an experimental link for magnesium efficacy in preeclampsia.<sup>137</sup> On the basis of these data, it is reasonable to administer magnesium to patients with tachydysrhythmias evidence of digoxin poisoning, even in the setting of normal digoxin concentrations.

Magnesium sulfate has been used sporadically to treat patients with other specific cardiovascular poisonings. In murine models of amitriptyline poisoning,  $\text{MgSO}_4$  was effective and superior to lidocaine in converting VTs and synergistic with norepinephrine in reducing occurrence of dysrhythmias.<sup>72,73</sup>

Case reports demonstrate similar benefit of magnesium in converting refractory ventricular dysrhythmias in cyclic antidepressant overdose.<sup>23,49,74,108</sup> In one randomized trial of 72 patients with cyclic antidepressant poisoning,  $\text{MgSO}_4$  1 g every 6 hours in addition to standard care with bicarbonate infusion decreased intensive care unit (ICU) duration and decreased the mortality rate from 33% to 14%.<sup>41</sup> In a review of ventricular dysrhythmias associated with aconite poisoning,  $\text{MgSO}_4$  terminated dysrhythmias in two of nine patients, although its precise role was unclear.<sup>29</sup>

Magnesium use in patients with cardiac dysrhythmias has demonstrated efficacy and safety. Large doses of  $\text{MgSO}_4$  (7–12 g) were initially explored to suppress multifocal atrial tachycardia.<sup>62</sup> As an adjunct,  $\text{MgSO}_4$  improved rate control and rhythm conversion in patients with atrial fibrillation primarily treated with digoxin.<sup>32</sup> A separate study found that twice as much IV digoxin was required for rate control of atrial fibrillation in hypomagnesemic patients (<1.5 mEq/L).<sup>34</sup> Intravenous  $\text{MgSO}_4$  (3±2 g initially) enhanced the efficacy of dofetilide to chemically cardiovert 160 patients with atrial fibrillation and flutter, a 107% increased odd of success.<sup>26</sup> From a safety perspective, in 20 patients who received ibutilide for atrial fibrillation and flutter, 2 g of  $\text{MgSO}_4$  eliminated the 29% increase in QT interval induced by ibutilide.<sup>57</sup> In a trial of 476 patients with atrial fibrillation and flutter, IV infusion of 5 g of  $\text{MgSO}_4$  for 1 hour before the ibutilide administration followed by an additional IV infusion of 5 g of magnesium increased the rate of conversion to sinus rhythm from 67.3% to 76.5% and decreased the incidence of ventricular dysrhythmias (including torsade de pointes) from 7.4% to 1.2%.<sup>95</sup> In a separate trial of 229 consecutive patients who received ibutilide,  $\text{MgSO}_4$  (1–4 g) was associated with a dose-responsive 78% increased odds of successful chemical conversion.<sup>117</sup> Magnesium sulfate (0.037 g/kg body weight followed by 0.025 g/kg/h) eliminated the need to administer amiodarone (for heart rate >110 or non-sinus rhythm) in 16 of 29 patients critically ill patients with new-onset atrial fibrillation who would have otherwise received it per protocol.<sup>113</sup> An oral dose of only 250 to 500 mg/day  $\text{MgSO}_4$  did not improve the efficacy of conversion of atrial fibrillation with sotalol.<sup>47</sup> However, in a study of 34 patients, oral magnesium (500 mg) reduced the QTc interval prolongation induced by sotalol and dofetilid.<sup>86</sup> Although one meta-analysis was unable to demonstrate a benefit of prophylactic  $\text{MgSO}_4$  in preventing postoperative atrial fibrillation in cardiac surgery,<sup>27</sup> subsequent evaluations have found a distinct dose-response benefit when magnesium was added to cardioplegic solutions.<sup>50</sup> These data suggest a benefit of magnesium as a primary antidysrhythmic and the ability of magnesium to mitigate cardiotoxicity from other antidysrhythmics.

Torsade de pointes is a subset of polymorphic VT that often self-terminates and occurs in the setting of a prolonged QT interval.<sup>14</sup> Not all polymorphic VT is torsade de pointes. This is a critical distinction in interpreting the literature. Previously unrecognized blockade of the cardiac rapidly activating delayed potassium rectifier current (*hERG/KCNH2* gene) has led to multiple drug withdrawals and led the FDA to mandate *hERG* assays and electrocardiogram trials since 2005 to evaluate “QT liability” and the prodysrhythmic cardiovascular risk of new chemical entities.<sup>80</sup> Many drugs possess QT liability, which can be exacerbated in overdose or occur with coingestants that modify metabolism. The QT interval has limitations as a surrogate marker for torsade de pointes, and toxins may be torsadogenic through mechanisms other than directly blocking *hERG*, such as by interfering with channel synthesis or surface expression (eg, pentamidine).<sup>80</sup> Furthermore, QT interval prolongation in poisoning is likely multifactorial.

The 2015 American Heart Association (AHA) guidelines update for emergency cardiovascular care did not readdress the use of magnesium in cardiac arrest with polymorphic VT.<sup>81</sup> These guidelines noted that routine use of magnesium for ventricular fibrillation (VF) or polymorphic VT was not recommended in adult patients on the basis of randomized trials showing no benefit of magnesium in patients with out-of-hospital cardiac arrest receiving cardiopulmonary resuscitation,<sup>43</sup> in-hospital cardiac arrest,<sup>118</sup> and refractory or recurrent VF.<sup>5,55,81</sup> These guidelines apply to a different population than those encountered in poisoning. The prehospital trial<sup>43</sup> did not mention polymorphic VT (or torsade de pointes); the in-hospital cardiac arrest

trial<sup>118</sup> specifically excluded patients with clinical indications for magnesium and torsade de pointes, the remaining trials<sup>55,81</sup> evaluated patients with VF (not with torsade de pointes or polymorphic ventricular tachycardia), and all failed to ascribe or associate a case of dysrhythmia or arrest to a toxicologic cause. The guidelines acknowledged that the most common cause of polymorphic VT in these cases was myocardial ischemia.<sup>81</sup> The importance of this distinction between ischemic versus xenobiotic-induced QT interval prolongation was highlighted by a study in which IV MgSO<sub>4</sub> (3.75 g over 3 minutes) in nine patients shortened QTc interval prolongation induced by amiodarone and quinidine (despite normal electrolytes and magnesium concentrations) but did not do so in those with a prolonged QTc interval because of ischemic coronary disease.<sup>53</sup> Low serum magnesium is associated with an increased risk of sudden cardiac death.<sup>67</sup> The AHA guidelines recommend “consideration of” IV MgSO<sub>4</sub> when polymorphic VT was secondary to a long QT interval (ie, torsade de pointes).<sup>81</sup>

Magnesium sulfate was first reported to treat three patients with torsade de pointes induced by quinidine and amiodarone, procainamide, and imipramine in 1984.<sup>123</sup> A subsequent case series of 6 and 12 patients demonstrated similar benefit for torsade de pointes, as well as a benefit in patients with intractable ventricular tachydysrhythmias despite normomagnesemia.<sup>62,97,122</sup> MgSO<sub>4</sub> also eliminated torsade de pointes in pediatric patients with congenital and acquired long QT syndrome.<sup>59,60</sup> Case reports variously describe the success of MgSO<sub>4</sub> in resolving QRS complex and QTc interval abnormalities in poisonings by escitalopram,<sup>109</sup> flecainide,<sup>129</sup> antipsychotics,<sup>90</sup> and arsenic trioxide.<sup>38</sup> There is significant divergence of opinion among toxicologists about what constitutes a prolonged or corrected QT interval, QT interval thresholds that require intervention (if any), and magnesium dosing (if any) in cases of drug-induced QT interval prolongation.<sup>92</sup> Other than where described in the clinical trials earlier, magnesium does not typically affect the QT interval, making ascertainment of efficacy difficult. Based on the limited available data, it is reasonable to ensure eumagnesemia in patients with prolonged QT interval and administer magnesium in patients with progressive QT interval prolongation due to poisoning. After an episode of torsade de pointes, it is recommended to administer IV MgSO<sub>4</sub>.<sup>81,119</sup>

## ROLE IN ETHANOL DISORDERS AND THIAMINE DEFICIENCY

Chronic alcohol use is associated with hypomagnesemia. In one series of 105 patients with heavy alcohol use, magnesium deficiency was present in 48%.<sup>36</sup> Magnesium deficiency correlated with worse cognitive test scores, even in the setting of normal thiamine pyrophosphate concentrations.<sup>36</sup> A smaller study found magnesium deficiency in 53% of patients admitted for detoxification.<sup>35</sup> In another study of 62 active drinkers, hypomagnesemia was present in 23% and directly correlated with QT interval prolongation.<sup>87</sup> Magnesium is an essential cofactor of the thiamine-dependent enzymes transketolase and pyruvate dehydrogenase, and magnesium increases the activity of a third critical thiamine-dependent enzyme  $\alpha$ -ketoglutarate dehydrogenase.<sup>94</sup> In people with alcoholism and nutritionally deficient patients, Wernicke's encephalopathy and thiamine deficiency remained refractory despite thiamine repletion until magnesium deficiency was addressed.<sup>28,39,121</sup> More than 4 decades ago, murine studies confirmed early human observations of the critical role of adequate magnesium in thiamine efficacy. Magnesium deficiency results in a loss of thiamine from tissues and limits the response to exogenous thiamine; magnesium supplementation augments the response to thiamine repletion in thiamine-deficient rats.<sup>138</sup> Furthermore, thiamine pyrophosphokinase, the enzyme that activates thiamine to thiamine pyrophosphate (thiamine diphosphate), requires magnesium as a cofactor.<sup>106</sup> In a controlled trial of 36 patients with chronic alcohol use disorders, those given MgSO<sub>4</sub> in addition to thiamine demonstrated significantly greater transketolase activity.<sup>96</sup>

Separately, magnesium was evaluated for its role in mitigating the consequences of alcohol withdrawal and neuronal hyperactivity. Hypomagnesemia is associated with higher structured scores of alcohol withdrawal.<sup>101</sup> The degree of hypomagnesemia in patients with alcoholism correlates with stroboscopic-inducible seizure (photoconvulsion) thresholds, which itself

correlates with incidence of spontaneous seizures and delirium tremens.<sup>132</sup> Unfortunately, there are few appropriately designed studies, and they are often limited in their clinical scope. In a randomized, parallel group, double-blind trial of 119 patients with mild to moderate alcohol withdrawal designed to evaluate biochemical parameters, 8 weeks of oral daily magnesium (500 mg) sped recovery of aspartate aminotransferase (AST).<sup>100</sup> In a randomized, placebo-controlled trial of 59 consecutive patients with alcoholic liver disease, 2 days of 729 mg (30 mmol)/day of IV MgSO<sub>4</sub> followed by 6 to 7 weeks of 304 mg (12.5 mmol)/day of oral magnesium (as magnesium oxide) did not improve muscle mass or strength beyond placebo but did improve serum magnesium concentrations and was associated with higher muscle magnesium concentrations in subsequent analysis.<sup>1</sup> The study was confounded by a failure to control for spironolactone treatment, which is magnesium-sparing. In 49 patients with alcoholism randomized in a double-blind fashion to receive either 364 mg (15 mmol) oral magnesium daily (as magnesium-lactate-citrate tablets) or matching placebo for 6 weeks, magnesium supplementation improved aminotransferases, maximal muscle hand grip strength, and sense of general well-being.<sup>52</sup> An early review of treatment of delirium tremens before the routine use of benzodiazepines found that MgSO<sub>4</sub> administration decreased the duration of tremor and visual hallucinations.<sup>45</sup> However, in one of the few studies evaluating acute withdrawal, a double-blind, placebo-controlled trial of 100 patients, four doses of IM MgSO<sub>4</sub> (2 g every 6 hours) did not alter chlorthalidoxepoxide use or the incidence of diaphoresis, tremor, vomiting, hallucinations, or withdrawal severity.<sup>130</sup> The study was underpowered to detect a difference in grand mal seizures and delirium tremens. This is in contrast to the findings of a retrospective review of 781 patients with alcoholism being treated for detoxification, which documented a lower seizure incidence in the patients treated with magnesium.<sup>31</sup> In a separate controlled study of eight patients with acute withdrawal, magnesium repletion either completely abolished inducible photoconvulsive responses or raised photoconvulsion thresholds.<sup>132</sup> Given the significant prevalence of magnesium and thiamine deficiency in individuals with alcoholism and magnesium's critical role for thiamine efficacy and its alteration of seizure thresholds in controlled human experimental studies, it is reasonable to actively screen for magnesium deficiency and administer magnesium to patients with hypomagnesemia, those with moderate to severe alcoholic withdrawal (including withdrawal seizures or associated with elevated aminotransferases), and those at risk for Wernicke's encephalopathy.

The importance of magnesium to thiamine pyrophosphate function is also reflected in the guidance to administer magnesium and thiamine as adjunctive treatments for ethylene glycol poisoning.<sup>10</sup> Metabolism of the ethylene glycol metabolite glyoxylic acid to 2-hydroxy-3-oxoadipate requires thiamine pyrophosphate and is facilitated by magnesium administration.<sup>88</sup> In one *in vitro* study, the lack of magnesium decreased glyoxylic acid metabolism to 2-hydroxy-3-oxoadipate by 60%.<sup>66</sup> Separately, glyoxylic acid covalently inactivates thiamine pyrophosphate, and thus the pyruvate decarboxylase complex, making ensuring sufficient thiamine of critical importance.<sup>44</sup> As a relatively benign intervention, it is reasonable to administer magnesium as adjunctive therapy to ethylene glycol-poisoned patients with normal kidney function while pursuing definitive management (eg, hemodialysis, fomepizole) as reviewed in Chap. 106.

## ROLE IN PESTICIDE POISONING

Because magnesium diminishes calcium channel mediated synaptic acetylcholine release, it was hypothesized that MgSO<sub>4</sub> might ameliorate organic phosphorus (OP) effects at the neuromuscular junction and elsewhere.<sup>40</sup> Magnesium sulfate blunted paraoxon-induced tachycardia, hypertension, and hemoconcentration in mini pigs.<sup>98,99</sup> In four OP-poisoned patients, MgSO<sub>4</sub> administration produced no appreciable clinical or electrophysiological change when given 9 days into poisoning; when given 2 to 3 days into care, electrophysiological alterations consistent with conversion of an OP depolarizing blockade to a presynaptic blockade occurred, with no clinical change.<sup>112</sup> A rat model of sarin poisoning highlighted the distinct importance of distinguishing tonic-clonic convulsions from ongoing seizure. Although magnesium

attenuated visible convulsions, sustained seizure activity and brain injury continued to occur.<sup>65</sup> In a small controlled trial of 11 patients given 4 g/day of IV MgSO<sub>4</sub> compared with 34 patients given usual care (multiple-dose activated charcoal, atropine, and oximes) the requirement for atropine and oximes did not differ, but the duration of hospitalization decreased, and the mortality rate decreased from 15% to 0%.<sup>93</sup> In a subsequent phase 2 trial, 40 patients received MgSO<sub>4</sub> 4, 8, 12, or 16 g in a 4:1 treatment:control pseudorandomization.<sup>11</sup> Compared with six patients (60%) who died in the total control group, 3 of 16 (19%), 2 of 8 (25%), 1 of 8 (13%), and 0 of 8 (0%) patients died in the 4-g, 8-g, 12-g, and 16-g groups, respectively. A double-blind, prospective randomized clinical trial of 100 patients with OP poisoning found that 4 g of MgSO<sub>4</sub> IV reduced atropine requirements over 30 minutes and reduced the need for intubation and ICU stay but did not alter the mortality rate.<sup>125</sup> Separately, the cardiovascular complications of organophosphorus compounds are well described. Severe rhythm and conductivity disorders resulted in cardiac arrest and death in 29 patients poisoned with organic phosphorus compounds.<sup>85</sup> In a review of 168 organ, QT interval prolongation, ST segment and T wave anomalies were present in 134 (80%), and frequent dysrhythmias appeared in 56 patients (33%).<sup>69,70</sup> A separate study confirmed these findings and reported QT interval prolongation in 14 of 15 patients (93%) and malignant dysrhythmias in 6 of 15 (40%).<sup>83</sup> Magnesium sulfate (dose unspecified) was used to suppress ventricular ectopy in these cases.<sup>70</sup> Given the available data, it would be reasonable to provide MgSO<sub>4</sub> in organic phosphorus compound poisoning.

Metal phosphides (eg, aluminum and zinc), used as rodenticides and fumigants, have become a common cause of self-poisoning in certain countries (Chap. 108). For example, phosphine was found in 619 of 674 cases (92%) of suicidal poisonings in Tehran.<sup>75</sup> Magnesium concentrations in the setting of poisoning are quite variable. The lack of specific antidotes and the significant toxicity of phosphides led to the search for other interventions. Administration of magnesium in the form of the novel pharmacophore porphyllyren-MC16 reversed aluminum phosphide-induced bradycardia, hypotension, energy depletion, and lipid peroxidation in mice.<sup>9</sup> One human trial found decreased markers of oxidative stress in aluminum phosphide-poisoned patients given MgSO<sub>4</sub>.<sup>22</sup> Human studies conflict as to the efficacy of magnesium administration; some demonstrate efficacy and other no benefit, leaving magnesium's role unclear.<sup>8,102</sup> Given the absence of any meaningful alternatives to supportive care in phosphide poisoning, it is reasonable to administer MgSO<sub>4</sub>. In barium poisoning, oral MgSO<sub>4</sub> is administered to precipitate insoluble barium sulfate to preclude absorption and is reviewed in Chap. 107.

## ROLE IN HYDROFLUORIC ACID AND FLUORIDE-RELEASING XENOBIOTICS

In addition to binding calcium, fluoride (Chap. 104) also binds to potassium and magnesium. Calcium administration (Antidotes in Depth: 32) remains a mainstay of treatment for hydrofluoric acid (HF) exposures. In murine studies, oral MgCl<sub>2</sub> administration for decontamination successfully increased the LD<sub>50</sub> of sodium fluoride, but oral MgSO<sub>4</sub> was unsuccessful in increasing survival in another pretreatment HF ingestion model.<sup>56,76,84</sup> Intravenous MgCl<sub>2</sub> increased the lethal dose and delayed death in a porcine HF ingestion model.<sup>24</sup> Clinical experience has demonstrated that relatively small skin surface HF burns (3.5% or less of concentration HF) in humans can lead to profound hypomagnesemia (in addition to hypocalcemia), which, if left unaddressed and not aggressively reversed (in addition to calcium administration), can contribute to death.<sup>30,116,134</sup> Survival and mitigation of lethal dysrhythmias in HF or sodium fluoride ingestion both typically require large amounts of magnesium and calcium.<sup>2,114</sup> It is reasonable to administer magnesium in cases of systemic toxicity from fluoride-releasing xenobiotics.

## ADVERSE EFFECTS AND SAFETY ISSUES

The side effects of MgSO<sub>4</sub> administration were all well described in a series of 100 parenteral administrations in 1941. These included cardiovascular effects of cutaneous vasodilation; conduction disturbances such as bradycardia,

hypotension, and cardiac arrest; respiratory depression; GI complaints of nausea, vomiting, and thirst; and neurologic sequelae of restlessness, confusion, a sense of impending doom, CNS depression, and paralysis.<sup>131</sup> The usefulness of surveillance of patellar reflexes in anticipating respiratory depression was also recognized.<sup>131</sup> Hypocalcemia and hyperkalemia are also reported with MgSO<sub>4</sub> treatment for preeclampsia.<sup>61</sup> Patients with acute or chronic kidney disease or low urine flow rates are at increased risk for hypermagnesemia.<sup>82,136</sup> Frequent serum magnesium concentrations should be obtained. Magnesium sulfate inhibits platelet function in vitro and in vivo, which is reported to prolong bleeding times.<sup>51,54</sup>

Case series and reports abound of iatrogenic hypermagnesemia through a variety of mechanisms. These include free-flowing (“runaway”) or misprogrammed pump infusions; confounding with IV bags of other infusing solutions (eg, oxytocin, lactated ringers); mislabeled infusions; 10-fold administration errors; and concentration, dilution, and admixture errors.<sup>19,111</sup> In the event of hypermagnesemia or hypocalcemia leading to significant symptoms (eg, respiratory muscle paralysis, hypotension, or dysrhythmia), IV calcium (Antidotes in Depth: 32) is used to counteract the effects.

## PREGNANCY AND LACTATION

In 2013, the status of magnesium was changed from Pregnancy Class A to D (positive evidence of human fetal risk, but the potential benefits are acceptable in certain situations despite its risks). An FDA safety alert cautioned that continuous MgSO<sub>4</sub> administration to pregnant women for longer than 5 to 7 days was associated with fetal hypocalcemia, osteopenia, skeletal abnormalities, and fractures.<sup>124</sup> Magnesium sulfate was associated with neonatal cord serum concentrations of 70% to 100% of maternal concentrations but did not lower neonatal Apgar scores.<sup>15</sup> Magnesium sulfate was not associated with congenital malformations.<sup>15</sup>

Magnesium distributes into breast milk during parenteral magnesium administration. Breast milk values in patients with preeclampsia given MgSO<sub>4</sub> were similar to those of control participants by 48 hours.<sup>15</sup> Although caution should be exercised when MgSO<sub>4</sub> is administered to a nursing mother, the American Academy of Pediatrics considers MgSO<sub>4</sub> to be compatible with breastfeeding.<sup>7</sup>

## DOSING AND ADMINISTRATION

Magnesium dosing varies significantly. In the setting of magnesium deficiency, several grams of MgSO<sub>4</sub> provided over the first day in divided doses of 1 to 2 g are often required for repletion, with frequent serum determinations to guide therapy. For torsade de pointes in adults, 2 g (25–50 mg/kg in children up to 2 g) of MgSO<sub>4</sub> intravenously is recommended.<sup>119</sup> The caveat for the potential need for repeated doses may be missed. In perspective, 2 to 5 g or more of MgSO<sub>4</sub> was typically used in the cardiac conversion and dysrhythmia trials. A dose of 2 g in adults followed by an infusion or intermittent doses of 0.5 to 1 g/h to sustain serum (and intracellular) concentrations appears more rational. Again by comparison, 4 g of IV MgSO<sub>4</sub> is recommended to initiate therapy for severe preeclampsia or eclampsia for maternal and fetal neuroprotection, with maintenance doses typically of 1 to 2 g/h.<sup>33,82,91</sup> Empiric IV MgSO<sub>4</sub> administration for a prolonged QT interval is controversial; approximately 50% of toxicologists use a QTc threshold of 500 ms, although this was scenario dependent.<sup>92</sup> Eumagnesemia (and normal potassium) should be ensured in patients with prolonged QT interval, and given the lack of consensus, it would be reasonable to administer magnesium in patients with progressive QT interval prolongation from poisoning. The recommended dose mirrors that for torsade de pointes: 2 g of MgSO<sub>4</sub> in adults followed by infusion or intermittent doses of 0.5 to 1 g/h with endpoints guided by the specific clinical circumstances. The rate of administration depends on the clinical scenario. For example, in a seizing patient with eclampsia, a dose of 4 g MgSO<sub>4</sub> is rapidly provided over 5 minutes.<sup>82</sup> Use in life-threatening ventricular dysrhythmia would predispose to a similar rapid rate, recalling that care should prioritize electrical therapy (cardioversion or defibrillation) in unstable rhythms. In nonemergent scenarios, MgSO<sub>4</sub> is administered at a rate not to exceed 150 mg/min. If used in organic

phosphorus compound poisoning, MgSO<sub>4</sub> doses mirroring the clinical trials (at least 4 g/day) are recommended. Magnesium requirements in fluoride poisoning are significant and guided by serum and clinical assessment. Magnesium sulfate should be diluted to a less than or equal to 20% concentration for IV administration.

## FORMULATION AND ACQUISITION

A variety of MgSO<sub>4</sub> formulations are available for parenteral administration: 4% (40 mg/mL) or 8% (80 mg/mL) in sterile water volumes ranging from 100 mL to 1 L. Magnesium sulfate injection, 50% in water (500 mg/mL), is typically supplied as 2 or 10 mL. Magnesium sulfate is also formulated in 5% dextrose in concentrations ranging from 1% (10 mg/mL) to 2% (20 mg/mL) and in similar volume ranges.

Magnesium in much smaller concentrations (eg, 0.3 mg/mL) is found as a component of multiple or mixed electrolyte or parenteral nutritional infusion formulations (eg, in combination with acetate, chloride, potassium, and sodium). These would not be anticipated to be sufficient for antidotal purposes. Of note, dialysate solutions containing magnesium present the potential for medication error and should not be confused with those intended for IV infusion.

## SUMMARY

- Magnesium sulfate is used to treat xenobiotic-associated hypomagnesemia and as an adjunctive therapy to treat cardiovascular toxins, fluoride toxicity, and pesticide poisoning.
- Ectopy in patients taking cardioactive steroids can be mitigated by MgSO<sub>4</sub> while awaiting definitive therapy (digoxin Fab fragments).
- Magnesium sulfate therapy and correction of electrolytes are mainstays of therapy to preclude recurrent torsade de pointes, although optimal dosing remains to be defined.
- The decision to intervene with MgSO<sub>4</sub> in isolated QT interval prolongation is complex. Repletion of hypomagnesemia should occur. An initial dose followed by an infusion is reasonable because cellular exchange of magnesium is slow compared with more rapid kidney excretion.
- Hypomagnesemia should be assessed and treated in patients with alcohol use disorders.

## ANTITHROMBOTICS

Betty C. Chen and Mark K. Su

### HISTORY AND EPIDEMIOLOGY

Antithrombotics have numerous clinical applications, including in the treatment of coronary artery disease, cerebrovascular events, hypercoagulable states, deep vein thrombosis (DVT), and pulmonary embolism (PE). The antithrombotics are a diverse group of xenobiotics that are widely studied and constantly in the process of therapeutic evolution.

The origins and discovery of antithrombotics are extraordinary.<sup>6,29,156,259</sup> The discovery of modern-day oral anticoagulants originated after investigations of a hemorrhagic disorder in Wisconsin cattle in the early 20th century that resulted from the ingestion of spoiled sweet clover silage. The hemorrhagic agent, eventually identified as bishydroxycoumarin, would be the precursor to its synthetic congener warfarin (named after the Wisconsin Alumni Research Foundation). Warfarin was rapidly marketed as both a medicine and a rodenticide. “Superwarfarins” were subsequently developed for the rat population that had developed increasing genetic resistance to warfarin.

The origins of the anticoagulant heparin are equally fascinating. A medical student initially attempting to study ether soluble procoagulants derived from porcine intestines serendipitously found that, over time, these apparent “procoagulants” actually prevented normal blood coagulation. The phospholipid anticoagulant responsible for this effect would later be identified as a variant form of heparin. Shortly thereafter, the water-soluble mucopolysaccharide termed *heparin* (because of its abundance in the liver) was discovered. *Unfractionated* heparin (UFH) is a mixture of polysaccharide chains with varying molecular weights. After the identification of the active pentasaccharide segment of heparin in the 1970s, multiple *low-molecular-weight* heparins (LMWHs) were isolated, and synthetic forms were created.

Hirudin, a 65–amino acid polypeptide, was produced by the salivary glands of the medicinal leech (*Hirudo medicinalis*).<sup>256</sup> Antistasin and antistasinlike proteins are naturally secreted by the Mexican leech, *Haementeria officinalis*, and the earthworm.<sup>106,370</sup> These xenobiotics have not been used therapeutically; however, they inspired the development of the synthetic factor inhibitors, such as direct thrombin inhibitors (DTIs) and factor Xa inhibitors.

In the late 19th century, human urine was noted to have proteolytic activity with specificity for fibrin. A substance found to be an activator of endogenous plasminogen leading to the consumption of fibrin, fibrinogen, and other coagulation proteins was isolated and purified and given the name *urokinase*. Streptokinase, a protein produced by  $\beta$ -hemolytic streptococci, tissue plasminogen activator (t-PA), and other synthetic thrombolytics were later discovered. Although known to exist for many years, ancrod, a purified derivative of Malayan pit viper, only recently gained therapeutic attention as a naturally occurring antithrombotic.

In the early 20th century, the antithrombotic properties of aspirin were noted in anecdotal reports of patients having a predisposition to bleeding while taking aspirin. Clinicians also noted lower rates of myocardial infarction (MI), and studies to elucidate the effects of aspirin on coagulation soon followed with further research exposing the role of platelet aggregation in thrombosis.<sup>251</sup> These discoveries led to the development of the antiplatelet xenobiotics.

The diversity of these antithrombotics led to ever-increasing use in many fields of medicine. Although warfarin is the most common oral anticoagulant in use today because of its utility in patients with cerebrovascular disease, cardiac dysrhythmias, and thromboembolic disease, the emergence of newly developed oral antithrombotics has changed the landscape of modern anticoagulation. During the period from 2011 to 2015, the American Association of Poison Control Centers has listed anticoagulants in the top 25 categories associated with the largest number of fatalities (Chap. 130).

The total number of cases of reported antithrombotic exposures to the American Association of Poison Control Centers was 96,498 with 130 deaths during that 5-year period (Chap. 130). During that time period, new antithrombotics such as apixaban, edoxaban, and ticagrelor joined the market. In 2011, dabigatran and warfarin led the US Food and Drug Administration (FDA) Safety Information and Adverse Event Reporting Program's list of adverse drug events, with 3,781 reports of serious adverse events associated with dabigatran, including 542 patient deaths. By comparison, warfarin alone accounted for 1,106 reports with 72 deaths.<sup>255</sup> Since then, the FDA is continually reviewing dabigatran and initiated its own study that demonstrated lower risks of death, stroke, and intracranial hemorrhage but higher risks of gastrointestinal (GI) bleeding in patients anticoagulated with dabigatran compared with warfarin.<sup>371</sup>

### PHYSIOLOGY

#### Balance Between Coagulation and Anticoagulation

An understanding of the normal function of the coagulation pathways is essential to appreciate the etiology of a coagulopathy. This section summarizes the critical steps of the coagulation cascade. For additional details, readers are referred to Chap. 20 and several reviews.<sup>135,252,257,304</sup>

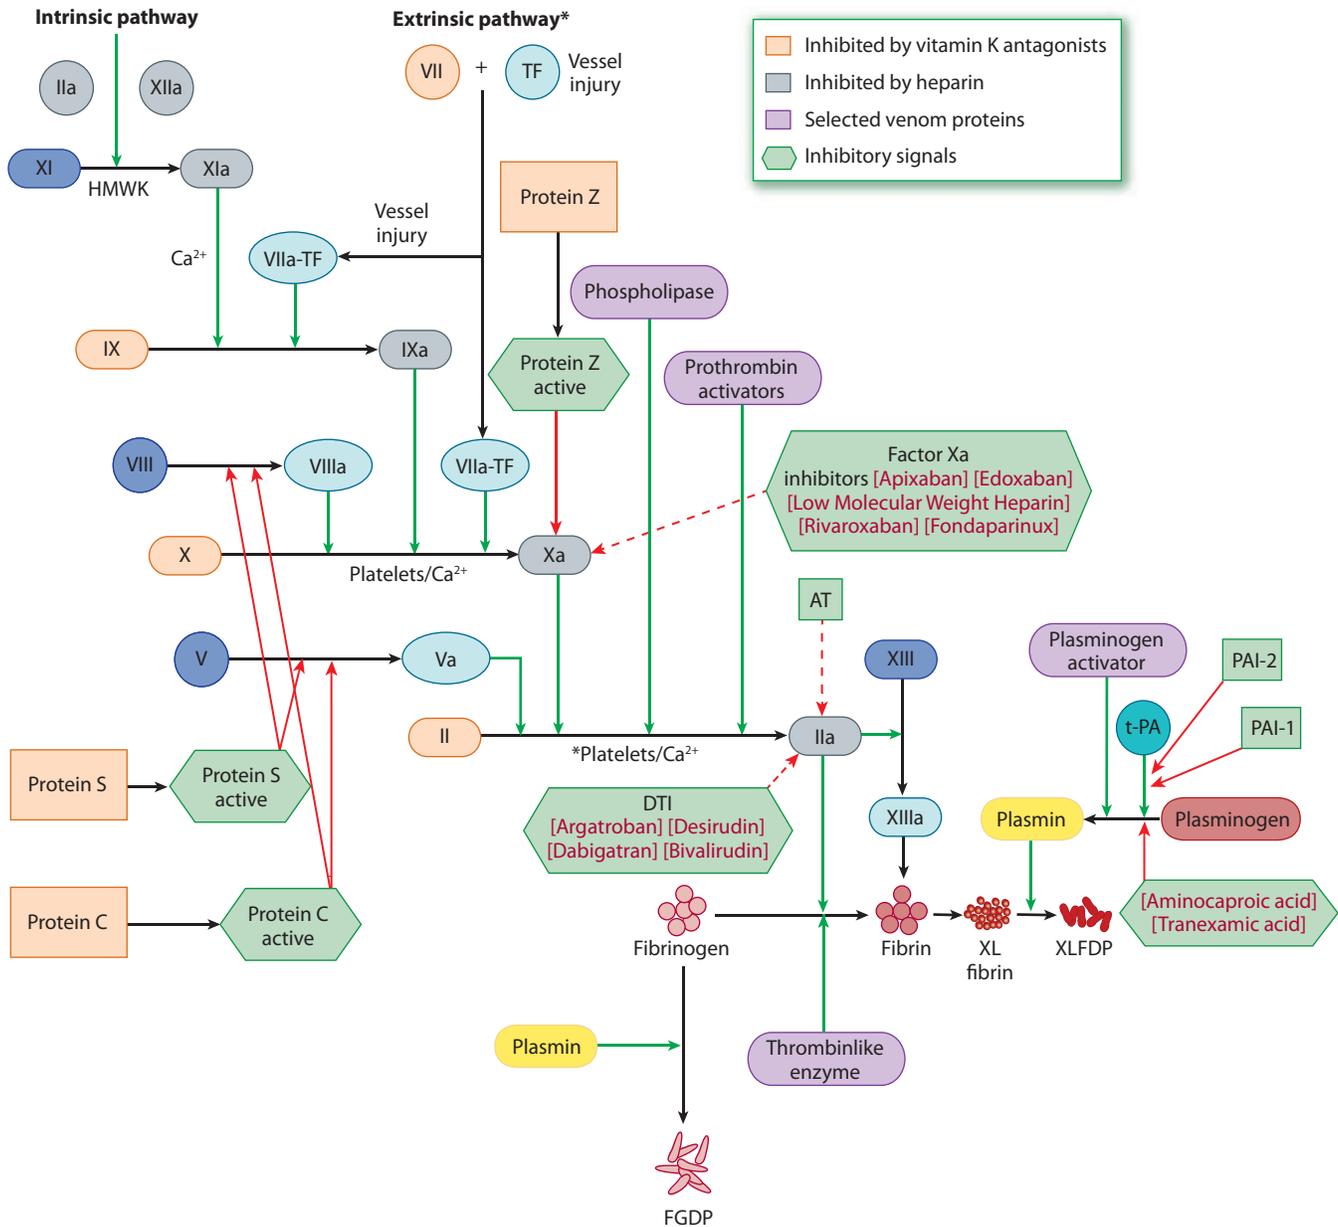

Coagulation consists of a series of events that prevent blood loss and assist in the restoration of blood vessel integrity. Although the traditional understanding of the events that occur in the coagulation cascade,<sup>91,231</sup> as discussed later, adequately describe in vitro events, the current understanding emphasizes some distinct differences that occur in vivo.<sup>135,257,304</sup> Despite these differences, an understanding of the traditional model is most useful for interpreting the results of diagnostic tests of coagulation.

Within the cascade, coagulation factors exist as inert precursors and are transformed into enzymes when activated. Activation of the cascade occurs through one of two distinct pathways, the *intrinsic* and *extrinsic* systems (Fig. 58–1).<sup>91,231</sup> After being activated, these enzymes catalyze a series of reactions that ultimately converge to generate thrombin with the subsequent formation of a fibrin clot.

The *intrinsic* pathway is activated by the complexation of factor XII (Hageman factor) with high-molecular-weight kininogen (HMWK) and prekallikrein or vascular subendothelial collagen. This results in sequential activation of factor XII, active kallikrein, active factors IX to XI, and prothrombin (factor II) (Fig. 58–1). Prothrombin is converted to thrombin in the presence of factor V, calcium, and phospholipid. The integrity of this system is usually evaluated by determining the partial thromboplastin time (PTT).

In the *extrinsic* or tissue factor–dependent pathway, a complex is formed between factor VII, calcium, and tissue factor, which is released after injury. A calcium- and lipid-dependent complex is then created between factors VII and X. The factor VII–X complex subsequently converts prothrombin to thrombin, which promotes the formation of fibrin from fibrinogen (Fig. 58–1). The integrity of this pathway is usually assessed by determining the prothrombin time (PT or international normalized ratio {INR})<sup>120</sup>. The distinction between PT and INR is discussed in Chap. 20.

Activation of factor X provides the important link between the intrinsic and extrinsic coagulation pathways. Additional evidence that tissue factors can activate both factors IX and X suggests that there are more interrelations between the two pathways.<sup>275</sup> Furthermore, cell surfaces facilitate the process of clotting. Platelets are also known to interact with proteins of the coagulation cascade through surface receptors for factors V, VIII, IX, and X.<sup>142,265,339</sup> As a final step, factor XIII assists in the cross-linking of fibrin to form a stable thrombus.

**FIGURE 58-1.** A schematic overview of the coagulation, platelet activation, and fibrinolytic pathways indicating where phospholipids on the platelet surface interact with the coagulation pathway intermediates. Arrows are not shown from platelets to phospholipids involved in the tissue factor VIIa and the factor IX to VIIIa interactions to avoid confusion. Interactions of selected venom proteins are indicated in the purple boxes. The diagram is not complete with reference to the multiple sites of interaction of the serine protease inhibitors (SERPINS) to avoid overcrowding. Solid red lines indicate inhibition of a reaction effect. Black arrows refer to chemical conversion of coagulation factors. Green arrows represent activation of the chemical conversion pathway. Dashed red lines indicate inhibition of a specific clotting factor. \*Refer to Figs. 58-4 and 58-5 for the platelet activation pathway. DTI = direct thrombin inhibitor; FDP = fibrin degradation products; FGDP = fibrinogen degradation product; HMWK = high-molecular-weight kinogen; TF = tissue factor; t-PA = tissue plasminogen activator; XL = cross-linked.

Antithrombin (AT), and proteins C, S, and Z serve as inhibitors, maintaining the homeostasis that is required to prevent spontaneous clotting and keep blood fluid. Protein C, when aided by protein S, inactivates two plasma factors, V and VIII.<sup>46,73,135</sup> Protein Z is a glycoprotein (GP) molecule that forms a complex with the protein Z-dependent protease inhibitor (ZPI) which, in turn, inhibits the activated factor X (Xa).<sup>380</sup> Antithrombin complexes with all the serine protease coagulation factors (factor Xa, factor IXa, and contact factors, including XIIa, kallikrein, and HMWK), except factor VII.<sup>46,135,304</sup>

Thrombolytics such as streptokinase, urokinase, anistreplase, and recombinant tissue plasminogen activator (rt-PA) enhance the normal processes that lead to clot degradation.<sup>257</sup>

Thrombosis is initiated when exposed endothelium or released tissue factors lead to platelet adherence and aggregation, the formation of thrombin, and cross-linking of fibrinogen to form fibrin strands.<sup>135,257,304</sup>

This results in a hemostatic plug or thrombus formation. Thrombus formation, in turn, leads to generation of plasmin from plasminogen, which causes fibrinolysis and eventual dissolution of the hemostatic plug.<sup>74,75</sup> Thus, the fibrinolytic system is a natural balance against unregulated coagulation. Thrombolytic therapy increases fibrinolytic activity by accelerating the conversion of plasminogen to plasmin, which actively degrades fibrin.<sup>74,75</sup> After the administration of thrombolytics, a drug-induced coagulopathy ensues, and fibrin degradation products (FDPs) are elevated secondary to the rapid turnover of clot.

### DEVELOPMENT OF COAGULOPATHY

Impaired coagulation results from decreased production or enhanced consumption of coagulation factors, the presence of inhibitors of coagulation, activation of the fibrinolytic system, or abnormalities in platelet number or

function. Platelets are involved in the initial phases of clotting after blood vessel injury by assisting in the formation of the fibrin plug.

Decreased production of coagulation factors results from congenital and acquired etiologies. Although congenital disorders of factor VIII (hemophilia A), factor IX (Christmas factor Hemophilia B), factor XI, and factor XII (Hageman factor) are all reported, their overall incidence is still quite low. Clinical conditions that result in acquired factor deficiencies are much more common and result from either a decrease in synthesis or activation. Factors II, V, VII, and X are entirely synthesized in the liver,<sup>135,257,304</sup> making hepatic dysfunction a common cause of acquired coagulopathy. In addition, factors II, VII, IX, and X also require postsynthetic modification by an enzyme that uses vitamin K as a cofactor,<sup>353,358,359</sup> such that vitamin K deficiency (from malnutrition, changes in gut flora secondary to xenobiotics, or malabsorption), and inhibition of vitamin K cycling (from warfarin) are capable of impairing coagulation.

Excessive consumption of coagulation factors usually results from massive activation of the coagulation cascade. Massive activation occurs during severe bleeding or disseminated intravascular coagulation (DIC). The latter results from infection, such as sepsis, and from conditions that introduce tissue factor into the blood, such as neoplasms, snake envenomations, stagnant blood flow, diffuse endothelial injury secondary to hyperthermia, ruptured aortic aneurysm, or aortic dissection. The hallmark of a consumptive coagulopathy is a depressed concentration of fibrinogen with an elevation of FDPs. This combination suggests the rapid turnover of fibrin in the coagulation process. In the other coagulopathic conditions, the failure to activate the coagulation cascade is associated with normal or high fibrin concentrations and low FDPs because of limited clot formation.

Hypothermia is a well-known cause of DIC leading to death.<sup>365</sup> Canine studies show decreased fibrinogen, factor II, and factor VII concentrations when cooled to 68°F (20°C) while a simultaneous rise in factor V concentration occurs.<sup>140</sup> In vitro studies show increased coagulation time, clot formation time, and maximum clot strength in hypothermic whole-blood samples from healthy volunteers.<sup>103,311</sup> In addition, thrombocytopenia occurs secondary to sequestration in the spleen, liver, and splanchnic circulation.<sup>301,355</sup> Infants with hypothermia have an increased risk for intracranial and pulmonary hemorrhage.<sup>62</sup>

Inhibitors of the coagulation cascade (circulating anticoagulants) are of two types: immunoglobulins to coagulation factors or antibodies to phospholipid membrane surfaces. Immunoglobulins develop without obvious cause, are part of a systemic autoimmune disorder, or result from repeated transfusions with exogenous factors (as occurs in patients with hemophilia).<sup>162,209,330</sup> Antibodies to factors V, VII to XI, and XIII are described.<sup>35,330</sup> The clinical syndromes associated with antibody inhibitors are similar to those associated with deficiencies of the particular coagulation factors involved. Antiphospholipid antibodies are directed against phospholipid membrane surfaces and  $\beta_2$ -GP I, also known as apolipoprotein H. This protein is essential in preventing hemostasis by inhibiting adenosine diphosphate (ADP)-induced platelet aggregation, inhibiting activation of the intrinsic pathway of the coagulation cascade, and inhibiting both platelet-mediated factor Xa and factor VII activation. Therefore, destroying  $\beta_2$ -GP I creates a prothrombotic clinical status.<sup>324,325,334</sup> Paradoxically, this antibody creates a prolonged PTT because the antibody also binds to most phospholipid-containing PTT reagents. This reduction in amount of active reagent results in a falsely elevated PTT.<sup>162,209</sup>

## GENERAL MANAGEMENT

Gastrointestinal decontamination should be performed on patients who are believed to have potentially significant life-threatening ingestions unless they already present with significant bleeding. For patients who present after a few hours of ingestion, gastric emptying is not indicated (Chap. 5). In general, a single dose of activated charcoal (AC) decreases absorption of some antithrombotics and should be given unless contraindicated.<sup>272,377,391</sup> Oral cholestyramine enhances warfarin elimination,<sup>299</sup> but no studies are available that compare these two therapies or evaluate the role of combined AC and

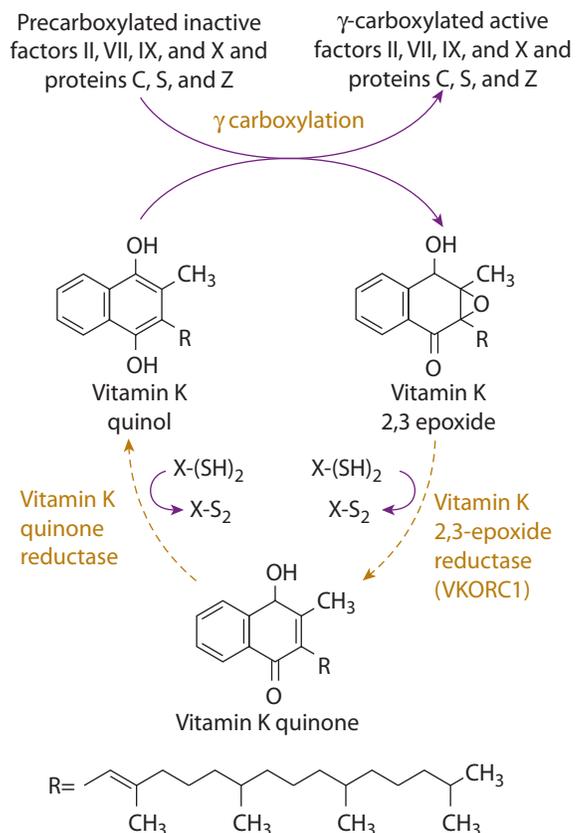

cholestyramine therapy. Therefore, early administration of AC after ingestion is the preferred form of GI decontamination, even for patients who overdose on warfarin. In addition to general supportive measures, the patient should be placed in a supervised medical and psychiatric environment that offers protection against external or self-induced trauma and permits observation for the onset of coagulopathy.

Blood transfusion is required for any patient with a history of blood loss or active bleeding who is hemodynamically unstable, has impaired oxygen transport, or is expected to become unstable. Although a transfusion of packed red blood cells (PRBCs) is ideal for replacing lost blood, it cannot correct a coagulopathy, so patients will continue to bleed. Massive transfusion protocols (MTPs) aim to correct coagulopathy with an array of blood products, electrolytes, and antifibrinolytics. If available, it is reasonable to use an MTP for unstable patients. If an MTP is not available, whole blood is reasonable in severe cases because it contains many components, including platelets, white blood cells, and non-vitamin K-dependent factors.

## VITAMIN K ANTAGONISTS

### Warfarin and “Warfarinlike” Anticoagulants

The vitamin K antagonist (VKA) anticoagulants can be divided into two groups: (1) hydroxycoumarins, including warfarin, difenacoum, coumatril, fumazol, prolin, ethyl biscoumacetate, phenprocoumon, dicumarol, bishydroxycoumarin, and acenocoumarin, and (2) indanediones, including chlorophacinone, diphacinone, diphenadione, phenindione, and anisindione. Regardless of the classification, their mechanism of action involves inhibition of the vitamin K cycle. Vitamin K is a cofactor in the postribosomal synthesis of clotting factors II, VII, IX, and X (Fig. 58–2). The vitamin K-sensitive enzymatic step that occurs in the liver involves the  $\gamma$ -carboxylation of 10 or more glutamic acid residues at the amino terminal end of the precursor proteins to form a unique amino acid  $\gamma$ -carboxyglutamate.<sup>104,353,358,359</sup> These

**FIGURE 58–2.** The vitamin K cycle. Dotted lines represent pathways that can be blocked with warfarin and warfarinlike anticoagulants. The aliphatic side chain (R) of vitamin K is shown below the metabolic pathway. VKORC1 = vitamin K reductase complex 1.

amino acids chelate calcium in vivo, which allows the binding of the four vitamin K-dependent clotting factors to phospholipid membranes during activation of the coagulation cascade.<sup>400</sup>

Vitamin K is inactive until it is reduced from its quinone form to a quinol (or hydroquinone) form in hepatic microsomes. This reduction of vitamin K must precede the carboxylation of the precursor factors. The carboxylation activity is coupled to an epoxidase activity for vitamin K, whereby vitamin K is oxidized simultaneously to vitamin K 2,3-epoxide (Fig. 58–2).<sup>358,399</sup> This inactive form of the vitamin is converted back to the active form by two successive reductions.<sup>104,233,277,395</sup> In the first step, an epoxide reductase (known as vitamin K 2,3-epoxide reductase) uses reduced nicotinamide adenine dinucleotide (NADH) as a cofactor to convert vitamin K 2,3-epoxide to a quinone form.<sup>270,271,358</sup> Subsequently, the quinone is reduced to the active vitamin K quinol form (Antidotes in Depth: A18).

Warfarin is a racemic mixture of R warfarin and S warfarin enantiomers. In humans, S warfarin is approximately 2.7 to 3.8 times more potent than R warfarin.<sup>37</sup> Warfarin and all warfarinlike compounds inhibit the activity of vitamin K 2,3-epoxide reductase, as is demonstrated by the observation of elevated concentrations of vitamin K 2,3-epoxide.<sup>69,403</sup> Vitamin K quinone reductase is also inhibited by warfarin and its related compounds (Fig. 58–2).<sup>104,121</sup> This reduction in the cyclic activation of vitamin K subsequently inhibits the formation of activated clotting factors.

### Pharmacology of Vitamin K Antagonists

Oral warfarin is well absorbed, and peak serum concentrations occur approximately 3 hours after administration.<sup>357</sup> Because only the free warfarin is therapeutically active, concurrent administration of xenobiotics that alter the concentration of free warfarin, either by competing for binding to albumin or by inhibiting warfarin metabolism, markedly influences the anticoagulant effect.<sup>24,126,357</sup> The pharmacologic response to warfarin is a polygenic trait with approximately 30 genes contributing to its therapeutic effects.<sup>195</sup> Readers are referred to a review of xenobiotics and foods that potentiate warfarin's effects.<sup>398</sup> Although vitamin K regeneration is altered almost immediately, the anticoagulant effect of warfarin and other warfarinlike anticoagulants is delayed until the existing stores of vitamin K are depleted and the active coagulation factors are removed from circulation. Because vitamin K turnover is rapid, this effect is largely dependent on factor half-life ( $t_{1/2}$ ), with factor VII ( $t_{1/2}$  ~5 hours) depleted most rapidly.<sup>126</sup> For a prolongation of the INR to occur, factor concentrations must fall to approximately 25% to 30% of normal values.<sup>72</sup> Assuming complete inhibition of the vitamin K cycle, this suggests that most patients require at least 15 hours (three factor VII half-lives) before the effect of warfarin is evident on the INR.<sup>123</sup> In fact, because complete inhibition does not occur, the onset of coagulation is delayed even further.

Because the half-life of warfarin in humans is 35 hours, its duration of action is documented to be as long as 5 days.<sup>50,357</sup> On average, it takes approximately 6 days of warfarin administration to reach a steady-state anticoagulant effect.

R warfarin is metabolized by enzymes CYP1A2 and CYP3A4, and S warfarin is metabolized by CYP2C9. Whereas R warfarin is metabolized by side-chain reduction to secondary alcohols that are subsequently excreted by the kidney, S warfarin is metabolized by hydroxylation to 7-hydroxy warfarin, which is excreted into the bile.<sup>357</sup> The elimination of S warfarin is more rapid than that of R warfarin.<sup>49</sup>

Dosing of warfarin and other VKAs is problematic in many patients. In one study, genetic polymorphisms of the vitamin K epoxide reductase complex 1 (VKORC1) and CYP2C9 genes were the strongest predictors of interindividual variability in the anticoagulant effect of warfarin.<sup>195</sup> Pharmacogenomic research with complex xenobiotics, such as warfarin, improves safety of treatment and predicts or prevents interactions with other xenobiotics. Although the FDA has approved a commercially available test to identify variants within these genes,<sup>193</sup> current guidelines do not advocate genetic testing to guide VKA dosing.<sup>154</sup>

Within the coumarin group are two 4-hydroxycoumarin derivatives, difenacoum and brodifacoum, that differ from warfarin by their longer,

higher molecular weight polycyclic hydrocarbon side chains. Together with chlorophacinone, an indandione derivative, they are known as *superwarfarins* or long-acting VKAs.

Long-acting VKAs were designed to be effective rodenticides in warfarin-resistant rodents.<sup>230</sup> Their mechanism of action is identical to that of the traditional warfarinlike anticoagulants, as demonstrated by increased concentrations of vitamin K 2,3-epoxide after administration.<sup>48,51,56,210,277</sup> The ability of these xenobiotics to perform as superior rodenticides is attributed to their high lipid solubility and concentration in the liver.<sup>210,230,277</sup> They also saturate hepatic enzymes at very low concentrations, as demonstrated by zero-order elimination after overdose.<sup>56</sup> These factors make them about 100 times more potent than warfarin on a molar basis.<sup>210,230,277</sup> In addition, they have a longer duration of action than the traditional warfarins.<sup>210,230,277</sup> For example, to obtain 100% lethality in a mouse, more than 21 days of feeding with a warfarin-containing rodenticide (0.025% anticoagulant by weight of bait) is required.<sup>230</sup> Similar efficacy is achieved with a single ingestion of brodifacoum (0.005% anticoagulant by weight of bait).<sup>230</sup> Furthermore, more concentrated liquid formulations, such as brodifacoum (0.5% anticoagulant), are available through illegal vendors and are implicated in prolonged coagulopathy in humans.<sup>138</sup> It should also be noted that although ingestion of these xenobiotics is the most common route of exposure and subsequent cause of toxicity, dermal absorption of liquid preparations occurs, also resulting in a coagulopathy.<sup>344</sup>

### Clinical Manifestations

Although intentional ingestions of warfarin-containing products are uncommon, adverse drug events resulting in excessive anticoagulation and bleeding frequently occur. The risk of bleeding during VKA therapy depends on a myriad of factors, including the intensity of anticoagulation, patient characteristics, and comorbid conditions. Clearly, the most serious complication of excessive anticoagulation is intracranial bleeding, which is reported to occur in as many as 2% of patients on long term therapy, which is an 8- to 10-fold increase in risk compared with patients who are not anticoagulated.<sup>125,126,405</sup> The overall risk of major bleeding in patients can be estimated using tools such as the Hypertension, Abnormal Renal/Liver Function, Stroke, Bleeding History or Predisposition, Labile INR, Elderly, Drugs/Alcohol Concomitantly (HAS-BLED) score, which was prospectively validated in patients with atrial fibrillation.<sup>225,285</sup> Bleeding ranges between 1 and 12.5 episodes per 100 patient-years, with a higher risk in patients with multiple risk factors.<sup>285</sup> Another study showed that patients older than the age of 80 years have a cumulative incidence of major bleeding at 13.1 per 100 person-years with major bleeding defined as bleeding at serious sites (eg, intracranial, retroperitoneal, intraspinal, or pericardial) or bleeding that results in blood transfusion or death. Patients between the ages of 65 and 80 years have a lower risk of 4.7 major episodes of bleeding per 100 person-years.<sup>176</sup> Major bleeding complications are associated with a fatality rate as high as 77%.<sup>239</sup> In patients with intracranial bleeding a decreased level of consciousness and an increased size of hematoma are predictors of poor prognosis.<sup>419</sup> Somewhat surprisingly, the degree of INR elevation was not associated with worse outcome.<sup>419</sup>

Many cases of intentional overdose of long-acting VKAs in humans are reported. The clinical courses of these patients are characterized by a severe coagulopathy that lasts weeks to months, often accompanied by consequential blood loss. Most patients do not seek medical care until bruising or bleeding is evident,<sup>19,56,57,119,170,194</sup> which often occurs many days after ingestion. The most common sites of bleeding are the GI and genitourinary tracts. In one study describing 12 patients with surreptitious ingestion of oral anticoagulants, nine were health care professionals.<sup>271</sup> These patients presented with bruising, hematuria, hematochezia, and menorrhagia. Bleeding into the neck with resultant airway compromise is a rare but life-threatening complication.<sup>43</sup>

Patients with unintentional ingestions must be distinguished from those with intentional ingestions because the former demonstrate a low likelihood of developing a coagulopathy and have rare morbidity or mortality. Most patients (usually children) are entirely asymptomatic and have a normal

coagulation profile after an acute unintentional exposure. Typical warfarin-like rodenticides contain only small concentrations of anticoagulant, 0.005% (or 5 mg of brodifacoum per 100 g of product). A 10-kg child would require an initial dose of 10 g of rodenticide (8 pellets, each of which is approximately 25 mm in size). These quantities are far greater than those that occur in typical “tastes.” Thus, single small unintentional ingestions of warfarin-containing rodenticides pose a minimal threat to normal patients.<sup>190</sup> Prolongation of the INR is unlikely with a single small ingestion of a long-acting VKA rodenticide. Clinically significant anticoagulation is even rarer. In a combined pediatric case series, prolongation of the INR occurred in only 8 of 142 children (5.6%) reported with single small ingestions of long-acting VKAs.<sup>28,189,190,342</sup> Only one child in this group was reported to have “abnormal prolonged bleeding,” but this required no medical attention.<sup>342</sup> In a single case report, a 36-month-old child developed a coagulopathy manifested by epistaxis and hematuria, with anticoagulation persisting for more than 100 days after a presumed, but unwitnessed, single unintentional ingestion of brodifacoum.<sup>366</sup> Clinically significant coagulopathy can result, however, after small repeated ingestions. Two children reportedly became poisoned by repeated ingestions of a long-acting anticoagulant. One child presented with a neck hematoma that compromised his airway and the other with a hemarthrosis.<sup>151</sup> Similarly, a 7-year-old girl required multiple hospitalizations over a 20-month period after repeated unintentional ingestions of brodifacoum.<sup>32</sup> Finally, a 24-month-old child who presented with unexplained bruising and a PT greater than 125 seconds was the victim of brodifacoum poisoning secondary to Munchausen syndrome by proxy, which is currently called *pediatric condition falsification* (Chap. 31).<sup>15</sup>

### Laboratory Assessment

Although warfarin concentrations are useful to confirm the diagnosis in unknown cases and to study drug kinetics,<sup>155,268</sup> the routine use of simple and inexpensive measures such as INR determination seems more appropriate (Table 58–1). When blood loss is evident, serial determinations of hemoglobin concentration are indicated.

For patients with an acute and significant long acting VKA overdose, daily INR evaluations for 2 days are adequate to identify most patients at risk for coagulopathy. Earlier detection through direct coagulation factor analysis is available but is typically reserved to trend patients with known coagulopathy for treatment purposes.<sup>155,170</sup> Concentrations of long-acting VKAs can now be measured, although they are usually only performed in reference laboratories.<sup>199,268</sup> We recommend that children with possibly significant exposures be followed up with at least a single INR at least 48 hours after the exposure. Even though significant toxicity from long-acting VKAs is rare, it should be recognized that the reported benign courses of exposures in children are somewhat misleading. Multiple retrospective studies suggest that children with unintentional acute exposures do not require any follow-up coagulation studies.<sup>256,260,279,332</sup> However, this conclusion and approach to management is an unjustified attempt to decrease the cost of “unnecessary” coagulation studies. There are clearly insufficient data to justify this conclusion because many of these “exposed” children were never documented to have ingested long-acting VKAs (Chap. 130). We recommend that clinicians continue to manage these children as possibly significant exposures and that all children be followed up with at least a single INR at a minimum of 2 days after the exposure. A baseline INR is usually unnecessary but is reasonable if there is a suspicion of an antecedent ingestion. A baseline INR is also helpful when chronic exposure is suspected.

### Treatment of Vitamin K Antagonist–Induced Coagulopathy

Life-threatening bleeding secondary to VKA toxicity should be immediately reversed with factor replacement followed by vitamin K<sub>1</sub> (Table 58–1). The American College of Chest Physicians (ACCP) and the FDA recommend factor replacement with four-factor prothrombin complex concentrate (PCC) as a first-line treatment for major bleeding in the setting of VKA-induced coagulopathy.<sup>172</sup> This recommendation is reasonable given the ease of administration as compared with fresh-frozen plasma (FFP). Most countries use traditional four-factor PCC, which contains concentrated factors II, VII,

IX, X, C, and S. Dosing of PCC is based on INR and body weight. The typical doses range between 25 and 50 units/kg with the largest dose based on a maximum weight of 100 kg. The PCC is contained in both 500-unit and 1,000-unit vials. However, the factor IX content of each vial is variable: 500-unit vial may contain between 400 to 620 units/vial, and a 1,000-unit vial may contain between 800 and 1,240 units/vial. Each individual vial states the actual factor IX content in each bottle, and the dosage should be based on the actual factor IX content in each vial.<sup>88</sup> Most forms of PCC, contain small amounts of heparin. These heparin-containing PCCs are contraindicated in patients with a history of heparin-induced thrombocytopenia (HIT) and heparin-induced thrombocytopenia and thrombosis syndrome (HITT). In those cases, factor eight inhibitor bypassing activity (FEIBA), an activated prothrombin complex concentrate (aPCC), is recommended. Activated aPCCs contain factors II, VII, IX, and X in inactive and activated forms. Factor eight inhibitor bypassing activity is typically used to treat patients with hemophilia A and B. Unfortunately, FEIBA has not been studied extensively in the setting of VKA-induced coagulopathy. Therefore, there is no standard dose for coagulopathy reversal. Typical doses for treating bleeding or for perioperative management range between 50 and 100 units/kg with the dose based on the amount of factor VIII inhibitor bypass activity.<sup>23</sup> Despite its increased cost, the rationale for using PCC instead of FFP includes less risk of infection transmission.<sup>172</sup> In addition, small-volume factor replacement is preferable in patients at risk of volume overload, such as patients with heart failure, chronic kidney disease (CKD), or intracranial bleeding.<sup>2</sup> Unfortunately, there are only a few studies comparing PCC with FFP in reversing coagulopathy. These studies show that PCC safely produces complete INR reversal faster than FFP with more consistent factor IX replacement.<sup>95,185,234</sup> However, unequal factor replacement in these small studies favors more factor replacement in patients receiving PCC.<sup>315</sup> Fresh-frozen plasma is rich in active vitamin K–dependent coagulation factors and will reverse oral anticoagulant-induced coagulopathy in most patients. In general, approximately 15 mL/kg of FFP should be adequate to reverse any VKA-induced coagulopathy.<sup>87</sup> However, the specific factor quantities and volume of each unit may be varied, leading to an unpredictable response.<sup>234</sup> In addition, delay to FFP administration is accentuated by requirements for blood type matching and thawing. Therefore, we recommend in acute major bleeding in the setting of VKA-induced coagulopathy the use of PCC as the preferred reversal agent.

Activated recombinant factor VII (rFVIIa) is approved for patients with hemophilia or various factor inhibitors and has successfully reversed warfarin toxicity.<sup>284</sup> The safety of off-label rFVIIa to reverse VKA coagulopathy is unclear. Preliminary data using rFVIIa suggested its utility for bleeding secondary to warfarin-induced excessive anticoagulation and a case series showing beneficial effects in four patients with long acting VKA toxicity.<sup>420</sup> However, adverse outcomes, such as arterial thrombotic events, occur at higher than acceptable rates. Initial concerns for thromboembolic adverse events were raised when review of the FDA's Adverse Event Reporting System database found that the majority of these complications arose in patients who received rFVIIa for off-label purposes. Cerebrovascular accident, acute MI, PE, venous thrombosis, and clotted devices all occurred at higher rates in off-label applications.<sup>269</sup> The Factor Seven for Acute Hemorrhagic Stroke Trial (FAST) showed that arterial thromboembolic adverse events increased in a dose-dependent fashion with the administration of rFVIIa.<sup>102</sup> A subsequent meta-analysis confirmed that an increased rate of arterial thrombosis occurs in patients who receive rFVIIa.<sup>219</sup> The risk of continued bleeding versus the benefit of rapid reversal of coagulopathy with rFVIIa is unknown, and further experience with rFVIIa is necessary to determine its safety and efficacy in anticoagulant-induced bleeding. We do not recommend routine use of rFVIIa for reversing VKA-associated coagulopathy. If FFP, PCC, and FEIBA are not available, then it is reasonable that rFVIIa be given in life-threatening situations.<sup>1</sup> It should also be noted that if rFVIIa is used, assays based on PT are inaccurate and should be avoided when administering rFVIIa.<sup>191</sup>

Treatment with vitamin K<sub>1</sub> takes several hours to activate enough factors to reverse a patient's coagulopathy,<sup>234,278</sup> and this delay is potentially fatal. Repetitive, large doses of vitamin K<sub>1</sub> (on the order of 60 mg/d or greater) are

TABLE 58–1 Antithrombotics: Laboratory Testing, Antidotes, and Treatment Strategies

	Laboratory Testing Results (Expected)	Antidotes and Treatment Strategies
<b>Antiplatelet Agents</b> Cyclooxygenase inhibitors Phosphodiesterase inhibitors Adenosine reuptake inhibitors Adenosine diphosphate receptor inhibitors Glycoprotein IIb/IIIa inhibitors	Bleeding time prolonged; platelet function assays abnormal	Desmopressin 0.3 mcg/kg IV over 15–30 min for life-threatening bleeding; platelet administration is controversial but is recommended in life-threatening situations.
<b>Antithrombin Agonists</b> Unfractionated heparin	PTT prolonged; TT abnormal; ACT elevated; fibrinogen normal, anti-factor Xa activity increased	1 mg of protamine per 100 units of heparin <sup>a</sup> . In overdose, if unknown quantity of heparin administered, treat based on ACT: <sup>b</sup> ACT <150 s: no protamine needed ACT 200–300 s: 0.6 mg/kg protamine ACT 300–400 s: 1.2 mg/kg protamine Alternatively, empiric treatment with 25–50 mg of protamine Ciraparantag (in clinical trials)
Low-molecular-weight heparin (eg, enoxaparin, dalteparin)	Anti-factor Xa activity increased; PTT is insensitive	1 mg of protamine per 100 antifactor Xa units (or 1 mg of enoxaparin) given in the previous 8 h. Administer an additional 0.5 mg protamine per 100 anti-factor Xa units if bleeding continues. Protamine does not completely neutralize LMWHs.
<b>Direct Thrombin Inhibitors</b>  Dabigatran  Bivalirudin Argatroban	PTT prolonged; TT prolonged; ECT prolonged; anti-factor Xa activity elevated (at low concentrations, PT and PTT may be normal); dTT prolonged <sup>d,351</sup>	Activated charcoal in overdose Idarucizumab 5 g IV If idarucizumab is unavailable: 4F-PCC administration with up to 100 units/kg in repeated 50 units/kg doses as needed. If bleeding continues 30 min after PCC <sup>c</sup> , give FEIBA ©. <sup>237,376</sup> Hemodialysis FFP 15 mL/kg Stop the infusion FFP 15 mL/kg
<b>Direct Factor Xa Inhibitors</b> Rivaroxaban Apixaban Edoxaban	PT and PTT can be normal or prolonged (varies with reagents); anti-factor Xa activity elevated with specific modified chromogenic antifactor Xa assay <sup>d</sup>	AC in overdose PCC <sup>c</sup> administration with up to 50 units/kg in repeated 25 units/kg doses as needed Andexanet alfa <sup>e</sup> Low dose: 400 mg IV High dose: 800 mg IV Ciraparantag (in clinical trials)
<b>Fibrinolytics</b>	PT and PTT prolonged; TT abnormal; fibrinogen abnormal	Cryoprecipitate Factor replacement with 15 mL/kg of FFP or 50 units/kg of PCC <sup>c</sup> For life-threatening hemorrhage, give tranexamic acid at 1 g intravenously over 10 minutes followed by 1 g over 8 h. If tranexamic acid is unavailable, IV aminocaproic acid is recommended as a loading dose of 5 g over 1 h followed by an infusion at 1 g/h for 23 h. Stop infusion if bleeding ceases.
<b>Pentasaccharide</b> Fondaparinux	Fondaparinux-specific anti-Xa assay PTT does not reflect degree of anticoagulation	PCC administration with up to 50 units/kg in repeated 25 units/kg doses as needed to maximum of 100 units/kg.
<b>Vitamin K Antagonist</b> Warfarin	Early (PT prolonged; PTT normal) Late (PT and PTT prolonged; TT and fibrinogen normal)	Vitamin K Factor replacement with 4F-PCC <sup>c</sup> or if not available FFP (15 mL/Kg) 4F-PCC for major or life-threatening hemorrhage See Table 58–2 for detailed management recommendations.

<sup>a</sup>May need to repeat in 2–8 h because of potential heparin rebound. <sup>b</sup>Use of activated clotting time (ACT) is only validated in the operative setting after cardiopulmonary bypass. <sup>c</sup>In patients with a history of heparin-induced thrombocytopenia, avoid prothrombin complex concentrate (PCC) (except Profilnine) and use factor eight inhibitor bypassing activity (FEIBA) or recombinant factor VII (rFVIIA). <sup>d</sup>No readily available method to assess extent of anticoagulation at this time. <sup>e</sup>FDA approved for rivaroxaban and apixaban (but should also be effective for edoxaban) and low dose vs high dose is based on timing and amount of last dose of Anti-Xa inhibitor.

AC = activated charcoal; ECT = ecarin clotting time; dTT = dilute thrombin time; FFP = fresh-frozen plasma; 4F-PCC = four-factor prothrombin complex concentrate; LMWH = low molecular weight heparin; PCC = prothrombin complex concentrate; PT = prothrombin time; PTT = partial thromboplastin time; TT = thrombin time.

reported in some patients with massive ingestion.<sup>155,271</sup> If complete reversal of INR prolongation occurs or is desirable (as in most cases of life-threatening bleeding) and the underlying medical condition of the patient still requires some degree of anticoagulation, the patient can then receive anticoagulation with heparin after the bleeding is controlled and clinical stability restored. Heparin anticoagulation was used without apparent bleeding complications in 25% of patients in one cross-sectional study.<sup>402</sup>

Vitamin K<sub>1</sub> is preferable over the other forms of vitamin K; the other forms are ineffective<sup>183,262,270,373</sup> are potentially toxic,<sup>17</sup> and are unavailable in the United States. Parenteral administration of vitamin K<sub>1</sub> (phytonadione) is traditionally preferred as initial therapy by many authors, but success can also be achieved with early oral therapy, especially when the coagulopathy is not severe.<sup>56</sup> In most cases, the patient can be switched to oral vitamin K<sub>1</sub> for long-term care. Vitamin K<sub>1</sub> can be administered intramuscularly, subcutaneously, intradermally, or intravenously. Although intravenous (IV) therapy has the most rapid onset of action of all routes of delivery, its use as the sole therapeutic is still associated with a delay of several hours<sup>278,395</sup> and carries the added risk of anaphylactoid reactions.<sup>302</sup> The use of low doses and slow rate of administration reduces this risk<sup>335</sup> (Antidotes in Depth: A18). In cases in which oral administration is undesirable, for example, with significant GI bleeding the subcutaneous (SC) route should not be used because absorption is erratic. In this case, we recommend the IV route of administration of vitamin K<sub>1</sub> because the benefits outweigh the risks.

For patients with non-life-threatening bleeding, the clinician must evaluate whether anticoagulation is required for long-term care. In patients not requiring chronic anticoagulation we recommend treating even small elevations of the INR with vitamin K<sub>1</sub> alone to prevent deterioration in coagulation status and reduce the risk of bleeding. In contrast to ingestions of warfarin, we recommend not to give prophylactic vitamin K<sub>1</sub> to asymptomatic patients with unintentional ingestions of long-acting warfarinlike anticoagulants because (1) if the patient develops a coagulopathy, it will last for weeks, and the one or two doses of vitamin K<sub>1</sub> given will not prevent complications; (2) a gradual decline in coagulation factors occurs over the first day of anticoagulation, so an individual would not be expected to develop a life-threatening coagulopathy in 1 or 2 days; and (3) after vitamin K<sub>1</sub> is administered, the onset of an INR abnormality will be delayed, which could impair the ability of the clinician to recognize a coagulation abnormality, possibly requiring the patient to undergo an unnecessarily prolonged observation period.

For patients requiring chronic anticoagulation we agree with the ACCP guidelines for the management of patients with elevated INRs (Table 58–2). It should also be noted that low-dose vitamin K is safe to administer to patients with mildly elevated INRs (4–10) to decrease the INR more rapidly; however, one study did not demonstrate decreased bleeding in the treatment group.<sup>86</sup> Furthermore, simply omitting warfarin

doses is usually adequate for a patient without active bleeding who has an INR between 4 and 9.<sup>86</sup>

It is often unclear why patients with consistent therapeutic dosing have seemingly random elevations in their INR. A case-control study identified the following risk factors associated with overanticoagulation from VKAs: previous medical history of increased INR, antibiotic therapy, fever, and concomitant use of amiodarone and proton pump inhibitors.<sup>60</sup> Clinicians should pay particular attention to patients with these conditions, and close monitoring of coagulation profiles should be performed.<sup>60</sup>

### Treatment of Long-Acting Vitamin K Antagonist Overdoses

In patients with unintentional, small ingestions of long-acting VKAs, the risk of coagulopathy is low. However, it takes days to develop coagulopathy. Administration of AC is recommended to prevent absorption in acute ingestions if no contraindication exists.<sup>190,342</sup>

Treatment of a patient with a coagulopathy resulting from a long-acting anticoagulant overdose is essentially the same as the treatment of oral anticoagulant toxicity with certain exceptions. Although initial parenteral vitamin K<sub>1</sub> doses as high as 400 mg have been required for reversal,<sup>57</sup> daily oral vitamin K<sub>1</sub> requirements are often in the range of 50 to 200 mg. Recent experience in both animals and humans suggests that parenteral vitamin K<sub>1</sub> therapy is not required after initial stabilization (Antidotes in Depth: A18).<sup>56,411</sup>

In one case report, a 2-year-old child with confirmed brodifacoum-associated coagulopathy developed anemia, epistaxis, ecchymosis and GI bleeding. She developed an anaphylactoid reaction after several doses of IV vitamin K<sub>1</sub>. Patients typically tolerate IV vitamin K<sub>1</sub> well as long as it is administered appropriately. In stable patients, oral vitamin K is recommended. However, because oral vitamin K was not available at this hospital, the patient received five plasma exchange treatments, which resulted in normalization of her coagulation studies. In addition, repeat brodifacoum concentrations were undetectable after her third plasma exchange treatment.<sup>94</sup> Because there are other less invasive methods of correcting VKA-induced coagulopathy and lack of established experience with plasma exchange beyond this case report, we do not recommend plasma exchange therapy for VKA-induced coagulopathy.

Long-acting VKAs are metabolized by the cytochrome P450 system.<sup>16,270</sup> In a rat model, the duration of coagulopathy was shortened by administering phenobarbital, a CYP3A4 inducer.<sup>16</sup> Although phenobarbital has never been systematically studied in humans, this approach was used by several authors in isolated human cases of long-acting anticoagulant toxicity.<sup>57,183,226,366,393</sup> These anecdotal reports suggest some improvement with phenobarbital therapy, but the risk of sedation in a patient who might be prone to bleeding complications outweighs any purported benefit.

Patients with long-acting VKA overdose should be followed until their coagulation studies remain normal without treatment for several days. This usually requires daily or even twice-daily INR measurements until the INR is at the lower limit of the therapeutic range. Monitoring of serial INR measurements should allow for a gradual decrease in vitamin K<sub>1</sub> requirement over time. Periodic coagulation factor analysis (particularly factor VII), however, provides an early marker of toxicity resolution.<sup>170</sup> An anticoagulated patient will require weeks to months of close observation for both psychiatric and medical management. A critical superwarfarin concentration below which anticoagulation does not occur is not defined.<sup>57</sup> In one case report, brodifacoum was observed to follow zero-order elimination kinetics.<sup>56</sup>

### Nonbleeding Complications of Vitamin K Antagonists

Warfarin therapy is associated with three nonhemorrhagic lesions of the skin: urticaria,<sup>323</sup> purple toe syndrome,<sup>122</sup> and warfarin skin necrosis.<sup>77,193,202,242,384</sup> Although warfarin skin necrosis was once thought to be a rare and idiosyncratic reaction,<sup>193,202</sup> more recent evidence suggests a link between this disorder and protein C deficiency.<sup>202,384</sup> Protein C synthesis is also dependent on vitamin K.<sup>73</sup> Patients who are homozygotes for protein C deficiency have an increased incidence of thrombosis and embolic events, such that they often require long-term anticoagulant therapy.<sup>73</sup> Because the half-life of

**TABLE 58–2** Recommendations for Management of Elevated International Normalized Ratio or Bleeding in Patients Receiving Vitamin K Antagonists<sup>154</sup>

International Normalized Ratio	Recommendation <sup>a</sup>
<4.5; no significant bleeding	Lower or omit the next dose of warfarin.
≥4.5–10; no significant bleeding	Omit warfarin for the next one or two doses.
>10; no evidence of bleeding	Give oral vitamin K <sub>1</sub> (1–2.5 mg). If more rapid reversal is necessary, give oral vitamin K <sub>1</sub> (≤5 mg) and wait 24 h. Give additional vitamin K <sub>1</sub> orally (1–2 mg) as needed.
Serious bleeding at any INR value or life-threatening bleeding	Hold warfarin therapy and give 4F-PCC supplemented with vitamin K <sub>1</sub> (5–10 mg by slow IV <sup>b</sup> infusion). Vitamin K <sub>1</sub> administration often needs to be repeated every 12 h.

<sup>a</sup>Intravenous (IV) infusion of vitamin K<sub>1</sub> rarely may cause severe anaphylactoid reactions  
 FFP = fresh-frozen plasma; 4F-PCC = four-factor prothrombin complex concentrate; INR = international normalized ratio; PCC = prothrombin complex concentrate.

protein C is shorter than that of many of the vitamin K–dependent coagulation factors, protein C concentrations fall rapidly during the first hours of warfarin therapy. This results in an imbalance that actually favors coagulation, and skin necrosis results because of microvascular thrombosis in dermal vessels.<sup>242,384</sup> Although warfarin skin necrosis is more common in patients with protein C deficiency, this disorder is also described in patients with protein S and AT deficiencies.<sup>77</sup> Unfortunately, these deficiencies are neither necessary nor sufficient to account for the incidence of warfarin necrosis.<sup>77</sup> If necrosis occurs, warfarin should be discontinued, and heparin should be initiated to decrease thrombosis of postcapillary venules. Some patients also require surgical debridement.<sup>314</sup>

The purple toe syndrome, in contrast to warfarin-induced skin necrosis, is presumed to result from small atheroemboli that are no longer adherent to their plaques by clot (Fig. 17–13).

Warfarin-related nephropathy (WRN) is a well-recognized form of non-hemorrhagic warfarin toxicity. In patients with CKD, an acute increase in the INR above 3 was associated with an increase in serum creatinine and accelerated reduction in kidney function. The etiology of the WRN is attributed to acute tubular injury and glomerular bleeding, demonstrated by the finding of red blood cell (RBCs) filling Bowman's capsule and RBCs casts obstructing glomeruli on specimens from kidney biopsies.<sup>54,55</sup> Further studies that retrospectively reviewed kidney function in patients on long-term warfarin anticoagulation showed 33% of patients with CKD and 16.5% of patients without CKD developed WRN. Warfarin-related nephropathy is associated with a mortality rate of 31.1%, a significant increase in risk compared with 18.9% in patients without WRN.<sup>54</sup>

An additional major nonhemorrhagic complication of warfarin therapy is warfarin embryopathy. Most warfarin-induced fetal abnormalities occur during weeks 6 to 12 of gestation, but central nervous system (CNS) and ocular abnormalities can develop at any time during gestation (Chap. 30).<sup>158,354</sup>

## ANTITHROMBIN AGONISTS

### Heparin

Conventional heparin also known as unfractionated heparin C or unfractionated heparin (UFH) is a heterogeneous group of molecules within the class of glycosaminoglycans.<sup>180</sup> The heparin precursor molecule is composed of long chains of mucopolysaccharides, a polypeptide, and carbohydrates. The main carbohydrate components of heparin molecules include uronic acids and amino sugars in polysaccharide chains. Heparin for pharmaceutical use is extracted from bovine lung tissue and porcine intestines.<sup>328</sup>

Heparin inhibits thrombosis by accelerating the binding of AT to thrombin (activated factor II) and other serine proteases involved in coagulation.<sup>232,308</sup> Thus, factors IX to XII, kallikrein, and thrombin are inhibited. Heparin also affects plasminogen activator inhibitor, protein C inhibitor, and other components of coagulation. The therapeutic effect of heparin is usually measured through the activated PTT. The activated clotting time (ACT) is more useful for monitoring large therapeutic doses or in the overdose situation.<sup>201</sup>

Low-molecular-weight heparins are 4,000- to 6,000-Da fractions obtained from conventional heparin.<sup>128</sup> As such, they share many of the pharmacologic and toxicologic properties of conventional heparin.<sup>45</sup> The various LMWHs (eg, nadroparin, enoxaparin, dalteparin) are prepared by different methods of depolymerization of heparin; consequently, they each differ to a certain extent regarding their pharmacokinetic properties and anticoagulant profiles. The major differences between LMWHs and conventional heparin are greater bioavailability, longer half-life, more predictable anticoagulation with fixed dosing, targeted activity against activated factor X, and less targeted activity against thrombin.<sup>45,128</sup> As a result of this targeted factor X activity, LMWHs have minimal effect on the activated PTT, thereby eliminating either the need for, or the usefulness of monitoring. They are therefore administered on a fixed dose schedule. However, in certain instances (eg, patients with CKD, pregnancy), monitoring of anti-factor Xa activity is performed to assess adequacy of anticoagulation and to prevent the risk of bleeding.<sup>159</sup> Controversy exists as to whether such testing is clinically necessary,<sup>44</sup> but

studies have not shown significant benefit in determining risk of thromboembolic recurrence or consistent risk of major bleeding. We do not recommend the routine testing of anti-factor Xa activity.

Studies investigating LMWHs for the prevention of thromboembolic disease after hip surgery and trauma, in patients with stroke or DVT, in pregnancy, and in other conditions where anticoagulation with heparin would otherwise be indicated (eg, at the onset of oral anticoagulation therapy) are numerous. Low-molecular-weight heparins have a minimal risk in pregnancy<sup>246</sup> because they do not cross the placenta,<sup>124,356</sup> and they are therefore preferred for the treatment or prophylaxis of thromboembolic disease in pregnancy.<sup>306</sup> Most studies demonstrate a lower incidence of embolization; however, there is still a trend toward increased bleeding.<sup>30,152,220</sup> The PROTECT trial, which compared dalteparin and UFH in terms of rates of proximal leg DVT, PE, and major bleeding in critically ill patients, found that patients randomized to the dalteparin group had statistically fewer PE. This study found no statistically significant differences in proximal DVT and major bleeding rates.<sup>153</sup>

### Pharmacology

Because of the large size of heparin and negative charge, the molecule is unable to cross cellular membranes. These factors prevent oral administration, and heparin must be administered parenterally. After parenteral administration, heparin remains in the intravascular compartment, in part bound to globulins, fibrinogen, and low-density lipoproteins, resulting in a volume of distribution of 0.06 L/kg in humans.<sup>118,273</sup> Because of its rapid metabolism in the liver by a heparinase, heparin has a short duration of effect.<sup>232</sup> Although the half-life of elimination is dose dependent and ranges from 1 to 2.5 hours,<sup>232,241,273</sup> the duration of anticoagulant effect is usually reported as 1 to 3 hours.<sup>232</sup> Dosing errors or drug interactions with thrombolytics, antiplatelet drugs, or nonsteroidal antiinflammatory drugs increase the risk of bleeding.<sup>161</sup> Low-molecular-weight heparins are nearly 90% bioavailable after SC administration and have an elimination half-life of 3 to 6 hours.<sup>137</sup> Anti-factor Xa activity peaks between 3 and 5 hours after dosing.<sup>137</sup> Low-molecular-weight heparins are renally eliminated and patients with stage 4 or 5 CKD are at increased risk of toxicity.<sup>386</sup> Although there are insufficient data guiding therapeutic LMWH dosing in patients with severe CKD, some advocate dose reduction to decrease the risk of bleeding. However, no dosage regimens are provided.<sup>154</sup>

### Clinical Manifestations

Intentional overdoses with heparin are rare.<sup>238</sup> Most reported cases involve iatrogenic toxicity in hospitalized patients.<sup>136,145,238,276,326</sup> These cases involved the administration of large amounts of heparin as a consequence of misidentification of heparin vials, during the process of flushing IV lines, and secondary to IV pump malfunction. Significant bleeding complications occurred in several cases, including at least one fatality.<sup>136</sup> However, intentional overdoses of LMWHs are reported, although none of them were fatal.<sup>58,254</sup>

Similar adverse effects to UFH are also reported with LMWHs and include epidural or spinal hematoma, intrahepatic bleeding,<sup>173</sup> abdominal wall hematomas,<sup>13</sup> psoas hematoma after lumbar plexus block,<sup>192</sup> and intracranial bleeding in patients with CNS malignancy.<sup>98</sup> Although these complications were all reported in patients who received the LMWH enoxaparin, there are no data to suggest differing toxicities among LMWHs.

### Diagnostic Testing

For therapeutic anticoagulation, the effect of heparin is usually monitored with activated partial thromboplastin time (aPTT). Most hospitals have heparin nomograms that recommend heparin dose alterations based on aPTT, although these nomograms need to be individualized by each hospital because of the variation expected from the particular aPTT reagent and laboratory technology used. For patients undergoing cardiovascular procedures, the ACT is used to monitor them because they require higher dose heparin.<sup>137</sup> More recently, an anti-Xa assay specific for heparin was FDA approved. Heparin dosing is titrated based on the anti-Xa assay results,

with therapeutic ranges higher than prophylactic ranges. Goal ranges also differ depending on whether LMWH or UFH is being used.

In patients with heparin resistance, in whom extremely high doses of heparin are required to accomplish a therapeutic aPTT, anti-Xa activity is recommended to guide heparin dosing. Despite lower heparin dosing and subtherapeutic aPTTs, patients monitored with anti-Xa activity had similar rates of recurrent thromboembolism and bleeding compared with the patients who were given high-dose heparin to maintain therapeutic aPTTs in a prospectively collected randomized control trial.<sup>221</sup>

Low-molecular-weight heparins are usually administered at fixed doses for venous thromboembolism (VTE) prophylaxis or at weight-based doses for VTE treatment. Laboratory monitoring is not done unless patients are pregnant, have CKD, or are obese. In these cases, anti-Xa activity is measured, with target ranges varying based on agent and dosing regimen.<sup>137</sup> In patients without the aforementioned risk factors, monitoring and dose adjustment are of no benefit compared with fixed-dose regimens of LMWH.<sup>5</sup> In addition, several studies show no correlation between anti-Xa activity and bleeding propensity.<sup>18,215,389</sup>

## Treatment

After stabilization of the airway and breathing and circulation is ensured, the physician should be prepared to replace blood loss and reverse the coagulopathy, if indicated. Because of the relatively short duration of action of heparin, observation alone is indicated if significant bleeding has not occurred. For a patient requiring anticoagulation, serial aPTT determinations will indicate when it is safe to resume therapy. If significant bleeding occurs, either removal of the heparin or reversal of its anticoagulant effect is indicated. Because heparin has a very small volume of distribution, it can be effectively removed by exchange transfusion.<sup>326</sup> Although this technique has been used successfully in neonates, protamine has also safely been given to neonates without a history of fish allergy or previous exposure to protamine or protamine-containing insulin.<sup>253</sup> Exchange transfusion to remove heparin should be performed in neonates with significant bleeding if protamine is contraindicated.

When severe bleeding occurs, protamine sulfate partially neutralizes UFH<sup>7</sup> (Table 58–1). Protamine is a low-molecular-weight protein found in the sperm and testes of salmon, which forms ionic bonds with heparin and renders it devoid of anticoagulant activity.<sup>232</sup> One milligram of protamine sulfate injected intravenously neutralizes 100 units of UFH.<sup>232</sup> The dose of protamine should be calculated from the dose of heparin administered if known and assuming the approximate half-life of heparin to be 60 to 90 minutes; the amount of protamine should not exceed the amount of heparin expected to be found intravascularly at the time of infusion. As with other foreign proteins, protamine administration is associated with numerous adverse effects such as hypotension, bradycardia, and allergic reactions. Because approximately 0.2% of patients receiving protamine experience anaphylaxis, a complication that carries a 30% mortality rate, we recommend that protamine be reserved for patients with life-threatening bleeding (Antidotes in Depth: A19).<sup>173</sup> Clinicians should be aware that excess protamine administration does result in paradoxical anticoagulation, but this should not deter clinicians from administering protamine in life-threatening situations.

Because of the severe adverse effects associated with protamine, research has focused on safer methods to reverse heparin anticoagulation. These agents include heparinase,<sup>248</sup> synthetic protamine variants,<sup>387,388</sup> and platelet factor 4 (PF4). These therapies are not widely available, and their efficacy and safety are not established.

If life-threatening bleeding occurs after LMWH administration we also recommend treating patients with protamine. Several studies show that protamine partially reverses LMWHs such as enoxaparin, dalteparin, and tinzaparin. In one case report of a 10-fold dosing error of enoxaparin, protamine effectively reversed the anticoagulant effects.<sup>404</sup> In a series of 14 bleeding patients given protamine to reverse LMWH, bleeding ceased in two-thirds of the patients. These data, however, are complicated by repeat dosing

of protamine as well as administration of other procoagulant antidotes such as clotting factors and vitamin K in a subset of patients. In addition, patients received protamine between 30 minutes and 48 hours after their last dose of LMWH.<sup>379</sup> Approximately 1 mg protamine will neutralize 100 anti-factor Xa units, and 1 mg of enoxaparin will neutralize 100 anti-factor Xa units for up to 8 hours after LMWH administration.<sup>137</sup> A second dose of 0.5 mg protamine per 100 anti-factor Xa units is reasonable if bleeding continues. If more than 8 hours has elapsed, a smaller dose of protamine should be administered. The maximum dose of 50 mg should not be exceeded.<sup>137</sup> The appropriate dosages for protamine are described in detail in the Antidotes in Depth: A19. The newer experimental protamine variants appear to be effective against LMWHs but are not yet clinically available.<sup>387,388</sup> Interestingly, there is one case report of recombinant activated factor VII (rFVIIa) reversing the effects of LMWH in the setting of postoperative acute kidney injury (AKI),<sup>96,249,264</sup> and there is also a single case report demonstrating efficacy at reversing severe bleeding caused by enoxaparin.<sup>175</sup> Based on this limited reported experience, we do not recommend rFVIIa for LMWH-associated bleeding.

## NONBLEEDING COMPLICATIONS

Postoperative thrombocytopenia that occurs in the first 1 or 2 days after surgery usually results from platelet consumption. This early fall in platelet count tends to cause concern for a drug-induced thrombocytopenia called HIT because postoperative VTE prophylaxis with heparin is usually started simultaneously.<sup>392</sup> However, postoperative thrombocytopenia usually improves by the third postoperative day, distinguishing itself from HIT, which typically occurs between days 5 and 10 after heparin initiation. In patients who were previously treated with heparin, HIT-related events sometimes occur within 24 hours after reexposure.<sup>223</sup>

Heparin-induced thrombocytopenia affects up to 5% of patients receiving heparin.<sup>223,392</sup> Heparin stimulates platelets to release PF4, which subsequently complexes with heparin to provoke an IgG response, causing platelet aggregation and thrombocytopenia.<sup>14,416</sup> A more severe form of thrombocytopenia, HITT (formerly known as HIT-2 or the white clot syndrome), occurs in up to 55% of patients with untreated HIT.<sup>223</sup> The antibodies against the heparin-PF4 complex activate platelets, which leads to platelet-fibrin thrombotic events.<sup>14,416</sup>

Patients present with either hemorrhagic or thromboembolic complications. Low-molecular-weight heparin is also associated with thrombocytopenia (isolated HIT) and less frequently with HITT.<sup>223</sup> Consequently, when HITT occurs, LMWH is contraindicated.<sup>223</sup> Treatment of patients with HIT includes discontinuation of heparin or LMWH and immediate use of alternative anticoagulant such as lepirudin, argatroban, or danaparoid.<sup>68,223</sup> In addition to HIT and HITT, necrotizing skin lesions<sup>286</sup> and hyperkalemia from aldosterone suppression<sup>274</sup> also rarely occur in patients receiving heparin therapy. These patients should not receive heparin or LMWH again, not even in low doses to maintain venous patency.

Some additional complications of heparin use include osteoporosis, which mostly occurs in patients on long-term therapy with UFH.<sup>174</sup> A small percentage of these patients develop bone fractures if treated continuously for more than 3 months. Data for LMWHs are limited, and the incidence of osteoporosis is less compared with UFH.<sup>174</sup> In 2008, an outbreak of adverse events was linked to heparin contaminated with oversulfated chondroitin sulfate.<sup>227</sup> The contaminated heparin, which was found in at least 10 countries, originated in China.<sup>38</sup> Many patients developed anaphylactoid-type reactions with at least 100 reported deaths.<sup>227</sup>

## DIRECT THROMBIN INHIBITORS

Hirudin and its congeners (lepirudin and desirudin) are used in patients with acute coronary syndromes, the prevention of thromboembolic disease, and in patients with HITT.<sup>36,322,329</sup> Desirudin is at least as effective as UFH and without an increased risk of bleeding or thrombocytopenia. However, in the Global Use of Strategies to Open Occluded Coronary Arteries (GUSTO) Iib study of patients with unstable angina or non-Q wave MI, there was an increase in the number of blood transfusions in patients

who received desirudin compared with those who received heparin.<sup>338</sup> This increased risk of bleeding compared with heparin has caused desirudin to fall out of favor. Instead bivalirudin and argatroban tend to be used more often, especially in the setting of HITT. In fact, initial studies using bivalirudin during coronary artery angioplasty for unstable or postinfarction angina showed that it is a safe substitute for heparin with lower bleeding rates.<sup>36</sup> Unfortunately, all of these DTIs are short acting and require parenteral administration.

Because of the potential therapeutic limitations of warfarin (eg, dosing, risk of bleeding, narrow therapeutic window), direct oral anticoagulants were developed with directed activity against specific clotting factors. The proposed benefits of these medications include the convenience of fixed dosing and avoidance of close therapeutic monitoring. Ximelagatran was one of the first DTIs that was as effective as warfarin in the treatment of stroke prevention, nonvalvular atrial fibrillation, and DVT.<sup>168</sup> Ximelagatran had many advantages over warfarin, including rapidity of onset, fixed dosing, stable absorption, decreased risk of drug interactions, and lack of necessity for therapeutic monitoring.<sup>168</sup> However, in 2006, drug manufacturers abandoned ximelagatran after noticing a high rate of hepatic failure. Countries that had approved ximelagatran withdrew the medication from the market.

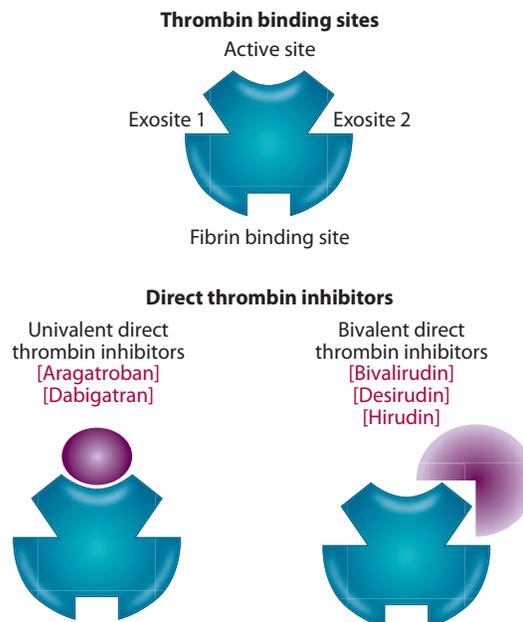

Subsequently, dabigatran was approved for systemic anticoagulation in patients with nonvalvular atrial fibrillation in the United States and many other countries. Later it was approved for the treatment and prophylaxis of VTE. The Randomized Evaluation of Long Term Anticoagulant Therapy (RE-LY) trial demonstrated that dabigatran administration was associated with lower rates of systemic embolic events, with similar rates of bleeding, compared with anticoagulation with warfarin.<sup>81</sup> However, subsequent evaluation of the data acquired from the RE-LY trial demonstrates that patients 75 years of age and older an increased risk of extracranial bleeding when compared with those taking warfarin.<sup>110</sup> In multiple noninferiority trials, dabigatran demonstrated similar efficacy to enoxaparin in reducing VTE without increasing bleeding risk after hip joint replacement.<sup>114,115</sup>

## Pharmacology

Thrombin has four separate binding sites, each of which is specific for substrate, inhibitor, or cofactors.<sup>368</sup> Whereas bivalent DTIs, such as hirudin and bivalirudin, bind the active site and one of two exosites (binding sites outside of the active site), univalent DTIs, such as dabigatran, bind just the active site<sup>97</sup> (Fig. 58–3). By directly inhibiting thrombin, anticoagulation is possible without the need for AT.<sup>329</sup> In addition, inhibiting thrombin also inhibits platelet activation because thrombin is a potent and direct-acting platelet activator. Unlike heparin, DTIs are able to enter clots and inhibit clot-bound thrombin because of their small size, offering the distinct advantage of restricting further thrombus formation.

Desirudin, bivalirudin, and argatroban are all administered parenterally. Desirudin is given as SC injections for VTE prophylaxis. Although the dosing for desirudin is 15 mg as a subcutaneous injection every 12 hours, this dose should be decreased or stopped in patients with stage 3 or greater CKD. In addition, patients previously treated with the hirudins develop antibodies, creating the potential for anaphylaxis with repeat dosing.<sup>137</sup> Bivalirudin is also an analogue of hirudin. It is used in patients with HITT who require cardiac catheterization or cardiopulmonary bypass surgery.<sup>137</sup> Argatroban binds noncovalently to the active site of thrombin to function as a competitive inhibitor.<sup>137</sup> It is metabolized by CYP3A4/5 in the liver and is particularly useful in patients with CKD.<sup>137</sup>

Dabigatran is orally administered as dabigatran etexilate. This prodrug has no anticoagulant properties, and serum esterase converts it to dabigatran, the active drug.<sup>347</sup> At therapeutic doses, peak concentrations occur in 2 hours (Table 58–3). Approximately 35% of dabigatran is protein bound; 85% is eliminated renally, with 78% of it is eliminated within the first 24 hours. Its mean terminal half-life is approximately 8 to 12 hours.<sup>37</sup> Contraindications to dabigatran are active hemorrhage or a hypersensitivity reaction to dabigatran. The manufacturer recommends either dose adjustment or avoidance

**FIGURE 58–3.** Thrombin has four separate binding sites. Each site is specific for substrate, inhibitor, or cofactors. Bivalent direct thrombin inhibitors, such as hirudin and bivalirudin, bind the active site and one of two exosites. Univalent direct thrombin inhibitors, such as dabigatran, bind only the active site.

of concomitant administration of P-glycoprotein inhibitors in patients with renal insufficiency. It also recommended to avoid coadministration of rifampin, a P-glycoprotein inducer.<sup>39</sup> P-glycoprotein activity prevents enteric absorption of dabigatran, and rifampin augments this activity, resulting in subtherapeutic dabigatran serum concentrations.

## Clinical Manifestations

Intentional overdoses with the DTIs are rare events. Although there are reports of patients who develop significant coagulopathy after unintentional ingestion of excess dabigatran,<sup>64,261,409</sup> the more common scenario is that patients become overanticoagulated because of improper dosing in patients with CKD or failure to adjust dosing in patients who develop AKI. In general, the parenterally administered medications have short elimination half-lives, and iatrogenic medication administration errors, if recognized, are often less risky than those that are longer acting.

Dabigatran, the newest of the DTIs, is orally administered with a longer duration of action. Since its approval in 2010, bleeding was rapidly recognized as a complication of therapy. Only recently has a specific monoclonal antibody reversal xenobiotic, idarucizumab (Praxbind), been approved by the FDA. In 2011, the FDA released an advisory announcing that a review of postmarketing reports of serious bleeding associated with dabigatran use was initiated. In addition, dabigatran leads the list of fatalities reported to the MedWatch system. There are many published case reports of patients bleeding while anticoagulated with dabigatran. Patients may have been subjected to increased risk of bleeding because of risk factors such as increased age or CKD. In New Zealand and Australia, a significant number of bleeding events, including intracranial bleeding, GI bleeding, hematuria, and hemoptysis, were reported in the period immediately after the approval of the medication. Up to 25% of the reports in this series involved errors in prescribing practices.<sup>160</sup> In particular, off-label use of dabigatran for anticoagulation in the setting of mechanical heart valves led to valve thrombosis.<sup>70,293</sup> Cardiac tamponade from hemopericardium, fatal epistaxis, serious GI bleeding, postoperative bleeding complications, and intracranial bleeding are all reported.<sup>26,65,107,340,367</sup> In addition, clinicians have expressed difficulties in treating hemorrhage in trauma victims while anticoagulated with dabigatran.<sup>85</sup>

Furthermore, several questions regarding other adverse effects related to dabigatran use have been raised. A meta-analysis comparing patients

TABLE 58–3 Pharmacology of Oral Antithrombotics<sup>a</sup>

	Warfarin	Dabigatran (Pradaxa)	Rivaroxaban (Xarelto)	Apixaban (Eliquis)	Edoxaban (Savayasa)

<sup>a</sup>Antithrombotic metabolism and plasma half-life (t<sub>1/2</sub>) may be altered by a number of factors such as diet, genetic polymorphisms, and kidney disease.

P-gp = P-glycoprotein; T<sub>max</sub> = time to maximum blood concentration.

anticoagulated with dabigatran versus warfarin, enoxaparin, or placebo showed higher rates of MI or acute coronary syndrome.<sup>372</sup> Additionally, though clinical trials implied that discontinuation of dabigatran does not cause rebound thrombosis, the authors of anecdotal reports of thrombotic events after cessation of dabigatran anticoagulation have questioned whether thrombosis is caused by rebound or just sequelae from underlying hypercoagulability or illness.<sup>364</sup>

### Laboratory Assessment

Monitoring the anticoagulant effect in the setting of DTI use is complex. For bivalirudin and argatroban, serial aPTT measurements are commonly used to estimate the degree of anticoagulation.<sup>137</sup> Admittedly, the aPTT is not a good test because the degree of anticoagulation does not follow a linear relationship. This is particularly emphasized with dabigatran, the most recently developed DTI. For example, the aPTT increases at higher dabigatran concentrations, but the relationship is nonlinear, with the aPTT plateauing at dabigatran concentrations greater than 200 ng/mL.<sup>346,378</sup> Furthermore, the PT and INR are usually elevated, but they do not correlate with the anticoagulant effect of dabigatran.<sup>349,378</sup> Dilute thrombin time (dTT) and ecarin clotting time (ECT) are proposed as more accurate reflections of the anticoagulation effect.<sup>378</sup> Several assays are used to measure serum dabigatran effect using the dTT assay. In these assays, standards with known dabigatran concentrations are used. Unfortunately, none of these modalities are FDA approved.<sup>105,317,348</sup> Ecarin clotting time is a laboratory assay that uses ecarin, a derivative of saw-scaled viper venom, as the reagent to activate prothrombin. Although some hospitals are able to obtain a thrombin time (TT) in a clinically relevant time, the dTT and the ECT are usually unavailable.

### Treatment of Direct Thrombin Inhibitor–Induced Coagulopathy

In the event of an acute ingestion of dabigatran, AC is indicated based on data from an in vitro model.<sup>377</sup> It should be noted that there have been at least two cases of intentional dabigatran overdose that were managed via orogastric lavage and AC. The initial dabigatran concentrations were later found to be 970 ng/mL and 4,170 ng/mL, respectively.<sup>261,410</sup> Based on a small prospective study with dabigatran assays, the average peak concentration in patients receiving therapeutic dosing of dabigatran was 112.7 ± 66.6 ng/mL.<sup>317</sup> However, because both patients after intentional dabigatran overdoses cases did not have bleeding complications, they were observed until the resolution of coagulopathy. One patient was given FFP for an aPTT of 79s (normal, 23–37 s) and an INR of 3.3. The other patient was noted to have a mild coagulopathy with an aPTT of 48.8 s and an INR of 1.3.<sup>261,410</sup> An overdose of argatroban was successfully treated with FFP in a case report.<sup>415</sup> With the widespread dabigatran use, the first of the novel oral anticoagulants, the absence of a reversal agent became a potentially deadly complication. The manufacturer fast-tracked the development of idarucizumab (Praxbind), a monoclonal antibody targeting dabigatran.<sup>374,375</sup> In murine and human studies, idarucizumab

administration results in normalization of a battery of functional clotting assays, including clotting time, aPTT, and TT.<sup>321</sup> In a prospective study containing 90 patients who received 5 g of IV idarucizumab for urgent reversal of dabigatran-induced coagulopathy, reversal of coagulopathy occurred in 100% of patients despite 18 deaths in the study population. Study investigators noted that hemostasis in bleeding patients was restored at a median of 11.4 hours after administration of idarucizumab. In addition, antidotal therapy restored ECT and dTT in 88% to 98% of the patients. In patients undergoing an emergent procedure, normal intraoperative hemostasis was noted in 85% of cases. There are a significant number of limitations with this particular study. It should be noted that in addition to idarucizumab, 56% of patients received some type of blood products, including PRBCs, FFP, platelets, cryoprecipitate, PCCs, or whole blood. Thrombotic events were noted in five patients. One thrombotic event (simultaneous DVT and PE) occurred within 72 hours of idarucizumab administration in a single patient. Other complications noted were left atrial thrombus at 9 days, DVT at 7 days, MI at 13 days, and ischemic stroke at 26 days. Unfortunately, there was no control group to determine if morbidity or mortality outcomes were changed by administration of idarucizumab. In addition, dabigatran concentrations in enrolled patients ranged between 5 and 3,600 ng/mL with a median of 132 and 114 ng/mL in the two study groups.<sup>287</sup> Although the majority of patients in the RE-LY trial had dabigatran concentrations less than 1,000 ng/mL, the literature reports exceedingly high dabigatran concentrations in many patients, particularly in patients who have kidney injury or in patients who have intentionally overdosed on dabigatran. The standard dose of idarucizumab, 5 g, will be insufficient in reversing coagulopathy in patients with these extremely high dabigatran concentrations.

There are many case reports describing the use of idarucizumab in various clinical scenarios. It has been used in life-threatening bleeding, intentional overdose, and therapeutic accumulation secondary to kidney injury and in the preoperative or preprocedural setting.<sup>47,140,165,166,235,282,303,307,319,331,351,363</sup> At least one case report showed continuation of life-threatening GI bleeding despite receiving recommended dosing of idarucizumab.<sup>4</sup> One report described using idarucizumab in conjunction with hemodialysis to achieve normal coagulation function.<sup>235</sup> It should be noted that several case reports demonstrated a rebound drug effect after administration of idarucizumab. One case described a patient with a massive dabigatran overdose with an initial dabigatran concentration of 3,337 ng/mL. After receiving idarucizumab, the patient's dabigatran concentration fell to 513 ng/mL, with improvement in his coagulopathy. However, 7 hours after receiving idarucizumab, the patient's<sup>294</sup> dabigatran concentration rebounded to 1,126 ng/mL with corresponding increases in INR, PT, and aPTT.<sup>309</sup> Dabigatran rebound after idarucizumab treatment is noted in other case reports.<sup>169</sup> Some advocate for idarucizumab administration before thrombolytic therapy for acute ischemic cerebrovascular accidents in patients anticoagulated with dabigatran.

In these case reports, patients received 5 g of idarucizumab followed by t-PA without adverse consequence.<sup>31,139,187,263,320,327</sup> Some clinicians routinely recommend idarucizumab treatment before thrombolytic therapy for acute ischemic stroke.<sup>100,139</sup> However, given the paucity of data and lack of a formal clinical trial, this should not be the standard of care as case reports cannot determine the efficacy and safety of this practice.

Before the FDA approval of idarucizumab in 2015, the manufacturer suggested several strategies to treat patients with significant bleeding while anticoagulated with dabigatran. Transfusion of RBCs and FFP in addition to supportive care were the mainstays of treatment (Table 58–1). Recombinant factor FVIIa, PCCs, and hemodialysis were also used, but these interventions are incompletely studied. In a murine study of dabigatran, collagenase-induced intracranial hematoma expansion was inhibited in a dose-dependent fashion by PCC with the best results at 100 units/kg, the equivalent of 200% factor replacement. In the same study, high-dose PCC decreased but did not normalize the tail vein bleeding time. Recombinant factor VIIa was ineffective in limiting intracranial hematoma volume, and FFP limited intracranial hematoma size in the mice given a lower dose of dabigatran.<sup>418</sup>

However, conclusions based on data obtained from murine studies should be interpreted with caution when treating humans. First, the hemostatic therapies used in these murine experiments are human derived, and cross-species effects cannot be predicted. Second, these mice had prolongation of their tail vein bleeding times, but dabigatran at therapeutic doses does not change bleeding time in humans.<sup>186</sup> Another study done in healthy humans found that aPTT, endogenous thrombin potential lag time, TT, and ECT did not decrease with the administration of four-factor PCC.<sup>108</sup>

One ex-vivo study showed that after a single dose of dabigatran in healthy volunteers, FEIBA decreased endogenous thrombin potential and lag time, and thrombin generation increased in a dose dependent fashion.<sup>237</sup> In a murine study, aPCC reduced bleeding time at low doses. Unfortunately, at high doses, this effect was reduced.<sup>376</sup>

Hemodialysis for dabigatran removal remains a controversial intervention. A single study showed that after a subtherapeutic dose of dabigatran in patients with stage 5 CKD, the extraction ratios were up to 68% at 4 hours after the initiation of hemodialysis.<sup>350</sup> Although this suggests that dabigatran is effectively removed from the serum, the greater implication of this finding is unknown. This study did not address the safety of hemodialysis in bleeding patients who are actively bleeding or the possibility of rebound concentrations after hemodialysis.<sup>349,350</sup> Several published case reports demonstrated significant drug rebound after hemodialysis in bleeding patients, up to 87% of the initial dabigatran concentration within 2 hours after the cessation of hemodialysis.<sup>63,64,340</sup> In one case, hemodialysis was not effective in stopping bleeding, and despite massive transfusion of RBCs, FFP, and platelets, deaths from exsanguination occurred. In some cases, a repeat hemodialysis session or continuous venovenous hemodiafiltration (CVVHD) was performed in anticipation of posthemodialysis rebound. Although they were successful in decreasing serum dabigatran concentrations, they did not normalize the aPTT or the TT.<sup>340</sup>

Although the safety and efficacy of these adjunctive therapies are unknown, they are reasonable in patients with serious bleeding if idarucizumab is not available or if a patient continues to have life-threatening hemorrhage despite idarucizumab administration. Repletion of blood volume and coagulation factors with PCC is reasonable. If maximal efforts at repletion of blood volume and coagulation factors are ineffective, then hemodialysis followed by CVVHD is reasonable if the patient can tolerate the procedure hemodynamically.

Ciraparantag is a “universal antidote” being developed to reverse the activity of a number of anticoagulants, including the oral DTIs, the factor Xa inhibitors, and the heparins.<sup>9-11</sup> Clinical trial results have yet to be published.

## FACTOR Xa INHIBITORS

Rivaroxaban was the first orally active direct factor Xa inhibitor approved for VTE and stroke prophylaxis and treatment. Development of this class of drugs started in the 1980s after the discovery of antistasin, a naturally

occurring factor Xa inhibitor found in leeches. After screening a library of more than 200,000 compounds, a pharmaceutical company was able to identify structures that inhibit factor Xa. After structure optimization, rivaroxaban was created for clinical trials.<sup>283</sup>

Numerous clinical trials investigated the efficacy and safety of rivaroxaban.<sup>22,113,114,188,203,369</sup> Compared with warfarin, rivaroxaban prevented more strokes or systemic thromboembolic events and significantly reduced the number of intracranial hemorrhages in patients with nonvalvular atrial fibrillation.<sup>281</sup> The most recent published trial compared the use of rivaroxaban compared with placebo in patients with acute coronary syndrome. There was a significant risk reduction in death attributed to any cardiac cause or stroke. However, rivaroxaban-treated patients had statistically significant increased rates of major and intracranial hemorrhages.<sup>243</sup>

Apixaban is another oral factor Xa inhibitor that is approved by the FDA for VTE prophylaxis in patients with atrial fibrillation. Numerous studies showed benefit of apixaban in preventing VTE in specific populations while simultaneously lowering mortality or specific types of bleeding, such as intracranial hemorrhage.<sup>80,147,150,203-206</sup>

In trials investigating the use of apixaban in patients with recent acute coronary syndrome, excess bleeding caused early cessation of trials; however, most patients were concurrently treated with dual antiplatelet therapy.<sup>3,76</sup>

Edoxaban is the newest of the approved factor Xa inhibitors based on studies for VTE prophylaxis in patients with atrial fibrillation and for the treatment of VTE disease.<sup>66,71,111,143,144,171,296,396,414</sup> Studies with edoxaban demonstrated promising results compared with enoxaparin in post-orthopedic surgery VTE prophylaxis, although it is not currently FDA approved for this indication.<sup>129-132,297</sup> The risk of hemorrhage compared with enoxaparin varies among the many studies.<sup>52,66,71,129-132,414</sup> Compared with warfarin in patients with nonvalvular atrial fibrillation, the ENGAGE AF-TIMI 48 trial demonstrated a lower risk of cardiovascular death and hemorrhage, including intracranial hemorrhages and fatal bleeding.<sup>111,143,144,396</sup> However, a study demonstrated the addition of an antiplatelet agent, such as aspirin, to edoxaban therapy in patients with atrial fibrillation resulted in a higher risk of hemorrhage compared with patients who received warfarin in conjunction with a single antiplatelet agent.<sup>412</sup>

Factor Xa inhibitor development continues. Betrixaban is undergoing clinical trials to determine its efficacy and safety in VTE prophylaxis.<sup>79</sup>

## Pharmacology

The factor Xa inhibitors are ideal anticoagulants because their site of action is the intersection of the intrinsic and extrinsic pathways, preventing thrombin activation.<sup>59</sup> These synthetic drugs reversibly inhibit factor Xa without any cofactor requirements. Theoretically, this class of anticoagulants is safer than the DTIs because they do not completely neutralize thrombin.

Rivaroxaban and apixaban selectively bind free and clot-bound factor Xa without inhibiting related serine proteases, including thrombin, trypsin, plasmin, or other activated clotting factors.<sup>116</sup> In addition, rivaroxaban and apixaban inhibit tissue factor or collagen-induced thrombin formation. In vitro, the factor Xa inhibitors hinder tissue factor–induced platelet aggregation.<sup>116,408</sup> Rivaroxaban does not directly inhibit platelet aggregation, and concomitant aspirin use does not affect the pharmacokinetics or safety of rivaroxaban in studies of healthy humans.<sup>59,116,196</sup>

Rivaroxaban has an oral bioavailability of approximately 80%.<sup>397</sup> Inhibition of factor Xa peaks approximately 3 hours after administration of the rivaroxaban. This inhibition lasts for approximately 12 hours.<sup>198</sup> However, kidney or liver disease lengthens its duration of action (Table 58–3). Dosing varies by indication and kidney function. The manufacturer provides recommended dose adjustments for each indication based on kidney function.

Approximately one-third of rivaroxaban is eliminated unchanged by the kidneys, and one-third is metabolized to an inactive form and excreted by the kidney. The remaining one-third is metabolized by the CYP3A4-dependent and -independent pathways in the liver and then excreted fecally. Concomitant use of CYP3A4 inhibitors or P-glycoprotein inhibitors is contraindicated because of increased risk of drug accumulation of up to 160%.<sup>164,397</sup>

In the future, rivaroxaban could be a suitable anticoagulant alternative in patients with HIT because *in vitro* studies do not show platelet aggregation or activation in the presence of HIT antibodies or release of PF4 from platelets.<sup>390</sup> Future studies proving efficacy and safety are needed before these xenobiotics can be recommended for use in patients with HIT.

In preclinical studies, the oral bioavailability of apixaban is approximately 66%. Apixaban is primarily distributed to the blood compartment and is approximately 87% protein bound.<sup>116</sup> Peak serum concentrations occur between 1 and 3 hours postingestion. There are multiple elimination pathways, suggesting that patients with either renal or hepatic impairment should be able to tolerate apixaban well. Approximately 25% of apixaban is excreted in the urine, and the majority of apixaban is excreted fecally between 24 to 48 hours after ingestion.<sup>116,295</sup> Simultaneous administration of strong CYP3A4 inhibitors is contraindicated with apixaban.

Apixaban is approved in the United States for stroke prevention in patients with nonvalvular atrial fibrillation, for VTE prophylaxis, and for VTE treatment.<sup>80,150</sup> Dosing is based on indication. The manufacturer recommends either decreasing the dose or avoiding coadministration of apixaban if strong inhibitors of CYP3A4 and P-glycoprotein are administered.<sup>53</sup>

Edoxaban is approved for the treatment of nonvalvular atrial fibrillation and for the treatment of DVT and PE. The dosage varies by indication. For patients with atrial fibrillation, the dosage also depends on creatinine clearance. Edoxaban is not recommended for patients with creatinine clearance less than 95 mL/min. Patients with VTE disease should receive edoxaban after 5 to 10 days of treatment with a parenteral anticoagulant.<sup>89,310</sup> The manufacturer also notes that coadministration of rifampin, due to CYP3A4 induction, and coadministration of other anticoagulants are contraindicated.<sup>89,247</sup> The prescribing information provided by the manufacturers of edoxaban also recommend a maximum dose of 30 mg/day for patients with body weight less than 60 kg.<sup>89</sup>

Edoxaban is orally administered and has a bioavailability of 61.8%.<sup>240,250</sup> P-glycoprotein appears to be the key factor as a transporter of edoxaban. Edoxaban metabolism is minor, and the compound is largely excreted in the urine and feces.<sup>250</sup> Approximately 35% of an oral dose is eliminated renally, and 49% of the oral dose is excreted in the feces.<sup>240</sup> Peak edoxaban concentrations occur 1 to 2 hours after ingestion, and the terminal half-life is 10 to 14 hours.<sup>89</sup>

## Clinical Manifestations

Hemorrhage is the most concerning consequence of the factor Xa inhibitors, even at therapeutic doses. However, hemorrhage does not always occur in overdose. There are reports of no hemorrhage despite acute overdoses of both rivaroxaban and apixaban. In a multi-poison control center study involving 223 rivaroxaban or apixaban exposures, 12 patients involved suicide attempts, and none of these patients developed hemorrhage, although confirmation of ingestion was not verified in all cases.<sup>345</sup> A case report describes a 21-month-old girl who developed an INR of 3.5 approximately 12 hours after ingesting an unknown quantity of rivaroxaban. She did not have any hemorrhagic consequences.<sup>245</sup> Another case report describes a 71-year-old man who intentionally ingested 1,940 mg of rivaroxaban, resulting in an INR of 7.2 drawn 2 hours after ingestion and rivaroxaban concentration of 160 ng/mL drawn 3 days after ingestion. He never developed bleeding, and he was monitored until his coagulopathy resolved. He did not receive any blood products or reversal agents.<sup>300</sup> In another case, a 42-year-old man intentionally ingested multiple pharmaceuticals, including 1,400 mg of rivaroxaban. He never developed any bleeding, but given his INR of 2.4 drawn 5 hours after ingestion, he was given 1 g of tranexamic acid and 3,000 units of PCC. He was discharged 1 day after this ingestion without any bleeding or adverse events.<sup>224</sup> There are many other cases reporting massive intentional factor Xa inhibitor overdose, resulting in abnormal coagulation studies or supratherapeutic concentrations.<sup>20,212,213</sup> More predictably, bleeding occurs at therapeutic doses. In the previously mentioned multi-poison control center study, all bleeding events occurred in patients on long-term anticoagulant therapy.<sup>345</sup> Another case report describes a 58-year-old man taking

10 mg of rivaroxaban per day who developed prolonged rectal bleeding 31 days after initiating treatment for prophylaxis after hip replacement.<sup>40</sup>

## Diagnostic Testing

Some studies done in healthy volunteers show that rivaroxaban inhibits factor Xa activity and prolongs PT, aPTT, and LMWH activity in a dose-dependent fashion.<sup>197,198</sup> Unfortunately, PT and aPTT are not reliable measures of the anticoagulant effect of rivaroxaban because results vary widely depending on the reagent used. Thrombin generation assays are prolonged, and endogenous thrombin potential is decreased. Unfortunately, these assays are not readily available in most medical centers. Chromogenic anti-factor Xa activity reliably measures rivaroxaban effect over a large range of concentrations.<sup>316</sup>

Studies investigating the effect of apixaban on hematologic laboratory studies are limited, but multiple *in vitro* studies show that aPTT and PT increase in a dose-dependent fashion. The Heptest, a newly developed clotting assay that measures anti-Xa and anti-IIa activity, correlates best with the antithrombotic effect of apixaban. Unfortunately, it is not widely available because it is not yet FDA approved.<sup>105,116,407</sup>

## Treatment of Factor Xa Inhibitor–Induced Coagulopathy

A study in healthy volunteers demonstrated that rivaroxaban absorption, as defined by area under the concentration–time curve, is decreased after AC administration up to 8 hours after a single oral dose of rivaroxaban. Absorption is decreased by 43% if AC is administered within 2 hours of a rivaroxaban ingestion. Activated charcoal given 8 hours after rivaroxaban ingestion resulted in a 29% decrease in absorption.<sup>272</sup> Another study showed that AC at 2 hours and 6 hours after single-dose apixaban ingestion also reduced apixaban absorption by 50% and 28%, respectively. In this study, the half-life of apixaban decreased from 13 hours to 5 hours after AC was administered at either 2 hours or 6 hours after apixaban ingestion.<sup>391</sup> The administration of AC after an acute overdose is therefore recommended (Table 58–1). A single human study evaluated the use of four-factor PCC in reversing patients given rivaroxaban 20 mg twice daily for 2.5 days. The PT and endogenous thrombin time rapidly normalized after administration of 50 units/kg of PCC.<sup>108</sup> Rivaroxaban anticoagulated rabbits showed improvements in coagulation assays after treatment with PCC and rFVIIa. However, these agents were clinically ineffective in achieving hemostasis.<sup>146</sup> Because of its high protein binding, hemodialysis is unlikely to be an effective adjunct method to accelerate rivaroxaban removal.

Preliminary *in vitro* studies show that four-factor PCC may improve thrombin generation and coagulation parameters in blood aliquots treated with apixaban.<sup>117</sup> However, there are no human studies with clinically relevant outcomes to support the use of PCC in factor Xa-associated bleeding.

Although edoxaban is the newest of the factor Xa inhibitors, hemorrhage remains a concern. There is a report of diffuse alveolar hemorrhage in addition to the bleeding complications mentioned in the numerous clinical trials.<sup>267</sup> There are few studies evaluating reversal methods. There is one human study evaluating four-factor PCC in the reversal after a single dose of edoxaban. In this study, participants received 10, 25, or 50 units/kg of 4 factor PCC after a single dose of edoxaban. Participants then underwent punch biopsy, and coagulation studies and clinical bleeding were evaluated. After 50 units/kg of 4 factor PCC the bleeding duration and endogenous thrombin potential normalized. However, the PT and bleeding volume were only partially reversed.<sup>417</sup> There are two animal studies showing that rFVIIa and FEIBA are effective in reversing edoxaban-induced coagulopathy.<sup>133,167</sup> However, given that these agents have not been studied in for this indication in humans, neither rFVIIa nor FEIBA are recommended as treatment for edoxaban-induced coagulopathy.

Although the half-lives of the factor Xa inhibitors are substantially shorter than that of warfarin, normalization of hemostasis because of drug clearance often requires more than 24 hours without intervention. During this time, supportive measures such as restoration of intravascular volume are helpful but do not correct the xenobiotic-induced coagulopathy. Prothrombin complex

concentrates at a starting dose of 25 units/kg appears to be the only antidote that improves laboratory parameters immediately after infusion, but their effect on hemostasis is unknown. Regardless, in the case of life-threatening bleeding, PCC is reasonable to attempt to achieve hemostasis. Their peak coagulation effect should occur immediately after administration. In severe cases, repeat doses may need to be administered. The risk of thrombosis is unknown, and providers should be aware of this adverse effect when administering PCC. If PCC is unavailable, FEIBA should be used as a second-line agent. If both PCC and FEIBA are unavailable, it is reasonable to use rFVIIa with the caveat that the risk of thrombosis is higher with this drug compared with PCC and FEIBA.

Andexanet alfa (Andexxa) is a recombinant protein recently FDA approved for reversal of anticoagulation caused by factor Xa inhibitors. This antidote was developed by altering the structure of factor X. Although the drug still binds factor Xa inhibitors, it has been altered to inhibit the catalytic activation of thrombin, and the factor Va binding site, which is necessary for anticoagulation, is no longer present.<sup>229</sup> Studies in healthy elderly volunteers demonstrated that andexanet alfa administration given to patients who had achieved a steady-state concentration of either apixaban or rivaroxaban resulted in rapid reduction in plasma-free inhibitor concentrations and increased thrombin formation. Antifactor Xa activity decreased by more than 90% immediately after andexanet alfa infusion but rebounded to placebo concentrations within 1 to 2 hours.<sup>337</sup> In an open-label single-group study, andexanet alfa was given to patients who had ingested a factor Xa inhibitor within 18 hours of acute major bleeding onset. After infusion of andexanet alfa, 79% of patients achieved hemostasis and antifactor Xa activity decreased 12 hours after andexanet alfa infusion. Thrombotic events occurred in 6% of patients within 3 days of andexanet alfa infusion, and 15% of the patients died. An unclear number of patients received blood products such as PRBCs, FFP, or PCC. There was no control group to determine if there were any changes in patient outcomes such as morbidity or mortality resulting from andexanet alfa administration (Antidotes in Depth: A17).<sup>32</sup>

## PENTASACCHARIDES

Pentasaccharides are synthetic anticoagulants that possess activity against factor Xa and are used for the prevention and treatment of VTE. Fondaparinux is the only pentasaccharide currently available for clinical use.<sup>217</sup> The pentasaccharide binds to AT with an affinity higher than that of heparin facilitating the formation of the AT-factor Xa complex. After this complex forms, fondaparinux dissociates from the AT-factor Xa complex and can bind and activate additional AT.<sup>137</sup> Routine measurements of coagulation are not generally performed. When the degree of anticoagulation needs to be assessed, the fondaparinux-specific anti-Xa assay is the most helpful. The pentasaccharides have long half-lives and have no reliable reversal agent if bleeding occurs; they do not bind to protamine.<sup>137</sup> Patients with stage 3 CKD should have their dose reduced 50%; fondaparinux is contraindicated in patients with stages 4 and 5 CKD.<sup>137</sup> No controlled trials are available yet. However, normalization of coagulation studies and thrombin generation occurred after healthy volunteers received fondaparinux followed by rFVIIa.<sup>34</sup> In a case series of eight patients who received 90 mcg/kg of rFVIIa for hemorrhage, only 50% of patients had favorable outcomes. Anti-Xa activity remained unchanged, and none of the patients had any thrombotic complications. However, many of these patients were on other antithrombotics, including antiplatelet drugs. With respect to PCCs, a single trial investigated the use of PCC and aPCC to reverse fondaparinux-induced anticoagulation. In this study, the effect of PCC could not be assessed because the coagulation assay was incompatible with the formulation of PCC used. However, the addition of aPCC to plasma samples from fondaparinux-treated volunteers reversed thrombin generation time. This study was an *ex vivo* study, and further studies are required before PCC can be routinely recommended for the purpose of reversing fondaparinux-induced coagulopathy.<sup>112</sup> If a patient develops significant bleeding from fondaparinux, based on opinion only, it is reasonable to administer 25 to 50 units of PCC in addition to standard supportive measures.

## ANTICOAGULANT APTAMERS

Aptamer anticoagulants are small nucleic acid molecules that are currently under development to target specific blood coagulation proteins.<sup>266</sup> They are direct protein inhibitors and function similarly to monoclonal antibodies.<sup>266</sup> Specific aptamers that are currently being studied include the anti-factor IX aptamer, the anti-activated protein C aptamer, and the anti-factor VIIa aptamer.<sup>149</sup> These xenobiotics may have future clinical utility because their anticoagulant effects appear to be easier to control, and consequently safer, compared with the most commonly used anticoagulants.

Although not yet approved, pegnivacogin is an RNA aptamer that inhibits factor IX and is undergoing human trials to evaluate its efficacy and safety. Several clinical trials are being conducted in healthy volunteers and patients with coronary artery disease.<sup>289,291</sup> The effects of pegnivacogin mimic hemophilia B, also known as Christmas disease. By inhibiting factor IX, the conversion of factor X to factor Xa is inhibited.<sup>382</sup> Studies show that approximately 1 mg/kg of pegnivacogin inhibits more than 99% of factor IX. Pharmacokinetic studies demonstrate a half-life of pegnivacogin to be approximately 100 hours with stable antithrombotic effects lasting for 30 hours.<sup>288,289</sup> Similar to the heparins, pegnivacogin anticoagulation should be monitored with aPTT because previous studies have demonstrated that the degree of factor IX inhibition correlates well with aPTT.<sup>289</sup> Unfortunately, despite its theoretical benefits, an unexpectedly high number of participants in the most recent clinical trial developed severe allergic reactions after pegnivacogin administration, causing the trial to be terminated early. In this study, pegnivacogin was being compared with bivalirudin in patients undergoing percutaneous coronary intervention (PCI). At the point of the trial's termination, there was no obvious difference in reduction of bleeding compared with the bivalirudin group.<sup>222</sup> Further studies demonstrated that these allergic reactions are the result of anti-polyethylene glycol antibodies.<sup>290</sup> Because this aptamer is a synthetically tailored nucleic acid sequence, its antidote is easily manufactured. By creating a complementary aptamer that possesses a nucleic acid sequence that binds to pegnivacogin through Watson-Crick base pairing, it can effectively neutralize the original xenobiotic by creating an inactive complex. In fact, pegnivacogin is being studied in conjunction with anivamersen, the complementary aptamer to pegnivacogin.<sup>381</sup>

## FIBRINOLYTICS

The fibrinolytic system is designed to remove unwanted clots while leaving those clots protecting sites of vascular injury intact. Plasminogen exists as a proenzyme that is converted to the active form, plasmin, by plasminogen activators.<sup>74,75</sup> The actions of plasmin are nonspecific in that it degrades fibrin clots and some plasma proteins and coagulation factors.<sup>395</sup> Inhibition of plasmin occurs through  $\alpha_2$ -antiplasmin.<sup>395</sup> Tissue plasminogen activator is released from the endothelium and is under the inhibitory control of two inactivators known as tissue plasminogen activator inhibitors 1 and 2 (t-PAI-1 and t-PAI-2).<sup>74,75,257,395</sup> Under physiological conditions, endogenous t-PA does not induce a fibrinolytic state because there is no fibrin to initiate the conversion of plasminogen to plasmin. However, exogenous t-PA administration results in supraphysiological concentrations that promote a fibrinolytic state.<sup>395</sup>

With their diverse indications in acute MI, unstable angina, arterial and venous thrombosis and embolism, and cerebrovascular disease, the thrombolytics are commonly used.<sup>27</sup> Readers are referred to a number of reviews for specific indications and dosing regimens.<sup>84,208,280,341,395,401</sup> Although all fibrinolytics enhance fibrinolysis, they differ in their specific sites of action and duration of effect. Tissue plasminogen activator is produced by recombinant DNA technology, and it is clot specific (ie, it does not increase fibrinolysis in the absence of a thrombus). Newer thrombolytics such as reteplase and tenecteplase possess longer half-lives that facilitate administration via bolus dosing rather than infusion.<sup>395</sup> On the other hand, streptokinase, urokinase, and anistreplase are not clot specific. Tissue plasminogen activator has the shortest half-life and duration of effect (5 minutes and 2 hours, respectively) and anistreplase the longest (90 minutes and 18 hours, respectively).<sup>280,341</sup> Streptokinase has the additional risk of potential severe allergic reaction on

rechallenge, limiting its use to once in a lifetime. In fact, streptokinase is no longer used in the United States.

Thrombolytics such as alteplase, tenecteplase, reteplase, and desmoteplase are used in other countries or are currently being evaluated for therapeutic use.<sup>228</sup> These fibrinolytics have longer half-lives and are administered via single or repeated bolus injections. They also have increased fibrin selectivity but no apparent improvement in mortality compared with t-PA.<sup>184</sup>

A number of contraindications preclude the use of fibrinolytics. Undesired bleeding occurs because of clot destruction at vascular compromised sites and destruction of coagulation factors from plasmin generation.<sup>395</sup> Risk factors for bleeding, such as recent surgery or bleeding, known vascular lesions, malignancy, or prior intracranial hemorrhage, are contraindications for fibrinolytic administration.

### Clinical Manifestations

Although the incidence of bleeding requiring transfusion is as high as 7.7% after high-dose (150 mg) t-PA and 4.4% after low-dose t-PA,<sup>84</sup> the incidence of intracranial hemorrhage with t-PA appears to be similar to the newer fibrinolytics (alteplase, tenecteplase, reteplase, and desmoteplase).<sup>383</sup> The addition of heparin to thrombolytic therapy increases the risk of bleeding. Reviews of multiple trials suggest that life-threatening events such as intracranial hemorrhage occur in 0.30% to 0.58% of patients receiving alteplase, 0.42% to 0.73% of patients receiving reteplase, and 0.08% to 0.30% of patients receiving streptokinase.<sup>401</sup> Regardless of the thrombolytic used, the frequency of bleeding events is similar, with the exception that alteplase has a decreased incidence of significant hemorrhage.<sup>93</sup>

### Treatment

Patients with minor hemorrhage complications caused by the fibrinolytic agents should receive supportive care as necessary, with focus on volume replacement and attempts to control the bleeding if possible. However, for patients with significant bleeding such as intracranial hemorrhage, it is reasonable to administer fibrinogen and coagulation factor replacement with cryoprecipitate, FFP, or PCC.<sup>318</sup> One study showed that after thrombolytic-induced intracranial hemorrhage, coagulopathy went untreated in 45% of cases.<sup>148</sup> A recent study of 3,894 patients showed that the mortality rate associated with postfibrinolytic intracranial hemorrhage is up to 52%, and the rate of intracranial hematoma expansion is 26.8%. When studied, postfibrinolytic patients with expanding intracranial hematomas tended to have severe hypofibrinogenemia, highlighting the need for cryoprecipitate repletion.<sup>413</sup> If fibrinogen and factor replacement are ineffective, then antifibrinolytics such as aminocaproic acid and tranexamic acid are recommended (Table 58–1). These fibrinolytics prevent activation of plasmin by competing with fibrin to bind to plasminogen and plasmin. Although a significant amount of fibrinolysis has already occurred, competitive inhibition of further plasmin-activated fibrinolysis is theoretically helpful in cases of life-threatening bleeding despite no clinical evidence available to show improved morbidity or mortality. Aminocaproic acid is also able to prevent the binding of t-PA to fibrin. Not only can these antifibrinolytics prevent fibrinolysis, but they can also reverse excessive fibrinolysis,<sup>318,395</sup> although it is not well studied in the setting of fibrinolytic therapy.

Aminocaproic acid is administered orally or intravenously. When administered intravenously, a loading dose of 4 to 5 g over 1 hour is followed by an infusion of 1 to 1.25 g/h with a maximum of 30 g given in 24 hours. The infusion should be stopped before 24 hours if the bleeding has ceased. Aminocaproic acid should not be given to patients with hematuria. These patients are at risk for developing obstructive AKI from ureteral clots that cannot be lysed. There are also rare reports of myopathy and muscle necrosis.<sup>395</sup> Although theoretically, aminocaproic acid could reverse hemorrhage after fibrinolytic therapy, there are no case reports or studies supporting its use in this situation.

Tranexamic acid is also reasonable to administer orally or intravenously. It is currently approved for the treatment of menorrhagia and is dosed at 1 g orally four times a day for four days.<sup>395</sup> It is also used in hemophilic patients undergoing cardiac surgery. However, recent studies received significant attention

for the use of tranexamic acid in patients with traumatic hemorrhage. The CRASH-2 study, a multicentered randomized controlled trial evaluating outcomes of patients receiving tranexamic acid with traumatic bleeding found that infusion of 1 g over 10 minutes, followed by 1 g over 8 hours, resulted in a significant reduction in mortality rate. In addition, the risk of arterial thrombosis, as well as fatal and nonfatal thrombosis, was significantly reduced compared with control participants who received placebo.<sup>305</sup> A case report describes the successful use of tranexamic acid in a patient who developed an intracranial hemorrhage after thrombolytic therapy. After receiving 1.675 g of IV tranexamic acid, repeat computed tomography and magnetic resonance imaging of the brain revealed no hematoma expansion, and the patient did not develop any thrombotic complications.<sup>127</sup> In the Japanese Observational Study for Coagulation and Thrombolysis in Early Trauma (J-OCTET) study, early administration of tranexamic acid resulted in lower rates of mortality, including in the subset of patients with primary brain injury.<sup>336</sup> An additional study demonstrates that tranexamic acid also has a protective effect on gut barrier function, particularly in ischemia-reperfusion injuries.<sup>99</sup>

Unfortunately, aminocaproic acid and tranexamic acid are associated with generalized tonic-clonic seizures in up to 7.6% of patients. The precise mechanism of seizures is not known. In murine studies, competitive antagonism of glycine receptors is suggested. When the mice were treated with isoflurane and propofol, seizure activity ceased.<sup>211</sup>

In summary, patients with severe bleeding, such as intracranial hemorrhage, after t-PA administration, replacement of coagulation factors and fibrinogen is recommended as soon as possible. While there are no significant studies using tranexamic acid or aminocaproic acid in factor and fibrinogen replacement failure, in patients who are gravely ill, tranexamic acid and aminocaproic acid could theoretically help decrease bleeding if all other measures fail. Because mortality rates in this population are so high, it is reasonable to recommend this intervention despite the lack of evidence.

### ANTIPLATELET DRUGS

Under normal conditions, vascular endothelium provides thromboregulators that prevent thrombus formation. When the endothelium becomes compromised, exposed collagen triggers two cascades of events to promote platelet aggregation. First, a tissue factor-mediated pathway indirectly activates platelets. Tissue factor, either from the damaged vessel wall or carried in the blood, complexes with factor VIIa and activates factor IX and the extrinsic pathway of the coagulation cascade. Thrombin then directly stimulates further platelet adhesion.<sup>134</sup> Second, when von Willebrand factor (vWF) adheres to the exposed endothelium, platelet GP Ib-V-IX binds to the vWF and anchors platelets to the site of vascular injury. In addition, platelet GP VI and Ia tether the platelets to exposed collagen.<sup>90,134,200</sup> (Fig. 58–4).

After platelet adhesion, modulators such as ADP and thromboxane A<sub>2</sub> (TXA<sub>2</sub>) maintain platelet activation.<sup>90,134,395</sup> Intracellular signaling results in the release of arachidonic acid (AA) via phospholipase A<sub>2</sub>. Next, AA is converted into prostacyclin via cyclooxygenase-1 (COX-1) or cyclooxygenase-2 (COX-2). This stimulates the production of TXA<sub>2</sub>, which further propagates platelet activation and aggregation.<sup>90,182</sup> (Fig. 58–5).

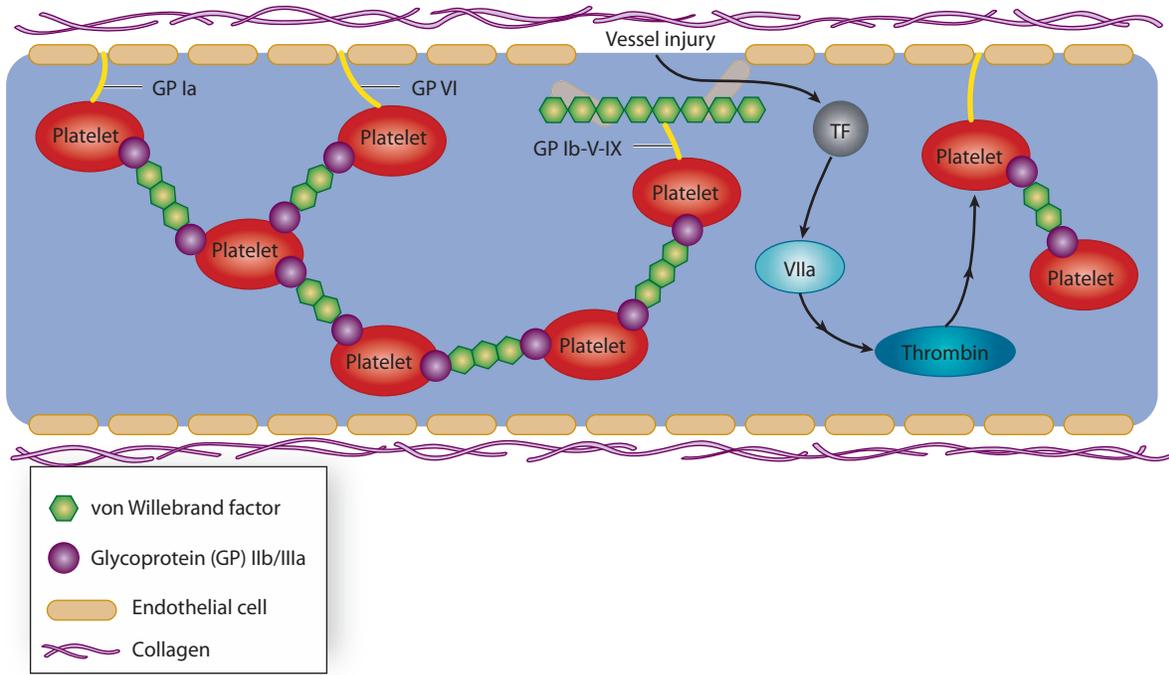

These mediators recruit more platelets to the area of vessel injury. Glycoprotein IIb/IIIa is expressed on the surface of the platelets and allows platelet cross-linking via this receptor with vWF acting as a bridge.<sup>90,134</sup>

Thrombus formation perpetuates platelet aggregation and adhesion to the vessel wall. Platelet GP IIb/IIIa activation results in further thrombus formation by binding fibrinogen and vWF, essential to the linking of platelets.<sup>90</sup>

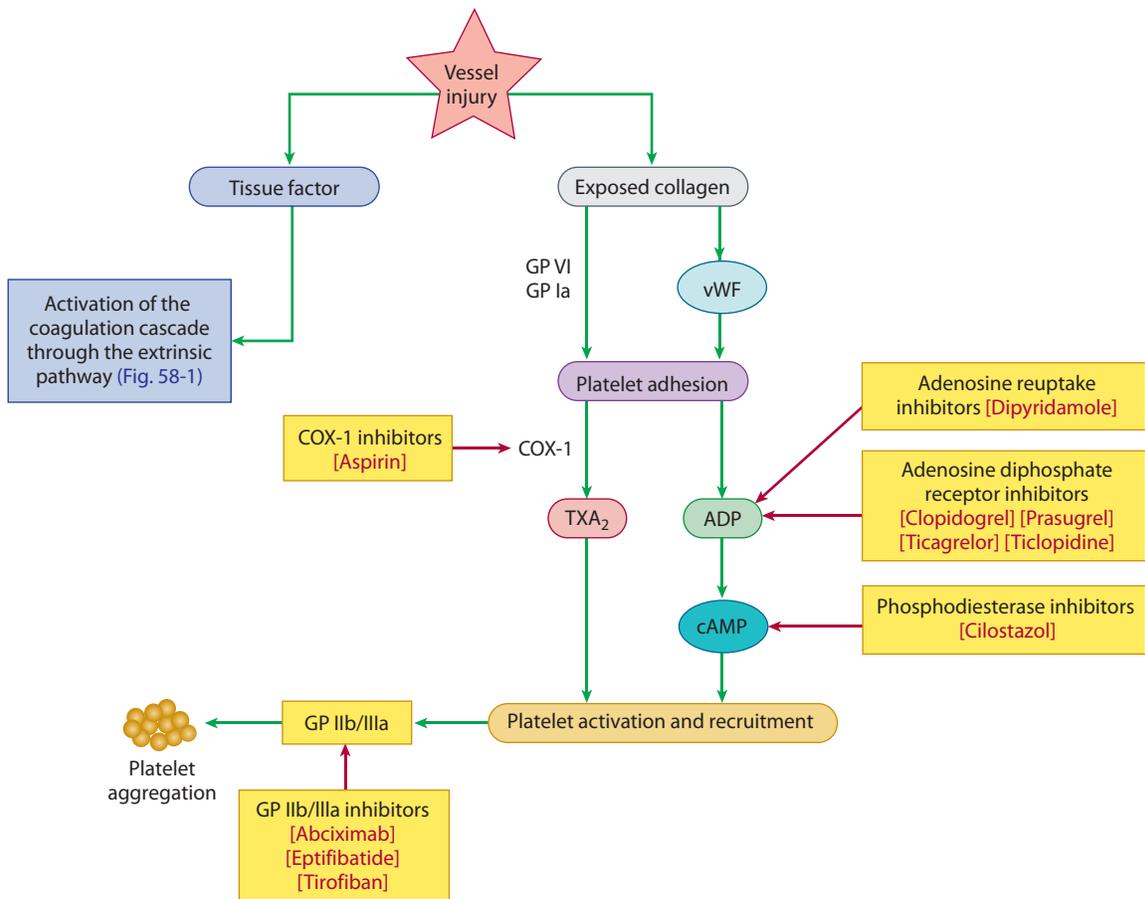

Antiplatelet therapies aim to decrease platelet activation or aggregation by inhibiting one of the steps in the many pathways, leading to GP IIb/IIIa activation of platelets.

### CYCLOOXYGENASE INHIBITORS

Widespread use of aspirin as an antiplatelet drug is associated with significantly decreased vascular events. Aspirin acetylates the COX-1 enzyme, prevents substrate binding to the enzyme, and results in irreversible inhibition

**FIGURE 58-4.** A schematic diagram of platelet aggregation. An injury to the endothelium results in initial platelet tethering by means of von Willebrand factor (vWF) and glycoprotein (GP) Ib-V-IX. Platelet GP VI and Ia tether the platelets to exposed collagen. GP IIb-IIIa is expressed on the surface of the platelets and allows platelet cross-linking with vWF bridging. TF = tissue factor.

**FIGURE 58-5.** The antiplatelet drugs act in various stages of platelet aggregation. ADP = adenosine diphosphate; cAMP = cyclic adenosine monophosphate; COX-1 = cyclooxygenase 1; GP = glycoprotein; TXA<sub>2</sub> = thromboxane A<sub>2</sub>; vWF = von Willebrand factor.

of TXA<sub>2</sub> generation. Daily low-dose aspirin fully inhibits COX-1 function and subsequent platelet aggregation because platelets are unable to regenerate COX-1.<sup>109</sup> However, although aspirin irreversibly inhibits COX-2, larger doses of aspirin are required to decrease COX-2–mediated processes because of rapid synthesis of new COX-2.<sup>109</sup>

Aspirin dosed between 75 and 150 mg showed the best odds reduction in preventing MI and stroke compared with other doses.<sup>12,109</sup> In fact, high-dose aspirin causes inhibition of other downregulators of platelet adhesion such as endothelium-derived prostacyclin. Although effective in preventing vascular events, the risks of bleeding and GI irritation are real. In a randomized trial comparing low dose (70–150 mg/d) and standard-dose (300–325 mg/d) aspirin in patients with acute coronary syndrome, standard-dose aspirin conferred an increased risk of GI bleeding without significant additional cardiovascular benefit.<sup>177</sup> However, even daily low-dose aspirin resulted in a significantly increased risk of GI bleeding compared with nonaspirin use, but this risk is outweighed by the benefits of cardiovascular disease and stroke prevention.<sup>394</sup>

## CYCLIC ADENOSINE MONOPHOSPHATE MODULATORS

### Phosphodiesterase Inhibitors

Cilostazol is a phosphodiesterase inhibitor marketed for the treatment of intermittent claudication secondary to peripheral vascular disease (PVD). By increasing cyclic adenosine monophosphate (cAMP), vasodilation is achieved by inhibiting myosin light-chain kinase, essential for smooth muscle contraction. Additionally, cAMP inhibits platelet aggregation. Small trials demonstrate that cilostazol improves walking distances, decreases arterial thrombosis, and improves rethrombosis rates in patients with PVD. In the Cilostazol for Prevention of Secondary Stroke (CSPS) study, cilostazol was not inferior to aspirin in preventing secondary stroke. However, because of its common GI adverse effects and headache, a high rate of discontinuation precludes this xenobiotic from being more widely used.<sup>109</sup>

### Adenosine Reuptake Inhibitors

Dipyridamole has antiplatelet properties, although its mechanism of action is not completely known. Evidence suggests that by inhibiting degradation of cAMP and by blocking adenosine reuptake, intracellular cAMP accumulates and inhibits platelet aggregation.<sup>109,395</sup> Dipyridamole also has antiinflammatory properties by decreasing monocyte gene expression of chemokines.<sup>400</sup> Dipyridamole 200 mg is marketed alone or in combination with 25 mg of aspirin (Aggrenox).

Randomized studies demonstrate a significant reduction in stroke in high-risk patients taking dipyridamole with aspirin compared with patients taking aspirin alone. However, many patients discontinue dipyridamole because of headache.<sup>101,157</sup> Unfortunately, compared with clopidogrel, dipyridamole and aspirin offer no improvement in stroke prevention and an increase in the risk of major bleeding.<sup>313</sup>

## ADENOSINE DIPHOSPHATE RECEPTOR INHIBITORS

Platelets require stimulation of P2Y<sub>1</sub> and P2Y<sub>12</sub>, ADP receptors, to inhibit adenylyl cyclase. Cyclic AMP formation decreases as a result of the inhibition of adenylyl cyclase, and the platelet loses its ability to activate. Clopidogrel, prasugrel, ticagrelor, cangrelor, and ticlopidine are ADP receptor inhibitors. By increasing cAMP concentrations through inhibition of the P2Y<sub>12</sub> receptor, these xenobiotics are able to inhibit platelet activation.<sup>109,395</sup>

Ticlopidine is a first-generation ADP receptor inhibitor. It is typically taken orally at 250 mg twice daily. Despite its rapid absorption with peak plasma concentrations between 1 and 3 hours, peak platelet inhibition occurs 1 week after initiation. Two of the many metabolites are noted to have significantly stronger ADP receptor inhibitor activity than the parent drug. Ticlopidine does not confer an overall reduction of cardiovascular death, stroke, or MI risk,<sup>141</sup> but coadministration with aspirin decreases stent thrombosis in some situations.<sup>216</sup>

The relatively high risk of neutropenia and the risks of agranulocytosis, thrombocytopenia, and thrombotic thrombocytopenic purpura–hemolytic

uremic syndrome and the development of newer generation ADP receptor inhibitors have rendered the use of ticlopidine nearly obsolete.<sup>109,395</sup>

Clopidogrel irreversibly binds and inhibits ADP receptors. Maximal platelet inhibition is achieved between day 4 and 7 after initiation of maintenance doses but occurs 2 to 4 hours after a 600-mg loading dose.<sup>109</sup> Clopidogrel requires conversion via CYP2C19 to form its active metabolite. Up to one-third of patients are resistant to clopidogrel. Many of these patients possess a CYP2C19 genetic polymorphism that results in loss of function, and these patients have an increased risk of major cardiovascular adverse events, especially after coronary artery stenting.<sup>109,244</sup> Similarly, concomitant administration of medications that inhibit numerous CYP enzymes may result in decreased efficacy. Further studies are required to determine if dosing modification may improve efficacy in preventing adverse vascular events.<sup>109</sup>

Clopidogrel is dosed at 75 mg/day. It is commonly administered with aspirin as numerous studies, such as the CREDO, COMMIT, and CLARITY trials, demonstrate that dual antiplatelet therapy to be beneficial in the reduction of vascular events.<sup>67,312,352</sup> However, in the ACTIVE trials, warfarin was superior to dual antiplatelet therapy with aspirin and clopidogrel in preventing major vascular events.<sup>78</sup> The risk of bleeding remains a major concern associated with the use of clopidogrel, particularly in dual antiplatelet regimens.<sup>67,83</sup>

Another ADP receptor inhibitor, prasugrel, similarly requires conversion to an active metabolite, which occurs within 30 minutes of dosing. CYP2C19 inhibition or concomitant proton pump inhibitor administration does not alter efficacy. A head-to-head comparison of prasugrel and clopidogrel in patients undergoing coronary artery intervention found a decreased incidence of overall vascular adverse outcomes and death and stent thrombosis in patients on prasugrel but no improvement in overall morbidity, mortality, or bleeding events.<sup>109,406</sup>

Cangrelor, approved in 2015, is another ADP receptor inhibitor with rapid onset of action. It has a short half-life, between 2.6 to 3.3 minutes.<sup>8</sup> Rates of adverse events such as severe bleeding are favorable compared with clopidogrel when used during PCI.<sup>33</sup>

Ticagrelor is the newest of the ADP receptor inhibitors that exerts its effects by allosterically and reversibly inhibiting the ADP receptor. Absorption is rapid with peak plasma concentrations in approximately 2.5 hours.<sup>362</sup> Dosing of ticagrelor includes a loading dose of 180 mg followed by a maintenance dose of 90 mg twice daily. The mortality and morbidity associated with ticagrelor has been compared with many other antiplatelet agents. Numerous studies delineate the risks of bleeding, in particular, based on antiplatelet therapy.<sup>41,42,258,385</sup>

## GLYCOPROTEIN IIb/IIIa INHIBITORS

Three GP IIb/IIIa inhibitors are available for use with patients with acute coronary syndromes. Abciximab is a monoclonal Fab antibody that binds the GP IIb/IIIa receptor. When administered with heparin and aspirin in patients undergoing coronary artery intervention, stent thrombosis, MI, and mortality all decrease. Abciximab is administered as an IV bolus dose of 0.25 mg/kg is followed by an infusion of 0.125 mg/kg/min. The plasma half-life is short, with plasma concentrations becoming negligible approximately 30 minutes after cessation of the infusion. However, the Fab fragments bind to the platelets and inhibit platelet function for up to 24 hours.<sup>395</sup>

Eptifibatide is a synthetic GP IIb/IIIa inhibitor used in patients with acute coronary syndrome undergoing coronary artery interventions. Its molecular structure is based on snake venom disintegrin. An IV loading dose of 180 mcg/kg is followed by an infusion of 2 mcg/kg/min.<sup>395</sup> Dosing in patients with CKD is unstudied, but there is a demonstrable increase in rates of bleeding in patients with a creatinine clearance less than 60 mL/min.<sup>298</sup> Tirofiban also inhibits the GP IIb/IIIa receptor and has similar clinical efficacy compared with eptifibatide.<sup>395</sup>

Up to 10% of patients treated with GP IIb/IIIa inhibitors have major bleeding events. Thrombocytopenia can also occur as a result of antigenic recognition of the xenobiotic-bound platelets.<sup>109</sup>

A number of trials examining the efficacy and safety of the GP IIb/IIIa inhibitors describe positive trends in decreasing predefined endpoints such

as 30-day mortality, stent rethrombosis, and MI. After evaluation of the combined data from multiple trials, the benefits of GP IIb/IIIa inhibitor therapy without early coronary artery revascularization are unclear when weighing the risks of bleeding. However, with early coronary artery revascularization, adding a GP IIb/IIIa inhibitor is beneficial, although the benefit of treatment in the highest risk patients is uncertain.<sup>92,109</sup>

### DEVELOPMENT OF NOVEL RECEPTOR AND ENZYME INHIBITORS

Recent pharmaceutical development has focused on inhibition of several key enzymes or receptors in platelet activation and aggregation. Thromboxane A<sub>2</sub> function is inhibited by TXA<sub>2</sub> synthase inhibitors or by antagonizing the TXA<sub>2</sub> receptor. Clinical trials are currently underway to evaluate the efficacy of inhibiting protease-activated receptors, also called thrombin receptors.<sup>361</sup>

### Laboratory Assessment

Bleeding time is traditionally the most useful and widely available used to assess platelet function. However, its popularity has decreased because of its insensitivity, invasiveness, scarring, and high degree of variability. A variety of platelet function assays exist, but few are widely available. The gold standard assay, light transmission aggregometry, is commonly used in specialty laboratories, but it does not reflect physiologic platelet adhesion or aggregation. Furthermore, this test is time consuming and expensive. Several widely used tests to assess platelet function, such as flow cytometry and serum TXA<sub>2</sub> assay, are available. Each of these tests has significant disadvantages such as being artifact prone, expensive, nonspecific, or insensitive to select antiplatelet agents. In addition, extrapolating these results to determine a patient's risk of bleeding or thrombosis is not possible.<sup>163</sup>

### Management

When managing bleeding in patients taking antiplatelet xenobiotics, blood transfusion should be used in patients with significant blood loss. However, transfusion of PRBCs will not increase platelet adhesion or aggregation. Unfortunately, the published literature that assesses interventions on bleeding patients maintained on antiplatelet xenobiotics is conflicting, and there is no clear consensus on appropriate reversal strategies and agents. The most widely evaluated intervention is platelet transfusion. The existing studies are small and mostly retrospective. Prospective studies are biased by non-randomization, specifically by the clinician ultimately deciding whether to transfuse the platelets. Many of these studies show that platelet transfusion is potentially harmful and independently predict increased mortality and bleeding (Table 58–1).<sup>21,61</sup> Although transfusing platelets is associated with worse outcomes, it is important to notice that these studies only demonstrate association and not causation. Therefore, blood transfusion to replace lost volume and coagulation factors is reasonable. It is also reasonable to administer platelets to patients in extremis, such as those requiring massive transfusion caused by extensive blood loss.

Desmopressin is approved for the treatment of inherited defects of hemostasis and potentiates thrombosis by releasing vWF and factor VIII from the endothelium into the plasma. In these patients, complications such as arterial thrombosis and MI are reported after desmopressin administration.<sup>207,218</sup> However, some proposed protocols for reversing antiplatelet xenobiotics in the setting of life-threatening bleeding include desmopressin. Most of these protocols are based on case reports because the majority of the studies evaluated prophylactic desmopressin before surgery to prevent blood loss. A single study evaluated the administration of desmopressin on platelet aggregation and platelet activity in healthy volunteers given a single dose of clopidogrel. They found that platelet reactivity and platelet aggregation increased after desmopressin administration. There was no mention of adverse outcomes in any of the study participants.<sup>214</sup> The risk of desmopressin-induced thrombosis in patients taking antiplatelet xenobiotics is unknown; in patients taking antiplatelet medications for atherosclerosis, the risk of thrombosis is greater.<sup>214</sup> There is not enough information to routinely recommend the use of desmopressin in this setting at this time.

In the case of abciximab, cessation of the infusion results in a rapid decrease in circulating antibodies. If severe bleeding occurs, platelet transfusion after discontinuation of the infusion is effective in restoring platelet activation and aggregation.<sup>395</sup> In most cases, discontinuation of eptifibatid and tirofiban results in restoration of normal platelet function within hours. However, patients with renal dysfunction have prolonged platelet inhibition. Both of these xenobiotics are renally cleared, and some have suggested hemodialysis as a means to enhance clearance.<sup>360</sup> Although not formally studied, case reports of patients with protracted platelet inhibition in the setting of eptifibatid use and end-stage CKD suggest that hemodialysis restores platelet aggregation capacity.<sup>343</sup> However, there are insufficient data at this time to routinely recommend this intervention, especially because initiating hemodialysis typically takes several hours, during which time platelet function typically improves. Unlike abciximab platelet toxicity, transfusion of platelets to patients receiving eptifibatid is believed to be ineffective in restoring platelet function. At therapeutic concentrations, the concentration of these xenobiotics far outnumbers the inhibited GP IIb/IIIa receptors by several orders of magnitude.<sup>360</sup> Further studies are required to produce recommendations or guidelines for emergent reversal of antiplatelet xenobiotics to determine if any interventions are effective and offer a favorable risk-to-benefit profile. In the meantime, clinicians should volume resuscitate accordingly with fluids and blood products as necessary.

### SNAKE VENOMS

A detailed discussion of snake envenomations is found in Chap. 119 and Special Considerations: SC10; only a few specific issues are discussed here. Snake venoms are composed of a vast number of complex proteins and peptides that interact with components of the human hemostatic system. In general, their functions may be thought of as being procoagulant, anticoagulant, fibrinolytic, vessel wall interactive, platelet active, or as protein inactivators. Additionally, they are more specifically classified based on their specific biologic activity; some of the various mechanisms include individual factor activation, inhibition of protein C and thrombin, fibrinogen degradation, platelet aggregation, and inhibition of serine protease inhibitors (SERPINS). Currently, more than 100 different snake venoms affect the hemostatic system.<sup>178,179</sup>

Figure 58–1 is an overview of their multiple interactions with the coagulation and fibrinolytic systems.<sup>236</sup>

Some of these venom proteins are being used as therapeutically for human diseases. Ancrod, a purified derivative of the Malayan pit viper, *Calloselasma rhodostoma* (formerly known as *Agkistrodon rhodostoma*), is therapeutically used because of its defibrinogenating property.<sup>25</sup> The mechanism of action of ancrod and other similar xenobiotics is to link fibrinogen end to end and subsequently prevent cross-linking. It is under investigation for the treatment of DVT, MI, PE, acute cerebrovascular thrombosis, HIT, and warfarin-related vascular complications. In a multicenter study of 500 patients with acute or progressing ischemic neurologic events, ancrod showed a favorable benefit-to-risk ratio compared with placebo.<sup>333</sup> As expected, an increased risk of bleeding is observed; however, the risk is less than that with thrombolytics.<sup>333</sup> Monitoring of fibrinogen concentrations is essential to avoid potential complications because no specific antidote exists. Following envenomation, snakes such as those of the Crotalinae family that induce bleeding, antivenin treatment is indicated.

### SUMMARY

- The development of new antithrombotics and the increasing frequency of antithrombotic therapeutic use are associated with complications and adverse outcomes.
- A complete understanding of the normal mechanisms of coagulation, anticoagulation, and thrombolysis combined with an understanding of the pharmacology of the xenobiotic and the clinical needs of the patient will allow clinicians to better choose among the complex therapies currently available.
- Complications of the antithrombotics should be managed with supportive care, starting with volume resuscitation and blood replacement.

- More aggressive interventions and specific reversal therapeutics are necessary depending if the patient is experiencing severe, life-threatening hemorrhage. In these instances, clinical studies do not always ensure a favorable risk-to-benefit profile because further studies are required.
- Ongoing development of new antithrombotics will raise new challenges for clinicians as adverse outcomes and bleeding complications arise, and new antidotes will be developed to address these issues.

# PROTHROMBIN COMPLEX CONCENTRATES AND DIRECT ORAL ANTICOAGULANT ANTIDOTES

Betty C. Chen and Mark K. Su

## INTRODUCTION

Prothrombin complex concentrate (PCC) is a lyophilized powder that consists of coagulation factors II, VII, IX, and X in addition to other factors and additives. Prothrombin complex concentrates come in two forms, activated and nonactivated. Activated PCCs (aPCCs) are typically used to treat hemophilia, and formulations consist of a mixture of nonactivated and activated factors. Nonactivated factors require activation by the other cofactors to function in the coagulation cascade. In the United States, nonactivated PCCs are available in both four-factor and three-factor formulations (4F-PCC and 3F-PCC, respectively). Prothrombin complex concentrates are also widely available in Europe, Asia, and Australia. In addition to clotting factors, 4F-PCC contains heparin and antithrombotic factors C and S.<sup>13</sup> Three-factor PCC contains only small amounts of factor VII and heparin.<sup>16</sup> Although some direct oral anticoagulants (DOACs) now have a reversal agent, PCCs are still used to attempt rapid reversal of DOAC-induced coagulopathy.

With dabigatran, the first of the DOACs, the need for a definitive reversal agent became apparent after adverse effects and fatalities were reported. The manufacturer of dabigatran developed idarucizumab, a monoclonal antibody, as a result.<sup>83,84</sup> Similarly, with the rising use of the oral Xa inhibitors, andexanet alfa (Andexxa), a recombinant modified human Factor Xa was recently approved.

## PROTHROMBIN COMPLEX CONCENTRATES

### History

Prothrombin complex concentrates were initially used for the treatment of patients with hemophilia A. This iteration of PCC is referred to as 3F-PCC because it contains a lower concentration of factor VII compared with 4F-PCC to limit thrombogenic complications. 3F-PCC is approved for the treatment of hemophilia A, but it was used off label to reverse warfarin-induced coagulopathy before the approval of 4F-PCC in the United States. The use of 4F-PCC became routine when consensus guidelines recommended their use to reverse warfarin-associated coagulopathy. Four Factor-PCC was approved for use in the United States in 2013 solely for the purpose of reversing warfarin-associated coagulopathy, but it is routinely used for other indications.

### Pharmacology

Prothrombin complex concentrates contain the coagulation factors that are inhibited by vitamin K antagonists (VKAs) such as warfarin. These factors include factors II, VII, IX, and X. They also include proteins C and S. Kcentra (a 4F-PCC) is manufactured from pooled United States sourced plasma. Other countries used pooled regionally sourced plasma. It is then purified, heat

treated, nanofiltered, and lyophilized to produce concentrated factors II, VII, IX, and X and proteins C and S (Table A17-1). Nonactivated PCCs also contain antithrombin, albumin, heparin, sodium chloride, and sodium citrate.<sup>44</sup> Three Factor-PCCs contain factors II, IX, and X. In addition, a small amount of factor VII is included. This decreased dose of factor VII is thought to limit thrombogenic complications in patients with hemophilia. The manufacturing process is similar to that of 4F-PCC and therefore contains factors C and S and heparins. Activated prothrombin complex concentrates do not contain heparins, but they do contain some factors of the kinin-generating system.<sup>6</sup>

### Mechanism of Action

Vitamin K antagonists impair the synthesis of gamma-carboxylated factors II, VII, IX, and X in the coagulation cascade. Prothrombin complex concentrates correct warfarin-associated coagulopathy by direct replacement of factors whose synthesis was inhibited.

### Pharmacokinetics and Pharmacodynamics

Because PCC products are administered intravenously, their bioavailability is 100%. In a study of 15 healthy volunteers receiving 50 IU/kg of 4F-PCC, maximal concentration of factors and proteins C and S occurred at the earliest sampling point, at 5 minutes postinfusion. These concentrations remained stable the first hour after infusion. Terminal half-lives of factors II, VII, IX, and X were calculated and are shown in Table A17-2.<sup>66</sup> In a prospective study, patients with an international normalized ratio (INR) greater than 2 and requiring emergency reversal of warfarin were treated with 25 to 50 IU/kg of 4F-PCC. The mean infusion rate of 4F-PCC was 7.5 mL/min or 188 IU/min, resulting in normalization of INR (<1.3) in 935 of patients within 30 minutes after completion of 4F-PCC infusion. In addition, the INR remained less than 1.3 for 48 hours after the infusion.<sup>67</sup> In another randomized controlled trial, the INR was reduced to less than 1.3 in 62% of participants at 30 minutes after 4F-PCC infusion.<sup>76</sup>

### Adverse Effects and Safety Issues

Most forms of PCC contain small amounts of heparin. These heparin-containing PCCs are contraindicated in patients with a history of heparin-induced thrombocytopenia (HIT) and heparin-induced thrombocytopenia and thrombosis syndrome (HITT). Prothrombin complex concentrates are also contraindicated in patients with disseminated intravascular coagulation (DIC) or with known anaphylactic or severe allergic reactions to any of its components.<sup>16</sup>

Because PCCs are made from human blood, they can theoretically transmit infectious diseases such as viruses, Creutzfeldt-Jakob disease agent, or the variant Creutzfeldt-Jakob disease agent. The manufacturing

NA = not available.

**TABLE A17-2** Coagulation Factor and Protein Pharmacokinetics After Four-Factor Prothrombin Complex Concentrate in Healthy Volunteers<sup>66</sup>

	Factor II	Factor VII	Factor IX	Factor X	Protein C	Protein S
Terminal half-life (h)	59.7 (45.5–65.9)	4.2 (3.9–6.6)	16.7 (14.2–67.7)	30.7 (23.7–41.1)	47.2 (28.4–65.1)	49.1 (39–59.7)
Volume of distribution (mL/kg)	71 (61.2–78.9)	41.8 (39.3–52.5)	92.4 (76.2–182.2)	56.1 (52.9–60.1)	62.9 (50.1–65)	76.6 (69.8–85.8)

process has minimized the likelihood of disease transmission by screening plasma via a polymerase chain reaction and including pasteurization and nanofiltration, two virus reduction steps. Although the risk of virus transmission is still theoretically possible, it is exceedingly low. Although there are cases of suspected hepatitis and HIV transmission in patients who have received PCCs, these patients also received other blood products, which could have been the source of infection. There are no proven virus transmission cases from 4F-PCC because the virus processing step was introduced in 1996.<sup>6,7,16,30,66</sup>

Fatal and nonfatal thrombotic events are reported with 4F-PCC use. These complications include myocardial infarction (MI), arterial thrombosis, venous thrombosis, pulmonary embolism (PE), cerebrovascular accident, and DIC.<sup>25,48</sup> The risk of developing a thrombotic complication is approximately 1.6% to 2.5% based on a review and meta-analysis that used PCC for reversing warfarin anticoagulation. Data from one publication cited a less than 1% rate of thrombosis based on 4F-PCC administration internationally.<sup>30</sup> Some study investigators have postulated that the rate of thrombotic complications is related to a patient's underlying risk of thrombosis and the original indication for systemic anticoagulation rather than as a result of the PCC.<sup>12,48</sup> This explanation is reasonable considering patients who received 4F-PCC for other indications had a lower rate of thrombosis at 0.9%.<sup>68</sup>

In one study of healthy volunteers receiving 4F-PCC, thrombogenicity was assessed via serial measurements of prothrombin fragment 1+2 ( $F_{1+2}$ ) and D-dimer. After 4F-PCC infusion, maximal  $F_{1+2}$  concentrations occurred 5 minutes postinfusion, the first sampling point.<sup>68</sup> However, many thrombogenic complications are reported to occur long after the first 5 minutes after PCC administration. Therefore, the risk of thrombosis does not seem to be related to thrombogenicity from PCCs alone. Other risk factors such as underlying thrombosis risk and prolonged immobilization also play a large role in risk of thrombogenic complications.

Further studies are required to assess the risk of thrombosis after 4F-PCC administration for the treatment of non-VKA antagonist factor deficiencies. The use of 4F-PCC should be used cautiously because the risk of thrombosis is likely higher than in patients requiring reversal of VKA antagonist coagulopathy. Several studies suggest that patients with liver disease who receive 4F-PCC are at a higher risk of thrombosis because of rebalanced hemostasis via intact thrombin generation and decreased fibrinolytic ability despite abnormal coagulation test results.<sup>50-52,82</sup>

Finally, hypersensitivity to 4F-PCC is reported to have an incidence of 3%. Other side effects include headache, gastrointestinal disturbances, arthralgias, and hypotension.<sup>16</sup> Other formulations of PCC such as 3F-PCC and aPCC also warn of possible hypersensitivity reaction. However, rates of these occurrences are not reported.<sup>6,7</sup>

### Pregnancy and Lactation

There are no studies or data available to elucidate the risks of 4F-PCC, 3F-PCC, or aPCC use in pregnancy or breastfeeding. Four Factor-PCC has not been evaluated in pregnant animals and therefore has the potential to cause harm to fetuses.<sup>16</sup> Warfarin is contraindicated in pregnancy because of its teratogenic potential. Therefore, PCCs have no current indication in pregnant women. However, if a pregnant woman is anticoagulated with warfarin and requires emergent reversal, fresh-frozen plasma (FFP) should be used. If the volume associated with FFP is a concern because of the risk of volume overload, then providers can use PCCs but with the caveat that the effects on the pregnancy and fetus are unknown.

There are also no available data regarding excretion of PCC in breast milk, and there is potential for PCC to be excreted in milk. There are also no data

on the effects of PCC on nursing infants or the ability of PCC on the reproductive system. Therefore, PCC should only be used in nursing mothers under severe circumstances, and babies should not be permitted to nurse from mothers who recently received PCC.

### Dosing and Administration

Most countries use 4F-PCC for the reversal of VKA-induced anticoagulation. The only brand of 4F-PCC currently available in the United States is Kcentra, although Octaplex is under review by the US Food and Drug Administration (FDA). Dosing of Kcentra is based on INR and actual body weight. The doses are based on factor IX concentration and range between 25 and 50 units/kg with a maximum weight of 100 kg (Table A17-3). The contents of each vial are variable and range between 400 and 620 IU of factor IX. Each individual vial states the actual factor IX content in each bottle, and the individual dosage should be based on the actual factor IX content in each vial.<sup>16,44</sup>

Kcentra must be administered within 4 hours of reconstitution. Reconstitution requires the use of the included Mix2 Vial and diluent vial. Kcentra must be stored at temperatures between 20° and 25°C prior to administration in a separate infusion line. The rate of administration should be started at a rate of 0.12 mL/kg/min (~3 units/kg/min) up to a maximum of 8.4 mL/min (~210 units/min).<sup>16</sup>

All US studies evaluating the safety and efficacy of 4F-PCC have enrolled adults. However, PCC has been used to correct warfarin-associated coagulopathy in a severely ill child with a favorable outcome.<sup>1</sup> Prothrombin complex concentrates have been increasingly used in pediatric patients undergoing cardiac surgery. However, these patients are given PCCs to correct coagulopathy associated with operative complications and not warfarin-associated coagulopathy.<sup>4</sup>

Although current PCC dosing is based on a patient's weight and INR, there has been at least one study evaluating the use of fixed dosing of PCC for the reversal of warfarin-associated coagulopathy. This study noted that this technique was not associated with any thromboembolic complications. Furthermore, the authors postulated that the main benefit of this method of PCC administration minimizes the time to administration of PCC.<sup>45</sup> Unfortunately, this study did not include a control group, and mortality and morbidity were not evaluated or discussed. There are insufficient data to recommend this dosing approach at this time.

### Four-Factor Versus Three-Factor Prothrombin Complex Concentrates

Numerous studies have evaluated the efficacy and safety of 4F-PCC versus 3F-PCC. Several retrospective studies indicate faster reversal, high rates of reversal, or lower mortality rates in patients receiving 4F-PCC compared with 3F-PCC.<sup>3,17,57,86</sup> One investigator concluded that the cost effectiveness of 4F-PCC was better than 3F-PCC because of its improved efficacy at reversing coagulopathy.<sup>57</sup> However, not all studies were resoundingly in favor of 4F-PCC over 3F-PCC. In several retrospective studies, the efficacy of reversing INR

**TABLE A17-3** Kcentra Dosing Recommendations from the Manufacturer<sup>16</sup>

Pretreatment INR	2–<4	4–6	>6
Dose of Kcentra (units of factor IX)/kg body weight	25	35	50
Maximum dose (units of factor IX)	Not to exceed 2,500 IU	Not to exceed 3,500 IU	Not to exceed 5,000 IU

INR = international normalized ratio.

Table from manufacturer's prescribing insert.

was about equal regardless of which formulation of PCC was used. Although the rates of thromboembolic complications were similar between the groups in one study, thrombosis complications were higher if 4F-PCC was given.<sup>38,46</sup>

One study evaluated the use of 4F-PCC versus 3F-PCC combined with recombinant factor VIIa (rFVIIa). Although the 3F-PCC with rFVIIa combination resulted in a lower INR, 4F-PCC alone resulted in both decreased deep vein thrombosis (DVT) rates and mortality.<sup>60</sup>

#### Four-Factor Prothrombin Complex Concentrates Versus Plasma

Numerous studies have evaluated the safety and efficacy of 4F-PCC compared with fresh frozen plasma (FFP) infusion for warfarin reversal.<sup>19,41,56,76</sup> The conclusions from many of these studies show that PCCs leads to more rapid correction of INR compared with plasma. However, it must be noted that the amount of factor replacement between the PCC groups versus the plasma groups was unequal. Typically, the patients in the PCC groups received a dose of 25 to 50 IU/kg, but patients in the plasma group received 10 to 15 mL/kg. These represent factor replacements at ranges of 50% to 100% versus 20% to 30%, respectively.<sup>43,56,75,76</sup> Mortality data have therefore been exceedingly difficult to quantify because of this disparity in factor replacement when comparing PCC versus plasma. A recently published meta-analysis claimed that the odds ratio of mortality for receiving 4F-PCC versus FFP was 0.64 showing an improved mortality rate with 4F-PCC.<sup>12</sup> However, the odds ratio was not statistically significant. Furthermore, when comparing the complications of 4F-PCC to FFP, the rate of thrombosis or thromboembolic disease was higher in patients who received FFP (6.4% versus 2.5%).<sup>12</sup> Despite the potential favorable risk-to-benefit ratio of PCC compared with FFP, it should be noted that these authors were compensated by the manufacturers of PCC. Additionally, there is one other study, included in the aforementioned meta-analysis, that demonstrated no difference in mortality in patients with intracranial hemorrhages.<sup>55</sup> There do appear to be several theoretical advantages of PCCs over FFP, including a smaller volume of infusion, bypassing blood type matching, avoidance of delay for thawing of plasma, and predictable dosing of factors. Despite its significantly increased cost, PCC possesses a lower risk of infection transmission compared with FFP.<sup>33</sup> Aside from four cases of parvovirus B19 transmission associated with Octaplex, there are very few reports of virus transmission associated with PCC administration, and risk is further minimized by additional protective steps added in the manufacturing process.<sup>16,44</sup>

#### Other Uses for Prothrombin Complex Concentrates

##### Prothrombin Complex Concentrates for Direct Oral Anticoagulants

Prothrombin complex concentrations can be used to treat coagulopathy from the DOACs. The manufacturers of dabigatran have suggested that PCC can be used to partially reverse the anticoagulant effect of dabigatran, but they admit that its efficacy and safety have not been evaluated in any clinical trials. They now recommended the use of a monoclonal antibody idarucizumab.<sup>11</sup> The manufacturers of rivaroxaban have noted that PCC can be used to partially reverse its anticoagulant activity, but this information is derived from healthy volunteers.<sup>23,37</sup> In theory, PCC can reverse anticoagulation from these DOACs if the amount of factor replacement overwhelms the amount of available DOAC. However, it is very difficult to determine what dose of PCC can establish normal hemostatic conditions, and clinical evidence is scant on their efficacy in this setting. For patients requiring emergent reversal of dabigatran-induced anticoagulation, PCC is a reasonable second-line agent for achieving reversal of anticoagulation after idarucizumab administration. For patients requiring emergent reversal of factor Xa inhibitor-induced anticoagulation, PCC is also a reasonable second line therapy after andexanet alfa administration.

##### Prothrombin Complex Concentrates in Liver Disease

There are studies evaluating the use of PCC to reverse coagulopathy associated with liver disease. Unfortunately, the rate of INR reversal in patients with liver disease treated with 4F-PCC seems to be significantly less than elevated INRs for other reasons such as warfarin-associated coagulopathy. In one study, INR less than 1.5 was achieved in only 19% of patients who

received 4F-PCC for elevated INR related to liver disease. On the other hand, 81.5% of non-liver disease patients had successful decreases in INR below 1.5 with 4F-PCC.<sup>36</sup> In another study evaluating the use of 3F-PCC or 4F-PCC for elevated INR, patients with nonwarfarin elevation of their INR, in general, had less success (27.7%) of INR reversal to less than 1.3.<sup>63</sup> However, in this study, the patients with liver disease and elevated INR had the most consistent correction to an INR below 1.3.<sup>63</sup> There has been one study comparing the use of FFP versus PCC versus rFVIIa to facilitate procedures in critically ill patients with liver disease. Although bleeding rates were similar among the groups, patients receiving PCC and rFVIIa experienced expedited procedures and fewer blood products compared with those receiving FFP.<sup>47</sup> At this time, there is currently insufficient information to routinely recommend PCC administration to patients with liver disease for the sole purpose of INR correction. For patients with the collective criteria of liver disease, elevated INR, and life-threatening hemorrhage, it would be reasonable to give PCC.

##### Prothrombin Complex Concentrates in Trauma

There have not been any high-quality studies evaluating the use of 4F-PCC in the setting of coagulopathy from trauma. There are some small studies that have evaluated the use of 3F-PCC in trauma, which have had varying results. There is no overall consensus of whether or not 3F-PCC resulted in a decreased requirement for red blood cell transfusion.<sup>39,61,71,73</sup> Therefore, there is not enough evidence to recommend routine use of PCC to correct coagulopathy from trauma at this time.

##### Availability

The only brand of 4F-PCC currently available in the United States is Kcentra. Another brand of 4F-PCC, Octaplex, is being evaluated for FDA approval. 3F-PCCs is available as Bebulin. Outside of the United States, the PCCs are available as Beriplex, Confidex, Cofact, OcPlex, Octaplex, Octaplex 1000, Octaplex 500, PPSB S.D., PPSB-HT Nichiyaku Profilnine, Profilnine SD, ProthroRAAS, Prothrombin Complex Octapharm, Prothrombinex-HT, Prothrombex, Prothromplex Immuno Tim 4, Prothrombex NF, Prothrombex Total, Prothrombex Total NF, Protromplex TIM3, Pushu Laishi, TachoSil, Uman Complex, and Uman-Complex D.I.

##### Activated Prothrombin Complex Concentrates

Similar to 4F-PCCs, aPCCs contain factors II, VII IX, and X. However, the difference between the two PCCs is that aPCCs contain *activated* factor VII instead of nonactivated factor VII. The other clotting factors are nonactivated in both concentrates. The only aPCC product currently available in the United States is factor eight inhibitor bypassing activity (FEIBA). Factor eight inhibitor bypassing activity is traditionally used for the treatment of hemophilia A or B, and it is not FDA approved for warfarin reversal. However, because FEIBA does not contain heparin, it is the recommended therapy to reverse warfarin-associated coagulopathy in critically ill patients with HIT or HITT.

Unfortunately, aPCC has not been studied extensively in the setting of VKA-induced coagulopathy. In one study comparing the aPCC FEIBA versus FFP for reversing warfarin-associated coagulopathy, aPCC was superior to FFP in time to reversal of anticoagulation. However, it should be noted that patients in the aPCC group received more overall factor replacement than the patients in the FFP group. Whereas dosing of the aPCC was either 500 or 1,000 units, the median dose of FFP given was 400 mL. This study did note that successful hemostasis was similar in both arms, and there was no significant difference in hospital length of stay.<sup>5,87</sup> For reversal of DOACs, studies have been limited to small studies, animal studies, or healthy volunteers.<sup>5</sup> In one small study, patients with intracranial hemorrhages who received aPCC did not have intracranial hematoma expansion or thrombotic complications.<sup>20</sup> However, another small study evaluating the use of aPCC in patients with intracranial hemorrhage found that patients receiving aPCC resulted in stable repeat head imaging without hematoma expansion 55% of the time, and 18% of patients experienced thromboembolic complications.<sup>58</sup> In a porcine model, dabigatran-treated study participants had less blood loss after polytrauma after receiving 50 U/kg of aPCC.<sup>34</sup> In the laboratory, both PCC and

aPCC corrected thromboelastography and rotational thromboelastometry (laboratory measures of thrombin generation) in patients receiving dabigatran or rivaroxaban.<sup>31</sup> One ex vivo study showed that after a single dose of dabigatran in healthy volunteers, aPCC decreased endogenous thrombin potential and lag time, and thrombin generation increased in a dose-dependent fashion.<sup>59</sup> In a murine study, aPCC reduced bleeding time from dabigatran at low doses. Unfortunately, at high doses, this effect was reduced.<sup>85</sup>

There is no standard dose of aPCC for coagulopathy reversal. Providers should weigh the risks and benefits of aPCC use in anticoagulated patients. If a patient is critically ill and FFP is not rapidly available to reverse warfarin coagulopathy, aPCC is a reasonable intervention. Typical doses for treating bleeding or for perioperative management range between 50 and 100 units/kg with the units measuring the amount of factor VIII inhibitor bypass activity.<sup>6</sup> However, one study evaluated fixed doses of aPCC in adult patients because lower doses which resulted in cessation of bleeding in 93% patients. In this study, patients with an INR of less than 5 received 500 units of aPCC. Patients with INR of greater than 5 received 1,000 units of aPCC; 87% of patients survived to discharge, and no thrombotic complications were noted.<sup>81</sup> Given the thrombogenic potential of FEIBA, this lower dose recommendation is reasonable if FFP is unavailable in warfarin-anticoagulated patients. In patients requiring reversal of direct factor Xa–induced anticoagulation, there are very little data on ideal dosing. Small studies have reported dosages of a PCC between 25 and 100 units/kg to reverse DOAC coagulopathy. If Andexanet alpha or another antidote is unavailable, it is reasonable to administer aPCC to patients with a contraindication to nonactivated PCC in aliquots of 25 units/kg up to a maximum of 100 units/kg. This therapy should be reserved for critically ill patients who need emergent reversal of their anticoagulation.

### Recombinant Factor VIIa

Recombinant factor VIIa is approved for patients with hemophilia or various factor inhibitors and has been successfully used to reverse VKA toxicity. However, the safety of off-label use of rFVIIa to reverse VKA coagulopathy is generally unfavorable. Despite weak evidence showing beneficial effects in four patients with long-acting VKA toxicity, there are several studies that consider rFVIIa inferior to PCC in terms of hospital length of stay, blood product transfusion requirements, or mortality.<sup>18,40,88</sup> These studies include both warfarin and other VKA antagonists, which needs to be considered when evaluating the specific effect of rFVIIa on warfarin reversal.

There is also concern that arterial thrombotic events may occur at higher than acceptable rates when factor rFVIIa is administered. Reviewing the data from the FDA's Adverse Event Reporting System database, thromboembolic adverse events were frequent in patients who received rFVIIa for off-label purposes.<sup>65</sup> The Factor Seven for Acute Hemorrhagic Stroke Trial (FAST) showed that arterial thromboembolic complications rose in a dose-dependent fashion with rFVIIa administration.<sup>22</sup> These findings were confirmed in subsequent studies and a meta-analysis.<sup>49</sup> The risk of continued bleeding versus the benefit of rapid reversal of coagulopathy with rFVIIa is unknown, but studies suggest the risk for complications is higher than that of other reversal agents such as PCC. The use of rFVIIa for reversing VKA-associated coagulopathy is generally not recommended given the availability of safer agents. However, if FFP and PCC (activated or nonactivated) cannot be administered or are unavailable, then it is reasonable to administer rFVIIa in life-threatening situations.<sup>2</sup>

## IDARUCIZUMAB

### History

Idarucizumab was approved by the FDA in 2015. It was designed specifically to reverse the effects of dabigatran, the first of the DOACs. It was approved through the FDA's accelerated approval program because there were no other definitive antidotes or reversal agents for dabigatran before idarucizumab's creation. Idarucizumab is recommended for reversal of dabigatran-associated coagulopathy in the setting of either emergency or urgent surgery (or procedures) and in uncontrolled or life-threatening bleeding.<sup>10</sup>

### Pharmacology and Chemistry

Idarucizumab is a humanized monoclonal antibody fragment to dabigatran. To create idarucizumab, mice are immunized with dabigatran-derived haptens, resulting in the production of antibodies targeted against dabigatran. Antibodies with the highest affinity for dabigatran are then chosen and processed to retain the Fab fragment, the antigen binding section of the antibody. Murine protein sequences are then replaced with human protein sequences and then further refined with recombinant DNA processing. The end result is a monoclonal antibody with lower immunogenicity.<sup>78</sup>

### Mechanism of Action

Idarucizumab binds directly to dabigatran at an affinity of approximately 350 times higher to the affinity of dabigatran to thrombin. When dabigatran is bound to idarucizumab, its anticoagulant effect is deactivated via normalization of various coagulation parameters.<sup>24,35,78</sup>

### Pharmacokinetics and Pharmacodynamics

The bioavailability of idarucizumab is 100% because it is administered intravenously. Peak plasma concentrations occur immediately after infusion.<sup>27</sup> Manufacturers state that the binding of idarucizumab is irreversible given its high affinity for dabigatran.

The volume of distribution of idarucizumab is approximately 0.06 L/kg.<sup>27</sup> Because idarucizumab is primarily located in plasma, it is able to bind plasma dabigatran and encourage extravascular unbound dabigatran to move into the vascular space to reequilibrate. If there is excess or unbound intravascular idarucizumab available, it will be able to bind any newly arriving dabigatran to further neutralize dabigatran and its anticoagulant effects.<sup>9,24,28</sup>

Idarucizumab possesses two half-lives. After peak concentrations are reached, the initial half-life of idarucizumab is approximately 45 minutes. Four hours after administration, only 4% of the peak idarucizumab concentration is detectable in plasma. At that point, the half-life ranges between 4.5 to 8.1 hours.<sup>28</sup> In one study, healthy volunteers were given 220 mg of dabigatran twice daily for 3 days. Then they were given 1 to 7.5 g of idarucizumab. After infusion of idarucizumab, thrombin time, ecarin clotting time, and activated partial thromboplastin time (aPTT) immediately normalized in a dose-dependent fashion. Thirty minutes after idarucizumab infusion, investigators noted that endogenous thrombin potential and thrombin lag time significantly trended toward baseline in a dose-dependent fashion for 4 hours.<sup>28,78</sup>

In a prospective study of patients taking dabigatran and requiring rapid reversal of anticoagulation for either life-threatening hemorrhage or for emergent surgery or procedures, patients who received 5 g of intravenous (IV) idarucizumab had a reversal rate of 100% of patients. However, despite this apparent success, there was a total of 18 deaths in the both study groups (9 in each group). Only 5 of the deaths appeared to be related to bleeding events, and 9 of the deaths occurred within the first 96 hours after idarucizumab administration. Causes of death included septic shock, intracranial hemorrhage, multiorgan failure, hemodynamic collapse, respiratory failure, and cardiac arrest. It is unclear whether the cause of death was related to poor hemostasis but in bleeding patients; hemostasis was restored at a median of 11.4 hours after administration of idarucizumab. In patients undergoing an emergent procedure, normal intraoperative hemostasis was noted in 85% of cases.<sup>70</sup>

Idarucizumab is renally eliminated. The proximal renal tubules are able to reuptake or degrade idarucizumab. However, this process is saturable. The remaining amount of idarucizumab is excreted in the urine unchanged.<sup>14,28,62</sup> There is a dose-dependent increase in the amount of idarucizumab that is recovered in urine. At a dose of 1 mg, 10% of idarucizumab is received in the urine. At 4 g, 40% of idarucizumab is recovered in the urine.<sup>24,27</sup> Dabigatran-bound idarucizumab is also processed in the renal tubules. If the renal tubules process the idarucizumab portion of the complex, then the free dabigatran may be renally excreted.<sup>29,69</sup>

In murine and human studies, idarucizumab administration results in normalization of a battery of functional clotting assays, such as clotting time, aPTT, and thrombin time.<sup>78</sup>

Several case reports suggest that a rebound drug effect occurs after idarucizumab administration. A patient with a massive dabigatran overdose with an initial dabigatran concentration of 3,337.3 ng/mL (the average peak concentration in patients receiving therapeutic dosing of dabigatran is  $112.7 \pm 66.6$  ng/mL<sup>74</sup>) received idarucizumab, resulting in a dabigatran concentration of 513 ng/mL and improvement in coagulopathy. However, 7 hours after receiving idarucizumab, the dabigatran concentration rebounded to 1,126 ng/mL with corresponding increases in INR, PT, and aPTT.<sup>72</sup> Dabigatran rebound after idarucizumab treatment was noted in other case reports.<sup>32</sup> Despite the apparent rapid reversal of anticoagulation by idarucizumab in most cases, some patients experience a recurrent coagulopathy between 12 and 24 hours after receiving idarucizumab, perhaps caused by dabigatran redistribution.<sup>10</sup>

### Adverse Effects and Safety Issues

Before approval of idarucizumab, it was tested in over 200 volunteers and well tolerated in doses up to 8 g. No hypersensitivity reactions were reported in any of the volunteers. In addition, no severe antibody reactions were reported in any of the volunteers.<sup>24</sup>

However, patients with hereditary fructose intolerance are at risk for serious adverse effects because the medication contains sorbitol.<sup>10</sup>

Thrombotic events such as DVT, PE, MI, or ischemic stroke are reported after idarucizumab use.<sup>24,70</sup> The true incidence of these thromboembolic complications is unknown, and neither idarucizumab nor its complex with dabigatran is believed to directly cause platelet aggregation or clot formation.<sup>24,78</sup>

### Other Uses of Idarucizumab

There are several case reports describing the use of idarucizumab to reverse dabigatran's anticoagulant effect before thrombolytic therapy in patients with acute ischemic strokes. Luckily, the patients in these handful of cases did not have adverse consequences as a result of this practice.<sup>8,26,42,64,77,79</sup> Because of these reports, some clinicians now routinely recommend idarucizumab treatment before thrombolytic therapy for acute ischemic stroke.<sup>21,26</sup> However, there are no quality clinical studies that accurately describes the safety of this practice; therefore, we cannot recommend this practice until better evidence of safety and efficacy is available.

### Pregnancy and Lactation

There are no studies or data available to elucidate the risks of idarucizumab use in pregnancy or while breastfeeding. Reproductive and developmental studies have not been performed in animals, and idarucizumab has the potential to cause harm to fetuses.<sup>10</sup>

There are also no available data regarding excretion of idarucizumab in breast milk. There is potential for idarucizumab to be excreted in milk, and its effects on nursing infants or the reproductive system are unknown.<sup>10</sup>

### Dosing and Administration

Idarucizumab is dosed at 5 g. Each package of idarucizumab contains two vials, each containing 50 mL of fluid and 2.5 g of idarucizumab. The medication is ready to be infused without the need to be reconstituted in a separate diluent. Vials must be stored between 2° and 8°C. Before drug administration, the IV line should be flushed with saline. The medication can then be administered in two fashions. One option is to infuse each vial as two consecutive infusions of 2.5 g as was done in phase III clinical trials. The second option is to use a syringe to bolus inject both vials intravenously. There is no evidence that one approach is better than the other. If the medication is withdrawn from the vial, it must be given within 1 hour.<sup>10,70</sup>

There is a small subset of patients who have recurrent coagulopathy between 12 and 24 hours after receiving idarucizumab.<sup>70</sup> For patients who have this rebound effect in conjunction with clinically significant bleeding or need for repeat surgery or procedure, it is reasonable to administer a second dose of idarucizumab at 5 g.<sup>10</sup> However, there have been no studies to evaluate the efficacy or safety of this practice.

### Availability

Idarucizumab is available as a parenteral solution with each vial containing 2.5 g of idarucizumab in 50 mL of fluid for injection. If idarucizumab is not immediately available, an online directory of available doses of idarucizumab is accessible on the manufacturer's website at [www.praxbind.com](http://www.praxbind.com).

## ANDEXANET ALFA

### History

Given the increasing use of oral factor Xa inhibitors for systemic anticoagulation, there was motivation to find a safe and efficacious reversal agent. Andexanet alfa "Andexxa" is a recombinant protein that reverses anticoagulation caused by factor Xa inhibitors. It is currently FDA approved.

### Pharmacology and Mechanism of Action

Andexanet alfa was created by altering the structure of factor X. Andexanet alfa binds factor Xa inhibitors, but its structure was modified to inhibit the catalytic activation of thrombin. In addition, the factor V<sub>a</sub> binding site on factor X, which is necessary for anticoagulation, is no longer present.<sup>53</sup>

### Pharmacokinetics and Pharmacodynamics

A study in healthy elderly volunteers demonstrated that andexanet alfa administration given to participants with a steady-state concentration of either apixaban or rivaroxaban resulted in rapid reduction in plasma free inhibitor concentrations and increased thrombin formation. Immediately after andexanet alfa infusion, antifactor Xa activity decreased by more than 90%. However, within 1 to 2 hours, concentrations rebounded to concentrations comparable to those of the placebo group.<sup>80</sup> In a multicenter, prospective, open-label, single-group study, andexanet alfa was given to patients who had ingested a factor Xa inhibitor within 18 hours of onset of acute hemorrhage. After infusion of andexanet alfa, anti factor Xa activity decreased 12 hours after andexanet alfa infusion, and 79% of patients achieved hemostasis.<sup>15</sup>

### Adverse Effects and Safety Issues

In the study in healthy volunteers, there were no serious or thrombotic complications in any of the participants.<sup>80</sup> However, in the aforementioned prospective study, thrombotic complications occurred in 18% of patients during the 30-day follow-up period. One-third of these events occurred in the first 72 hours after infusion. Documented thrombotic events included MI, stroke, DVT, and PE. Some patients had more than one thrombotic complication. Only 27% of patients were restarted on their anticoagulation during the 30-day follow-up period. In this study, 15% of patients died. The only reported details regarding these deaths were that 60% of them were related to cardiovascular events, and 40% of deaths were related to noncardiac events. There was no control group to determine if there were any changes in patient outcomes such as morbidity or mortality resulting from andexanet alfa administration.<sup>15</sup>

There have been no reports of anaphylaxis in human or animal studies.<sup>15,54,80</sup>

### Pregnancy and Lactation

There are no data available to elucidate the risks of andexanet alfa use in pregnancy or while breastfeeding. Reproductive and developmental studies were not performed in animals, and andexanet alfa has the potential to cause harm to fetuses.

### Dosing and Administration

Andexanet alfa is administered intravenously in a low dose/high dose protocol based on the timing and amount of the last dose of rivaroxaban and apixaban. All patients receive a loading dose administered over 15 to 30 minutes. A 2-hour infusion dose is then given immediately after the loading dose. For patients who received a factor Xa inhibitor more than 7 hours before AnXa administration, the loading dose is 400 mg, and the infusion dose is 480 mg. For patients who received a factor Xa inhibitor within 7 hours of AnXa administration, the loading dose is 800 mg, and the infusion dose is 960 mg.<sup>15</sup>

## Availability

Andexanet alfa received FDA approval in May 2018 for the reversal of rivaroxaban and apixiban-associated hemorrhage. It is available as a lyophilized powder in single use vials of 100 mg of recombinant coagulation factor Xa (recombinant-inactivated-zhzo).

## SUMMARY

- Patients with life-threatening bleeding secondary to anticoagulants should be treated with appropriate antidotal therapy.
- VKA coagulopathy is reversed with factor replacement in bleeding patients. If bleeding is severe or life threatening or if the patient requires emergent surgical intervention, 4F-PCC is recommended as first-line treatment. It is recommended that IV vitamin K<sub>1</sub> be administered to  $\gamma$ -carboxylate factors II, VII, IX and X when the effects of 4F-PCC have disappeared.
- Alternatives to 4F-PCC include FFP, 3F-PCC, rFVIIa, and aPCCs. However, in the absence of 4F-PCC, 3F-PCC, rFVIIa and aPCC are all reasonable alternatives despite their less favorable risk profiles.
- For dabigatran-induced anticoagulation, we recommend reversal with idarucizumab for patients requiring emergent interventions or for patients who have life-threatening bleeding.
- For patients with hemorrhage from rivaroxaban or apixiban we recommend andexanet alfa.

VITAMIN K<sub>1</sub>

Mary Ann Howland

Vitamin K<sub>1</sub> (phytonadione) is the commercial preparation of the natural form of vitamin K (phylloquinone) that is indicated for the reversal of an elevated prothrombin time (PT) or an international normalized ratio (INR) in patients with vitamin K deficiency. Acquired vitamin K deficiency most commonly results from the therapeutic administration of warfarin or after an overdose of warfarin or a long-acting anticoagulant rodenticide (LAARs), such as brodifacoum. The optimal dosage regimen of vitamin K<sub>1</sub> to treat patients who develop an elevated INR while receiving warfarin was given in the 2012 American College of Chest Physicians consensus guidelines.<sup>1</sup> Oral administration of vitamin K<sub>1</sub> is safe and effective. Because intravenous (IV) administration of vitamin K<sub>1</sub> is associated with anaphylactoid reactions, its use is not recommended unless serious or life-threatening hemorrhage is present. Subcutaneous (SC) administration should only be used when a patient is unable to tolerate oral vitamin K therapy and is not clinically compromised enough to necessitate IV vitamin K<sub>1</sub>.<sup>10</sup>

## HISTORY

It was noted in 1929 that chickens fed a poor diet developed spontaneous bleeding. In 1935, Dam and coworkers discovered that incorporating a fat-soluble substance, defined as a “koagulation factor,” into the diet could correct the bleeding, leading to the name vitamin K.<sup>23,40,45</sup>

## PHARMACOLOGY

### Chemistry

Vitamin K is an essential fat-soluble vitamin that encompasses at least two distinct natural forms. Vitamin K<sub>1</sub> (phytonadione, phylloquinone) is the only form synthesized by plants and algae. Vitamin K<sub>2</sub> (menaquinones) is actually a series of compounds with the same 2-methyl-1,4-naphthoquinone ring structure as phylloquinone but with a variable number (1–13) of repeating five-carbon units on the side chain. Bacteria synthesize vitamin K<sub>2</sub> (menaquinones). Most of the vitamin K ingested in the diet is phylloquinone (vitamin K<sub>1</sub>).

### Related Vitamin K Compounds

Vitamin K<sub>1</sub> (phytonadione) is the only vitamin K preparation that should be used to reverse anticoagulant-induced vitamin K deficiency or to treat infants or pregnant women. Vitamin K<sub>1</sub> is superior to the other previously commercially available vitamin K preparations because it is more active, requires smaller doses, and has fewer associated risks.<sup>19,42</sup> In addition, patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency have an increased risk of hemolysis with other vitamin K preparations.

Vitamins K<sub>3</sub> (menadione) and K<sub>4</sub> (menadiol sodium diphosphate) are no longer approved by the US Food and Drug Administration (FDA) because they produce hemolysis, hyperbilirubinemia, and kernicterus in neonates, as well as hemolysis in G6PD-deficient patients. The only advantage that menadione and menadiol sodium diphosphate have is their direct

absorption from the intestine by a passive process that does not require the presence of bile salts. However, even for patients with cholestasis or severe pancreatic insufficiency, they are neither interchangeable with vitamin K<sub>1</sub> nor a substitute for vitamin K<sub>1</sub> when anticoagulants such as warfarin or a LAAR are responsible for coagulation deficits. Therefore, for a patient deficient in bile salts who requires vitamin K<sub>1</sub>, exogenous bile salts, such as ox bile extract 300 mg or dehydrocholic acid 500 mg, are recommended with each dose of oral vitamin K<sub>1</sub>.<sup>32</sup>

### Mechanism of Action

A postsynthetic modification of coagulation factors II, VII, IX, and X and proteins S, C and Z requires  $\gamma$ -carboxylation of the glutamate residues in a vitamin K-dependent process. Only the reduced (K<sub>1</sub>H<sub>2</sub>, hydroquinone) form of vitamin K manifests biologic activity. During the carboxylation step, the active reduced vitamin K<sub>1</sub> is converted to an epoxide. This 2,3-epoxide is reduced and recycled to the active K<sub>1</sub>H<sub>2</sub> in a process that is inhibited by warfarin (Fig. 58–2). For further details, readers are referred to an in-depth model of the chemical basis of this reaction.<sup>13,51</sup> The phytonadione form of vitamin K is activated to the reduced, vitamin K<sub>1</sub>H<sub>2</sub> form directly by nicotinamide adenine dinucleotide (phosphate) (NAD(P)H)-dehydrogenase (DT-diaphorase) enzymes that use both NADH and NADPH in a pathway that is relatively insensitive to warfarin; the vitamin K 2,3-epoxide form cannot be activated through this pathway.<sup>38,40,44,45,47</sup> Exogenous phytonadione allows  $\gamma$ -carboxylation of clotting factors that are present and does not rely on recycling.<sup>11,38</sup>

### Daily Requirement

The human daily requirement for vitamin K is small; the Food and Nutrition Board set the recommended daily allowance at 1 mcg/kg/d of phylloquinone for adults, although 10 times that amount is required for infants to maintain normal hemostasis.<sup>39</sup> Vitamin K-dependent extrahepatic enzymatic reactions relate to carboxylation of proteins in the bone, kidney, placenta, lung, pancreas, and spleen and include the synthesis of osteocalcin, matrix Gla protein, plaque Gla protein, and one or more renal Gla proteins.<sup>39,40,44</sup> Variations in dietary vitamin K intake while receiving therapeutic oral anticoagulation with warfarin can result in significant over- or underanticoagulation.<sup>1,18</sup> One study measured vitamin K concentrations before and after treatment with warfarin, and as expected, the concentrations fell from 1.72 ng/mL to 0.59 ng/mL. Patients taking warfarin exhibited large inter- and intravariability in vitamin K concentrations (0.2–4.2 ng/mL).<sup>24</sup>

### Pharmacokinetics of Dietary Vitamin K

Dietary vitamin K in the forms of phylloquinone and menaquinones is solubilized in the presence of the bile salts, free fatty acids, and monoglycerides, which enhance absorption. Vitamin K is incorporated into chylomicrons, entering the circulation through the lymphatic system in transit to the liver.<sup>40</sup> In the plasma, vitamin K is primarily in the phylloquinone form, but liver stores are 90% menaquinones and 10% phylloquinone.<sup>40</sup> Within 3 days of a diet low in vitamin K, a group of surgical patients showed a fourfold decrease of liver vitamin K concentrations without an effect on their PTs.<sup>43</sup> Rats given a vitamin K-deficient diet develop severe bleeding within 2 to 3 weeks.

### Pharmacokinetics of Administered Vitamin K<sub>1</sub>

There are only a limited number of pharmacokinetic studies of vitamin K<sub>1</sub>.<sup>8,20,31,52</sup> One study evaluated the pharmacokinetics of vitamin K<sub>1</sub> in healthy volunteers,

brodifacoum-anticoagulated rabbits, and a patient poisoned with brodifacoum.<sup>31</sup> In the volunteers and the poisoned patient, a 10-mg IV dose of vitamin K<sub>1</sub> had a half-life of 1.7 hours. After oral administration of doses of 10 and 50 mg of vitamin K<sub>1</sub>, peak concentrations of 100 to 400 ng/mL and 200 to 2,000 ng/mL, respectively, occurred at 3 to 5 hours. Bioavailability varied significantly among patients (10%–65%) for both doses and in individual patients with the 50-mg dose. Oral vitamin K<sub>1</sub> is absorbed in an energy-dependent saturable process in the proximal small intestine, which contributes to the variability.<sup>31</sup> In maximally brodifacoum-anticoagulated rabbits, IV vitamin K<sub>1</sub> (10 mg/kg) increased prothrombin complex activity from 14% to 50% by 4 hours and to 100% by 9 hours, after which it declined with a half-life of 6 hours.<sup>31</sup> High doses of oral vitamin K<sub>1</sub> were effectively used to treat a patient anticoagulated with brodifacoum.<sup>8</sup>

The pharmacokinetics of oral and intramuscular (IM) vitamin K<sub>1</sub> were compared in eight healthy female volunteers. Baseline serum vitamin K<sub>1</sub> concentrations were 0.23 ng/mL. After the oral administration of 5 mg of vitamin K<sub>1</sub>, peak serum concentrations of 90 ng/mL were achieved between 4 and 6 hours. These concentrations dropped to a steady state of 3.8 ng/mL and exhibited a half-life of about 4 hours.

The pharmacokinetics were distinctly different and quite variable after IM administration. Intramuscular administration of 5 mg of vitamin K<sub>1</sub> resulted in peak serum concentrations of only 50 ng/mL, with delays from 2 to 30 hours after administration and with the maintenance of a plateau for about 30 hours.<sup>20</sup> Consequently, IM administration is not recommended; either oral or IV administration is more appropriate, and the route will be defined by the severity of bleeding. Only in the case of acute gastrointestinal disease in a patient without serious life-threatening hemorrhage is the SC route an appropriate alternative to the oral route (Table 58–2).

### Pharmacodynamics of Administered Vitamin K<sub>1</sub>

The time necessary for the INR to return to a safe or normal range is variable and dependent on the rate of absorption of vitamin K<sub>1</sub>, the serum concentration achieved, and the time necessary for the synthesis of activated clotting factors. A decrease in the INR often occurs within several hours, although it often takes 8 to 24 hours to reach target values.<sup>1,7,16,28,35</sup> Maintenance of a normal INR depends on the half-life of the vitamin K<sub>1</sub>, maintenance of an effective serum concentration, and the half-life of the anticoagulant involved. The IV route is unpredictably faster than the oral route in restoring the INR to the chosen target range.<sup>1,20,26</sup> However, the onset of action for the IV route is faster.<sup>26,48</sup> A comparison of oral versus IV vitamin K<sub>1</sub> therapy for excessive anticoagulation, without major hemorrhage, demonstrated that individuals with INRs of 6 to 10 had similarly improved INRs at 24 hours.<sup>26</sup> The onset of action began at 2 hours with IV compared with 6 hours with oral.<sup>26</sup> The IV group more often overcorrected to an INR of less than 2.<sup>26</sup> In a retrospective analysis of 64 patients requiring vitamin K for nonurgent reversal of anticoagulation before a procedure, the IV route corrected more patients to an INR less than 4 at 4 hours than the oral route.<sup>48</sup> In a randomized controlled trial in asymptomatic patients on warfarin with an INR between 4.5 and 10, the administration of 1 mg of vitamin K orally was associated with a faster return to a therapeutic INR than with 1 mg administered subcutaneously.<sup>10</sup>

### Vitamin K Deficiency and Monitoring

Vitamin K deficiency results from inadequate intake, malabsorption, or interference with the vitamin K cycle. Malnourishment and any condition in which bile salts or fatty acids are inadequate, such as extrahepatic cholestasis or severe pancreatic insufficiency, often leads to vitamin K deficiency. Multifactorial etiologies place newborns at risk for hemorrhage. Phylloquinone does not readily cross the placenta, and breast milk contains less phylloquinone than vitamin K–fortified formula. Fetal hepatic stores of phylloquinone are low, and treatments such as maternal antiepileptic therapy lead to increased vitamin K metabolism.<sup>40,44</sup> Although menaquinones are produced in the colon by bacteria, it is unlikely that enteric production contributes significantly to vitamin K stores or that eradication of the bacteria with antibiotics, without a coexistent dietary deficiency of vitamin K, results in deficiency.<sup>40</sup> Determination of vitamin K deficiency is usually established

on the basis of a prolonged PT or INR, which are surrogate markers of specific coagulation factors. Measurement of the vitamin K–dependent factors, II, VII, IX, and X, is an effective way to determine the adequacy of vitamin K<sub>1</sub> dosing.<sup>21</sup> Serial measurements of factor VII, the factor with the shortest half-life, allow for the early detection of inadequate vitamin K in the diet or a therapeutic regimen.<sup>8</sup> Direct measurement of serum vitamin K concentrations is done by high-performance liquid chromatography analysis. The human serum vitamin K concentration required for adequate production of activated clotting factors in the presence of long-acting vitamin K antagonists (LAARs) is still unclear. A single study in a patient who overdosed on brodifacoum suggested that a serum vitamin K concentration of 200 to 400 ng/mL was sufficient to achieve a normal coagulation profile. Prior studies suggested 1,000 ng/mL was necessary in rabbits.<sup>8,31</sup>

### ROLE IN XENOBIOTIC-INDUCED VITAMIN K DEFICIENCY

Warfarin and LAARs are vitamin K antagonists that interfere with the vitamin K cycle, causing the accumulation of vitamin K 2,3-epoxide, an inactive metabolite. Warfarin is a strong irreversible inhibitor of the vitamin K 2,3-epoxide reductase, which regenerates vitamin K into its active (K<sub>1</sub>H<sub>2</sub>, hydroquinone) form.<sup>3</sup> The superwarfarins are even more potent vitamin K reductase inhibitors. Under ideal nutritional circumstances in a healthy individual, vitamin K is recycled, and only 1 mcg/kg/d is required in adults to maintain adequate coagulation. DT-diaphorases are warfarin-insensitive enzymes capable of reducing vitamin K<sub>1</sub> to its active hydroquinone form, but they are incapable of regenerating vitamin K from vitamin K 2,3-epoxide after carboxylation of the coagulation factor (Fig. 58–2).<sup>3</sup> Thus, in the presence of warfarin or superwarfarins, additional vitamin K<sub>1</sub> must be administered to supply this active cofactor for each and every carboxylation step because it can no longer be recycled.<sup>8,15</sup> The minimum vitamin K<sub>1</sub> requirement in the presence of a LAAR is unknown. Other compounds including the *N*-methyl-thiotetrazole side chain–containing antibiotics such as moxalactam and cefamandole (Chap. 54), as well as salicylates have varying degrees of vitamin K antagonistic activity (Chap. 37).<sup>9,40</sup>

### ADVERSE EFFECTS AND SAFETY ISSUES

Although vitamin K<sub>1</sub> can be administered orally, subcutaneously, intramuscularly, or intravenously, the oral route is preferred for maintenance therapy. When administered orally, vitamin K<sub>1</sub> is virtually free of adverse effects, except for overcorrection of the INR for a patient requiring maintenance anticoagulation. The preparations available for IV administration are rarely associated with anaphylactoid reactions. Because of the lipid solubility of vitamin K, these preparations are not available in solution but rather as an aqueous colloidal suspension of a polyoxyethylated castor oil derivative, dextrose, and benzyl alcohol. Intravenous administration has resulted in death secondary to anaphylactoid reactions, probably as a result of the colloidal formulation of the preparation.<sup>4,12,27</sup> Numerous anaphylactoid reactions are reported, even when the preparation is properly diluted and administered slowly.<sup>17,30,36,50</sup> In a 5-year retrospective study, two patients experienced presumed anaphylactoid reactions shortly after initiation of 0.5 to 1 mg of IV vitamin K<sub>1</sub> diluted in 50 mL of dextrose 5% in water to be infused over 1 hour. Based on the total number of 6,572 administered doses of vitamin K<sub>1</sub> infused according to this protocol, the estimated incidence of presumed anaphylactoid reactions was 3 in 10,000.<sup>6,17</sup> Rarely, the SC and IM routes of administration also result in anaphylactoid reactions.<sup>17</sup> Liposomal preparations, which may become safer alternatives, are in development.

### PREGNANCY AND LACTATION

Vitamin K<sub>1</sub> is listed as FDA pregnancy Category C. There are no reproductive studies in animals. Vitamin K is the treatment of choice for vitamin K deficiency during pregnancy and for prevention of hemorrhagic disease in newborns.<sup>5</sup> A standard textbook on drugs in pregnancy also states that vitamin K is compatible with breastfeeding. However, the amount of vitamin K transferred in mother's milk is not usually adequate to prevent hemorrhagic disease in a newborn without supplementing the newborn directly.<sup>5</sup>

## DOING AND ADMINISTRATION

The optimal regimen for vitamin K<sub>1</sub> remains unclear. Variables include the vitamin K<sub>1</sub> pharmacokinetics and the amount and type of anticoagulant ingested.<sup>37</sup> Reported cases of LAAR poisoning have required as much as 50 to 250 mg of vitamin K<sub>1</sub> daily for weeks to months.<sup>2,8,14,15,22,25,41,49</sup> A recommended initial regimen starting approach for a patient who has overdosed on LAAR is 25 to 50 mg of vitamin K<sub>1</sub> orally three to four times a day for 1 to 2 days. For unusually large oral vitamin K doses, the IV formulation can be given orally.<sup>10</sup> The INR should be monitored, and the vitamin K<sub>1</sub> dose adjusted accordingly. When the INR is less than 2, a downward titration in the dose of vitamin K<sub>1</sub> should be made on the basis of factor VII analysis. For an ingestion of brodifacoum, serial serum concentrations of brodifacoum are recommended in determining the ultimate duration of treatment, although the effect of brodifacoum is demonstrated to persist at very low or undetectable blood concentrations.<sup>8,29</sup>

The management of patients with elevated INRs secondary to excessive warfarin is described in Table 58–2. Intravenous administration of vitamin K<sub>1</sub> should be reserved for serious or life-threatening hemorrhage at any elevation of INR.<sup>1</sup> Under these circumstances, supplementation with prothrombin complex concentrate (PCC) and fresh-frozen plasma (FFP) is recommended, based on a risk-to-benefit analysis. A starting dose of 10 mg of vitamin K<sub>1</sub> is recommended. To minimize the risk of an anaphylactoid reaction, the preparation should be diluted with preservative-free 5% dextrose, 0.9% sodium chloride, or 5% dextrose in 0.9% sodium chloride and administered slowly, using an infusion pump, over a minimum of 20 minutes.<sup>1</sup> The administration recommended rate is not to exceed 1 mg/min in adults.<sup>46</sup> Precautions should be anticipated in the event of an anaphylactoid reaction.

Because the duration of action of vitamin K<sub>1</sub> is short lived, the dose is recommended for administration two to four times daily. The onset of the effect of vitamin K<sub>1</sub> is not immediate regardless of the route of administration.

## FORMULATION AND ACQUISITION

Vitamin K<sub>1</sub> is available for IV and SC administration as phytonadione injection emulsion in 2 mg/mL (0.5-mL ampule and vial or prefilled drug delivery system) and 10-mg/mL (1-mL ampule) concentrations by different manufacturers. Each 1 mL of the 10-mg/mL preparations contain benzyl alcohol (0.9%) as a preservative and 70 mg of polyoxyethylated fatty acid derivative (polyoxyl 35 castor oil).<sup>33</sup> Many of the 2-mg/mL (0.5-mL) preparations also contain these excipients, and one manufacturer offers a 2-mg/mL (0.5-mL) preparation that is free of the polyoxyl 35 castor oil and instead contains 1 mg of phytonadione, 10 mg of polysorbate 80, 10.4 mg of propylene glycol, 0.17 mg of sodium acetate anhydrous, and 0.0002 mL of glacial acetic acid.<sup>34</sup> Oral vitamin K<sub>1</sub> is available as Mephyton in 5-mg tablets.

## SUMMARY

- Vitamin K<sub>1</sub> (phytonadione) is recommended for the reversal of an elevated PT or INR in patients with xenobiotic-induced vitamin K deficiency.
- Intravenous administration is reserved for patients with serious or life-threatening hemorrhage. The IV route is rarely associated with serious anaphylactoid reactions.
- Vitamin K<sub>1</sub> is administered with other therapies such as PCC and FFP that have rapid onsets of action.
- The onset of action of vitamin K<sub>1</sub> is delayed for several hours with the IV route and even longer delays occur with the oral route.
- Patients with LAAR poisoning usually require large doses of oral vitamin K<sub>1</sub> for weeks to months.

# PROTAMINE

Mary Ann Howland

Protamine is a rapidly acting antidote that physically complexes unfractionated heparin (UFH) and reverses its anticoagulant effects. Protamine neutralizes the anti-IIa activity of low-molecular-weight heparin (LMWH) and incompletely neutralizes the anti-Xa activity of LMWH, which often normalizes the activated partial thromboplastin time (aPTT) and the thrombin time but minimally affects the anti-factor Xa activity and cannot be expected to limit hemorrhage. Protamine has no effect on heparin pentasaccharide fragments or analogs such as fondaparinux.

## HISTORY

In 1868, Friedric Miescher discovered and named the basic protein that resides in the sperm of salmon as protamine.<sup>91</sup> The antidotal properties of protamine were recognized in the late 1930s, leading to its approval as an antidote for heparin overdose in 1968.<sup>30</sup> However, the largest body of literature pertaining to protamine originates from its use in neutralizing heparin after cardiopulmonary bypass and dialysis procedures.

## PHARMACOLOGY

### Chemistry

The protamines are a group of simple basic cationic proteins found in fish sperm that bind to heparin to form a stable neutral salt. The effects of protamine sulfate and protamine chloride are comparable.<sup>62</sup> The binding of heparin to protamine is stronger than the binding of heparin to antithrombin (AT), consequently protamine rapidly inactivates heparin and reverses its anticoagulant effects.<sup>45,86</sup> Commercially available protamine sulfate is derived from the sperm of mature testes of salmon and related species. Upon hydrolysis, protamine yields basic amino acids, particularly arginine, proline, serine, and valine, but not tyrosine and tryptophan.

### Related Protamine Variants

In animal studies, synthetic protamine variants, not available for clinical use, were effective in reversing the anticoagulant effects of LMWH, and are reported to be less toxic than protamine.<sup>13,49,98,99</sup>

### Mechanism of Action

Heparins are large electronegative xenobiotics that are rapidly complexed by the electropositive protamine, forming an inactive salt. Heparin is an indirect anticoagulant, requiring a cofactor. This cofactor, AT, was formerly called AT III. Heparin alters the stereochemistry of AT, thereby catalyzing the subsequent inactivation of thrombin and other clotting factors.<sup>38</sup> Only about one-third of an administered dose of UFH binds to AT, and this fraction is responsible for most of its anticoagulant effect.<sup>1,64</sup> Low-molecular-weight heparin has a reduced ability to inactivate thrombin as a result of lesser AT binding, but the smaller fragments of LMWH inactivate factor Xa almost as well as the larger molecules of UFH, allowing for equivalent efficacy. Immunoelectrophoretic studies demonstrate that because of the net positive charge of protamine, it has a greater affinity for heparin than heparin for AT, producing a dissociation of the heparin-AT complex and favoring a protamine-heparin complex.<sup>83</sup> This complex is removed by the reticuloendothelial system.<sup>3</sup> The ability of protamine to bind to LMWH is limited by the smaller chain length and molecular weight (MW) and the lesser sulfate charge density.<sup>32,45</sup>

## PHARMACOKINETICS AND PHARMACODYNAMICS

Normal volunteers, free from cardiovascular disease and heparin free, received 0.5 mg/kg of protamine intravenously over 10 min. In this study, the protamine plasma half-life was 7.4 minutes, and it was undetectable within 20 minutes. Pharmacokinetic modeling did not fit a typical pattern.<sup>10</sup> When the same investigators administered 250 mg of protamine intravenously over 5 minutes at the end of cardiopulmonary bypass for heparin reversal, the total protamine half-life (free plus bound to heparin) was 4.5 minutes, and a two-compartment model best explained the data. Protamine has a very rapid onset of action and can neutralize the effects of heparin within 5 min.<sup>86</sup>

## ROLE IN REVERSING HEPARIN

Protamine is indicated to reverse anticoagulant effects of heparin.<sup>34</sup> It is commonly used during coronary artery bypass graft (CABG) and cardiac valve surgeries, during abdominal aortic aneurysm and other open abdominal surgeries, in fistula placement and noncardiac vascular surgeries, during catheterization for cardiac or electrophysiologic procedures, and in hemodialysis.<sup>11,43,70,105</sup> Multiple controlled human trials substantiate the effectiveness of protamine in terminating the effects of heparin.<sup>39,43,105</sup> Protamine should be used in patients with consequential bleeding from excessive heparin.<sup>29,34,47</sup>

## ROLE IN REVERSING LOW-MOLECULAR-WEIGHT HEPARIN

In contrast to heparin, there is no proven method for completely neutralizing LMWH. Protamine neutralizes the anti-IIa activity of LMWH and a variable portion of the anti-Xa activity of LMWH.<sup>34</sup> Because the interaction of protamine and heparin is dependent on the MW of heparin, LMWH (mean MW, 4,500 Da) has reduced protamine binding. The protamine-resistant fraction in LMWH is an ultra-low-molecular-weight fraction with a low sulfate charge.<sup>21</sup> No human studies offer strong evidence for or against a beneficial effect of protamine as treatment for hemorrhage after LMWH use.<sup>34</sup> Case studies and case reviews report both success and failure of protamine administration to reverse LMWH-associated bleeding.<sup>7,12,13,18,49,71,73,75,96-99,108</sup> Not all LMWHs are the same and tinzaparin, a highly sulfated LMWH, is more responsive to protamine than enoxaparin and dalteparin but still incomplete.<sup>5,32,45</sup> Protamine is reasonable therapy for LMWH excess associated with hemorrhage, but complete reversal should not be expected, and caution should limit the protamine dose.

## ADVERSE EFFECTS AND SAFETY ISSUES

Protamine is routinely used in the neutralization of heparin at the completion of CABG surgery. More than 1 million coronary revascularizations are performed each year in the United States. However, unlike previous years, only one-fourth of these cases are now CABGs and routinely expose patients to protamine. Since the advent of CABG surgery, there have been approximately 100 deaths reported in total associated with the use of protamine. It is largely in this setting that the adverse effects of protamine are also documented and studied.<sup>44,46,60,68,82</sup> It is often difficult to separate the adverse effects caused by protamine from those of the protamine-heparin complex or those actually related to heparin. Adverse effects associated with protamine include both administration rate- and non-rate-related hypotension,<sup>20,27-31,35,37,51,54,90,93</sup> anaphylaxis,<sup>50,67</sup> anaphylactoid reactions,<sup>53,76,78</sup>

bradycardia,<sup>2</sup> thrombocytopenia,<sup>103</sup> thrombogenicity,<sup>22</sup> leukopenia, decreased oxygen consumption,<sup>100,102</sup> acute respiratory distress syndrome (ARDS),<sup>9,95</sup> pulmonary hypertension and pulmonary vasoconstriction,<sup>15,41</sup> cardiovascular collapse,<sup>65,88</sup> and dose-dependent paradoxical anticoagulation with protamine excess.<sup>3,8,55,60,80,81</sup>

Mechanisms for these adverse effects are multifactorial.<sup>91</sup> Some contribution results from the significant electropositivity of protamine.<sup>87</sup> The protamine–heparin complex activates the arachidonic acid pathway, and the production of thromboxane A<sub>2</sub> is at least partly responsible for some of the hemodynamic changes, including pulmonary hypertension.<sup>15,21,42,77,104</sup> Pretreatment with indomethacin limits these effects.<sup>21,42,77,104</sup> Free protamine or protamine complexed with heparin converts L-arginine to nitric oxide (formerly called endothelium-derived relaxing factor), which in turn causes vasodilation and inhibits platelet aggregation and adhesion, potentially increasing bleeding risks.<sup>84</sup> Methylene blue, via reduction in the amount and effect of nitric oxide, was used with success to treat the vasoplegia secondary to a severe protamine reaction.<sup>1,24,69,97</sup> Protamine in excess of heparin enters the myocardium and decreases cyclic adenosine monophosphate (cAMP), causing myocardial depression.<sup>15,92</sup> Protamine and protamine–heparin complexes activate the complement pathway and contribute to vasoactive events.<sup>15,85</sup> Mast cells in the human heart and skin to be stimulated by protamine to release histamine.<sup>15,69</sup> In the absence of heparin or in an amount exceeding that necessary for heparin neutralization protamine acts as an anticoagulant through several mechanisms. Protamine impairs adenosine diphosphate–induced platelet aggregation, clot initiation, clot kinetics, and platelet function, resulting in weaker clot formation.<sup>52,55,100</sup> Additionally, protamine reduces factor V activation by both thrombin and factor Xa, decreases factor VII<sup>8,80,81</sup> activation by tissue factor, and enhances tissue-type plasminogen activator mediated fibrinolysis. A study in patients undergoing CABG reported higher rates of microvascular bleeding and coagulation factor replacement in those receiving excess protamine.<sup>60</sup>

Risk factors for protamine-induced adverse reactions include prior exposure to protamine in insulin, exposure during previous surgery with protamine reversal, vasectomy, fish allergy, or a rapid protamine infusion rate.<sup>65,85</sup> A prospective study reported a 0.06% incidence of anaphylactic reactions to protamine in all patients undergoing CABG, but a 2% incidence in diabetics using neutral protamine Hagedorn (NPH) insulin.<sup>14</sup> Patients with diabetes receiving daily subcutaneous injections of a protamine containing insulin (NPH) have a 40% to 50% increased risk of immune-mediated adverse reactions, including anaphylaxis.<sup>34,36,40,50,59,93</sup> A systematic review of the literature revealed an anaphylaxis incidence of 1%, but the authors were cautious in interpreting the results because of study heterogeneity.<sup>82</sup> Histamine concentrations; the activation of complement; and elevated IgE, IgA, and IgG concentrations are mechanisms for the immune-mediated adverse effects.<sup>63,94,106,107</sup>

Occasionally, patients manifesting a protamine allergy are incorrectly presumed to have an insulin allergy.<sup>58</sup> In patients with diabetes receiving protamine insulin injections, the presence of serum anti-protamine IgE antibody is a significant risk factor for acute protamine reactions. Only patients with previous exposure to protamine insulin injections had serum anti-protamine IgE antibodies. However, in the group without previous protamine insulin exposure, anti-protamine IgG antibody was noted as a risk factor for protamine reactions.<sup>107</sup> Either naturally occurring cross-reacting antibodies or perhaps previously unrecognized protamine exposure was responsible for the generation of these IgG antibodies.

## ALTERNATIVES TO PROTAMINE IN PATIENTS AT RISK FOR ADVERSE DRUG REACTIONS

There are limited options to replace protamine for the reversal of heparin in patients who have previously experienced anaphylaxis after protamine therapy or in patients who are suspected of being at high risk. Recommended strategies usually depend on local preferences and include clotting factor replenishment, exchange transfusion in neonates, protamine avoidance, protamine administration with expectant management of anaphylaxis, or

heparin avoidance and use of bivalirudin.<sup>61</sup> Several investigational alternatives include heparin removal devices in the coronary artery bypass extracorporeal circuit, as well as the use of hexadimethrine, methylene blue, platelet factor-4, and heparinase antidotes.<sup>14,57</sup> Pretreatment with antihistamines and corticosteroids is often sufficient for immune-mediated mechanisms but will probably not be beneficial for pulmonary vasoconstriction and non-immune-mediated anaphylactoid reactions.<sup>48</sup>

## PREGNANCY AND LACTATION

Protamine is FDA Pregnancy Category C. No animal studies have been done on reproduction. Taking into consideration the benefit-to-risk assessment, protamine is reasonable to reverse or partially reverse the bleeding in a pregnant woman considered secondary to UFH or LMWH, respectively.<sup>6</sup> Protamine excretion in breast milk is unknown.

## DOSING AND ADMINISTRATION

### Dosing in Cardiopulmonary Bypass

Protamine is most frequently used at the conclusion of cardiopulmonary bypass operations to reverse the effects of heparin. Many regimens are used for protamine dosing. These include using arbitrary amounts of protamine and dosing on the basis of the total amount of heparin used. We recommend the most commonly used approach using a ratio of 0.3 to 1 mg of protamine to 100 units of heparin and subsequently titrating based on activating clotting time (ACT) point-of-care testing.<sup>25,39,52,66,109</sup>

### Heparin Rebound

A heparin anticoagulant rebound effect is noted after cardiopulmonary bypass and is attributed to the presence of detectable circulating heparin several hours after apparently adequate heparin neutralization with protamine. It is likely that the rapid clearance of protamine and redistribution of heparin from reservoirs in plasma proteins and vascular cytology contributes to this finding. The incidence of heparin rebound and the need for additional protamine range from 4% to 42%, depending on the neutralization protocol.<sup>38,72,89</sup> It is probable that larger heparin doses prolong the heparin clearance, contributing to higher than expected heparin concentrations.<sup>89</sup> When 300 units/kg of body weight doses of heparin were reversed with 3 mg/kg of protamine at the conclusion of cardiopulmonary bypass, a 14% incidence of small but detectable concentrations of circulating heparin was noted at 2 hours, which lasted less than 1 hour in all but one case.<sup>72</sup> A prolonged prothrombin time (PT) and thrombocytopenia occurred without increase in hemorrhage.

### Dosing for Heparin and Low-Molecular-Weight Heparin

Approximately 1 mg of protamine will neutralize about 100 units (1 mg) of heparin (UFH). In the case of unintentional overdose, the half-life of heparin should be used to calculate the remaining quantity of heparin because half of the administered dose of heparin is eliminated within 60 to 90 minutes under normal dosing conditions. This means that if bleeding occurs 2 hours after a single dose, only half of that initial dose will require reversal with protamine.<sup>34</sup> We recommend this kinetic dosing, which is slightly more conservative than the package insert, which states that if protamine is administered 30 minutes after heparin, half of the usual dose of protamine is likely sufficient.<sup>86</sup> In the case of an unintentional overdose without hemorrhage, the short half-life of heparin and the potential risks of protamine diminish the benefit from protamine administration. If protamine is necessary to reverse active hemorrhage, it must be administered very slowly intravenously either undiluted or diluted in dextrose 5% in water or 0.9% sodium chloride over 10 to 15 minutes to limit the incidence of rate-related hypotension.<sup>56,86,101</sup> The dose of protamine should not exceed 50 mg intravenously.<sup>32,34,86</sup> In the absence of hemorrhage, repeat doses should be guided by the severity of the clinical status of the patient and the level of abnormality of the aPTT, thrombin time and antifactor Xa (anti-FXa) heparin concentrations.<sup>32,86</sup> The package insert has a specific warning: “Hyperheparinemia or bleeding has been reported in experimental animals and in some patients 30 minutes to 18 hours after cardiac surgery (under cardiopulmonary bypass) in spite of complete

neutralization of heparin by adequate doses of protamine sulfate at the end of the operation. It is important to keep the patient under close observation after cardiac surgery. Additional doses of protamine sulfate should be administered if indicated by coagulation studies, such as the heparin titration test with protamine and the determination of plasma thrombin time.”

Most studies demonstrate incomplete protamine neutralization of the LMWHs enoxaparin, dalteparin, and tinzaparin. We recommend administering 1 mg of protamine per 100 anti-factor Xa units, in which 1 mg of enoxaparin equals 100 anti-factor Xa units if administered within 8 hours of the LMWH. A second dose of 0.5 mg protamine should be administered per 100 anti-factor Xa units if bleeding continues.<sup>26,34,86</sup> If more than 8 hours has elapsed, then a smaller fractional dose of protamine should be administered based on the actual time from the initiation of therapy.

A number of tests directly measure heparin concentrations or indirectly measure the effect of heparin on the clotting cascade.<sup>16,19,25</sup> These tests are helpful in determining the appropriate protamine dosing. Because excessive protamine acts as an anticoagulant, the dose chosen should be an underestimation of that which is needed.

The dosing of protamine in children for the reversal of heparin is similar to that of adults if the dose of heparin was given within 30 minutes and is 1 mg of protamine/100 units heparin received.<sup>74</sup> However if the dose of heparin has been 30 to 60 minutes earlier, then the dose of protamine should be 0.5 to 0.75 mg/100 units of heparin received. For 60 to 120 minutes after the heparin dose, the protamine dose is 0.375 to 0.5 mg/100 units heparin received, and for longer than 120 minutes, the protamine dose is 0.25 mg to 0.375 mg/100 units of heparin received. The maximum dose in each of these circumstances is 50 mg.<sup>74</sup>

## DOSING IN THE OVERDOSE SETTING

When a patient is believed to have received an overdose of an unknown quantity of heparin, the decision to use protamine should be determined by the presence of a prolonged aPTT and thrombin time (TT) and antifactor Xa heparin concentration or the presence of persistent hemorrhage. The risks of protamine use, especially in those who have had a prior life-threatening reaction to protamine, as well as in a patient with diabetes receiving protamine-containing insulin, and the risks of continued heparin anticoagulation are essential to determine the appropriate use. A baseline ACT, TT, heparin-neutralized TT, heparin activity, platelets, PT, partial thromboplastin time, hemoglobin, and hematocrit ideally should be obtained. Because of the routine nature of heparin reversal after cardiopulmonary bypass, consultation with members of the bypass team would be reasonable. An empiric dose of protamine is determined by the baseline ACT: (1) an ACT of less than 200 seconds necessitates no protamine, (2) an ACT of 200 to 300 seconds necessitates 0.6 mg/kg, and (3) an ACT of 300 to 400 seconds necessitates 1.2 mg/kg. These doses should be given up to a single maximum dose of 50 mg. The dose can be repeated if dictated by persistent bleeding and an elevated aPTT, TT, and ACT. These doses have not been validated outside of the operating room. The ACT should be repeated 5 to 15 minutes after protamine administration and in 2 to 8 hours to evaluate for potential heparin rebound. Further dosing should be based on these values and the patient's clinical condition.<sup>33</sup>

When an ACT is unavailable, protamine 25 mg to a maximum of 50 mg should be administered to an adult and adjusted accordingly.<sup>86</sup> Repeat dosing in several hours will be necessary with heparin rebound if bleeding or ACT is prolonged. The dose should be administered slowly intravenously over 15 minutes with resuscitative equipment immediately available. Neonates should not receive protamine that has been diluted with bacteriostatic water containing benzyl alcohol.

## AVAILABILITY

Protamine is available as a parenteral solution ready for injection in a concentration of 10 mg/mL in either a 5-mL or 25-mL vial containing totals of 50 mg and 250 mg, respectively, with and without preservatives.<sup>86</sup>

## SUMMARY

- Protamine effectively and rapidly reverses the anticoagulant effect of UFH.
- Protamine variably reverses the anticoagulant effects of LMWH and cannot be expected to limit hemorrhage.
- Protamine has no effect on heparin pentasaccharide fragments or analogs.
- Protamine should only be used for a prolonged aPTT in the presence of active hemorrhage, given the risks of hypotension, anaphylaxis, anaphylactoid reactions, dysrhythmias, leukopenia, thrombocytopenia, and ARDS.
- Protamine must be given intravenously over 10 to 15 min because faster administration is likely to produce hypotension.
- In most circumstances outside of the operating room, the maximum single dose of protamine is 50 mg.

## CASE STUDY 8

**History** A 48-year-old woman was transported to the hospital by emergency medical services (EMS). According to the paramedics, they were called to the house after the patient sent a text message to a friend saying that she no longer wanted to live. The friend went to the patient's house, and when no one answered, she called 911 to have the police break down the door. The patient was found on her bed with a suicide note. The friend related that the patient had migraine headaches but did not know what medications she used.

Emergency medical services personnel reported that at the scene the patient was lethargic with the following vital signs: blood pressure, 70/40 mm Hg; pulse, 25 beats/min; and respiratory rate, 8 breaths/min. Emergency medical services administered oxygen via nasal cannula at 4L/min inserted an intravenous (IV) catheter, infused 0.9% sodium chloride running wide open, and administered 0.5 mg of atropine IV before arrival to the hospital.

**Physical Examination** On arrival to the hospital, the patient had the following vital signs: blood pressure, 76/42 mm Hg; pulse, 35 beats/min; respiratory rate, 10 breaths/min; temperature, 98.3°F; O<sub>2</sub> saturation, 99% on room air; end-tidal CO<sub>2</sub>, 38 mm Hg; and rapid reagent bedside glucose, 58 mg/dL. Physical examination was notable for pupils that were 2 to 3 mm and sluggishly reactive to light. Gag reflex was intact, and there were no secretions, pills, or blood in the mouth. The patient's chest was clear to auscultation, and other than bradycardia, her cardiac examination was normal. The abdomen was soft with normal bowel sounds, and her skin was normal. The patient responded to sternal rub by opening her eyes but mumbled incoherently. She moved all four extremities to pain and was able to localize the source of the pain.

**Initial Management** Dextrose (50 g IV) and naloxone (0.04 mg followed by 0.08 mg and 0.4 mg IV) were given with no clinical response. Blood samples were sent for a complete blood count, electrolytes, ethanol, and acetaminophen (APAP), and an electrocardiogram (ECG) was ordered.

### What Is the Differential Diagnosis?

Many xenobiotics cause bradycardia (Chap. 15), but this patient has the combined features of hypotension and bradycardia. Here, the differential diagnosis is narrower, with the most common causes listed in [Table CS8-1](#).

### What Clinical and Laboratory Analyses Help Exclude Life-Threatening Causes of This Patient's Presentation?

Often, the physical examination provides significant insight into the diagnosis. Patients who overdose with either opioids or  $\alpha_2$ -adrenergic agonists may present with the classic opioid toxic syndrome (Chaps. 3, 36, and 61 and [Table 3-2](#)) that is manifested by miosis and depression of both the central nervous system and the respiratory drive. Although this patient has many features consistent with that toxic syndrome, the normal oxygen saturation on room air, normal end-tidal CO<sub>2</sub>, and failure to respond to naloxone essentially exclude the diagnosis of an opioid overdose. Also, most other causes of hypotension and bradycardia routinely decrease the level of consciousness except for nondihydropyridine calcium channel blockers, which tend to preserve the level of consciousness (Chap. 60).

An ECG should be evaluated ([Fig. CS8-1](#)). Although patients with all of the causes listed in [Table CS8-1](#) can present with sinus bradycardia, certain features may be suggestive of the etiology. When bradycardia is associated with traditional class I antidysrhythmics, the QRS complex is usually significantly widened as a result of sodium channel blockade (Chap. 57). Patients prescribed

cardioactive steroids often have underlying atrial fibrillation or demonstrate a "digoxin effect" (Chap. 62). In overdose, they may have ventricular premature beats, high degrees of atrioventricular blockade, or delayed after depolarizations on their ECGs (Chap. 15). Finally, although a prolongation of the QT interval is nonspecific, it is expected with class IA and IC antidysrhythmics and some opioids, most notably methadone (Chap. 36).

Rapid laboratory testing may also be of some utility. With acute toxicity from cardioactive steroids, the serum potassium concentration rises, and this increase has prognostic implications (Chap. 62). Less dramatic rises occur with  $\beta$ -adrenergic antagonist overdose but have unclear prognostic value. This patient's serum potassium concentration was 5.2 mEq/L.  $\beta$ -Adrenergic antagonists also tend to cause hypoglycemia. In contradistinction, hyperglycemia, although not only common with calcium channel blockers, has prognostic implications.

### Further Diagnosis and Treatment

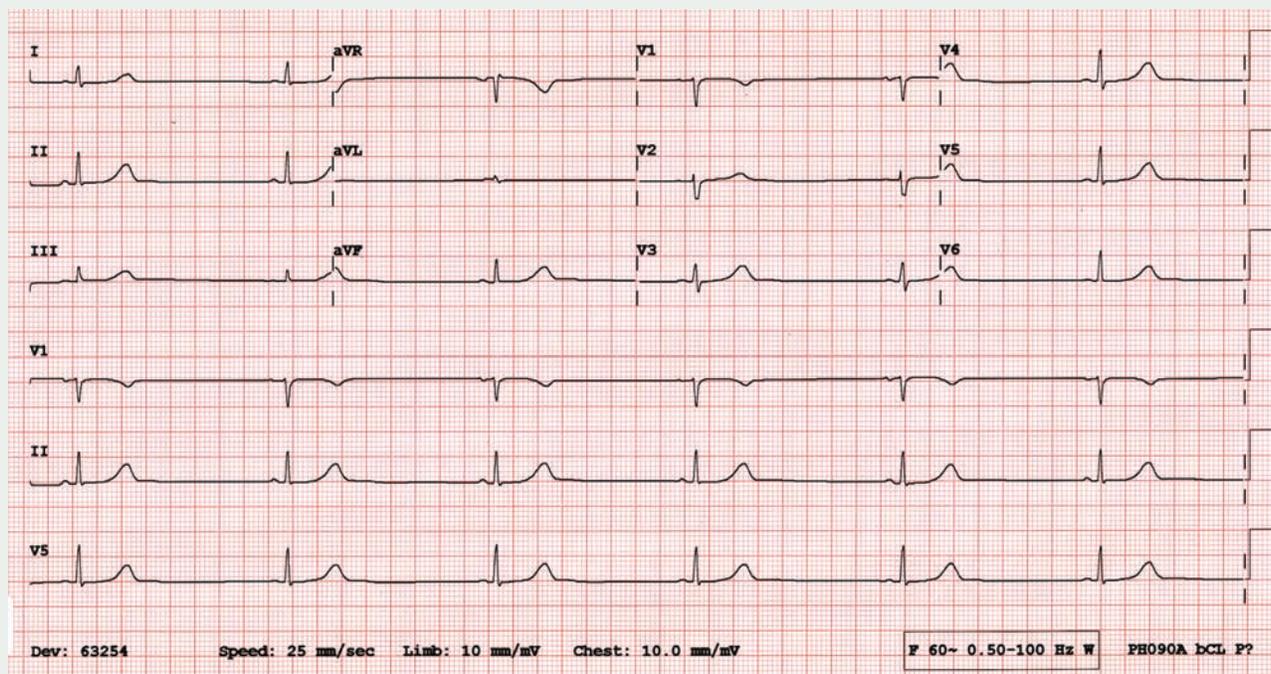

A clinical decision was made to forgo attempts at gastrointestinal decontamination given the patient's mental status. She was infused a second liter of 0.9% sodium chloride intravenously and administered glucagon for a presumed  $\beta$ -adrenergic antagonist overdose (Antidotes in Depth: A20). This diagnosis was suspected given the history of migraines (because this class of medication is commonly prescribed prophylactically for migraine headache), the ECG, the serum potassium concentration, and the blood glucose concentration. After 3 mg of glucagon IV, the patient's blood pressure rose to 102/62 mm Hg with a pulse of 60 beats/min, and this dose was repeated in 15 minutes when her blood pressure fell again. Her anion gap was normal, and both APAP and ethanol concentrations were negative. By the next day, she was awake, and her vital signs remained normal. During a subsequent psychiatric evaluation, she admitted to taking an unspecified amount of propranolol. She was voluntarily admitted for psychiatric care.

**TABLE CS8-1** Differential Diagnosis

#### Most Common Toxicologic Causes of Combined Hypotension and Bradycardia

$\alpha_2$ -Adrenergic agonists	Calcium channel blockers
$\beta$ -Adrenergic antagonists	Cardioactive steroids
Antidysrhythmics (Class I)	Opioids
Baclofen	

## CASE STUDY 8 (CONTINUED)

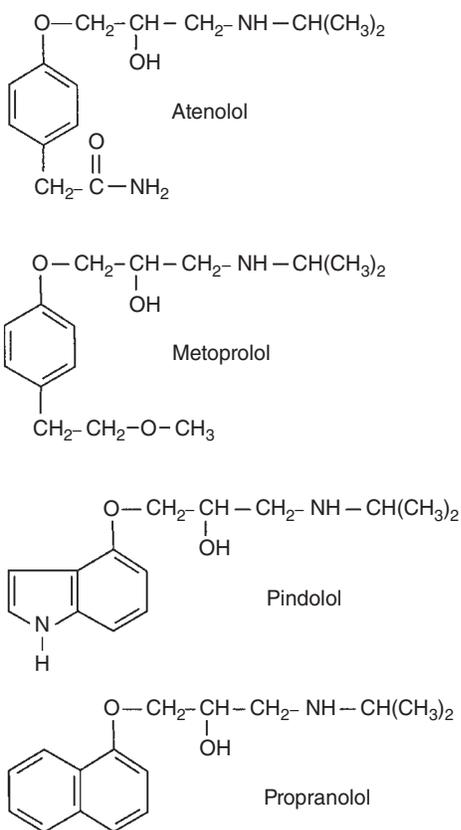

**FIGURE CS8-1.** Electrocardiogram on presentation showing profound sinus bradycardia with a heart rate of 36 beats/min. The axis is normal, as are the PR interval of 120 ms and the QRS complex duration of 80 ms. The QT interval is slightly prolonged at 510 ms, and there is no evidence of ischemia or infarction.

## β-ADRENERGIC ANTAGONISTS

Jeffrey R. Brubacher

### HISTORY

In 1948, Raymond Alquist postulated that epinephrine's cardiovascular actions of hypertension and tachycardia were best explained by the existence of two distinct sets of receptors that he generically named  $\alpha$  and  $\beta$  receptors. At that time, the contemporary "antiepinephrine" agents such as phenoxybenzamine reversed the hypertension but not the tachycardia associated with epinephrine. According to Alquist's theory, these xenobiotics acted at the  $\alpha$  receptors. The  $\beta$  receptors, in his schema, mediated catecholamine-induced tachycardia. British pharmacist Sir James Black was influenced by Alquist's work and recognized the potential clinical benefit of a  $\beta$ -adrenergic antagonist. In 1958, Black synthesized the first  $\beta$ -adrenergic antagonist, pronethalol. Pronethalol was briefly marketed as "Alderlin," named after Alderly Park, the research headquarters of ICI Pharmaceuticals. Pronethalol was discontinued because it produced thymic tumors in mice. Propranolol was soon developed and marketed as "Inderal" (an incomplete anagram of Alderlin) in the United Kingdom in 1964<sup>31,235</sup> and in the United States in 1973. Before the introduction of  $\beta$ -adrenergic antagonists, the management of angina was limited to xenobiotics such as nitrates, which reduced preload through dilation of the venous capacitance vessels and increased myocardial oxygen delivery by vasodilation of the coronary arteries. Propranolol gave clinicians the ability to decrease myocardial oxygen utilization. This new approach decreased morbidity and mortality in patients with ischemic heart disease.<sup>134</sup> New medications soon followed, and by 1979, there were 10  $\beta$ -adrenergic antagonists available in the United States.<sup>74</sup> Unfortunately, it soon became apparent that these xenobiotics were dangerous when taken in overdose, and by 1979, severe toxicity and death from  $\beta$ -adrenergic overdose

were reported.<sup>74</sup> There are currently 20 US Food and Drug Administration–approved  $\beta$ -adrenergic antagonists with additional  $\beta$ -adrenergic antagonists available worldwide (Table 59–1). They are commonly used in the treatment of cardiovascular disease: hypertension, coronary artery disease, and tachyarrhythmias. Other indications for  $\beta$ -adrenergic antagonists include congestive heart failure, migraine headaches, benign essential tremor, panic attack, stage fright, and hyperthyroidism. Ophthalmic  $\beta$ -adrenergic antagonists are used in the treatment of glaucoma.<sup>101</sup> The pharmacology, toxicology, and poison management issues discussed in this chapter are applicable to all of these indications.

### EPIDEMIOLOGY

Intentional  $\beta$ -adrenergic antagonist overdose, although relatively uncommon, continues to account for a number of deaths annually. The number of exposures to  $\beta$ -adrenergic antagonists reported to the American Association of Poison Control Centers (AAPCC) increased from 9,500 in 1999 to almost 25,000 in 2014. During the 5-year period from 2010 to 2014, there were 120,409  $\beta$ -adrenergic antagonist exposures reported to the AAPCC (Chap. 130). These exposures resulted in 326 deaths of which  $\beta$  adrenergic antagonists were the first listed cause of death in 216 cases. Children younger than the age of 6 years accounted for 15,623 exposures and no fatalities. The youngest fatality attributed to  $\beta$ -adrenergic antagonists in this period was aged 14 years. Just under half of these exposures (52,347) were single-substance exposures. Each year since 2010, single-substance exposures to  $\beta$ -adrenergic antagonists resulted in 70 to 110 cases with major morbidity and 5 to 14 fatalities (Chap. 130).<sup>39,184,186</sup>

Compared with the other  $\beta$ -adrenergic antagonists, propranolol accounts for a disproportionate number of reported cases of self-poisoning<sup>50,204</sup> and deaths.<sup>130,156</sup> This may be explained by the fact that propranolol is frequently prescribed to patients with diagnoses such as anxiety, stress, and migraine who may be more prone to suicide attempts. Propranolol is more lethal because of its lipophilic and membrane-stabilizing properties.<sup>96,204</sup>

### PHARMACOLOGY

#### The Cardiac Cycle

Normal cardiac electrical activity involves a complex series of ion fluxes that result in myocyte depolarization and repolarization. Cardiac electrical activity is coupled to myocyte contraction and relaxation, respectively, by increases and decreases in intracellular calcium concentrations. Cardiac electrical and mechanical activity is closely regulated by the autonomic nervous system.

Under normal conditions, heart rate is determined by the rate of spontaneous discharge of specialized pacemaker cells that comprise the sinoatrial (SA) node (Fig. 59–1). Pacemaker cells are also found in the atrioventricular (AV) node and in Purkinje fibers. Spontaneous pacemaker cell depolarization was once attributed to inward cation current through "pacemaker channels."<sup>2,60</sup> More recent research suggests that spontaneous depolarization of pacemaker cells involves several mechanisms, including a "membrane clock," consisting of "pacemaker channels" and other inward cation channels located on the cell membrane, and a "calcium clock," which is driven by rhythmic release of calcium from the sarcoplasmic reticulum (SR).<sup>47,133,139,164,167,267</sup>  $\beta$ -Adrenergic stimulation significantly increases the rate of pacemaker cell depolarization by phosphorylating proteins within the SR, thereby increasing the rate of the "calcium clock." There is also a direct, phosphorylation-independent action of cyclic adenosine monophosphate (cAMP) at the pacemaker channels, which increases the rate of the "membrane clock."<sup>47</sup> Depolarization of cells in the SA

**FIGURE 59-1.** The cardiac conduction system. **(A)** The cardiac cycle begins when pacemaker cells in the sinoatrial (SA) node depolarize spontaneously. Traditionally, this depolarization was attributed to inward “pacemaker” currents ( $I_f$ ). There is now evidence that pacemaker cell depolarization may also be driven by cyclical calcium release from a “calcium clock” in the sarcoplasmic reticulum (SR).  $\beta$ -Adrenergic stimulation increases both the frequency of the “calcium clock” by a phosphokinase A (PKA)-mediated effect and the magnitude of the pacemaker current secondary to a direct effect of cyclic adenosine monophosphate (cAMP). These effects both increase the heart rate. Cholinergic stimulation has the opposite effects and results in bradycardia. Pacemaker cells lack fast  $\text{Na}^+$  channels. Pacemaker cell depolarization triggers the opening of voltage-gated type calcium channels ( $I_{\text{Ca}^{2+}\text{-L}}$ ), and the impulse is transmitted to surrounding cells. **(B)** Coordinated SA nodal depolarization generates an impulse sufficient to open fast  $\text{Na}^+$  channels in surrounding atrial tissue, and the impulse spreads along specialized pathways to depolarize the atria and ventricles. AV = atrioventricular.

**FIGURE 59-2.** Fluctuations in  $\text{Ca}^{2+}$  concentrations couple myocyte depolarization with contraction and myocyte repolarization with relaxation. (1) Depolarization, driven by  $\text{Na}^+$  influx through  $\text{Na}^+$  channels, causes voltage-gated  $\text{Ca}^{2+}$  channels to open and calcium to flow down its concentration gradient into the myocyte. (2) This  $\text{Ca}^{2+}$  current triggers the opening of  $\text{Ca}^{2+}$  release channels in the sarcoplasmic reticulum (SR), and calcium pours out of the SR. The amount of  $\text{Ca}^{2+}$  released from the SR is proportional to the initial inward  $\text{Ca}^{2+}$  current and to the amount of calcium stored in the SR. (3) At rest, actin–myosin interaction is prevented by troponin. When  $\text{Ca}^{2+}$  binds to troponin, this inhibition is removed, actin and myosin slide relative to each other, and the cell contracts.

After contraction, calcium is actively removed from the myocyte to allow relaxation. (4) Most  $\text{Ca}^{2+}$  is actively pumped into the SR, where it is bound to calsequestrin. Calcium stored in the SR is thus available for release during subsequent depolarizations. The sarcoplasmic  $\text{Ca}^{2+}$  ATPase is inhibited by phospholamban (Fig. 59-3). (5) NCX, the  $\text{Ca}^{2+}$ ,  $\text{Na}^+$  antiporter, couples the flow of three molecules of  $\text{Na}^+$  flow in one direction to that of a single molecule of  $\text{Ca}^{2+}$  in the opposite direction. This transporter is passively driven by electrochemical gradients, which usually favor the inward flow of sodium coupled to the extrusion of calcium. Extrusion of  $\text{Ca}^{2+}$  is inhibited by high intracellular sodium or extracellular  $\text{Ca}^{2+}$  concentrations and by cell depolarization. Under these conditions, the pump may “run in reverse.” (6) Some calcium is actively pumped from the cell by a  $\text{Ca}^{2+}$  ATPase. (7) As myocyte  $\text{Ca}^{2+}$  concentrations fall,  $\text{Ca}^{2+}$  is released from troponin, and the myocyte relaxes.

calcium concentrations drop during diastole, calcium dissociates from troponin, and relaxation occurs.<sup>21,26,28,223</sup>

### $\beta$ -Adrenergic Receptors and the Heart

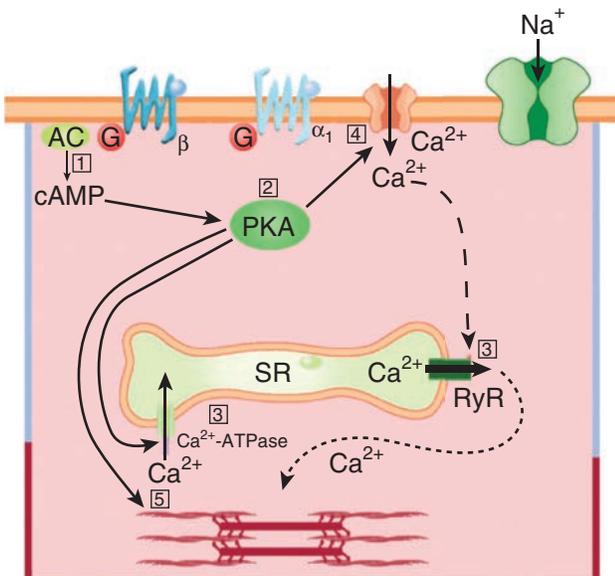

$\beta$ -Adrenergic receptors are divided into  $\beta_1$ ,  $\beta_2$ , and  $\beta_3$  subtypes. In the healthy heart, approximately 80% of human cardiac  $\beta$ -adrenergic receptors are  $\beta_1$ , and 20% are  $\beta_2$ . Human hearts also contain a small number of  $\beta_3$ -adrenergic receptors.<sup>24,81,177</sup> The relative density of cardiac  $\beta_2$ -adrenergic receptors increases with heart failure.<sup>38,236</sup>  $\beta_1$ -Adrenergic receptors mediate increased inotropy by a well-described pathway involving cAMP, which acts as a second messenger to activate protein kinases (Fig. 59-3).  $\beta_1$ -Adrenergic receptors are coupled to  $G_s$  proteins that activate adenylate cyclase when the receptor is stimulated. This increases intracellular production of cAMP, which binds to and activates protein kinase A (PKA) and other cAMP-dependent protein kinases.<sup>145</sup> Protein kinase A (PKA), in turn, phosphorylates important myocyte proteins, including phospholamban, the voltage-sensitive calcium channels, the calcium release (RyR) channels, and troponin.<sup>28,223</sup> Phosphorylation of the L-type calcium channel increases contractility by increasing the influx of calcium during each cell depolarization triggering

node spreads to surrounding atrial cells, where it triggers the opening of fast sodium channels. This initiates an electric current that spreads from cell to cell along specialized pathways to depolarize the entire heart. This depolarization, referred to as cardiac excitation, is linked to mechanical activity of the heart by the process of electrical–mechanical coupling (Chap. 15).

### Myocyte Calcium Flow and Contractility

During systole, voltage-gated slow  $\text{Ca}^{2+}$  channels (L-type channels) on the myocyte membrane open in response to cell depolarization, allowing  $\text{Ca}^{2+}$  to flow down its concentration gradient into the myocyte (Fig. 59-2). Invaginations of the myocyte membrane known as T-tubules place L-type  $\text{Ca}^{2+}$  channels in close approximation to  $\text{Ca}^{2+}$  release channels (ryanodine receptors: RyR) on the SR. The local increase in calcium concentration that follows the opening of a single L-type  $\text{Ca}^{2+}$  channel on the cell membrane triggers the opening of the associated RyR channels, resulting in a large release of calcium from the SR, a phenomenon known as calcium-induced calcium release.<sup>87,269</sup> Myocytes contain tens of thousands of *couplons*, clusters of L-type calcium channels and RyR channels. The  $\text{Ca}^{2+}$  released from one *couplon* is not sufficient to trigger firing of neighboring couplons.<sup>41</sup> Organized myocyte contraction requires synchronized release of calcium from numerous couplons throughout the myocyte. This process depends on membrane depolarization to synchronize opening of L-type channels and subsequent calcium release. This occurs rapidly throughout an extensive network of T-tubules that spans the myocyte.<sup>106</sup> After release from the SR, cytosolic calcium binds to troponin C and allows actin myosin interaction and subsequent myocyte contraction. The strength of contraction is proportional to the amount of calcium release from the SR during depolarization, which depends, in part, on the magnitude of SR calcium stores. Actin–myosin interaction is also modulated by  $\beta$ -adrenergic-mediated troponin phosphorylation, ischemia, intracellular pH, and myofilament stretch.<sup>13,27,28,247</sup>

During diastole, several ion pumps actively remove calcium from the cytoplasm (Fig. 59-2). The most important of these are the SR  $\text{Ca}^{2+}$  ATPase (SERCA2a) that pumps cytosolic  $\text{Ca}^{2+}$  into the SR, and the calcium–sodium transporter (NCX) that exchanges one intracellular  $\text{Ca}^{2+}$  ion for three sodium ions from extracellular fluid. The SR  $\text{Ca}^{2+}$  ATPase is important for maintaining SR  $\text{Ca}^{2+}$  stores and is modulated by  $\beta$ -adrenergic stimulation (see later). When

**FIGURE 59-3.**  $\beta_1$ -Adrenergic agonists are positive inotropes by virtue of their ability to activate protein kinase A (PKA). (1)  $\beta_1$ -adrenergic receptors are coupled to  $G_s$  proteins, which activate adenylate cyclase when catecholamines bind to the receptor. This causes increased formation of cyclic adenosine monophosphate (cAMP) from adenosine triphosphate (ATP). (2) Increased cAMP concentrations activate PKA, which mediates the ultimate effects of  $\beta$ -adrenergic receptor stimulation by phosphorylating key intracellular proteins. (3) Phosphorylation of phospholamban disinhibits the sarcoplasmic reticulum (SR)  $Ca^{2+}$  ATPase, resulting in increased SR calcium stores available for release during subsequent depolarizations, and phosphorylation of SR calcium release channels enhances  $Ca^{2+}$  release from SR stores during contraction. (4) Phosphorylation of voltage-gated  $Ca^{2+}$  channels increases  $Ca^{2+}$  influx through these channels during systole. (5) Troponin phosphorylation improves cardiac performance by facilitating  $Ca^{2+}$  unbinding during diastole.  $\beta_2$  adrenergic receptors are also coupled to  $G_s$  proteins and mediate positive inotropy through a cAMP mechanism (see text). Increased cAMP directly increases heart rate (Fig. 59-1A).

greater release of calcium from the SR.<sup>206,226,233</sup> Phospholamban inhibits SERCA2a. Phosphorylation of phospholamban by PKA at Ser16 and at Thr17 by  $Ca^{2+}$ /calmodulin-dependent protein kinase removes this inhibition<sup>46,170</sup> and increases the activity of SERCA2a, resulting in increased “reloading” of SR calcium stores and hence enhanced subsequent contractility.<sup>55,241</sup> Improved activity of the SR  $Ca^{2+}$  ATPase also results in more rapid removal of cytoplasmic  $Ca^{2+}$  during diastole and aids in myocyte relaxation (ie, lusitropy). Phosphorylation of the RyR channels results in more rapid release of  $Ca^{2+}$  from SR stores.<sup>28,223,247</sup> Troponin phosphorylation facilitates  $Ca^{2+}$  unbinding and thus improves cardiac performance by enhancing myocyte relaxation.<sup>3,21,146,241</sup>  $\beta_1$ -Adrenergic receptors increase chronotropy by an incompletely understood mechanism that is hypothesized to involve phosphorylation of SR proteins, resulting in an increased rate of  $Ca^{2+}$  discharge from the SR,<sup>164,166</sup> in addition to direct cAMP interaction with membrane-bound pacemaker channels.<sup>2,35</sup> Although  $\beta$ -adrenergic stimulation acutely improves cardiac function, chronic  $\beta$ -adrenergic stimulation, acting through  $\beta_1$ -adrenergic receptors, results in a number of detrimental effects including calcium overload, increased risk of dysrhythmias, impaired excitation–contraction coupling, takotsubo stress cardiomyopathy, and myocyte apoptosis.<sup>28,38,275,248</sup>

Cardiac  $\beta_2$ -adrenergic receptors are dually linked to both excitatory  $G_s$  proteins and inhibitory  $G_i$  proteins.<sup>122,212,276</sup> Under normal conditions, the  $G_s$  pathway predominates in human cardiac  $\beta_2$ -adrenergic receptors, and  $\beta_2$ -adrenergic stimulation increases contractility, relaxation, and chronotropy through the PKA pathway described earlier. However, in a failing heart, the inhibitory  $G_i$  protein pathway becomes dominant, and  $\beta_2$ -adrenergic stimulation inhibits cardiac function.<sup>38,94,223</sup> Chronic  $\beta_2$ -adrenergic stimulation reportedly prevents myocyte apoptosis.<sup>275</sup> The  $\beta_3$ -adrenergic receptors are best understood as metabolic regulators in adipose tissue.<sup>64</sup> The role of

cardiac  $\beta_3$ -adrenergic receptors is poorly understood, but evidence suggests that they prevent the maladaptive myocardial remodeling that occurs with chronic sympathetic overstimulation.<sup>17,18,24</sup>

### Noncardiac Effects of $\beta$ -Adrenergic Receptor Activation

$\beta$ -Adrenergic agonists have important noncardiac effects.  $\beta$ -Adrenergic receptors mediate smooth muscle relaxation in several organs. Relaxation of arteriolar smooth muscle, predominately by  $\beta_2$ -adrenergic stimulation, reduces peripheral vascular resistance and decreases blood pressure. This counteracts  $\alpha$ -adrenergic-mediated arteriolar constriction. In the lungs,  $\beta_2$ -adrenergic receptors mediate bronchodilation. Unfortunately, chronic  $\beta$ -adrenergic stimulation causes adverse pulmonary effects, including mucous cell proliferation, hyperreactive airways, and inflammation.<sup>52</sup> Third trimester uterine tone and contractions are inhibited by  $\beta_2$ -adrenergic agonists, and gut motility is decreased by both  $\beta_1$ - and  $\beta_2$ -adrenergic stimulation. Chronic, high-dose  $\beta_2$ -adrenergic stimulation causes skeletal muscle hypertrophy.<sup>125</sup>

$\beta$ -Adrenergic receptors play a role in the immune system. Mast cell degranulation is inhibited by  $\beta_2$ -adrenergic stimulation, explaining the role of epinephrine in aborting and treating anaphylaxis. Polymorphonuclear leukocytes demarginate in response to  $\beta$ -adrenergic stimulation, resulting in the increased white blood cell counts with catecholamine infusions or with increased endogenous release of epinephrine that occurs with pain or physiological stress.

$\beta$ -Adrenergic agonists also have important metabolic effects. Insulin secretion is increased by  $\beta_2$ -adrenergic receptor stimulation. Despite increased insulin concentrations, the net effect of  $\beta_2$ -adrenergic receptor stimulation is to increase glucose because of increased skeletal muscle glycogenolysis and hepatic gluconeogenesis and glycogenolysis.  $\beta_2$ -Adrenergic receptors also cause glucagon secretion from pancreatic  $\alpha$  cells.<sup>132</sup>  $\beta$ -Adrenergic agonists act at fat cells to cause lipolysis and thermogenesis. Stimulation of adipocyte  $\beta$ -adrenergic receptors results in breakdown of triglycerides and release of free fatty acids. Skeletal muscle potassium uptake is increased by  $\beta_2$ -adrenergic stimulation, resulting in hypokalemia, explaining the role of  $\beta_2$ -adrenergic agonists in the treatment of hyperkalemia. Finally, renin secretion is increased by  $\beta_1$ -adrenergic stimulation, resulting in increased blood pressure.<sup>268</sup>

### Action of $\beta$ -Adrenergic Antagonists

$\beta$ -Adrenergic antagonists competitively antagonize the effects of catecholamines at  $\beta$ -adrenergic receptors and blunt the chronotropic and inotropic response to catecholamines. Severe bradycardia and hypotension often results in patients who take additional medications that impair cardiac conduction or contractility or in those with underlying cardiac or medical conditions that make them reliant on sympathetic stimulation. In addition to slowing the rate of SA node discharge,  $\beta$ -adrenergic antagonists inhibit ectopic pacemakers and slow conduction through atrial and AV nodal tissue.  $\beta$ -Adrenergic antagonists limit the detrimental effects of chronic adrenergic overstimulation and have become standard of care for patients with all stages of compensated chronic heart failure, including patients with stable New York Heart Association class III or IV disease.<sup>1,86,271</sup>  $\beta$ -Adrenergic antagonism occasionally exacerbates symptoms in patients with decompensated congestive heart failure, but in the absence of cardiogenic shock or symptomatic bradycardia,  $\beta$ -adrenergic antagonists should not be routinely discontinued in heart failure patients admitted to hospital.<sup>274</sup>  $\beta$ -Adrenergic antagonists reduce the number of adverse cardiac events in patients with recent myocardial infarctions (MIs) but not in patients with prior myocardial infarct, stable coronary artery disease, or risk factors for coronary artery disease.<sup>19</sup>

The antihypertensive effect of  $\beta$ -adrenergic antagonists is counteracted by a reflex increase in peripheral vascular resistance. This effect is augmented by the  $\beta_2$ -adrenergic antagonism of nonselective  $\beta$ -adrenergic antagonists. By causing increased peripheral vascular resistance,  $\beta_2$ -adrenergic antagonists rarely worsen peripheral vascular disease.

Some patients with reactive airways disease experience severe bronchospasm after using  $\beta$ -adrenergic antagonists because of loss of

$\beta_2$ -adrenergic-mediated bronchodilation. Catecholamines inhibit mast cell degranulation through a  $\beta_2$ -adrenergic mechanism. Interference with this can predispose to life-threatening effects after anaphylactic reactions in atopic individuals.<sup>109</sup>  $\beta_2$ -Adrenergic antagonists impair the ability to recover from hypoglycemia and sometimes mask the sympathetic discharge that serves to warn of hypoglycemia. This combination of effects is dangerous for patients with diabetes at risk for hypoglycemic episodes.<sup>268</sup>

$\beta$ -Adrenergic antagonism inhibits catecholamine-mediated potassium uptake at skeletal muscle. This causes slight elevations in serum [potassium], especially after exercise,<sup>48,245</sup> and in rare cases is associated with severe hyperkalemia.<sup>23,80,88,89,168</sup> Although  $\beta_2$ -adrenergic stimulation augments insulin release,  $\beta$ -adrenergic antagonists seldom lower insulin concentrations. In fact, they occasionally cause hypoglycemia, especially in children, by interference with glycogenolysis and gluconeogenesis.<sup>200</sup> These effects are important in people with diabetes, who are at risk for hypoglycemia.  $\beta$ -Adrenergic antagonists also alter lipid metabolism. Although the release of free fatty acids from adipose tissue is inhibited, patients taking nonselective  $\beta$ -adrenergic antagonists typically have increased plasma concentrations of triglycerides and decreases in high-density lipoproteins.<sup>268</sup> There are reports of cardiac arrest, believed secondary to reduced cardiac output, when propranolol was used in patients with thyrotoxic cardiomyopathy.<sup>51,190</sup>

## PHARMACOKINETICS

The pharmacokinetic properties of the  $\beta$ -adrenergic antagonists depend in large part on their lipophilicity. Propranolol is the most lipid soluble of the  $\beta$ -adrenergic antagonists, and atenolol is the most water soluble. The oral bioavailability of the  $\beta$ -adrenergic antagonists ranges from approximately 25% for propranolol to almost 100% for pindolol and penbutolol.

The highly lipid-soluble  $\beta$ -adrenergic antagonists cross lipid membranes rapidly and concentrate in adipose tissue. These properties allow rapid entry into the central nervous system (CNS) and typically result in large volumes of distribution. In contrast, highly water-soluble medications, cross lipid membranes slowly, distribute in total body water, and tend to have less CNS toxicity. Volumes of distribution range from about 1 L/kg for atenolol to more than 100 L/kg for carvedilol.

The highly lipid-soluble  $\beta$ -adrenergic antagonists are highly protein bound and poorly excreted by the kidneys. They require hepatic biotransformation before they can be eliminated and accumulate in patients with liver failure. In contrast, the water-soluble  $\beta$ -adrenergic antagonists tend to be slowly absorbed, poorly protein bound, and renally eliminated. They accumulate in patients with kidney failure. Esmolol, although water soluble, is rapidly metabolized by red blood cell esterases and does not accumulate in patients with renal failure. The half-life of esmolol is about 8 minutes. Half-lives of the other  $\beta$ -adrenergic antagonists range from about 2 hours for oxprenolol to as long as 32 hours for nebivolol. The  $\beta$ -adrenergic antagonists also differ in their  $\beta_1$ -adrenergic selectivity, intrinsic sympathomimetic activity (ISA), and vasodilatory properties<sup>191,202,207,243,268</sup> (Table 59–1 and later discussion).

### $\beta_1$ Selectivity (Acebutolol, Atenolol, Betaxolol, Bisoprolol, Celiprolol, Esmolol, Metoprolol, and Nebivolol)

$\beta_1$ -Selective antagonists avoid some of the adverse effects of the nonselective antagonists. Short-term use of  $\beta_1$ -adrenergic selective antagonists appears to be safe in patients with mild to moderately severe reactive airways.<sup>217</sup> These medications are safer for patients with diabetes mellitus or peripheral vascular disease. Their  $\beta_1$ -adrenergic selectivity, however, is incomplete, and adverse reactions secondary to  $\beta_2$ -adrenergic antagonism occur with therapeutic dosage as well as in overdose.<sup>147,268</sup>

### Membrane-Stabilizing Effects (Acebutolol, Betaxolol, Carvedilol, Oxprenolol, and Propranolol)

$\beta$ -Adrenergic antagonists that inhibit fast sodium channels (also known as type I antidysrhythmic activity) are said to possess “membrane-stabilizing activity.” No significant membrane stabilization occurs with therapeutic

use of  $\beta$ -adrenergic antagonists, but this property contributes to toxicity in overdose.

### Intrinsic Sympathomimetic Activity (Acebutolol, Carteolol, Oxprenolol, Penbutolol, and Pindolol)

These xenobiotics are partial agonists at  $\beta$ -adrenergic receptors and are said to have ISA. This property is unrelated to  $\beta_1$ -adrenergic selectivity. These xenobiotics theoretically avoid the dramatic decrease in resting heart rate that occurs with  $\beta$ -adrenergic antagonism in susceptible patients, but their clinical benefit is not demonstrated in controlled trials.<sup>70,77</sup>

### Potassium Channel Blockade (Acebutolol and Sotalol)

Sotalol is a nonselective  $\beta$ -adrenergic antagonist with low lipophilicity, no membrane stabilizing effect, and no ISA. Sotalol is unique because of its ability to block the delayed rectifier potassium current responsible for repolarization. This prolongs the action potential duration and is manifested on the electrocardiogram by a prolonged QT interval.<sup>102</sup> The prolonged QT interval predisposes to torsade de pointes, and ventricular dysrhythmias rarely complicate the therapeutic use of sotalol.<sup>129</sup> In a case series of 672 patients started on sotalol, 7 (1%) developed torsade de pointes, and this complication typically occurred within the first days of starting the xenobiotic.<sup>262</sup> In patients taking sotalol therapeutically, torsade de pointes is most common in those who have kidney failure; use other medications that prolong the QT interval; or have predisposing factors for QT interval prolongation such as hypokalemia, hypomagnesemia, bradycardia, or congenital QT interval prolongation.<sup>53,102</sup> QT interval prolongation is relatively easy to monitor; it is a poor indicator of risk of torsade de pointes. Other ECG findings such as changes in T wave morphology are better indicators of torsade de pointes risk, but identifying these changes requires sophisticated analysis that is not readily available in the clinical setting.<sup>180,240</sup> Sotalol was associated with increased mortality in the SWORD trial, a randomized trial comparing sotalol with placebo for patients with recent MI or remote MI with symptomatic heart failure.<sup>259</sup> The cause of excess mortality in the SWORD trial was assumed to be from dysrhythmias, but that assumption is unproven and has been challenged.<sup>61</sup> Acebutolol also prolongs the QT interval presumably secondary to blockade of outward potassium channels.<sup>149</sup>

### Vasodilation (Betaxolol, Bucindolol, Carteolol, Carvedilol, Celiprolol, Labetalol, and Nebivolol)

Labetalol and some newer  $\beta$ -adrenergic antagonists (betaxolol, bucindolol, carteolol, carvedilol, celiprolol, nebivolol) are also vasodilators. Labetalol and carvedilol are nonselective  $\beta$ -adrenergic antagonists that also possess  $\alpha$ -adrenergic antagonist activity. Nebivolol is a selective  $\beta_1$ -adrenergic antagonist that causes vasodilation by release of nitric oxide.<sup>169</sup> Bucindolol, carteolol, and celiprolol vasodilate because they are agonists at  $\beta_2$ -adrenergic receptors. Celiprolol and carteolol also vasodilate because of nitric oxide-mediated effects. Bucindolol was recently approved while celiprolol are not yet FDA approved. Carteolol is currently available as an ocular preparation. Betaxolol and carvedilol also have calcium channel blocking properties that result in vasodilation (Table 59–1). Despite theoretical advantages,  $\beta$ -adrenergic antagonists with vasodilating properties have not been proven to be more beneficial than other  $\beta$ -adrenergic antagonists for patients with congestive heart failure.<sup>36,203</sup> These xenobiotics also have a theoretical advantage over other  $\beta_2$ -adrenergic agonists for managing hypertension in patients with peripheral vascular disease, but there is very little research on this topic.<sup>194</sup> Xenobiotics with  $\beta_2$ -adrenergic agonist activity are likely safer in patients with reactive airways.

$\beta$ -Adrenergic antagonists should not be given without appropriate  $\alpha$ -adrenergic blockade in situations of catecholamine excess such as pheochromocytoma. In these conditions,  $\beta_2$ -adrenergic-mediated vasodilation is essential to counteract  $\alpha$ -adrenergic-mediated vasoconstriction, and  $\beta$ -adrenergic antagonists result in “unopposed  $\alpha$ -adrenergic effect, causing dangerous increases in vascular resistance.<sup>67,268</sup> Even xenobiotics with combined  $\alpha$ - and  $\beta$ -adrenergic antagonist properties, such as labetalol, can

cause this problem.<sup>69,131</sup> Labetalol, for example, is 5- to 10-fold more potent as a  $\beta$ -adrenergic antagonist than as an  $\alpha$ -adrenergic antagonist.<sup>83</sup> Medications with  $\beta_2$ -adrenergic agonist properties might avoid the “unopposed  $\alpha$  adrenergic” effect, but their use in this situation has not been investigated.

### Other Preparations (Ophthalmic Preparations and Combined Products)

Therapeutic use of ophthalmic solutions containing  $\beta$ -adrenergic antagonists rarely causes systemic adverse effects such as bradycardia, high-grade AV block, heart failure, and bronchospasm.<sup>33,76,179,225,227,258,268</sup>

Several combination tablets containing both  $\beta$ -adrenergic antagonists and thiazide diuretics are available to treat hypertension in the United States. These include atenolol–chlorthalidone, bisoprolol–hydrochlorothiazide, metoprolol–chlorthalidone, metoprolol–hydrochlorothiazide, nadolol–bendroflumethiazide, and propranolol–hydrochlorothiazide.<sup>9</sup> Internationally, products containing  $\beta$ -adrenergic antagonists in combination with calcium channel antagonists are available. These include amlodipine in combination with atenolol, bisoprolol, or metoprolol and nifedipine in combination with acebutolol, atenolol, or metoprolol. None of these products are FDA approved.<sup>8</sup>

### PATHOPHYSIOLOGY

Most of the toxicity of  $\beta$ -adrenergic antagonists is due to their ability to competitively antagonize the action of catecholamines at cardiac  $\beta$ -adrenergic receptors. The peripheral vascular effects of  $\beta$ -adrenergic antagonism are less prominent in overdose.  $\beta$ -Adrenergic antagonists also appear to have toxic effects independent of their action at catecholamine receptors. In catecholamine-depleted, spontaneously beating isolated rat hearts, propranolol, timolol, and sotalol all decreased heart rate and contractility.<sup>58</sup> Surprisingly, these effects were similar in catecholamine-depleted and non-depleted hearts.<sup>137</sup> A membrane-depressant effect likely contributes to the negative inotropic effects of propranolol but not to that of timolol or sotalol. Hence,  $\beta$ -adrenergic antagonists appear to possess myocardial depressant properties that are independent of catecholamine antagonism or membrane depressant activity, possibly because of interference with calcium handling at the level of the SR.<sup>137</sup>

$\beta$ -Adrenergic antagonists also interfere with calcium uptake into intracellular organelles. Interference with cytosolic calcium handling stimulates calcium-sensitive outward potassium channels, resulting in myocyte hyperpolarization and subsequent refractory bradycardia. Lowering extracellular potassium or raising extracellular sodium concentrations was conjectured to counteract this effect and, in fact, partially reversed propranolol and atenolol toxicity in isolated rat hearts.<sup>118</sup> In another series of experiments with isolated rat hearts, calcium improved the function of rat hearts poisoned with  $\beta$ -adrenergic antagonists.<sup>137</sup>

Although cardiovascular effects are most prominent in overdose,  $\beta$ -adrenergic antagonists also cause respiratory depression.<sup>136</sup> This effect is centrally mediated and is an important cause of death in spontaneously breathing animal models of  $\beta$ -adrenergic antagonism toxicity.<sup>138</sup> There is evidence that propranolol is concentrated in synaptic vessels and impairs synaptic function by inhibition of membrane ion pumps, including the  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase, the  $\text{Ca}^{2+}$  ATPase, and the  $\text{Mg}^{2+}$  ATPase pumps. These actions likely explain some of the CNS effects noted in propranolol overdose.<sup>84</sup>

### CLINICAL MANIFESTATIONS

The clinical findings of toxicity generally occur within hours after  $\beta$ -adrenergic antagonist overdose. Propranolol overdose, in particular, is often complicated by the rapid development of hypoglycemia, seizures, coma, and dysrhythmias. In a retrospective review of published report of adult  $\beta$ -adrenergic antagonist overdose, there were 39 symptomatic patients with well-documented times from ingestion to symptom onset. Only 1 patient had ingested a sustained-release product. Thirty-one patients (80%) displayed signs and symptoms of toxicity at 2 hours, all but one (97%) at

4 hours, and everyone within the first 6 hours. The authors conclude that there are no well-documented reports of immediate release  $\beta$ -adrenergic antagonist overdose resulting in toxicity delayed more than 6 hours after ingestion.<sup>148</sup> The authors of an Australian series also noted that in their 58 patients with  $\beta$ -adrenergic antagonist overdose, all major clinical findings of poisoning began within 6 hours of ingestion.<sup>204</sup> These observations do not apply to sotalol, which is well known to cause delayed toxicity in overdose, or to sustained-release preparations of any of the  $\beta$ -adrenergic antagonists.

Isolated  $\beta$ -adrenergic antagonist overdose in healthy people is often benign. In several series, one-third or more of patients reporting a  $\beta$ -adrenergic overdose remained asymptomatic.<sup>63,71,150,243</sup> This is partially explained by the fact that  $\beta$ -adrenergic antagonism is often well tolerated in healthy persons who do not rely on sympathetic stimulation to maintain cardiac output. In particular, unintentional ingestions in children rarely result in significant toxicity.<sup>25</sup> In fact, a review of published cases found a few reports of hypoglycemia but no deaths or serious cardiovascular morbidity after  $\beta$ -adrenergic antagonist ingestion in children younger than the age of 6 years.<sup>158</sup>

$\beta$ -Adrenergic antagonists severely impair the ability of the heart to respond to peripheral vasodilation, bradycardia, or decreased contractility caused by other xenobiotics. Therefore, even relatively benign vasoactive xenobiotics cause catastrophic toxicity when coingested with  $\beta$ -adrenergic antagonists.<sup>78</sup> The most important predictor of toxicity in patients with  $\beta$ -adrenergic antagonist overdose is likely the presence of a cardioactive coingestant.<sup>152</sup> Isolated  $\beta$ -adrenergic antagonist overdose is most likely to cause clinical abnormalities in persons with congestive heart failure, sick sinus syndrome, or impaired AV conduction who rely on sympathetic stimulation to maintain heart rate or cardiac output. Nevertheless, severe toxicity and death occur in healthy persons who have ingested  $\beta$ -adrenergic antagonists alone.<sup>74,204,234</sup> This is explained by an increased susceptibility of certain persons to  $\beta$ -adrenergic antagonism or by special properties that increase the toxicity of certain  $\beta$ -adrenergic antagonists (see later). In patients without a coingestant, toxicity is most likely to occur in those who ingest a  $\beta$ -adrenergic antagonist with membrane-stabilizing activity.<sup>152</sup>

Patients with symptomatic  $\beta$ -adrenergic antagonist overdose are most often hypotensive and bradycardic. Decreased SA node function results in sinus bradycardia, sinus pauses, or sinus arrest. Impaired AV conduction manifested as prolonged PR interval or high-grade AV block occurs rarely. Prolonged QRS complex duration and QT interval duration occur, and severe poisoning results in asystole. Congestive heart failure often complicates  $\beta$ -adrenergic antagonist overdose. Delirium, coma, and seizures occur most commonly in the setting of severe hypotension but also occur with normal blood pressure, especially with exposure to the more lipophilic medications such as propranolol.<sup>74,204</sup> Respiratory depression and apnea may have an additional role in toxicity.<sup>7</sup> In a review of reported cases, 18% of patients with propranolol toxicity and 6% of those with atenolol toxicity had a respiratory rate less than 12 breaths/min.<sup>204</sup> Respiratory depression after  $\beta$ -adrenergic antagonist overdose typically occurs in patients who are hypotensive and comatose but is reported in awake patients.<sup>182</sup> Hypoglycemia often complicates  $\beta$ -adrenergic antagonist poisoning in children<sup>98,158</sup> but is uncommon in acutely poisoned adults. In a series of 15 cases of  $\beta$ -adrenergic antagonist overdose, none of the 13 adults were hypoglycemic, but both of the 2 children had symptomatic hypoglycemia.<sup>74</sup> Bronchospasm is relatively uncommon after  $\beta$ -adrenergic antagonist overdose and appears to occur only in susceptible patients. In the series mentioned, only 2 of the 15 patients developed bronchospasm,<sup>74</sup> and in a review of 39 cases of symptomatic adults with  $\beta$ -adrenergic antagonist overdose, only 1 patient developed bronchospasm.<sup>148</sup> Clinical use of  $\beta$ -adrenergic antagonists slightly increases serum potassium,<sup>159</sup> but significant hyperkalemia is rare.

### $\beta_1$ Selectivity (Acebutolol, Atenolol, Betaxolol, Bisoprolol, Esmolol, Metoprolol, and Nebivolol)

In overdose, cardioselectivity is largely lost, and deaths caused by the  $\beta_1$ -adrenergic selective antagonists, including acebutolol,<sup>96</sup> atenolol,<sup>156</sup> betaxolol,<sup>29</sup> and metoprolol,<sup>209,234</sup> are reported. There are reports of minor toxicity after

acute overdose with bisoprolol<sup>253</sup> and with nebivolol.<sup>95</sup> There is also one report of death after an iatrogenic overdose of bisoprolol in an older adult patient with impaired bisoprolol metabolism.<sup>93</sup>

### Membrane-Stabilizing Effects (Acebutolol, Betaxolol, Carvedilol, Oxprenolol, and Propranolol)

Propranolol possesses the most membrane-stabilizing activity of this class, and propranolol poisoning is characterized by coma, seizures, hypotension, bradycardia, impaired AV conduction, and a widened QRS interval. Ventricular tachydysrhythmias can occur.<sup>5,156</sup> A Brugada pattern on the ECG caused by Na<sup>+</sup> channel blockade or by revealing underlying Brugada syndrome is reported after propranolol overdose.<sup>10,205</sup> Hypotension is often out of proportion to bradycardia, and deaths from propranolol overdose are well reported.<sup>74,96,156</sup> Acebutolol, betaxolol, and oxprenolol also possess significant membrane-stabilizing activity and have caused fatalities when taken in overdose.<sup>29,96,121,191,201</sup>

### Lipid Solubility

In overdose, the more lipophilic  $\beta$ -adrenergic antagonists more often cause delirium, coma, and seizures even in the absence of hypotension.<sup>74,204</sup> Atenolol, the least lipid soluble of  $\beta$ -adrenergic antagonists, appears to be one of the safer  $\beta$ -adrenergic antagonists when taken in overdose.<sup>96</sup> In fact, in one series of  $\beta$ -adrenergic antagonist overdoses, none of the 18 patients with atenolol overdose had seizures compared with 8 of 28 patients with propranolol overdose.<sup>204</sup> Nevertheless, atenolol overdose is reported to result in severe toxicity and cardiovascular death.<sup>156,197,238</sup>

### Intrinsic Sympathomimetic Activity (Acebutolol, Carteolol, Oxprenolol, Penbutolol, and Pindolol)

There is little experience with overdose of these xenobiotics, but ISA would theoretically make these xenobiotics safer than the other  $\beta$ -adrenergic antagonists. Sympathetic stimulation with mild tachycardia or hypertension often predominates in pindolol overdose, and this class of xenobiotics appears to be relatively safe in overdose.<sup>74,130,202</sup> In addition to ISA, acebutolol and oxprenolol have significant membrane-stabilizing activity, making them dangerous in overdose, and deaths due to acute toxicity from these xenobiotics are reported.<sup>74,96,149,201</sup> Overdose with carteolol or penbutolol has not been reported.

### Potassium Channel Blockade (Acebutolol and Sotalol)

In six patients with sotalol overdose, the average QT interval was 172% of normal, and five patients had ventricular dysrhythmias, including multifocal ventricular extrasystoles, ventricular tachycardia, and ventricular fibrillation.<sup>189</sup> Sotalol overdose is also complicated by hypotension, bradycardia, and asystole,<sup>6,189</sup> and fatalities are well documented.<sup>181,196</sup>

Sotalol overdose often causes delayed and prolonged toxicity, although ECG changes appear to occur early. In a series of six patients with sotalol overdose, all had prolonged QT intervals noted on the initial ECG taken 30 minutes to 4.5 hours after ingestion. It is not clear whether these patients were taking sotalol therapeutically before their overdoses, so it is possible that the prolonged QT interval on the initial ECG was present before the overdoses. The greatest QT interval prolongation occurred 4 to 15 hours after ingestion, and the risk of ventricular dysrhythmias was highest between 4 and 20 hours. All four patients who developed ventricular tachycardia did so after 4 hours, and in two patients, ventricular dysrhythmias first occurred 9 hours after ingestion. One patient continued to have ventricular dysrhythmias at 48 hours, and abnormally prolonged QT intervals were noted as long as 100 hours after ingestion. In this series, the average sotalol half-life was 13 hours, and the average time until normalization of the QT interval was 82 hours.<sup>189</sup> Acebutolol-induced QT interval prolongation likely contributes to the ventricular tachydysrhythmias that occur in patients with severe acebutolol toxicity.<sup>62,149,156</sup>

### Vasodilation (Betaxolol, Bucindolol, Carteolol, Carvedilol, Celiprolol, Labetalol, and Nebivolol)

The vasodilatory properties of these xenobiotics should theoretically act in synergy with  $\beta$ -adrenergic antagonism to increase toxicity. Conversely, the

low membrane-stabilizing effect of these xenobiotics would be expected to make them relatively safe in overdose. Betaxolol is the sole medication in this class with membrane-stabilizing properties. Overdose with labetalol appears to be similar to that of other  $\beta$ -adrenergic antagonists with hypotension and bradycardia as prominent features.<sup>124,126,230</sup> Experience with overdose of the newer vasodilating  $\beta$ -adrenergic antagonists is limited. Similar to conventional  $\beta$ -adrenergic antagonists, carvedilol overdose causes hypotension and bradycardia.<sup>32,90,242</sup> In a case report from Germany, nebivolol overdose was complicated by bradycardia, lethargy, and hypoglycemia. The patient received standard treatment and had a benign outcome.<sup>95</sup> Another patient who overdosed on nebivolol became hypotensive and bradycardic and then had a cardiac arrest. That person was successfully resuscitated with lipid emulsion and high-dose insulin.<sup>237</sup> Severe toxicity and death have occurred after betaxolol<sup>29,30</sup> and celiprolol<sup>1213</sup> poisoning. Overdoses with bucindolol or carteolol have not been reported.

### Other Preparations (Ophthalmic Preparations, Sustained Release, and Combined Products)

There is very little published experience with overdoses of the sustained-release  $\beta$ -adrenergic antagonists, but it is reasonable to expect that overdose with these xenobiotics will result in both a delayed onset and prolonged duration of toxicity. Acute overdose of ophthalmic  $\beta$ -adrenergic antagonists has not been reported. Patients who take mixed overdoses with calcium channel antagonists and  $\beta$ -adrenergic antagonists are difficult to manage because of synergistic toxicity.<sup>59,216,224,231,249</sup> Overdoses with combined  $\beta$ -adrenergic antagonist and calcium channel blocker preparations such as felodipine and metoprolol or atenolol and nifedipine have not been reported, but these combinations would be expected to be quite dangerous in overdose.

## DIAGNOSTIC TESTING

All patients with an intentional overdose of a  $\beta$ -adrenergic antagonist require a 12-lead ECG and continuous cardiac monitoring. Serum glucose should be measured regardless of mental status because  $\beta$ -adrenergic antagonists can cause hypoglycemia. A chest radiograph and assessment of oxygen saturation should be obtained if the patient is at risk for or has symptoms of congestive heart failure. Patients with bradycardia of uncertain etiology should have thyroid function, potassium, renal function, and cardiac enzymes measured. Digoxin concentration should be measured for bradycardic patients who have access to digoxin or who have a clinical presentation suggestive of cardioactive steroid poisoning (Chap. 62). Serum concentrations of  $\beta$ -adrenergic antagonists are not readily available for routine clinical use but may prove helpful in making a retrospective diagnosis in selected cases. Lactate concentration should be measured in patients who are symptomatic after a  $\beta$ -adrenergic antagonist overdose. Elevated lactate is associated with increased likelihood of fatality in these patients. However, because  $\beta$ -adrenergic antagonists inhibit the development of hyperlactatemia in the presence of shock, lactate is a poor predictor of survival, and fatalities are reported in  $\beta$ -adrenergic antagonist-poisoned patients with normal or modestly elevated lactate concentrations.<sup>174</sup>

## MANAGEMENT

Airway and ventilation should be maintained with endotracheal intubation if necessary. Because laryngoscopy sometimes induces a vagal response, it is reasonable to give atropine before intubation of patients with bradycardia. This is particularly true for children, who are more susceptible to this complication. The initial treatment of patients with bradycardia and hypotension consists of atropine and intravenous (IV) fluids. These measures will likely be insufficient in patients with severe toxicity but often suffice in patients with mild poisoning or other causes of bradycardia.

Gastrointestinal (GI) decontamination is warranted for all persons who have ingested significant amounts of a  $\beta$ -adrenergic antagonist. Induction of emesis is contraindicated because of the potential for catastrophic deterioration of mental status and vital signs in these patients and because vomiting increases vagal stimulation that could potentially worsen bradycardia.<sup>232</sup>

Orogastric lavage is recommended for patients with significant toxic effects such as seizures, hypotension, or bradycardia if the patient presents in a time frame when the medication is still expected to be in the stomach. Orogastric lavage is also recommended for all patients who present shortly after ingestion of large (gram amount) ingestions of propranolol or one of the other more toxic  $\beta$ -adrenergic antagonists (ie, acebutolol, betaxolol, metoprolol, oxprenolol, sotalol). Orogastric lavage causes vagal stimulation and carries the risk of worsening bradycardia, so it is reasonable to pretreat patients with standard doses of atropine or, at a minimum, be prepared to treat if it develops. Activated charcoal alone is recommended for persons with minor effects after an overdose with one of the more water-soluble  $\beta$ -adrenergic antagonists who present within several hours after ingestion (Antidotes in Depth: A1). Whole-bowel irrigation with polyethylene glycol is reasonable in patients who have ingested sustained-release preparations (Antidotes in Depth: A2).

Seizures or coma associated with cardiovascular collapse is treated by attempting to restore circulation. Seizures in the patient with relatively normal vital signs should be treated with an adequate trial of benzodiazepines followed by barbiturates if benzodiazepines fail. Refractory seizures are rare in patients with isolated  $\beta$ -adrenergic antagonist overdose.

### Specific Management

Patients who fail to respond to atropine and fluids require management with the inotropic agents discussed later (Fig. 59–4). When time permits, it is

preferable to introduce new medications sequentially so that the effects of each may be assessed. The author recommends glucagon followed by calcium and high-dose insulin euglycemia therapy. In critically ill patients, there may not be enough time for this stepwise approach, and multiple treatments may be started simultaneously. If these therapies fail, the author suggests starting a catecholamine pressor. Advanced hemodynamic monitoring, when available, is advisable to guide therapy for all patients receiving catecholamine pressors or phosphodiesterase inhibitors. Lipid emulsion therapy is reasonable in  $\beta$ -adrenergic antagonist–poisoned patients who have cardiovascular collapse unresponsive to other interventions, but caution is warranted given reports of sudden asystole after lipid emulsion in this situation.<sup>49</sup> Mechanical life support with intraaortic balloon pump (IABP) or extracorporeal circulation is recommended when medical management fails.

### Glucagon

Cardiac glucagon receptors, like  $\beta$ -adrenergic receptors, are coupled to  $G_s$  proteins.<sup>264</sup> Glucagon binding increases adenylate cyclase activity independent of  $\beta$ -adrenergic receptor binding.<sup>272</sup> Glucagon's inotropic effect is enhanced by its ability to inhibit phosphodiesterase and thereby prevent cAMP breakdown.<sup>176</sup>

There have been no controlled trials of glucagon in human cases of  $\beta$ -adrenergic antagonist poisoning.<sup>16,34</sup> Nevertheless, with more than 45 years of clinical use,<sup>128,260</sup> glucagon is still recognized as a useful treatment of choice for severe  $\beta$ -adrenergic antagonist toxicity.<sup>117,199,243,266</sup> This is supported by animal models<sup>82,127,155</sup> and a case series suggesting that glucagon is also effective in correcting symptomatic bradycardia and hypotension secondary to therapeutic  $\beta$ -adrenergic antagonist use.<sup>157</sup> Glucagon is a vasodilator, and in animal models of propranolol poisoning, it is more effective in restoring contractility, cardiac output, and heart rate than in restoring blood pressure.<sup>16,155</sup>

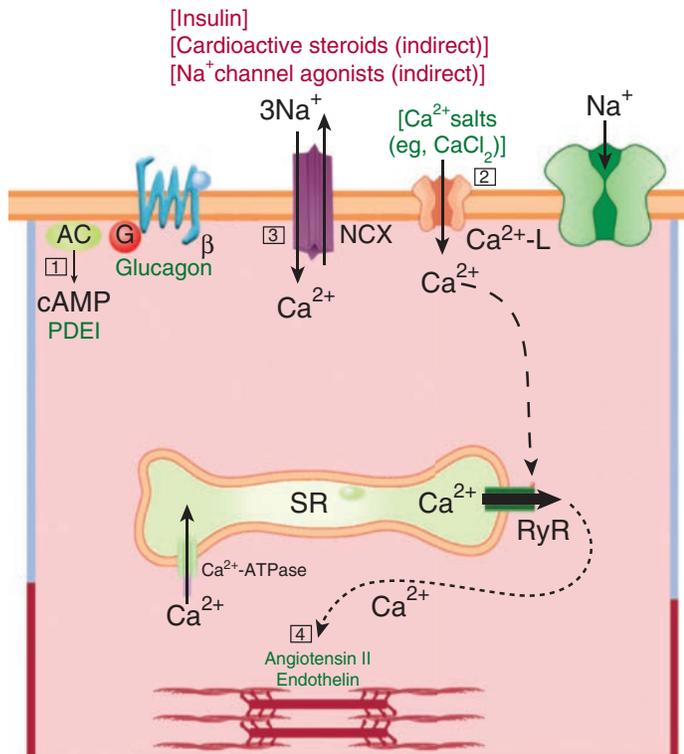

The initial adult dose of glucagon for  $\beta$ -adrenergic antagonist toxicity is 3 to 5 mg given slowly over 1 to 2 minutes. The initial pediatric dose is 50 mcg/kg. If there is no response to the initial dose, titrated doses, up to a cumulative dose of approximately 10 mg, is recommended. When a response occurs, a glucagon infusion is started. It is reasonable to start the glucagon infusion at the “response dose” per hour. Thus, for example, if the patient receives 7 mg of glucagon before a response occurs, the glucagon infusion should be started at 7 mg/h. When a full 10-mg dose of glucagon fails to restore blood pressure and heart rate and the diagnosis of  $\beta$ -adrenergic antagonist toxicity is probable, we still recommends starting an infusion of glucagon at 10 mg/h because glucagon will have synergistic effects with subsequent antidotes. Glucagon sometimes causes vomiting with risk of aspiration, and it is reasonable to pretreat with an antiemetic but to remain cognizant of the fact that many antiemetics cause QT interval prolongation. Other side effects of glucagon in this setting include hyperglycemia and mild hypocalcemia,<sup>107</sup> and these should be treated appropriately if they develop. Patients also develop rapid tachyphylaxis to glucagon, and the need for increasing doses and additional therapies should be expected even when patients initially respond (Antidotes in Depth: A20).

### Calcium

Calcium salts effectively treat hypotension but not heart rate in animal models of  $\beta$ -adrenergic antagonist toxicity.<sup>137,151</sup> Calcium chloride successfully reverses hypotension in patients with  $\beta$ -adrenergic antagonist overdose<sup>37,197</sup> and in combined calcium channel blocker and  $\beta$ -adrenergic antagonist toxicity.<sup>97</sup> The adult starting dose of calcium gluconate is 3 g of the 10% solution given intravenously. For patients with persistent hypotension, the author recommends repeat at this same dose of calcium gluconate every 10 to 20 minutes up to a total of 9 g. The initial dose of calcium gluconate in children is 60 mg/kg up to 3 g followed by repeat boluses every 10 to 20 minutes, as needed for persistent hypotension, up to a total of 180 mg/kg (Antidotes in Depth: A32).

### Insulin and Glucose

High-dose insulin improves cardiac function after cardiac surgery<sup>85</sup> and survival after MI.<sup>68,161,163</sup> There is evidence that high-dose insulin combined with sufficient glucose to maintain euglycemia is beneficial in  $\beta$ -adrenergic

**FIGURE 59–4.** Positive inotropes improve cardiac function by a number of mechanisms, which usually result in increased intracellular  $Ca^{2+}$ . (1) Xenobiotics that increase cyclic adenosine monophosphate (cAMP). Glucagon receptors and  $\beta$ -adrenergic receptors are coupled to  $G_s$  proteins so that receptor binding increases cAMP by activation of adenylate cyclase. Phosphodiesterase inhibitors increase cAMP by inhibiting its breakdown. (2) Xenobiotics that increase calcium influx. Calcium salts increase calcium influx through L-type  $Ca^{2+}$  channels by a direct mass effect. (3) Xenobiotics that inhibit extrusion of calcium via the  $Na^+$ ,  $Ca^{2+}$  exchange pump: Xenobiotics that increase intracellular sodium such as digoxin and  $Na^+$  channel agonists (eg, aconitine) and those such as 4-aminopyridine that prolong the action potential duration alter the electrochemical gradients in a way that hinders the extrusion of calcium. (4) Xenobiotics that increase the sensitivity of the contractile elements to calcium. Angiotensin II and endothelin do this by inducing an intracellular alkalosis. The calcium sensitizers levosimendan and pimobendan are used to treat heart failure in some countries. NCX = the calcium sodium antiporter

antagonist poisoning. In a canine model of propranolol toxicity, all six animals treated with insulin and glucose survived compared with four of six in the glucagon group along with one of six in the epinephrine group and no survivors in the sham treatment group.<sup>120</sup> Insulin plus glucose was markedly more effective than vasopressin plus epinephrine in a porcine model of propranolol toxicity. In that experiment, all five animals in the insulin group survived the 4-hour protocol, and all five in the vasopressin plus epinephrine group died within 90 minutes.<sup>103</sup> In a rabbit model of severe propranolol toxicity, high-dose insulin was more effective than lipid emulsion in restoring blood pressure and heart rate, but there was no difference in survival rate.<sup>91</sup> Clinical experience with high dose insulin for  $\beta$ -adrenergic antagonist poisoning is increasing but still limited to case reports and case series.<sup>65</sup> Improvements in heart rate and blood pressure after high-dose insulin are reported in patients with isolated overdoses of metoprolol, nebivolol, and propranolol.<sup>105,193,237</sup> High-dose insulin was also effective in combined poisoning with  $\beta$ -adrenergic antagonists and calcium channel blockers.<sup>105,273</sup>

High-dose insulin is simple to use and safe (with appropriate monitoring of glucose and potassium) and does not require invasive monitoring. For these reasons, we recommend using high-dose insulin and glucose infusions for patients with  $\beta$ -adrenergic antagonist toxicity who have not responded to fluids, atropine, and glucagon. Although the dose of insulin is not definitively established, therapy typically begins with a bolus of 1 unit/kg of regular human insulin along with 0.5 gm/kg of dextrose. If blood glucose is greater than 300 mg/dL (16.7 mmol/L), the dextrose bolus is not necessary. An infusion of regular insulin should follow the bolus starting at 1 unit/kg/h. A continuous dextrose infusion, beginning at 0.5 gm/kg/h, should also be started. Glucose should be monitored every 15 to 30 minutes until stable and then every 1 to 2 hours and titrated to maintain the blood glucose between 100 and 250 mg/dL. Cardiac function should also be reassessed every 10 to 15 minutes, and if it remains depressed, the insulin infusion should be increased up to 10 units/kg/h as required (rarely higher). The goal of therapy is improved organ perfusion with improvements in cardiac output, mental status, urine output, and acid-base abnormalities. The response to insulin is typically delayed for 15 to 60 minutes, so it will usually be necessary to start a catecholamine infusion before the full effects of insulin are apparent. It is important to continue monitoring glucose and electrolytes for several hours after insulin is discontinued (Antidotes in Depth: A21).

### Catecholamines

Patients who do not respond to the preceding therapies usually require a catecholamine infusion. The choice of catecholamine is somewhat controversial. Theoretically, the pure  $\beta$ -adrenergic agonist isoproterenol would seem to be the ideal agent because it can overcome  $\beta$ -adrenergic blockade without causing any  $\alpha$ -adrenergic effects. Unfortunately, this therapy has several potential drawbacks that limit its efficacy. In the presence of  $\beta$ -adrenergic antagonism, extraordinarily high doses of isoproterenol and other catecholamines are frequently required.<sup>50,201,208,243,256</sup> Individual case reports document isoproterenol infusions as high as 800 mcg/min.<sup>202</sup> At these high doses, the  $\beta_2$ -adrenergic effects of isoproterenol cause peripheral vasodilation and can result in lower blood pressure.<sup>208</sup> Nevertheless, in some animal models, isoproterenol is the most effective catecholamine and is even more effective than glucagon in reversing  $\beta$ -adrenergic antagonist toxicity.<sup>239,263</sup> Clinical experience, however, has not shown this to be the case. In a review of reported cases, glucagon increased heart rate 67% of the time and blood pressure 50% of the time. In contrast, isoproterenol was effective in increasing heart rate only 11% of the time and blood pressure only 22% of the time. Epinephrine was more effective than isoproterenol.<sup>266</sup> The selective  $\beta_1$ -adrenergic agonist prenalterol, which is not FDA approved, may avoid some of the problems associated with isoproterenol and was used successfully to treat  $\beta$ -adrenergic antagonist overdose.<sup>72,130</sup> Prenalterol would be expected to be especially effective after overdose of the cardioselective  $\beta$ -adrenergic antagonists.<sup>72</sup> Prenalterol therapy is limited by its relatively long half-life (~2 hours), which makes titration difficult.<sup>210</sup> Dobutamine is a  $\beta_1$ -adrenergic agonist with relatively little effect on vascular resistance that might be useful in this setting. However,

experience is limited and dobutamine is not always effective in patients with  $\beta$ -adrenergic antagonist overdose.<sup>201,229</sup> In the setting of  $\beta$ -adrenergic antagonism, catecholamines with substantial  $\alpha$ -adrenergic agonist properties can increase peripheral vascular resistance without improving contractility, resulting in acute cardiac failure. Severe hypertension caused by a lack of  $\beta_2$ -adrenergic-mediated vasodilation is another potential adverse reaction from this so-called unopposed  $\alpha$ -adrenergic effect.<sup>79</sup> Because of these potential problems, it is recommended that catecholamine use be guided by hemodynamic monitoring either using noninvasive techniques such as bioimpedance or echocardiographic monitoring or by direct invasive measures of determining cardiac performance. Catecholamine infusions should be started at the usual rates and then increased rapidly until a clinical effect is obtained. If advanced monitoring is impossible and the diagnosis of  $\beta$ -adrenergic antagonist overdose is fairly certain, it is reasonable to begin an isoproterenol or epinephrine infusion with careful monitoring of the patient's blood pressure and clinical status. The infusion should be stopped immediately if the patient becomes more hypotensive or develops congestive heart failure.

### Lipid Emulsion

Lipid emulsion is intravenous has a potential role in selected cases of severe  $\beta$ -adrenergic antagonist overdose. Intravenous administration of lipid emulsion is hypothesized to reduce the toxicity of lipid-soluble xenobiotics by lowering free serum concentrations of these compounds as they partition into the lipemic component of blood and improve the bioenergetics of the heart. Intravenous lipid emulsion was effective in some animal models of poisoning with propranolol, a highly lipid-soluble  $\beta$ -adrenergic antagonist, but not with the water-soluble atenolol or metoprolol.<sup>40,42,43,45,160</sup> Lipid emulsion was less effective than high-dose insulin in restoring heart rate and blood pressure in a rabbit model of propranolol poisoning.<sup>91</sup> Human experience with the use of lipid emulsion in  $\beta$ -adrenergic antagonist overdose is limited largely to case reports, but dramatic recoveries from severe toxicity or cardiac arrest are reported in adults poisoned with  $\beta$ -adrenergic antagonists alone or in combinations with other toxins.<sup>22,44,111,218,237,242,257</sup> There is also a report of improvement after IV lipid emulsion in a case of severe propranolol toxicity in a 7-month-old infant.<sup>250</sup> However, there is a report of two cases of asystole developing immediately after IV lipid emulsion in two cases of  $\beta$ -adrenergic antagonist overdose. The authors postulate that asystole in these cases may have been caused by interaction of lipid emulsion with other resuscitation medications or "brief lack of oxygen in lipid-laden blood."<sup>49</sup> Another concern with using lipid emulsion in severely poisoned patients is that it may cause mechanical problems with the equipment used in extracorporeal membrane oxygenation (ECMO). This has been reported in vitro and clinically when lipid emulsion was used as parenteral nutrition for patients on ECMO but has not been reported in the overdose setting.<sup>140</sup> Given these concerns and limited evidence supporting its efficacy in  $\beta$ -adrenergic antagonist overdose, lipid emulsion should not be used routinely in patients poisoned with  $\beta$ -adrenergic antagonists. It is reasonable to administer lipid emulsion in patients poisoned with a lipid-soluble  $\beta$ -adrenergic antagonist who have cardiac arrest or circulatory failure that does not respond to usual therapy,<sup>45,92</sup> especially if mechanical life support is not promptly available (see later). The optimal dose and formulation of lipid emulsion for this purpose is unknown. One protocol calls for a 1.5 mL/kg of 20% lipid emulsion followed by an infusion of 0.25 mL/kg/min. The bolus can be repeated in 3 to 5 minutes if necessary. The total dose should be less than 8 mL/kg<sup>265</sup> (Antidotes in Depth: A23).

### Phosphodiesterase Inhibitors

The phosphodiesterase inhibitors amrinone, milrinone, and enoximone are theoretically beneficial in  $\beta$ -adrenergic antagonist overdose because they inhibit the breakdown of cAMP by phosphodiesterase and hence increase cAMP independently of  $\beta$ -adrenergic receptor stimulation. Phosphodiesterase inhibitors increase inotropy in the presence of  $\beta$ -adrenergic antagonism in both animal models<sup>141</sup> and in humans.<sup>254</sup> Although these xenobiotics

appear to be as effective as glucagon in animal models of  $\beta$ -adrenergic antagonist toxicity,<sup>155,221</sup> controlled dog models were unable to demonstrate an additional benefit over glucagon.<sup>154,222</sup> Phosphodiesterase inhibitors have been used clinically to treat  $\beta$ -adrenergic antagonist-poisoned patients, but experience is limited.<sup>100,124,219,220</sup> Therapy with phosphodiesterase inhibitors is often limited by hypotension secondary to peripheral vasodilation. Furthermore, these xenobiotics are difficult to titrate because of relatively long half-lives (30–60 minutes for milrinone, 2–4 hours for amrinone, and ~2 hours for enoximone).<sup>115,183</sup> For these reasons, they are not routinely recommended in  $\beta$ -adrenergic antagonist-poisoned patients, especially in patients without arterial and pulmonary artery pressure monitoring.

### Ventricular Pacing

Ventricular pacing is not a particularly useful intervention in patients with  $\beta$ -adrenergic antagonist toxicity, but it will increase the heart rate in some patients.<sup>116</sup> Unfortunately, there will frequently be failure to capture or pacing increases the heart rate with no increase in cardiac output or blood pressure.<sup>5,130,135,243</sup> In fact, some authors have noticed that ventricular pacing occasionally decreases blood pressure perhaps secondary to loss of organized atrial contraction or because of impaired ventricular relaxation.<sup>243</sup> For these reasons, ventricular pacing is not recommended for management of  $\beta$ -adrenergic antagonist toxicity except for heart rate control in patients with an IABP.

### Extracorporeal Removal

Extracorporeal removal is not routinely recommended in patients with  $\beta$ -adrenergic antagonist overdose. It is ineffective for the lipid-soluble  $\beta$ -adrenergic antagonists because of their large volumes of distribution. Hemodialysis does remove water-soluble renally eliminated  $\beta$ -adrenergic antagonists such as atenolol<sup>215</sup> and acebutolol<sup>211</sup> but is often technically difficult in  $\beta$ -adrenergic antagonist-poisoned patients because of hypotension and bradycardia. Extracorporeal removal is reasonable in certain circumstances such as patients with severe toxicity from a water-soluble  $\beta$ -adrenergic antagonist whose blood pressure is maintained with mechanical life support.

### Mechanical Life Support

It is important to remember that a patient with circulatory failure from an acute overdose will typically recover without sequelae if ventilation and circulation are maintained until the xenobiotic is eliminated. When the preceding medical treatment fails, it is recommended to use extracorporeal life support (ECLS). Extracorporeal life support includes venoarterial extracorporeal membrane oxygenation (VA-ECMO), emergency cardiac bypass, IABP, or left ventricular assist devices. Several case reports describe remarkable recoveries after the use of these therapies for refractory  $\beta$ -adrenergic antagonist toxicity<sup>30,66,135,173</sup> or combined  $\beta$ -adrenergic antagonist and calcium channel blocker overdose.<sup>73,108,123,198,214,270</sup> In one report, a neonate who developed refractory circulatory collapse from an iatrogenic overdose of propranolol was supported with VA-ECMO for 5 days and survived neurologically intact.<sup>57</sup> A case series documents experience with ECLS for patients with cardiac arrest caused by cardiovascular medication poisoning. In this series of 6 patients, 2 deaths were attributed to delayed institution of ECLS. The other 4 patients survived without sequelae.<sup>15</sup> In another series, ECLS was used in 17 patients with circulatory failure after an overdose. Eight patients had taken  $\beta$ -adrenergic antagonists either alone or in combination with other cardiovascular toxins. A total of 13 of the 17 patients had long-term survival. The authors conclude that ECLS is efficient and relatively safe as a last resort treatment for patients with cardiac arrest or refractory shock after an overdose.<sup>54</sup> More recently, researchers studied 62 poisoned patients with persistent cardiac arrest or circulatory failure and compared survival in 14 patients treated with ECLS versus 48 managed with conventional therapy. Six patients in the ECLS group and 10 in the conventional therapy group had ingested  $\beta$ -adrenergic antagonists. In this series, 12 of 14 (86%) of the ECLS patients survived compared with 23 of 48 (48%) in the conventional therapy

group. None of the patients with persistent cardiac arrest survived without ECLS. The outcome of the patients poisoned with  $\beta$ -adrenergic antagonists was not reported separately, but the authors commented that these patients had a lower mortality rate and that ECLS was associated with a lower mortality rate after adjusting for  $\beta$ -adrenergic antagonist intoxication.<sup>171</sup> Consistent with several recent reviews of ECLS in poisoned patients,<sup>56,110,192</sup> we recommend that ECLS be used, in centers where it is available, in  $\beta$ -adrenergic antagonist-poisoned patients with persistent cardiac arrest or circulatory failure unresponsive to standard therapy. Given the high risk of complications, including severe bleeding, stroke, and intracranial hemorrhage, ECLS should be reserved for severely poisoned patients who are failing medical therapy. Because there is evidence that lipid emulsion can cause mechanical problems with VA-ECMO circuits,<sup>140</sup> the author suggests that lipid emulsion be withheld and the patient supported with cardiopulmonary resuscitation if ECLS can be initiated promptly.

### Experimental Treatment

Vasopressin is a hypothalamic hormone that acts at G protein-coupled receptors to mediate vasoconstriction (at  $V_1$  receptors), water retention (at  $V_2$  receptors), and corticotropin secretion (at  $V_3$  receptors) and to increase the response to catecholamines. Vasopressin analogues have been used as vasopressors clinically in shock states and for patients in cardiopulmonary arrest.<sup>20,255</sup> Vasopressin was as effective as glucagon but less effective than high-dose insulin in a porcine model of propranolol toxicity.<sup>103,104</sup> Clinical experience with vasopressin in  $\beta$ -adrenergic antagonist poisoning is limited. Vasopressin was used without effect in a patient in cardiac arrest after metoprolol poisoning who subsequently survived after initiation of mechanical life support.<sup>66</sup> The American Heart Association has removed vasopressin from its most recent Adult Cardiac Arrest Algorithm.<sup>188</sup> Methylene blue inhibits guanylate cyclase and acts as a vasoconstrictor. It is reported to reverse refractory vasodilatory shock after cardiac surgery.<sup>178</sup> Methylene blue was used in a patient who had overdosed on atenolol and amlodipine. In that case, calcium, glucagon, high-dose insulin, and three other pressors (dopamine, norepinephrine, and vasopressin) failed to reverse hypotension (mean arterial pressure in the low 40s), but there was a marked improvement in blood pressure 20 minutes after 1 mg/kg of methylene blue was infused over 10 minutes.<sup>4</sup> The routine use of either vasopressin or methylene blue is not recommended in patients with  $\beta$ -adrenergic antagonist poisoning.

The calcium sensitizers levosimendan and pimobendan interact with the contractile proteins to improve cardiac function and are used clinically to treat heart failure.<sup>11,142,143,195</sup> Levosimendan is both a positive inotrope and a vasodilator and has a better safety profile than pimobendan. It is approved in Europe for use in heart failure patients and is as effective as dobutamine in increasing contractility. Levosimendan infusions allow uptitration of  $\beta$ -adrenergic antagonists in patients with severe heart failure.<sup>274</sup> Levosimendan improved survival in a porcine model of propranolol toxicity<sup>144</sup> and improved cardiac output in a murine model of metoprolol toxicity<sup>114</sup> but was not beneficial in a murine model of propranolol toxicity.<sup>113</sup> Calcium sensitizers are not available in the United States or Canada. They may eventually prove to have a role in managing patients poisoned with  $\beta$ -adrenergic antagonists.

Fructose 1, 6-diphosphate (FDP) is an intermediate in the glycolytic pathway. Fructose 1, 6-diphosphate is able to cross cell membranes, and it increases cardiac contractility.<sup>187,246</sup> Compared with glucose infusion, FDP infusion resulted in improved survival in murine models of propranolol toxicity and verapamil toxicity.<sup>112</sup> Fructose 1, 6-diphosphate may eventually prove to have a role in the management of  $\beta$ -adrenergic antagonist poisoning but cannot be recommended at this time.

### Special Circumstances

The preceding discussion applies to the generic management of patients with  $\beta$ -adrenergic antagonists. Certain  $\beta$ -adrenergic antagonists have unique properties that modify their toxicity. The management considerations for these unique agents are discussed next.

### Sotalol

In addition to bradycardia and hypotension, sotalol toxicity results in a prolonged QT interval and ventricular dysrhythmias, including torsade de pointes. Sotalol-induced bradycardia and hypotension should be managed as with other  $\beta$ -adrenergic antagonists. Specific management of patients with sotalol overdose includes correction of hypokalemia and hypomagnesemia. Overdrive pacing and magnesium infusions are recommended for prevention of recurrent episodes in patients who have developed sotalol induced torsade de pointes.<sup>12,252</sup> Lidocaine is also reportedly effective for sotalol-induced torsade de pointes.<sup>14</sup> In the future, potassium channel openers such as the cardioprotective medication nicorandil may prove effective for sotalol-induced torsade de pointes.<sup>228,244,261</sup>

### Peripheral Vasodilation (Betaxolol, Bucindolol, Carteolol, Carvedilol, Celiprolol, Labetalol, and Nebivolol)

Treatment of patients who have overdosed with one of the vasodilating  $\beta$ -adrenergic antagonists is similar to that for patients who ingest other  $\beta$ -adrenergic antagonists. Decisions about the need for vasopressors should be guided by clinical findings. If vasodilation is a prominent feature, then high doses of pressors with  $\alpha$ -adrenergic agonist properties (eg, norepinephrine or phenylephrine) would be reasonable.<sup>99</sup> Conversely, if  $\beta$ -adrenergic antagonism is prominent, glucagon is recommended to increase intracellular cAMP.<sup>95,124</sup>

### Membrane-Stabilizing Effects (Acebutolol, Betaxolol, Carvedilol, Oxprenolol, and Propranolol)

It might be expected that hypertonic sodium bicarbonate would be beneficial in treating the ventricular dysrhythmias that occur with these xenobiotics. Unfortunately, there is limited experience with the use of sodium bicarbonate in this situation, and the experimental data are mixed. Sodium bicarbonate was not beneficial in a canine model of propranolol toxicity, although there was a trend toward QRS complex duration narrowing in the sodium bicarbonate group.<sup>153</sup> In models with propranolol-poisoned isolated rat hearts, however, hypertonic sodium chloride proved beneficial.<sup>118,119</sup> Perhaps most compelling is the fact that sodium bicarbonate appeared to reverse ventricular tachycardia in a human case of acebutolol poisoning.<sup>62</sup> Because sodium bicarbonate is a relatively safe and simple intervention, we recommend that it be used in addition to standard therapy for  $\beta$ -adrenergic antagonist-poisoned patients with QRS duration prolongation, ventricular dysrhythmias, or severe hypotension. Sodium bicarbonate would not be expected to be beneficial in sotalol-induced ventricular dysrhythmias and, by causing hypokalemia, may actually increase the risk of torsade de pointes. The usual dose of hypertonic sodium bicarbonate is 1 to 2 mEq/kg given as an IV bolus. This should either be followed by an infusion or by repeated boluses as needed. Care should be taken to avoid severe alkalosis or hypokalemia (Antidotes in Depth: A5).

### Observation

All patients who have bradycardia, hypotension, abnormal ECGs, or CNS toxicity after  $\beta$ -adrenergic antagonist overdose should be observed in a critical care setting until these findings resolve. Toxicity from regular release  $\beta$ -adrenergic antagonist poisoning other than with sotalol almost always occurs within the first 6 hours.<sup>148,152,204</sup> Therefore, patients without any findings of toxicity after an overdose of a regular release  $\beta$ -adrenergic antagonist other than sotalol can safely be discharged from medical care after an observation time of 6 to 8 hours if they remain asymptomatic with normal vital signs and a normal ECG and have had GI decontamination with activated charcoal. Because ingestion of extended-release preparations is associated with delayed toxicity, these patients should be observed for 24 hours in an intensive care unit. It would also be reasonable to extend the observation period for patients at risk for delayed absorption because of a mixed overdose or underlying GI disease. Sotalol toxicity is sometimes delayed with ventricular dysrhythmias first occurring as late as 9 hours after ingestion.<sup>189</sup> We recommend that all patients with sotalol overdose be monitored for at

least 12 hours. Patients who remain stable without QT interval prolongation can then be discharged from a monitored setting.

### SUMMARY

- $\beta$ -Adrenergic antagonists are commonly used to treat hypertension, angina, tachydysrhythmias, tremor, migraine, and panic attacks.
- Overdoses of  $\beta$ -adrenergic antagonists are relatively uncommon but continue to cause deaths worldwide.
- Patients who develop clinical findings after ingesting regular release  $\beta$ -adrenergic antagonists do so within the first 6 hours. Patients with sotalol ingestions are an exception to this in that sotalol causes delayed and prolonged toxicity. Extended-release formulations also result in delayed toxicity and require 24-hour observation.
- Patients with consequential  $\beta$ -adrenergic antagonist overdose typically develop bradycardia and hypotension.
- Propranolol and other  $\beta$ -adrenergic antagonists with membrane-stabilizing properties and high lipid solubility are the most toxic in overdose. They cause prolongation of the QRS complex, severe hypotension, coma, seizures, and apnea.
- Sotalol and acebutolol are unique in their ability to prolong the QT interval, and sotalol toxicity often results in refractory ventricular dysrhythmias, which should be treated by cardioversion followed by overdrive pacing or magnesium infusion.
- In addition to supportive and symptomatic care, the most important initial therapies for patients with  $\beta$ -adrenergic antagonist toxicity are calcium salts and glucagon if available. High doses of insulin together with glucose is recommended early in the course of treatment if the response to the initial therapy is not rapid and complete. Catecholamine infusions should be closely monitored and large doses are typically required. Patients who fail treatment with glucagon, insulin, and catecholamines are critically ill and may respond to IV lipid emulsion therapy, phosphodiesterase inhibitors, or mechanical support of circulation. Fortunately, most patients respond to simpler measures, and this aggressive therapy is rarely required.

## GLUCAGON

Mary Ann Howland and Silas W. Smith

**INTRODUCTION**

The traditional role of glucagon was to reverse life-threatening hypoglycemia in patients with diabetes unable to receive dextrose in the outpatient setting. However, in clinical toxicology, glucagon is used early in the management of  $\beta$ -adrenergic antagonist and calcium channel blocker toxicity to increase heart rate, contractility, and blood pressure by increasing myocardial cyclic adenosine monophosphate (cAMP) via a non- $\beta$ -adrenergic receptor mechanism of action. The use of glucagon is based primarily on animal studies as well as human case series and case reports. The effects of glucagon are often transient.

**HISTORY**

Glucagon was discovered in 1922, the year after insulin's discovery, when acetone precipitates of pancreatic extracts were found to produce "a distinctly hyperglycemic effect" in animals.<sup>34</sup> Originally viewed as a mere contaminant in insulin products, glucagon was eventually attributed to pancreatic  $\alpha$ -cells and sequenced in 1957.<sup>7,22</sup> The positive inotropic and chronotropic effects of glucagon were recognized in the 1960s.<sup>18,20</sup> Clinical use in human poisonings began in 1971.<sup>39</sup>

**PHARMACOLOGY****Chemistry and Preparation**

Glucagon is a single-chain polypeptide counterregulatory hormone with a molecular weight of 3,500 Da that is secreted by the  $\alpha$ -cells of the pancreas. The previously animal-derived product was possibly contaminated with insulin; the form approved in 1998 by the US Food and Drug Administration (FDA) is synthesized by recombinant DNA technology and thus is free of insulin and the prior phenol preservative.<sup>31,57</sup>

**Mechanism of Action**

In both animals and humans, glucagon receptors are found in the heart, brain, and pancreas.<sup>26,42,90</sup> Binding of glucagon to cardiac receptors is closely correlated with activation of cardiac adenylate cyclase.<sup>68</sup> A large number of glucagon binding sites are demonstrated, and as little as 10% occupancy produces near maximal stimulation of adenylate cyclase. Binding of glucagon to its receptor results in coupling with two isoforms of the  $G_s$  protein and catalyzes the exchange of guanosine triphosphate (GTP) for guanosine diphosphate on the  $\alpha$  subunit of the  $G_s$  protein.<sup>25,67,95</sup> One isoform is coupled to  $\beta$ -adrenergic agonists, and both isoforms are coupled to glucagon.<sup>95</sup> The GTP- $G_s$  units stimulate adenylate cyclase to convert adenosine triphosphate (ATP) to cAMP.<sup>41,51</sup> In animal hearts, glucagon inhibits the phosphodiesterase PDE<sub>3</sub>.<sup>6,56</sup> Selective inhibition of PDE<sub>4</sub> potentiated the cAMP response to glucagon in adult rat ventricular myocytes.<sup>66</sup> Glucagon, along with  $\beta_2$ -adrenergic agonists (not  $\beta_1$ -adrenergic agonists), histamine, and serotonin, also activates  $G_i$ , which inhibits cAMP formation in human atrial heart tissue.<sup>33</sup>

Evidence suggests an additional mechanism of action for glucagon independent of cAMP and dependent on arachidonic acid.<sup>76</sup> Cardiac tissue metabolizes glucagon, liberating mini-glucagon, an active smaller terminal fragment.<sup>76,92</sup> Mini-glucagon stimulates phospholipase A<sub>2</sub>, releasing arachidonic acid. Arachidonic acid acts to increase cardiac contractility through an effect on calcium. The effect of arachidonic acid—and therefore of mini-glucagon—is synergistic with the effect of glucagon and cAMP.<sup>61,75</sup> Stimulation of glucagon receptors in the liver and adipose tissue

increases cAMP synthesis, resulting in glycogenolysis, gluconeogenesis, and ketogenesis.<sup>41</sup> Other properties of glucagon include relaxation of smooth muscle in the lower esophageal sphincter, stomach, small and large intestines, common bile duct, and ureters.<sup>21,25,64</sup>

**Cardiovascular Effects**

Investigations of the mechanism of action of glucagon on the heart were performed on cardiac tissue obtained from patients during surgical procedures and in a variety of in vivo and ex vivo animal studies. The results are often species specific and are affected by the presence or absence of congestive heart failure. The inotropic action of glucagon is related to an increase in cardiac cAMP concentrations.<sup>18,41,51</sup> Glucagon increases cAMP to augment the sarcoplasmic reticulum calcium pool.<sup>16</sup> Glucagon improves chronotropy at both the sinus node and the atrioventricular (AV) junctional region, even in the presence of escape rhythms.<sup>57</sup> Both the positive inotropic and chronotropic actions of glucagon are very similar to those of the  $\beta$ -adrenergic agonists, except that they are not blocked by  $\beta$ -adrenergic antagonists.<sup>5,16,18,20,36,49,51,59,64,93,95</sup> Glucagon also improves coronary blood flow.<sup>3</sup> Although in some canine experiments, glucagon caused ventricular tachycardia, glucagon is not dysrhythmogenic in patients with severe chronic congestive heart failure or myocardial infarction-related acute congestive heart failure or in postoperative patients with myocardial depression.<sup>31,44,50,53</sup> The effects of glucagon diminish markedly as the severity and chronicity of congestive heart failure increases.<sup>59</sup>

**Pharmacokinetics and Pharmacodynamics**

The volume of distribution of glucagon is 0.25 L/kg.<sup>57</sup> The plasma, liver, and kidney extensively metabolize glucagon with an elimination half-life of 8–18 minutes.<sup>57</sup> In human volunteers, after a single IV bolus, the cardiac effects of glucagon begin within 1 to 3 minutes, is maximal within 5 to 7 minutes, and persists for 10 to 15 minutes.<sup>59</sup> The time to maximal glucose concentration is 5 to 20 minutes, with a duration of action of 60 to 90 minutes.<sup>57</sup> Smooth muscle relaxation begins within one minute and lasts 10 to 20 minutes.<sup>57</sup> The onset of action after intramuscular and subcutaneous administration occurs in about 10 minutes, with a peak at about 30 minutes.<sup>57</sup> Activation of adenylate cyclase in adipose, myocardial, and hepatic tissue and myocardial contractility requires pharmacologic concentrations of glucagon greater than 0.1 nM.<sup>68</sup> At physiologic concentrations of glucagon of less than 0.1 nM, glucagon enhances the cardiac metabolic effects of insulin by activating a phosphatidylinositol-3 kinase (PI3K)-dependent signal without stimulating adenylate cyclase.<sup>68</sup> Tachyphylaxis (desensitization of receptors) may occur with repetitive dosing. Experimental heart preparations exposed to glucagon for varying lengths of time demonstrated a decrease in the amount of generated cAMP.<sup>28,96</sup> Possible explanations for tachyphylaxis include uncoupling from the glucagon receptor, increased PDE hydrolysis of cAMP, or both.<sup>28,92,96,99</sup> Other experiments demonstrated a limited effect of glucagon on contractility and hyperglycemia, suggesting tachyphylaxis.<sup>24,32</sup>

**Volunteer Studies**

Cardiovascular effects were extensively studied in 21 patients with heart failure who were given varied doses and durations of glucagon therapy.<sup>60</sup> Eleven patients who received 3 to 5 mg via intravenous (IV) bolus had increases in the force of contraction, as measured by maximum dP/dT (upstroke pattern on apex echocardiogram), heart rate, cardiac index, blood pressure, and stroke

work. There were no changes in systemic vascular resistance, left ventricular end-diastolic pressure, or stroke index. Additionally, glucose concentrations increased by 50%, and the potassium concentrations fell. A study of nine patients demonstrated a 30% increase in coronary blood flow after a 50-mcg/kg IV dose.<sup>53</sup> Patients who received 1 mg via IV bolus also had an increase in cardiac index, but systemic vascular resistance fell, probably secondary to splanchnic and hepatic vascular smooth muscle relaxation.<sup>60</sup> Patients who received an infusion of 2 to 3 mg/min for 10 to 15 minutes responded similarly to those who received the 3- to 5-mg IV boluses, but patients receiving boluses experienced significant dose-limiting nausea and vomiting.<sup>60</sup>

### ROLE IN THE MANAGEMENT OF $\beta$ -ADRENERGIC ANTAGONIST TOXICITY

$\beta$ -adrenergic antagonist toxicity is manifested by hypotension, bradycardia, prolonged AV conduction times, depressed cardiac output, and cardiac failure. Other noncardiovascular effects include alterations in consciousness; seizures; and, rarely, hypoglycemia.<sup>1,19,23,91</sup> Original management of  $\beta$ -adrenergic antagonist toxicity included provision of large doses of competitive  $\beta$ -agonists such as isoproterenol.<sup>38</sup> Glucagon was found superior to this approach in animal evaluations and human cases.<sup>14,38,39,62,94</sup> Animal studies document the ability of glucagon to increase contractility, restore the sinus node function after sinus node arrest, increase AV conduction, and rarely improve survival.<sup>4,46,59,74</sup> Glucagon successfully reversed bradycardias and hypotension in patients unresponsive to the aforementioned traditional xenobiotics and is recommended for administration early in the management of patients with severe toxicity.<sup>72,89</sup> By increasing myocardial cAMP concentrations independent of the  $\beta$  receptor, glucagon is able to increase both inotropy and chronotropy.<sup>5,20,46,49,58,59,93</sup>

Glucagon successfully reversed the bradycardia, low-output heart failure, and hypotension that developed in a premature newborn, presumably as a result of an inappropriately large prenatal dose of labetalol given to the mother. This neonate, delivered at 32 weeks' gestation and weighing 1.8 kg, received 0.3 mg/kg of glucagon IV initially and five additional doses of 0.3 to 0.6 mg/kg over the next 5 hours, with improvement in heart rate, blood pressure, and perfusion. Epinephrine and diuretics were also used.<sup>81</sup> Other case reports, case series, and reviews document full or partial beneficial hemodynamic response to glucagon administration in  $\beta$ -adrenergic antagonist toxicity, although at times, it has yielded no effect.<sup>47,54,80</sup> Because the management of  $\beta$ -adrenergic antagonist toxicity is often complicated, many other therapies, including atropine, epinephrine, norepinephrine, dopamine, dobutamine, and various combinations are used with variable success.<sup>19,37</sup> High-dose insulin (HDI) (Antidotes in Depth: A21) and lipid emulsion (Antidotes in Depth: A23) were added to the available therapeutic interventions. In canine studies, HDI therapy has a more sustained effect on hemodynamic parameters and an improved survival rate compared with glucagon.<sup>26</sup> We recommend HDI early in the resuscitation of severe  $\beta$ -adrenergic antagonist overdoses with myocardial depression.

Glucagon was used to improve blood pressure in cases of anaphylactic shock refractory to epinephrine in patients on  $\beta$ -adrenergic antagonists.<sup>85</sup> A small pretreatment study demonstrated a survival advantage of glucagon over epinephrine in anaphylaxis induced in guinea pigs that were pretreated with propranolol.<sup>79</sup> In addition to previously described mechanisms of action, glucagon decreases histamine release and concentrations, increases nitric oxide release, and prevents the increased release of free radicals during ex vivo animal models of anaphylaxis.<sup>2,43,69</sup> We recommend glucagon use in refractory anaphylaxis in patients taking  $\beta$ -adrenergic antagonists.<sup>8,30</sup>

### Combined Effects with Phosphodiesterase Inhibitors and Calcium

Previous strategies for enhancing the effects of glucagon have involved combining it with the PDE<sub>3</sub> inhibitor amrinone (inamrinone), its derivative milrinone, and the now discontinued selective PDE<sub>4</sub> inhibitor rolipram. In a canine model of propranolol toxicity, both amrinone and milrinone alone were comparable to glucagon,<sup>46,73</sup> but the combination of amrinone and glucagon

resulted in a decrease in mean arterial pressure.<sup>45</sup> Tachycardia occurred when milrinone was used with glucagon.<sup>74</sup> In an ex vivo model using strips of rat ventricular heart, rolipram enhanced the inotropic effect of glucagon and limited glucagon tachyphylaxis.<sup>28</sup> Although the evidence for the effectiveness of combining glucagon with a PDE inhibitor was demonstrated in animal models and human case reports, we recommend against the use of this approach. The relationship between calcium and the chronotropic effects of glucagon was demonstrated in rats.<sup>11</sup> Maximal chronotropic effects of glucagon are dependent on a normal circulating ionized calcium. Both hypocalcemia and hypercalcemia blunt the maximal chronotropic response.<sup>10,11</sup>

### ROLE IN CALCIUM CHANNEL BLOCKER TOXICITY

Calcium channel blocker toxicity produces a constellation of clinical findings similar to those recognized with  $\beta$ -adrenergic antagonist toxicity, including hypotension, bradycardia, conduction block, and myocardial depression. Animal studies demonstrate the ability of glucagon to improve heart rate and AV conduction and reverse the myocardial depression produced by nifedipine, diltiazem, and verapamil.<sup>4,27,71,82,83,86,97,98</sup> However, there was no survival benefit attributed to glucagon in these studies, and a canine model of verapamil toxicity comparing glucagon to HDI only revealed a survival benefit for HDI.<sup>4,35</sup> Human case reports demonstrate improved hemodynamics, including in cases refractory to other standard measures. Therefore, it is reasonable to continue glucagon therapy while preparing for HDI utilization.<sup>13,17,52,58,80,88</sup>

### ROLE IN OTHER CARDIOVASCULAR TOXINS

A bolus of glucagon followed by infusion significantly increased the mean arterial pressure and decreased the QRS complex duration in amitriptyline-poisoned rats.<sup>29</sup> In human pediatric and adult cases of cyclic antidepressant overdoses refractory to multiple measures, glucagon produced immediate hemodynamic improvement.<sup>70,77,78,80</sup> Sodium bicarbonate (Antidotes in Depth: A5) remains the treatment of choice for cyclic antidepressant poisoning followed by other treatment strategies outlined in Chap. 68. Glucagon should be a reasonable therapeutic option if appropriate therapeutic use of sodium bicarbonate fails to improve the hemodynamic status.

### ROLE IN REVERSAL OF HYPOGLYCEMIA

Glucagon was once proposed as part of the initial treatment for all comatose patients because it stimulates glycogenolysis in the liver.<sup>65</sup> The theoretical rationale for this approach is only partially sound in that glucagon requires time to act and will often be ineffective in a patient with depleted glycogen stores, such as in patients with prolonged fasting, severe liver disease, alcoholism, starvation, adrenal insufficiency, or chronic hypoglycemia.<sup>15,57</sup> Patients with type 2 diabetes are more likely to respond than are patients with type 1 diabetes. The IV administration of 0.5 to 1.0 g/kg of 50% dextrose in adults rapidly reverses hypoglycemia and does not rely on glycogen stores for its effect. Therefore, IV dextrose is preferred over glucagon as the initial substrate to be given to all patients with an altered mental status presumed to be related to hypoglycemia (Antidotes in Depth: A8). Glucagon is reasonable as a temporizing measure, until medical help can be obtained, in the home where IV dextrose is not an option or when IV access is not rapidly available. In patients with an insulinoma, after an initial hyperglycemic response to glucagon, an increase in insulin will exacerbate the hypoglycemia.<sup>55</sup>

### ADVERSE EFFECTS AND SAFETY ISSUES

Side effects associated with glucagon include dose-dependent nausea, vomiting, hyperglycemia, hypoglycemia, and hypokalemia; relaxation of the smooth muscle of the stomach, duodenum, small bowel, and colon; and, rarely, urticaria, respiratory distress, and hypotension.<sup>50,57</sup> Hypotension is reported up to 2 hours after administration in patients receiving glucagon as premedication for upper gastrointestinal (GI) endoscopy procedures.<sup>57</sup> Hyperglycemia is followed by an immediate rise in insulin, which causes an intracellular shift in potassium, resulting in hypokalemia.<sup>24,50,59</sup> It is unclear whether stimulation of the Na<sup>+</sup>,K<sup>+</sup>-ATPase in skeletal muscle also contributes

to the hypokalemia as occurs with  $\beta$ -adrenergic agonists.<sup>35,40,63</sup> Glucagon increases the anticoagulant effect of warfarin.<sup>57</sup>

Glucagon also increases the release of catecholamines in a patient with a pheochromocytoma, resulting in a hypertensive crisis,<sup>24</sup> which is treated with phentolamine.<sup>57</sup> Continuous prolonged exposure to glucagon in a patient with a glucagonoma led to a reversible dilated cardiomyopathy.<sup>9</sup> The smooth muscle relaxation associated with a continuous infusion might impede attempts at GI decontamination with multiple-dose activated charcoal or whole-bowel irrigation.

## PREGNANCY AND LACTATION

Glucagon is FDA Pregnancy Category B. It is presumed that benefit exceeds risk. There are no reports of glucagon use during lactation. However, the size and peptide nature of glucagon suggest that the exposure to a lactating infant would be limited.

## DOSAGE AND ADMINISTRATION

The dosing regimen for glucagon administration in toxicologic emergencies has never been formally studied and is based on case reports. Intravenous infusion of an initial dose of 50 mcg/kg (3-5 mg in a 70 kg adult) over 3 to 10 min is recommended and likely minimizes nausea and vomiting. If the initial dose is inadequate, a higher dose (up to 10 mg) is recommended.<sup>26</sup> Using too small a dose can potentially decrease systemic vascular resistance.<sup>60</sup> The effect of glucagon is often transient. We recommend either repeat doses of 3 to 5 mg as needed or a continuous infusion of 2 to 5 mg/h (10 mg/h or less) in 5% dextrose in water to be tapered as the patient improves and allows time for HDI to become effective.<sup>1,21,22,47,54,65</sup> Experimental heart preparations clearly demonstrate tachyphylaxis with continuous infusion, but whether this occurs in humans is unclear.<sup>28,96</sup>

## FORMULATION AND ACQUISITION

Glucagon (rDNA origin) for injection is available as a sterile, lyophilized white powder in a vial alone or accompanied by sterile water for reconstitution, also in a vial. It is also supplied in the form of a kit for treatment of hypoglycemia with one vial containing 1 mg (1 unit) of glucagon (rDNA origin) for injection with a disposable prefilled syringe containing sterile water for reconstitution, as well as a "10-pack" with 10 vials, each containing 1 mg (1 unit of glucagon {rDNA origin} for injection). The glucagon powder should be reconstituted with 1 mL of sterile water for injection, after which the vial should be shaken gently until the powder completely dissolves. The final solution should be clear, without visible particles.<sup>57</sup> The reconstituted glucagon should be used immediately after reconstitution and any unused part discarded. Concentrations greater than 1 mg/mL should not be used. An adequate supply of glucagon in the emergency department is at least 20 (1-mg) vials, with assurance of another 90 mg for up to 8 hours of therapy (Special Considerations: SC1).<sup>12,48</sup> Severe cases requiring prolonged infusions have exhausted local supplies.<sup>84</sup> The use of HDI has reduced the need for prolonged glucagon administration.

## SUMMARY

- Glucagon produces positive inotropic and chronotropic effects despite  $\beta$ -adrenergic antagonism and calcium channel blockade.
- Glucagon is often beneficial in the treatment of patients with severe  $\beta$ -adrenergic antagonist and calcium channel blocker toxicity.
- The effects of glucagon are not persistent, and other therapies, such as HDI, are recommended (Chaps. 59 and 60 and Antidotes in Depth: A21).
- The relatively benign character of an IV bolus of glucagon in the patient with a serious  $\beta$ -adrenergic antagonist or calcium channel blocker toxicity should lead the clinician to use glucagon early in patient management.
- Rapid administration of glucagon results in nausea and vomiting will limit the adverse effects. Diminishing the initial dose, rate of infusion, or both will limit the adverse effects.

# CALCIUM CHANNEL BLOCKERS

David H. Jang

## HISTORY AND EPIDEMIOLOGY

In 1964, Albrecht Fleckenstein described an inhibitory action of verapamil and prenylamine on excitation–contraction coupling that was similar to calcium depletion.<sup>3</sup> By the late 1970s, the clinical use of calcium channel blockers (CCBs) was widely accepted for a variety of cardiovascular indications, including hypertension, dysrhythmias, and angina. Later indications for the use of CCBs include Raynaud phenomenon and disease, migraine and cluster headaches and subarachnoid hemorrhage.<sup>1</sup> There are currently 10 individual CCBs marketed in the United States that are available as immediate- or sustained-release formulations and as combination products with other antihypertensives.<sup>31</sup>

The cardiovascular drug class is one of the leading classes of drugs associated with poisoning fatality. Over the past 5 years of available data, there were more than 12 million poisonings with more than 7,000 poisoning-related deaths reported to the American Association of Poison Control Centers National Poisons Data System (NPDS). Cardiovascular drugs were involved in more than 400,000 of the reported poisonings and accounted for nearly 15% of the overall poisoning fatalities. Within this class, CCBs were the most common cardiovascular drugs involved in poisoning fatalities. Calcium channel blockers accounted for more than 50,000 cases reported over the past 5 years, with more than 300 cases resulting in major effects and more than 100 deaths (Chap. 130).<sup>15,16,77,78</sup> There is a bimodal distribution within the pediatric population that involves unintentional exposures in young infants and toddlers with intentional ingestions in teenagers.<sup>40</sup>

## PHARMACOLOGY

Calcium ( $\text{Ca}^{2+}$ ) ion channels exist as either voltage-dependent or ligand-gated channels. There are many types of voltage-gated  $\text{Ca}^{2+}$  channels that include P-, N-, R-, T-, Q-, and L-type channels (Table 60–1). Ligand-gated  $\text{Ca}^{2+}$  channels include  $\text{IP}_3$  and ryanodine receptors, which are found intracellularly and play a critical role in cell signaling. Voltage-gated  $\text{Ca}^{2+}$  channels are located throughout the body in the heart, nervous system, pancreas, and muscles.<sup>106</sup> Voltage-gated  $\text{Ca}^{2+}$  channels are composed of several components, including  $\alpha_1$ ,  $\beta$ ,  $\delta$ , and the ion-conducting  $\alpha_1$ -subunit. The  $\alpha_1$ -subunit is the most important component of the  $\text{Ca}^{2+}$  channel because it contains the actual pore through which  $\text{Ca}^{2+}$  ions pass, and it also serves as the binding

site of all CCBs. The other subunits such as  $\beta$  and  $\delta$  act to modulate the function of the  $\alpha_1$ -subunit.<sup>79,122</sup>

The primary action of all CCBs available in the United States is antagonism of the L-type or “long-acting” voltage-gated  $\text{Ca}^{2+}$  channels. Calcium channel blockers are often classified into three groups based on their chemical structure (Table 60–2).<sup>41,71,79</sup> A fourth class, the diarylamino-propylamines included mibefradil, but this drug was withdrawn because of significant adverse drug interactions.<sup>114</sup> Each group binds a slightly different region of the  $\alpha_{1c}$  subunit of the  $\text{Ca}^{2+}$  channel and thus has different affinities for the various L-type  $\text{Ca}^{2+}$  channels, both in the myocardium and the vascular smooth muscle.<sup>18</sup> It is often more logical to classify them as nondihydropyridine versus dihydropyridine CCBs. Whereas the former includes verapamil and diltiazem, the latter includes many drugs, the chemical names of which all currently end in –pine, such as nifedipine and amlodipine. Verapamil and diltiazem have inhibitory effects on both the sinoatrial (SA) and atrioventricular (AV) nodal tissue and thus are commonly used for the treatment of hypertension, to reduce myocardial oxygen demand, and to achieve rate control in a variety of tachydysrhythmias. In contrast, the dihydropyridines have very little direct effect on the myocardium at therapeutic doses and act primarily as peripheral vasodilators.<sup>122</sup> They are therefore commonly used as vasodilators for conditions with increased vascular tone such as hypertension, migraine headaches, and postintracranial hemorrhage–associated vasospasm. Dihydropyridines bind to a site that is formed by amino acid residues in two adjacent S6 segments plus the S5 segment between them, and in some cases, enantiomeric pairs are activators or inhibitors, respectively, indicating that very subtle changes in the drug–receptor interaction are sufficient to convert from agonist to antagonist action.<sup>64</sup>

Experimental studies suggest an additional vasodilatory effect of some CCBs caused by stimulation of nitric oxide release. Amlodipine and other dihydropyridine CCBs release nitric oxide in a dose-dependent fashion from canine coronary microvessels.<sup>127–129</sup> Although the exact mechanism is uncertain, it is hypothesized that this amlodipine-induced nitric oxide production results from increasing endothelial nitric oxide synthase activity through phosphorylation of this enzyme. Bradykinin  $\text{B}_2$  receptors also contribute to vasodilation. Bradykinin is a vasodilator that exerts its action by causing endothelial release of prostacyclin, nitric oxide, and endothelium-derived hyperpolarizing factor.<sup>128</sup>

**TABLE 60–1 Voltage-Gated Calcium Channel Subtypes**

Type	Distribution	Function	Blocked By
T (transient)	Polysynaptic nerve terminals and cardiac nodal tissue	Pacemaker activity	Mibefradil
R	Neural tissue	Neurotransmitter release	Cadmium
Q	Presynaptic nerve terminals	Neurotransmitter release	Agatoxin
P (Purkinje)	Cerebellar Purkinje neurons	Neurotransmitter release	Agatoxin
N (neuronal)	Presynaptic nerve terminals	Catecholamine release	$\omega$ -Conotoxin
L (long-acting)	Myocardium and smooth muscle	Muscular contraction	Verapamil, diltiazem, dihydropyridines

Class	Specific Compounds	Volume of Distribution (L/kg)	Time to Peak* Concentrations (h)
Phenylalkylamine	Verapamil	3–5	1–2
Benzothiazepine	Diltiazem	5.3	2–4
Dihydropyridines	Amlodipine	21	6–12
	Clevidipine	0.17	<1
	Felodipine	10	2.5–5
	Isradipine	3	1–2
	Nicardipine	8.3	1–4
	Nifedipine	0.75	2.5–5
	Nimodipine	2	1–2
	Nisoldipine	1.6	>6

\*All are oral ingestion of an immediate release formulation: at therapeutic doses.

## PHARMACOKINETICS AND TOXICOKINETICS

### Absorption

All CCBs are well absorbed orally, but many exhibit low bioavailability because of extensive hepatic first-pass metabolism. When the CCBs reach the liver, they undergo hepatic oxidative metabolism predominantly via the CYP3A4 subgroup of the enzyme system.<sup>76</sup>

### Distribution

All CCBs are highly protein bound which limits the role of extracorporeal removal. Volumes of distribution are large for amlodipine (21 L/kg), verapamil (3–5 L/kg), and diltiazem (5.3 L/kg) and somewhat smaller for nifedipine (0.75 L/kg).<sup>47,84</sup>

### Metabolism

Norverapamil, formed by *N*-demethylation of verapamil, is the only active metabolite and retains 20% of the activity of the parent compound. Diltiazem is predominantly deacetylated into minimally active deacetyldiltiazem, which is then eliminated via the biliary tract.<sup>48,57</sup> After repeated doses, as well as after overdose, these hepatic enzymes become saturated, reducing the potential of the first-pass effect and increasing the quantity of active drug absorbed systemically.<sup>124</sup> Saturation of metabolism as well as the modified-release dosage form contribute to the prolongation of the apparent half-lives reported after overdose of various CCBs.<sup>95</sup>

### Excretion

The CCBs undergo a significant, but variable, amount of renal excretion after metabolism with a small percentage eliminated in the urine unchanged. For example, amlodipine undergoes 60% renal excretion after metabolism to inactive metabolites compared with 70% for verapamil (3.4% as unchanged drug) and 90% for nifedipine as inactive metabolites.<sup>34,80</sup>

One interesting aspect of the pharmacology of CCBs is their potential for drug–drug interactions. CYP3A4, which metabolizes most CCBs, is also responsible for the initial oxidation of numerous other xenobiotics. Verapamil and diltiazem specifically compete for this enzyme and can decrease the clearance of many drugs, including carbamazepine, cisapride, quinidine, various  $\beta$ -hydroxy- $\beta$ -methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors, cyclosporine, tacrolimus, most human immunodeficiency virus–protease inhibitors, and theophylline (Chap. 11 and Appendix).<sup>39,92</sup> In June 1998, mibefradil, a structurally unique CCB, was voluntarily withdrawn after several reports of serious adverse xenobiotic interactions caused in part by its potent inhibition of CYP3A4.<sup>66</sup> Other inhibitors of CYP3A4, such as cimetidine, fluoxetine, some antifungals, macrolide antibiotics, and even the flavonoids in grapefruit juice, raise serum concentrations of several CCBs, which results in toxicity.<sup>38,102</sup>

In addition to affecting CYP3A4, verapamil and diltiazem also inhibit P-glycoprotein–mediated drug transport into peripheral tissue that results in elevated serum concentrations of xenobiotics such as cyclosporine and digoxin that use this transport system (Chap. 11 and Appendix). Unlike diltiazem and verapamil, nifedipine and the other dihydropyridines do not appear to affect the clearance of other xenobiotics via CYP3A4 or P-glycoprotein–mediated transport. Similarly, inhibition of P-glycoprotein–mediated transport by certain xenobiotics such as statins result in increased oral bioavailability of CCBs, which requires closer outpatient follow-up for the development of bradycardia or hypotension.

## PHYSIOLOGY AND PATHOPHYSIOLOGY

Calcium plays an essential role in many cellular processes throughout the body, and many types of cells depend on the maintenance of a  $\text{Ca}^{2+}$  concentration gradient across cell membranes in order to function. The extracellular  $\text{Ca}^{2+}$  concentration is approximately 10,000 times greater than the intracellular concentration. This concentration gradient is important for contraction and relaxation of muscle cells (Fig. 60-1).  $\text{Ca}^{2+}$  channels and various exchange pumps located on the cell membrane play a key role in maintaining this concentration gradient within muscle cells.<sup>59,81</sup>

Calcium is driven down a large electrical and concentration gradient through L-type  $\text{Ca}^{2+}$  channels located in all muscle cell types (cardiac, striated, and smooth). This influx of  $\text{Ca}^{2+}$  is critical for the function of both cardiac and smooth muscle cells; however, skeletal muscle depends primarily on intracellular  $\text{Ca}^{2+}$  stores for excitation–contraction coupling and not the intracellular influx of  $\text{Ca}^{2+}$ . In smooth muscle, the rapid influx of  $\text{Ca}^{2+}$  binds calmodulin, and the resulting complex stimulates myosin light chain kinase activity. The myosin light chain kinase phosphorylates, and thus activates, myosin, which subsequently binds actin, causing contraction.<sup>74</sup>

Calcium plays a similarly important role in myocardial contractility. In myocardial cells,  $\text{Ca}^{2+}$  influx is slower relative to the initial  $\text{Na}^{+}$  influx that

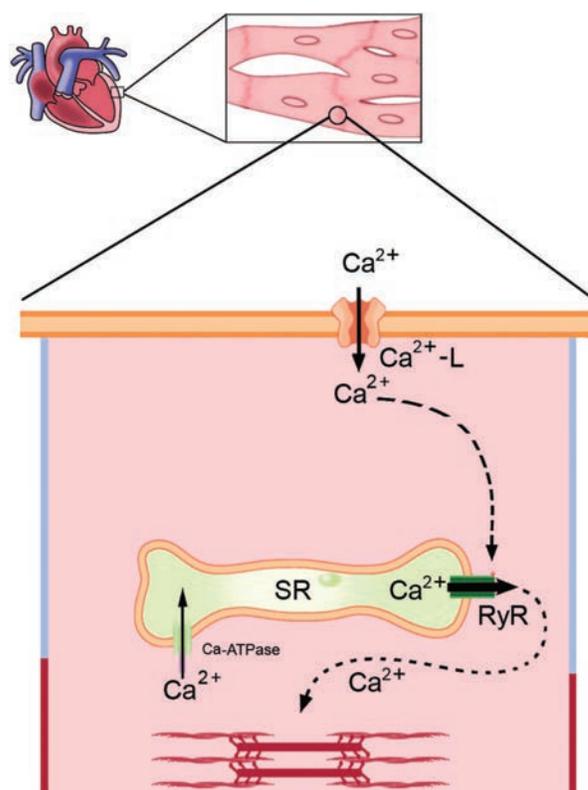

FIGURE 60-1. Normal contraction of myocardial cells. The L-type voltage-gated  $\text{Ca}^{2+}$  channels (Cav-L) open to allow  $\text{Ca}^{2+}$  ion influx during myocyte depolarization. This causes the concentration-dependent release of more  $\text{Ca}^{2+}$  ions from the ryanodine receptor (RyR) of the sarcoplasmic reticulum (SR).

initiates cellular depolarization and prolongs this depolarization, creating the plateau phase (phase 2) of the action potential (Chap. 15 and Fig. 15–2). The  $Ca^{2+}$  subsequently stimulates a receptor-operated  $Ca^{2+}$  channel on the sarcoplasmic reticulum (SR), known as the ryanodine receptor, releasing  $Ca^{2+}$  from the vast stores of the SR into the cytosol.<sup>87</sup> This is often termed *Ca<sup>2+</sup>-induced Ca<sup>2+</sup> release*. Calcium then binds troponin C, which causes a conformational change that displaces troponin and tropomyosin from actin, allowing actin and myosin to bind, resulting in a contraction.<sup>19,28</sup> Calcium influx is also plays important in the spontaneous depolarization (phase 4) of the action potential in the SA node. This  $Ca^{2+}$  influx also allows normal propagation of electrical impulses via the specialized myocardial conduction tissues, particularly the AV node. After opening, the rates of recovery of these slow  $Ca^{2+}$  channels, in both the SA and AV nodal tissue, determine the rate of conduction.

The nondihydropyridine CCBs such as verapamil and diltiazem have the greatest affinity for the myocardium, with verapamil considered the most potent. In addition, not only do verapamil and, to a lesser extent, diltiazem impede  $Ca^{2+}$  influx and channel recovery in the myocardium, but their blockade is also potentiated as the frequency of channel opening increases. Dihydropyridines are modulated by the membrane potential and calcium channel blockade is more pronounced when current is measured from depolarized holding potentials as opposed to verapamil; where this voltage-dependent block occurs in the absence of repetitive depolarizations.<sup>44,89</sup> Therefore, in frequently contracting tissue, such as myocardium, the blockade of verapamil and diltiazem is augmented. Verapamil and diltiazem are therefore commonly used for controlling the ventricular rate in patients with atrial tachydysrhythmia.

At therapeutic doses, the dihydropyridine CCBs such as nifedipine have little effect at the myocardium and have most of their effect at the peripheral vascular tissue; thus, they have the most potent vasodilatory effects compared with the nondihydropyridine CCBs. Dihydropyridines bind the  $Ca^{2+}$  channel best at less-negative membrane potentials. Because the resting potential for myocardial muscle (–90 mV) is lower than that of vascular smooth muscle (–70 mV), dihydropyridines bind preferentially in the peripheral vascular tissue.<sup>89</sup>

The toxicity of CCBs is largely an extension of their therapeutic effects within the cardiovascular system. Inhibition of the L-type  $Ca^{2+}$  channels within both the myocardium and peripheral vascular smooth muscle results in a combination of decreased inotropy and heart rate, as well as arterial vasodilation. Because dihydropyridines have limited myocardial effect at therapeutic concentrations, the baroreceptor reflex remains intact, and slight increases in heart rate and cardiac output often occur. Isradipine is the only dihydropyridine whose inhibitory effect on the SA node is significant enough to blunt any reflex tachycardia. Calcium channel blocker poisoning also results in blockade of L-type  $Ca^{2+}$  channels located in the pancreas. This results in decreased insulin release, resulting in hyperglycemia.

## CLINICAL MANIFESTATIONS

The hallmarks of CCB poisoning are hypotension and bradycardia, which result from depression of myocardial contraction and peripheral vasodilation.<sup>100</sup> Myocardial conduction is impaired, producing AV conduction abnormalities, idioventricular rhythms, and complete heart block, most commonly with nondihydropyridine poisoning. Junctional escape rhythms occur in patients with significant poisonings.<sup>13,45,51,91,125</sup> The negative inotropic effects are often so profound, particularly with verapamil, that ventricular contraction is completely ablated.<sup>5,9,11,23</sup>

Hypotension is the most common and life-threatening finding in acute CCB poisoning, caused by a combination of decreased inotropy, bradycardia, and peripheral vasodilation.<sup>93</sup> Patients can present asymptotically early after ingestion and subsequently deteriorate rapidly to severe cardiogenic shock.<sup>5,9,54</sup> The associated clinical findings reflect the degree of cardiovascular compromise and hypoperfusion, particularly to the central nervous system. Early symptoms include fatigue, dizziness, and lightheadedness. Alteration in mentation in the absence of hypotension should

prompt the clinician to evaluate for other causes and ingestions. Severely poisoned patients manifest syncope, altered mental status, coma, and sudden death.<sup>97,101</sup> Gastrointestinal (GI) effects, such as nausea and vomiting, are not a typical feature of CCB poisoning. Acute respiratory distress syndrome (ARDS) is also described with severe CCB poisoning. This is due to precapillary vasodilation with a subsequent increase in transcapillary pressure. The elevated pressure gradient results in increased capillary transudates and possible interstitial edema.<sup>33,53</sup>

In mild to moderate overdose of dihydropyridine CCBs, the predominantly peripheral effect induces a reflex tachycardia. However, severe poisoning with any CCBs can result in loss of receptor selectivity, resulting in bradycardia. A prospective poison control center study noted AV nodal block to occur more frequently with verapamil poisoning.<sup>94</sup> Although deaths are attributed mainly to the nondihydropyridines, a significant number of dihydropyridine-related deaths are also reported, which likely reflects the wider use of dihydropyridine CCBs.<sup>94,107</sup>

Several factors ultimately determine CCB toxicity. These include medication formulation, dose, and coingestion with other cardioactive medications such as  $\beta$ -adrenergic antagonists, underlying comorbidities, and age. Older adult patients and those with underlying cardiovascular disease such as congestive heart failure are more sensitive to CCBs.<sup>75</sup> Even at therapeutic doses, these patients are more susceptible to the cardioactive effects of these medications and develop symptomatic hypotension.

Pediatric cases of CCB overdose commonly result from medication errors or unwitnessed ingestions of pills found at home.<sup>12,40</sup> Children with CCB poisoning can develop nonspecific clinical effects such as lethargy, emesis, and confusion. Although CCB poisoning in children is uncommon, there are reported cases of severe poisoning and death.<sup>107</sup>

## DIAGNOSTIC TESTING

All patients with suspected CCB poisoning should be considered at risk for cardiovascular collapse and be evaluated with a 12-lead electrocardiogram (ECG) followed by continuous cardiac and hemodynamic monitoring. A chest radiograph, pulse oximetry, end-tidal carbon dioxide ( $EtCO_2$ ), and serum chemistry should also be obtained if any degree of hypoperfusion is suspected. Assessment of electrolytes, including magnesium, and a serum digoxin concentration in a bradycardic patient with unknown exposure history are indicated, although a careful history, if possible, may narrow down the etiology. Cardioactive steroids should be a consideration in a patient with undifferentiated bradycardia with hyperkalemia but are less likely in the setting of hypotension. Assays for CCB serum concentrations are not routinely available and therefore have no role in the management of patients poisoned with CCBs.

Hyperglycemia is considered a prognostic sign in cases of severe CCB poisoning. The release of insulin from the  $\beta$ -islet cells in the pancreas is dependent on  $Ca^{2+}$  influx through the L-type  $Ca^{2+}$  channel. Calcium channel blocker poisoning reduces insulin release with resultant hyperglycemia. An additional mechanism also includes dysregulation of the insulin-dependent phosphatidylinositol-3 kinase (PI3K) pathway.<sup>11</sup> It should be noted that hyperglycemia might also be the result of diabetes or the administration of glucagon for suspected  $\beta$ -adrenergic antagonist poisoning. A retrospective study suggests that serum glucose concentration correlated with the severity of nondihydropyridine CCB poisoning. The initial mean serum glucose concentration was 188 mg/dL in patients who met a composite endpoint of requiring vasopressors, a pacemaker, or death versus 122 mg/dL in those not requiring intervention. Peak serum glucose concentrations were also significantly different.<sup>69</sup> This finding is interpreted to be an early sign of severity and an indicator for when to initiate high dose insulin (HDI) (Antidotes in Depth: A21) therapy.

## MANAGEMENT

### Overview

All patients with suspected CCB poisoning should undergo prompt evaluation even when the initial vital signs are normal. This urgency is due to the

potential to initiate early GI decontamination and pharmacologic therapies before patients manifest severe poisoning. This is particularly important with ingestions involving sustained-release formulations. Intravenous (IV) access should be obtained, and initial treatment should be directed toward aggressive GI decontamination of patients with large recent ingestions. All patients who become hypotensive should initially receive a fluid bolus of 10 to 20 mL/kg of crystalloid. This is repeated as needed with constant monitoring of volume status with repeat serial examinations for volume overload. Caution is required because aggressive fluid resuscitation should not be given to patients with congestive heart failure, evidence of ARDS, or chronic kidney disease. Although there are currently both outpatient and inpatient consensus guidelines in the management of CCB poisoning, there is still no clear pathway for treatment, and the inpatient guidelines are too ambiguous for clinicians unfamiliar with this type of poisoning to be useful.<sup>82,108</sup>

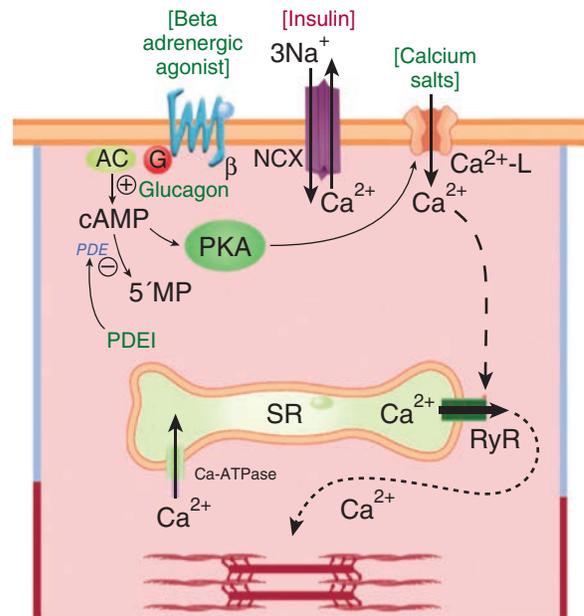

Pharmacotherapy should focus on maintenance or improvement of both cardiac output and peripheral vascular tone. Although atropine, calcium, insulin, glucagon, isoproterenol, dopamine, epinephrine, norepinephrine, and phosphodiesterase (PDE) inhibitors have been used with reported success in CCB-poisoned patients, no single intervention has consistently demonstrated efficacy. It is also important to be aware that certain treatments such as vasopressors are detrimental with long-term use, so these should be avoided when there are more effective and safer treatment options.

Although therapy for hypotension and bradycardia should begin with crystalloids and atropine, most critically poisoned patients do not respond to these initial efforts and require further pharmacotherapy. Although it would be ideal to initiate each therapy individually and monitor the patient's hemodynamic response, in the most critically ill patients, multiple therapies are administered simultaneously. A reasonable treatment sequence based on existing data and clinical experience should initially consist of isotonic fluids, atropine, calcium, and glucagon (Antidotes in Depth: A20). If the patient does not respond to these initial treatments, HDI therapy should be initiated. Because the onset of effect of HDI is delayed for 15 to 40 minutes and given the relative safety of its use, earlier initiation is preferable. The use of vasopressors such as norepinephrine or dopamine can result in tissue ischemia with long-term use and thus should be avoided, when possible, in favor of HDI therapy. Phosphodiesterase inhibitors such as inamrinone, milrinone, and enoximone have been used to treat patients with CCB poisoning.<sup>65,98,121</sup> These xenobiotics inhibit the breakdown of cyclic adenosine diphosphate (cAMP) by PDE inhibition, thereby increasing intracellular cAMP concentrations, resulting in increased cardiac output. Despite some reported success, PDE inhibitors are not readily available, other xenobiotics are more effective and easier to use and we do not recommend routine use (Fig. 60-2).

### Gastrointestinal Decontamination

Because CCB poisoning is a leading cause of poisoning fatality, attempts to prevent absorption from the GI tract are recommended, assuming there are no contraindications for the described techniques in this chapter. This is particularly important if sustained-release CCBs are suspected. Patients who present early with minimal or no symptoms can have delayed cardiovascular toxicity, which can be profound and refractory to conventional treatment, making early GI decontamination a cornerstone in CCB management.

We recommend that all patients with CCB ingestions should receive 1 g/kg of activated charcoal (AC) orally or via nasogastric tube as long as the airway is stable or protected. Multiple-dose activated charcoal (MDAC) (0.5 g/kg every 4–6 hours) without a cathartic is reasonable for nearly all patients with either sustained-release pill ingestions or signs of continuing absorption. Although data are limited, there is no evidence that MDAC increases CCB clearance from the serum.<sup>95</sup> Rather, its efficacy is a result of the continuous presence of AC throughout the GI tract, which adsorbs any active xenobiotic from its slow-release formulation. Multiple-dose activated charcoal should not be administered to a patient with inadequate GI function (eg, hypotension, diminished peristaltism sounds (Antidotes in Depth: A1).

**FIGURE 60-2.** Myocardial toxicity of calcium channel blockers (CCBs) and use of antidotal therapies. Calcium channel blockers reduce calcium ion influx through the L-type  $\text{Ca}^{2+}$  channel ( $\text{Ca}^{2+}$ -L) and thus reduce contractility. The entry of calcium via voltage-gated channels ( $\text{Ca}^{2+}$ -L) initiates a cascade of events that result in actin–myosin coupling and contractions. Mechanisms to increase intracellular  $\text{Ca}^{2+}$  include recruitment of new or dormant  $\text{Ca}^{2+}$  channels by increasing cyclic adenosine monophosphate (cAMP) by stimulating its formation by adenylate cyclase (AC) with glucagon (see text). The use of calcium salts may increase the  $[\text{Ca}^{2+}]$  gradient across the cellular membrane to further its influx and improve contractility. The mechanism by which insulin therapy enhances inotropy is not fully known.  $5'\text{MP}$  = 5'-monophosphate;  $\text{NCX}$  =  $\text{Ca}^{2+}$ ,  $\text{Na}^{+}$  antiporter;  $\text{PDEI}$  = phosphodiesterase inhibitor;  $\text{PKA}$  = protein kinase A;  $\text{RyR}$  = ryanodine receptor;  $\text{SR}$  = sarcoplasmic reticulum.

Orogastric lavage is recommended for all patients who present early (1–2 hours postingestion) after large ingestions and for those who are critically ill and require immediate endotracheal intubation, although the effects of orogastric lavage after overdose of a sustained-release CCB are not specifically studied. When performing orogastric lavage in a CCB-poisoned patient, it is important to remember that lavage increases vagal tone and potentially exacerbates any bradydysrhythmias; we routinely pretreat with atropine.<sup>111</sup> It is important to note that although AC is less invasive than lavage, orogastric lavage followed by AC may be more practical in critically ill patients who are intubated.<sup>68,110</sup>

Whole-bowel irrigation (WBI) with polyethylene glycol solution (1–2 L/h orally or via nasogastric tube in adults, up to 500 mL/h in children) is recommended for patients who ingest sustained-release products and for whom there are no contraindications. Although the benefit is uncertain, in patients with severe poisoning. The risk of WBI is limited in these cases. It should be continued until the rectal effluent is clear (Antidotes in Depth: A2).<sup>17,24</sup>

### Atropine

Atropine is often first-line therapy for patients with symptomatic bradycardia from xenobiotic poisoning such as organic phosphorus compounds,  $\beta$ -adrenergic antagonists, and CCBs. Although the use of atropine improved both heart rate and cardiac output in an early dog model of verapamil poisoning and a few patients with bradycardia from CCB poisoning,<sup>37,94</sup> reports of patients with severe CCB poisoning demonstrate atropine to be largely ineffective.<sup>56,90,105</sup> The decreased effectiveness is largely due to the negative inotropic effects or peripheral vasodilation of CCBs. Given its availability, familiarity, efficacy in mild poisonings, and safety profile, atropine is recommended as initial therapy in patients with symptomatic bradycardia.

### Dose

The dosing of atropine for xenobiotic induced bradycardia is similar to the dose used for Advanced Cardiac Life Support. Dosing should begin with 0.5 to 1.0 mg (minimum of 0.1 mg in children >5 kg; 0.02 mg/kg in children) intravenously every 2 or 3 minutes up to a maximum dose of 3 mg in all patients with symptomatic bradycardia. However, treatment failures should be anticipated in severely poisoned patients and other therapies such as calcium and glucagon should be administered. In patients in whom WBI or MDAC will be used, the use of atropine should also be administered particularly if increased vagal tone is apparent.

### Calcium

Calcium is another treatment often used for CCB poisoning to increase extracellular  $\text{Ca}^{2+}$  concentration with an increase in transmembrane concentration gradient. Pretreatment with IV  $\text{Ca}^{2+}$  prevents hypotension without diminishing the antidysrhythmic efficacy before therapeutic verapamil use in reentrant supraventricular tachydysrhythmias.<sup>29,104</sup> This also is observed with CCB poisoning in which  $\text{Ca}^{2+}$  tends to improve blood pressure more than heart rate. Experimental models demonstrate the utility of  $\text{Ca}^{2+}$  salts with CCB poisoning. In verapamil-poisoned dogs, improvement in inotropy and blood pressure was demonstrated after increasing the serum  $\text{Ca}^{2+}$  concentration by 2 mEq/L with an IV infusion of 10% calcium chloride ( $\text{CaCl}_2$ ) at 3 mg/kg/min.<sup>37,45</sup>

Clinical experience demonstrates that  $\text{Ca}^{2+}$  reverses the negative inotropy, impaired conduction, and hypotension in many humans poisoned by CCBs.<sup>67,72,95</sup> Unfortunately, this effect is often short lived, and more severely poisoned patients do not improve significantly with  $\text{Ca}^{2+}$  administration alone.<sup>22,56,99</sup> Although some authors believe that these failures might represent inadequate dosing, optimal effective dosing of  $\text{Ca}^{2+}$  is unclear, and they recommend repeat doses of  $\text{Ca}^{2+}$  to markedly increase the serum ionized  $\text{Ca}^{2+}$  concentrations.<sup>51,67</sup> The excessive use of  $\text{Ca}^{2+}$  can result in significant complications such as vasoconstriction and renal failure, particularly if a  $\text{Ca}^{2+}$  infusion is used.<sup>103</sup> Caution should be exercised in the administration of  $\text{Ca}^{2+}$  in patients suspected of an acute cardioactive steroid poisoning as a cause of their bradycardia.<sup>14</sup> The use of  $\text{Ca}^{2+}$  in the setting of cardioactive steroid poisoning is reported to result in cardiac complications such as dysrhythmia (Chap. 62).

### Dose

For poisoned adults, an initial IV infusion of approximately 13 to 25 mEq of  $\text{Ca}^{2+}$  (10–20 mL of 10%  $\text{CaCl}_2$  or 30–60 mL of 10%  $\text{Ca}^{2+}$  gluconate) is given over 10 minutes followed by repeat doses every 10 minutes up to two doses then every 20 to 60 minutes as needed. It is important to monitor  $[\text{Ca}^{2+}]$  every 30 to 60 minutes (Antidotes in Depth: A32). Careful selection and attention to the type of  $\text{Ca}^{2+}$  used is critical for dosing. Although there is no difference in efficacy of  $\text{CaCl}_2$  or calcium gluconate, 1 g of  $\text{CaCl}_2$  contains 13.4 mEq of  $\text{Ca}^{2+}$ , which is about three times the 4.65 mEq found in 1 g of calcium gluconate. Thus, to administer equal doses of  $\text{Ca}^{2+}$ , three times the volume of calcium gluconate compared with that of  $\text{CaCl}_2$  is required. The main limitation of using  $\text{CaCl}_2$ , however, is that it has significant potential for causing tissue injury if extravasated we recommend administration through a central venous line, intraosseous line or peripheral line if no other route is accessible. Adverse effects of IV  $\text{Ca}^{2+}$  include nausea, vomiting, flushing, constipation, confusion, hypercalcemia, and hypophosphatemia.

### Glucagon

Glucagon is an endogenous polypeptide hormone secreted by the pancreatic  $\alpha$  cells in response to hypoglycemia and catecholamines. In addition, it has significant inotropic and chronotropic effects (Antidotes in Depth: A20).<sup>20,21,109,126</sup> Glucagon is a therapy of choice for  $\beta$ -adrenergic antagonist poisoning (Chap. 59) because of its ability to bypass the  $\beta$ -adrenergic receptor and activate adenylate cyclase via a  $G_s$  protein in the myocardium.<sup>123</sup> Thus, glucagon is unique in that it is functionally a “pure”  $\beta_1$  agonist, with no peripheral vasodilatory effects (Fig. 60–2). Although there are reports of both successes and failures of glucagon in CCB-poisoned patients who failed

to respond to fluids,  $\text{Ca}^{2+}$ , or dopamine and dobutamine, the authors recommend a trial of glucagon.<sup>23,30,46,56</sup>

### Dose

Dosing for glucagon is not well established.<sup>6</sup> An initial dose of 3 to 5 mg IV, slowly over 3 to 5 minutes and if there is no hemodynamic improvement within 5 minutes, and retreatment with a dose of 4 to 10 mg is effective. The initial pediatric dose is 50 mcg/kg. Because of the short half-life of glucagon, repeat doses are often required. A maintenance infusion should be initiated after a desired effect is achieved. Adverse effects include vomiting and hyperglycemia, particularly in patients with diabetes or during continuous infusion. In other models repeat administration leads to tachyphylaxis, which is an acute decrease in response to a drug after repeated administration.

### High-Dose Insulin Therapy

High-dose insulin (HDI) therapy is the treatment of choice for patients who are severely poisoned by CCBs. The mechanisms of action for HDI are varied and include utilization of free fatty acids for myocardial metabolic needs; CCB poisoning forces the myocardium to become more carbohydrate dependent.<sup>60,61,63</sup> At the same time, CCBs inhibit  $\text{Ca}^{2+}$ -mediated insulin secretion from the  $\beta$ -islet cells in the pancreas, making glucose uptake in myocardial cells dependent on passive diffusion down a concentration gradient rather than insulin-mediated active transport.<sup>27</sup> In addition, there is evidence that the CCB-poisoned myocardium also becomes insulin resistant, possibly by dysregulation of the PI3K pathway (Antidotes in Depth: A21). This prevents normal recruitment of insulin-responsive glucose transporter proteins. The combination of inhibited insulin secretion and impaired glucose utilization may explain why severe CCB toxicity often produces significant hyperglycemia.<sup>61,62</sup> However, the current accepted mechanism is that insulin impairs the  $\text{Na}^+$ - $\text{Ca}^{2+}$  antiporter, resulting in an increase in the intracellular  $[\text{Ca}^{2+}]$ . This increase of calcium results in an increase in the  $\text{Ca}^{2+}$  load from the SR, leading to increased cardiac contractility.<sup>52,113</sup>

Many CCB-poisoned patients have been successfully treated with HIE therapy as demonstrated by improved hemodynamic function, mainly resulting from improved contractility, with little effect on heart rate. There are also reports of the failure of this treatment, but this represents initiation of therapy in terminally ill patients with multiple organ failure and delayed initiation of treatment.<sup>35</sup>

### Dose

We recommend to begin therapy with a bolus of 1 unit/kg of regular human insulin along with 0.5 g/kg of dextrose. If blood glucose is greater than 300 mg/dL (16.65 mmol/L), the dextrose bolus is unnecessary. An infusion of regular insulin should follow the bolus starting at 1 units/kg/h titrated up to 2 units/kg/h if there is no improvement after 30 minutes. Even higher doses (10 units/kg h) of insulin have been successfully reported, and we recommend escalating to this dose if 1 to 2 units/kg/h is not successful.<sup>32</sup> A continuous dextrose infusion, beginning at 0.5 g/kg/h, should also be started. Glucose should be monitored every 30 minutes for the first 4 hours and titrated to maintain euglycemia. The response to insulin is typically delayed for 15 to 40 minutes, so early use of HDI should be initiated very early in the patient's course if severe CCB poisoning is suspected. Primary complications of HDI include hypoglycemia and hypokalemia from intracellular shifting of potassium. It is essential to note that the development of hypoglycemia is an indication to increase glucose delivery rather than decrease the insulin infusion rate. The blood glucose should be monitored every 15 to 30 minutes until stable and then every 1 to 2 hours. Kidney failure will alter the pharmacokinetics of insulin elimination and we recommend closer glucose monitoring and to use the dosing of insulin as recommended. Concentrating the insulin infusion to 10 units/mL prevents fluid overload from large doses of insulin.

### Intravenous Lipid Emulsion

The use of intravenous lipid emulsion (ILE) as an antidote is best studied for the treatment of local anesthetic systemic toxicity with expanded use for the treatment of nonlocal anesthetic overdose such as with CCBs. Xenobiotics

that are highly lipophilic may benefit more from the use of ILE in severe poisoning (Antidotes in Depth: A23).

There is controversy whether ILE is a valuable treatment for CCB poisoning because of inconsistent reported outcomes.<sup>43</sup> Existing experimental evidence supports that ILE decreases the toxicity of several intravenously administered lipid-soluble drugs, most notably bupivacaine.<sup>117,118</sup> Pretreatment with ILE also increased the dose of certain medications to cause toxicity, but its generalizability to CCBs is debatable.<sup>119</sup>

Intravenous lipid emulsion was used on a patient with severe verapamil poisoning who failed Ca<sup>2+</sup> and HDI but when given ILE showed improvement and survival. Serum verapamil concentrations were measured before and after ILE treatment. There was a decrease in verapamil after ILE administration after the lipid was removed from the samples, which demonstrate sequestration of verapamil.<sup>35</sup> However, there are also reports that ILE enhances intestinal absorption of other xenobiotics and lacks clinical benefit.<sup>85,86</sup> Intravenous lipid emulsion has the potential for interfering with the circuitry of extracorporeal membrane oxygenation (ECMO), and it is not clear what interaction ILE has on other medications being used as treatment. The Lipid Emulsion Workgroup is composed of representatives of all major toxicology associations' published evidence-based recommendations in which ILE was recommended for cardiac arrest from bupivacaine toxicity. At this time, the Workgroup's evidence-based recommendation on the use of ILE in CCB poisoning state that in the setting of life-threatening and non-life-threatening CCB poisoning, ILE should not be used as first-line therapy. The use of ILE is reasonable for CCB induced severe cardiovascular toxicity that persists despite maximal treatment with standard resuscitative measures (including GI decontamination) and ECMO and other ECLS are not available.<sup>42,43</sup>

### Adjunctive Pharmacologic Treatment

Other pharmacotherapies are studied in the setting of CCB poisoning. There are limited data with these therapies, and therefore we do not recommend routine use. Digoxin was evaluated experimentally in CCB poisoning because it raises the intracellular Ca<sup>2+</sup> concentration.<sup>8</sup> In a canine model of verapamil poisoning, digoxin, in conjunction with atropine or Ca<sup>2+</sup>, improved both systolic blood pressure and myocardial inotropy.<sup>7</sup> However, because digoxin requires a significant amount of time to distribute into tissue and because limited efficacy data and no safety data have yet been collected, we do not recommend use of digoxin in CCB poisoning. Another xenobiotic that was used as a treatment for CCB poisoning is levosimendan. Levosimendan is a Ca<sup>2+</sup> sensitizer used in the management of acutely decompensated congestive heart failure. Although there are reported cases of success with the use of this drug, there is also existing experimental evidence that does not support its use.<sup>2,83,112</sup>

Methylene blue (Antidotes in Depth: A43) was reported in a confirmed ingestion of amlodipine poisoning in a patient who failed conventional therapy, including HIE treatment. A Swan-Ganz catheter confirmed pure vasodilatory shock, which responded to methylene blue (2 mg/kg).<sup>56</sup> Methylene blue is also reported with success in a case of a mixed  $\beta$ -adrenergic antagonist and CCB overdose,<sup>4</sup> and it is used in other causes of refractory vasodilatory shock such as anaphylaxis and sepsis caused by inhibition of methylene blue along the nitric oxide–cyclic guanosine monophosphate pathway and contributes electrons to mitochondrial glycerophosphate dehydrogenase to improve mitochondrial respiration. Experimental evidence also shows improvement in hemodynamics with no change in mortality rate.<sup>55</sup> Some evidence suggests that certain dihydropyridines, such as amlodipine mediate, their vasodilatory effects via nitric oxide, but the importance of this pathway in acute poisoning is unclear. Further investigation is required before methylene blue can routinely be recommended in patients with CCB poisoning.<sup>115</sup>

### Inotropes and Vasopressors

Catecholamines are often administered after first-line therapy such as atropine, Ca<sup>2+</sup>, glucagon, and isotonic fluids fail. There are numerous cases that describe either success or failure with various inotropes and vasopressors, including epinephrine, norepinephrine, dopamine, isoproterenol,

dobutamine, and vasopressin.<sup>22,46,50,73</sup> Based on experimental and clinical data, no single inotrope or vasopressor is consistently effective. The variability in response is from the differences of CCB involved, coingestants with other cardioactive medications, and patient response. Calcium channel blocker poisoning often involve the myocardium (verapamil and diltiazem) resulting in negative chronotropy or inotropy or peripheral smooth muscle relaxation (dihydropyridines) with vasodilation mediated by  $\alpha_1$ -adrenergic receptors. In a retrospective study in a series of patients with nondihydropyridine poisoning, they were managed with the use of multiple vasopressors and without HDI in all but three cases. Despite high doses of vasopressors, ischemic complications were uncommon and were attributed to the hypotension related to the poisoning. In this study, the use of vasopressors after nondihydropyridine poisoning was associated with good clinical outcomes.<sup>70</sup> Despite variable success in CCB poisoning, the existing data described previously show that all vasopressors are generally inferior with significantly more adverse effects such as tissue ischemia with long-term use. The authors therefore recommend avoiding their use if possible or using as a bridge to HDI.

### Adjunctive Hemodynamic Support

The most severely CCB-poisoned patients will not respond to any pharmacologic intervention. Transthoracic or IV cardiac pacing is reasonable to improve heart rate, as several case reports demonstrate.<sup>105,116</sup> However, in a prospective cohort of CCB poisonings, two of four patients with significant bradycardia requiring electrical pacing had no electrical capture.<sup>93</sup> In addition, even if electrical pacing is effective in increasing the heart rate, blood pressure often remains unchanged.<sup>49,50</sup>

Intraaortic balloon pump (IABP) is another invasive supportive option that is reasonable to attempt in CCB poisoning refractory to pharmacologic therapy.<sup>58</sup> Because IABPs are ECG gated, in patients with very low heart rates, IABP is often not effective with increasing cardiac output with counterpulsation. Insertion of an IABP successfully improved cardiac output and blood pressure in a patient with a mixed verapamil and atenolol overdose.<sup>36</sup>

Severely CCB-poisoned patients have also been supported for days and subsequently recovered fully with much more invasive and technologically demanding ECMO and emergent open and percutaneous cardiopulmonary bypass.<sup>49,96</sup> Extracorporeal membrane oxygenation has been increasingly used in pharmacology-refractory CCB poisoning.<sup>26,120</sup> The advantage of ECMO over IABP is that it is independent of cardiac electrical and mechanical activity. There are currently two ECMO modalities available, which include venovenous EMCO (VV-EMCO) and venoarterial ECMO (VA-EMCO). Venovenous-extracorporeal membrane oxygenation is used primarily for patients with refractory respiratory failure and is not adequate in shock from severe CCB poisoning. Venoarterial-extracorporeal membrane oxygenation is recommended in severe circulatory shock. Reported complications of VA-EMCO include bleeding at the cannulation site, leg ischemia, and clotting of the machine circuitry, especially if ILE is given.<sup>10,25</sup>

Molecular adsorbents recirculating system (MARS) therapy is a specific extracorporeal albumin dialysis that is reported in the treatment of patients with severe CCB poisoning. Molecular adsorbents recirculating system therapy has the unique ability to selectively remove from circulation protein-bound xenobiotics that are not cleared by conventional hemodialysis. The use of MARS therapy is under current investigation with *Amanita* poisoning but reportedly was successfully used in three patients with severe nondihydropyridine CCB poisoning.<sup>88</sup> Despite potential application, we recommend the use of VA-EMCO or some other form of ECLS. The major limitation of all these technologies, however, is that they are available only at tertiary care facilities.

### DISPOSITION

Patients who manifest signs or symptoms of toxicity should be admitted to an intensive care setting. Because of the potential for delayed toxicity, patients who ingest sustained-release products should be admitted for

24 hours to a monitored setting even if they are asymptomatic. This precautionary approach is particularly important for toddlers and small children in whom even one or a few tablets may produce significant toxicity. Criteria for safe discharge or medical stability apply only to patients with a reliable history of an ingestion of an “immediate-release” preparation who have received adequate GI decontamination, had serial ECGs over 6 to 8 hours that have remained unchanged, and are asymptomatic.

## SUMMARY

- The hallmarks of CCB toxicity include bradycardias and hypotension, which are an extension of their pharmacologic effects.
- Although most patients develop symptoms and clinical findings of hypoperfusion, such as lightheadedness, nausea, or fatigue, within hours of a significant ingestion, ingestion of sustained-release formulations result in significant delays in any hemodynamic consequences with prolonged toxicity.
- Aggressive decontamination of patients with exposures to sustained-release products should begin as soon as possible and should not be delayed while awaiting signs of toxicity.
- Because HDI therapy has a delay to onset on action, it should be instituted early in the clinical course in an attempt to avoid the use of vasopressors.
- Patients who fail to respond to all pharmaceutical interventions should be considered for lipid emulsion adjunctive hemodynamic support, such as VA-ECMO, whenever available.

## HIGH-DOSE INSULIN

Samuel J. Stellpflug and William Kerns II

## HISTORY

Insulin was discovered and named in 1922, although its existence had been previously surmised. Clinicians at Toronto General Hospital successfully achieved glycemic control in a 14-year-old boy with diabetes by injecting him with pancreatic extract, culminating more than 30 years of research.<sup>76</sup> In the past 2 decades, insulin has gained increased attention and importance in the management of a spectrum of critical illnesses, including sepsis, heart failure, and cardiovascular drug toxicity. The benefits of insulin go well beyond simple glucose control. In xenobiotic-induced myocardial depression, the use of high-dose insulin (HDI) along with sufficient dextrose can restore normal hemodynamic status.

## PHARMACOLOGY

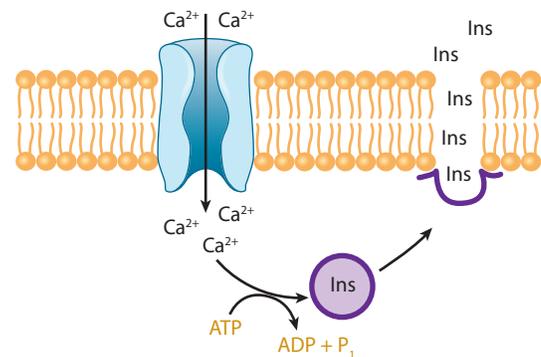

## Chemistry and Physiology

To understand the role of insulin specifically for resuscitating patients with cardiac drug toxicity, the altered myocardial physiology that occurs during drug-induced shock is briefly reviewed. The hallmarks of severe  $\beta$ -adrenergic antagonist (BAA) and calcium channel blocker (CCB) toxicity are bradycardia and decreased inotropy that compromise cardiac output and produce cardiogenic shock.<sup>17</sup> This is caused by direct  $\beta$ -adrenergic receptor antagonism and calcium channel blockade. In some cases, peripheral vasodilation also occurs, especially in the context of dihydropyridine CCB ingestions.<sup>22,75</sup> In addition to direct receptor and ion channel effects, metabolic derangements occur that closely resemble diabetes with hyperglycemia, insulin deficiency, insulin resistance, and acidemia.

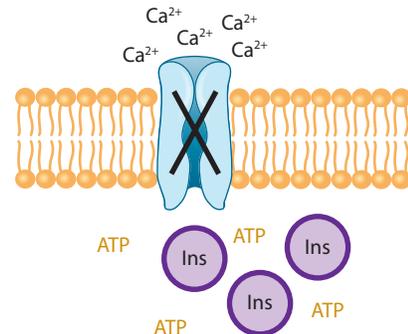

In the nonstressed state, the heart primarily catabolizes free fatty acids for its energy needs. On the other hand, the stressed myocardium switches its preferred energy substrate to carbohydrates, as demonstrated in models of both BAA and CCB toxicity.<sup>21,42,70</sup> The greater the degree of shock, the greater the carbohydrate demand.<sup>43</sup> The liver responds to stress by making more glucose available via glycogenolysis. As a result, blood glucose concentrations increase. Hyperglycemia is noted both in animal models and in human cases of some cardiac drug overdoses; it can be especially

evident with CCB toxicity.<sup>10,23,45,71</sup> The degree of hyperglycemia can correlate directly with the severity of shock for cases involving verapamil and diltiazem.<sup>48</sup> Calcium channel blockers interfere with carbohydrate processing by inhibiting pancreatic insulin release, which is necessary to transport glucose across cell membranes. Insulin release from islet cells requires functioning L-type or voltage-gated calcium channels similar to those found in myocardial and vascular tissue. Calcium channel blockers directly inhibit pancreatic calcium channels (Fig. A21-1).<sup>16</sup> In vitro models of verapamil infusion confirm this toxicity; circulating glucose concentrations increase without an associated increase in insulin.<sup>43</sup> Calcium channel blockers also create a state of insulin resistance by interfering with glucose transporter 1 (GLUT-1) and phosphatidylinositol 3-kinase (PI3K) glucose transport (Fig. A21-2).<sup>5,50</sup> As a result of diminished circulating insulin and inhibited enzymatic glucose uptake, glucose movement into

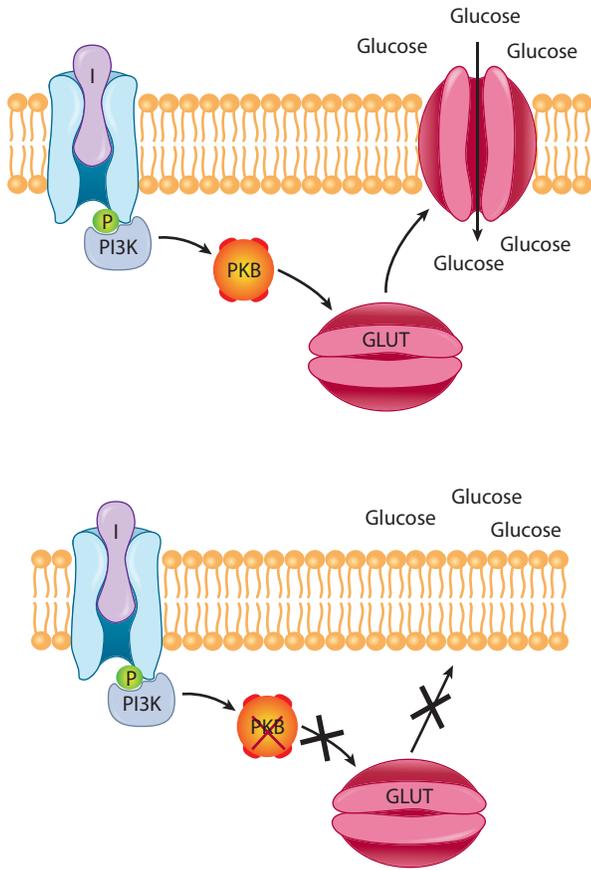

## L-type calcium channel

## L-type calcium channel

**FIGURE A21-1.** (A) Insulin (Ins) release from the  $\beta$ -pancreatic islet cell is mediated via influx of calcium through voltage-gated (L-type) calcium channels and requires adenosine triphosphate (ATP). (B)  $\text{Ca}^{2+}$  channel blockers (CCBs) inhibit pancreatic insulin release by antagonizing calcium entry via L-type calcium channel. This results in insufficient insulin to support the glucose demands of the stressed heart and contributes to hyperglycemia that occurs with CCB toxicity. ADP = adenosine diphosphate.

**FIGURE A21-2.** (A) The binding of insulin (I) to its receptor stimulates glucose entry into cells via a series of phosphorylation reactions involving phosphatidylinositol 3-kinase (PI3K) and protein kinase B (PKB). Ultimately, glucose transporters (GLUTs) are recruited from the cytosol into the cell membrane to facilitate glucose entry. (B) Calcium channel blockers (CCBs) interfere with the PI3K pathway for glucose entry by inhibiting PKB. Inhibition of this pathway creates a state of insulin resistance and provides one plausible explanation for the need for high doses of insulin to treat drug-induced myocardial depression.

cells becomes concentration dependent and may not sufficiently support myocardial demand. Calcium channel blockers further contribute to metabolic abnormalities by inhibiting lactate oxidation.<sup>42,46</sup> This likely occurs through inhibition of pyruvate dehydrogenase, the enzyme responsible for conversion of pyruvate to acetylcoenzyme A (acetyl-CoA). As a result, pyruvate is preferentially converted to lactate rather than the acetyl-CoA that would ordinarily enter the citric acid cycle; lactate then accumulates. Lactate accumulation and acidemia are consistent manifestations of CCB toxicity<sup>17,46</sup> and are also observed in some BAA models.<sup>12</sup>

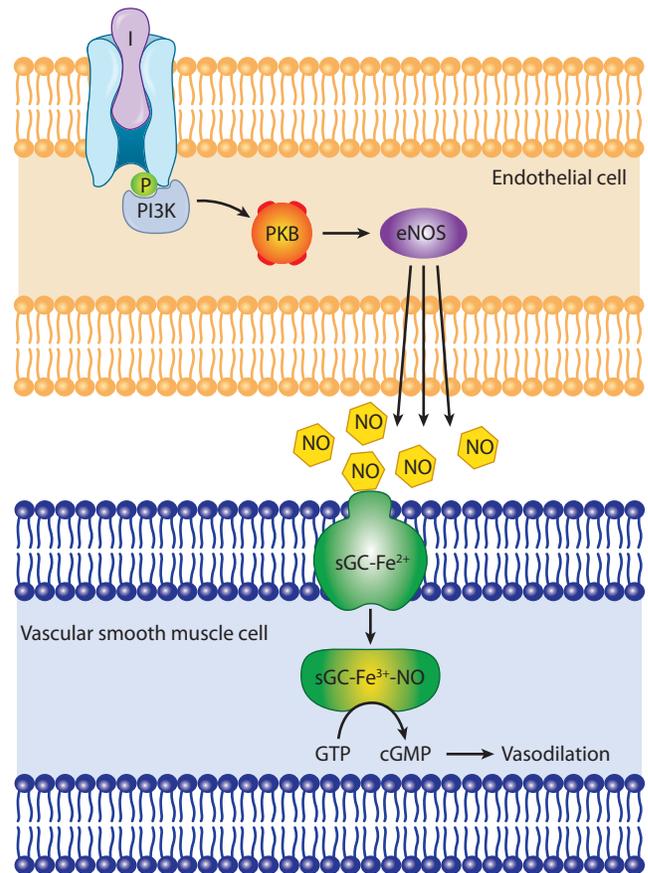

**Mechanism of Action**

High-dose insulin therapy supports the metabolic demands associated with cardiogenic shock and augments calcium processing, thereby increasing myocardial contractility and improving tissue perfusion.

Insulin-mediated improved contractility appears to be a critical factor leading to survival from cardiogenic shock. In studies comparing insulin with more traditional therapies such as epinephrine and glucagon, insulin improves drug-induced cardiac function and work efficiency.<sup>32,44</sup> Epinephrine and glucagon performed less well, possibly because they promote free fatty acid utilization. As such, epinephrine and glucagon afforded limited increases in contractility at the expense of less efficient work, increased oxygen demand, and ultimately a higher mortality rate. Similar observations were noted when HDI was studied in cardiothoracic surgery postoperative care: improved myocardial function with economy

of oxygen demand and work.<sup>24,30,81</sup> Interestingly, in BAA and CCB studies using HDI, survival occurs without dramatic improvement in hypotension or bradycardia.<sup>22,32,42,46</sup> The lack of effect on drug-induced hypotension in animal studies and human cases may be due to the vasodilatory properties of insulin.<sup>19</sup> These vasodilatory effects occur in the systemic, coronary, and pulmonary vasculature; this vasodilation contradicts the occasionally published idea that insulin is a vasopressor. The mechanism is likely due to activation of the PI3K pathway enhancing endothelial nitric oxide synthase (eNOS) activity (Fig. A21-3).<sup>5,33</sup> Vasodilation in concert with improved cardiac contractility allows for improved tissue perfusion. Improved tissue perfusion explains why insulin is associated with superior survival effect compared with vasopressor adrenergic xenobiotics such as epinephrine.<sup>32</sup>

Initially, the ability of insulin to improve cardiac function was attributed to increased catecholamine release. However, evidence does not support this explanation. For example,  $\beta$ -receptor antagonism did not prevent improved contractility that followed insulin administration.<sup>51,70</sup> In a CCB toxic model, insulin therapy improved cardiac function and survival without increasing circulating catecholamine concentrations.<sup>45</sup> Evidence demonstrates that the positive inotropic effects of insulin occur because of metabolic support of the heart during hypodynamic shock. As alluded to earlier, during drug-induced shock, the heart switches preferred energy precursors from fatty acids to carbohydrates, and insulin facilitates this demand.<sup>42</sup> Studies demonstrate a direct correlation between carbohydrate metabolism and the improved indices of cardiac function that occur with insulin therapy. Despite  $\beta$ -adrenergic antagonism by propranolol, insulin increased myocardial glucose uptake

**FIGURE A21-3.** Nitric oxide (NO) is released from endothelial cells in response to insulin. This process involves two kinases: phosphatidylinositol 3-kinase (PI3K) and protein kinase B (PKB). NO diffuses into adjoining vascular smooth muscle cells and binds at a ferric site on the enzyme soluble guanylate cyclase (sGC). Activation of sGC produces cyclic guanosine monophosphate (cGMP) a signaler of cell relaxation, ultimately leading to vasodilation. GTP = guanosine triphosphate.

with subsequent increased contractility.<sup>70</sup> In a model of verapamil toxicity, insulin increased glucose uptake with resultant improved contractility.<sup>42</sup> Insulin therapy also increased lactate uptake by restoring pyruvate dehydrogenase activity.<sup>44</sup> In this way, lactate serves as a carbohydrate energy source after conversion to pyruvate and ultimately acetyl-CoA, which can then enter the citric acid cycle.

There is also evidence that insulin exerts an effect beyond enhanced carbohydrate usage via direct effects on calcium and, to a lesser extent, potassium and sodium ion homeostasis.<sup>19,51</sup> Insulin increases available intracellular calcium by enhancing reverse mode sodium–calcium exchange, with a resultant increase in the sarcoplasmic reticulum (SR) calcium load, thus causing increased contractility.<sup>35,86</sup> Furthermore, insulin-mediated increase in SR calcium availability seems to result from further activation of sodium/hydrogen exchange (Fig. 60–2).<sup>35</sup> An additional and unexplored mechanism is insulin's effect on protein kinase B (PKB or Akt), a kinase that influences contractile function and glucose uptake. Insulin stimulates PKB/Akt<sup>3</sup> and in turn PKB/Akt phosphorylates phospholamban, a protein that regulates calcium cycling in the SR.<sup>11</sup>

### Pharmacokinetics and Pharmacodynamics

Regular insulin administered as HDI therapy is given intravenously, so gastrointestinal absorption is not an issue. The peak plasma concentration is essentially immediate. The onset and peak of the cardiovascular effect of insulin is roughly 15 to 40 minutes.<sup>12,32,33,44,46</sup> Insulin is slightly soluble in water, has a volume of distribution of roughly 21 L in an adult human, and demonstrates protein binding of roughly 5%, which can increase in a patient with diabetes with insulin antibodies.<sup>55,72</sup> More than half of insulin metabolism occurs in the liver, but there is also a sizable degree that occurs in adipose tissue, muscle, and the kidneys.<sup>66</sup> The elimination half-life of intravenously administered insulin is roughly 5 to 10 minutes, and it is partially eliminated in both the kidneys and the bile.<sup>69,72</sup>

### ROLE IN DRUG-INDUCED CARDIOVASCULAR TOXICITY

As mentioned earlier, the positive inotropic effects of insulin were recognized in 1927; however, HDI therapy for drug-induced shock in humans was first reported in 1999.<sup>84,87</sup> This case series included four patients who overdosed on verapamil and one with a combined amlodipine–atenolol overdose. All patients failed traditional antidote therapy but responded to rescue insulin therapy. Since this initial case series, more than 90 cases have been published reporting use of insulin therapy for treatment of isolated or mixed drug-induced cardiac drug toxicity.<sup>12,46-9,13-15,18,20,25-29,31,38,52,53,56-59,61,62,64,65,67,68,71,74,77-79,82,83</sup> The vast majority of cases involved primary ingestion of  $\beta$ -adrenergic antagonists or calcium channel blockers. High-dose insulin was also used for poison-induced shock resulting from amiodarone,<sup>18</sup> amitriptyline, citalopram,<sup>31</sup> and morphine.<sup>49</sup> In one case of digoxin and insulin overdose, the coingested insulin was thought to be protective.<sup>4</sup> Various regimens of classic antidotes were used before insulin therapy in many of these cases. No direct outcome comparisons can be made between insulin and these other therapies once thought to be standard care. That being said and recognizing the inherent reporting bias, overall survival was very good when insulin was included in resuscitation. Further review of these cases and animal models yields important clinical information that can be used to guide HDI therapy.

Experimental models suggest that large doses of regular insulin (2.5–10 units/kg/h) are necessary to provide inotropic support.<sup>5,12,41,44,46</sup> The most recent human case series used 10 units/kg/h as the standard dose.<sup>34</sup> In one case, 22 units/kg/h was used with survival after cardiac arrest from nebivolol.<sup>78</sup> However, humans respond to less insulin. Most patients in the early reports were treated with HDI ranging between 0.5 and 2 units/kg/h. Many of the literature reported patients received an initial insulin bolus (between 0.1 and 1 unit/kg) before continuous infusion. The theoretical advantage to giving an initial insulin bolus is to rapidly saturate insulin receptors to speed the physiological response. Interestingly, one report noted that patients receiving an insulin bolus before the infusion showed a better blood pressure response than patients

who received only a continuous infusion.<sup>25</sup> Three patients received bolus insulin without continuous infusion, including a patient who inadvertently received 1,000 units.<sup>68</sup> In this case, hemodynamics improved, and there were no adverse events related to the extreme insulin dose. The typical reported duration of insulin infusion is 24 to 48 hours, with a range of 0.75 to 96 hours. The need for prolonged infusion likely reflects prolonged drug toxicokinetics often observed after overdose.

The predominant clinical effect of insulin is increased cardiac contractility with subsequent improvement in perfusion, often without initial increase in blood pressure. Contractility typically increased within 15 to 40 minutes after initiating insulin and often allowed a decrease in concurrent vasopressor use, sparing the toxicity of these xenobiotics. The timing of increased contractility is consistent with the observed response times in animal models.<sup>12,32,33,41,46</sup> Although prior studies did not find a survival benefit for vasopressors compared with insulin, a recent investigation demonstrated synergy between HDI and vasopressors regarding cerebral perfusion when norepinephrine was added after reaching severe malperfusion despite maximal HDI therapy.<sup>39</sup> In this swine model of severe propranolol shock, combined HDI and norepinephrine increased cerebral perfusion compared with HDI alone or vasopressors alone.

Other salutary effects were observed during insulin therapy. In one case of a combined amlodipine and valsartan overdose, blood pressure increased directly because of increased vascular resistance rather than increased cardiac function.<sup>77</sup> Two patients converted from third-degree heart block to normal sinus rhythm with an increased pulse in temporal relationship to insulin.<sup>87</sup> Except for these two patients, insulin therapy did not significantly affect heart rate in other reports. One reported case, technically a HDI failure, strongly supports the idea of insulin as an inotrope.<sup>79</sup> A patient with baseline hypertrophic cardiomyopathy but no baseline obstructive pathophysiology ingested diltiazem, metoprolol, and amiodarone. With insulin dosing quickly escalating to 10 units/kg/h, there was increased cardiac contractility documented by ultrasonography to the point of inducing hemodynamically significant obstructive outflow. The patient's clinical course ultimately improved after intravenous lipid emulsion administration. There are cases in which authors reported a lack of response to insulin. Reasons for no response in three of these reports include inadequate dosing and excessive delay to insulin therapy.<sup>14</sup>

Based on the sum of experimental and clinical experience, we recommend using HDI (bolus of regular insulin 1 unit/kg {total body weight} followed by 1 to 10 units/kg/h continuous infusion) early in the resuscitation of severe BAA- and CCB-induced myocardial depression. This recommendation is supported by multidisciplinary consensus guidelines.<sup>80</sup> It is also reasonable to use HDI for other xenobiotic-induced cardiogenic shock that is failing resuscitation with inotropes and vasopressors.

### ADVERSE EVENTS AND SAFETY ISSUES

The major anticipated adverse event associated with the use of large amounts of insulin, especially in patients naïve to insulin, is hypoglycemia, defined as blood glucose less than 60 mg/dL (3.3 mmol/L) regardless of the presence or absence of symptoms. Because of potential hypoglycemia, all experimental animals received sufficient dextrose during insulin infusion to maintain euglycemia. In the aggregate human cases, patients typically received empiric supplemental dextrose based on frequent glucose monitoring. The typical dextrose dose was 25 g/h, but requirements varied widely from 0.5 to 75 g/h. The duration of exogenous dextrose supplementation was roughly 2 days, but it varied significantly from 9 to 100 hours. Dextrose supplementation was necessary beyond cessation of insulin for most cases. Despite empiric dextrose and blood glucose monitoring (albeit with no standard frequency of testing), hypoglycemia was observed in some patients. In one retrospective series, hypoglycemia occurred in 5 of 37 patients and resulted in HDI cessation.<sup>57</sup> In a prospective evaluation of seven separate CCB overdoses, there was one clinically insignificant episode.<sup>25</sup> In another retrospective 12-patient case series, there were 6 patients with a total of 19 hypoglycemic events (8 in one patient), all of uncertain but unlikely

clinical significance.<sup>34</sup> Of note, dextrose requirement does not directly correlate well with insulin dose or severity of shock. Patients with severe shock and marked hyperglycemia often do not need any supplemental dextrose during the initial hours of insulin therapy because of insulin deficiency and insulin resistance. Additionally, there is likely a ceiling requirement for dextrose as glucose transport is saturable. One animal model demonstrated that dextrose need was greater for animals treated with 5 versus 1 unit/kg/h of insulin but not between groups treated with 5 versus 10 units/kg/h.<sup>12</sup> There is other evidence that glucose requirements are not predictable.<sup>54</sup> Overall, hypoglycemia is a potential consequence of HDI therapy, but clinically significant hypoglycemia is rare. A combination of rigorous glucose monitoring and dextrose administration can prevent hypoglycemia and avoid unnecessary cessation of insulin treatment.

Another anticipated consequence of insulin treatment is hypokalemia. Although serum potassium concentrations often falls below normal laboratory ranges, HDI does not typically cause profound hypokalemia. The observed decrease reflects a shifting of potassium from the extracellular to intracellular space that occurs as a result of the action of insulin. Patients maintain normal total body potassium stores and do not experience true deficiency unless they have other reasons for potassium loss. In the initial case series, three patients had a nadir of potassium ranging from 2.2 to 2.8 mEq/L without sequelae.<sup>85</sup> In two case series of 7 and 12 patients, there were 2 of 7 and 7 of 12 patients, respectively, who demonstrated clinically insignificant hypokalemia.<sup>25,34</sup> There is a theoretical risk of excessive potassium replacement in the instance of lowered serum potassium but normal total body stores. Hyperkalemia is also reported to worsen verapamil-induced myocardial depression.<sup>37,60</sup>

Other observed ion changes during insulin therapy include hypomagnesemia and hypophosphatemia. Similar to action on potassium, insulin causes an intracellular shift of both phosphorus and magnesium.<sup>40,63</sup> In the initial series of drug-induced shock treated with insulin, four patients had lowered magnesium (0.4–0.6 mmol/L; normal, 0.8–1.2 mmol/L) and phosphorus (0.2–0.5 mmol/L; normal, 1–1.4 mmol/L) concentrations. No symptoms were attributed to these lowered serum concentrations, but three patients received supplementation of both electrolytes. No other insulin-treated CCB cases address these two electrolytes. Insulin (0.1 units/kg/h) for diabetic ketoacidosis is likewise associated with similar effects on magnesium and phosphorus, so it is unlikely that alterations of magnesium and phosphorus are dose related.<sup>36</sup>

## PREGNANCY AND LACTATION

Regular insulin is Pregnancy Category B and is compatible with breastfeeding.

## DOSING AND ADMINISTRATION

Based on the experimental studies and aggregate human cases, HDI will most likely benefit patients with cardiac drug-induced myocardial depression. High-dose insulin is recommended for patients with malperfusion refractory to large doses of vasopressors even when there is no associated poor contractility. The experimental evidence and human case experience are strongest for CCB toxicity. Animal studies and growing human experience also support its use for BAA toxicity.

Myocardial function should be measured or estimated. Options include cardiac ultrasonography or through machine-estimated cardiac output using pulse contour analysis attached to a standard arterial catheter. This can be done more invasively via placement of a pulmonary artery catheter. When myocardial function is decreased, insulin therapy is initiated by first administering a 1-unit/kg bolus of regular human insulin along with 0.5-g/kg bolus of dextrose; if blood glucose is greater than 300 mg/dL (16.7 mmol/L), the dextrose bolus is not necessary. An infusion of regular insulin should immediately follow the bolus starting at 1 unit/kg/h. Ideally, this insulin infusion should be concentrated to prevent fluid overload that would occur with large doses. We typically concentrate the infusion at 10 unit/mL compared with the typical insulin infusion concentration of

1 unit/mL used for diabetic ketoacidosis. This unusual pharmacy formulation requires close collaboration with hospital pharmacists. Concentrated insulin solutions are stable for 14 days.<sup>47</sup> A continuous dextrose infusion, beginning at 0.5 g/kg/h, is concurrently recommended when necessary. Dextrose can be started as D<sub>10</sub>, especially without central venous access and while determining the dextrose need, but it is ultimately best delivered as D<sub>25</sub> or D<sub>50</sub> via central venous access, also with the intent to lessen large fluid volumes that would otherwise be necessary with administration of more dilute dextrose solutions. Recently, more concentrated dextrose (D<sub>70</sub>) was safely used in two patients with BAA shock to support HDI therapy while minimizing total fluid infusion.<sup>73</sup>

If possible, cardiac function should be reassessed every 10 to 15 minutes after starting HDI therapy. If cardiac function remains depressed, then the insulin dose should be increased. This assessment can be done with complex cardiac output measurement or simply as a gross bedside ultrasound interpretation, depending on availability. Although we typically recommend dosing up to 10 units/kg/h, doses up to 22 units/kg/h have been used, and the maximum dose is not established.<sup>12,78</sup> The blood glucose should be monitored every 15 to 30 minutes until stable and then every 1 to 2 hours. The dextrose infusion should be increased to maintain blood glucose concentrations between 100 and 250 mg/dL (5.5–14 mmol/L) rather than reducing the insulin.

The serum potassium concentration should be measured during HDI therapy. If it is low, especially when potassium loss is suspected, then supplementation is indicated to maintain the concentration in the “mildly hypokalemic” range (2.8–3.2 mEq/L). A reasonable time frame is to evaluate serum potassium hourly while actively titrating the insulin infusion and every 6 hours after the infusion rate is stabilized. Magnesium and phosphorus should also be measured and supplemented as indicated. However, unless there is reason for loss of these three electrolytes, lowered serum concentrations likely reflect compartmental shifts, not depletion.

The ultimate goal of HDI is improvement in organ perfusion as demonstrated by increased cardiac output, improved mental status, adequate urine output, and reversal of metabolic abnormalities, as indicated by serum lactate, bicarbonate, pH, and base excess. This improvement is often, but not always, accompanied by an improvement in mean arterial blood pressure. Because insulin improves both cardiac function and perfusion while slightly vasodilating, treatment goals should focus more on organ perfusion and outcome as opposed to simply the numerical blood pressure. An increase in the rate of dextrose infusion to maintain euglycemia often accompanies hemodynamic and metabolic improvements. This increase in dextrose demand is due, in part, to increased CCB or BAA metabolism and loss of the CCB-induced diabetogenic influences, and it can be regarded as a favorable prognostic indicator.

The typical duration of therapy is 1 to 2 days, although HDI has been used for up to 4 days. We recommend reducing the insulin infusion rate by 1 unit/kg/h after the patient has stabilized and reassessing hourly for additional infusion reduction while maintaining adequate perfusion. In many patients, the dextrose infusion will continue to be necessary after the insulin is reduced and ultimately eliminated. The reduction of insulin and dextrose will cause potassium shifting, which should also be monitored.

## SUMMARY

- High-dose insulin is recommended to augment cardiac function and perfusion in the context of cardiogenic shock caused by CCBs and BAAs.
- This therapy supports the metabolic demands associated with the cardiogenic shock and augments calcium processing, thereby increasing myocardial contractility and improving tissue perfusion.
- High doses of concentrated regular insulin are given intravenously, along with appropriate amounts of dextrose, and specific monitoring is required of serum glucose and potassium, in addition to surrogate markers of tissue perfusion, such as cardiac output, urine output, bicarbonate, pH, and lactate.

# MISCELLANEOUS ANTIHYPERTENSIVES AND PHARMACOLOGICALLY RELATED AGENTS

Hallam Melville Gugelmann and Francis Jerome DeRoos

Hypertension is one of the most prevalent chronic medical problems and one of the most readily amenable to pharmacotherapy. Antihypertensive pharmacotherapeutics were first used in the 1960s after two studies independently linked asymptomatic hypertension to significant adverse effects such as stroke, myocardial infarction (MI), and sudden death.<sup>74,92</sup> The first antihypertensives used included centrally acting sympatholytics, direct vasodilators, sodium nitroprusside, and diuretics. Unfortunately, these often had significant adverse events, leading to the development of  $\beta$ -adrenergic antagonists, calcium channel blockers (CCBs), angiotensin-converting enzyme inhibitors (ACEIs), angiotensin receptor blockers (ARBs), and direct renin inhibitors (DRIs) (Table 61-1). This chapter reviews early antihypertensives, as well ACEIs, ARBs, and DRIs. In general, the majority of antihypertensives manifest clinical signs and symptoms in terms of the degree of hypotension produced. Particular attention will be placed on mechanisms of action and unique toxicologic considerations for each of these xenobiotics.

## CLONIDINE AND OTHER CENTRALLY ACTING ANTIHYPERTENSIVES

Clonidine is an imidazoline compound synthesized in the early 1960s. Because of its potent peripheral  $\alpha_2$ -adrenergic agonist effects, it was initially studied as a topical nasal decongestant.<sup>218</sup> However, hypotension

was a common adverse event, which redirected its consideration for other therapeutic applications.<sup>101</sup> Clonidine is the most commonly used of all the centrally acting antihypertensives, a group that includes methyldopa, guanfacine, and guanabenz. Although these drugs differ chemically and structurally, they all decrease blood pressure in a similar manner. The imidazoline compounds oxymetazoline and tetrahydrozoline, which are used as ophthalmic topical vasoconstrictors and nasal decongestants (Chap. 49), produce similar systemic effects when ingested.<sup>101</sup>

Although the increased efficacy and improved adverse event profiles of newer antihypertensives diminished the use of the  $\alpha_2$ -adrenergic agonists in routine hypertension management, use of these xenobiotics is increasing as a result of a wide variety of applications, including attention deficit hyperactivity disorder, peripheral nerve and spinal anesthesia, and compounded skin creams<sup>181</sup> and as an adjunct in the management of opioid, ethanol, and nicotine withdrawal.<sup>117,122</sup> In addition, abuse of clonidine remains a problem in opioid-dependent patients and is reportedly used in criminal acts of chemical submission.<sup>21,137</sup>

Ingestion of centrally acting imidazolines can cause significant toxicity, particularly in children. One report from two large pediatric hospitals identified 47 children requiring hospitalization for unintentional clonidine ingestions over a 5-year period.<sup>239</sup> Significant clonidine poisoning also results from formulation and dosing errors in children<sup>193,221</sup> and after imidazolines used as ocular vasoconstrictors, especially if ingested.<sup>129,141,184</sup>

TABLE 61-1 Antihypertensives and Pharmacologically Related Xenobiotics

$\beta$ -Adrenergic antagonists (Chap. 59)
Calcium channel blockers (Chap. 60)
Sympatholytics (antagonize $\alpha$ -adrenergic vasoconstriction)
Central $\alpha_2$ -adrenergic agonists
Clonidine, dexmedetomidine, guanabenz, <sup>a</sup> guanfacine, <sup>a</sup> methyldopa, <sup>a</sup> tizanidine
Central imidazoline agonists
Moxonidine, rilmenidine
Ganglionic blockers
Trimethaphan <sup>a</sup>
Peripheral adrenergic neuron antagonists
Guanadrel, <sup>a</sup> metyrosine, <sup>a</sup> reserpine <sup>a</sup>
Peripheral $\alpha_1$ -adrenergic antagonists
Doxazosin, prazosin, silodosin, terazosin
Diuretics
Thiazides
Bendroflumethiazide, <sup>a</sup> chlorthalidone, <sup>a</sup> chlorothiazide, hydrochlorothiazide, hydroflumethiazide, <sup>a</sup> indapamide, methyclothiazide, <sup>a</sup> metolazone, polythiazide, <sup>a</sup> trichlormethiazide <sup>a</sup>
Loop diuretics
Bumetanide, ethacrynic acid, furosemide, torsemide
Potassium-sparing diuretics
Amiloride, eplerenone, spironolactone, triamterene
Vasodilators
Diazoxide, <sup>a</sup> hydralazine, minoxidil, <sup>a</sup> nitroprusside
Angiotensin-converting enzyme inhibitor
Benazepril, captopril, enalapril, fosinopril, lisinopril, moexipril, perindopril, quinapril, ramipril, spirapril, trandolapril
Angiotensin II receptor blockers
Azilsartan, candesartan, eprosartan, irbesartan, losartan, olmesartan, telmisartan, valsartan
Direct renin inhibitors
Aliskiren

<sup>a</sup>Included for historical reference; use as an antihypertensive is limited in the United States.

## Pharmacology

Clonidine and the other centrally acting antihypertensives exert their hypotensive effects primarily by stimulating two sets of receptors: presynaptic  $\alpha_2$ -adrenergic receptors<sup>22,75</sup> and imidazoline receptors.<sup>135,187</sup> Central  $\alpha_2$ -adrenergic receptor agonism enhances the activity of inhibitory neurons in the vasoregulatory regions of the central nervous system (CNS), including the locus ceruleus, the nucleus tractus solitarius in the medulla, and—possibly most prominently—in the rostral ventrolateral medulla,<sup>35</sup> resulting in decreased norepinephrine release.<sup>200</sup> Central agonism by imidazolines results in decreased sympathetic outflow from the intermediolateral cell columns of the thoracolumbar spinal tracts into the periphery and reduces the heart rate ‘vascular tone’ and, ultimately, arterial blood pressure.<sup>231</sup> This centrally mediated sympatholytic effect is partially modulated by nitric oxide and  $\gamma$ -aminobutyric acid (GABA), which explains some of the clinical variability that occurs among patients who overdose with clonidine.<sup>33,84,233</sup> Imidazolines also have profound effects at imidazoline receptors, one of their primary sites of action. There are three recognized classes of imidazoline receptors. Imidazoline-1 ( $I_1$ ) receptors mediate hypotensive effects of imidazolines by functioning upstream from presynaptic  $\alpha_2$ -adrenergic receptors, likely in addition to other physiologic effects. Imidazoline-2 ( $I_2$ ) receptors are involved in pain perception modulation and interact with monoamine oxidases A and B. Imidazoline-3 ( $I_3$ ) receptors have effects on glucose homeostasis within pancreatic  $\beta$ -islet cells.<sup>135</sup> In addition to  $\alpha$ - and imidazoline receptor-mediated effects, clonidine has opioidlike effects that are mediated through  $I_2$  receptors<sup>22</sup> and through the release of  $\beta$ -endorphin, which directly stimulates opioid receptors.<sup>242</sup>

## Pharmacokinetics

Clonidine is well absorbed from the gastrointestinal (GI) tract (~75%) with an onset of action within 30 to 60 minutes. The peak serum concentration

occurs at 2 to 3 hours and lasts as long as 8 hours.<sup>54</sup> Clonidine has 20% to 40% protein binding (primarily to albumin) and an apparent volume of distribution of 3.2 to 5.6 L/kg.<sup>130</sup> The majority of clonidine is eliminated unchanged via the kidneys.<sup>134</sup>

Clonidine is available in both oral and transdermal (“patch”) forms. Transdermal systems allow slow, continuous delivery of drug over a prolonged period of time, ranging from 72 hours to 1 week (Special Considerations: SC3). This formulation, however, offers unique clinical challenges. Each patch contains significantly more drug than is typically delivered during the prescribed duration of use. For example, a patch that delivers 0.1 mg/day of clonidine contains a total of 2.5 mg, the product that delivers 0.3 mg/day contains a total of 7.5 mg.<sup>32</sup> Even after 1 week of use, between 35% and 50% and, in some instances, as much as 70% of the drug remains in the patch.<sup>32,95</sup> Puncturing the outer membrane layer or backing opens the drug reservoir and allows a significant amount of the drug to be released rapidly. In addition, patients do not perceive this delivery system as a medication and thus do not always exercise appropriate precautions when disposing of used patches. For example, numerous reports of toxicity in both adults and children have resulted from dermal exposure of discarded patches, mouthing, or ingesting a clonidine patch.<sup>32,45,185</sup> Compounding creams, often inadvertently containing massive amounts of clonidine, have caused significant toxicity.<sup>193</sup>

Guanfacine and guanabenz are structurally and pharmacologically very similar to each other. They are well absorbed orally, achieving peak concentrations within 3 to 5 hours, and both have large volumes of distribution (4–6 L/kg for guanfacine and 7–17 L/kg for guanabenz).<sup>104,216</sup> Whereas guanabenz is metabolized predominantly in the liver and undergoes extensive first-pass effect, guanfacine is eliminated equally by the liver and kidney.<sup>104,216</sup> The metabolism of neither drug results in the production of significant active metabolites. Guanabenz is infrequently used.<sup>145</sup>

Whereas clonidine, guanabenz, and guanfacine are all active drugs with direct  $\alpha_2$ -adrenergic agonist effects, methyldopa is a prodrug. It enters the CNS, probably by an active transport mechanism, before it is converted into its pharmacologically active degradation products.<sup>24</sup>  $\alpha$ -Methylnorepinephrine is the most significant of its metabolites, although  $\alpha$ -methyldopamine and  $\alpha$ -methylepinephrine also are active.<sup>71,97,191</sup> These metabolites are direct  $\alpha_2$ -adrenergic agonists and have similar effects and mechanism as the other centrally acting antihypertensives. Approximately 50% of an oral dose of methyldopa is absorbed, and peak serum concentrations are achieved in 2 to 3 hours.<sup>158</sup> However, because methyldopa requires metabolism into its active form, these concentrations have little correlation with its clinical effects. Methyldopa has a small volume of distribution (0.24 L/kg) and little protein binding (15%).<sup>158</sup> It is eliminated in the urine, both as parent compound and after hepatic sulfation.<sup>165</sup> Methyldopa is still used for the management of postpartum hypertension.<sup>87</sup>

### Pathophysiology

In therapeutic oral dosing, clonidine and the other centrally acting antihypertensives have little effect on the peripheral  $\alpha_2$  receptors, the peripheral sympathetic nervous system, or the normal circulatory responses that occur with exercise or the Valsalva maneuver.<sup>157,169</sup> However, when serum concentrations increase above 2 ng/mL, as in the setting of intravenous (IV) administration or oral overdose, peripheral postsynaptic  $\alpha_2$ -adrenergic stimulation occurs, producing temporary vasoconstriction and hypertension.<sup>42,54</sup> Shortly afterward, however, potent centrally mediated sympathetic inhibition becomes the predominant effect, and bradycardia with hypotension ensues.<sup>5,156,191</sup>

### Clinical Manifestations

Although the majority of the published cases involve clonidine, the signs and symptoms of poisoning with any centrally acting antihypertensive are similar. The CNS and cardiovascular toxicity reflect an exaggeration of their pharmacologic action. In the context of large overdoses, initial  $\alpha_1$  agonism results in hypertension and tachycardia, typically transient,<sup>113</sup> followed by the more predominant signs of imidazoline toxicity, including CNS depression, bradycardia,

hypotension, and occasionally hypothermia.<sup>7,208,229</sup> Most patients who ingest clonidine or the other similarly acting drugs manifest symptoms rapidly, typically within 30 to 90 minutes.<sup>239</sup> The exception is methyldopa, a prodrug, which requires metabolism to be activated, delaying toxicity for hours.<sup>208,241</sup>

Central nervous system depression is the most frequent clinical finding, ranging from mild lethargy to coma.<sup>147</sup> In addition, severely obtunded patients often experience decreased ventilatory effort and hypoxia.<sup>5</sup> Respirations are often slow and shallow, with intermittent deep, sighing breaths. Various other terms are used to describe this phenomenon, including gasping, Cheyne-Stokes respirations, and periodic apnea.<sup>7,11,147</sup> This hypoventilation is characteristically responsive to tactile stimuli in children, although mechanical ventilation is required in severe cases.<sup>5,98</sup> The associated CNS depression typically resolves over 12 to 36 hours.<sup>11,168</sup> Other manifestations of this CNS depression include hypotonia, hyporeflexia, and irritability.<sup>42,147,220</sup> The cranial nerve examination often demonstrates miotic pupils, typically reactive to light.<sup>5,7,223</sup> Two unusual case reports describe seizures in the setting of clonidine poisoning,<sup>42,176</sup> the mechanism of which is unclear.

Hypothermia is associated with overdoses involving centrally acting antihypertensives.<sup>7,147,176,191</sup> This is thought to be a consequence of  $\alpha$ -adrenergic effects within the thermoregulatory center, although some authors suggest that these drugs activate central serotonergic pathways that alter normal thermoregulation.<sup>130,151</sup> Although this phenomenon sometimes lasts for several hours, it rarely requires treatment and typically responds well to passive rewarming.<sup>42,176</sup> Sinus bradycardia occurs in up to 50% of patients who ingest clonidine, resulting from the combination of an exaggerated centrally mediated sympatholytic effect, a centrally mediated increase in vagal tone or a direct stimulation of  $\alpha_2$ -adrenergic receptors on the myocardium.<sup>33,50,127,220,239</sup>

Other conduction abnormalities, including first-degree heart block, type 1 and 2 Mobitz atrioventricular block, and complete heart block, are described both in overdose and after therapeutic dosing.<sup>119,168,202</sup> It appears that very young patients and patients who have underlying sinus node dysfunction, concurrent sympatholytic drug therapy, or chronic kidney disease (CKD) are at particular risk of developing bradydysrhythmia after central antihypertensive ingestion.<sup>28,220,224</sup> Hypotension is the major cardiovascular manifestation of central antihypertensive toxicity.<sup>7,32</sup> Although studies suggest a dose–response relationship between the estimated quantity of the centrally acting antihypertensive ingested and the severity of the clinical manifestations, clonidine ingestions as small as 0.2 mg can cause clinically severe poisoning, mandating the necessity to individually assess each exposure. The presence of any symptoms should prompt immediate medical evaluation,<sup>19,168</sup> especially in pediatric patients and exposures to compounding creams.<sup>34</sup> Fatalities from any of these xenobiotics are rare.<sup>109</sup>

After deaths of four children who were prescribed clonidine were reported, concerns that there was a causal association between combination clonidine–methylphenidate therapy and sudden death were raised.<sup>67</sup> Closer scrutiny of these cases revealed significant confounders, however, and a formal investigation by the US Food and Drug Administration concluded that there was inadequate evidence to confirm this association.<sup>222</sup>

### Diagnostic Testing

Clonidine and other centrally acting antihypertensives are not routinely included in rapidly accessible serum or urine toxicologic assays. Consequently, management decisions should be based on clinical parameters. No electrolyte or hematologic abnormalities are associated with this exposure. Because of the potential for bradydysrhythmia and hypoventilation, 12-lead electrocardiography (ECG), end-tidal  $\text{CO}_2$ , and continuous cardiac and pulse oximetry monitoring are recommended.

### Management

Appropriate therapy begins with particular focus on the patient’s respiratory and hemodynamic status. Administration of activated charcoal (AC) is the primary mode of GI decontamination in most cases of ingestion; however, altered mental status and severe respiratory depression typically limit the ability to administer AC. Patients often present after the onset of symptoms

rather than immediately after ingestion, and patients respond well to supportive care. In cases involving clonidine patch ingestions, whole-bowel irrigation (WBI) appears to be an effective intervention and is reasonable only if the airway status is stable or secure.<sup>99,106</sup>

All patients with CNS depression should be evaluated for hypoxia and hypoglycemia. Those with respiratory compromise, including apnea, often respond well to simple auditory or tactile stimulation.<sup>5,7,98</sup> Significant arousal during preparation for intubation often precludes the need for mechanical ventilation.<sup>5</sup> Endotracheal intubation should be performed in patients who fail to arouse to stimuli or those with evidence of airway compromise.

Patients with isolated hypotension should initially be treated with IV boluses of crystalloid: 20 mL/kg in children and 500 to 1,000 mL in adults. Bradycardia is typically mild and usually does not require any therapy if adequate peripheral perfusion exists. If symptomatic bradycardia occurs, then atropine is recommended but, frequently requires multiple doses.<sup>5,7,140</sup>

It is likely that naloxone was first used in clonidine-poisoned patients because the clinical findings of CNS and respiratory depression and miosis are similar to opioid-poisoned patients.<sup>163</sup> Clonidine-poisoned patients, particularly children, often show increased arousal, respiratory effort, heart rate, and blood pressure after naloxone administration.<sup>11,125,163,223</sup> Although unclear mechanistically, this effect is likely related to modulation of CNS sympathetic outflow by endogenous CNS opioids.<sup>25,66</sup> This concept is supported by a clinical study in which clonidine administration to hypertensive patients for 3 days resulted in a significant decrease in blood pressure. Subsequent administration of 0.4 mg of parenteral naloxone reversed the decrease in blood pressure and heart rate in almost 60% of the patients.<sup>65</sup> Because of the short duration of effects of naloxone (20–60 minutes), redosing or continuous infusions are often required. As with some synthetic opioids, such as propoxyphene and fentanyl, clinical improvement sometimes occurs only after high doses (4–10 mg) of naloxone.<sup>70,144</sup> and some patients have no response regardless of dose used.<sup>140,239</sup> Hypertension can occur after administration of naloxone in pediatric clonidine overdoses.<sup>86</sup>

Early-onset hypertension in imidazoline toxicity is typically self-limited, and therapy should be cautiously undertaken. Treatment with esmolol theoretically can exacerbate this paradoxical hypertension in a manner similar to that which occurs when  $\beta$ -adrenergic antagonists are used in cocaine toxicity, namely by inducing unopposed  $\alpha_1$ -receptor stimulation (Chap. 75). Although oral nifedipine has been used,<sup>53</sup> it cannot be titrated and has unpredictable efficacy. If hypertension is severe or prolonged, treatment with a short-acting and titratable antihypertensive such as IV nicardipine and sodium nitroprusside is reasonable.<sup>147</sup>

## Withdrawal

Abrupt cessation of central antihypertensive therapy results in withdrawal, typically characterized by excessive sympathetic activity. Symptoms include agitation, insomnia, tremor, palpitations, tachycardia, and hypertension that begin between 16 and 48 hours after cessation of therapy.<sup>29,186,197</sup> Complications of clonidine withdrawal can include ventricular tachycardia and MI.<sup>20,160,177</sup> The frequency and severity of symptoms appear to be greater in patients treated with higher doses for several months and in those with the most severe pretreatment hypertension.<sup>186</sup> Shorter acting xenobiotics such as clonidine and guanabenz are more frequently associated with withdrawal.<sup>79,183</sup> In addition, because of prolonged and continuous exposures, children being treated with extended-release guanfacine formulations and transdermal patches are at greater risk of developing withdrawal upon cessation. The mechanism for this hyperadrenergic phenomenon involves an increase in CNS noradrenergic activity in the setting of decreased  $\alpha_2$ -receptor sensitivity.<sup>61</sup> Animal and human data suggest that  $\beta$ -adrenergic antagonists, including labetalol, are contraindicated in clonidine withdrawal.<sup>10,114</sup> As noted earlier, esmolol can, in theory, exacerbate this paradoxical hypertension in a manner similar to that which is proposed when these xenobiotics are used for patients manifesting cocaine toxicity (ie, by inducing unopposed  $\alpha_1$ -receptor stimulation) (Chap. 75). Reasonable treatment strategies include administering clonidine

or benzodiazepines, via either the oral or IV route, followed by a closely monitored tapering of the dosing over several weeks.

## CENTRAL IMIDAZOLINE AGONISTS

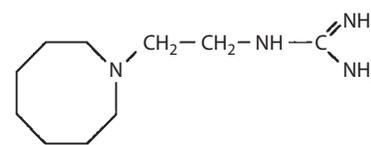

Moxonidine and related rilmenidine are known as second-generation centrally acting oral antihypertensives.<sup>58</sup> They are structurally similar to clonidine but selectively attach at  $I_1$  imidazoline binding sites (found predominantly in the rostral ventrolateral medulla), with much less affinity for the  $\alpha_2$ -adrenergic receptor.<sup>62</sup> As noted earlier,  $I_1$  binding ultimately leads to decreased sympathetic outflow from the medulla, vasodilation, and reduction in blood pressure. Although nitric oxide or GABA mechanisms are also contributory,<sup>174,175</sup> animal studies suggest that  $\alpha_2$ -adrenergic receptor effects predominantly mediate central effects with these xenobiotics.<sup>41</sup> Therapeutically, moxonidine is used both as monotherapy or in combination with other antihypertensives. Patients with diabetes or metabolic syndrome benefit from moxonidine because of its positive effects on insulin resistance, impaired glucose tolerance, and hyperlipidemia.<sup>58,68</sup> Case reports of seizures (resolving with benzodiazepines) without development of hypotension suggest that weak  $\alpha_2$ -adrenergic receptor affinity is overwhelmed in overdose.<sup>139</sup>

Dexmedetomidine is a newer centrally acting imidazoline agonist used for sedation in intensive care settings. In contrast to moxonidine and rilmenidine, dexmedetomidine is highly selective for the  $\alpha_2$ -adrenergic receptor and has profound sedating, analgesic-sparing, and sympatholytic effects. Side effects include bradycardia and hypotension.<sup>118</sup> Withdrawal from this xenobiotic can result in tachycardia, agitation, and hypertension.<sup>124</sup>

## OTHER SYMPATHOLYTIC ANTIHYPERTENSIVES

Several other xenobiotics also exert their antihypertensive effect by decreasing the effects of the sympathetic nervous system. Often termed *sympatholytics*, they can be classified as ganglionic blockers (eg, trimetaphan), presynaptic adrenergic blockers (eg, reserpine), or  $\alpha_1$ -adrenergic antagonists (eg, prazosin), depending on their mechanism of action. Of these xenobiotics, the ganglionic blockers are rarely used clinically, and little is known about their effects in overdose; the presynaptic adrenergic blockers and  $\alpha_1$ -adrenergic antagonists are reviewed briefly next.

### Presynaptic Adrenergic Antagonists

Guanethidine

These xenobiotics exert their sympatholytic action by decreasing norepinephrine release from presynaptic nerve terminals. Whereas guanethidine and guanadrel interfere with the action potential that triggers norepinephrine release,<sup>205</sup> reserpine depletes norepinephrine, serotonin, and other catecholamines from the presynaptic nerve terminals by direct binding and inactivation of catecholamine storage vesicles.<sup>80</sup> Adverse events limit their clinical usefulness. These effects include a high incidence of orthostatic and exercise-induced hypotension, diarrhea, increased gastric secretions, and impotence;<sup>161</sup> hypotensive effects have lasted for as long as 1 week.<sup>116,206</sup> Likely because of its ability to cross the blood–brain barrier, reserpine depletes central catecholamines and produces drowsiness, extrapyramidal symptoms, hallucinations, migraine headaches, or depression.<sup>133</sup> In overdose, an extension of their pharmacologic effects is expected. Patients with severe orthostatic hypotension are treated with IV crystalloid boluses and a direct-acting vasopressor. If reserpine is involved, significant CNS depression should also be anticipated.<sup>133</sup>

### Peripheral $\alpha_1$ -Adrenergic Antagonists

The selective  $\alpha_1$ -adrenergic antagonists include prazosin, terazosin, and doxazosin. The  $\alpha_1$  receptor is a postsynaptic receptor primarily located on vascular smooth muscle, although they are also found in the eye and in the GI and genitourinary tracts.<sup>46,103</sup> These xenobiotics are used to treat urinary dysfunction secondary to benign prostatic hyperplasia.<sup>18</sup> They produce arterial smooth muscle relaxation, vasodilation, and a reduction of the blood pressure. Although better tolerated than ganglionic blockers and peripheral adrenergic neuron blockers, these medications are associated with significant symptoms of postural hypotension, including lightheadedness, syncope, or palpitations, particularly after the first dose or if the dosing is rapidly increased.<sup>18</sup> Hypotension and CNS depression ranging from lethargy to coma are reported in overdose.<sup>128,131,199</sup> Their use has also resulted in priapism.<sup>189</sup> Treatment of peripheral  $\alpha_1$ -adrenergic agonist includes supportive care, IV crystalloid boluses, and a vasopressor, with phenylephrine being a logical initial choice.

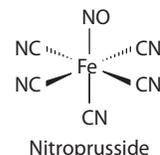

### DIRECT VASODILATORS

#### Hydralazine, Minoxidil, and Diazoxide

These xenobiotics produce vascular smooth muscle relaxation independent of innervation or known pharmacologic receptors.<sup>56,115,121</sup> This vasodilatory effect is attributed to stimulation of nitric oxide release from vascular endothelial cells. The nitric oxide then diffuses into the underlying smooth muscle cells, stimulating guanylate cyclase to produce cyclic guanosine monophosphate (cGMP). This second messenger indirectly inhibits calcium entry into the smooth muscle cells, producing vasodilation.<sup>198</sup> Minoxidil, however, also has direct potassium channel activation effects;<sup>123,161</sup> the opening of these adenosine triphosphate-linked potassium channels results in potassium influx and cell depolarization, thereby reducing calcium influx and ultimately relaxing vascular smooth muscle.<sup>30</sup> As this vasodilation occurs, the baroreceptor reflexes, which remain intact, produce an increased sympathetic outflow to the myocardium, resulting in an increase in heart rate and contractile force. Historically, these xenobiotics were used therapeutically in patients with severe, refractory hypertension and in conjunction with a  $\beta$ -adrenergic antagonist to diminish reflex tachycardia. Hydralazine continues to be used for the management of severe postpartum hypertension.<sup>234</sup> Hydralazine, minoxidil, and diazoxide are effective orally, but sodium nitroprusside is only used intravenously. Minoxidil is also used topically in a 2% solution to promote hair growth, and ingestion can cause significant poisoning.<sup>64,150</sup> Diazoxide, although previously used to rapidly reduce blood pressure in hypertensive emergencies, is rarely used for this indication now, given that it is not easily titrated and causes a variable, occasionally profound, hypotensive effect.<sup>120</sup> Adverse effects associated with daily hydralazine use include several immunologic phenomena such as hemolytic anemia, vasculitis, acute glomerulonephritis, and most notably a lupuslike syndrome.<sup>178</sup> Minoxidil is associated with changes on ECG, both in therapeutic doses and in overdose. Sinus tachycardia, ST-segment depression, and T-wave inversion are all reported.<sup>91,180,213</sup> There also appears to be an association with suprathreshold doses of minoxidil and left ventricular multifocal, subacute necrosis, and subsequent fibrosis.<sup>93,94</sup> The significance of either of these changes is unknown; they typically resolve with either continued therapy or as other toxic manifestations resolve.<sup>91,94</sup> The common toxic manifestations of these xenobiotics in overdose are an extension of their pharmacologic action. Symptoms include lightheadedness, syncope, palpitations, and nausea.<sup>3,138</sup> Signs include tachycardia alone<sup>180</sup> or with flushing or alterations in mental status, typically related to the degree of hypotension.<sup>150</sup>

In the case of hydralazine, minoxidil, or diazoxide overdose, GI decontamination—including AC and, possibly, WBI—is reasonable followed by routine supportive care, with special consideration to maintaining adequate mean arterial pressure. If intravenous crystalloid boluses are insufficient, then a peripherally acting  $\alpha$ -adrenergic agonist, such as norepinephrine or phenylephrine, is reasonable as the next therapy. Dopamine and epinephrine should be avoided to prevent an exaggerated myocardial response and tachycardia from  $\beta$ -adrenergic stimulation.

### Nitroprusside

Sodium nitroprusside is effectively a prodrug, exerting its vasodilatory effects only after its breakdown and the release of nitric oxide. The nitroprusside molecule also contains five cyanide radicals that, although gradually released, occasionally produce cyanide or thiocyanate toxicity.<sup>164,203</sup> Methemoglobin binds small amounts of liberated cyanide, which are also cleared by interacting with various sulfhydryl groups and enzymatically in the liver by rhodanese, which couples them to thiosulfate-producing thiocyanate.<sup>73</sup> This cyanide detoxification process in healthy adults occurs at a rate of about 1 mcg/kg/min, which corresponds to a sodium nitroprusside infusion rate of 2 mcg/kg/min.<sup>48,203</sup> A variety of factors—including poor nutrition, critical illness, surgery, diuretic use, and young age—place patients at risk for developing cyanide toxicity.<sup>37,48</sup> The hemolysis associated with cardiopulmonary bypass (CPB) places patients at particular risk because the elevated free hemoglobin accelerates the release of cyanide from the sodium nitroprusside moiety.<sup>37</sup> Therefore, depending on the balance of cyanide release (eg, rate of sodium nitroprusside infusion) and the rate of cyanide detoxification (eg, sulfur donor stores), cyanide toxicity can develop within hours. Infusion rates greater than 4 mcg/kg/min of nitroprusside for longer than 12 hours are expected to overwhelm the capacity of rhodanese for detoxifying cyanide.<sup>188</sup> Signs and symptoms of cyanide toxicity include alteration in mental status; anion gap metabolic acidosis; elevated lactate concentration; and in late stages, hemodynamic instability. If cyanide poisoning does occur, hydroxycobalamin is the current treatment of choice (Chap. 123).

One method of preventing cyanide toxicity from sodium nitroprusside is to expand the thiosulfate pool available for detoxification by the concomitant administration of sodium thiosulfate.<sup>48,89,153</sup> Dosing of 1 g of sodium thiosulfate for every 100 mg of nitroprusside is typically sufficient to prevent cyanide accumulation.<sup>188</sup> Thiocyanate thus formed accumulates, particularly in patients with CKD or acute kidney injury (AKI), and produces thiocyanate toxicity.<sup>73,203</sup> Simultaneous infusion of thiosulfate does not interfere with the vasodilatory effects of sodium nitroprusside (Antidotes in Depth: A42).<sup>100</sup>

Thiocyanate is almost exclusively renally eliminated, with an elimination half-life of 3 to 7 days. It is postulated that a continuous sodium nitroprusside infusion of 2.5 mcg/kg/min in patients with normal renal function could produce thiocyanate toxicity within 7 to 14 days, although it may be as short as 3 to 6 days or as little as 1 mcg/kg/min in patients with CKD who are not receiving hemodialysis.<sup>203</sup> The signs and symptoms of thiocyanate toxicity begin to appear at serum concentrations of 60 mcg/mL (1 mmol/L) and are very nonspecific, ranging from nausea, vomiting, fatigue, and dizziness to confusion, delirium, and seizures.<sup>73</sup> Severe thiocyanate toxicity causes life-threatening effects, such as hypotension with intracranial pressure elevation, when serum concentrations are above 200 mcg/mL.<sup>48,73,89</sup> Anion gap metabolic acidosis and hemodynamic instability do not occur with thiocyanate toxicity. Although cyanide or thiocyanate concentrations are not typically useful in the management of patients with cyanide toxicity, they should be considered for monitoring critically ill patients who are at risk of thiocyanate poisoning. Hemodialysis clears thiocyanate from the serum; patients with significant clinical manifestations of thiocyanate toxicity benefit from hemodialysis.<sup>60,146,154</sup>

Another therapy used to prevent cyanide toxicity from sodium nitroprusside is a simultaneous infusion of hydroxocobalamin.<sup>123</sup> Dosing of 25 mg/h has successfully reduced cyanide poisoning in humans.<sup>146</sup> As with thiosulfate, simultaneous infusion of hydroxocobalamin does not interfere with the vasodilatory effects of sodium nitroprusside.<sup>100</sup> Because of the relative higher cost of hydroxocobalamin as well its interactions with some laboratory tests, thiosulfate should remain the mainstay of prophylaxis

against sodium nitroprusside-induced cyanide toxicity (Antidotes in Depth: A41 and A42).

## DIURETICS

Diuretics are divided into three main groups: (1) the thiazides and related compounds, including hydrochlorothiazide and chlorthalidone; (2) the loop diuretics, including furosemide, bumetanide, and ethacrynic acid; and (3) the potassium-sparing diuretics, including amiloride, triamterene, and spironolactone. Two other groups of diuretics—the carbonic anhydrase inhibitors, such as acetazolamide, and osmotic diuretics (eg, mannitol)—are not used in the treatment of hypertension.

The thiazides produce their diuretic effect by inhibition of sodium and chloride reabsorption in the distal convoluted tubule. Loop diuretics, in contrast, inhibit the coupled transport of sodium, potassium, and chloride in the thick ascending limb of the loop of Henle. Although their exact antihypertensive mechanism is unclear, an increased urinary excretion of sodium, potassium, and magnesium results from the use of loop diuretics. Potassium-sparing diuretics act either as aldosterone antagonists, such as spironolactone, or as renal epithelial sodium channel antagonists, such as triamterene, in the late distal tubule and collecting duct.<sup>111</sup>

The majority of toxicity associated with diuretics is metabolic and occurs during chronic therapy or overuse.<sup>237</sup> Hyponatremia develops within the first 2 weeks of initiation of diuretic therapy in more than 67% of susceptible patients, and female sex, old age, and malnourishment are the greatest risk factors.<sup>9,215</sup> Manifestations of severe hyponatremia ( $[Na^+] < 120$  mEq/L) include headache, nausea, vomiting, confusion, seizures, or coma (Chap. 12). The osmotic demyelination syndrome, formally known as central pontine myelinolysis, is reported during rapid correction of severe hyponatremia secondary to diuretic abuse.<sup>44</sup>

Diuretic use is associated with hypokalemia and hypomagnesemia and can thus precipitate ventricular dysrhythmias such as torsade de pointes and sudden death.<sup>23,72,209,211</sup> Although it is unclear how great a risk, if any, diuretic use poses, it remains prudent to monitor and correct potassium and magnesium concentrations.<sup>27,209</sup> This is particularly important in older adult patients and for patients who concomitantly use digoxin, in which setting hypokalemia is clearly associated with dysrhythmias (Chap. 62).<sup>27</sup> Potassium-sparing diuretics can cause hyperkalemia, particularly in the setting of CKD or AKI or when combined with other hyperkalemia-producing drugs such as ACEIs.<sup>115</sup>

Thiazide diuretics can cause hyperglycemia, particularly in patients with diabetes mellitus, through depletion of total-body potassium stores. Because insulin secretion is dependent on transmembrane potassium fluxes, an overall decrease in potassium concentration reduces the amount of insulin secreted.<sup>136</sup> This effect is dose dependent and reversible either by potassium supplementation or discontinuation of the thiazide diuretic.<sup>36,96</sup> Thiazide diuretics are also associated with inducing hyperuricemia, renal calculi, and gout.<sup>31,88,90</sup> This is because the renal elimination of uric acid is extremely dependent on intravascular and urinary volume, so diuretic-induced volume depletion reduces uric acid filtration and increases its proximal tubule resorption.<sup>207,219</sup> Several unusual reactions are associated with thiazide diuretic use, including pancreatitis; cholecystitis; and hematologic abnormalities, such as hypercoagulability, thrombocytopenia, and hemolytic anemia.<sup>57,59,194,196,228,235</sup>

Despite the widespread use of these xenobiotics, isolated acute overdoses are distinctly rare. Major signs and symptoms include GI distress, brisk diuresis, possible hypovolemia and electrolyte abnormalities, and altered mental status.<sup>132</sup> Typically, the diuresis is short lived because of the limited duration of effect and the rapid clearance of the majority of diuretics. Assessment should focus on fluid and electrolyte status, which should be corrected as needed. If hyperkalemia is unexpectedly discovered, it could be due to either the ingestion of a potassium-sparing xenobiotic or, more likely, an overdose of potassium supplements, which are frequently prescribed in conjunction with thiazide and loop diuretics.<sup>107,108</sup> Diuretic overdose can cause altered mental status, including coma, without evidence of any fluid or electrolyte abnormalities.<sup>132,195</sup> Postulated mechanisms include a direct drug effect and induction of transient cerebral ischemia caused by hypotension.<sup>166</sup>

## ANGIOTENSIN-CONVERTING ENZYME INHIBITORS

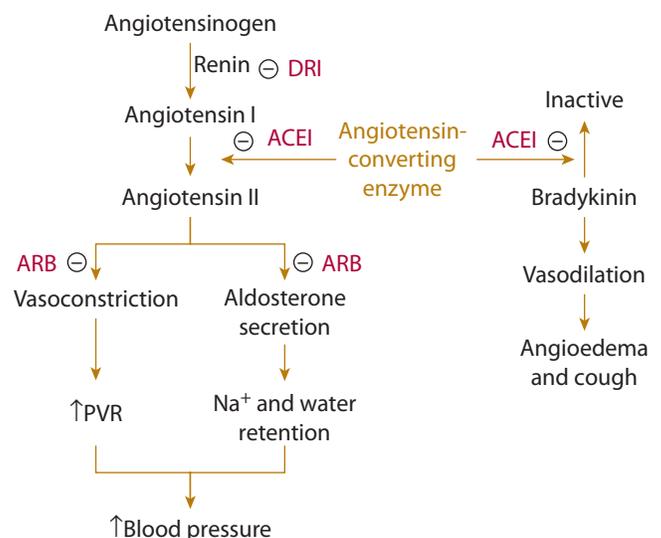

Angiotensin-converting enzyme inhibitors are among the most widely prescribed antihypertensives (Table 61–1). In general, they are well absorbed from the GI tract, reaching peak serum concentrations within 1 to 4 hours. Enalapril and ramipril are prodrugs and require hepatic metabolism to produce their active forms. Elimination is primarily via the kidneys.

All ACEIs have a common core structure of a 2-methylpropanolol-L-proline moiety.<sup>78</sup> This structural element binds directly to the active site of ACE, which is found in the lung and vascular endothelium, preventing the conversion of angiotensin I to angiotensin II. Because angiotensin II is a potent vasoconstrictor and stimulant of aldosterone secretion, it causes vasodilation; decreased peripheral vascular resistance; decreased blood pressure; increased cardiac output; and a relative increase in renal, cerebral, and coronary blood flow.<sup>78</sup> This hypotensive response can be severe in select patients after their initial dose, resulting in syncope and cardiac ischemia.<sup>39,102</sup> Patients with renovascular-induced hypertension and patients who are hypovolemic from concomitant diuretic use appear to be at greatest risk.<sup>102</sup> Overall, however, these drugs are well tolerated and have a very low incidence of side effects. Some reported adverse effects include rash, dysgeusia, neutropenia, hyperkalemia, chronic cough, and angioedema.<sup>15,52,78</sup> Because of their interference with the renin–angiotensin system, ACEIs are potential teratogens and should never be used by pregnant women or women of childbearing age.<sup>15</sup>

### Angiotensin-Converting Enzyme Inhibitor–Induced Angioedema

Angioedema is an inflammatory reaction in which there is increased capillary blood flow and permeability, resulting in an increase in interstitial fluid. If this process is confined to the superficial dermis, urticaria develops; if the deeper layers of the dermis or subcutaneous tissue are involved, angioedema results. Angioedema most commonly involves the periorbital, perioral, or oropharyngeal tissues.<sup>190</sup> This swelling can progress rapidly over minutes and result in complete airway obstruction and death.<sup>77,81</sup>

The pathogenesis of acquired angioedema involves multiple vasoactive substances, including histamine, prostaglandin D<sub>2</sub>, leukotrienes, and bradykinin.<sup>105</sup> Because ACE also inactivates bradykinin and substance P, ACE inhibition results in elevations in bradykinin concentrations that appear to be the primary cause of both ACEI angioedema and cough (Fig. 61–1).<sup>4,110</sup> Unlike anaphylaxis, there is no evidence that the ACEI angioedema phenomenon is immunoglobulin E (IgE) mediated,<sup>4</sup> although these two entities can be difficult to differentiate clinically.

**FIGURE 61–1.** An overview of the normal function of the renin–angiotensin–aldosterone system (RAAS) and the mechanisms of action of angiotensin-converting enzyme inhibitors (ACEIs), angiotensin II receptor blockers (ARBs), and direct renin inhibitors (DRIs) on that system. PVR = peripheral vascular resistance.

Although the literature is replete with reports of ACEI angioedema, the overall incidence is only approximately 0.1%, and it is idiosyncratic.<sup>69,110,212</sup>

One-third of these reactions occur within hours of the first dose, and another third occurs within the first week.<sup>143,212</sup> It is important to remember that the remaining third of cases occur at any time during therapy, even after years.<sup>88</sup> Women, African Americans, and patients with a history of idiopathic angioedema appear to be at greater risk.<sup>143,170</sup> In addition, there is evidence that patients who develop ACEI angioedema are at increased subsequent risk of developing angioedema from any etiology.<sup>17</sup>

Treatment varies depending on the severity and rapidity of the swelling. Because of its propensity to involve the tongue, face, and oropharynx, the airway must remain the primary focus of management. A nasopharyngeal airway is often helpful. If there is any potential for or suggestion of airway compromise, then early endotracheal intubation should be performed. Severe tongue and oropharyngeal swelling make orotracheal or nasotracheal intubation extremely difficult, if not impossible. If this is a concern, then fiberoptic nasal intubation is a viable solution, if available. Other potential intubation techniques include retrograde intubation over a guidewire passed through the cricothyroid membrane and emergent cricothyrotomy.<sup>82</sup> However, the most important aspect of airway management in patients experiencing ACEI angioedema is early risk assessment for airway obstruction and rapid intervention before the development of severe and obstructive swelling.<sup>2</sup>

Because ACEI angioedema is not an IgE-mediated phenomenon, pharmacologic therapy targeting an allergic cascade—such as epinephrine, diphenhydramine, and corticosteroids—should not be expected to be effective. However, when the history is unclear, these medications should not be withheld to ensure providing life-saving therapy to someone having a severe IgE-mediated allergic reaction.

Newer potential treatment modalities target various points along the cascade of events associated with hereditary angioedema. Hereditary angioedema results from a genetically mediated defect in C<sub>1</sub> esterase inhibitor, resulting in limited activity of this enzyme and an increase in kallikrein concentrations. Kallikrein is a protease that cleaves kininogen into bradykinin. The end result is very similar to the cause of ACEI angioedema, namely an activation of vascular bradykinin B<sub>2</sub> receptors.<sup>15</sup> Additional treatments include the C<sub>1</sub> esterase inhibitor Berinert, the kallikrein inhibitor ecallantide, and the bradykinin B<sub>2</sub> receptor antagonist icatibant. Some case reports of successful treatment of ACEI angioedema with these xenobiotics exist,<sup>16,76,162</sup> and a review summarized clinical trials (phase II for icatibant and phases II and III for ecallantide).<sup>201</sup> Significant costs associated with these treatment modalities should limit their use to patients with rapidly progressive or severe angioedema.

Fresh-frozen plasma (FFP) is described in case reports to reverse or slow the progression of both hereditary and ACEI angioedema.<sup>227</sup> Fresh-frozen plasma contains kinase II, which acts as an ACE and thus leads to the degradation of accumulated bradykinin. In these case reports, doses range from 1 to 5 units of FFP (200–250 mL/unit) with most using an infusion of 2 units of FFP as initial, and typically definitive, treatment.<sup>182,227</sup> Fresh-frozen plasma is a reasonable intervention for patients experiencing severe angioedema.

All patients with mild or rapidly resolving angioedema should be observed for several hours to ensure that the swelling does not progress or return. Outpatient therapy with a short course of oral antihistamines and corticosteroids is reasonable if there is any question as to whether ACEI therapy produced the angioedema because allergic-mediated angioedema will benefit from this treatment. Patients developing angioedema from ACEI therapy should be instructed to discontinue them permanently and to consult their primary care physicians about other antihypertensive options. Because this is a mechanistic and not allergic adverse effect, the use of any other ACEIs is contraindicated.

### Angiotensin-Converting Enzyme Inhibitor Overdose

The toxicity of ACEIs in overdose appears to be limited.<sup>40,132</sup> Although several reports of overdoses involving ACEIs have been published, the majority of the cases reported manifested toxicity of a coingestant.<sup>49,85,236</sup> Although hypotension is reported,<sup>12,13,126</sup> deaths are rarely related to isolated ACEI

ingestions.<sup>172</sup> Other patients remain asymptomatic despite high serum drug concentrations.<sup>126</sup>

Treatment should focus on supportive care and on identifying any potentially toxic coingestants, particularly other antihypertensives such as  $\beta$ -adrenergic antagonists and CCBs. In most cases, AC alone is adequate GI decontamination. Intravenous crystalloid boluses are often effective in correcting hypotension, although catecholamines are often required.<sup>12</sup> Naloxone is another potential treatment option. Angiotensin-converting enzyme inhibitors inhibit the metabolism of enkephalins and potentiate their opioid effects, which include lowering blood pressure.<sup>51,155</sup> In a controlled human volunteer study, continuous naloxone infusion effectively blunted the hypotensive response of captopril.<sup>1</sup> In one case report, naloxone appeared to be effective in reversing symptomatic hypotension secondary to a captopril overdose;<sup>232</sup> in another published case, naloxone was ineffective.<sup>12</sup> Although its role in the setting of ACEI overdose remains unclear, a trial of naloxone is reasonable in opioid-naïve patients.

### ANGIOTENSIN II RECEPTOR BLOCKERS

Angiotensin II receptor blockers (ARBs) were first introduced in 1995. These xenobiotics are rapidly absorbed from the GI tract, reaching peak serum concentrations in 1 to 4 hours, and then are eliminated either unchanged in the feces or, after undergoing hepatic metabolism predominantly CYP 3A4 and 2C9,<sup>14</sup> eliminated in the bile.<sup>167</sup>

Although these xenobiotics are similar to ACEIs in that they decrease the effects of angiotensin, they may have similar effects on blood pressure. The ARBs block whereas the ACEIs decrease the formation of angiotensin II, they act by antagonizing angiotensin II at the type 1 angiotensin (AT-1) receptor (Fig. 61-1).<sup>226</sup> This inhibits the vasoconstrictive- and aldosterone-promoting effects of angiotensin II and reduces blood pressure by blunting both the sympathetic as well as the renin-angiotensin systems.<sup>149</sup> Despite the mechanistic evidence that ARBs do not affect bradykinin degradation and therefore have a much lower incidence of angioedema compared with ACEIs, serious cases of angioedema associated with ARB therapy are reported.<sup>143,230</sup> In addition, there is a significantly higher incidence of angioedema associated with ARBs compared with other antihypertensives, such as  $\beta$ -adrenergic antagonists.<sup>225</sup> One meta-analysis found that the incidence of angioedema with ARBs was less than half that with ACEIs and not significantly different from placebo.<sup>142</sup> Similar to ACEIs, ARBs should never be used by pregnant patient because of their teratogenic potential.<sup>15,210</sup> In addition, when initiating ARB therapy, up to 1% develop of patients first-dose orthostatic hypotension.<sup>83</sup>

There are few published reports of isolated overdoses involving ARBs. Adverse signs and symptoms reflect orthostatic or absolute hypotension and include palpitations, diaphoresis, dizziness, lethargy, or confusion.<sup>26,152,214</sup> Hypotension should be treated with crystalloid boluses and catecholamine therapy.<sup>152,214</sup> Significant hypotension can occur during the induction of general anesthesia in patients who chronically taking ARBs. Hypotension in this case is reportedly refractory to traditional vasoconstrictor therapy, such as norepinephrine, ephedrine, and phenylephrine but appear to respond to vasopressin.<sup>63</sup>

One promising treatment for hypotension produced by ARBs and ACEIs is methylene blue<sup>148,159</sup> (Antidotes in Depth: A43). This treatment was first explored in patients placed on cardiopulmonary bypass (CPB).<sup>171,217</sup> During CPB, systemic blood pressure and peripheral vascular resistance decrease because of a number of factors, including acute hemodilution, citrate use during cardioplegia, a poorly defined inflammatory response that results in nitric oxide release, and an increase in circulating bradykinin.<sup>43,47,240</sup> This increase in bradykinin, which also mediates its vasodilatory effects via nitric oxide, occurs because bradykinin metabolism is primarily in pulmonary tissue and CPB mechanically bypasses the pulmonary system.<sup>43,47</sup> Angiotensin-converting enzyme inhibitors and ARBs exacerbate this vasodilation by further inhibiting bradykinin metabolism.<sup>179</sup> In a double-blind, placebo-controlled study of 30 patients taking ACEIs who were undergoing elective cardiac surgery requiring CPB, administration of methylene blue at the onset of CPB resulted in an increase in mean arterial pressure and systemic vascular

resistance and less use of phenylephrine and norepinephrine.<sup>148</sup> A reasonable starting dose of methylene blue, when used as a vasopressor, is 2 mg/kg with subsequent intermittent boluses or possibly continuous infusions starting at 0.5 mg/kg/h.<sup>112,148</sup>

## DIRECT RENIN INHIBITORS

Direct renin inhibitors such as aliskiren exert their antihypertensive effects by directly inhibiting circulating renin in the renin-angiotensin-aldosterone system (RAAS).<sup>238</sup> Unfortunately, all RAAS acting antihypertensives such as ACEIs, ARBs, and DRIs induce a compensatory increase in serum renin concentrations; however, only DRIs are able to blunt the physiologic effects of this rise.<sup>204,238</sup> Aliskiren is well tolerated and is an effective antihypertensive both as monotherapy and in combination with other antihypertensives, including hydrochlorothiazide, CCBs, and  $\beta$ -adrenergic antagonists.<sup>136</sup> However, significant controversy surrounds aliskiren use when combined ARBs or ACEIs after a clinical trial was halted because of an increased incidence of ischemic stroke, AKI, hyperkalemia, and hypotension was noted in patients with diabetes and CKD.<sup>173</sup> Currently, aliskiren is contraindicated in patients receiving ARBs or ACEIs.<sup>6</sup> There are no reported cases of poisoning or overdose; however, hypotension should be anticipated and treatment that includes supportive care, including IV crystalloid and catecholamines, seems reasonable.

## SUMMARY

- These xenobiotics are not often associated with severe poisonings, either because of limited use, as with most of the sympatholytics and direct vasodilators, or because of limited toxicity, as is the case of diuretics, ACEIs, ARBs, and DRIs.
- Severe clonidine poisoning classically presents as the opioid toxidrome producing profound CNS depression and bradycardia.
- Clonidine withdrawal manifests as agitation, tachycardia, and hypertension and should be treated with clonidine or benzodiazepines.
- Nitroprusside infusions greater than 4 mcg/kg/min result in cyanide poisoning, which can be prevented with coadministration of thiosulfate or hydroxycobalamin.
- Because of the pathogenesis of ACEI-induced angioedema, it is unlikely to respond to “typical” allergic treatment such as antihistamines, epinephrine, and corticosteroids. Rather, focus should be on definitive airway management in patients with rapidly progressing swelling or symptoms.

## HISTORY AND EPIDEMIOLOGY

The *Ebers Papyrus* provides evidence that the Egyptians used plants containing cardioactive steroids (CASs) at least 3,000 years ago. However, it was not until 1785, when William Withering wrote the first systematic account about the effects of the foxglove plant, that the use of CASs was more widely accepted into the Western apothecary. Foxglove, the most common source of plant CASs, was initially used as a diuretic and for the treatment of “dropsy” (edema), and Withering eloquently described its “power over the motion of the heart, to a degree yet unobserved in any other medicine.”<sup>123</sup>

In the past, CASs were the primary treatment for congestive heart failure and control of ventricular response rate in atrial tachyarrhythmias. Because of their narrow therapeutic index, acute and chronic toxicities remain important problems.<sup>84</sup> According to the American Association of Poison Control Centers data, between the years 2011 and 2015, there were more than 7,000 exposures to CAS-containing plants with five attributable deaths and about 12,000 exposures to CAS-containing xenobiotics resulting in more than 120 deaths (Chap. 130).

Most cases of pharmaceutically induced CAS toxicity encountered in the United States result from digoxin; other internationally available but much less commonly used preparations are digitoxin, ouabain, lanatoside C, deslanoside, and gitalin. Digoxin toxicity most commonly occurs in patients at the extremes of age or those with chronic kidney disease (CKD). In children, most acute overdoses are unintentional, either by mistakenly ingesting an adult’s medication or iatrogenically resulting from decimal point dosing errors. (Digoxin is prescribed in microgram doses, inviting 10-fold calculation errors.) In older adults, digoxin toxicity most commonly occurs either from interactions with another medication in their chronic regimen or indirectly as a consequence of an alteration in the absorption or elimination kinetics. These drug–drug interactions result from an adult’s chronic polypharmacy or from the addition of a new xenobiotic that changes CAS clearance in the liver or kidney or alters protein binding resulting in increased bioavailability.

Cardioactive steroid toxicity also results from exposure to certain plants or animals, including oleander (*Nerium oleander*); yellow oleander (*Thevetia peruviana*), which are implicated in the suicidal deaths of thousands of patients in Southeast Asia;<sup>25,26</sup> foxglove (*Digitalis* spp); lily of the valley (*Convallaria majalis*); common milkweed (*Asclepias syriaca*);<sup>104</sup> sea mango (*Cerbera manghas*);<sup>89</sup> dogbane (*Apocynum cannabinum*); and red

squill (*Urginea maritima*). Cardioactive steroid poisoning results from teas containing seeds of these plants and herbal products contaminated with plant CASs (Chaps. 43 and 118).<sup>16,19,53,77,89,91,97,104,115</sup> Toxicity has resulted from ingestion, instead of the intended topical application, of a purported aphrodisiac derived from the dried secretion of toads from the *Bufo* species, which contains a bufadienolide-class CAS.<sup>10–12</sup> Although there have been no reported human exposures, fireflies of the *Photinus* species (*P. ignitus*, *P. marginellu*, and *P. pyralis*) contain the CAS lucibufagin that is structurally a bufadienolides (see Chemistry).<sup>28,63</sup>

## CHEMISTRY

Cardioactive steroids contain an aglycone or “genin” nucleus structure with a steroid core and an unsaturated lactone ring attached at C-17. Cardioactive glycosides contain additional sugar groups attached to C-3. The sugar residues confer increased water solubility and enhance the ability of the molecule to enter cells. Cardenolides are primarily plant-derived aglycones with a five-membered unsaturated lactone ring. The bufadienolide and lucibufagin groups of CAS molecules are mainly animal derived and contain a six-membered unsaturated lactone ring (a plant derived exception is scillaren from red squill). Thus, when the aglycone digoxigenin is linked to one or more hydrophilic sugar (digitoxoses) moieties at C-3, it forms digoxin, a cardiac glycoside. The aglycone of digitoxin differs from that of digoxin by the absence of a hydroxyl group on C-12, and ouabain differs from digoxin by both the absence of a hydroxyl group on C-12 and the addition of hydroxyl groups on C-1, C-5, C-10, and C-11. The cardioactive components in toad secretions are genins and lack sugar moieties.

## PHARMACOKINETICS

The correlation between clinical effects and serum concentrations is based on steady-state concentrations, which is dependent on absorption, distribution, and elimination (Table 62–1). Although not proven,

TABLE 62–1 Pharmacology of Selected Cardioactive Steroids

Pharmacology	Digoxin	Digitoxin
Onset of action		
PO	1.5–6 h	3–6 h
IV	5–30 min	30 min–2 h
Maximal effect (h)		
PO	4–6	6–12
IV	1.5–3	4–8
Intestinal absorption (%)	40–90 (mean, 75)	>95
Plasma protein binding (%)	25	97
Volume of distribution (L/kg)	5–7 (adults) 16 (infants) 10 (neonates) 4–5 (adults with kidney failure)	0.6 (adults)
Elimination half-life (days)	1.6	6–7
Route of elimination (%)	Renal (60%–80%), with limited hepatic metabolism	Hepatic metabolism (80%)
Enterohepatic circulation (%)	7	26

IV = intravenous; PO = oral.

nonpharmaceutical CASs likely follow the absorption and distribution pattern of digoxin or digitoxin, therefore obtaining a serum concentration before 6 hours after ingestion (when tissue concentrations ultimately reach steady state) will give a misleadingly high (predistribution) serum concentration. After therapeutic dosing, the intravascular distribution of digoxin from the plasma is best described using a two-compartment model. The distribution or  $\alpha$  phase represents the decrease in intravascular drug concentration and is dependent on whether the route of exposure was intravenous (IV) or oral (PO). Blood concentrations decline exponentially with a distribution half-life of 30 minutes as the drug moves from the blood to the peripheral tissues. Most of the intravascular CAS leaves the blood and distributes to the tissues, resulting in a large volume of distribution ( $V_d$ ) (eg, the  $V_d$  of digoxin is 5–7 L/kg with therapeutic use). The  $\beta$  or elimination phase for digoxin has a half-life of approximately 36 hours and represents the total-body clearance of the drug, which is achieved primarily by the kidneys (70% of its clearance in a person with normal kidney function).<sup>18,47</sup>

After a massive acute digoxin overdose, the apparent half-life shortens to as little as 13 to 15 hours because elevated serum concentrations result in greater renal clearance before distribution to the tissues.<sup>51,111</sup> Even with therapeutic administration of CAS, adjustments to the dosing regimen must be made to avoid toxicity caused by the physiologic changes associated with aging, including hypothyroidism, chronic hypoxemia with alkalosis, and decreased glomerular filtration rate. Physiologic changes in CAS kinetics occur with functional decline of the liver, kidney, and heart and dynamics with electrolyte abnormalities, including hypomagnesemia, hypercalcemia, hyponatremia, and commonly hypokalemia. Therefore, serum concentrations of CAS should be monitored to avoid inadvertent toxicity. Hypokalemia resulting from a variety of mechanisms (eg, loop diuretics, poor dietary intake, diarrhea, and administration of potassium-binding resins) enhances the effects of CASs on the myocardium and is associated with toxicity at lower serum CAS concentrations. Chronic hypokalemia reduces the number of  $\text{Na}^+$ ,  $\text{K}^+$  adenosine triphosphatase (ATPase) units in skeletal muscle, which also alters drug effects.<sup>15</sup>

Drug interactions between digoxin and quinidine, verapamil, diltiazem, carvedilol, amiodarone, and spironolactone are common.<sup>20,23,46,66,93</sup> For example, quinidine decreases CAS tissue binding, which causes a reduction in the volume of distribution of the CAS, increasing its serum concentration; a reduction in excretion as a consequence of a decrease in renal perfusion; or, as a result of interference with secretion by the kidneys and intestines, because of inactivation of P-glycoproteins. Also, in approximately 10% to 15% of patients receiving digoxin, a significant amount of digoxin is inactivated in the gastrointestinal (GI) tract by enteric bacterium, primarily *Eubacterium lentum*. Inhibition of this inactivation by the alteration of the GI flora by many antibiotics, particularly macrolides, results in increased bioavailability<sup>71</sup> and increased serum CAS concentrations.<sup>92</sup>

## MECHANISMS OF ACTION AND PATHOPHYSIOLOGY

### Electrophysiologic Effects on Inotropy

Cardioactive steroids increase the force of contraction of the heart (positive inotropic effect) by increasing cytosolic  $\text{Ca}^{2+}$  during systole. Both  $\text{Na}^+$  and  $\text{Ca}^{2+}$  ions enter and exit cardiac muscle cells during each cycle of depolarization–contraction and repolarization–relaxation. During depolarization–contraction, sodium entry heralds the start of the action potential (phase 0) and carries the inward, depolarizing positive charge. Calcium subsequently enters the cardiac myocyte through L-type calcium channels during late phase 0 and the plateau phase of the action potential. This extracellular  $\text{Ca}^{2+}$  entry into the cell triggers the release of additional  $\text{Ca}^{2+}$  into the cytosol from the sarcoplasmic reticulum (SR). During repolarization–relaxation (diastole),  $\text{Ca}^{2+}$  removed from the cytosol by two mechanisms—it is sequestered back into the SR by a local  $\text{Ca}^{2+}$ -ATPase and is moved out of the cell by an  $\text{Ca}^{2+}$ ,  $\text{Na}^+$ -antiporter (Fig. 62–1 and Chap. 15).<sup>76</sup>

Cardioactive steroids inhibit active transport of  $\text{Na}^+$  and  $\text{K}^+$  across the cell membrane during repolarization by binding to a specific site on the extracellular face of the alpha-subunit of the membrane  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase. This inhibits the cellular  $\text{Na}^+$  pump activity, which decreases  $\text{Na}^+$  extrusion and increases  $\text{Na}^+$  in the cytosol, thereby decreasing the transmembrane  $\text{Na}^+$  gradient. Because the  $\text{Ca}^{2+}$ ,  $\text{Na}^+$ -antiporter is not driven by adenosine triphosphate (ATP) but rather from the  $\text{Na}^+$  gradient generated by the  $\text{Na}^+$ ,  $\text{K}^+$  transport mechanism (the antiporter extrudes one calcium ion from the cell in exchange for three sodium ions moving into the cell down a concentration gradient),<sup>27</sup> the dysfunction of the  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase pump reduces  $\text{Ca}^{2+}$  extrusion from the cell. The accumulation of cytoplasmic  $\text{Ca}^{2+}$  enhances the  $\text{Ca}^{2+}$  release from the SR during systole,<sup>7</sup> which increases the force of contraction of the cardiac muscle. Additional mechanisms of action are being explored and include creation of transmembrane calcium channels by cardioactive glycosides.<sup>1</sup>

### Effects on Cardiac Electrophysiology

At therapeutic serum concentrations, CASs increase automaticity and shorten the repolarization intervals of the atria and ventricles (Table 62–2). There is a concurrent decrease in the rate of depolarization and conduction through the sinoatrial (SA) and atrioventricular (AV) nodes, respectively. This is mediated directly by depression of myocardial tissue and indirectly via an enhancement in vagally mediated parasympathetic tone. These changes in nodal conduction are reflected on the electrocardiogram (ECG) by a decrease in ventricular response rate to suprajunctional rhythms and by PR interval prolongation. The effects of CASs on ventricular repolarization are related to the elevated intracellular resting potential caused by accumulated cytosolic  $\text{Ca}^{2+}$  that manifests on the ECG as QT interval shortening and ST-segment and T-wave forces opposite in direction to the major QRS forces. The last effect results in the characteristic scooping of the ST segments (referred to as the *digitalis effect*; Fig. 62–2).

Excessive increases in intracellular  $\text{Ca}^{2+}$  caused by CAS toxicity result in delayed afterdepolarizations (DADs). Delayed afterdepolarizations are fluxes in membrane potential caused by  $\text{Ca}^{2+}$  release from the SR, which is caused by excess cytosolic  $\text{Ca}^{2+}$  and appear on the ECG as U waves. Occasionally, DADs initiate a cellular depolarization that manifests as a premature ventricular contraction (Chap. 16).<sup>27,58</sup>

Hypokalemia reduces  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase activity and enhances pump inhibition induced by CASs. This enhances myocardial automaticity and increases myocardial susceptibility to CAS-related dysrhythmias, partly as a result of decreased competitive inhibition between the CAS and potassium at the  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase exchange.<sup>95</sup> Severe hypokalemia (<2.5 mEq/L) reduces the efficacy of sodium–potassium pump function, slowing the pump and exacerbating concomitant  $\text{Na}^+$ – $\text{K}^+$  ATPase exchange inhibition by CASs.<sup>58</sup> Magnesium is a cofactor of the  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase exchange.<sup>29</sup> Hypomagnesemia reduces the  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase exchange activity, enhancing the inhibition affects and increasing the sensitivity to CASs.<sup>95</sup> Cardioactive steroid toxicity, evidenced by increased dysrhythmias and myocardial irritability, is closely associated with magnesium deficiency.<sup>118,125</sup>

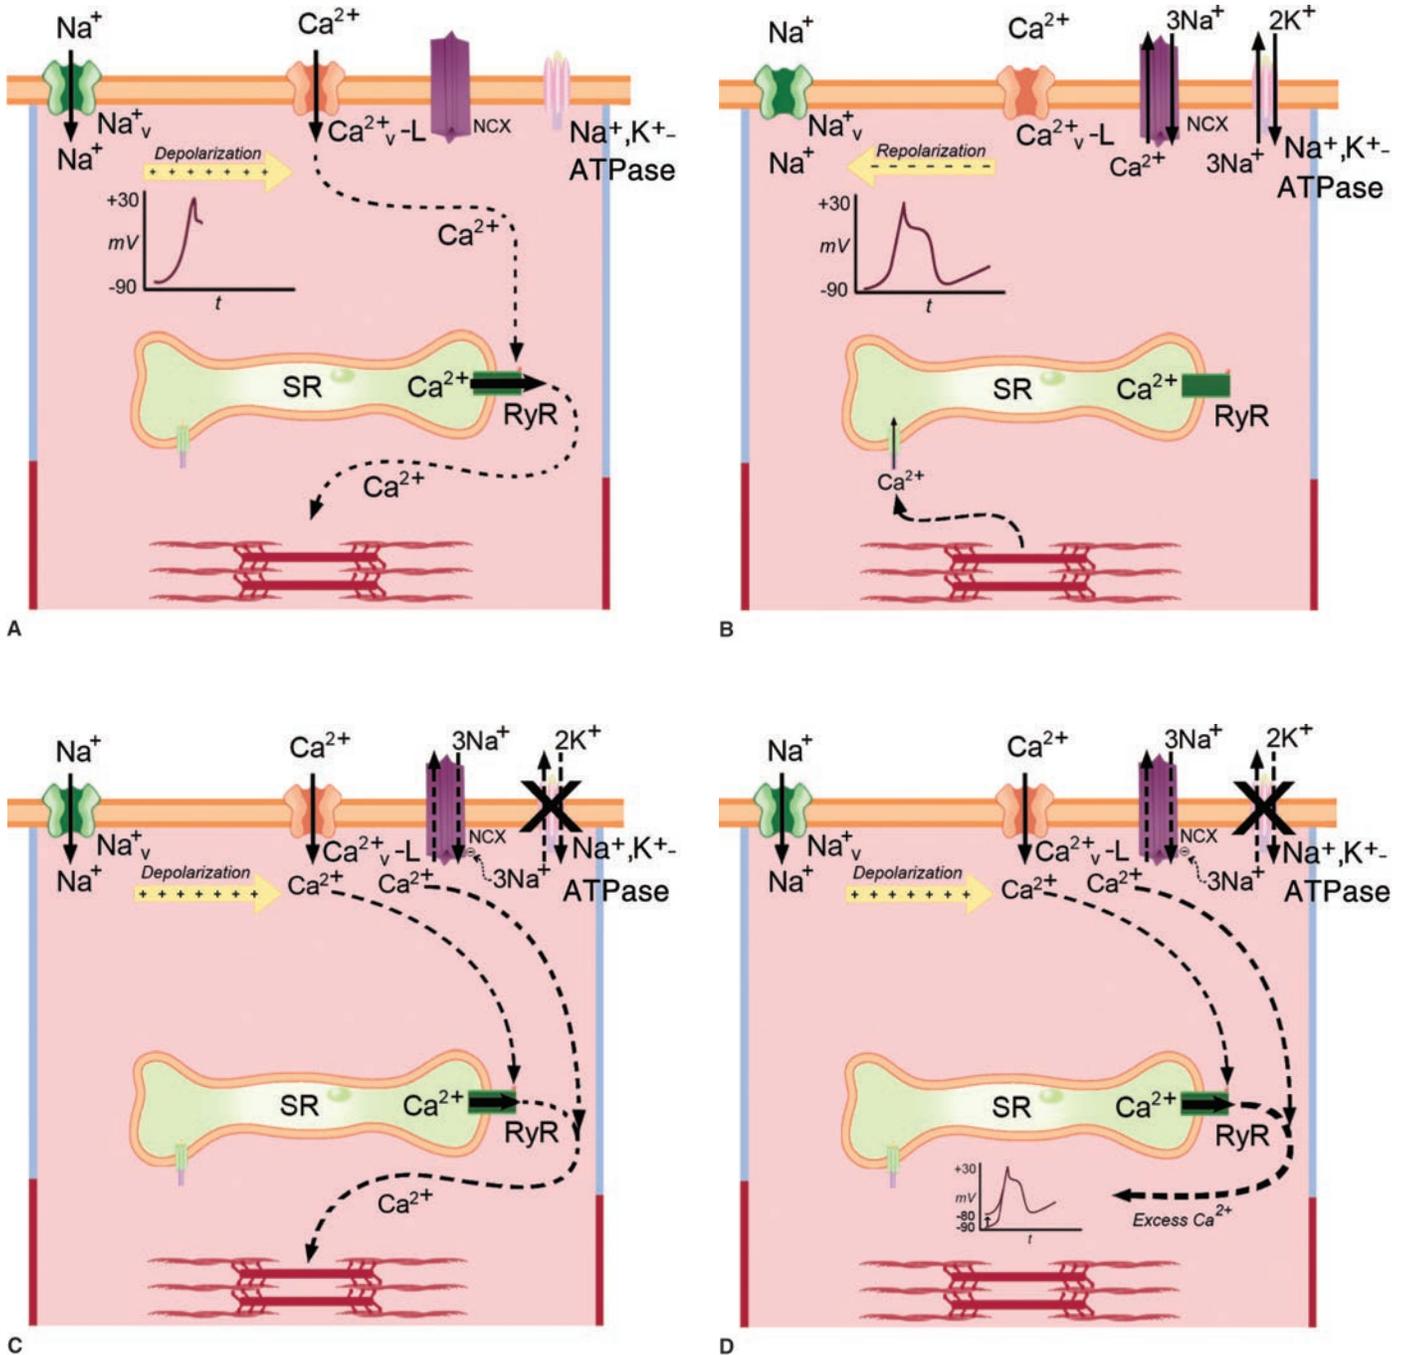

### Effects of Cardioactive Steroids on the Autonomic Nervous System

The parasympathetic system is affected by CASs by an increase in release of acetylcholine from vagal fibers,<sup>72,114</sup> possibly through augmentation of intracellular  $\text{Ca}^{2+}$ .

The sympathetic system is affected by CASs by an increase in efferent sympathetic discharge,<sup>85,109</sup> which exacerbates dysrhythmias.

## MANIFESTATIONS OF CARDIOACTIVE STEROID TOXICITY

Detection of CAS toxicity is based on an accurate history of CAS exposure, high clinical suspicion based on subtle symptoms, and ECG and electrolyte abnormalities, coupled with a detectable CAS concentration. Although there are differences in the signs and symptoms of acute versus chronic CAS poisoning, adults and children have similar manifestations when poisoned.

**FIGURE 62-1.** Pharmacology and toxicology of the cardioactive steroids (CASs). **(A)** Normal depolarization. Depolarization occurs after the opening of fast Na<sup>+</sup> channels; the increase in intracellular potential opens voltage-dependent Ca<sup>2+</sup> channels, and the influx of Ca<sup>2+</sup> induces the massive release of Ca<sup>2+</sup> from the sarcoplasmic reticulum (SR), producing contraction. **(B)** Normal repolarization. Repolarization begins with active expulsion of 3Na<sup>+</sup> ions in exchange for 2K<sup>+</sup> ions using an ATPase. This electrogenic (3Na<sup>+</sup> for 2K<sup>+</sup>) pump creates a Na<sup>+</sup> gradient used to expel Ca<sup>2+</sup> via an antiporter (NCX). The SR sequesters its Ca<sup>2+</sup> load via a separate ATPase. **(C)** Pharmacologic CAS. Digitalis inhibition of the Na<sup>+</sup>,K<sup>+</sup>-ATPase raises the intracellular Na<sup>+</sup> content, preventing the antiporter from expelling 1Ca<sup>2+</sup> in exchange for 3Na<sup>+</sup>. The net result is an elevated intracellular Ca<sup>2+</sup>, resulting in enhanced inotropy through enhanced SR calcium release. **(D)** Toxicologic CAS. Excessive elevation of the intracellular Ca<sup>2+</sup> elevates the resting potential, producing myocardial sensitization and predisposing to dysrhythmias. RyR = ryanodine receptor.

**Noncardiac Manifestations**

**Acute Toxicity**

An asymptomatic period of several minutes to several hours often follows a single administered toxic dose of CAS. The first clinical effects are typically nausea, vomiting, or abdominal pain. Central nervous system effects of acute toxicity include lethargy, confusion, and weakness that are not caused by hemodynamic changes.<sup>3,16</sup> The absence of nausea and vomiting within several hours after exposure makes severe acute CAS poisoning unlikely.

**Chronic Toxicity**

Chronic toxicity is often difficult to diagnose as a result of its insidious development and protean manifestations, including weakness, anhedonia, and loss of appetite.<sup>84</sup> Symptoms also include those that occur with acute poisonings; however, they are often less obvious. Gastrointestinal findings include anorexia, nausea, vomiting, abdominal pain, and weight loss. Neuropsychiatric disorders include delirium, confusion, drowsiness, headache, hallucinations, and, rarely, seizures.<sup>16,39,41</sup> Visual disturbances include transient

**TABLE 62–2** Electrophysiologic Effects of Cardioactive Steroids on the Myocardium

	Atria and Ventricles	AV Node	Electrocardiography Findings
Excitability	↑	—	Extrasystoles, tachydysrhythmias
Automaticity	↑	—	Extrasystoles, tachydysrhythmias
Conduction velocity	↓	↓	↑ PR interval, AV block
Refractoriness	↓	↑	↑ PR interval, AV block, decreased QT interval

AV = atrioventricular.

amblyopia, photophobia, blurring, scotomata, photopsia, decreased visual activity, and aberrations of color vision (chromatopsia) such as yellow halos (xanthopsia) around lights.<sup>67,68</sup>

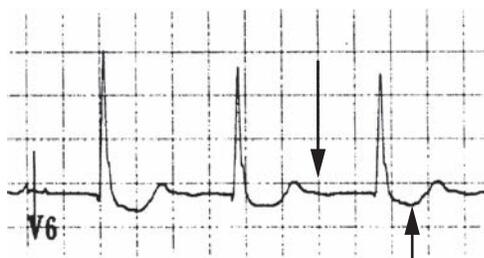

### Electrolyte Abnormalities

Elevated serum potassium concentrations frequently occur in patients with acute CAS poisoning.<sup>15,58</sup> Hyperkalemia has important prognostic implications because the serum potassium concentration is a better predictor of lethality than either the initial ECG changes or the serum CAS concentration.<sup>5,6</sup> In a study of 91 acutely digitoxin-poisoned patients conducted before digoxin-specific Fab was available, approximately 50% of the patients with serum potassium concentrations of 5.0 to 5.5 mEq/L died. Although a serum potassium concentration lower than 5.0 mEq/L was associated with no deaths, all 10 patients with serum potassium concentrations above 5.5 mEq/L died.<sup>5</sup> Elevation of the serum potassium concentration after administration of CASs is a result of CAS inhibition of the Na<sup>+</sup>, K<sup>+</sup>-ATPase pump, which results in the inhibition of potassium uptake in exchange for Na<sup>+</sup> by skeletal muscle (the largest potassium reservoir). Hyperkalemia probably causes further hyperpolarization of myocardial conduction tissue, increasing AV nodal block, thereby exacerbating CAS-induced bradydysrhythmias and conduction delays.<sup>58</sup> However, correction of the hyperkalemia alone does not increase patient survival;<sup>5</sup> it is a marker for, but not the cause of, the morbidity and mortality associated with CAS poisoning in a single study. Hyperkalemia was a marker of increased morbidity and subsequent mortality with chronic digoxin overdose.<sup>74</sup> The interrelationships between intracellular and extracellular potassium and CAS therapy are complex and incompletely understood.

### Cardiac Manifestations

#### General

With therapeutic use, CASs slow tachydysrhythmias without causing hypotension. With poisoning, alterations in cardiac rate and rhythm result in nearly any dysrhythmia with the exception of a rapidly conducted supraventricular tachydysrhythmia because of the prominent AV nodal depressive effect of CASs. In 10% to 15% of cases, the first sign of toxicity is the appearance of an ectopic ventricular rhythm.<sup>95</sup> Although no single dysrhythmia is pathognomonic of CAS toxicity, toxicity should be suspected when

**FIGURE 62–2.** Digitalis effect noted in the lateral precordial lead, V6. Note the prolonged PR interval (long arrow) and the repolarization abnormality (scooping of the ST segment) (short arrow).

**TABLE 62–3** Cardiac Dysrhythmias Associated With Cardioactive Steroid Poisoning

#### Myocardial Irritability Causing Dysrhythmias

Atrial flutter and atrial fibrillation with AV block  
Bidirectional ventricular tachycardia  
Nonparoxysmal atrial tachydysrhythmias with AV block  
Nonsustained ventricular tachycardia  
Premature and sustained ventricular contractions  
Ventricular bigeminy  
Ventricular fibrillation

#### Primary Conduction System Dysfunction Causing Dysrhythmias

Junctional tachycardia  
AV dissociation  
High-degree AV block  
Sinus bradycardia  
Exit blocks  
His-Purkinje dysfunction  
SA nodal arrest

AV = atrioventricular; SA = sinoatrial.

there is increased automaticity with impaired conduction through the SA and AV nodes.<sup>58</sup> Bidirectional ventricular tachycardia is nearly diagnostic, although it may also occur with poisoning by aconitine and other uncommon xenobiotics<sup>106</sup> (Fig. 15–19). Dysrhythmias, including atrial tachycardia with high-degree AV block, result from the complex electrophysiologic influences on both the myocardium and conduction system of the heart that stem from direct, vagotonic, and other autonomic actions of the CASs.

The effects of digoxin vary with dose and the type of cardiac tissue involved. The atrial and ventricular myocardial tissues exhibit increased automaticity and excitability, resulting in tachydysrhythmias and extrasystoles. In atrial and nodal conducting system tissues, signal velocity is reduced, resulting in an increased PR interval and AV nodal block. Atrioventricular junctional blocks of varying degrees associated with increased ventricular automaticity are the most common cardiac manifestations, occurring in 30% to 40% of patients with CAS toxicity.<sup>73</sup> Atrioventricular dissociation results from suppression of the dominant pacemaker with escape of a secondary pacemaker or from inappropriate acceleration of a ventricular pacemaker. Hypotension, shock, and cardiovascular collapse may ensue. Table 62–3 summarizes these findings.

#### Acute Toxicity

A variety of cardiac dysrhythmias are associated with CAS toxicity. These dysrhythmias are unified by the presence of a sensitized myocardium and a depressed AV node (Table 62–3). Early bradydysrhythmias result from increased vagal tone at the SA and AV nodes and are often responsive to atropine.<sup>37,80</sup>

#### Chronic Toxicity

Later appearing bradydysrhythmias in both acute and chronic CAS toxicity occur by direct actions on the heart and often are minimally responsive to atropine.<sup>37</sup> Ventricular tachydysrhythmias are more common in patients with chronic or later in acute poisoning.

### DIAGNOSTIC TESTING

Properly obtained and interpreted serum digoxin concentrations aid significantly in the management of patients with suspected digoxin toxicity, as well as in the management of patients poisoned by other CASs. Although most institutions report a therapeutic range for serum digoxin concentration from 0.5 to 2.0 ng/mL (SI units, 1.0–2.6 nmol/mL), current understanding suggests an upper limit of 1.0 ng/mL to maintain benefit while decreasing

the risk of toxicity.<sup>98,107</sup> In addition to determining a serum CAS concentration, care must be taken to interpret the concentration as a correlate with other factors—the clinical condition of the patient; the interval between the last dose and the time the blood sample was taken; the presence of other metabolic abnormalities, including hypokalemia, hypomagnesemia, hypercalcemia, hypernatremia, alkalosis, hypothyroidism, and hypoxemia; and the use of xenobiotics such as amiodarone, calcium channel blockers, catecholamines, quinidine, and diuretics.

Cardioactive steroid poisoning is multifactorial, and using the upper limit of the therapeutic range of digoxin as the sole indicator of toxicity is misleading<sup>101</sup> because there is an overlap in serum digoxin concentrations between toxic and nontoxic patients. In general, a patient's clinical condition and serum concentration correlate well; the significance of a serum concentration depends on when the value is obtained after an acute ingestion to account for the distribution phase of the drug. Asymptomatic patients with CAS concentrations obtained before completion of the  $\alpha$  distribution, found to be above the therapeutic range, are less often toxic but require close observation and retesting. Patients with mean pharmaceutical CAS serum concentrations above 2 ng/mL for digoxin and above 40 ng/mL for digitoxin measured 6 hours after the last dose often are clinically toxic.<sup>59</sup> A patient with a markedly elevated CAS concentration at any point after ingestion (eg, 15 ng/mL or greater for digoxin) requires definitive therapy.

In most hospitals, “digoxin levels” are the only estimation available to physicians in the acute setting when evaluating a patient for presumed nondigoxin CAS poisoning. The assays typically used in most institutions frequently, but unpredictably, cross-react with other plant- or animal-derived CASs. Although a monoclonal digoxin immunoassay accurately only quantifies the serum digoxin concentration, an elevated digoxin concentration in the correct clinical setting will qualitatively assist in making a presumptive diagnosis of nonpharmaceutical CAS exposure (Chaps. 43 and 118).<sup>13,88</sup> For example, using various techniques, including high-performance liquid chromatography and monoclonal and polyclonal antibody analysis, “digoxin” concentrations were determined from serum to which oleandrin and oleandrinogenin from *Nerium oleander* was added or from patients exposed to *Thevetia peruviana* (yellow oleander) or toad-secreted bufadienolides.<sup>11,25,55</sup> Patients with CAS poisoning from plant- or animal-derived CASs may have a positive detection of CAS when using a polyclonal digoxin assay and a low or negative finding when using a monoclonal assay (Chaps. 43 and 118).

Serum concentrations of digoxin are measured in one of two ways: free digoxin and total digoxin. The most common method of quantifying total digoxin in the serum is by fluorescence polarization immunoassay. Under normal circumstances, 6 hours after the last dose, measuring total digoxin in the serum accurately predicts cardiac concentrations.<sup>13,24</sup> However, after the administration of digoxin-specific Fab (which remains almost entirely within the intravascular space ( $V_d$ , 0.40 L/kg), there is a large elevation in blood CAS concentrations because the CAS is drawn from the tissues and complexes with the antibody fragment. A large increase in total serum digoxin concentrations occurs, representing free CAS plus bound (inactivated) CAS. In this situation, requesting a “free digoxin level” will avoid this spurious increase and reflect clinically relevant unbound digoxin concentration. Paradoxically, excess digoxin Fab may itself cause a false elevation in digoxin concentration (Chap. 7).

## ENDOGENOUS DIGOXINLIKE IMMUNOREACTIVE SUBSTANCE

Some patients have a positive digoxin assay resulting from an endogenous digoxinlike immunoreactive substance (EDLIS) that is structurally and functionally similar to prescribed CASs.<sup>45,46</sup> This substance is found in patients with increased inotropic need or reduced renal clearance, including neonates,<sup>116</sup> patients with end-stage kidney disease,<sup>17,42,54</sup> liver disease,<sup>79</sup> subarachnoid hemorrhage,<sup>122</sup> congestive heart failure,<sup>40,102</sup> insulin-dependent diabetes,<sup>35</sup> stress,<sup>41,117</sup> or hypothermia<sup>52</sup>; after strenuous exercise;<sup>117</sup> and in pregnancy.<sup>31,43,50</sup> An endogenous  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase-inhibiting dihydropyrene-substituted bufadienolide CAS was isolated from human placenta.<sup>32</sup> It differs from the toad bufadienolides by a single double-bond pyrone ring. Because

bufadienolides are not normally found in either healthy humans or edible plants, a synthetic pathway to produce dihydropyrene-substituted steroids in humans is thought to be responsible for EDLIS. Further research is necessary to confirm this pathway.<sup>50</sup> A clinician suspecting this problem should consult the clinical laboratory.<sup>34</sup> Clinical observations indicate that the serum digoxin concentration contributed by EDLIS is usually less than 2 ng/mL.

Other endogenous substances that can cross-react with the digoxin assay to produce a false-positive result include bilirubin<sup>79</sup> and xenobiotics, such as spironolactone.<sup>103</sup>

## THERAPY

### Acute Management Overview

Initial treatment of a patient with acute CAS poisoning includes providing general care (eg, GI decontamination, monitoring for dysrhythmias, measuring electrolyte and digoxin concentrations) and definitive care (eg, administering digoxin-specific antibody fragments {DSFab}). Secondary care includes treating complications such as dysrhythmias and electrolyte abnormalities.

### Gastrointestinal Decontamination

The initial treatment should be directed toward prevention of further GI absorption. Rarely, if ever, is emesis or lavage recommended because efficacy is limited because of rapid absorption from the gut and to the emetic effects of the drug itself. Because many CASs, such as digitoxin and digoxin, are recirculated enterohepatically, both late and repeated activated charcoal (AC) administration (1 g/kg of body weight every 2–4 hours for up to four doses) are beneficial in reducing serum concentrations.<sup>18,21,65,69,86,120</sup> Activated charcoal prevents reabsorption of CAS from the GI tract and reduces the serum half-life. Activated charcoal is recommended in CAS-toxic patients if definitive therapy with digoxin-specific Fab is not immediately available or when kidney function is impaired.<sup>21</sup>

### Advanced Management

#### Digoxin-Specific Antibody Fragments

Definitive therapy for patients with life-threatening dysrhythmias from CAS toxicity (in descending order of associated mortality: ventricular tachycardia, AV junctional tachycardia, and AV block<sup>33</sup>) is to administer DSFab.<sup>2,34,36,87,91,97,108,112,124</sup> Purified digoxin-specific Fab administration causes an immediate sharp decrease in free serum digoxin concentrations; a concomitant, but clinically unimportant, massive increase in total serum digoxin concentration; an increase in renal clearance of inactivated bound CAS; and a decrease in serum potassium concentration.<sup>2</sup> In addition, the administration of digoxin-specific Fab is pharmacoconomically advantageous in economically developed countries.<sup>22</sup> Although the antidote itself is expensive, its expense is far outweighed by obviating the need, risk, and expense of long-term intensive care unit stays and of repetitive evaluation of potassium and digoxin concentrations. Table 62–4 lists the indications for administering digoxin-specific Fab. Extensive discussion is found in Antidotes in Depth: A22.

#### Other Cardiac Therapeutics

Secondary treatments used in patients with symptomatic CAS poisoning include the use of atropine for supraventricular bradydysrhythmias or high degrees of AV block. Atropine dosing is 0.5 mg administered IV to an adult or 0.02 mg/kg with a minimum of 0.1 mg to a child. Atropine should be titrated to block the vagotonic effects of CASs. The dose should be repeated at 5-minute intervals if necessary. Therapeutic success is unpredictable because the depressant actions of CASs are mediated only partly through the vagus nerve.

Phenytoin and lidocaine were used to manage CAS-induced ventricular tachydysrhythmias and ventricular irritability. These xenobiotics depress the enhanced ventricular automaticity without significantly slowing, and perhaps enhancing, AV nodal conduction.<sup>96</sup> In fact, phenytoin reverses digitalis-induced prolongation of AV nodal conduction while suppressing digitalis-induced ectopic tachydysrhythmia without diminishing myocardial contractile forces.<sup>49</sup> In addition, phenytoin terminates supraventricular dysrhythmias induced by digitalis more effectively than lidocaine.<sup>96</sup>

**TABLE 62–4** Indications for Administration of Digoxin-Specific Antibody Fragments

Any digoxin related life-threatening dysrhythmias, regardless of SDC  
 —Includes ventricular tachycardia or ventricular fibrillation or progressive bradycardia such as atropine-resistant symptomatic sinus bradycardia or second or third-degree heart block  
 Potassium concentration >5 mEq/L in the setting of acute digoxin poisoning  
 Chronic elevation of SDC associated with dysrhythmias, significant GI symptoms, or altered mental status  
 SDC ≥15 ng/mL at any time or ≥10 ng/mL 6 h postingestion, regardless of clinical effects  
 Acute ingestion of 10 mg of digoxin in an adult  
 Acute ingestion of 4 mg of digoxin in a child  
 Poisoning with a nondigoxin cardioactive steroid

**Digoxin-specific Fab dosing (round up to number of whole vials in calculation)**

$$\text{No. of vials} = \frac{\text{SDC (ng/mL)} \times \text{Patient weight (kg)}}{100}$$

$$\text{No. of vials} = \frac{\text{Amount ingested (mg)}}{0.5 \text{ (mg/vial)}} \times 80\% \text{ bioavailability}$$

Empiric therapy for acute poisoning:

10–20 vials (adult or pediatric {must watch for volume overload})

Empiric therapy for chronic poisoning:

Adults: 3–6 vials

Children: 1–2 vials

GI = gastrointestinal; SDC = serum digoxin concentration.

patients treated with immunotherapy and 23% of patients treated with internal pacemakers. The main reasons for failure of digoxin-specific Fab were pacing-induced dysrhythmias and delayed or insufficient doses of digoxin-specific Fab. Iatrogenic complications of pacing occurred in 36% of patients. Thus, overdrive suppression with a temporary transvenous pacemaker would only be reasonable in the scenario of unavailability or failure of digoxin-specific Fab in the presence of CAS poisoning.<sup>6,113</sup> In the setting of digoxin poisoning, administration of transthoracic electrical cardioversion for atrial tachydysrhythmias is associated with the development of potentially lethal ventricular dysrhythmias. The dysrhythmias were related to the degree of toxicity and the amount of administered current in cardioversion.<sup>99</sup> It is reasonable to attempt transthoracic pacing for atropine unresponsive bradycardia in settings when definitive care (digoxin-specific Fab fragments) is delayed or unavailable. In CAS-poisoned patients with unstable rhythms, such as unstable ventricular tachycardia or ventricular fibrillation, cardioversion, and defibrillation, respectively, are indicated.

**Electrolyte Therapy****Potassium**

Hypokalemia and hyperkalemia exacerbate CAS cardiotoxicity even at “therapeutic” digoxin concentrations. When hypokalemia is noted in conjunction with tachydysrhythmias or bradycardia, potassium replacement should be administered with serial monitoring of the serum potassium concentration. Digoxin-specific Fab administration generally should be withheld until the hypokalemia is corrected because the life-threatening manifestations of CAS cardiotoxicity often resolves.

In hyperkalemic patients, reduction in potassium concentrations should be judiciously initiated with care to avoid hypokalemia prior to initiating DsFab. Any exacerbation of CAS cardiotoxicity despite this correction should be treated immediately with Fab fragments.

In acute CAS toxicity, if potassium is at least 5 mEq/L, DS Fab are recommended. If digoxin-specific Fab is not available immediately and ECG evidence of a dysrhythmia suggests hyperkalemia is present, an attempt should be made to lower the serum potassium with IV insulin, dextrose, sodium bicarbonate and PO administration of an ion-exchange substrate (eg, resin sodium polystyrene sulfonate) as indicated. Caution should be applied to the subsequent administration of digoxin-specific Fab because of concern for profound hypokalemia.

Although calcium is beneficial in most hyperkalemic patients, in the setting of CAS poisoning, administration of calcium salts is considered to be potentially dangerous. A number of experimental studies cite the additive or synergistic actions of calcium and CAS on the heart (because intracellular hypercalcemia is already present), resulting in dysrhythmias,<sup>38,82,105</sup> cardiac dysfunction<sup>60</sup> (eg, hypercontractility, so-called stone heart hypocontractility), and cardiac arrest.<sup>70,105,118</sup> Although a 2004 study was unable to show an adverse effect,<sup>44</sup> there exist three case reports<sup>8,62</sup> of CAS-poisoned patients who died at various intervals after calcium administration, which supports the withholding of calcium administration in the setting of hyperkalemia induced by CAS poisoning.

Although rate of administration of Ca<sup>2+</sup> may play a role in exaggerating CAS cardiac toxicity,<sup>70,82</sup> calcium administration should be avoided because better, safer, alternative treatments, such as digoxin-specific Fab, insulin, and sodium bicarbonate, are available for CAS-induced hyperkalemia.<sup>14,58,87,108,112,124</sup> The purported mechanism of exaggerated cardiac effects in CAS-toxic patients with the administration of Ca<sup>2+</sup> is attributed to the preexisting CAS augmented intracellular cytoplasmic Ca<sup>2+</sup>. Exogenous Ca<sup>2+</sup> is thought to increase Ca<sup>2+</sup> transmembrane concentration gradient that further inhibits calcium extrusion through the Na<sup>+</sup>-Ca<sup>2+</sup> exchange or increased intracytoplasmic stores.<sup>59</sup> This additional cytoplasmic calcium results in altered contraction of myofibril organelles,<sup>60</sup> less negative intracellular resting potential that allows delayed afterdepolarizations to reach firing threshold,<sup>48,59,82</sup> altered function of the SR,<sup>60,94</sup> or increased calcium interfering with myocardial mitochondrial function (Chaps. 15 and 16).<sup>60</sup>

Underlying atrial fibrillation and flutter typically do not convert to a normal sinus rhythm with administration of phenytoin or lidocaine. When used, phenytoin should be slowly IV infused (~50 mg/min) or in boluses of 100 mg repeated every 5 minutes until control of the dysrhythmias is achieved or a maximum of 1,000 mg has been given in adults or 15 to 20 mg/kg in children.<sup>9,78</sup> Fosphenytoin has not been evaluated in this setting. Maintenance PO doses of phenytoin (300–400 mg/day in adults and 6–10 mg/kg/day in children) should be continued until digoxin toxicity is resolved. Lidocaine is given as a 1- to 1.5-mg/kg IV bolus followed by continuous infusion at 1 to 4 mg/min in adults or as a 1- to 1.5-mg/kg IV bolus followed by 30 to 50 mcg/kg/min in children as required to control the rhythm disturbance (Chap. 57). Indications for the use of phenytoin and lidocaine in the setting of CAS toxicity are rare because of the effectiveness and definitiveness of Fab fragments, which has obviated their utility.

Class IA antidysrhythmics (eg, quinidine, procainamide, disopyramide) are contraindicated in the setting of CAS poisoning because they may induce or worsen AV nodal block by increasing vagal tone and decreasing His-Purkinje conduction by blocking fast Na<sup>+</sup> channel opening and because their α-adrenergic receptor blockade and vagal inhibition may induce significant hypotension and tachycardia.<sup>37,83</sup> Class IA antidysrhythmics are also proarrhythmic, and their safety in the setting of CAS poisoning is unstudied. Additionally, quinidine reduces renal clearance of digoxin and digitoxin.<sup>23</sup> The use of isoproterenol should be avoided in CAS-induced conduction disturbances because there may be an increased incidence of ventricular ectopic activity in the presence of toxic concentrations of CAS.

**Pacemakers and Cardioversion**

External or transvenous pacemakers have had limited indications in the management of patients with CAS poisoning. In one retrospective study of 92 digitalis-poisoned patients, 51 patients were treated with cardiac pacing, digoxin-specific Fab, or both; the overall mortality rate was 13%.<sup>113</sup> Prevention of life-threatening dysrhythmias failed in 8% of

## Magnesium

Hypomagnesemia also occurs in CAS-poisoned patients secondary to the contributory factors mentioned with hypokalemia, such as long-term diuretic use to treat congestive heart failure. The theoretical benefits of magnesium therapy in the setting of hypomagnesemia include blockade of the transient inward calcium current, antagonism of calcium at intracellular binding sites, decreased CAS-related ventricular irritability,<sup>61</sup> and blockade of potassium egress from CAS-poisoned cells.<sup>4,30,56,90,100,110,121</sup> Although hypomagnesemia increases myocardial digoxin uptake and decreases cellular Na<sup>+</sup>,K<sup>+</sup>-ATPase activity, there is conflicting evidence as whether magnesium “reactivates” the CAS-bound Na<sup>+</sup>,K<sup>+</sup>-ATPase activity.<sup>81,100,110</sup>

Cardioactive steroid-toxic patients found to be hypomagnesemic should have magnesium repleted. A common regimen uses 2 g of magnesium sulfate IV over 20 minutes in adults (25–50 mg/kg/dose to a maximum of 2 g in children). After stabilization, adult patients with severe hypomagnesemia require a magnesium infusion of 1 to 2 g/h (25–50 mg/kg/h to a maximum of 2 g in children), with serial monitoring of serum magnesium concentrations, telemetry, respiratory rate (observing for bradypnea), deep tendon reflexes (observing for hyporeflexia), and monitoring of blood pressure.

## Extracorporeal Removal of Cardioactive Steroids

Forced diuresis,<sup>64</sup> hemoperfusion,<sup>75,119</sup> and hemodialysis<sup>119</sup> are ineffective in enhancing the elimination of digoxin because of its large volume of distribution (4–10 L/kg), which makes it relatively inaccessible to these techniques. Because of its high affinity for tissue proteins, only approximately 10% of the amount of the total body digoxin is found in the serum, and of that amount, approximately 20% to 40% is protein bound.<sup>57</sup>

## SUMMARY

- Digoxin and digitoxin are the most commonly prescribed members of the drugs classified as CASs, and they have a narrow therapeutic index.
- Both cardiac and noncardiac effects occur after CAS poisoning, including nausea, vomiting, headache, weakness, altered mental status, bradycardia, atrial and ventricular ectopy with block, or hyperkalemia.
- Dysrhythmias in patients with therapeutic cardioactive steroid concentrations often occur from hypokalemia and hypomagnesemia and these dysrhythmias will only be resolved with electrolyte repletion.
- Definitive therapy for acute CAS poisoning is the early administration of digoxin-specific Fab immunotherapy coupled with decontamination techniques, including AC and supportive therapy.

# DIGOXIN-SPECIFIC ANTIBODY FRAGMENTS

Silas W. Smith and Mary Ann Howland

## INTRODUCTION

Digoxin-specific antibody fragments (DSFab) are indicated for the management of patients with digoxin and digitoxin toxicity, as well as toxicity from other pharmaceutical, plant, and animal cardioactive steroids (CASs, eg, ouabain, dogbane, oleander, squill, and *Bufo* and *Birgus* species). Digoxin-specific antibody fragments have an excellent record of efficacy and safety, and they should be administered early in both established and suspected CAS poisoning.

## HISTORY

The production of antibody fragments to treat patients poisoned with digoxin followed the development of digoxin antibodies for measuring serum digoxin concentrations by radioimmunoassay (RIA).<sup>21</sup> This RIA technique permitted the correlation between serum digoxin concentrations and clinical digoxin toxicity.<sup>10,31,38,91</sup> In 1967, Butler and Chen suggested that purified antidigoxin antibodies with a high affinity and specificity should be developed to treat digoxin toxicity in humans.<sup>21</sup> The digoxin molecule alone, with a molecular weight of 780 Da, was too small to be immunogenic. But digoxin could function as a hapten when joined to an immunogenic protein carrier such as albumin. These investigators immunized sheep with this conjugate to generate antibodies.<sup>115,117</sup> The immunized sheep subsequently produced a mixture of antibodies that included antialbumin antibodies and antidigoxin antibodies. The antibodies were separated and highly purified to retain the digoxin antibodies while removing the antibodies to the albumin and all other extraneous proteins. The antibodies that were developed had a high affinity for digoxin and sufficient cross-reactivity with digitoxin and other CASs to be clinically useful for the treatment of all CAS poisonings.<sup>23,106,107</sup>

Intact IgG antidigoxin antibodies reversed digoxin toxicity in dogs.<sup>22</sup> Unfortunately, the urinary excretion of digoxin was delayed, and free digoxin was released after antibody degradation occurred. Furthermore, there was significant concern with regard to the development of hypersensitivity reactions. To make such antibodies both safer and effective in humans, whole IgG antidigoxin antibodies were cleaved with papain, yielding two antigen-binding fragments (Fab) and one (discarded) Fc fragment.<sup>22</sup> Affinity chromatography was used to isolate and purify the DSFab after papain digestion. Because the Fc fragment does not bind antigen and increases the potential for hypersensitivity reactions, it was eliminated. When compared with whole IgG antibodies, the advantages of DSFab included a larger volume of distribution ( $V_d$ ) and distribution to the extravascular space, more rapid onset of action, diminished risk of adverse immunologic effects, and more rapid elimination.<sup>22,76,79,83,117</sup> In 1976, Digibind was used with clinical success,<sup>116</sup> and it became commercially available in 1986, before being discontinued in 2011.<sup>59</sup> Another commercial product, DigiFab, approved by the US Food and Drug Administration (FDA) in 2001, is currently available.<sup>20</sup>

## PHARMACOLOGY

### Chemistry and Preparation

DigiFab is prepared from the blood of healthy sheep that were immunized with a digoxin derivative, digoxin-dicarboxymethoxylamine (DDMA).<sup>20</sup> Digoxin-dicarboxymethoxylamine contains a functionally essential cyclopentaperhydrophenanthrene:lactone ring moiety coupled to keyhole limpet hemocyanin (KLH), a metalloprotein found in the hemolymph of the great keyhole limpet (*Megathura crenulata*) that functions as the hapten instead

of the previously used albumin. Papain digestion yields digoxin-specific Fab fragments, which are isolated by affinity chromatography.<sup>20</sup> The molecular weight of each fragment is approximately 46,200 Da.

### Mechanism of Action

Immediately after intravenous (IV) administration, the antigen-binding fragments bind intravascular free digoxin (or digitoxin). Uncomplexed antibody fragments then diffuse into the interstitial space, where they bind free digoxin. A concentration gradient is then established, which facilitates movement into the interstitial or intravascular spaces of both the free intracellular digoxin and digoxin that is dissociated from its binding sites on the external surface of  $\text{Na}^+, \text{K}^+$ -adenosine triphosphatase (ATPase) enzyme in the heart and in skeletal muscles.<sup>84,105</sup> The dissociation rate constant of digoxin for  $\text{Na}^+, \text{K}^+$ -ATPase, therefore, affects the time course for binding to DSFab and, consequently, the onset of action.<sup>62,86,109</sup> The binding affinities of DSFab for digoxin and digitoxin are about  $10^9$  to  $10^{10} \text{ M}^{-1}$  and  $10^8$  to  $10^9 \text{ M}^{-1}$ , respectively. They are greater than the affinities of digoxin or digitoxin for the  $\text{Na}^+, \text{K}^+$ -ATPase enzyme.<sup>20</sup>

### Pharmacokinetics

The pharmacokinetics of Digibind and DigiFab (previously named DigiTAB) were compared in human volunteers.<sup>129</sup> Sixteen participants received 1 mg of digoxin intravenously as a 5-minute bolus followed 2 hours later by a 30-minute IV infusion of 76 mg (an equimolar neutralizing dose) of either Digibind or DigiFab. Free and total digoxin (free plus DSFab bound) were assayed using an ultrafiltration method over 48 hours. At 30 minutes after infusion of either DSFab, the serum free digoxin concentration was below the level of assay detection and remained so for several hours. A few patients in both groups had free digoxin concentrations rebound to 0.5 ng/mL at approximately 18 hours, and the area under the serum drug concentration versus time curve (AUC) for 2 to 48 hours for free digoxin was similar for both treatment groups. The elimination half-life of total digoxin averaged 18 hours for DigiFab and 21 hours for Digibind, and the distribution half-life was 1 hour for each. In another study, the elimination half-life of the DSFab-glycoside complex was 20 to 30 hours, with free digoxin concentrations rising between 8 and 12 hours.<sup>118</sup> The volumes of distribution were 0.3 L/kg for DigiFab versus 0.4 L/kg for Digibind.<sup>25,20</sup> Systemic clearance of DigiFab was higher than for Digibind, accounting for the shorter elimination half-life of DigiFab (15 hours versus 23 hours).<sup>129</sup> Urine sampling over the first 24 hours demonstrated mostly free digoxin and very little free DSFab for both groups. The authors postulated that during renal excretion, the DSFab digoxin complex is metabolized in the kidney by the proximal tubular cells, releasing free digoxin and unmeasured DSFab metabolites.<sup>129</sup>

Similar findings were described after the first clinical use of Digibind in a patient who gave a history of ingesting 90 (0.25 mg) digoxin tablets.<sup>116</sup> The total serum digoxin concentration, which was 17.6 ng/mL at the time Digibind infusion was initiated, rose to 226 ng/mL at 1 hour and remained there for 11 hours, before falling off the next 44 hours, with a half-life of 20 hours.<sup>116</sup> Digibind concentrations peaked at the end of the infusion and then apparently exhibited a biphasic or triphasic decline, probably reflecting distribution into different compartments, as well as excretion and catabolism. Free serum digoxin concentrations were undetectable for the first 9 hours; rose to a peak of 2 ng/mL at 16 hours; and fell to 1.5 ng/mL at both 36 hours and 56 hours, at which time sampling stopped. An analysis of

renal elimination based on an incomplete collection suggested that digoxin was excreted only in the bound form during the first 6 hours, but by 30 hours after Fab administration, all digoxin in the urine was free digoxin.

A study designed to measure efficacy of DS Fab delivery compared a loading dose of DS Fab followed by an infusion of the DS Fab dose infused over a short amount of time.<sup>105</sup> The former strategy increased the ratio of digoxin bound to uncomplexed DS Fab in the serum from 50% to 70%.<sup>105</sup> The authors hypothesized that a very rapid infusion regimen would result in the elimination of DS Fab before the fragments could optimally bind the digoxin redistributing from tissue sites.<sup>105</sup>

Digoxin takes several hours to distribute from the blood to the tissue compartment. As expected, a rodent model demonstrated that DS Fab was more effective when administered before complete distribution of digoxin.<sup>101</sup> When distribution was complete, increasing the dose of DS Fab significantly improved efficacy, as measured by comparing the AUC of digoxin with that of the Fab–digoxin complex.<sup>101</sup>

Pharmacokinetic studies in patients with kidney failure demonstrate that the half-life of DS Fab is prolonged 10-fold, with no change in the apparent DS Fab  $V_d$ . In this situation, serum DS Fab concentrations can remain detectable for 2 to 3 weeks or more.<sup>87</sup> Total serum digoxin concentrations generally follow DS Fab serum concentrations. Case reports and series demonstrate that free digoxin concentrations can persist and reappear up to 10 days after administration of DS Fab to patients end-stage kidney disease compared with 12 to 24 hours in patients with normal kidney function.<sup>39,43,68,87,88,111,113,121–123,133</sup> In one series of patients with end-stage kidney disease, the maximum average concentration of free digoxin was  $1.30 \pm 0.7$  ng/mL and occurred at  $127 \pm 40$  hours.<sup>122</sup> After the peak, there is a slow decline that parallels the elimination of DS Fab.

In an attempt to hasten digoxin elimination with and without DS Fab treatment, various extracorporeal modalities were explored, with predictably disappointing results given digoxin's  $V_d$  and the digoxin–antibody complex's size. The inability of extracorporeal elimination has been demonstrated in several experimental models and case reports. Continuous arteriovenous hemofiltration was ineffective in removing the digoxin–Fab fragment complex in a piglet model.<sup>96</sup> Low concentrations of total digoxin were measured in peritoneal dialysate of a 3-day-old child with digoxin overdose.<sup>11</sup> Plasmapheresis was capable of clearing DS Fab-bound digoxin and preventing rebound in one case.<sup>97</sup> In another case, a 4-hour session was used to reverse persistent cardiotoxicity from recrudescence at 18 hours after a massive digoxin ingestion (serum concentration 35.6 ng/mL > 20 hours after overdose).<sup>100</sup> In another patient, plasma exchange was capable of removing DS Fab–digoxin complexes and precluding rebound, but it was without significant impact in improving total digoxin clearance (< 1% of the total amount of ingested drug) because of digoxin's large apparent  $V_d$ .<sup>139</sup> Last, plasma exchange closely after DS Fab administration in a patient with junctional rhythm, hemodynamic instability, and a digoxin concentration of 16.7 ng/mL was associated with gradual recovery of consciousness and sinus rhythm, although discerning the effect of plasma exchange from antidotal administration was unclear.<sup>104</sup> A multispecialty-working group, which reviewed the available literature, recommended against performing extracorporeal treatments in severe digoxin poisoning when DS Fab is administered.<sup>85</sup> Provision of additional DS Fab is recommended as a more rational approach.

### Pharmacodynamics

At the tissue level, in ex vivo isolated human ventricular myocardium with a 1.5-fold higher molar DS Fab dosing, digoxin toxicity was reversed within 30 minutes.<sup>86</sup> A key finding from this study and an additional investigation in human postmortem left ventricles was that the maximal rate of digoxin removal from  $\text{Na}^+\text{K}^+\text{-ATPase}$  was limited by the dissociation rate of digoxin from  $\text{Na}^+\text{K}^+\text{-ATPase}$ , with a half-life for this decay ranging from 46 to 54 minutes.<sup>86,109</sup> Later pharmacokinetic and pharmacodynamic studies inferred two digoxin receptor subtypes, (1) a high-affinity, low-capacity binding site that constituted 11% of receptors and mediates digoxin-induced positive inotropic effect and (2) a low-affinity, high-capacity binding site that

constituted 89% of total receptors.<sup>62,131</sup> The effects of the low-affinity receptor increased as dose increased, and its dissociation time constant was 18 times lower than high-affinity, low-capacity receptor, implying kinetic limits to DS Fab efficacy even in the setting of sufficient molar administration.<sup>62,85</sup> At the blood compartment level, in six patients in whom free digoxin or digitoxin concentrations were measured in a clinical toxicity scenario, free serum concentrations decreased to zero or near zero within 1 to 2 minutes after administration of the antibody fragments.<sup>134</sup> In a later study in 36 patients with chronic digoxin poisoning who received one, two, or three or more DS Fab vials, free digoxin concentrations decreased to almost zero after administration, regardless of dose.<sup>27</sup>

Clinically, in the multicenter study of 150 patients, the mean time to initial response from the completion of the Digibind infusion (accomplished over 15 minutes to 2 hours) was 19 minutes (range, 0–60 minutes), and the time to complete response was 88 minutes (range, 30–360 minutes). Time to response was not affected by age, concurrent cardiac disease, or presence of chronic or acute ingestion.<sup>5</sup> In another study of 63 adult and pediatric patients, therapeutic response generally occurred by 30 minutes, although some pediatric patients responded within minutes, and complete response sometimes took hours.<sup>134</sup> Dysrhythmia reversal occurred within an average of 3.2 hours (range, 0.5–13 hours) in 34 patients with life threatening dysrhythmias.<sup>118</sup> In another series, 15 of 19 pediatric patients had complete resolution within 180 minutes, with a median time to initial response of 25 minutes.<sup>135</sup>

### ROLE IN DIGOXIN TOXICITY

A large study evaluating adults and pediatric patients with acute and chronic digoxin toxicity established the efficacy of Digibind.<sup>5</sup> Of the 150 patients treated, 148 were evaluated for cardiovascular manifestations of toxicity before treatment: 79 patients (55%) had high-grade atrioventricular (AV) block, 68 (46%) had refractory ventricular tachycardia, 49 (33%) had ventricular fibrillation, and 56 (37%) had hyperkalemia. Complete resolution of all signs and symptoms of digoxin toxicity occurred in 80% of cases. Partial response was observed in 10% of patients, and of the 15 patients who did not respond, 14 were moribund before initiation of therapy or later found to not be digoxin toxic. The success of Digibind was demonstrated by the fact that of the 56 patients who had cardiac arrest caused by digoxin, 54% survived to discharge compared with 100% mortality before the availability of DS Fab.<sup>5</sup> In 34 patients (27 with suicidal intent) with life-threatening dysrhythmias and a mean serum digoxin concentration of 12.2 ng/mL (range, 3.4–29 ng/mL), 32 (94%) made a full recovery after administration of DS Fab (as Digitalis Antidote BM).<sup>118</sup> In a prospective study of suicidal, acute, and chronic patients poisoned by digoxin and digitoxin, in which 22 required cardiopulmonary resuscitation (ie, chest compressions), 53 of 56 (95%) patients responded to DS Fab.<sup>134</sup> The three deaths were associated with nonequimolar DS Fab administration, concomitant cyclic antidepressant overdose, and severe underlying cardiac disease. In a postmarketing observational surveillance study of 717 patients, 50% of patients had a complete response to treatment, 24% had a partial response, and 12% had no response.<sup>54</sup> In the 89 patients with no response, digoxin was deemed contributory in only 14 patients. Four of these patients had unexplained treatment failure; 2 received inadequate Digibind dosing; and 8 were moribund, unevaluable, or of questionable toxicity.<sup>54</sup> A later single-center, retrospective review of 66 patients used equimolar therapy in cases of lethal dysrhythmia, arrest, bradycardia less than 40 beats/min, potassium greater than 5 mEq/L, cardiogenic shock, and half-molar reversal in patients at risk for deterioration; DS Fab treatment reversed poisoning in 91%.<sup>75</sup> In the 5 patients who ultimately died, 3 had successful responses to DS Fab but died of other complications, 1 had iatrogenic digoxin administration for dysrhythmia associated with septic shock, and 1 had a combined verapamil poisoning. Repeat therapy was required in 11 of 66 (16.7%) patients initially treated with a median dose of three vials.<sup>75</sup> In a large retrospective, multicenter review of 838 patients, the mortality rate was significantly decreased with DS Fab use from 15% (117 of 770 patients) to 6% (4 of 67 patients).<sup>74</sup> A prospective study of 36 patients was confounded by patients' use of multiple cardiac medications, potential

spironolactone interference with the digoxin assay, digoxin clearance, potassium elimination, and digoxin concentrations with unclear relationship to the distributional phase.<sup>32,89,126</sup> The administration of DS Fab eliminated gastrointestinal (GI) symptoms suggestive of toxicity, increased heart rate in a dose-dependent fashion when one, two, or three or more vials were provided by 4.5, 10, and 17.3 beats/min, respectively, and decreased potassium by 0.3 mmol/L in an apparent dose-independent fashion.<sup>27</sup> As was demonstrated by multiple studies, DS Fab is efficacious in reversing digoxin-associated cardiac arrest.<sup>5,75,94,134</sup> Newborns, infants, and children have all been successfully treated with DS Fab.<sup>11,44,65,110,111</sup> In a large series of 29 pediatric patients poisoned with digoxin or digitoxin, DS Fab at doses of 0.30 to 0.96 mg/kg reversed severe cardiac manifestations or hyperkalemia in 27 (93%).<sup>135</sup>

## ROLE OF DIGOXIN-SPECIFIC ANTIBODY FRAGMENTS WITH OTHER CARDIOACTIVE STEROIDS

Digoxin-specific antibody fragments were designed to have high-affinity binding for digoxin and digitoxin. There are structural similarities, however, among the CASs. In fact, detectable “digoxin concentrations” using immunoassays were reported with some, but not all, nondigoxin CASs.<sup>17,34,35,46,64,92</sup> This interference suggested a potential for cross-reactivity between DS Fab and other CASs. Thus, DS Fab can have variable efficacy for multiple natural CAS poisonings, including those unique CASs in common and yellow oleander (*Nerium oleander* and *Thevetia peruviana*), dogbane (*Apocynum cannabinum*), lily of the valley (*Convallaria majalis*), the ordeal bean (*Tanghinia venenifera*), (red) squill (sea onion, *Urginea maritima*), sea mango (*Cerbera manghas*), Bufo toad species, coconut crab (*Birgus latro* L.).<sup>8,18,19,29,40,51,67,81,103</sup>

In vitro studies also suggested the remarkable diagnostic importance and clinical efficacy of the binding affinity of DS Fab for CASs such as bufalin, convallatoxin, cinobufotalin, oleandrin, oleandrigenin, and oubain and those in the balloon plant (*Gomphocarpus physocarpus* and *fruticosus*), bushman's poison (*Carissa acokanthera*), conkerberry (*Carissa laxiflora*), frangipani (*Plumeria rubra*), king's crown (*Calotropis procera*), mother of millions (*Bryophyllum tubiflorum*), pheasant eye (*Adonis microcarpa*), sea mango (*Cerbera manghas*), redheaded cotton-bush (*Asclepias curassavica*), rubber vine (*Cryptostegia grandifolia*), and winter-sweet (*Carissa spectabilis*).<sup>29,33,35,95,98,132</sup> Distinctions between assay detection and DS Fab efficacy are critical. One in vitro study demonstrated cross-reactivity of steroidal alkaloidal compounds in *Veratrum viride* (false hellebore) with the digoxin assay but no binding to DigiFab.<sup>9</sup> Conversely, DS Fab binds the cardioactive steroid cerberin, although serum cerberin did not react with a clinical digoxin assay.<sup>64</sup> Highlighting the heterogeneity of DS Fab antibodies, only a fraction of the total DigiFab and DigiFab antibodies bound to ouabain with high affinity in vitro, and the ouabain-binding capacity of DigiFab was approximately twice that of DigiFab.<sup>95</sup> Both older and newer immunoassays were capable of detecting oleandrin (from *N. oleander*) in human serum, with the Digoxin III assay being highly sensitive.<sup>34</sup>

Several animal studies explored DS Fab use in atypical CAS poisoning. In mice poisoned with an LD<sub>50</sub> of Chan Su extract containing bufalin, cinobufotalin, and cinobufagin, DigiFab at doses of 1,600 mg/kg followed by 800 mg/kg decreased the mortality rate from 100% to 47%.<sup>18</sup> A placebo-controlled canine study of experimentally induced *N. oleander* poisoning used 60 mg/kg of DS Fab to prevent death and normalize dysrhythmias.<sup>30</sup> Larger doses may be required in cases of poisoning by other CAS because of the lower affinity binding of DS Fab for these toxins. DigiFab is expected to have similar affinity binding toward CASs as DigiFab. Both products are polyclonal, contributing to their broad spectrum of affinity for nondigoxin CASs. Several case reports discuss successful use of DS Fab to reverse cardiotoxicity resulting from ingestion of *N. oleander* and *T. peruviana* at dose up to 480 mg of DigiFab.<sup>24,103,112</sup> A double-blind study in patients with severe poisoning from yellow oleander provided 1,200 mg of DigiFab to reverse serious dysrhythmias.<sup>40</sup> An observational study confirmed a threefold rise in oleander fatalities when DS Fab was unavailable.<sup>41</sup> Twenty vials and more of DigiFab have been required in cases of Chan Su poisoning.<sup>19</sup> A case of toad egg poisoning was successfully reversed with three vials

of brand-unspecified DS Fab.<sup>70</sup> Twenty vials of brand-unspecified DS Fab successfully reversed cardiotoxicity from suicidal ingestion of seeds from the pong-pong (“suicide”) tree (*Cerbera odollam*), which contains the CAS cerberin.<sup>64</sup> Similarly, 20 vials (760 mg) of DigiFab were required to reverse life-threatening coconut crab poisoning, from the CAS neriifolin.<sup>81</sup> Complicating the diagnosis and therapeutic decision-making, *Digitalis* species lanatosides have contaminated botanical dietary supplements not otherwise anticipated to contain CASs.<sup>8,114</sup> On the basis of the common and yellow oleander poisonings studies, a minimum of 20 vials (800 mg) DS Fab is recommended.<sup>7</sup> We recommend that treatment decisions be based on clinical and diagnostic findings such as ECG or electrolyte abnormalities (eg, life-threatening dysrhythmias, shock or hemodynamic instability, potassium concentrations > 5 mEq/L and those provided in Table 62–4), with initial therapy consisting of 10 to 20 vials in cases of nonpharmaceutical cardiac glycoside poisonings. Subsequent doses should be based on clinical response. Gastrointestinal decontamination is recommended because of the potential ongoing absorption of ingested products.

In humans, DS Fab were also used to mitigate preeclampsia (toxemia of pregnancy) associated with endogenous digitalis-like substances (EDLIS) such as marinobufagenin.<sup>2,45,50</sup> DigiFab neutralizes EDLIS and reverses preeclampsia-induced Na<sup>+</sup>,K<sup>+</sup>-ATPase inhibition in a manner similar to DigiFab.<sup>58</sup> The effects of EDLIS are mitigated, and DS Fab effectiveness is potentiated in the presence of magnesium, providing an experimental link for magnesium efficacy in preeclampsia.<sup>138</sup> In a randomized, double-blind trial of women with severe preeclampsia, DS Fab administration was associated with prevention of maternal renal impairment, lowered rates of maternal pulmonary edema, and prevention of neonatal intraventricular hemorrhage.<sup>3,72</sup> Definitive therapy in preeclampsia remains delivery.

## INDICATIONS FOR DIGOXIN-SPECIFIC ANTIBODY FRAGMENTS

Life-threatening, or potentially life-threatening, toxicity from any CAS should prompt DS Fab treatment.<sup>20</sup> Patients with known or suggestive CAS exposure with progressive bradydysrhythmias, including symptomatic sinus bradycardia or second- or third-degree heart block unresponsive to atropine, and patients with severe ventricular dysrhythmias, such as ventricular tachycardia or ventricular fibrillation, should also be treated with DS Fab.<sup>75</sup> Ventricular tachycardia with a fascicular block is likely to be a digoxin-toxic rhythm.<sup>82</sup> We recommend treating with DS Fab patient with a potassium concentration exceeding 5 mEq/L that is attributable to a CAS in the presence of other manifestations of acute or chronic digoxin toxicity.<sup>13</sup> Digoxin-specific antibody fragments is recommended for acute ingestions greater than 4 mg in a healthy child (or > 0.1 mg/kg) or 10 mg in a healthy adult, with a lower threshold in compromised patients. Serum digoxin concentrations do not correlate with myocardial concentrations until 4 to 6 hours after ingestion, when an equilibrium from the serum to the myocardium is achieved. Serum concentrations of greater than or equal to 10 ng/mL soon after an acute ingestion may predict the need for treatment with DS Fab. Because older adults are at greatest risk of lethality with digoxin poisoning,<sup>14</sup> the treatment threshold for patients older than 60 years of age is recommended to be lower. Some authors decrease this age threshold to 55 years.<sup>75</sup> This approach is reasonable in the setting of other comorbidities. Before the advent of DS Fab, the mortality rate in patients older than 60 years of age was 58% compared with 8% in patients younger than 40 years of age and 34% in patients between 40 and 50 years of age.<sup>14</sup> A rapid progression of clinical signs and symptoms, such as cardiac and GI toxicity and an elevated or rising potassium concentration, in the presence of an acute overdose, suggests a potentially life-threatening exposure and the need for DS Fab.

Cardioactive steroid toxicity causes an increase in intracellular calcium, and the administration of exogenous calcium may further exacerbate conduction abnormalities and potentially result in cardiac arrest, unresponsive to further resuscitation. Thus, in a patient with an unknown exposure who is clinically ill with characteristics suggestive of poisoning by a CAS, DS Fab should be administered early in the management and always before administration of calcium gluconate or chloride. The CAS effects can be reversed,

obviating the risk associated with the administration of calcium. It also can be difficult to distinguish clinically between digoxin poisoning and intrinsic cardiac disease, which the administration of DS Fab can resolve.

A computer-based simulation model compared the treatment of non-life-threatening digoxin toxicity with standard therapy. The authors concluded that treatment with DS Fab could decrease length of hospitalization by 1.5 days, a major cost containment benefit.<sup>37</sup> In a 2016, US national hospital database study of 24,547 patients, in patients treated with DS Fab for digoxin toxicity, the length of stay was significantly shorter than the remainder of the cohort (7.2 days versus 11.6 days), and even after adjusting for disease and severity variables, DS Fab reduced the mean length of stay by 0.3 to 0.7 days.<sup>53</sup> The sometimes rapidly changing pharmaceutical, personnel, and facility costs likely will modify local pharmacoeconomic considerations for DS Fab administration.

## ADVERSE EFFECTS AND SAFETY ISSUES

Digoxin-specific antibody fragments are generally safe and effective. Reported adverse effects include hypokalemia as a consequence of reactivation of the  $\text{Na}^+, \text{K}^+$ -ATPase; withdrawal of the inotropic or AV nodal blocking effects of digoxin, leading to congestive heart failure or a rapid ventricular rate in patients with atrial fibrillation; and, rarely, allergic reactions.<sup>25,20</sup> Hypokalemia with associated cardiac dysrhythmia requiring potassium repletion was reported in one of 29 children in a multicenter study.<sup>135</sup> Serum potassium should be monitored after DS Fab administration because potassium can rapidly shift intracellularly.<sup>20</sup> In a multicenter study of 150 patients treated with Digibind, hypokalemia was reported in 6 patients (4%), worsening of congestive heart failure occurred in 4 patients (3%), and transient apnea was reported in a neonate who was several hours old.<sup>5</sup> There were no other reactions reported in any of the patients in this series. In a postmarketing surveillance study of Digibind that included 717 patients, 6 patients (0.8%) had an allergic reaction to DS Fab, of whom 3 of the 6 had a prior history of allergy to antibiotic drugs.<sup>54</sup> One of these patients developed a total-body rash, facial swelling, and a flush during the infusion. Two others experienced a pruritic rash. Three other reported adverse reactions were thrombocytopenia and rigors, and there were two episodes of wheezing and dyspnea that appeared to be unrelated to Digibind use.<sup>54</sup> One patient received Digibind on three separate occasions over the course of 1 year for multiple suicide attempts, with no adverse effects.<sup>15</sup> During the clinical trials with DigiFab, one patient developed pulmonary edema, bilateral pleural effusions, and kidney failure, most likely caused by the loss of the inotropic and chronotropic digoxin effects.<sup>20</sup> Phlebitis and postural hypotension were related to the infusion of DigiFab in two healthy volunteers.<sup>20</sup>

Patients with allergies to papain, chymopapain, or other papaya extracts or the pineapple enzyme bromelain may be at risk for allergic reactions because trace residues of papaya may remain in the DS Fab.<sup>20</sup> Patients with an allergy to sheep protein or those who have previously received ovine antibodies or ovine Fab may also be at risk for allergic reactions, although this is not reported.

## PREGNANCY AND LACTATION

Digoxin-specific antibody fragments are FDA Pregnancy Category C. Reproduction studies have not been done, and human case reports are limited. However, considering the maternal benefit of DS Fab, it should be used as clinically indicated to protect the maternal-fetal dyad. At least one randomized trial used DS Fab for up to eight total doses therapeutically in pregnancy.<sup>3,72</sup> Digoxin-specific antibody fragments use should not be withheld in maternal poisoning because of pregnancy. It is unknown whether DS Fab is excreted into breast milk, but it is considered compatible with breastfeeding.<sup>16</sup>

## DOSING AND ADMINISTRATION

The dose of DS Fab depends on the total body load (TBL) of digoxin. This amount varies depending on the size of the patient and the  $V_d$ . Adults and children receiving digoxin therapeutically who develop chronic digoxin toxicity require small doses of DS Fab because their total body burden of digoxin is usually small. Tolerance to digoxin does not appear to develop in

patients.<sup>108</sup> Children with acute overdoses require DS Fab doses based on the amount of digoxin ingested and their subsequent total body load, as in adults.

Estimates of digoxin TBL can be made in three ways: (1) estimate the quantity of digoxin acutely ingested and assume 80% bioavailability (milligrams ingested  $\times$  0.8 equals TBL), which is on the higher end of the value incorporated into successful treatment regimens;<sup>5,75,118</sup> (2) obtain a serum digoxin concentration and, using a pharmacokinetic formula, incorporate the apparent  $V_d$  of digoxin and the patient's body weight (in kilograms); or (3) use an empiric dose based on the average requirements for an acute or chronic overdose in an adult or child.

Each of these methods of estimating the dose of DS Fab has limitations. The history of ingestion is often unreliable, and empiric doses based on averages can overestimate or underestimate DS Fab requirements. Additionally, bioavailability varies by P-glycoprotein (MDR1) genotype and the gut microbiome.<sup>71,80</sup> Using the pharmacokinetic formula assumes a steady-state  $V_d$  of 5 L/kg.<sup>5</sup> In studies reviewing efficacy, a value of 5.6 L/kg has been used previously.<sup>5,75</sup> Although the value of 5 L/kg achieves mathematical simplicity in equations (because each vial binds 0.5 mg of digoxin), this  $V_d$  is not accurate in the acute setting and can change with comorbid disease. In addition, the  $V_d$  of 5 L/kg is a population average that varies with the individual, lean body mass, kidney disease, thyroid disease, and pharmacokinetic model and is lower than a more typical  $V_d$  of 7 L/kg.<sup>26,28,42,102,137</sup> Acknowledging these limitations, sample calculations for each of these methods are shown in Tables A22-1 to A22-3. Each vial contains 40 mg (DigiFab) of purified DS Fab that will bind approximately 0.5 mg of digoxin or digitoxin. The number of vials is rounded up to the next whole vial, which provides some margin when not incorporating higher values for  $V_d$  or bioavailability. If the quantity of ingestion cannot be reliably estimated, it is safest to use the largest calculated estimate. The clinician should always be prepared to increase or repeat the dose if symptoms fail to resolve.

Because of the increasing cost of DS Fab and availability concerns, several authors have suggested partial or non-neutralization in various scenarios, particularly in cases of chronic toxicity. We do not recommend this approach. Part of the difficulty lies within heterogeneity of clinically meaningful endpoints and determining the contribution of digoxin to the overall clinical presentation or outcome. In a study of 20 patients with severe digoxin poisoning, 30% failed a strategy of providing only two DS Fab vials and waiting for ECG signs of digoxin toxicity to abate, with a mortality rate of 5%.<sup>12</sup> Repeat DS Fab therapy was required in 3 of 21 patients (14%) with equimolar dosing compared to 8 of 45 patients (18%) treated with half-molar reversal, despite the full reversal patients having more severe clinical presentations.<sup>75</sup> A significant mortality rate of 15% is associated with therapeutic nihilism (failure to administer DS Fab) in acute and chronic toxicity.<sup>74</sup>

Given that studies demonstrate a mean  $\text{Na}^+, \text{K}^+$ -ATPase occupancy of 24% in digitalized patients, poisoned patients are anticipated to have an even higher occupancy, risking clinical and pharmaceutical recrudescence (rebound toxicity).<sup>108</sup> In 717 patients, recrudescence was seen in 2.8%, which

No. of vials <sup>c</sup> = $\frac{10 \text{ ng/mL} \times 5 \text{ L/kg} \times 70 \text{ kg}}{1,000 \times 0.5 \text{ mg/vial}}$ No. of vials = 7		

<sup>a</sup>If the serum digoxin concentration (SDC) is provided in units of nmol/L, a factor of 0.78 is used to convert to ng/mL. <sup>b</sup>1,000 is a conversion factor to change ng/mL to mg/L. <sup>c</sup>Round up to the nearest whole vial to determine the number of vials indicated.

$V_d$  = volume of distribution.

was correlated with less than equimolar DSFab dosing.<sup>54</sup> In a pediatric series, 3 of 29 (10%) received retreatment with DSFab; 1 case was associated with half molar dosing, 1 had concomitant quinidine poisoning, and 1 had it provided empirically after initial reversal of cardiac toxicity.<sup>135</sup> In a kinetic evaluation, continuous infusion of DSFab at 0.5 mg/min was sufficient to absorb digoxin rediffusing into the serum during the first 8 hours, suggesting a requirement for sufficient ongoing DSFab.<sup>105</sup> Lower DSFab doses were less efficacious in increasing heart rate in a prospective observational study, and rebound was frequent (25 of 36 patients), with 9 patients achieving a rebound of greater than 2 nmol/L (1.56 ng/mL).<sup>27</sup> Such a rate of recrudescence would require ongoing monitoring, and studies advocating partial reversal have not completely accounted for the attendant facility, monitoring, and personnel costs in the event that a full equimolar reversal is not provided, which might mitigate any pharmaceutical cost saving. Given the known inherent rate limitations of digoxin removal from  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase(s),<sup>62,86,109</sup> the need to create sufficient gradient for redistribution to serum for this to occur, the efficacy seen with higher than equimolar dosing,<sup>25,101,120</sup> and inadequate free DSFab monitoring at most institutions, until pharmacokinetic arguments for partial dosing are rigorously tested in sufficiently powered clinical trials, the authors believe that equimolar DSFab dosing should be employed. Slower or ongoing administration of DSFab<sup>105</sup> has a rational basis to preclude antidotal elimination but awaits further definitive study.

Each 40-mg vial of DigiFab (which binds 0.5 mg of digoxin) should be reconstituted with 4 mL of sterile water for IV injection and gently mixed to provide a solution containing 10 mg/mL of DSFab.<sup>20</sup> The reconstituted product should be used promptly, or if refrigerated, it should be used within 4 hours. This preparation can be further diluted with sterile isotonic saline for injection. DigiFab should be administered slowly as an IV infusion over at least 30 minutes unless the patient is critically ill, in which case the DigiFab can be given by IV bolus. If a rate-related infusion reaction occurs, the infusion should be stopped, the patient stabilized, and the infusion restarted at a slower rate. For infants and small children, the manufacturer recommends diluting the 40-mg vial with 4 mL of sterile water for IV injection and

administering the dose undiluted using a tuberculin syringe. For very small doses, this preparation can be further diluted with an additional 36 mL of sterile 0.9% sodium chloride for injection (for a total of 40 mL) to achieve a 1-mg/mL concentration.

### MEASUREMENT OF SERUM DIGOXIN CONCENTRATION AFTER DIGOXIN-SPECIFIC ANTIBODY FRAGMENT ADMINISTRATION

Most laboratories are not equipped to determine free serum digoxin concentrations within a clinically reasonable timeframe. This is relevant because after DSFab administration, total serum digoxin concentrations are clinically meaningless because they represent both free and bound digoxin and may rise up to 10- to 20-fold compared with pretreatment values.<sup>6,49,57,77,84,119,134</sup> The type of test for total digoxin concentrations used can either result in falsely high or falsely low serum concentrations, depending on which phase (solid or supernatant) is sampled.<sup>56,83</sup> Free serum digoxin concentrations should be near zero after initial DSFab administration.<sup>26,27,133</sup> Free digoxin concentrations begin to reappear 5 to 24 hours or longer after Fab administration, depending on the antibody dose, infusion technique, and the patient's renal function. Newer commercial methods, using ultrafiltration or immunoassays, make free digoxin concentration measurements easier to perform and therefore more clinically useful, but they remain associated with errors in the underestimation or overestimation of the free digoxin concentration.<sup>48,61,90,99,121,124</sup> Free digoxin concentrations are particularly useful in patients with end-stage kidney disease. Independent of the availability of these data, serum digoxin values represent only an imperfect marker of target (cardiac) organ toxicity and only approximate the need for ongoing therapy. As such, and given the experimental data demonstrating that digoxin  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase is rate limited, the patient's cardiac status must be carefully clinically and electrocardiographically monitored for signs of persistent or recurrent toxicity and need for additional DSFab.

Additional pitfalls in the measurement and utility of serum digoxin concentrations include endogenous and exogenous factors. Spironolactone, eplerenone, canrenone, and canrenone's prodrug potassium canrenoate can positively or negatively interfere with serum digoxin measurements, depending on the analytical method.<sup>32,136</sup> Endogenous digitalis-like substances are described in infants, women in the third trimester of pregnancy, high altitude exposure, hypothermia, acute respiratory distress syndrome, essential hypertension, congestive heart failure, right ventricular dysfunction, hypertrophic cardiomyopathy, kidney and liver failure, kidney and liver transplant recipients, and critically ill patients without liver or kidney disease.<sup>1,32,36,47,52,55,63,66,125,127,130</sup> Exogenous measurement factors relate primarily to EDLIS measurement techniques and interpretation.<sup>69</sup> When EDLISs are free or weakly bound, as in

**TABLE A22-3** Empiric Dosing Recommendations

Acute Ingestion	Chronic Toxicity

these circumstances, they are measurable by the typical RIA and can account for factitiously high reported serum digoxin concentrations in the absence of digoxin treatment, although the degree of interference, if any, depends on the assay and can vary significantly between assays.<sup>60,73</sup> The role of EDLIS is incompletely elucidated; however, sympathetic stimulation of adrenal cortex leads to endogenous marinobufagenin production, which causes decreased sodium reabsorption, arterial constriction, and salt-sensitive hypertension.<sup>4</sup> Endogenous digoxinlike immunoreactive substances are thus implicated as a causative factor in cardiac and kidney disease, including kidney and cardiac fibrosis and preeclampsia.<sup>93</sup> Additionally, digoxin metabolites have varying degrees of cardioactivity.<sup>78</sup> Some metabolites cross-react and are measured by RIA, but others do not. The in vivo production of these metabolites varies in patients and may depend on intestinal metabolism by gut flora as well as renal and liver clearance.<sup>128</sup>

## FORMULATION AND ACQUISITION

Digoxin-specific antibody fragments are available as DigiFab. Vials contain 40 mg of purified lyophilized digoxin-immune ovine immunoglobulin fragments, approximately 75 mg of mannitol USP, and approximately 2 mg of sodium acetate USP as a buffer. The diluent is not included. The product contains no preservatives and is intended for IV administration after reconstitution with 4 mL of sterile water for injection USP. Each vial binds approximately 0.5 mg of digoxin.

## SUMMARY

- Digoxin-specific antibody fragments have dramatically advanced the care and are lifesaving in patients poisoned with CASs.
- In the more than 40 years since the release of DSFab, a potentially lethal overdose of a CAS has become manageable, allowing clinicians to treat patients with minimal risks.
- Recrudescence after therapy is reported, particularly in cases of kidney failure, and patients should be monitored for recurrence of symptoms in these cases. Rarely, additional dosing of DSFab is needed.
- Nonpharmaceutical CAS poisoning often requires large doses for reversal.

# METHYLXANTHINES AND SELECTIVE $\beta_2$ -ADRENERGIC AGONISTS

Robert J. Hoffman

## Caffeine

Molecular weight = 194.19 Da  
Therapeutic serum concentration = 1–10 mcg/mL

## Theophylline

Molecular Weight = 180.17 Da  
Therapeutic serum concentration = 5–15 mcg/mL  
= 28–83  $\mu$ mol/L

## Theobromine

Molecular weight = 180.17 Da

## HISTORY AND EPIDEMIOLOGY

Methylated derivatives of xanthine, or methylxanthines, are plant-derived alkaloids that include caffeine (1,3,7-trimethylxanthine), theobromine (3,7-dimethylxanthine), and theophylline (1,3-dimethylxanthine). Members of this group share pharmacologic properties and clinical effects. The naturally occurring methylxanthines caffeine and theobromine are used ubiquitously throughout the world. Caffeine is most commonly contained in beverages imbued for their stimulant, mood-elevating, and fatigue-abating effects. The plant *Coffea arabica* and related species are used to make coffee, a beverage rich in caffeine. Cocoa and chocolate are derived from the seeds of *Theobroma cacao*, which contains theobromine and to a lesser extent caffeine. *Thea sinensis*, a shrub native to China but now cultivated worldwide, produces leaves from which various teas, rich in caffeine and containing small amounts of theophylline and theobromine, are brewed. *Paullinia* spp, commonly known as guarana, is a South American plant that produces berries with caffeine content much greater than that of coffee beans.

Selective  $\beta_2$ -adrenergic agonists were developed for the treatment of bronchoconstriction. Their receptor selectivity improved therapy for patients with reversible airways disease, allowing avoidance of the adverse effects of the previously used therapies: epinephrine, an  $\alpha$  and  $\beta$ -adrenergic agonist, as well as isoproterenol, a  $\beta_1$  and  $\beta_2$ -adrenergic agonist. Most selective  $\beta_2$ -adrenergic agonists are pharmacodynamically similar, with similar clinical effects; the principal differences are their pharmacokinetics. Clenbuterol and ritodrine have unique toxicities distinct from other  $\beta_2$ -adrenergic agonists. This chapter does not examine each  $\beta_2$ -adrenergic agonist individually but instead discusses them as a class, with a separate discussion of the unique toxicities of clenbuterol and ritodrine. The  $\beta_2$ -adrenergic agonists in the United States include arformoterol, albuterol, clenbuterol, bitolterol, formoterol, levalbuterol, metaproterenol, pirbuterol, ritodrine, salmeterol, terbutaline, although numerous others are used outside the United States.

The American Association of Poison Control Centers (AAPCC) follows trends in methylxanthine and  $\beta_2$ -adrenergic agonists exposures in National Poisoning Data System (NPDS). Theophylline exposures, which previously caused thousands of poisonings and dozens of deaths annually, have

remained uncommon and are continuing to decrease in frequency. From 2012 to 2015, there were approximately 200 exposures annually, consistent with how infrequently theophylline is now used therapeutically. Caffeine exposures continue to slowly decrease. In 1998, there were 7,390 reported caffeine exposures, with a steady decline: from 2007 with 5,448 exposures, to 2011 with 3,667 exposures, and to 2015 with 3,598 exposures. Caffeine is an important component of many energy drinks, and these have only been included as a subcategory of poisoning in NPDS since 2010, when there were 308 reported exposures. In 2015, the number of reported exposures to caffeine-containing energy drinks increased to 1,161, and exposures to caffeine-containing alcoholic beverages was 150.

The number of selective  $\beta_2$ -adrenergic agonist exposures is decreasing, with approximately 6,500 cases annually from 2012 to 2015, which is a decrease from the past 5 years, which had approximately 8,000 to 9,000 reported in 2007 to 2011 reports annually. There are no reported deaths from these substances (Chap. 130).

Most caffeine consumed is in beverages, with a lesser but concerning portion of caffeine consumed as in concentrated form as powders or liquids.<sup>6</sup> With limited scientific evidence demonstrating benefit, caffeine use is advocated for various beneficial health effects, as well as to improve athletic performance and concentration.<sup>16,53,77</sup> Products with high caffeine content are widely available as dietary supplements, which are generally not regulated by the Food and Drug Administration (FDA). These include powder, tablets, concentrated liquid, and liquid energy “shots” all for oral (PO) consumption as well as newer topical and transdermal caffeine products (Table 63–1).<sup>64</sup>

Energy drinks, which are FDA regulated, typically containing caffeine and other stimulant ingredients are increasingly popular, particularly with adolescents and athletes. A surge in poisoning from pure caffeine powder prompted the FDA to issue warning letters to manufacturers in 2015,<sup>32</sup> and the FDA also issued a safety alerts advising consumers to avoid use of these powdered caffeine products because of the potential for severe illness or death.<sup>34</sup> These drinks also have significant adverse side effects.<sup>61,42</sup> Although these do not routinely result in severe toxicity, major morbidity and mortality result from their use and misuse. Between 30% and 50% of adolescents and young adults in the United States regularly consume energy drinks.<sup>79</sup> Surveys of parents in the United States reveal that children as young as 5 years of age drink caffeinated beverages daily.<sup>97</sup>

Beverages that combine alcohol with relatively large doses of caffeine are commonly used, particularly among young adults and underage drinkers. Toxicity from use of such drinks became apparent very soon after they were introduced in the United States.<sup>21</sup> In some instances, the incidence of toxicity and adverse events associated with such drinks was so significant that some were banned because they are considered exceptionally dangerous. Caffeine is a very common ingredient as well as adulterant in illicit stimulants sold by Internet vendors.<sup>28</sup>

Caffeine, theophylline, and aminophylline are used in neonates to treat the apnea and bradycardia syndrome of prematurity. The result of such treatment is an increased respiratory rate, decreased apnea, increased cardiac chronotropy and inotropy, and increased cardiac output.<sup>13</sup> Caffeine is also used as an analgesic adjuvant, particularly when combined acetaminophen, aspirin, and ibuprofen or ergots.<sup>30</sup>

Theophylline or its water-soluble salt, aminophylline, is used to treat varied respiratory conditions, primarily reversible bronchospastic airway disease, particularly asthma. Theophylline was once the mainstay of therapy for such diseases, but inhaled selective  $\beta_2$ -adrenergic agonists with fewer adverse effects have almost completely replaced theophylline.

TABLE 63–1 Caffeine and Stimulant Content of Commonly Used Products

Product	Caffeine Content in Typical Single Serving (mg)	Volume of Typical Single Serving (mL)	Other Relevant Beverage Ingredients	Category
Arizona AZ RX Energy Shot	110	240	Niacin, vitamin B <sub>12</sub>	Dietary supplement
Caffeine pill (Vivarin, No-Doz)	200	—	—	Medication
Chocolate (Hershey Kiss)	1	—	—	Food
Chocolate milk	10–15	240	Theobromine	Beverage
Coffee (regular)	115–175	330		Beverage
Cola	30	330		Beverage
Espresso	55	30		Beverage
Five-Hour Energy	207	60	Niacin, taurine, vitamin B <sub>6</sub> , vitamin B <sub>12</sub>	Dietary supplement
Hot chocolate	8	240	Theobromine	Beverage
Red Bull	110	250	Taurine	Beverage
Tea (black)	40–100	240	Theobromine, theophylline	Beverage

### Spectrum of Toxicity

Methylxanthine toxicity is generally classified as acute, acute on chronic, or chronic in nature. In neonates receiving methylxanthine therapy, both acute and chronic toxicities are reported, and acute-on-chronic toxicity occurs in acute overdose in adults already being treated with theophylline therapeutically.

Chronic toxicity from caffeine most typically results from frequent self-administration of excessive caffeine. The *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition, notes five distinct caffeine-related disorders: caffeine toxicity, caffeine withdrawal, caffeine use disorder, other caffeine-induced disorders, and unspecified caffeine-related disorder.<sup>1</sup> *Caffeinism* is the classical syndrome associated with chronic caffeine use, consisting of headache, palpitations, tachycardia, insomnia, and delirium.

Theobromine poisoning is reported in veterinary literature and typically results from dogs or other small animals ingesting cocoa or chocolate. In 2015, the death of four wild bears after they ingested of chocolate used as bait demonstrated the potential for theobromine lethality in large animals.<sup>22</sup> Because of its greater thermogenic and ergogenic activity relative to caffeine, theobromine is now an ingredient of numerous energy and sports drinks used for stimulation and athletic enhancement, but human toxicity is unreported.

Use of selective  $\beta_2$ -adrenergic agonists is widespread. Adverse effects are associated with both therapeutic dosing and overdose. Excessive use of  $\beta_2$ -adrenergic agonists results in tachyphylaxis, a phenomenon in which downregulation of receptors occurs and the effects of the xenobiotic diminish as a result of excessive use.<sup>52</sup> Consequently, patients require higher doses to achieve the same clinical effects previously experienced at lower doses, resulting in consequential adverse effects. The most common acute selective  $\beta_2$ -adrenergic agonist toxicity results from children ingesting albuterol syrup. Toxicity associated with terbutaline and ritodrine is infrequently reported. Clenbuterol, a long-acting  $\beta_2$  adrenergic agonist used in countries outside the United States for treating bronchoconstriction in countries outside the United States, emerged as an abused anabolic xenobiotic as well as additive in street drugs.<sup>45</sup> Epidemic clenbuterol toxicity occurs as a result of both its admixture with illicit drugs and its intentional use for bodybuilding purposes in the United States.<sup>27</sup> These outbreaks demonstrate that, for reasons incompletely understood, clenbuterol has unique toxicities relative to other  $\beta_2$ -adrenergic agonists. Food poisoning by consumption of animal meat from livestock treated with clenbuterol occurs in Europe.<sup>5</sup> Ritodrine, removed from the US market in 2013 but still used in other countries, was used in parenteral and PO formulations as a tocolytic. Besides typical adverse effects

of other  $\beta_2$ -adrenergic agonists, it is associated with acute development of pulmonary edema, rhabdomyolysis, and agranulocytosis.<sup>56,105</sup>

## PHARMACOLOGY

### Methylxanthines

Methylxanthines cause the release of endogenous catecholamines, resulting in stimulation of  $\beta_1$  and  $\beta_2$  receptors. Endogenous catecholamine concentrations are extremely elevated in patients with methylxanthine poisoning.<sup>7</sup> Methylxanthines are structural analogs of adenosine and function pharmacologically as adenosine antagonists. Adenosine modulates histamine release and causes bronchoconstriction. This is a putative mechanism explaining the primary therapeutic efficacy of adenosine antagonists in the treatment of bronchospasm. Additionally, adenosine antagonism results in release of norepinephrine, and to a lesser extent epinephrine, through blockade of presynaptic A<sub>2</sub> receptors. The additional methyl group possessed by caffeine (1,3,7-trimethylxanthine) permits greater central nervous system (CNS) penetration relative to theophylline and theobromine, which are dimethylxanthines. Caffeine is an effective analgesic adjuvant, possibly because of its stimulant properties.

Methylxanthines also inhibit phosphodiesterase, the enzyme responsible for degradation of intracellular cyclic adenosine monophosphate (cAMP), which has many effects, including an increase in intracellular calcium concentrations. Phosphodiesterase inhibition was long considered to be the primary therapeutic mechanism of the methylxanthines, but clinically significant elevations in cAMP concentrations are not achieved until serum methylxanthine concentrations are well above the therapeutic range. This likely occurs as a result of the structural similarity of the adenosine moiety of cAMP and the methylxanthines. Cyclic AMP is involved in the postsynaptic second messenger system of  $\beta$ -adrenergic stimulation. Thus, elevated cAMP concentrations cause clinical effects similar to adrenergic stimulation, including smooth muscle relaxation, peripheral vasodilation, myocardial stimulation, skeletal muscle contractility, and CNS excitation.

### Selective $\beta_2$ -Adrenergic Agonists

Selective  $\beta_2$ -adrenergic agonists act very specifically at  $\beta_2$ -adrenergic receptors, resulting in an increase in intracellular cAMP. Effects of  $\beta_2$  agonism include relaxation of vascular, bronchial, and uterine smooth muscle; glycogenolysis in skeletal muscle; and hepatic glycogenolysis and gluconeogenesis. Selective  $\beta_2$ -adrenergic agonists are characterized as directly activating the  $\beta_2$  receptor, such as albuterol; being taken up into a membrane depot, such as formoterol; or interacting with a receptor-specific auxiliary binding

site, such as salmeterol. These differences do not appear to be relevant in acute toxicity. However, emerging evidence suggests that chronic use of long-acting  $\beta_2$ -adrenergic agonists is associated with increased incidence of intubation as well as fatalities with future exacerbations of asthma.<sup>77</sup>

## PHARMACOKINETICS AND TOXICOKINETICS

### Caffeine Pharmacokinetics

Caffeine is bioavailable by all routes of administration. Oral administration, which is by far the most common route of exposure, results in nearly 100% bioavailability. Peak concentration of caffeine occurs 30 to 60 minutes after oral intake, and food in the gastrointestinal (GI) tract delays the time to peak concentration. Caffeine rapidly diffuses into the total body water and all tissues and readily crosses the blood-brain barrier and into the placenta. The volume of distribution ( $V_d$ ) is 0.6 L/kg, and 36% is protein bound. Caffeine is secreted in breast milk with concentrations of 2 to 4 mcg/mL in breast milk after 100 mg PO dosing in a breastfeeding mother. Consumption of caffeine does not result in clinically relevant breast milk caffeine concentrations in lactating women or toxicity in their breastfeeding children. Breast milk caffeine concentrations are much lower than maternal serum caffeine concentrations, with breast milk having 0.006% to 1.5% of the quantity of maternal serum.<sup>8</sup>

When taken in amounts that produce serum caffeine concentrations exceeding a therapeutic range, or approximately 20 mg/kg, caffeine exhibits Michaelis-Menten kinetics and is metabolized, primarily by CYP1A2. The major pathway involves demethylation to 1,7-dimethylxanthine (paraxanthine) followed by hydroxylation or repeated demethylation followed by hydroxylation. To a lesser extent, caffeine is also metabolized to theobromine and theophylline. Neonates demethylate caffeine, producing theophylline, and possess the unique ability to convert theophylline to caffeine by methylation.<sup>39</sup> By 4 to 7 months of age, infants metabolize and eliminate caffeine in a manner similar to adults. All patients demethylate some quantity of caffeine to active metabolites, including theophylline and theobromine. The degree to which this occurs depends on the patient's age, CYP1A2 induction status, and other factors.

Less than 5% of caffeine is excreted in the urine unchanged. The half-life of caffeine is highly variable and dependent on several factors. In a healthy, nonsmoking, adult patient, the half-life is 4.5 hours; in smokers, the half-life shortened by up to 50%. Younger patients, particularly infants, and patients with CYP1A2 inhibition, such as pregnant patients or patients with cirrhosis, have longer caffeine half-lives.

### Caffeine Toxicokinetics

Caffeine toxicity is a dose-dependent phenomenon. The range of toxic concentrations reported in different references varies greatly, suggesting there is a wide range of clinical effects at any given serum concentration. Therapeutic dosing in neonates is typically consists of a loading dose of 20 mg/kg, with daily maintenance dosing of 5 mg/kg. Based on case reports and series, a lethal dose in adults is estimated at 150 to 200 mg/kg, and death is reported with serum concentrations above 80 mcg/mL. Numerous fatalities are reported with serum concentrations under 200 mcg/mL, and survival is reported of a patient with an acute caffeine overdose and a serum concentration over 400 mcg/mL.<sup>93</sup> Infants tolerate greater serum concentrations of caffeine than do children and adults.

### Theophylline Pharmacokinetics

Theophylline is nearly 100% orally bioavailable. Many of the available PO preparations are sustained-release ones designed to provide stable serum concentrations over a prolonged period of time with less frequent dosing. Peak absorption for immediate-release preparations is 60 to 90 minutes; peak absorption of sustained-release preparations generally occurs 6 to 10 hours after ingestion. Theophylline rapidly diffuses into the total body water and all tissues, readily crosses the blood-brain barrier, and crosses into the placenta and breast milk. The  $V_d$  of theophylline is 0.5 L/kg, and 56% of it is protein bound at therapeutic concentrations.

Theophylline is metabolized primarily by CYP1A2. The major pathway is demethylation to 3-methylxanthine in addition to being demethylated or oxidized to other metabolites. Less than 10% of theophylline is excreted in the urine unchanged. The half-life of theophylline is highly variable and depends on several factors. In healthy, adult, nonsmoking patients, the half-life is 4.5 hours. Infants and older adults as well as patients with CYP1A2 inhibition, pregnant patients, and those with cirrhosis have theophylline half-lives twice as long as healthy children and nonsmoking adults.<sup>24</sup> Factors that induce CYP1A2, such as cigarette smoking, decrease methylxanthine half-life and increase clearance, but others that inhibit CYP1A2, such as exposure to cimetidine, macrolides, and oral contraceptives can significantly decrease theophylline clearance.<sup>95</sup> Cessation of smoking, such as when a patient with chronic obstructive pulmonary disease develops bronchitis, leads to a reversal of CYP1A2 induction and predisposes to the development of chronic toxicity.

### Theophylline Toxicokinetics

As in the case of caffeine, theophylline exhibits Michaelis-Menten kinetics, presumably when greater than a single therapeutic dose is taken. At higher doses and in overdose, it undergoes zero-order elimination, and only a fixed amount of the xenobiotic is eliminated in a given time because of saturation of metabolic enzymes.<sup>43</sup>

Therapeutic serum concentrations of theophylline are 5 to 15 mcg/mL. Although morbidity and mortality are not always predictable based on serum concentrations, life-threatening toxicity is associated with serum concentrations of 80 to 100 mcg/mL in acute overdoses and of 40 to 60 mcg/mL in chronic overdoses.<sup>82,84</sup>

### Theobromine Toxicokinetics and Pharmacokinetics

Theobromine is well absorbed from the GI tract and taken as food, such as in chocolate, is 77% bioavailable.<sup>90</sup> Theobromine has 21% protein binding, a  $V_d$  of 0.62 L/kg, and a serum half-life of 6 to 10 hours.<sup>74</sup> Theobromine undergoes hepatic metabolism by CYP1A2 and CYP2E1. Theobromine is excreted in breast milk. Toxic concentrations of theobromine in animals are known, but comparable human data are lacking.

### Selective $\beta_2$ -Adrenergic Agonist Pharmacokinetics

The  $\beta_2$ -adrenergic agonists are bioavailable by both inhalation and ingestion, and much of "inhaled"  $\beta_2$ -adrenergic agonists may actually be swallowed and absorbed from the GI tract. Absorption, distribution, and elimination are quite variable. The half-life of albuterol is approximately 4 hours, and less than 5% crosses the blood-brain barrier. It is metabolized extensively in the liver, and it is excreted in urine and feces as albuterol and metabolites.

Terbutaline is partially metabolized in the liver, mainly to inactive conjugates. With parenteral administration, 60% of a given dose is excreted in the urine unchanged.

Clenbuterol has a terminal half-life of approximately 22 hours and a prolonged duration of action. It is more potent than other  $\beta_2$ -adrenergic agonist, with a typical therapeutic dose of 20 to 40 mcg, as opposed to milligram doses for other  $\beta_2$ -adrenergic agonists. Clenbuterol has lipolytic and anabolic effects desired by athletes and others who use the drug.

### Selective $\beta_2$ -Adrenergic Agonist Toxicokinetics

Overdose of albuterol, which happens predominantly in young children treated with PO albuterol preparations, uncommonly causes significant effects. For PO albuterol poisoning, 1 mg/kg appears to be the dose threshold for developing clinically significant toxicity.<sup>101</sup> Clenbuterol toxicity occurs after illicit drug use by ingestion, intranasal, and IV use of clenbuterol or clenbuterol-tainted street drugs.<sup>49</sup>

## METHYLXANTHINE AND $\beta_2$ -ADRENERGIC AGONIST TOXICITY

Caffeine, theobromine, and theophylline affect the same organ systems and cause qualitatively similar effects. Toxicity affects the GI, cardiovascular, central nervous, and musculoskeletal systems in addition to causing a constellation of metabolic derangements. A putative cause for toxicity involves

the increase in metabolism that occurs with methylxanthine toxicity, particularly in the setting of a decreased tissue perfusion. Concomitant poisoning with other xenobiotics that result in adrenergic stimulation, such as pseudoephedrine, ephedrine, amphetamines, or cocaine, may be particularly severe.<sup>29</sup>

### Gastrointestinal

In overdose, methylxanthines cause nausea, and most significant acute overdoses result in severe and protracted emesis. Whereas emesis occurs in 75% of cases of acute theophylline poisoning, only 30% of cases of chronically poisoned patients experience emesis.<sup>85</sup> When it occurs, the emesis is usually severe and requires use of potent antiemetics. This is especially evident with sustained-release theophylline preparations.<sup>2</sup> Emesis is less common and less severe with selective  $\beta_2$ -adrenergic agonist toxicity.

Methylxanthines increase gastric acid secretion and relax smooth muscle. These factors contribute to the gastritis and esophagitis reported in chronic methylxanthine users. Gastritis is noted in drinkers of decaffeinated coffee, and therefore some adverse gastric effects associated with coffee drinking are caused by ingredients other than caffeine such as the pH of the beverage.

### Cardiovascular

Methylxanthines are cardiac stimulants and result in positive inotropy and chronotropy even with therapeutic dosing. Dysrhythmias, particularly tachydysrhythmias, are common in patients with methylxanthine overdose. Tachydysrhythmias, particularly ventricular extrasystoles, are more common after methylxanthine overdose.<sup>19,82</sup> Cardiac dysrhythmias, although described with selective  $\beta_2$ -adrenergic agonist poisoning, are most frequently supraventricular in origin and clinically inconsequential. Dysrhythmias other than sinus tachycardia associated with  $\beta_2$ -adrenergic agonist toxicity are not routinely noted with toxicity from other  $\beta_2$ -adrenergic agonists, but clenbuterol is known to cause atrial fibrillation.<sup>27</sup> Palpitations, tachycardia, and chest pain are common presenting complaints for patients with clenbuterol toxicity.

In the setting of acute poisoning, generally benign sinus tachycardia is nearly universal in patients without antecedent cardiac disease. In any patient, particularly those with underlying cardiac disease, sinus tachycardia degenerates to a more severe rhythm disturbance, and these represent the most common causes of fatality associated with methylxanthine poisoning. Both atrial and ventricular dysrhythmias, including supraventricular tachycardia (SVT), multifocal atrial tachycardia, atrial fibrillation, premature ventricular contractions, and ventricular tachycardia, result from methylxanthine toxicity.<sup>9</sup> Concomitant electrolyte disturbances, particularly hypokalemia, contribute to the development of dysrhythmias. Dysrhythmias occur more commonly and at lower serum concentrations in cases of chronic poisoning with methylxanthines. Consequential dysrhythmias occur in 35% of patients with chronic theophylline poisoning but in only 10% of patients with acute poisoning.<sup>84</sup> Ventricular dysrhythmias occur at serum concentrations of 40 to 80 mcg/mL in patients with chronic theophylline overdoses and most commonly at serum concentrations greater than 80 mcg/mL in patients with acute overdoses. Neonates born to mothers who consumed more than 500 mg/day of caffeine are more likely to have dysrhythmias compared with cohorts born to mothers consuming less than 250 mg/day of caffeine. See [Table 63–1](#) for the caffeine content of popular products.

Myocardial ischemia and myocardial infarction (MI) are associated from acute caffeine or theophylline poisoning. Myocardial infarction is also associated with albuterol and more recently clenbuterol overdose. Isoproterenol, once a common asthma therapy before widespread use of selective  $\beta_2$ -adrenergic agonists, has both  $\beta_1$  and  $\beta_2$ -adrenergic agonist activity and is a well-reported cause of MI. Given the frequency of use of selective  $\beta_2$ -adrenergic agonists and in light of the well-known safety and toxicity profile, MI is very unlikely to occur from selective  $\beta_2$ -adrenergic agonists other than clenbuterol. Clenbuterol is clearly capable of causing myocardial ischemia and MI in young otherwise healthy patients without coronary artery disease.<sup>72</sup>

Elevation of troponin, muscle creatine phosphokinase (CK-MM) and cardiac (CK-MB) fractions are described and expected after large doses of  $\beta_2$ -adrenergic agonists, particularly terbutaline infusions and continuous albuterol nebulization.<sup>23,91</sup> In the absence of electrocardiographic (ECG) changes suggestive of ischemia, the clinical significance of increased CK-MB and cardiac troponin concentrations in patients receiving terbutaline infusions, particularly children, is unclear and does not correlate with clinically adverse effects.<sup>20</sup>

In therapeutic doses, methylxanthines cause cerebral vasoconstriction. In overdose, this effect likely exacerbates CNS toxicity by diminishing cerebral perfusion. Tolerance to the vasopressor effects of methylxanthines develops after several days of use and rapidly disappears after relatively brief periods of abstinence.

Dietary caffeine increases blood pressure, which is believed to contribute to population levels of morbidity and mortality.<sup>51</sup> At elevated serum concentrations, patients with methylxanthine or selective  $\beta_2$ -adrenergic agonist poisoning often develop a characteristic widened pulse pressure. This is caused by enhanced inotropy ( $\beta_1$ ) that increases in systolic blood pressure combined with peripheral vasodilation ( $\beta_2$ ), which causes diastolic hypotension. In cases of acute theophylline overdose, serum concentrations greater than 100 mcg/mL are usually associated with severe toxicity, and the associated shock involves significant hypotension rather than simply widened pulse pressure. Methylxanthines cause renal vasodilation that, in addition to the increased cardiac output, results in a mild diuresis.

### Pulmonary

Methylxanthines stimulate the CNS respiratory center, causing an increase in respiratory rate. For this reason, caffeine and theophylline are used to treat neonatal apnea syndromes. Severe caffeine and theophylline overdoses cause hyperventilation, respiratory alkalosis, respiratory failure, respiratory arrest, and acute respiratory distress syndrome.

### Neuropsychiatric

The stimulant and psychoactive properties of methylxanthines, particularly caffeine, elevate mood and improve performance of manual tasks. The CNS stimulation associated with use is an effect sought by users of coffee, tea, cocoa, and chocolate. Central nervous system stimulation resulting from therapeutic use of theophylline is generally considered to be an undesirable side effect. Although at low doses, methylxanthines have beneficial effects, with increasing doses, they result in adverse effects. Headache, anxiety, agitation, insomnia, tremor, irritability, hallucinations, and seizures occur from caffeine or theophylline poisoning. In adults, caffeine doses of 50 to 200 mg result in increased alertness, decreased drowsiness, and lessened fatigue, and caffeine doses of 200 to 500 mg produce adverse effects such as tremor, anxiety, diaphoresis, and palpitations. Children tend to develop CNS symptoms at lower serum theophylline concentrations than adults, and such excitation is a significant clinical disadvantage of theophylline use.

Seizures are a major complication of methylxanthine poisoning. The ability of caffeine to both promote and prolong seizures is well recognized, and caffeine was once used to prolong therapeutically induced seizures in electroconvulsive therapy.<sup>26</sup> Seizures resulting from methylxanthine overdose tend to be severe and recurrent and refractory to conventional treatment. Antagonism of adenosine, the endogenous neurotransmitter responsible for halting seizures, contributes to the profound seizures associated with methylxanthine overdose.<sup>31,87</sup> When studied prospectively, chronic theophylline toxicity results in seizures in 14% of patients, but 5% of acutely poisoned patients experience seizures. In cases of chronic and acute-on-chronic toxicity, seizures are more likely to occur, and they occur at lower serum concentrations.<sup>68</sup> Patients at extremes of age—those younger than age 3 years and older than age 60 years—are more likely to experience seizures with overdose.

### Musculoskeletal

Methylxanthines increase striated muscle contractility, secondarily decreasing muscle fatigue. They also increase muscle oxygen consumption and

increase the basal metabolic rate. These effects are sought by users to enhance or improve athletic performance or weight loss. All methylxanthines cause smooth muscle relaxation.

Tremor is the most common adverse effect of methylxanthines. Skeletal muscle excitation associated with methylxanthine overdose includes fasciculation, hypertonicity, myoclonus, or even rhabdomyolysis.<sup>63</sup> Mechanisms for rhabdomyolysis include increased muscle activity, particularly from seizures, and direct cytotoxicity from excessive sequestered intracytoplasmic calcium. The mechanism of injury is unknown, but multiple case reports associate a nontraumatic compartment syndrome with rhabdomyolysis with theophylline overdose.<sup>62,94</sup>

### Metabolic

Numerous metabolic derangements result from acute methylxanthine toxicity and are similar to those in other hyperadrenergic situations.<sup>43</sup> Methylxanthines result in adrenal release of endogenous catecholamines,<sup>89</sup> which contribute to the metabolic effects associated with methylxanthine exposure. Severe hypokalemia from  $\beta_2$ -adrenergic stimulation is well reported.<sup>96</sup> This results from influx of extracellular potassium into the intracellular compartment despite normal total body potassium content. Both ECG and neuromuscular complications secondary to hypokalemia are possible. Other metabolic effects of methylxanthine and selective  $\beta_2$ -adrenergic agonist poisoning include hypomagnesemia and hypophosphatemia.<sup>12</sup>

Transient hypokalemia resulting from  $\beta$ -adrenergic agonism occurs in 85% of patients with acute theophylline overdose, and typically the serum potassium decreases to approximately 3 mEq/L.<sup>2,86</sup> Stimulation of  $\text{Na}^+, \text{K}^+$ -ATPase results in a shift of serum potassium to the intracellular compartment of skeletal muscle. Total body potassium stores are unchanged. The significance of hypokalemia in patients with methylxanthine overdose or in patients with hypokalemia secondary to selective  $\beta_2$ -adrenergic agonists, is unclear. Hyperkalemia secondary to rhabdomyolysis or overly aggressive repletion of potassium is a rare but potential adverse effect of methylxanthine poisoning.

Metabolic acidosis with an increased serum lactate concentration is commonly noted as a complication of theophylline overdose and is also described as a result of clenbuterol overdose and with therapeutic albuterol use.<sup>9,49,76</sup> Tachypnea and respiratory alkalosis secondary to stimulation of the respiratory center are also common with methylxanthine toxicity, but this does not result from selective  $\beta_2$ -adrenergic agonists.

Hyperglycemia with serum glucose of approximately 200 mg/dL in those without diabetes is common and occurs in 75% of patients with acute theophylline overdose. Rebound hypoglycemia after albuterol overdose is reported in children,<sup>98</sup> but this is probably an extraordinarily rare occurrence. Hyperthermia caused by increased metabolic activity and increased muscle activity occurs after caffeine and theophylline overdose. Leukocytosis, probably secondary to the high concentrations of circulating catecholamines, results from acute methylxanthine overdose and lacks clinical significance. In the absence of seizures or protracted emesis, chronic methylxanthine poisoning does not typically lead to metabolic derangements other than mild hypokalemia because such toxicity is an ongoing, compensated process.

### CHRONIC METHYLXANTHINE TOXICITY

The distinction between acute and chronic toxicity is based on the duration of exposure. Signs and symptoms of chronic toxicity are usually more subtle or nonspecific, such as anorexia, nausea, palpitations, or emesis, but chronic toxicity also presents as seizures or dysrhythmias. Patients chronically receiving theophylline or caffeine have higher total body stores of these xenobiotics and often underlying medical disorders and thus develop toxicity with a smaller amount of additional theophylline or caffeine. Chronic methylxanthine poisoning typically occurs in the setting of therapeutic use of theophylline or caffeine, as well as from frequent, chronic consumption of caffeinated products. Patients often manifest subtle signs of illness, such as anorexia, nausea, palpitations, or emesis. However, the initial presentation in these patients, even with serum concentrations in the 40- to 60-mcg/mL

range, can be a seizure. Children chronically overdosed with theophylline often have peak serum theophylline concentrations in the high end of the normal range, and thus this laboratory testing fails to identify some who will progress to life-threatening toxicity. In the absence of protracted emesis or seizures, the initial electrolytes other than potassium and blood gases are expected to be normal in patients with chronic methylxanthine toxicity.

### CHRONIC METHYLXANTHINE USE

Data on the effect of caffeine on many chronic health issues are mixed and highly contradictory. Studies show inconclusive links to Alzheimer's disease, depression, cancer, heart disease, osteoporosis, hyperlipidemia, and hypercholesterolemia associated with caffeine use.<sup>17,41,99,102,103</sup> Hypokalemia secondary to excessive consumption of caffeine-containing beverages is reported.

### CAFFEINE WITHDRAWAL

Caffeine induces tolerance, and a withdrawal syndrome, including headache, yawning, nausea, drowsiness, rhinorrhea, lethargy, irritability, nervousness, a disinclination to work, and depression, occurs on abstinence in tolerant users. Use of caffeinated analgesics to treat headache causes rebound headaches upon cessation. Caffeine withdrawal symptoms are described in neonates born to mothers with consequential caffeine use.<sup>65</sup> The onset of caffeine withdrawal symptoms begins 12 to 24 hours after cessation and lasts up to 1 week. In a double-blind trial, 52% of adults with low to moderate caffeine intake, defined as 2.5 cups of coffee daily, developed a withdrawal syndrome on caffeine abstinence.<sup>91</sup>

### REPRODUCTION

Massive doses of methylxanthines are teratogenic, but the doses of typical use are not associated with birth defects. Decreased fecundity and adverse fetal outcome are noted in animals with chronic exposure to methylxanthines. Human studies of fertility, fetal loss, and fetal outcome produce divergent results, and the effects of methylxanthine use during gestation are unclear.<sup>15</sup>

### DIAGNOSTIC TESTING

An ECG, serum electrolytes, and serum caffeine or theophylline concentrations are indicated in cases of suspected methylxanthine toxicity. Because toxicity is dose related in acute overdose, serum concentrations of caffeine and theophylline correlate with toxicity, but for caffeine, there is a much wider range of severity associated with a given serum concentration.

Hospitals that use caffeine therapeutically can typically assay serum caffeine concentration within the institution, and likewise hospitals using theophylline therapeutically typically can assay serum theophylline concentrations. Overdose of caffeine causes a spuriously elevated serum theophylline concentration.<sup>35</sup>

Theophylline concentrations—and to a lesser extent, caffeine concentrations—are used prognostically to guide management of poisoning. Proper interpretation requires knowledge of whether the poisoning is acute, chronic, or acute on chronic. In the setting of toxicity, serum caffeine or theophylline concentrations should be obtained immediately and then serially every 1 to 2 hours until a downward trend is evident.

Likewise, serum electrolytes, particularly potassium, should be monitored serially as long as the poisoned patient remains symptomatic and significantly abnormal values warrant treatment. Cardiac monitoring should continue until the patient is free of dysrhythmias other than sinus tachycardia, has a falling serum methylxanthine concentration, and is clinically stable. In patients with systemic illness, hyperthermia, or increased muscle tone, assessing serum CK and urinalysis to detect rhabdomyolysis is also indicated.

### MANAGEMENT

#### General Principles and Gastrointestinal Decontamination

After assuring adequacy of airway, breathing, and circulation, supportive care and maintenance of vital signs within acceptable limits are the mainstays of therapy for patients with methylxanthine and selective  $\beta_2$ -adrenergic agonist toxicity. Decisions regarding GI decontamination, including orogastric

lavage, administration of activated charcoal (AC), or whole-bowel irrigation (WBI), depend on the dosage and type of preparation involved, the time since exposure, and the patient's physical condition. Activated charcoal is the only GI decontamination that is routinely recommended for selective  $\beta_2$ -adrenergic agonist ingestion.

### Orogastric Lavage

Orogastric lavage is an acceptable option for patients with methylxanthine ingestions capable of causing severe toxicity or fatality given an appropriate time frame (Chap. 5) and who are not already experiencing spontaneous emesis. If orogastric lavage can be performed safely by a skilled clinician, an approximated dose of ingestion of 50 mg/kg of theophylline tablets is a reasonable threshold. Most patients with caffeine ingestion are unlikely to be appropriate for orogastric lavage because concentrated caffeine is most commonly in powder, liquid, or rapidly disintegrating tablets, and caffeine is very rapidly absorbed from the stomach. Therefore, we recommend orogastric lavage for caffeine tablet ingestions of 50 mg/kg or greater that have occurred 60 minutes or less from the time orogastric lavage can be started. Lavage after ingestion of caffeine powder or liquid would preferably be performed with a nasogastric tube rather than an orogastric tube. Caffeine powder or liquid could be readily retrieved through a nasogastric tube. Because of the much greater ease, greater safety, and lesser need for clinician experience to safely perform, nasogastric lavage is reasonable after recent ingestion of 50 mg/kg or more caffeine liquid or powder. If the patient has ingested an unknown but likely greater than 1 tsp of concentrated powder, which would contain nearly 5 g, it should be presumed this is a massive mg/kg dose, and similarly nasogastric lavage is reasonable. At the completion of orogastric or nasogastric lavage, the lavage tube should be used to deliver an appropriate dose of AC. If a nasogastric tube is used, it may be left in place for delivery of multiple-dose activated charcoal (MDAC).

Likewise, for patients with recent ingestion of large quantities of selective  $\beta_2$ -adrenergic agonist in liquid form who have not already had spontaneous emesis, aspiration of gastric contents with a small nasogastric tube is reasonable followed by administration of AC.

### Activated Charcoal

Activated charcoal is essential for the treatment of methylxanthine poisoning. Activated charcoal can adsorb methylxanthines and selective  $\beta_2$ -adrenergic agonist present in the GI tract and limit their absorption. Multiple-dose activated charcoal is helpful to enhance the elimination of methylxanthines but is not indicated for selective  $\beta_2$ -adrenergic agonist ingestion. Multiple-dose activated charcoal is recommended for any significant methylxanthine ingestion. Multiple-dose activated charcoal enhances elimination of theophylline, and probably caffeine and theobromine, by "gut dialysis" (Antidotes in Depth: A1). Although MDAC's utility is only proven for theophylline, the pharmacologic similarity of the methylxanthines and the relative safety of MDAC therapy warrant the use of such treatment for patients with any methylxanthine toxicity.

### Whole-Bowel Irrigation

Whole-bowel irrigation for the xenobiotics covered in this chapter is reasonable for sustained-release pills, with very specific limitations. Ingestion of sustained-release theophylline tablets is associated with the formation of bezoars that are difficult to remove or dislodge and require endoscopic removal.<sup>18</sup> Use of a brief period of initial WBI for patients with ingestion of sustained-release theophylline tablets is reasonable to prevent bezoar formation (Antidotes in Depth: A2). Polyethylene glycol electrolyte lavage solution used for WBI can displace theophylline already bound to AC.<sup>47</sup> This is a concern in patients who have taken several doses of AC before WBI, in which desorption of methylxanthine from AC will result in some additional methylxanthine available for GI absorption. Also, WBI is experimentally demonstrated to provide no additional benefit to AC in treatment of sustained-released theophylline ingestion.<sup>14</sup> Thus if orogastric lavage was not used, MDAC, possibly preceded by an initial period of WBI to prevent bezoar formation, is reasonable treatment of a patient with ingestion of sustained-release theophylline.

## Specific Treatment

### Gastrointestinal Toxicity

Use of a highly effective antiemetic, such as ondansetron or granisetron, sometimes in doses used for chemotherapy, plays a role in management of methylxanthine-induced vomiting, which is usually severe and prolonged. However, ondansetron is capable of resulting in QT interval prolongation,<sup>33</sup> particularly in the setting of likely hypokalemia and hypomagnesemia, both common with methylxanthine toxicity. We recommend confirmation of a normal QT interval before ondansetron use. Phenothiazine antiemetics are contraindicated in methylxanthine poisoning because they are typically ineffective, and they lower the seizure threshold. Less effective antiemetics such as metoclopramide are reasonable if ondansetron or granisetron is unavailable or if the maximal ondansetron or granisetron dose has been reached or if the QT interval is already prolonged.<sup>75</sup> Histamine ( $H_2$ ) blockers and proton pump inhibitors are reasonable in any patient with hematemesis. Cimetidine is contraindicated because it inhibits multiple CYP enzymes, delaying clearance of methylxanthines.

### Cardiovascular Toxicity

Patients with hypotension should initially be treated by administration of isotonic intravenous (IV) fluid, such as 0.9% sodium chloride or lactated Ringer solution, in bolus volumes of 20 mL/kg. If acceptable blood pressure cannot be maintained despite several fluid boluses or if there are contraindications to fluid bolus, additional therapy using vasopressors or  $\beta$ -adrenergic antagonists such as esmolol is recommended. There are less available data on use of esmolol for this purpose, but animal models<sup>36</sup> and human case reports confirm its efficacy.<sup>80</sup>

Methylxanthine and selective  $\beta_2$ -adrenergic agonist toxicity cause hypotension via  $\beta$ -adrenergic agonism; therefore, administration of vasopressors with  $\beta$ -adrenergic agonist effects, such as epinephrine, dobutamine, or isoproterenol, is suboptimal. An  $\alpha$ -adrenergic agonist such as phenylephrine is the first-line pressor of choice in such a situation, although norepinephrine is also acceptable.

In cases of refractory hypotension, the administration of a  $\beta$ -adrenergic antagonist is recommended. Administration of a  $\beta$ -adrenergic antagonist to a hypotensive patient is counterintuitive, but it can reverse  $\beta_2$ -adrenergic-mediated vasodilation. In addition,  $\beta_1$ -adrenergic blockade treats tachycardia and any associated decreased cardiac output. In dogs with aminophylline-induced tachycardia and hypotension, administration of esmolol results in a return to normal heart rate and blood pressure, and it does not exacerbate hypotension.<sup>36</sup> Propranolol, esmolol, and metoprolol were used successfully to treat methylxanthine-induced hypotension and dysrhythmias in humans.<sup>1071</sup> It is most appropriate to use a  $\beta$ -adrenergic antagonist with a brief duration of action, such as esmolol, at least initially, in such circumstances. In the event of an adverse reaction or side effect such as hypotension or bronchospasm were to occur, the duration of such will be relatively brief. Any  $\beta$ -adrenergic antagonist therapy should ideally be preceded and accompanied by assessment of cardiac output and central venous pressure, either directly or noninvasively.<sup>55</sup> Because of its long half-life and possibly potency, toxicity from clenbuterol exposure appears more likely to require treatment with  $\beta$ -adrenergic antagonist medications.<sup>48</sup>

When xenobiotic toxicity is not causal, adenosine or electrical cardioversion is the preferred treatment for SVT. This is not so for SVT resulting from methylxanthine toxicity. Because of the antagonist effects at the adenosine receptor, administration of adenosine is not expected to convert a methylxanthine-induced SVT. Even if adenosine is successfully used to convert an SVT, the effect is likely to be transient. Because methylxanthine toxicity has a global effect on the myocardium and methylxanthine concentrations do not change rapidly, cardioversion, which is effective in electrically "reorganizing" depolarization, is unlikely to result in a sustained normal rhythm.

The primary treatment for methylxanthine-induced SVT includes administration of benzodiazepines, and focused pharmacologic therapy to treat SVT would be use of a  $\beta$ -adrenergic antagonist such as esmolol, of if that were not possible, we recommend cautious administration of a

conduction-attenuating calcium channel blocker such as diltiazem or verapamil. Pharmacologic treatment of methylxanthine-induced ventricular dysrhythmias would involve, in addition to typical Advanced Cardiovascular Life Support resuscitation medications, use of esmolol.<sup>58</sup>

In animal models, treatment of patients with acute theophylline toxicity with the calcium channel blockers diltiazem, verapamil, and nifedipine each results in decreased cardiac-related deaths and prevention of dysrhythmias, hypotension, myocardial necrosis, and seizures.<sup>100</sup> In addition to the cardiovascular benefit of calcium channel blockers, they also afford neurologic protection and prevention of seizure.

### Central Nervous System Toxicity

Administration of a benzodiazepine, such as diazepam, lorazepam, or midazolam, is the recommended treatment for anxiety, agitation, or seizure. Because of the long duration of effect of methylxanthines, lorazepam is preferable, and if diazepam or midazolam is used, the need for multiple doses should be expected. Seizures associated with methylxanthine toxicity are severe and often refractory to treatment. In patients with seizures not controlled with one or two therapeutic doses of a benzodiazepine we recommend treatment with a barbiturate such as phenobarbital or pentobarbital or another suitable sedative-hypnotic such as propofol. No delay should occur before escalating management to include more potent medications. Unsuccessful antiepileptic therapy of methylxanthine-induced seizures should quickly be escalated to use a more potent antiepileptic. The administration of barbiturates or propofol may result in, or exacerbate hypotension. Treatment of agitation or seizure with benzodiazepines, barbiturates, propofol, or other sedative-hypnotic requires repeated dosing until clinical effect is achieved.

Administration of phenobarbital to prevent seizures in theophylline-poisoned rabbits and mice increases survival by decreasing the incidence of seizures.<sup>25,40</sup> Although historically phenobarbital was the recommended medication for such prophylaxis, use of a benzodiazepine such as lorazepam seems preferable based on pharmacokinetic and practical considerations. Patients at risk for seizure include those identified earlier in this chapter—patients older than age 60 years or younger than age 3 years, those with chronic overdose and a serum concentration above 40 mcg/mL, and acutely overdosed patients with serum concentrations greater than 100 mcg/mL.

Phenytoin and fosphenytoin are contraindicated to treat methylxanthine-induced seizures. Phenytoin and fosphenytoin are of no benefit in controlling methylxanthine-induced seizures. Phenytoin shortens the time to seizure and increases the mortality rate when administered to theophylline-poisoned animals.<sup>11,46</sup> Retrospective review of human cases demonstrated phenytoin to be ineffective in treating seizures in nearly all cases.<sup>70</sup>

### Metabolic Abnormalities

Patients with symptomatic hypokalemia should be treated with electrolyte repletion. Most cases of hypokalemia are well tolerated and do not require potassium supplementation, but any patient with symptomatic hypokalemia, particularly those associated with ECG changes of abnormal T waves or QT interval prolongation, should be treated. The frequency of ventricular dysrhythmias in methylxanthine poisoning is exacerbated by hypokalemia coupled with increased intrinsic catecholamine release. Correction of hypokalemia is crucial in methylxanthine poisoning associated with ventricular dysrhythmias.

There is no specific degree of hypokalemia that absolutely necessitates treatment, and potassium supplementation should not be routinely used. In the absence of associated dysrhythmias or prolonged QT interval, the clinical significance of such hypokalemia is unclear. When potassium correction is needed, it is generally performed with the administration of IV or PO potassium, but hypokalemia experimentally responds to treatment with  $\beta$ -adrenergic antagonists.

If administration of potassium to treat symptomatic hypokalemia is indicated, it is in lesser quantities than that needed for total body potassium repletion. Methylxanthine and  $\beta_2$ -adrenergic agonists result in a potassium shift rather than potassium loss. In cases of hypokalemia secondary to  $\beta$ -adrenergic

agonism, after the  $\beta$ -adrenergic agonism resolves, an efflux of potassium from the intracellular compartment occurs with a concomitant increase in the serum potassium concentration. Aggressive attempts to correct hypokalemia result in hyperkalemia after the  $\beta$ -adrenergic agonist effects abate.

Experimentally, administration of propranolol to theophylline-poisoned dogs prevented or partially reversed hypokalemia, hypophosphatemia, hyperglycemia, and metabolic acidosis as well as hypotension.<sup>54</sup> Prevention or correction of the metabolic derangements associated with theophylline toxicity by administration of  $\beta$ -adrenergic antagonists is congruent with the fact that these derangements, particularly hypokalemia, are the consequence of  $\beta$ -adrenergic agonism. Indications to treat hypomagnesemia, hypophosphatemia, or hypocalcemia include ECG abnormalities such as prolongation of the QT interval or dysrhythmia.

Hyperglycemia, likely resulting from increased circulating catecholamines, is common. This hyperglycemia does not necessitate treatment, both because it is a transient effect and because in other situations of hyperglycemia resulting from adrenergic agonism, rebound hypoglycemia is a risk.

### Musculoskeletal Toxicity

The use of benzodiazepines is a reasonable treatment for fasciculations, hypertonicity, myoclonus, and rhabdomyolysis. Rhabdomyolysis necessitates aggressive therapy with IV fluid and sodium bicarbonate (Antidotes in Depth: A5).

### Enhanced Elimination

Fortunately, methylxanthine toxicity lends itself well to several methods of enhanced elimination, including disrupting enterohepatic or enteroenteric recirculation with MDAC or hemodialysis as well as increasingly used methods such as continuous arteriovenous and continuous venovenous hemoperfusion.<sup>50,60</sup>

Although intermittent hemodialysis has a long record of efficacy in treating methylxanthine toxicity, in some settings when hemodialysis is not an option, continuous renal replacement therapy (CRRT) is an alternative treatment. Particularly in infants, MDAC, CRRT, and exchange blood transfusion are effective methods of enhanced elimination, and these may be used concurrently, particularly if hemodialysis is not feasible.<sup>69,86,88</sup>

Enhanced elimination of methylxanthines by use of MDAC is recommended for toxicity with elevated serum methylxanthine concentrations unless there is a specific contraindication. Such MDAC use allows elimination of theophylline limiting enteroenteric or enteroenteric recirculation.<sup>4</sup> Multiple-dose activated charcoal is extremely effective at enhancing elimination of theophylline.<sup>37,59,67</sup> Experimentally in animals and human volunteers, AC administered after IV aminophylline administration results in increased systemic clearance and decreased half-life of theophylline.<sup>57,66,73</sup> The pharmacologic similarity of the methylxanthines suggests that MDAC is probably effective in caffeine or theobromine poisoning, and MDAC certainly is effective in eliminating theophylline generated from metabolism of caffeine or theobromine. The efficacy of MDAC combined with the safety and ease with which this therapy can be administered makes MDAC the mainstay of enhanced elimination in methylxanthine toxicity. Severe emesis associated with methylxanthine poisoning results in intolerance of MDAC (Antidotes in Depth: A1).<sup>81</sup>

Charcoal hemoperfusion was once considered the most effective method of enhanced elimination of methylxanthines, decreasing theophylline's half-life to 2 hours and increasing its clearance up to sixfold.<sup>104</sup> Variations of charcoal hemoperfusion, including albumin colloid hemoperfusion, resin hemoperfusion, and charcoal hemoperfusion in series with hemodialysis, are reported. Because of widespread availability and efficiency, hemodialysis is the recommended first-line method of extracorporeal treatment (ECTR) for methylxanthine poisoning.<sup>38</sup> In addition to the extracorporeal removal of methylxanthines, hemodialysis can also correct fluid and electrolyte imbalances, is more widely available,<sup>83</sup> is technically easier, with lower complication rates.

Consensus guidelines give specific indications for extracorporeal removal of theophylline,<sup>38</sup> which should also be applied to caffeine

**TABLE 63–2** Methylxanthine Poisoning: Indications for Hemodialysis or Charcoal Hemoperfusion

1. Extracorporeal xenobiotic removal is recommended if:
  - a. Serum theophylline or caffeine concentration >100 mg/L (555 μmol/L).
  - b. Seizures are present.
  - c. Life-threatening dysrhythmias are present.
  - d. Shock is present.
  - e. Theophylline or caffeine concentration is rising despite optimal treatment.
  - f. Clinical deterioration occurs despite optimal therapy.
2. Extracorporeal xenobiotic removal is suggested if:
  - a. Theophylline or caffeine >60 mg/L (333 μmol/L) in chronic exposure.
  - b. The patient is <6 months or >60 years of age and the theophylline or caffeine >50 mg/L (278 μmol/L) in chronic exposure.
  - c. Gastrointestinal decontamination cannot be performed.

poisoning. These include theophylline concentration greater than 100 mg/L (555 μmol/L); presence of seizures; life-threatening dysrhythmias, or shock; a rising serum concentration despite optimal GI decontamination; and clinical deterioration despite optimal care. In patients with chronic poisoning, extracorporeal removal is suggested if the theophylline serum concentration is greater than 60 mg/L (333 μmol/L) or a lower cutoff of concentration greater than 50 mg/L (278 μmol/L) for patients younger than 6 months of age or older than 60 years of age. Another suggested indication for extracorporeal removal is inability to administer GI decontamination. Extracorporeal treatment should be continued until clinical improvement is apparent or the concentration is less than 15 mg/L (83 μmol/L). Intermittent hemodialysis is the preferred method of extracorporeal removal but hemoperfusion or CRRT are reasonable if hemodialysis is not feasible. Exchange transfusion is an adequate alternative to hemodialysis in neonates. Multiple-dose activated charcoal should be continued during extracorporeal treatment. Although CRRT is less effective than intermittent hemodialysis, it is more widely available and easier to perform, particularly in children (Table 63–2).

## SUMMARY

- Caffeine is one of the most commonly consumed xenobiotics worldwide, and as a result of novel products such as pure caffeine in powder or tablet form, energy drinks and caffeinated alcoholic beverages, poisoning from these products is a continuing problem.
- There are significant differences in the clinical presentation and management of patients with acute and chronic methylxanthine poisoning. Supportive care and treatment of GI, cardiovascular, CNS, metabolic, and musculoskeletal effects are the mainstay of therapy. The unique properties of methylxanthines necessitate specific therapies for the GI, cardiovascular, and CNS toxicities of methylxanthines.
- Methylxanthines result in much more severe poisoning than selective β<sub>2</sub>-adrenergic agonists. Cardiotoxicity with dysrhythmias and neurotoxicity with severe seizures and status epilepticus are the most significant results of methylxanthine poisoning.
- Clenbuterol is unique among β<sub>2</sub>-adrenergic agonists. It has a long half-life and results in cardiotoxicity as well as metabolic toxicity with metabolic acidosis with elevated lactate concentration. Treatment includes supportive care and use of β-adrenergic antagonists.
- Methods of enhanced elimination, particularly extracorporeal elimination by hemodialysis, and gut dialysis with MDAC, are effective treatments for patients with methylxanthine toxicity.

## F. Anesthetics and Related Medications

# LOCAL ANESTHETICS

Matthew D. Sztajnkrycer

### HISTORY AND EPIDEMIOLOGY

Local anesthetics block excitation of and transmission along a nerve axon in a predictable and reversible manner. In contrast to the nonselective effects of a general anesthetic, the anesthesia produced is selective to the chosen body part. Because local anesthetics do not require the circulation as an intermediate carrier and usually are not transported to distant organs, their actions are largely confined to the structures with which they come into direct contact. Local anesthetics are used to provide analgesia in various parts of the body by topical application, injection in the vicinity of peripheral nerve endings and major nerve trunks, or via instillation within the ophthalmic, epidural or subarachnoid spaces. The various local anesthetics differ with regard to their potency, duration of action, and degree of effects on sensory and motor nerve fibers. Toxicity is either local or systemic. With systemic toxicity, central nervous system (CNS) and cardiovascular effects are of greatest concern.

Until the 1880s, the only available analgesics were centrally acting depressants such as alcohol and opioids, which blunted the perception of pain rather than addressing the underlying cause. In 1860, the chemist Albert Niemann extracted the active alkaloid *cocaine* (Chap. 75) from the leaves of the coca shrub (*Erythroxylon coca*). Over the next 2 decades, the local anesthetic properties of the drug were identified. In 1884, Koller performed glaucoma surgery with only topical cocaine anesthesia.<sup>54</sup>

Although the clinical benefits of cocaine anesthesia were significant, so were its toxic and addictive potential. At least 13 deaths were reported in the first 7 years after the introduction of cocaine in Europe, and within 10 years after the introduction of cocaine as a regional anesthetic, reviews of “cocaine poisoning” appeared in the literature.<sup>89,111</sup> The toxicity of cocaine, coupled with the tremendous advantages it provided for surgery, led to a search for less toxic substitutes.

After the elucidation of the chemical structure of cocaine (the benzoic acid methyl ester of the alkaloid ecgonine) in 1895, other amino esters were examined. Synthetic compounds with local anesthetic activity were introduced but were highly toxic or irritating or had an impractically brief clinical effect. In 1904, Einhorn synthesized procaine, but its short duration of action limited its clinical utility. Research turned to focus on synthesis of local anesthetics with more prolonged durations of action.

The potent, long-acting local anesthetics dibucaine and tetracaine were synthesized in 1925 and 1928, respectively, and were introduced into clinical practice shortly thereafter. These anesthetics were not safe for regional anesthetic techniques because of potential systemic toxicity secondary to the combination of high potency, delayed metabolism, and the larger volumes of drug required for regional anesthesia compared with local anesthesia. On the other hand, these anesthetics were very useful for spinal anesthesia, which required much smaller volumes.

Lofgren synthesized lidocaine in 1943 from a series of aniline derivatives. This amino amide combined high tissue penetrance and a moderate duration of action with acceptably low systemic toxicity. Additionally, unlike amino ester anesthetics, the metabolites of lidocaine did not include *para*-aminobenzoic acid (PABA), responsible for allergic reactions. Subsequent to the release of lidocaine in 1944, several other amino amide compounds were introduced into clinical practice including mepivacaine (1956), prilocaine (1959), bupivacaine (1963), etidocaine (1971), and ropivacaine (1996).

Considering the frequency of local anesthetic use, both within and outside health care facilities, clinically significant toxic reactions are relatively

uncommon. In reports of fatalities resulting from toxic exposures reported to US poison control centers, local anesthetics are rarely implicated, representing fewer than 0.5% of cases (Chap. 130). Iatrogenic poisonings result from inadvertent injection of a therapeutic dose into a blood vessel, repeated use of a therapeutic dose, or unintentional administration of a toxic dose. The amide local anesthetics have largely replaced the esters in clinical use because of their increased stability and relative absence of hypersensitivity reactions (see Pharmacology later). Poisoning from topical benzocaine is relatively common because of the large number of nonprescription products available for treatment of teething and hemorrhoids. With nonprescription use, toxic effects after exposure are typically mild, and death rarely occurs. Toxicity usually occurs as a therapeutic misadventure, the potential for child abuse or neglect should be evaluated if the patient is younger than 2 years, and potential suicide should be evaluated in older children and adults.

Benzocaine spray is the most important cause of severe acquired methemoglobinemia in the hospital setting (Chap. 124).<sup>33</sup> Between November 1997 and March 2002, the US Food and Drug Administration (FDA) received 198 reported adverse events secondary to benzocaine products. A total of 132 cases (66.7%) involved definite or probable methemoglobinemia; most were serious adverse events, and 2 deaths occurred.<sup>98</sup> In these cases, a single spray of unspecified duration of 20% benzocaine was the dose most commonly reported. In 2003 and again in 2006, the FDA issued advisories regarding the use of benzocaine spray for topical mucosal anesthesia before intubation, upper endoscopy, and transesophageal echocardiography. In 2006, the US Veterans Health Administration halted the use of benzocaine spray for topical anesthesia. At this point in time, any continued use of topical benzocaine spray should be undertaken with extreme caution after careful assessment of risks, benefits, and alternatives, with antidotal therapy readily available.

### PHARMACOLOGY

Local anesthetics fall into one of two chemically distinct groups: amino esters and amino amides (Fig. 64–1). The basic structure of all local anesthetics consists of three major components: a lipophilic, aromatic ring connected by an ester or amide linkage to a short alkyl intermediate chain that in turn is bound to a hydrophilic tertiary (or less commonly, secondary) amine. The amine group acts as a base, accepting protons and becoming charged at a higher pH. The proportion of charged molecules is dependent upon the pKa of the specific local anesthetic.

All local anesthetics function primarily by reversibly binding to specific receptor proteins within the membrane-bound sodium channels of conducting tissues. These receptors are reached only via the cytoplasmic (intracellular) side of the cell membrane. Blockade of ion conductance through the sodium channel eventually leads to failure to initiate and propagate action potentials (Fig. 64–2). The analgesic effect results from inhibiting axonal transmission of the nerve impulse in small-diameter myelinated A $\delta$  (“fast pain”) and unmyelinated C (“slow pain”) nerve fibers carrying pain and temperature sensation. Conduction block of these fibers occurs at lower local anesthetic concentrations than required for the larger fibers responsible for touch, motor function, and proprioception.<sup>30</sup> This likely occurs in myelinated nerves because smaller fibers have closer spacing of the nodes of Ranvier. Given that a fixed number of nodes must be blocked for conduction failure to occur, the shorter critical length of nerve is reached sooner by

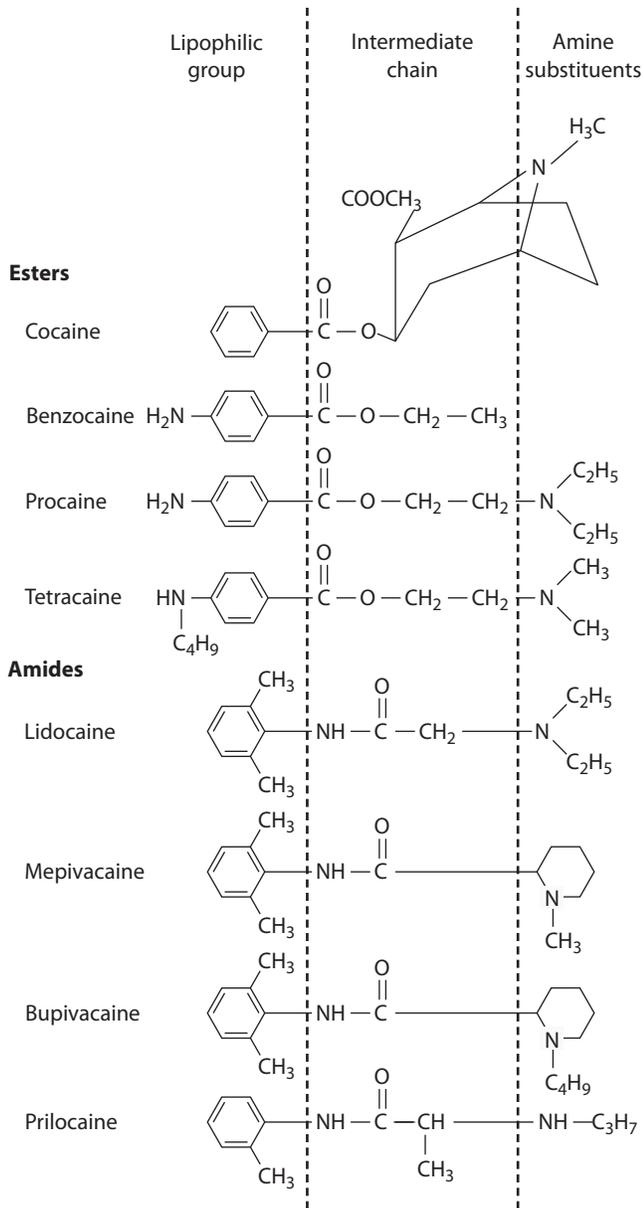

FIGURE 64-1. Representative local anesthetics.

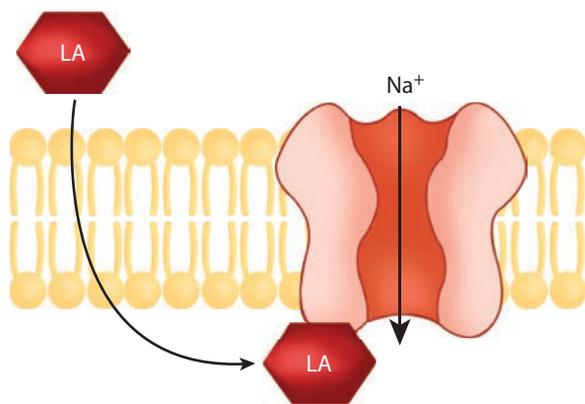

FIGURE 64-2. The multi-unit sodium channel is embedded in the nerve cell membrane. Local anesthetics (LAs) enter the nerve cell at the exposed membranes of the nodes of Ranvier and bind to the cytoplasmic side of the sodium channel (also located at the node of Ranvier) and alter sodium conductance.

the locally placed anesthetic in small fibers.<sup>46</sup> For unmyelinated fibers, the smaller diameter limits the distance that such fibers can passively propagate the electrical impulse. Differential nerve blockade is also related to voltage- and time-dependent affinity of local anesthetics to the sodium channels.

The sodium channel exists in three classes (Chap. 15 and Fig. 15-2). At resting membrane potential or in the hyperpolarized membrane, the channel is closed to sodium conductance. With an appropriate activating stimulus, the channel opens, allowing rapid sodium influx and membrane depolarization. Milliseconds later, the channel is inactivated, terminating the fast sodium current. Local anesthetic blockade is much stronger for channels that are activated (open) or inactivated than for channels that are resting. Analogous to the use-dependent kinetics of class I antidysrhythmics, pain fibers have a higher firing rate and longer action potential (ie, more time with the sodium channel open or inactivated) than other fiber types and therefore are more susceptible to local anesthetic action.<sup>62</sup>

These effects also occur in conductive tissues in the heart and brain that rely on sodium current. Although sodium channel blockade initially was believed to be the sole cause of systemic toxicity, mechanisms are more complex, especially in the heart, and occur at systemic concentrations lower than previously thought.<sup>91</sup> Recent proteomics analyses suggest that phosphatidylinositol-3-kinase (PI3K) plays a central role in pathways associated with bupivacaine-associated neurotoxicity.<sup>145</sup>

Growing evidence indicates that local anesthetics directly affect many other organ systems and functions such as the coagulation, immune, and respiratory systems, all at concentrations much lower than those required to achieve sodium channel blockade.<sup>20,61,62</sup> For example, lidocaine inhibited muscarinic signaling in *Xenopus* oocytes at less than 50% of the concentration required for sodium channel blockade.<sup>62</sup> Study of these less well-described effects may help elucidate both therapeutic and toxic phenomena that are incompletely explained.

The primary determinant of the onset of action of a local anesthetic is its  $\text{pK}_a$ , which affects its lipophilicity (Table 64-1). All local anesthetics are weak bases, with a  $\text{pK}_a$  between 7.8 and 9.3. At physiologic pH (7.4), xenobiotics with a lower  $\text{pK}_a$  have more uncharged molecules capable of crossing nerve cell membranes, producing a faster onset of action than xenobiotics with a higher  $\text{pK}_a$ . The onset of action also is influenced by the total dose of local anesthetic administered, which effects the concentration responsible for diffusion.

Local anesthetic potency is highly correlated with the lipid solubility of the xenobiotic. Therefore, the aromatic side of the anesthetic is the primary determinant of potency. The hydrophilic amine is important in occupying the sodium channel, which involves an ionic interaction with the charged form of the tertiary amine. The length of the intermediate chain is another determinant of local anesthetic activity, with three to seven carbon equivalents providing maximal activity.<sup>30</sup> Shorter or longer intermediate chain lengths are associated with rapid loss of local anesthetic action, suggesting that a critical length of physical separation between the aromatic group and the tertiary amine is required for sodium channel blockade to occur.

The degree of protein binding influences the duration of action of a local anesthetic. Anesthetics with greater protein binding remain associated with the neural membrane for a longer time interval and therefore have longer durations of action.<sup>30</sup> When high serum concentrations are achieved, a higher degree of protein binding increases the risk for cardiac toxicity.

### PHARMACOKINETICS

A distinction must be made between local disposition (distribution and elimination) and systemic disposition of the anesthetic. Local distribution is influenced by several factors, including spread of local anesthetic by bulk flow, diffusion, transport via adjacent blood vessels, and binding to proximate tissues. Local elimination occurs through systemic absorption, transfer into the general circulation, and local hydrolysis of amino ester anesthetics. Systemic absorption decreases the amount of local anesthetic that is available for anesthetic effect, thereby limiting the duration of the block. Systemic absorption depends on the avidity of binding of local anesthetics to tissues

TABLE 64-1 Pharmacologic Properties of Local Anesthetics<sup>48,100</sup>

	$pK_a$	Protein Binding (%)	Log D <sup>a</sup>	Relative Potency	Duration of Action	Approximate Maximum Allowable Subcutaneous Dose (mg/kg)

Ropivacaine	8.2	95	1.92	Intermediate	Long	2-3

<sup>a</sup>Log D is the octanol/water partition coefficient at a pH of 7. <sup>b</sup>Log D for etidocaine is at a pH of 7.4.

near the site of injection and on local perfusion. Both these factors vary with the site of injection. In general, areas with greater blood flow will have more rapid and complete systemic uptake of local anesthetic; for example, intravenous (IV) > tracheal > intercostal > paracervical > epidural > brachial plexus > sciatic > subcutaneous.

Because of their lipophilicity, local anesthetics readily cross cell membranes, the blood-brain barrier, and the placenta. After being absorbed, systemic tissue distribution is highly dependent on tissue perfusion. After local anesthetics enter the venous circulation, they pass through the lungs, where significant uptake occurs, thereby lowering peak arterial concentrations. Thus, the lungs serve as a buffer against systemic toxicity, but the capacity of the lungs to accumulate drug is saturable.<sup>80</sup> Part of the reason why most local anesthetic-induced seizures result from unintentional intravascular bolus injection rather than absorptive uptake is that lung uptake of these drugs exceeds 90%. The very high peak venous concentrations produced by rapid injection usually are necessary to produce toxic arterial concentrations.

All local anesthetics, except cocaine, cause peripheral vasodilation by direct relaxation of vascular smooth muscle. Vasodilation enhances vascular absorption of the local anesthetic. Addition of epinephrine (5 mcg/mL or 1:200,000) to the local anesthetic solution decreases the rate of vascular absorption, thereby improving the depth and prolonging the duration of local action, and mitigating risk of systemic toxicity. Local anesthetic mixed with epinephrine also decreases bleeding into the surgical field and serves as a marker for inadvertent intravascular injection (by producing tachycardia) when a test dose of the mixture is injected through a needle or catheter.<sup>95</sup> Significant drawbacks to epinephrine use include uncomfortable side effects such as palpitations and tremors, local tissue ischemia, and life-threatening systemic adverse reactions in susceptible patients (eg, myocardial ischemia and hypertensive crises). Inadvertent intravascular injection of local anesthetics mixed with epinephrine can be fatal, although generally the epinephrine in these mixtures is very dilute.<sup>86</sup>

The two classes of local anesthetics undergo metabolism by different routes (Chap. 75). The amino esters are rapidly metabolized by plasma cholinesterase to the major metabolite, PABA. The amino amides are metabolized more slowly in the liver to a variety of metabolites that do not include PABA.<sup>29</sup> Patients with enzymatic mutations or low or absent concentrations of plasma cholinesterase (pseudocholinesterase) are at increased risk for systemic toxicity from amino ester local anesthetics. Factors that decrease hepatic blood flow or impair hepatic function increase the risk for toxic reactions to the amino amides and make management of serious reactions more difficult. Patient age, as it relates to liver enzyme activity and plasma protein binding, influences the rate of metabolism of local

anesthetics. Whereas lidocaine's terminal half-life after IV administration averaged 80 minutes in volunteers aged 22 to 26 years, the half-life was 138 minutes in those aged 61 to 71 years (Chap. 32).<sup>103</sup> Newborns with immature hepatic enzyme systems have prolonged elimination of amino amides, which is associated with seizures when high continuous infusion rates are used.<sup>1,92</sup> Lidocaine elimination is reduced by congestive heart failure or coadministration of xenobiotics that reduce hepatic blood flow, thus explaining the increased risk of toxicity with cimetidine and propranolol.<sup>117</sup> Propranolol and cimetidine also potentially decrease lidocaine clearance by inhibiting hepatic CYP450 enzymes, including CYP1A2 and CYP3A4 involved in lidocaine *N*-deethylation and 3-hydroxylation in humans.<sup>137</sup>

Local anesthetics are often mixed to take advantage of desirable pharmacokinetics. In theory, rapid-acting, relatively short-duration local anesthetics such as chloroprocaine and lidocaine can be combined with the longer latency, long-acting tetracaine or bupivacaine to enable an immediate and prolonged anesthetic response. In practice, the advantages of the mixtures are small, and toxicities are additive.<sup>6</sup> Administration of one local anesthetic increases the free plasma fraction of another by displacement from protein-binding sites.<sup>67</sup>

Local anesthetics usually cannot penetrate intact skin in sufficient quantities to produce reliable anesthesia.<sup>14</sup> Efficient skin penetration requires the combination of a high water content and a high concentration of the water-insoluble base form of the local anesthetic. This combination of properties is achieved by mixing lidocaine and prilocaine in their base forms in a 1:1 ratio (eutectic mixture of local anesthetics {EMLA}).<sup>18</sup> Application for at least 45 minutes is required to achieve adequate dermal analgesia. Local anesthetic uptake continues for several hours during application. A liposomal formulation of 4% lidocaine (ELA-Max) facilitates skin absorption.<sup>49</sup> It is as effective as lidocaine-prilocaine base for topical anesthesia.<sup>40,71</sup> In addition, a 4% tetracaine gel preparation is used in children for topical skin anesthesia with an onset of action and efficacy at least as good as lidocaine-prilocaine base without any systemic side effects.

The low molecular weight of local anesthetics is associated with rapid absorption and subsequent elimination and therefore relatively short duration of action. Recently, a liposomal bupivacaine formulation was introduced as a long acting postsurgical anesthetic.<sup>22,85</sup> After local infiltration, the product has a terminal half-life 9.8-fold greater than that of plain bupivacaine. Significantly elevated plasma bupivacaine concentrations were observed for 96 hours after local infiltration of the liposomal formulation but do not correlate with local efficacy.<sup>3,64</sup> Current manufacturer recommendations warn against use of all local anesthetics within 96 hours of liposomal bupivacaine administration because local infiltration has the potential to precipitate an

immediate release of local anesthetic from the liposomal formulation, with subsequent systemic toxicity.

## CLINICAL MANIFESTATIONS OF TOXICITY

Although the most common adverse reactions to local anesthetics are vasopressor syncopal events associated with injection, the following sections focus on their local and systemic toxicity.<sup>134</sup>

### Toxic Reactions

#### Regional Side Effects and Tissue Toxicity

At a sufficient concentration, all local anesthetics are directly cytotoxic to nerve cells. However, in clinically relevant doses, they rarely produce localized nerve damage.<sup>73,102</sup> Significant direct neurotoxicity results from intrathecal injection or infusion of local anesthetics for spinal anesthesia. In this setting, lidocaine has an increased risk for both persistent lumbosacral neuropathy and a syndrome of painful but self-limited postanesthesia buttock and leg pain or dysesthesia referred to as *transient neurologic symptoms*.<sup>66</sup> Nerve damage often is attributed to the use of excessively concentrated solutions or inappropriate formulations. Several reports of cauda equina syndrome are associated with use of hyperbaric 5% lidocaine solutions for spinal anesthesia. Hyperbaric solutions are denser than cerebrospinal fluid. This neurotoxicity appears to be a phenomenon that occurs when the anesthetic is injected through narrow-bore needles or through continuous spinal catheters. This process results in very high local concentrations of the anesthetic that might pool around the sacral roots because of inadequate mixing.<sup>118</sup> The mechanism of this neurotoxicity is unknown but is believed to be independent of sodium channel blockade.<sup>66</sup> Because an equally effective block can be achieved with injection of larger volumes of lower concentration, 5% lidocaine is generally avoided and bupivacaine used instead. There is a significant (up to 10-fold) increase in the development of new neurologic dysfunction after receiving a neuraxial block in patients with preexisting peripheral neuropathy, a fact emphasizing the importance of informed consent and risk communication.<sup>57</sup>

Similar severe neurotoxic reactions occur after massive subarachnoid injection of chloroprocaine during attempted epidural anesthesia.<sup>115</sup> The neurotoxicity initially was attributed to use of the antioxidant sodium bisulfite and the low pH of the commercial solution rather than use of the anesthetic itself.<sup>136</sup> Despite reformulation without bisulfite, subsequent animal data suggest that chloroprocaine itself is responsible for the neurotoxicity.<sup>131</sup> Skeletal muscle changes are observed after intramuscular injection of local anesthetics, especially the more potent, longer acting local anesthetics. The effect is reversible, and muscle regeneration is complete within 2 weeks after injection of local anesthetics.<sup>10</sup>

Although rare, after peripheral nerve or plexus block, transient or prolonged postoperative neuropathy is well recognized. Likely mechanisms include direct injury of the nerve related to intraneuronal injection and local anesthetic neurotoxicity. The frequency of peripheral neuropathies reported after peripheral nerve blockade varies from 0% to more than 5%.<sup>15</sup> Direct visualization of peripheral nerves via ultrasonography reduces this complication, avoiding traumatic injury and allowing for injection of less local anesthetic to produce adequate nerve block.<sup>80,126</sup> In one study, intraneural injection occurred in 17% of supraclavicular or interscalene blocks, but ultrasonographic identification prevented further injection.<sup>8</sup> Analysis of 12,668 ultrasound-guided nerve blocks for peripheral regional anesthesia found that the incidences of postoperative neurologic symptoms lasting longer than 5 days and 6 months were 0.18% and 0.008%, respectively.<sup>126</sup> Visualization of the target site via ultrasound guidance also decreases local anesthetic systemic toxicity, likely because of reduced incidence of inadvertent vascular puncture.<sup>8</sup>

#### Systemic Side Effects and Toxicity

##### Allergic Reactions

Allergic reactions to local anesthetics are extremely rare. Fewer than 1% of all adverse drug reactions caused by local anesthetics are immunoglobulin (Ig) E mediated.<sup>49</sup> In one study designed to determine the prevalence of true local

anesthetic allergy in patients referred to an allergy clinic for suspected hypersensitivity, skin prick and intradermal testing results were negative for all 236 participants tested.<sup>11</sup> As noted, the amino esters are responsible for the majority of true allergic reactions. When hydrolyzed, the amino ester local anesthetics produce PABA, a known allergen (Chap. 46). Cross-sensitivity to other amino ester anesthetics is common. Some multidose commercial preparations of amino amides contain the preservative methylparabens (Chap. 46), chemically related to PABA, and most likely the cause of the much rarer allergic reactions attributed to amino amides. Preservative-free amino amides, including lidocaine, are appropriate for use in patients who have reactions to drug preparations containing methylparabens unless the patient is specifically sensitive to lidocaine. If the patient with a history of allergic reaction to a particular anesthetic requires a local anesthetic, a paraben preservative-free drug from the opposite class can be chosen because there is no cross-reactivity between the amides and esters.

##### Methemoglobinemia

Methemoglobinemia is a frequent adverse effect of topical and oropharyngeal benzocaine and is occasionally reported with lidocaine, tetracaine, or prilocaine use. Most reports of methemoglobinemia associated with local anesthetics are the result of an excessive dose or a break in the normal mucosal barrier for topical anesthetics (Chap. 124).

Benzocaine is initially metabolized to aniline and then further metabolized to phenylhydroxylamine and nitrobenzene, which are both potent oxidizing agents (Chap. 124). Although reports describe methemoglobinemia resulting from standard doses of benzocaine topical oropharyngeal spray given for laryngoscopy or gastrointestinal upper endoscopy, affected patients commonly have abnormal mucosal integrity as occurs with thrush or mucositis.<sup>38,98</sup> Prilocaine is an amino ester local anesthetic primarily used in obstetric anesthesia because of its rapid onset of action and low systemic toxicity in both the mother and fetus. Use of large doses of prilocaine lead to the development of methemoglobinemia.<sup>59,82</sup> An aniline derivative, prilocaine undergoes hepatic metabolism to produce *ortho*-toluidine, another oxidizing agent.<sup>59</sup> A direct relationship exists between the amount of epidural prilocaine administered and the incidence of methemoglobinemia. A dose greater than approximately 8 mg/kg is generally necessary to produce effects and symptoms, which are often not apparent until several hours after epidural administration of the drug. Lidocaine–prilocaine cream, often used in the outpatient setting for minor dermal procedures, is associated with significant methemoglobinemia, more commonly in children than in adults.<sup>53</sup> Standard doses of lidocaine–prilocaine cream used for circumcision in term neonates are associated with minimal production of methemoglobin, but risks may be increased in neonates with metabolic disorders.<sup>129</sup> The diagnosis of methemoglobinemia is suggested by cyanosis unresponsive to oxygen in individuals with normal cardiopulmonary examinations and known oxidant exposure and presence of chocolate brown blood. It is confirmed by direct measurement of methemoglobin with a cooximeter. When clinically indicated, we recommend treating affected patients with symptomatic methemoglobinemia with IV methylene blue (Chap. 124 and Antidotes in Depth: A43).

##### Local Anesthetic Systemic Toxicity

Systemic toxicity for all local anesthetics correlates with serum concentrations. Factors that determine the concentration include dose; rate of administration; site of injection (absorption occurs more rapidly and completely from vascular areas, such as with neck and intercostal blocks); the presence or absence of a vasoconstrictor; and the degree of tissue–protein binding, fat solubility, and  $pK_a$  of the local anesthetic.<sup>97</sup> The brain and heart are the primary target organs for systemic toxicity because of their rich perfusion, moderate tissue–blood partition coefficients, lack of diffusion limitations, and presence of cells that rely on voltage-gated sodium channels to produce an action potential.

Recommendations for maximal local anesthetic doses designed to minimize the risk for systemic toxic reactions were developed but remain controversial.<sup>127</sup> These maximal recommended doses aim to prevent

TABLE 64-2 Toxic Intravenous (IV) Doses of Local Anesthetics

Local Anesthetic	Minimum IV Toxic Dose of Local Anesthetic in Humans (mg/kg)
Bupivacaine	1.6
Chloroprocaine	22.8
Etidocaine	3.4
Lidocaine	6.4
Mepivacaine	9.8
Procaine	19.2
Tetracaine	2.5

infiltration of excessive drug. However, because most episodes of systemic toxicity from local anesthetics, with the exception of methemoglobinemia from topical drug, occur secondary to unintentional intravascular injection rather than from overdosage, limiting the maximal dose will not prevent most toxic systemic reactions.<sup>123</sup>

Toxicity is also related to the metabolism of a given local anesthetic. The rapidity of elimination from the plasma influences the total dose delivered to the CNS or heart. The amino esters are rapidly hydrolyzed in the plasma and eliminated, explaining their relatively low potential for systemic toxicity. The amino amides have a much greater potential for producing systemic toxicity because termination of the therapeutic effect of these drugs is achieved through redistribution and slower metabolic inactivation.<sup>45</sup> Another factor that creates difficulty in specifying the minimal toxic plasma concentration of lidocaine results from the fact that its *N*-dealkylated metabolites are pharmacologically active and monoethylglycylxylide has a prolonged half life (Chap. 57 and Fig. 57-3). Although these factors make it difficult to establish safe doses of local anesthetics, Table 64-2 summarizes the estimates of minimal toxic IV doses of various local anesthetics.

### Central Nervous System Toxicity

Systemic toxicity in humans usually presents initially with CNS abnormalities. Intravenous infusion studies in volunteers demonstrate an inverse relationship between anesthetic potency and dose required to induce signs of CNS toxicity.<sup>125</sup> A similar relationship exists between the convulsive concentration and the relative anesthetic potency. In humans, seizures are reported at serum concentrations of approximately 2 to 4 mcg/mL for bupivacaine and etidocaine. Concentrations in excess of 10 mcg/mL are usually required for production of seizures when less potent drugs such as lidocaine are administered. Despite the strong relationship between local anesthetic potency and CNS toxicity, several other factors influence the CNS effects, including the rate of injection, drug interactions, and acid-base status.<sup>32</sup>

The rapidity with which a particular serum concentration is achieved influences anesthetic toxicity. Volunteers tolerated an average dose of 236 mg of etidocaine and a serum concentration of 3 mcg/mL before onset of CNS effects and symptoms when the anesthetic was infused at a rate of 10 mg/min. However, when the infusion rate was increased to 20 mg/min, the same individuals only tolerated an average of 161 mg which produced a serum concentration of approximately 2 mcg/mL.<sup>124</sup>

Both metabolic and respiratory acidoses increase local anesthetic induced CNS toxicity. Acidemia decreases plasma protein binding, increasing the amount of free drug available for CNS diffusion despite promoting the charged form of the amine group. The convulsive threshold of various local anesthetics is inversely related to arterial PCO<sub>2</sub>.<sup>34,41,42</sup> Hypercarbia lowers the seizure threshold by several mechanisms: (1) increased cerebral blood flow, which increases drug delivery to the CNS; (2) increased conversion of the drug base to the active cation in the presence of decreased intracellular pH; and (3) decreased plasma protein binding, which increases the amount of free drug available for diffusion into the brain.<sup>19,34,41,42</sup> In general, CNS depressants

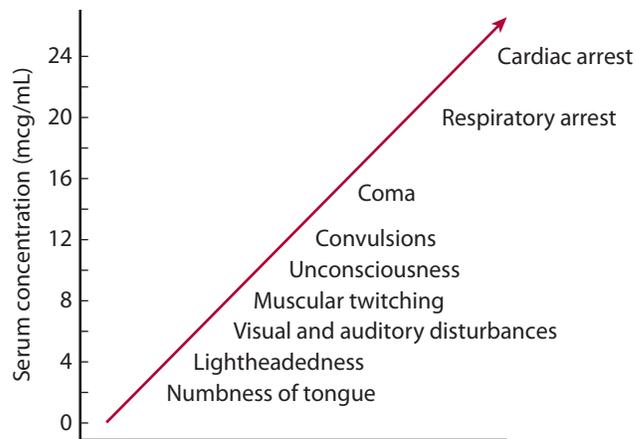

FIGURE 64-3. Relationship of signs and symptoms of toxicity to serum lidocaine concentrations.

minimize the signs and symptoms of CNS excitation and increase the threshold for local anesthetic-induced seizures. Flumazenil increases the sensitivity of the CNS to the amino amide anesthetics.<sup>17</sup>

A gradually increasing serum lidocaine concentration usually produces a stereotypical pattern of signs and symptoms (Fig. 64-3). In an awake patient, the initial effects include tinnitus, lightheadedness, circumoral numbness, disorientation, confusion, auditory and visual disturbances, and lethargy. Subjective side effects occur at serum concentrations between 3 and 6 mcg/mL. Significant psychological effects of local anesthetics are also reported. Near-death experiences and delusions of actual death are described as specific symptoms of local anesthetic toxicity.<sup>87</sup> Thus, the appearance of psychological symptoms during administration of local anesthetics should not be disregarded as unrelated nervous reactions or effects of sedatives given as premedication but rather as a possible early sign of CNS toxicity.

Clinical signs, usually excitatory, then develop, and include shivering, tremors, and ultimately generalized tonic-clonic seizures.<sup>106</sup> Objective CNS toxicity usually is evident at lidocaine concentrations between 5 and 9 mcg/mL. Seizures typically occur at concentrations above 10 mcg/mL, with higher concentrations producing coma, apnea, and cardiovascular collapse. The excitatory phase has a wide range of intensity and duration, depending on the chemical properties of the local anesthetic. With the highly lipophilic, highly protein-bound local anesthetics, the excitement phase is brief and mild. Toxicity from large IV boluses of bupivacaine often present without CNS excitement, with bradycardia, cyanosis, and coma as the first signs.<sup>120</sup> Rapid intravascular injection of lidocaine produces a brief excitatory phase followed by generalized CNS depression with respiratory arrest. Seizures are reported after even small doses injected into the vertebral or carotid artery (as rarely occurs during stellate ganglion block).<sup>72</sup> A relative overdose produces a slower onset of effects (usually within 5–15 minutes of drug injection), with irritability progressing to seizures.

The mechanism of the initial CNS excitation involves selective sodium channel blockade of cerebral cortical inhibitory pathways in the amygdala.<sup>130,135</sup> The resulting increase in unopposed excitatory activity leads to seizures. As the concentration increases further, both inhibitory and excitatory neurons are blocked, and generalized CNS depression ensues. Levobupivacaine causes increased neuronal excitation and neurotoxicity by inhibition of KCNQ2/3 channels, an effect reversed by the channel activator retigabine.<sup>25</sup>

### Cardiovascular Toxicity

Cardiovascular side effects are the most feared manifestations of local anesthetic toxicity. Shock and cardiovascular collapse are related to effects on vascular tone, inotropy, and dysrhythmias related to indirect CNS and direct cardiac and vascular effects of the local anesthetic. Animal studies and clinical observations clearly demonstrate that for most local anesthetics, CNS toxicity develops at significantly lower serum concentrations than those

needed to produce cardiac toxicity. With the exception of bupivacaine, local anesthetics have a high cardiovascular:CNS toxicity ratio.<sup>72,100,101,120</sup>

Some of the discrepancy between the incidence of CNS and cardiac toxicity result from a detection bias. Not only can the treating physicians fail to recognize cardiac effects because of preoccupation with CNS manifestations of toxicity, but early cardiac toxicity is often quite subtle. An experimental study attempting to identify early warning signs of bupivacaine-induced cardiac toxicity in pigs evaluated bupivacaine induced changes in cardiac output, heart rate, blood pressure, and electrocardiogram (ECG).<sup>108</sup> A 40% reduction in cardiac output was not associated with significant change in heart rate or blood pressure, the latter secondary to a direct vasoconstrictive effect of bupivacaine at the concentrations produced.<sup>23</sup> If cardiac toxicity develops, management is exceedingly difficult.

Changes in systemic vascular tone induced by local anesthetics are mediated by direct effect on vascular smooth muscle or indirectly via effects on spinal cord sympathetic outflow. Predictably, sympathetic blockade after spinal anesthesia or epidural anesthesia above the T5 dermatome results in peripheral venodilation and arterial dilation. Shock results when high doses of anesthetic are used in hypovolemic patients. Local anesthetics have a biphasic effect on peripheral vascular smooth muscle. Whereas lower doses produce direct vasoconstriction, higher doses are associated with severe cardiovascular toxicity and cause vasodilation, contributing to cardiovascular collapse.

All local anesthetics directly produce a dose dependent decrease in cardiac contractility, with the effects roughly proportional to their peripheral anesthetic effect. Although the classic anesthetic action of sodium channel blockade in heart muscle accounts in large part for the negative inotropy by affecting excitation-contraction coupling, it does not explain the entire difference in myocardial depression produced by different anesthetics.<sup>36</sup> Poorly understood effects on calcium handling or effects of the intracellular drug directly on contractile proteins or mitochondrial function underlie these effects.<sup>36,43</sup> Bupivacaine impairs regulation of glucose homeostasis through inhibition of protein kinase B (Akt) and activation of 5'-adenosine monophosphate activated protein kinase (AMPK) activities: interacts with peripheral  $\delta$ - and  $\kappa$ -opioid receptors; and inhibits myosin phosphatase target subunit I (MYPTI), protein kinase C (PKC), and phosphorylation-dependent inhibitory protein of myosin phosphatase (CPI-17).<sup>27,109</sup>

Blockade of the fast sodium channels of cardiac myocytes decreases maximum upstroke velocity ( $V_{max}$ ) of the action potential (Chaps. 15 and 16 and Fig. 15-2). This effect slows impulse conduction in the sinoatrial and atrioventricular (AV) nodes, the His-Purkinje system, and atrial and ventricular muscle.<sup>28</sup> These changes are reflected on ECG by increases in PR interval and QRS complex duration. At progressively higher anesthetic concentrations, hypotension, sinus arrest with junctional rhythm, and eventually cardiac arrest occur.<sup>5</sup> Asystole is described in patients who received unintentional IV bolus injections of 800 to 1,000 mg of lidocaine.<sup>5,44</sup> Cardiovascular toxicity of local anesthetics usually occurs after a sudden increase in serum concentration, as in unintentional intravascular injection. Cardiovascular toxicity is rare in other circumstances because high serum concentrations are necessary to produce this effect and because CNS toxicity precedes cardiovascular events, providing a warning. Cardiac toxicity usually is not observed with lidocaine use in humans until the serum lidocaine concentration greatly exceeds 10 mcg/mL unless the patient is also receiving xenobiotics that depress sinus and AV nodal conduction such as calcium channel blockers,  $\beta$ -adrenergic antagonists, or cardioactive steroids. Intravascular lidocaine injection used to diminish pain associated with IV propofol injection was associated with episodes of bradycardia (heart rate <30 beats/min) and sinus arrest in a 69-year-old man later diagnosed with sick sinus syndrome.<sup>69</sup>

Animal studies compared the dose or serum concentrations of local anesthetics required to produce irreversible circulatory collapse with those necessary to produce seizures.<sup>33,100,101</sup> The cardiovascular collapse:CNS toxicity (CC:CNS) ratio for lidocaine is approximately 7; therefore, CNS toxicity should become evident well before potentially cardiotoxic concentrations are reached. In contrast, bupivacaine is significantly more cardiotoxic than most other local anesthetics commonly used, with a CC:CNS ratio of 3:7.

Inadvertent intravascular injection produces near simultaneous signs of CNS and cardiovascular toxicity. Bupivacaine produces myocardial depression out of proportion to its anesthetic potency and, more importantly, causes refractory ventricular dysrhythmias.<sup>122</sup> The enhanced cardiovascular toxicity of bupivacaine relates to enhanced CNS effects at cardiovascular centers, direct effects on myocyte metabolism, and important differences related to sodium channel blockade.<sup>132</sup> Although lidocaine and bupivacaine both block sodium channels in the open or inactivated states, lidocaine quickly dissociates from the channel at diastolic potentials, allowing rapid recovery from block during diastole (known as fast on-fast off kinetics). Therefore, sodium channel blockade with lidocaine is much more pronounced at rapid heart rates (accounting for the antidysrhythmic effects for ventricular tachycardia).<sup>86</sup> In contrast, at high concentrations, bupivacaine rapidly binds to and slowly dissociates from sodium channels (fast on-slow off kinetics), with significant block accumulating at all physiologic heart rates.<sup>28</sup> Accordingly, at heart rates of 60 to 150 beats/min, approximately 70 times more lidocaine is needed than bupivacaine to produce an equal effect on  $V_{max}$  of the action potential. Enhanced conduction block in Purkinje fibers and ventricular muscle cells sets up a reentrant circuit responsible for the ventricular tachydysrhythmias induced by bupivacaine.<sup>93</sup>

Bupivacaine is problematic both in terms of having the highest potential for cardiovascular toxicity and for the refractoriness of its toxicity to conventional therapy. Bupivacaine has an asymmetrically substituted carbon, and the kinetics of sodium channel binding are stereospecific.<sup>75</sup> The S (levo)-enantiomer levobupivacaine is significantly less cardiotoxic than the R (dextro)-enantiomer despite having similar anesthetic properties.<sup>7,91</sup> Consequently, bupivacaine, the racemic mixture of both enantiomers, is more cardiotoxic than levobupivacaine, which contains only the levo-enantiomer.<sup>52</sup> The stereospecific effect on sodium channels seems to differ between the heart and the peripheral nerves because the local anesthetic potency of levobupivacaine is the same as, or perhaps even greater than, that of bupivacaine.<sup>39,104</sup> Ropivacaine is a pure enantiomer and is less cardiotoxic than bupivacaine, but it is also slightly less potent as an anesthetic.<sup>112,113</sup>

Effects other than sodium channel blockade contribute to cardiotoxicity. Lipophilic local anesthetics such as bupivacaine directly impair mitochondrial energy transduction via two mechanisms: (1) uncoupling of oxygen consumption and adenosine triphosphate (ATP) synthesis and (2) inhibition of complex I in the respiratory chain.<sup>122</sup> These effects are related to the lipophilic properties of the drug rather than to stereospecific effects on ion channels. Lidocaine has no effect on mitochondrial respiration, and ropivacaine has less effect than bupivacaine.<sup>142</sup> There is no difference between the two bupivacaine enantiomers. These effects occur with higher concentrations of the local anesthetic, as occur after unintentional intravascular injection.

Low-dose bupivacaine-induced cardiotoxic effects are described in humans under certain circumstances and at concentrations that are not associated with seizures in pigs.<sup>68,140</sup> Severe cardiac toxicity is described after injection of a small subcutaneous dose of bupivacaine in a patient with secondary carnitine deficiency.<sup>140</sup> Myocytes are highly dependent on oxidation of free fatty acids for energy. Interference with this mechanism via bupivacaine-induced inhibition of carnitine-acylcarnitine translocase contributes to the cardiotoxicity of lipophilic local anesthetics (Chap. 48, Fig. 48-3, and Antidotes in Depth: A10).<sup>141</sup> Bupivacaine produce dysrhythmias by blocking GABAergic neurons that tonically inhibit the autonomic nervous system.<sup>59</sup> In addition to its other effects on the heart, bupivacaine induces a marked decrease in cardiac contractility by altering  $Ca^{2+}$  release from sarcoplasmic reticulum.<sup>84</sup>

In a large series of patients receiving bupivacaine, systemic toxicity occurred in only 15 of 11,080 nerve blocks.<sup>96</sup> Of these patients, 80% manifested seizures; the other 20% had milder symptoms. Bupivacaine use, particularly at 0.75% concentration, is associated with severe cardiovascular depression, ventricular dysrhythmias, and even death.<sup>116</sup> Pregnant women were disproportionately affected. Some of these patients required prolonged resuscitation, and restoration of adequate spontaneous circulation proved exceedingly difficult.<sup>116</sup> In 1983, 49 incidents of cardiac arrest or ventricular tachycardia occurring over a 10-year period were presented to the

**TABLE 64-3** Types of Local Anesthetic Reactions

Cause	Major Clinical Features
Local anesthetic toxicity (intravascular injection)	Immediate seizure or dysrhythmias
Reaction to adjuvant catecholamine	Tachycardia, hypertension, headache
Vasodepressor syncope	Bradycardia, hypotension, pallor rapid onset and recovery, loss of consciousness
Allergic reaction	Anaphylaxis
High spinal or epidural block	Bradycardia, hypotension, respiratory distress, respiratory arrest

FDA Anesthetic and Life Support Advisory Committee. Among these cases, 0.75% bupivacaine was used in 27 obstetric patients with 10 deaths, and 0.5% bupivacaine was used in 8 obstetric patients with 6 deaths. Among the 14 nonobstetric patients, 5 died. The overall mortality rate was 43% (21 of 49). Partly as a result of these reports, in 1984, the FDA withdrew approval of bupivacaine 0.75% for use as obstetric anesthesia.<sup>116</sup>

Acid-base and electrolyte status influence the cardiac toxicity of a given drug because all depressant properties are potentiated by acidosis, hypoxia, or hypercarbia.<sup>16</sup> Table 64-3 outlines the spectrum of acute local anesthetic reactions.

## DIAGNOSTIC TESTING

In cases of possible local anesthetic toxicity, the patient should be attached to continuous cardiac monitoring, and an ECG should be obtained to detect dysrhythmias and conduction disturbances. Serum electrolytes, blood urea nitrogen, creatinine, and blood gas analysis should be obtained to help assess the cause of cardiac dysrhythmias. Cooximetry should be obtained in patients in whom methemoglobinemia is suspected clinically. Rapid, sensitive assays are available for measuring concentrations of lidocaine and its monoethylglycinexylidide (MEGX) metabolite. When properly interpreted, the results of these assays are used to prevent lidocaine toxicity and to identify lidocaine toxicity in the nontherapeutic setting (Chap. 57, Fig. 57-3). Assays for determining serum concentrations of other local anesthetics are not routinely available. Treatment should never be delayed while waiting for results of xenobiotic concentration determinations.

## TREATMENT

If toxicity results from ingestion of liquid medications, it is reasonable to give oral activated charcoal within 1 to 2 hours of ingestion, provided airway protective reflexes are intact. Contaminated mucous membranes should be washed off. Neither hemodialysis nor hemoperfusion has proven utility.

### Treatment of Local Anesthetic Central Nervous System Toxicity

At the first sign of possible CNS toxicity, administration of the drug must be discontinued. One hundred percent oxygen should be supplied immediately, and ventilation should be supported if necessary. Patients with minor symptoms usually do not require treatment, provided adequate respiratory and cardiovascular functions are maintained. The patient must be followed closely so that progression to more severe effects can be detected.

Although most seizures caused by local anesthetics are self-limited, they should be treated quickly because the hypoxia and acidemia produced by prolonged seizures increase both CNS and cardiovascular toxicity.<sup>99,101</sup> Intubation is not mandatory, and the decision to intubate must be individualized. Maintaining adequate ventilation is of proven value. Modest hyperventilation extracorporeal life support (ECLS) is reasonable to produce respiratory alkalemia. By decreasing CNS extraction of drug, lowering extracellular potassium, and hyperpolarizing the neuronal cell membrane, normalizing (lowering) PCO<sub>2</sub> decreases the affinity for, or accelerates separation of, the local anesthetic from the sodium channel. Ultra-short-acting

barbiturates and benzodiazepines are recommended for treatment of local anesthetic-induced seizures, but either of these medication groups can also exacerbate circulatory and respiratory depression.<sup>32,94</sup> Propofol 1 mg/kg IV was as effective as thiopental 2 mg/kg IV in stopping bupivacaine induced seizures in rats and was used successfully in a patient with uncontrolled muscle twitching secondary to local anesthetic toxicity.<sup>13,55</sup> However, propofol causes significant bradycardia and even asystole, especially when used with other xenobiotics that cause bradycardia. Based on currently available data, benzodiazepines are recommended as the first-line treatment for local anesthetic CNS toxicity. Neuromuscular blockers are proposed as adjunctive treatment for local anesthetic-induced seizures. They block muscular activity, decreasing oxygen demand and lactic acid production. However, neuromuscular blockers should never be used to treat seizures per se because they have no anticonvulsant effect and can make clinical diagnosis of ongoing seizures problematic by abolishing muscle contractions. To avoid this potentially lethal complication, chemical paralysis should be used only to facilitate endotracheal intubation if needed, unless continuous electroencephalography is also used. If used, short-acting neuromuscular blockers are desirable, facilitating subsequent repeated neurologic assessments. Succinylcholine is not routinely recommended because of significant side effects, including hyperkalemia and dysrhythmias. Given less potential for adverse cardiac effects, nondepolarizing neuromuscular blockers such as rocuronium are preferentially recommended (Chap. 66).

When severe systemic toxicity occurs, the cardiovascular system must be monitored closely because cardiovascular depression often goes unnoticed while seizures are being treated. Because local anesthetic-induced myocardial depression occurs even with preserved blood pressure, it is important to be aware of early signs of cardiac toxicity, including ECG changes.

### Treatment of Local Anesthetic Cardiovascular Toxicity

Treatment of cardiovascular toxicity is complicated by the complex effects of local anesthetics on the heart. Initial therapy should focus on correcting the physiologic derangements that potentiate the cardiac toxicity of local anesthetics, including hypoxemia, acidemia, and hyperkalemia.<sup>16,119</sup> Prompt support of ventilation and circulation limits hypoxia and acidemia. Early recognition of potential cardiac toxicity is critical to achieving a good outcome because patients with cardiac toxicity that goes unrecognized for any interval are more difficult to resuscitate.<sup>9</sup> If a potentially massive intravascular local anesthetic injection is suspected, maximizing oxygenation of the patient before cardiovascular collapse occurs is critical.

Standard Advanced Cardiac Life Support (ACLS) protocols should be followed when dealing with most local anesthetic cardiac toxicity. Bupivacaine-induced dysrhythmias often are refractory to cardioversion, defibrillation, and pharmacologic treatment. Lidocaine, phenytoin, magnesium, bretylium, amiodarone, calcium channel blockers, and combined therapy with clonidine and dobutamine were all used in animal models with variable results.<sup>37,88,90</sup> Lidocaine competes with bupivacaine for cardiac sodium channels and at high doses may displace it. Anecdotal reports suggest that lidocaine has occasionally helped in this application.<sup>31</sup> However, concern exists about additive CNS effects when lidocaine is used to treat bupivacaine cardiac toxicity, and its use in this manner cannot be routinely recommended.

With toxicity from the longer acting, highly lipid-soluble, protein-bound amide local anesthetics (bupivacaine and etidocaine), if the patient does not respond promptly to therapy, cardiopulmonary resuscitation is expected to be difficult and prolonged (1–2 hours) before depression of the cardiac conduction system spontaneously reverses as a result of redistribution and metabolism of the drugs.<sup>2,114</sup> Vital organ perfusion is seriously compromised during CPR despite optimal chest compression. The significance of this problem increases with the duration of resuscitation; therefore, rapid initiation of is recommended when practical. Cardiopulmonary bypass resulted in successful outcomes in some cases of lidocaine and bupivacaine overdose.<sup>47,81</sup> Cardiopulmonary bypass provides circulatory support that is far superior to that provided by closed-chest cardiac massage. The improved perfusion prevents tissue hypoxia and the development of metabolic acidosis, which in

turn decreases the binding of local anesthetics to myocardial sodium channel receptors. Hepatic blood flow is better maintained, enhancing local anesthetic metabolism, and increased myocardial blood flow helps redistribute local anesthetics out of the myocardium.<sup>81</sup> Increasingly, ECLS using venoarterial extracorporeal membrane oxygenation (VA-ECMO) is being used in the management of critically ill overdose patients in both the emergency department and intensive care unit environments.<sup>35</sup>

Atropine supplemented with electrical pacing is reasonable to treat bradycardia. Cardiac pacing was used successfully for treatment of cardiac arrest after unintentional administration of a 2-g bolus of lidocaine into a cardiopulmonary bypass circuit as the patient was being removed from bypass.<sup>107</sup> Pharmacologic therapy was unsuccessful, and resumption of bypass was necessary. Forty-five minutes after the injection, AV pacing restored perfusion and permitted discontinuation of bypass.

Use of sodium bicarbonate early in resuscitation to prevent acidemia-mediated potentiation of cardiac toxicity is reasonable.<sup>31</sup> Although a canine model of bupivacaine-induced cardiotoxicity demonstrated utility of high dose insulin compared with saline or dextrose, its use cannot be routinely recommended at this time (Antidotes in Depth: A21).<sup>26</sup>

### Intravenous Lipid Emulsion

While investigating the relationship between lipid metabolism and bupivacaine toxicity, a rat study of bupivacaine induced asystolic arrest showed that pretreatment with IV lipid emulsion (ILE) increased the toxic dose of bupivacaine by 50%.<sup>143</sup> In addition, a dose of bupivacaine that was uniformly fatal in control rats resulted in universal survival in animals that also received fat emulsion.<sup>143</sup> Subsequent studies of local anesthetic toxicity demonstrated accelerated return of cardiac function and systemic vascular resistance after ILE both in isolated hearts and in intact animals.<sup>21,58,139,140</sup>

Numerous case reports describe successful use of ILE (in various formulations) to treat patients (including pregnant and pediatric patients) in cardiac arrest after regional anesthesia with various local anesthetics, including bupivacaine, ropivacaine, and levobupivacaine (Antidotes in Depth: A23).<sup>12,60</sup>

The most recent guidelines by the American Society of Regional Anesthesia and Pain Medicine (ASRA) suggest dosing for a patient in cardiac arrest is a 1.5-mL/kg bolus of 20% ILE over 1 minute while continuing chest compressions followed by continuous infusion of 0.25 mL/kg/min.<sup>105</sup> For persistent cardiovascular collapse, it is reasonable to repeat the bolus once or twice and double the infusion rate. If there is evidence of recovery, it is reasonable to continue the infusion for at least 10 minutes after stability. After initiating standard ACLS protocols, including ensuring adequate oxygenation and ventilation, we recommend that ILE be given as soon as possible after signs of significant local anesthetic toxicity become manifest (Antidotes in Depth: A23).<sup>143</sup> Initiation of VA-ECMO in association with ILE use is associated with fat deposition in the VA-ECMO circuit and increased blood clot formation within the circuit.<sup>74</sup> However, given that ILE administration can be accomplished more readily than initiation of VA-ECMO, it is reasonable to administer ILE to the severely intubated patient even if the patient eventually is transitioned to VA-ECMO.

### Prevention of Systemic Toxicity of Local Anesthetics

Despite the development of new, relatively less toxic amino amide local anesthetics such as levobupivacaine and ropivacaine, severe CNS and cardiovascular effects remain a risk. Several cases of ropivacaine-induced cardiac arrest are reported.<sup>24,70</sup> In these cases, patients with both asystolic arrest and ventricular fibrillation-associated arrest were successfully resuscitated. Nonetheless, it is clear that prevention is more prudent and effective than treatment of toxicity. The keys to prevention are to use the lowest possible anesthetic concentration and volume consistent with effective anesthesia and to avoid a significant intravascular injection. The latter is accomplished by ensuring extravascular placement demonstrated repetitively by ultrasonographic guidance and by careful, slow aspiration of a needle or catheter before injection; injection of a small test dose of anesthetic mixed with

epinephrine to assess a cardiovascular response if injection is intravascular; and use of slow, fractional dosing of large-volume injections with vigilance for early signs of CNS and cardiac toxicity.

### SUMMARY

- Local anesthetics are frequently used xenobiotics that provide surgical analgesia and acute and chronic pain relief.
- The analgesic effect of local anesthetics is primarily caused by inhibition of neural conductance secondary to sodium channel blockade.
- Systemic toxicity, which primarily affects the heart and brain, is also largely related to sodium channel blockade.
- Severe systemic toxicity usually occurs secondary to inadvertent intravascular injection.
- If cardiovascular collapse and cardiac arrest occur, especially in the setting of bupivacaine toxicity, resuscitation is difficult and prolonged. In addition to standard ACLS protocols emphasizing maintenance of oxygenation and ventilation, ILE is recommended.
- Cardiopulmonary bypass is useful because it provides cardiovascular support, limits exacerbating factors such as tissue hypoxia and acidemia, and improves hepatic blood flow, thereby increasing local anesthetic metabolism, but it is difficult to initiate in a timely manner. Although increasingly available, extracorporeal life support will be limited by the use of ILE, which has been noted to clog the VA-ECMO circuit.

## LIPID EMULSION

Sophie Gosselin and Theodore C. Bania

**INTRODUCTION**

The use of intravenous lipid emulsion (ILE) as an antidote is best studied for the treatment of local anesthetic systemic toxicity. However, it is also used for the treatment of overdose from other lipophilic xenobiotics such as calcium channel blockers, cyclic antidepressants, insecticides, and  $\beta$ -adrenergic antagonists, among many others.

**HISTORY**

Lipid emulsion was used as one component of parenteral nutrition for more than 40 years and is also used as a diluent for intravenous (IV) drug delivery of highly lipophilic xenobiotics such as amphotericin and propofol. More recently, liposomal suspensions containing local anesthetics such as bupivacaine were formulated that slowly release xenobiotics to increase their duration of anesthetic effect.

Bupivacaine toxicity is uncommon and sometimes refractory to Advanced Cardiac Life Support measures (Chap. 64). In the setting of local anesthetic-induced cardiovascular collapse, fatalities occur. Previously, cardiopulmonary bypass was essentially the only effective treatment for these patients.<sup>4</sup> Intravenous lipid emulsion (ILE) was initially evaluated in animal models of bupivacaine toxicity with some reported efficacy. Because of the success in animal models and the limitations of other therapies, ILE was attempted in humans with local anaesthetic toxicity. Multiple reports are published that suggest benefit.<sup>34,41</sup> Intravenous lipid emulsion was subsequently recommended by several anesthesia and medical toxicology specialty societies for the treatment of local anesthetic toxicity, especially bupivacaine.<sup>56</sup> The most commonly proposed mechanism of action is the entrapment of local anesthetic in the serum lipid phase thus, likely decreasing the amount of xenobiotic at the site of toxicity.

In 2008, the first case of nonlocal anaesthetic toxicity treated with ILE was published. After this report, ILE was evaluated in animal models of toxicity from a multitude of lipid-soluble xenobiotics. Based on these studies, ILE was used in many cases of human and animal clinical poisoning.<sup>41</sup>

**PHARMACOLOGY****Chemistry and Preparation**

Lipid emulsion is composed of two types of lipids, triglycerides and phospholipids. Triglycerides are hydrophobic molecules that are formed when three fatty acids are linked to one glycerol. The fatty acid chain lengths vary, producing different triglycerides. The primary triglycerides in lipid emulsions are linoleic, linolenic, oleic, palmitic, and stearic acids; their concentrations vary slightly in the different commercially available formulations. These long-chain triglycerides (12 or more carbons) are extracted from safflower oil or soybean oil (or both), depending on the brand.<sup>25</sup> Newer lipid emulsions containing long-chain triglycerides in addition to medium-chain triglycerides (6–12 carbons) are derived from coconut, olive, and fish oils, and their availability and cost vary.<sup>51</sup>

Phospholipids contain two fatty acids bound to glycerol and a phosphoric acid moiety that is located at the third hydroxyl group. Phospholipids are amphipathic; the nonpolar fatty acids are hydrophobic, and the polar phosphate head is hydrophilic. This imparts important pharmacologic properties to this carrier molecule, allowing it to solubilize nonpolar xenobiotics in aqueous serum.

The lipids are dispersed in the serum by forming an emulsion of small lipid droplets, in which the phospholipids form a layer around a triglyceride core. The hydrophobic fatty acid component of the phospholipid molecule is directed toward the triglycerides while the hydrophilic glycerol component is directed outward away from the triglyceride core. The presence of small amounts of glycerol, which is hydrophilic, allows the lipid droplets to be suspended as an emulsion in water and serum.

The lipid emulsion per se is a white, milky liquid. It is sterile and nonpyrogenic with an average pH of 8 (range, 6–9). Lipid emulsions are isoosmotic solutions (260–310 mOsm/L) made for parenteral use and thus are easily delivered through a peripheral or central vein<sup>49</sup> and intraosseously.<sup>16</sup>

Lipid emulsions have different globule sizes depending on their uses.<sup>13</sup> Microemulsions containing droplet sizes less than 0.1  $\mu\text{m}$  are used for drug delivery. Miniemulsions containing droplet sizes greater than 0.1  $\mu\text{m}$  but less than 1.0  $\mu\text{m}$  are used for parenteral nutrition and are the ones used off label in clinical toxicology. Droplet sizes in commercially available nutritional lipid emulsions range from 0.4 to 0.5  $\mu\text{m}$ . Phospholipid emulsifiers such as egg phosphatide are added and prevent droplet coalescence. After IV administration, lipid emulsions are found in the serum as lipid droplets that resemble chylomicrons and turn the serum turbid or milky.<sup>10</sup> Macroemulsions containing droplet sizes greater than 1.0  $\mu\text{m}$  are used for chemoembolization. These macroemulsions contain chemotherapeutics that are delivered intraarterially directly into the tumor blood supply. The lipid droplets occlude the artery and slowly release the chemotherapeutic.

**Related Lipid Formulations**

Most case reports that support the treatment of local anesthetic toxicity with ILE use branded Intralipid or standard long-chain triglyceride mixtures. Other lipid emulsions, that contain mixtures of long-chain and medium-chain triglycerides, are also reportedly successful in clinical cases of poisoning.<sup>29,81</sup> However, formulations containing oleic acid are theoretically problematic at high doses because IV sodium oleate is used in animal models to induce acute respiratory distress syndrome (ARDS) and ingestion of sodium oleate was reported to produce severe respiratory distress.<sup>58,68</sup>

Controversy exists as to whether or not lipid emulsions containing both long- and medium-chain triglyceride mixtures are more effective at partitioning xenobiotics than are long-chain triglycerides.<sup>43</sup> In one rodent model of bupivacaine toxicity, although the rate of return to spontaneous circulation was identical in both groups, asystole recurred 15 to 45 minutes after ILE administration, and serum and cardiac bupivacaine concentrations were lower in the group treated with the long-chain mixtures.<sup>43</sup> In human serum, a mixture of long- and medium-chain triglycerides increased the extraction of bupivacaine, ropivacaine, and mepivacaine compared with long-chain triglyceride mixtures alone.<sup>66</sup> However, in a rodent model of bupivacaine toxicity, long- and medium-chain mixtures were equally effective in reversing bupivacaine toxicity, but the long-chain mixture resulted in fewer recurrences of asystole and lower myocardial bupivacaine concentrations.<sup>44</sup>

**Mechanism of Action**

The mechanisms of action of parenteral lipid emulsion in toxicology are not clearly understood. The three proposed mechanisms of action of ILE are modulation of intracellular metabolism; a lipid sink, sponge, or conduit mechanism; and activation of ion channels.

### Modulation of Intracellular Metabolism

In experimental models of poisoning from xenobiotics that alter intracellular energy metabolism, toxicity was successfully treated with ILE, suggesting that repairing or circumventing this dysfunction is involved. Bupivacaine blocks carnitine-dependent mitochondrial lipid transport and inhibits adenosine triphosphatase (ATPase) synthetase in the electron transport chain.<sup>9,85</sup> Verapamil inhibits intracellular processing of fatty acids,<sup>38,39</sup> but it also inhibits insulin release and produces insulin resistance.<sup>39</sup> This reduces the consumption of free fatty acid during shock, perhaps caused by the high oxygen demand required of fatty acid oxidation.<sup>26</sup> The cyclic antidepressant amitriptyline depresses human myocardial contraction independent of an effect on conduction<sup>29</sup> and inhibits medium- and short-chain fatty acid metabolism.<sup>81</sup> Propranolol changes intracellular energy from primarily fatty acid to carbohydrate-dependent metabolism.<sup>46</sup>

Theoretically, the addition of excess fatty acids overcomes blocked or inhibited enzymes by mass action, providing energy to an energy “starved” heart, reversing toxicity. Some support for this mechanism comes from the ability of ILE to reverse myocardial depression resulting from myocardial ischemia.<sup>76</sup> In a canine model using 10 minutes of regional myocardial ischemia, treatment with ILE after ischemia resulted in improved systolic wall contraction. In the same canine model, pretreatment with oxfenicine, which blocks carnitine palmitoyltransferase-1, blocked the beneficial effect of lipid emulsion.<sup>39</sup> This finding suggests that the effects of ILE on myocardial contraction after ischemia are mediated by mitochondrial metabolism. However, other authors reported increased myocardial free fatty acid (FFA) uptake and increased oxygen consumption in dogs given an infusion of ILE without any change in left ventricular pressure, heart rate, or cardiac output.<sup>53</sup> Moreover, in a human septic shock model studying the various substrates used by the myocardium, the contribution of FFAs as a myocardial energy source was markedly diminished (12% versus 54% in the control group), but that of lactate was increased (36% versus 12%). The observed shift in myocardial substrate extraction was associated with a discrepancy between measured myocardial oxygen consumption: 41% of myocardial oxygen consumption was not explained by the utilization of commonly available substrates extracted from coronary circulation.<sup>12</sup> This raises the question as to whether or not an exogenous source of FFAs such as provided by lipid emulsion, is actually useful in a xenobiotic induced shock state.

Unfortunately, there is limited experimental evidence to support a modulation of intracellular energy metabolism as the mechanism of action of the ILE. Some evidence comes from experimental studies in bupivacaine toxicity. In an isolated rat heart model of bupivacaine-induced cardiotoxicity, doses of lipid emulsion in the perfusate that were thought to be too low to significantly decrease bupivacaine concentrations reversed bupivacaine-induced cardiac dysfunction.<sup>73</sup> Similarly, in an in vivo model of bupivacaine-induced toxicity rodents pretreated with a single dose of a fatty acid oxidation inhibitor (CVT-4325) were unable to be rescued by ILE, suggesting that lipid emulsion works by providing energy in the form of FFAs.<sup>60</sup> Although these results suggest that lipid emulsion works by a mechanism other than binding bupivacaine and suggest a metabolic effect, other studies support the theory that lipid emulsion works by a nonmetabolic mechanism. In one study, verapamil toxicity was induced in rodents that were pretreated with the fatty acid oxidation inhibitor oxfenicine or control solution. Both groups were then resuscitated with ILE.<sup>2</sup> There were no significant differences in survival time and mean arterial pressure between the oxfenicine-treated and control groups. Analogous to some models of bupivacaine toxicity, this study suggests that in verapamil toxicity, ILE works by a mechanism other than mitochondrial energy supply.

### Lipid Sink, Sponge, or Conduit Mechanism

This mechanism theorizes that lipid emulsion “soaks up” lipid-soluble xenobiotic, removing it from the site of toxicity. In a variation of this proposed mechanism, ILE sequesters the xenobiotic out of the aqueous plasma, which bathes the tissue, and within a nonaqueous part of the plasma that is not in contact with the site of toxicity. Intravenous lipid emulsion is also

thought to alter the distribution of lipid-soluble xenobiotics and redistribute them away from the site of toxicity into an area with high lipid content (ie, create a “lipid conduit”). Some experimental support comes from studies of bupivacaine toxicity.

Stronger evidence for the lipid sink or sponge mechanism is seen in the effect of lipid emulsion on the pharmacokinetics and tissue distribution of bupivacaine in rats. Lipid emulsion decreased the distribution of bupivacaine into tissue, resulting in decreased concentrations in the brain and myocardium.<sup>69</sup> Similarly, in a pharmacokinetic study of clomipramine toxicity, after infusion of lipid emulsion into the peritoneal cavity, concentrations of clomipramine increased and volume of distribution decreased in addition to an increase in blood pressure.<sup>27</sup> In a pharmacokinetic study of amiodarone toxicity, ILE pretreatment resulted in higher concentrations of amiodarone and higher blood pressures compared with pretreatment with saline.<sup>57</sup> In a well-perfused swine model, ILE decreased amitriptyline concentrations in the brain by 25% and decreased the heart-to-plasma amitriptyline ratio.<sup>29</sup> In a successful resuscitation from bupropion overdose, bupropion concentrations increased dramatically after ILE administration.<sup>77</sup> Concentrations also increased after successful treatment of verapamil.<sup>18</sup> These findings in experimental models and case reports are used to support the lipid sink or sponge model, in which ILE removes a xenobiotic away from the compartment of toxicity, although the increased concentrations is also explained by an increased perfusion of tissues and release of the drug.

Additional indirect evidence supports the lipid sink or sponge and a nonmetabolic mechanism. Although the myocardium can utilize fatty acids for metabolism, the central nervous system (CNS) does not use fatty acids to a substantial degree, implying that the reversal of sedation results from xenobiotic removal from the CNS as opposed to an altered metabolism. This reversal of CNS effects was demonstrated in two animal models of thiopental sedation,<sup>8,67</sup> but in another animal model of thiopental anesthesia, ILE increased the CNS effects. These findings are also used to support the lipid sink or sponge mechanism because in this model, it was proposed that the lipid emulsion maintained a high serum thiopental concentration, permitting subsequent thiopental diffusion into the CNS.<sup>37</sup>

The degree of lipid solubility of a xenobiotic is measured using the partition coefficients log P or log D. Both measure the xenobiotic distribution between a lipophilic organic phase (usually octanol) and a polar aqueous phase (usually water) and report the logarithm of the ratio of concentration of the xenobiotic between the two phases. Whereas log P measures the partition of the nonionized form of the xenobiotic between the two phases, log D measures the partition of both the nonionized and the ionized form of the xenobiotic and varies based on pH. Whereas log P is reported across a range of often unspecified pH values, the log D at pH of 7 is considered by the editors of this text as an acceptable evaluation of lipid solubility in normal plasma. Conditions that vary the lipid solubility are likely clinically important because they will alter the amount of xenobiotic partitioning into the serum lipid. In an in vitro model, the distribution of bupivacaine and ropivacaine in lipid emulsion decreased at lower pH.<sup>48</sup>

### Activation of Ion Channels

Lipid emulsion was also hypothesized to activate either or both Ca<sup>2+</sup> and Na<sup>+</sup> channels. Linolenic and stearic acids decreased bupivacaine-induced Na<sup>+</sup> channel blockade in an experimental model of human embryonic kidney cell expression of human cardiac Na<sup>+</sup> channels bathed in lipid emulsion.<sup>54</sup> Fatty acids directly activated myocardial Ca<sup>2+</sup> channels and induced a dose-dependent increase in the Ca<sup>2+</sup> current, promoting dysrhythmias. Oleic, linoleic, and linolenic acids act directly on the Ca<sup>2+</sup> channel to increase Ca<sup>2+</sup> current.<sup>31</sup> None of these studies are representative of the administration of ILE in humans or animals, and the amount of ILE used in this setting cannot be converted to a meaningful dosing regimen.

### Mechanism of Action: Conclusion

Despite the lack of definitive studies on mechanisms of action, the lipid sink, conduit, and sponge model is the most compelling because beneficial effects from ILE are most frequently noted for lipid-soluble xenobiotics independent

of their mechanisms of toxicity.<sup>19</sup> Multiple consequential mechanisms of action may exist, and depending on the xenobiotic, the mechanisms of action likely vary and are multifactorial.

### Pharmacokinetics

Lipid droplets that are smaller than 1  $\mu\text{m}$  are primarily removed from circulation as they move through the capillaries of adipose and hepatic tissue. The capillary endothelium in these tissues contains lipoprotein lipase, which hydrolyzes triglycerides, releasing fatty acids and glycerol that then diffuses into the cells. Fatty acids enter the cardiac myocyte either by passive diffusion or protein-mediated transport.<sup>72</sup>

The half-life of intravenously administered lipid emulsion is 30 to 60 minutes and can vary substantially depending on the patient's clinical status, lipid emulsion dose, and droplet size.<sup>17</sup> More than 2.5 g of lipid/kg/d (12.5 mL/kg of 20% ILE or 875 mL in a 70-kg person) overwhelms lipoprotein lipase activity, resulting in decreased clearance.<sup>59</sup> Mean droplet sizes vary across lipid emulsion formulations and the number of fat globules per milliliter of lipid emulsion solution are affected by the time to expiration date, storage temperature, and possibly plastic bag versus glass containers.<sup>13</sup> Larger droplet sizes have lower clearances and are removed by reticulo-endothelial phagocytosis. Solutions containing larger than recommended droplets are considered unstable and increase the risk of triglyceride accumulation in various target organs. These larger droplets are more likely to induce an inflammatory response, obstruct the microvasculature, and produce capillary fat emboli. The liver is the organ most commonly involved in accumulation of larger lipid emulsion droplets.<sup>13</sup>

### Pharmacodynamics

When inside the cells, fatty acids are used as energy or resynthesized into triglycerides and stored. For use as energy, triglycerides are transported into the mitochondria by carnitine palmitoyltransferase, where they undergo  $\beta$  oxidation sequentially releasing acetylcoenzyme A (acetyl-CoA) as the fatty acid chain is reduced in length. These acetyl-CoA molecules enter the citric acid cycle, where they ultimately generate adenosine triphosphate (ATP) (Figs. 11–3 and 11–9). Although glucose, lactate, and fatty acid metabolism all are used in the production of acetyl-CoA, fatty acid metabolism produces the largest amount of energy. For example, whereas 1 mole of glucose produces 36 moles of ATP, 1 mole of stearic acid produces 146 moles of ATPs;<sup>86</sup> the metabolism of longer fatty acid chains may produce even more ATP.

### ROLE IN LOCAL ANESTHETIC TOXICITY

The swine model appropriateness to evaluate lipid resuscitation therapy was questioned. Certain species of swine develop complement activation-related pseudoallergy (CARPA), an acute hypersensitivity reaction to liposomes. Complement activation-related pseudoallergy is characterized by mottling, hypoxia, and cardiovascular instability, which might compromise ILE resuscitation. This was thought to explain the incongruous effect of ILE in these swine models and hypotension when ILE is administered in some swine models.<sup>29,83</sup> However, subsequent adequately powered studies reported no difference in the hemodynamic parameters of swine treated with ILE and a veterinary literature review on the use of ILE in pets does not mention this rare pseudoallergy as a contraindication.<sup>11,24</sup>

Based on the experimental evidence in bupivacaine toxicity, ILE was reportedly successfully used in several reported human cases of cardiovascular collapse from local anesthetic overdose. The first human case occurred after the inadvertent IV administration of bupivacaine and mepivacaine during an interscalene block.<sup>64</sup> The patient developed cardiac arrest and was treated with cardiopulmonary resuscitation (CPR) and Advanced Cardiac Life Support (ACLS) for 20 minutes but only had return of spontaneous circulation after administration of the first dose of ILE (100 mL of 20% ILE followed by 0.5 mL/kg/min for 2 hours). Of note, cardiac catheterization revealed total occlusion of the right coronary artery, and the patient was discharged with an implantable cardiac defibrillator.

In addition to its use during resuscitation, ILE was used to treat milder clinical scenarios of local anesthetic toxicity such as altered consciousness and cardiac dysrhythmias without loss of pulse. A recent review of 76 human case reports documented using ILE for resuscitation for local anesthetic toxicity, and the majority report some improvement, especially with bupivacaine toxicity.<sup>34</sup> The nature of the clinical findings as well as the dose and the duration of ILE administration reported were heterogeneous. The absence of a control group and publication bias inherent to case reporting remains significant confounders in interpretation.<sup>34</sup> A randomized trial with healthy volunteers and subtoxic doses of local anesthetics given to reach the threshold of early neurotoxicity gave 120 mL of ILE 20% and could not find a difference between its groups.<sup>15</sup> Another study used 1.5 mL/kg of 20% ILE in pretreatment for a dose of 1 mL/kg of lidocaine and found no difference in the lipid phase entrapment of lidocaine or in patient electroencephalographic patterns.<sup>30</sup>

For local anesthetic poisoning, earlier recommendations limited use of ILE to situations after the failure of standard resuscitative measures. As a result of the experimental evidence and many successful case reports, some authors recommend adding ILE at the first signs of local anesthetic toxicity, but others suggest using it only in the setting of cardiovascular collapse. In the latter setting, ILE should be used concomitantly with CPR and ACLS, and high doses of epinephrine should be avoided.<sup>84</sup>

We recommend administering ILE when there is rapid progression of bupivacaine toxicity affecting the CNS (agitation, confusion, seizures) or cardiovascular system (hypertension, tachycardia, ventricular dysrhythmias, hypotension, conduction blocks). In the setting of cardiovascular collapse, ILE is recommended with CPR and standard ACLS. Lipid emulsion should be stored for easy and rapid access in operating rooms or in areas where local anesthetics are frequently used.

### ROLE IN NON-LOCAL ANESTHETIC TOXICITY

After the experience with bupivacaine toxicity, ILE was evaluated for toxicity of calcium channel blockers, cyclic antidepressant,  $\beta$ -adrenergic antagonists, organic phosphorus compounds, amiodarone, cocaine, and many other xenobiotics, with conflicting results.<sup>41</sup>

Based on some positive experimental evidence, ILE use was expanded to non-local anesthetic toxicity. Intravenous lipid emulsion was successfully used to resuscitate a 17-year-old patient with prolonged cardiovascular collapse after bupropion and lamotrigine overdose. In this case, the patient experienced seizures and received ACLS and CPR for 70 minutes, with return of spontaneous circulation after ILE administration (a bolus of 100 mL of 20%). Asystole recurred 90 minutes after ILE administration and resolved with epinephrine.<sup>70</sup>

To date, the latest and most exhaustive systematic review<sup>41</sup> found more than 159 case reports, 137 of which are in humans, three low-quality randomized control trials,<sup>20,36,42,74</sup> and one observational study of ILE for resuscitation in non-local anesthetic toxicity.<sup>20</sup>

The first randomized trial explored the efficacy of 10 mL/kg of 10% ILE on 30 patients with various sedative-hypnotic poisonings. The trial unfortunately suffers from serious methodological flaws in the authors' selection bias, lack of blinding, and outcome measurement in which the statistically significant outcome represents a change of 1 point on the pre- and postintubation Glasgow Coma Scale.<sup>74</sup> The other two studies on tricyclic antidepressant overdoses did not show a difference in mortality rate.<sup>36</sup> An isoflurane study gave 2 mL/kg of 30% ILE to patients receiving anesthesia for various procedures. It reported a benefit of 4 and 5 minutes in time to eye opening and time to exit of the operating room, respectively, between the groups but no difference on time to extubation.<sup>42</sup> Other case studies report improvement with varied amounts of ILE for poisonings with diverse amounts of amlodipine, diltiazem, verapamil, atenolol, nebivolol, propranolol, carvedilol, flecainide, haloperidol, amitriptyline, dosulepin, doxepin, imipramine, quetiapine, venlafaxine, carbamazepine, lamotrigine, phenobarbital, diphenhydramine, bupropion, hydroxychloroquine, cocaine, and bromadiolone.

Subsequently, the largest case series of ILE was published reporting an overall survival rate of 69% in 25 of 36 patients poisoned with various non-local anesthetics such as calcium channel blockers and  $\beta$ -adrenergic antagonists (10 of 36), cyclic antidepressant (5 of 36), or bupropion (3 of 36).<sup>52</sup> This study failed to demonstrate a meaningful increase in mean arterial pressure (MAP) a priori defined as a sustained increase of 10 mm Hg for 1 hour even in the survivor-only group. Wide variability in the dosing regimen, total lipid emulsion amount, and additional treatment received was noted. Despite successful reports, data on the efficacy of ILE are severely limited by reporting biases, therapeutic effects resulting from additional coadministered therapies, and coingestant xenobiotic toxicity. A study on fatality cases of the US National Poison Database system from 2006 to 2016 reported more than 450 cases of unsuccessful use of ILE for various overdoses, attesting to the fact that this therapy requires controlled studies to determine its effectiveness and adverse effect profile when used for poisonings.<sup>71a</sup>

The Lipid Emulsion Workgroup, composed of representative of all major toxicology associations, published evidence-based recommendations in which ILE was recommended for cardiac arrest from bupivacaine toxicity and after failure of other modalities in amitriptyline, bupropion, and toxicity from other local anesthetics. The workgroup could not find evidence to recommend ILE in other situations because of a lack of data or balance between risks and possible benefits.<sup>21</sup> Based on the current data available from animal models and clinical case reports, the Lipid Emulsion Workgroup published recommendations that ILE is a reasonable consideration in cardiac arrest from bupivacaine toxicity and serious hemodynamic instability from a bupropion, amitriptyline, and other local anaesthetics after conventional treatments failed.<sup>21</sup> However, given the lack of data, which yield overall neutral opinions from the Lipid Emulsion workgroup, the authors of this textbook provide the following recommendation pending new available evidence. Lipid emulsion can be administered for patients with hemodynamic instability refractory to standard resuscitation measures when the risk-to-benefit ratio of interaction with other pharmacological or specific antidotal therapies or extracorporeal life support (ECLS) measures such as extracorporeal membrane oxygenation (ECMO) is carefully evaluated. Thus it is reasonable that lipid emulsion be used in the setting of severe toxicity (prolonged cardiovascular instability with nonperfusion or poor perfusion caused by hypotension, or dysrhythmias or seizures) resulting from a lipid soluble xenobiotic(s) despite maximal treatment with standard resuscitation measures even if the current available evidence for the efficacy of this therapy is of very low grade. Standard antidotal therapy and resuscitative measures are shown to be superior or equivalent to lipid emulsion and should not be abandoned in a rush to administer ILE.

## ADVERSE EFFECTS AND SAFETY ISSUES

The adverse effects attributed to ILE administration are infrequently reported in the poisoning literature.<sup>7</sup> A systematic review evaluated all possible adverse effects with ILE given for parenteral nutrition or poisoning up to 14 days. Potential complications of ILE include acute kidney injury, cardiac arrest, ventilation perfusion mismatch, ARDS, venous thromboembolism, hypersensitivity, fat embolism, fat overload syndrome, pancreatitis, extracorporeal circulation machine circuit obstruction, allergic reaction, and increased susceptibility to infection.<sup>28</sup>

Because of the limited number of case reports, complications or toxicity from ILE at dosages exceeding the daily recommended amount for parenteral nutrition remains a concern. Pulmonary toxicity is reported when ILE is used as a source of parenteral nutrition. In patients with ARDS, 500 mL of 20% ILE administered over 8 hours resulted in increased pulmonary artery pressures, pulmonary shunting, increased pulmonary vascular resistance, and decreased partial pressures of oxygen in the alveoli/fraction of inspired oxygen ratio ( $PAO_2/FIO_2$ ).<sup>79</sup> Similar results were found in patients with ARDS administered 500 mL of 10% ILE over 4 hours, resulting in an increase in pulmonary shunting and a decrease in the fraction of  $PAO_2/FIO_2$ .<sup>35</sup> The pulmonary effect of ILE in ARDS may be related to infusion rate. In patients with ARDS, 500 mL of 20% ILE infused over 5 hours resulted in an increase

in pulmonary pressures, but a slower infusion over 10 hours left pulmonary pressures unchanged.<sup>47</sup>

In these studies, when pulmonary effects occurred, they were mild and resolved after the ILE infusion was stopped or within 3 to 4 hours. Larger doses may result in clinically significant toxicity and more prolonged effects. However, studies using lipid emulsions with medium-chain triglycerides have shown less pulmonary toxicity.<sup>17,71</sup>

Intravenous lipid emulsion causes pulmonary toxicity by at least two mechanisms. Intravenous lipid emulsion may occlude the pulmonary vasculature with microfat emboli. Macrophages containing lipid droplets are demonstrated in the bronchioalveolar lavage fluid of ARDS patients treated with ILE.<sup>40</sup> Experimental evidence also suggests that a substantial amount of the high concentrations of linoleic acid in ILE is converted to arachidonic acid and then into vasoactive prostaglandins. Indomethacin, an inhibitor of prostaglandin synthesis, prevented any pulmonary vascular effect caused by ILE in one sheep model.<sup>50</sup>

Elevated triglycerides and pancreatitis are reported when ILE is used for parenteral nutrition. The precise mechanism of ILE-induced pancreatitis is unknown but may be the result from the large concentration of triglycerides forming large lipid droplets that obstruct the small vessels of the pancreas, leading to ischemia. Lipase then degrades the triglycerides, releasing cytotoxic FFAs. Laboratory assays differ in how they measure triglycerides.

Hyperamylasemia and pancreatitis were reported in two cases of ILE use in treatment of xenobiotic toxicity. After successful resuscitation with ILE from bupivacaine-induced cardiac arrest, an elevated amylase concentration without associated elevated lipase or associated symptoms was reported.<sup>77</sup> Elevated lipase concentrations were reported after administering ILE to a 13-year-old girl who developed delayed seizures and cardiac arrest after amitriptyline ingestion. Lipase concentrations peaked at 1,849 IU/L 5 days after ILE and were associated with elevated triglycerides and abdominal pain.<sup>40</sup>

Large doses or rapid infusions of ILE have the potential to induce a fat overload syndrome. Fat overload syndrome is characterized by hyperlipemia, fever, fat infiltration, hepatomegaly, jaundice, splenomegaly, anemia, leukopenia, thrombocytopenia, coagulation disturbances, seizures, and coma. Multiple end-organ dysfunction is attributed to inadequate clearance of lipids and sludging in the lungs, brain, kidney, retina, and liver. Because of the rapid redistribution of most local anesthetics, prolonged ILE infusion should not be required (Chap. 64). However, many other lipid-soluble xenobiotics have a long duration of toxicity, and prolonged and repeated ILE infusions, if given, increase the risk of fat overload syndrome.

Particularly when administered early in the clinical course of an oral overdose, ILE has the potential to increase gastrointestinal absorption or facilitate distribution of lipid-soluble xenobiotics, resulting in increased toxicity. In an orogastric model of amitriptyline and verapamil overdose, ILE increased amitriptyline concentrations and resultant toxicity.<sup>62,63</sup> Gastric decontamination should be performed under these circumstances.

Intravenous lipid emulsions also have the potential to interact with other essential antidotes and especially epinephrine and vasopressin.<sup>5,31,33</sup> If an antidote is lipid soluble, it may be incorporated by the ILE and result in decreased effectiveness. Intravenous lipid emulsion was also used with several other medications during resuscitation for toxicity, including atropine, amiodarone, sodium bicarbonate, magnesium sulfate, calcium chloride, naloxone, and metaraminol.<sup>6,37,65,80</sup>

The addition of ILE to high dose insulin (HDI) therapy was evaluated in a model of severe verapamil toxicity, and there were no improvements in hemodynamics, metabolic parameters, or survival.<sup>3</sup> Also, ILE did not improve hypotension in a swine model of amitriptyline-induced toxicity<sup>78</sup> Therefore, although other resuscitative xenobiotics should be used as indicated, there is no evidence yet to support or refute the simultaneous use of ILE and bicarbonate or HDI therapy.

Hyperlipidemia after using ILE interferes with many laboratory studies, making them uninterpretable.<sup>23</sup> This interference lasts for several hours and is dependent in part on the type of laboratory system used. Intravenous lipid

emulsion variably alters analytical test results and results in erroneous measurement, no significant effect, or the inability to perform a laboratory test. In vitro testing of ILE demonstrated that colorimetric methods were more prone to the effects of ILE than potentiometric methods. In the setting of ILE, glucose measurement by colorimetric method did not accurately report hypoglycemia. For example, a glucose concentration of 48.6 mg/dL (2.7 mmol/L) may be falsely reported as 223.2 mg/dL (12.4 mmol/L). Centrifugation at 140,000 g for 10 minutes minimized most interference. Troponin-I, sodium, potassium, chloride, calcium, bicarbonate, or urea assays had the least interference. Albumin and magnesium assays demonstrated significant interference. Amylase, lipase, phosphate, creatinine, total protein, alanine aminotransferase, creatine kinase, and bilirubin became unmeasurable.<sup>22</sup> The effect of ILE on toxic drug concentrations assays is largely unknown. Ideally, analytic testing should be performed before ILE administration.<sup>23</sup>

## DOSING AND ADMINISTRATION

Although the optimal dosing regimen for human poisonings remains undefined, several animal models evaluate the effects of high-dose ILE. In both rodent and canine models of verapamil toxicity, 12.4- and 7-mL/kg boluses of 20% ILE were given,<sup>3,75</sup> and in a rabbit model of clomipramine, 12 mL/kg of 20% ILE was used.<sup>49</sup> In a small rodent model, the median lethal dose of ILE 20% was reported at 67 mL/kg,<sup>32</sup> which is much higher than the current recommended clinical doses, but an LD<sub>50</sub> cannot be used to guide safety. In a model of IV verapamil toxicity in which ILE was administered 5 minutes after the start of the verapamil infusion, higher doses up to a maximum of 18.6 mL/kg of 20% ILE were more effective in improving blood pressure, acidemia, and mean time survival than lower doses. Higher doses than 18.6 mL/kg improved hemodynamic parameters transiently but resulted in overall decreased survival times than the 18.6-mL/kg dose but twice the time than the 12.4-mL/kg dose.<sup>61</sup> These animal models used large doses of xenobiotic and were designed to produce a rapid onset of toxicity; it is difficult to extrapolate their findings to typical human overdose cases. One controlled human study used as much as 10 mL/kg of 10% ILE with questionable clinical results and did not report on adverse effects.<sup>74</sup>

Dosing was initially arbitrarily defined for local anesthetic toxicity, specifically bupivacaine, with generalization of this dosing regimen to poisoning by other local anesthetics and other xenobiotics. The American Society of Regional Anesthesia and Pain Management, the Association of Anesthetists of Great Britain and Ireland, and the American Heart Association<sup>55</sup> accepted similar guidelines and recommendations on the use of ILE in local anesthetic toxicity.

These societies recommend a dose of 1.5 mL/kg bolus of 20% ILE followed by 0.25 mL/kg/min or 15 mL/kg/h to run for 30 to 60 minutes.<sup>55</sup> They suggest repeating this bolus several times for persistent dysrhythmias and that the infusion rate can be increased if blood pressure decreases.

The precise dose of ILE for non-local anesthetics has not been studied, and it is not known if boluses or infusion are more effective. The reasonable safe total dose is also unknown but would depend on the degree of toxicity and response to previous doses of ILE.

The most common route of administration is IV either peripherally or via central catheters. The intraosseous route was also, albeit seldom, reported as successful.<sup>16</sup>

The American College of Medical Toxicology published interim guidance on the use of ILE in lipophilic xenobiotic toxicity.<sup>1</sup> When ILE is used, they recommend a bolus dose of 1.5 mL/kg of 20% ILE. They also recommend that repeat boluses of ILE can be administered for persistent severe symptoms and that the bolus “may” be followed by an infusion for 30 to 60 minutes of 0.25 mL/kg/min or to a maximum total dose of 10 mL/kg. To date, no experimental, animal, or human clinical studies exist to inform on what benefit, if any, could be expected from any infusion of ILE. We agree on a maximum total dose of 10 mL/kg.

Propofol is formulated as a 10% lipid emulsion, but it is not recommended for use in ILE therapy because of the adverse effect of the propofol from the dose needed to achieve the doses of lipid typically used in ILE therapy.<sup>82</sup> A 1.5-mL/kg

bolus of 20% ILE equates to 3 mL/kg of the 10% lipid emulsion in the propofol solution. A normal dose of propofol (1%) for general anesthesia is 2.5 mg/kg or 0.25 mL/kg.<sup>68</sup> If propofol is used as a ILE therapy, it would deliver a bolus of 12 times the recommended dose of propofol. This would exacerbate any drug-induced hypotension and bradycardia and therefore is not recommended.

## Pregnancy and Lactation

Intravenous lipid emulsion is a Pregnancy Category C pharmaceutical. It is not known whether ILE can cause fetal harm when administered to gravid patients. Few cases of ILE resuscitation have been published in pregnant patients.<sup>14,45</sup> Potentially, large doses can result in elevated triglyceride concentrations, and lipid globules may occlude placental vasculature. The risk of potential toxicity should be weighed against potential benefit to the pregnant woman and fetus. There is no reported risk of ILE on breastfeeding infants.

## FORMULATION AND ACQUISITION

Lipid emulsion is available in parenteral formulation of 5%, 10%, 20%, and 30% solutions. The 20% solution is the formulation we recommend and the one used most often. The 30% solution is a pharmacy bulk admixture and is used to prepare dilute concentrations. The 30% solution should be diluted before administration and has not been used clinically for xenobiotic toxicity.

## SUMMARY

- Lipid emulsion is recommended for the treatment of local anesthetic systemic toxicity, particularly bupivacaine, in the case of rapidly progressive toxicity or cardiac arrest.
- In local anesthetic systemic toxicity, a bolus of ILE is recommended if still needed after standard resuscitation medications and should be stored where local anesthetics are administered.
- Lipid emulsion use for other xenobiotics is only reasonable when severe toxicity resulting from a lipid-soluble xenobiotic persists despite maximal treatment with standard resuscitation measures.
- When used for either local anesthetic or non-local anesthetic toxicity, we recommend a bolus dose of 1.5 mL/kg of 20% ILE. Repeat boluses of ILE are reasonable for persistent severe signs and symptoms to a maximum total dose of 10 mL/kg.
- The IV route is preferred although in absence of IV access, the intraosseous route can be used.

# 65 INHALATIONAL ANESTHETICS

Caitlin J. Guo and Brian S. Kaufman

## HISTORY AND EPIDEMIOLOGY

Paracelsus, a Swiss physician and alchemist, is credited with the earliest use of an inhalational anesthetic when he prepared a mixture of diethyl ether, alcohol, and water called sweet oil of vitriol. He described the administration of this preparation to hens that fell into what appeared to be a deep sleep from which they recovered unharmed. In 1735, Wilhelm Froben gave this substance its modern name of “ether.” Ether was used topically, particularly via the intranasal route, as a treatment of headache, nervous diseases, and fits.

Modern anesthetic practice began in 1846 at the Massachusetts General Hospital, when the dentist William Morton gave the first public demonstration of the ability of inhaled ether vapor to alleviate the pain of surgery. Oliver Wendell Holmes chose the Greek-related noun *anesthesia* (without feeling) to characterize the process.

Observations on circulatory and respiratory physiology eventually led to an understanding of the effects of inhalation gases and vapors. In the last decade of the 18th century, centers for the “pneumatic treatment” of disease were established in Birmingham and Bristol, England. Experiments with ether that was inhaled via a funnel and with nitrous oxide were conducted at these institutions. After Humphry Davy described his own pleasurable and exhilarating experience when he inhaled the “laughing” gas, many of his colleagues and friends inhaled nitrous oxide to experience its inebriating effects. Davy also described how inhalation of nitrous oxide relieved headache and the pain of an erupting molar tooth. Although Davy recognized the analgesic properties of nitrous oxide and its possible application for surgery, he failed to pursue the idea.

The public soon took up the use of nitrous oxide in the form of nitrous oxide frolics. Audience members at itinerant medicine shows volunteered to experience the exhilarating effects of nitrous oxide inhalation. At one such show in 1844 in Hartford, Connecticut, a man under the influence of nitrous oxide injured his leg but felt no pain. Dr. Horace Wells, a dentist in the audience that day, inhaled nitrous oxide the following day and had his partner painlessly remove a troublesome tooth. A subsequent public demonstration of the use of nitrous oxide for dental extraction had limited success, leaving his colleagues doubtful regarding its efficacy and safety and thereby impeding its general acceptance as a surgical anesthetic.

In Great Britain in 1847, James Simpson, an obstetrician, first used ether to relieve the pain of labor. He subsequently adopted chloroform for this purpose because of its more pleasant odor and more rapid induction and emergence. The clergy and other physicians opposed the concept of relieving pain during childbirth, but the method ultimately was accepted after Queen Victoria gave birth to Prince Leopold while receiving chloroform administered by John Snow.

Over the next century, several “volatile” anesthetics were introduced, including ethyl chloride in 1848, divinyl ether in 1933, trichloroethylene in 1934, and ethyl vinyl ether in 1947. All of these inhalational anesthetics had significant safety problems associated with their use, including combustibility and direct organ toxicity.

Advances in fluorine chemistry led to the cost-effective incorporation of fluorine into molecules used in the development of modern anesthetics. Fluoroxene was the first of the new fluorinated anesthetics to be widely used clinically. However, this anesthetic was flammable and hepatotoxic. It was largely replaced by the nonflammable halothane, which was synthesized in 1951 and introduced into clinical practice in 1956. Methoxyflurane was evaluated in humans in 1960 but is no longer used because of nephrotoxicity (Chap. 27) and hepatotoxicity. Other halogenated hydrocarbons with improved clinical

properties were introduced, including enflurane, isoflurane, desflurane, and sevoflurane (Fig. 65–1). The inert gas xenon holds promise as a useful anesthetic and is both cardio- and neuroprotective in experimental studies.<sup>47</sup> The clinical use of xenon is limited both by its cost and difficulty to manufacture. Although xenon is environmentally friendly compared with presently used anesthetic gases, its toxicity is relatively unknown but is believed to be minimal.

## PHARMACOLOGY

Inhalational anesthetics remain the most popular anesthetics used for maintenance of anesthesia primarily because they are easily and safely administered by modern anesthesia machines and are rapidly titratable to effect. Inhalational anesthetics used in current clinical practice are available as either volatile liquids (halothane, isoflurane, sevoflurane, and desflurane) or as compressed gases (nitrous oxide).

Because a wide range of chemically distinct xenobiotics can produce anesthesia, a unique receptor for the inhaled anesthetics is improbable. More likely, the volatile anesthetics cause general anesthesia by modulating synaptic function from within cell membranes. The most likely, but not yet proven, targets for the inhalational anesthetics are the ion channels that control ion flow across the cytoplasmic membrane.<sup>13</sup> An in-depth discussion is beyond the scope of this chapter, but several concepts are important to consider. First, more than 20 different ion channels are identified, each controlling various anion and cation flows. The results of these ion channel effects include release of inhibitory neurotransmitters and inhibition of excitatory neurotransmitters. In fact, each anesthetic type has variable actions. The receptor for  $\gamma$ -aminobutyric acid type A (GABA<sub>A</sub>) is the best studied and is important because GABA<sub>A</sub> is an inhibitory neurotransmitter. The interaction of all of these receptor effects produces the condition we refer to as general anesthesia. Many of the adverse effects of the inhalational anesthetics result directly from ion channel effects in non-neural tissue, primarily cardiac cell membranes.

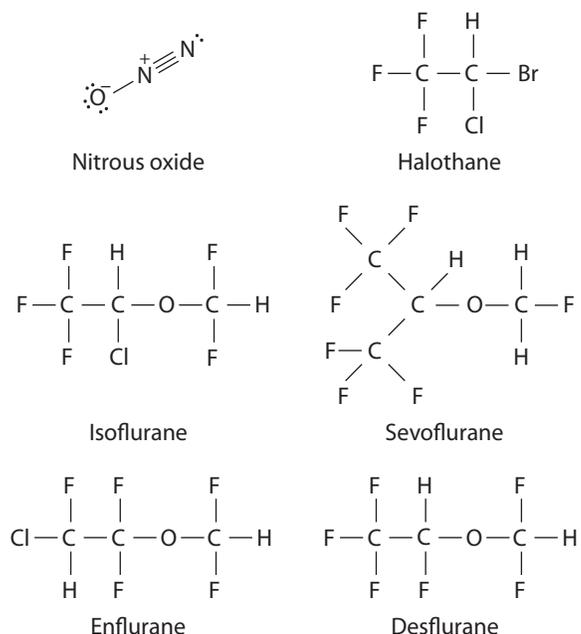

FIGURE 65–1. The inhalational anesthetics.

Reversible changes in neurologic function cause loss of perception and reaction to pain, unawareness of immediate events, and loss of memory of those events. The common pharmacologic mechanisms for general anesthesia include the physical–chemical behavior of volatile hydrocarbons with lipids and proteins within the hydrophobic regions of biologic membrane.

The potency of the various inhaled anesthetics correlates with their physicochemical properties. The dominant theories of the molecular mechanisms by which volatile anesthetics affect membrane function are based on the lipid solubility of the anesthetic and experimental demonstration of pressure reversal of anesthesia. Anesthetic potency correlates directly with the relative lipid solubility of each gaseous anesthetic, suggesting that the primary molecular actions occur in the lipid portion of cell membranes. This mechanism described by the Meyer-Overton lipid solubility theory.<sup>37</sup> Potential membrane regions for anesthetic action include the hydrophobic areas of proteins and protein–lipid interface regions, as well as the phospholipid matrix. High atmospheric pressures can reverse the effects of several anesthetics, suggesting that anesthesia results from increasing membrane volume at normal atmospheric pressure, an effect described by the volume expansion theory.<sup>33</sup>

## PHARMACOKINETICS

The route of exposure of inhaled anesthetics are the lungs. Factors that influence their absorption by blood and distribution to other tissues, particularly the brain, include anesthetic solubility, pulmonary pathology, lung and tissue blood flow, and tissue solubility. The goal of inhalational anesthesia is to develop and maintain a satisfactory partial pressure of anesthetic in the brain, the primary site of action.

The pharmacokinetics of anesthetics are linked to their pharmacodynamic effects through the concept of anesthetic potency. The linkage exists because anesthesia strives to achieve and maintain a desired alveolar concentration. For the inhaled anesthetics, potency is commonly designated by the minimum alveolar concentration (MAC) of the anesthetic. The MAC is the alveolar concentration at 1 atm that prevents movement in 50% of participants in response to a painful stimulus (ie, it is the analgesic median effective concentration { $EC_{50}$ }). Minimum alveolar concentration is used when comparing the effects of equipotent doses of anesthetics on various organ functions.

## NITROUS OXIDE

Nitrous oxide ( $N_2O$ ), a compresses gas, is the most commonly used inhalational anesthetic in the world, but its safety is debated.<sup>30</sup> Its advantages include a mild odor, absence of airway irritation, rapid induction and emergence, potent analgesia, and minimal respiratory and circulatory effects. When administered in a modern operating room (OR) using current standards of monitoring to prevent unintentional hypoxia, nitrous oxide is remarkably safe. Unfortunately, nitrous oxide also has a potential for abuse because of its euphoric effects, particularly among hospital and dental personnel.<sup>29</sup> Death and permanent brain injury are reported but do not generally result from direct toxic effects; instead, they are secondary to hypoxia as a result of simple asphyxiation (Chap. 121).<sup>17</sup>

Nitrous oxide is also used as a food additive to generate foam, a property exploited to produce whipped cream. Sold in supermarkets as “bulbs,” death has occurred secondary to asphyxiation, when homemade mouthpieces failed to separate from the user after unconsciousness occurred during use.<sup>46</sup> Recreational abuse of nitrous oxide among teenagers and adults of all ages is on the rise. In 2015, the National Institute on Drug Abuse reported that 527,000 people aged 12 years or older reported using inhalants, and many of them used whippets. This is most assuredly an underestimate of true usage.

Death also occurred when patients received commercially prepared nitrous oxide from tanks contaminated with impurities such as nitric oxide or nitrogen dioxide. Pulmonary toxicity resulting from similar contaminants was reported after illicit preparation of nitrous oxide from the combustion of ammonium nitrate fertilizer.<sup>36</sup>

Injury results from the physical properties of this anesthetic. Nitrous oxide is 35 times more soluble in blood than is nitrogen. When nitrous oxide

is inhaled, any compliant air-containing space, such as the bowel, increases in size; noncompliant spaces, such as the Eustachian tubes, exhibit an increase in pressure. These effects occur because nitrous oxide diffuses along the concentration gradient from the blood into a closed space much more rapidly than nitrogen can be transferred in the opposite direction. Clinical consequences include rapid progression of a pneumothorax to a tension pneumothorax, tympanic membrane rupture with hearing loss, bowel distension, and tracheal or laryngeal trauma caused by increased endotracheal cuff pressure resulting from replacement of air by a larger volume of nitrous oxide. Nitrous oxide is particularly dangerous in patients who have suffered air emboli, and its use should be immediately discontinued upon recognition of these events. When intracranial or neuraxial air is injected during placement of an epidural catheter, it also can theoretically expand upon subsequent exposure to nitrous oxide.

## Hematologic Effects

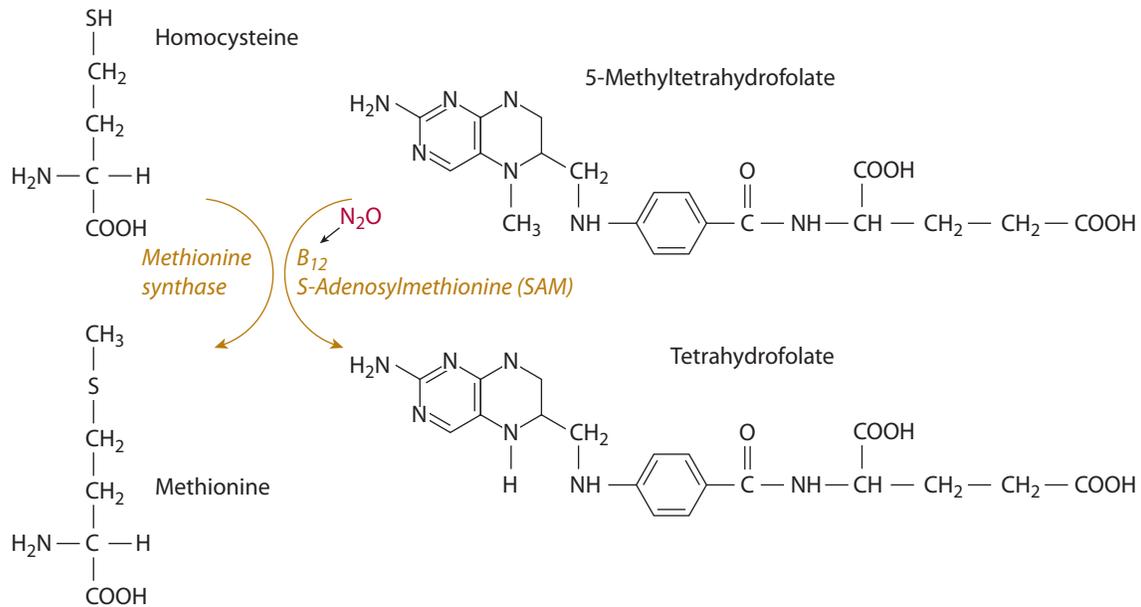

Bone marrow suppression was first recognized as a complication of long-term nitrous oxide exposure in the 1950s, when the gas was used to sedate intubated patients who had severe tetanus.<sup>28</sup> Leukopenia with hypoplastic bone marrow and megaloblastic erythropoiesis typically developed 3 to 5 days after initial exposure and was followed by thrombocytopenia. Recovery usually occurred within 4 days after discontinuation of the anesthetic. Healthy patients undergoing routine surgical procedures demonstrate mild megaloblastic bone marrow changes within 12 hours of exposure to 50% nitrous oxide and marked changes within 24 hours of exposure.<sup>44</sup> Critically ill patients appear to be more sensitive to the effects of nitrous oxide on the bone marrow, with megaloblastic changes described after only one hour of exposure, but changes are unlikely in individuals with less than 6 hours of exposure in the absence of preexistent folate or vitamin  $B_{12}$  deficiencies.<sup>3</sup>

The hematologic effects of exposure to nitrous oxide strongly resemble the biochemical characteristics of pernicious anemia.<sup>2,42,43</sup> Vitamin  $B_{12}$ , or cyanocobalamin, is a bound coenzyme of cytoplasmic methionine synthase. The cobalt moiety in the enzyme functions as a methyl carrier in its transfer from 5-methyltetrahydrofolate to homocysteine to form methionine (Fig. 65–2). Nitrous oxide oxidizes the cobalt ion, converting vitamin  $B_{12}$  from the active monovalent form ( $Co^+$ ) to the inactive divalent form ( $Co^{2+}$ ), which irreversibly inhibits methionine synthase.<sup>42</sup> The metabolic consequences of this inhibition are significant because methionine and tetrahydrofolate are required for both DNA synthesis and myelin production. This interference is responsible for the development of bone marrow depression and polyneuropathy resembling the characteristic findings that occur in pernicious anemia.<sup>43</sup>

## Neurologic Effects

Disabling polyneuropathy in health care workers who habitually abused nitrous oxide was first described in 1978.<sup>29</sup> This neurologic disorder improved slowly when the patients abstained from further nitrous oxide abuse. This neuropathy is clinically indistinguishable from subacute combined degeneration of the spinal cord associated with pernicious anemia.<sup>48</sup> The syndrome of nitrous oxide neuropathy is characterized by sensorimotor polyneuropathy, often combined with signs of posterior and lateral spinal cord involvement. Signs and symptoms include numbness and paresthesias in the extremities, weakness, and truncal ataxia. Magnetic resonance imaging (MRI) findings typically show abnormal signal involving in the posterior and anterior spinal cord columns (Fig. 65–3).<sup>24</sup>

Neurologic changes usually develop after several months of frequent exposure to nitrous oxide, although neurologic manifestations may develop within days of use in patients with subclinical vitamin  $B_{12}$  deficiency. Those at risk include individuals who chronically abuse the gas and those who are occupationally exposed for prolonged periods to environments contaminated with high concentrations of nitrous oxide.<sup>6</sup> Animal studies demonstrate that methionine synthase is inactivated by exposure to greater than 1,000 per million (ppm) of nitrous oxide. This scenario is highly unlikely in modern ORs, where inhalational anesthetics are scavenged, but it may occur

**FIGURE 65-2.** Hematologic effects of exposure to nitrous oxide (N<sub>2</sub>O) resemble those characteristic of pernicious anemia and are related to oxidation and inactivation of vitamin B<sub>12</sub>. The irreversible blockade of methionine synthase impairs DNA synthesis and myelin production.

in poorly ventilated dental offices. This problem probably is underdiagnosed because the neurologic changes that occur in mild cases mimic other more common neurologic conditions.<sup>11</sup>

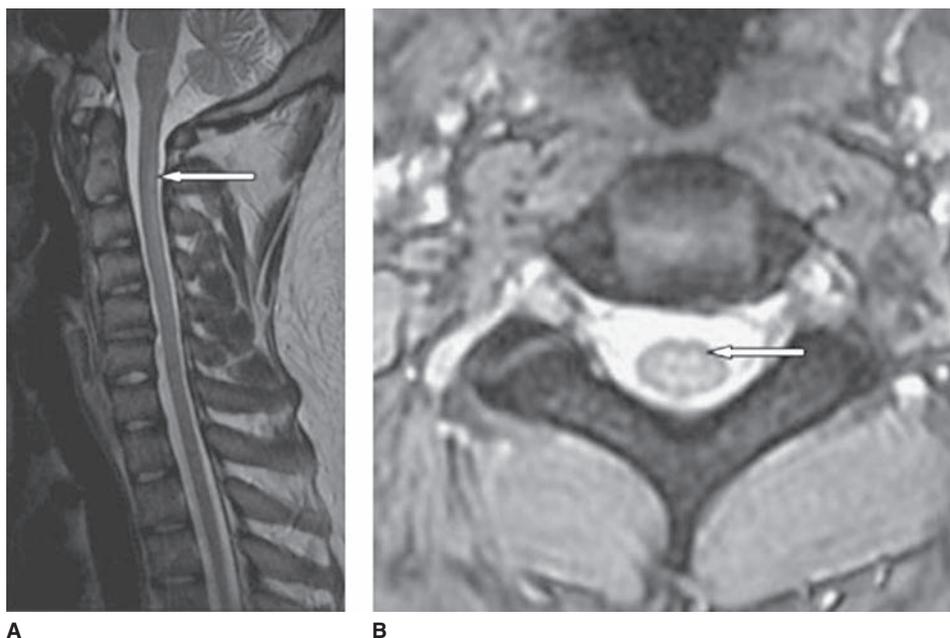

### Immunologic Effects

Concern has been raised regarding detrimental effects of nitrous oxide on immune function. Nitrous oxide is associated with varied effects on immune function with evidence of decreased proliferation of human peripheral blood mononuclear cells and decreased neutrophil chemotaxis. The ENIGMA trial evaluated patients undergoing major surgery comparing nitrous oxide-based and nitrous oxide-free anesthesia, and showed an increase in secondary outcomes including wound infection, pneumonia, and atelectasis.<sup>38</sup> However, ENIGMA-II, the follow-up trial with a much larger sample size of

7,112 patients, did not demonstrate any differences in any of the previous reported results.<sup>40</sup>

### Cardiovascular Effects

Concern over nitrous oxide and increased risk of cardiovascular complications is mostly theoretical. Nitrous oxide increases postoperative homocysteine concentrations and impairs endothelial function by inhibiting an enzyme that converts homocysteine to methionine.<sup>39</sup> Chronic homocysteinemia is associated with cardiovascular disease. Although the initial ENIGMA trial<sup>38</sup> showed an increase of long-term myocardial infarctions, the most recent ENIGMA-II, with a much larger sample size and a study design that specifically evaluated cardiovascular complications, did not demonstrate any difference (8% versus 8%;  $P = 0.64$ ).<sup>40</sup>

**FIGURE 65-3.** Magnetic resonance imaging findings in a 19-year-old man with a 4-month history of nitrous oxide abuse who presented with gait imbalance, limb weakness, and numbness from the nipples to the toes. (A) T<sub>2</sub>-weighted (4,000/120) sagittal image shows increased signal intensity (arrow) in the cervical spinal cord. (B) T<sub>2</sub>-weighted (4,000/120) axial image shows (arrow) abnormal signal involvement in the posterior and anterior spinal cord columns.<sup>24</sup>

## Treatment

### General

Removal of the acutely affected person from the toxic environment should be the initial intervention in addition to ensuring adequate oxygenation and ventilation. Individuals who have developed toxicity from occupational exposure or abuse of the gas should be educated about the relationship between their activities and their clinical findings.

### Specific

Acute overdose of nitrous oxide can lead to life-threatening hypoxia. Patients admitted with respiratory compromise should be administered supplemental oxygen and monitored for 24 hours. Supportive treatment such as intensive care unit (ICU) care and mechanical ventilation is warranted in the presence of severe respiratory failure.

The treatment regimen for the neurologic sequelae of vitamin B<sub>12</sub> deficiency from nitrous oxide toxicity includes parenteral vitamin B<sub>12</sub> and oral methionine. Vitamin B<sub>12</sub> is recommended in a manner similar to that used in the treatment of pernicious anemia by either (1) intramuscular injection of 1,000 mcg vitamin B<sub>12</sub> daily for 1 week followed by weekly injection of 1,000 mcg for 4 to 9 weeks and then monthly injection of 1,000 mcg until clinical resolution or (2) daily oral administration of 1,000 to 2,000 mcg of vitamin B<sub>12</sub> until clinical resolution.<sup>50</sup>

Up to 20% of the population may have unrecognized vitamin B<sub>12</sub> deficiency from dietary restriction, malabsorption, or autoimmune gastritis, which is exacerbated when exposed to nitrous oxide.<sup>50</sup> It is worth noting that in some of the early case reports, before recognition of vitamin B<sub>12</sub> deficiency in nitrous oxide toxicity, many had improvement of symptoms simply after cessation. Methionine was also successfully used when vitamin B<sub>12</sub> treatment alone failed to improve neurologic effects. There is no guideline for dosing vitamin B<sub>12</sub> for patients with nitrous oxide toxicity, although case reports have used a 3-g daily oral regimen.<sup>51</sup>

The bone marrow abnormalities associated with nitrous oxide toxicity should be treated with a single 30-mg intravenous (IV) dose of folinic acid (Antidotes in Depth: A12).

## HALOGENATED HYDROCARBONS

The volatile anesthetics which are liquids under standard conditions with a very high vapor pressure, were initially considered biochemically inert. Toxicity after administration was poorly explained. It is now clear that the metabolites of the inhalational anesthetics are responsible for acute and chronic toxicities, which are predictable and dose related.

## Halothane Hepatitis

Two distinct types of hepatotoxicity are associated with halothane use. The first is a mild dysfunction that develops in approximately 20% of exposed patients. Patients often are asymptomatic but exhibit mild elevated serum aminotransferase concentrations within a few days after anesthetic exposure. Recovery is usually complete.<sup>25</sup> In contrast, appearance of serum aminotransferase concentrations above 10 times the upper normal limits indicates a life-threatening hepatitis that occurs in approximately 1 in 10,000 exposed patients and produces fatal massive hepatic necrosis in 1 in 35,000 patients.<sup>4</sup> Because the histologic findings of massive hepatocellular necrosis are indistinguishable from many of the causes of viral hepatitis,<sup>55</sup> differentiating halothane hepatitis from other causes of hepatitis in the postoperative period is difficult. Jaundice, which is common after anesthesia and surgery, can result from many factors such as preexisting liver disease, perioperative hypotension, blood transfusion, sepsis, or other causes of hepatitis. Thus, halothane hepatitis is a diagnosis of exclusion or inclusion based on the clinical history and time course.

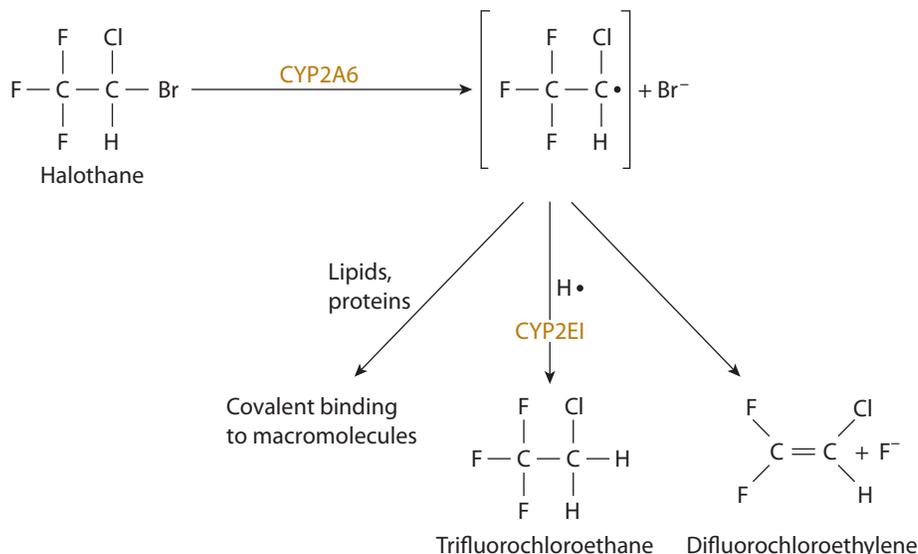

Several studies report an association between multiple exposures to halothane and subsequent development of hepatitis.<sup>48,54,59</sup> In one study, 95% of cases of halothane hepatitis occurred after repeated exposures, 55% of which involve reexposure within 4 weeks.<sup>59</sup> Under these circumstances, hepatic dysfunction usually is more severe, and the latency before clinical presentation usually is shorter compared with the initial exposure.<sup>54</sup>

Obesity is a risk factor commonly implicated in halothane hepatotoxicity.<sup>1,56</sup> Increased fat stores act as a reservoir for halothane, with slow and prolonged release into the circulation and subsequent increase in production of potentially hepatotoxic metabolites.

Most cases of halothane hepatitis occur in middle-aged patients; with women having twice the risk.<sup>25</sup> Genetic factors likely play an important role in some patients, as indicated by a case report of this syndrome in three pairs of related Mexican women.<sup>23</sup>

## Mechanism of Toxicity

Halothane is the most extensively metabolized inhalational anesthetic. Approximately 20% of the absorbed anesthetic undergoes oxidative metabolism, principally by CYP2E1 in the liver, to trifluoroacetic acid. Reduction to trifluorochloroethane and difluorochloroethylene is a minor route of halothane metabolism that requires the absence of oxygen and the presence of an electron donor (Fig. 65-4). These volatile metabolites are free radicals, which directly produce acute hepatic toxicity by irreversibly binding to and destroying hepatocellular structures. Alternatively, by acting as haptens, they trigger an immune-mediated hypersensitivity response.<sup>45,57</sup> The high

**FIGURE 65-4.** Reductive metabolism of halothane results in the formation of a reactive metabolite that may directly bind macromolecules and create neoantigens or undergo further metabolism to trifluorochloroethane and difluorochloroethylene. CYP = cytochrome P450.

percentage of patients with halothane hepatitis who had recent reexposure is most consistent with the latter mechanism in which the first exposure primes the development of antibodies to a haptenized protein.<sup>25</sup>

The use of halothane for inhalational anesthesia has markedly decreased in North America with the widespread availability of newer, safer halogenated anesthetics. Halothane is still widely used in some countries because it is inexpensive and provides a smooth induction of anesthesia.

Isoflurane and desflurane are pungent gases that can be airway irritants. Isoflurane, desflurane, and sevoflurane all appear to have low hepatotoxic potential. Rare case reports of hepatitis are still reported with all anesthetics but at a much lower incidence compared to halothane. Cross-sensitivity may exist, such that prior exposure to one anesthetic triggers hepatotoxicity upon subsequent exposure to a different anesthetic.

### Nephrotoxicity

The kidneys are at risk for toxicity from modern inhalational anesthetics. Methoxyflurane is an anesthetic that was introduced in 1962. By 1966, this anesthetic was linked to the development of vasopressin-resistant polyuric renal insufficiency (nephrogenic diabetes insipidus) in 16 of 94 patients receiving prolonged methoxyflurane anesthesia for abdominal surgery (Chap. 27).<sup>15</sup> Polyuria was associated with a negative fluid balance, elevations of serum sodium and urea nitrogen concentrations, osmolality, and a fixed urinary osmolality approximating that of serum. Kidney abnormalities lasted from 10 to 20 days in most patients but persisted for more than one year in 3 of the 17 patients.<sup>15</sup> Subsequent studies demonstrated that kidney toxicity was caused by inorganic fluoride released during biotransformation of methoxyflurane.<sup>53</sup> The risk of toxicity was highly correlated with both the total dose of methoxyflurane (concentration times duration) and the peak serum fluoride concentration.<sup>14</sup> The nephrotoxic serum fluoride concentration is 50 to 60  $\mu\text{mol/L}$ .<sup>14</sup> The factors that enhance biotransformation such as obesity and enzyme induction also increase the risk of toxicity. Although the precise mechanism by which fluoride produces its toxic effect in the kidneys is not clear, one hypothesis is that fluoride inhibits adenylate cyclase, thereby interfering with the normal action of antidiuretic hormone on the distal convoluted tubules.

Although methoxyflurane is no longer used, lessons learned regarding its toxicity are applicable when evaluating the nephrotoxic potential of other fluorinated anesthetics. Of the currently used anesthetics (halothane, isoflurane, desflurane, sevoflurane), only sevoflurane undergoes biotransformation by defluorination.

Approximately 5% of sevoflurane is metabolized by defluorination, occasionally resulting in sufficient serum fluoride concentrations to produce transient decreases in urine-concentrating ability.<sup>27</sup> However, clinically evident renal impairment almost never occurs with use of sevoflurane.<sup>20</sup> In volunteer studies, exposure to sevoflurane that resulted in high serum fluoride concentrations did not result in any urine concentrating defects. In patients with chronic kidney disease (CKD), the risk of postoperative kidney dysfunction is believed to be worse with exposure to inhalational anesthetics. However, studies demonstrate that deterioration of kidney function does not occur after exposure to desflurane and isoflurane,<sup>32</sup> possibly because intrarenal fluoride concentrations are more important than serum fluoride concentrations in the development of nephrotoxicity.

Sevoflurane reacts with the alkali within carbon dioxide absorbers to produce several degradation products, including a vinyl ether called compound A ( $\text{CF}_2\text{C}(\text{CF}_3)\text{OCH}_2\text{F}$ ). Compound A causes renal tubular necrosis in rats, especially at the corticomedullary junction.<sup>26,58</sup> The extent of nephrotoxicity is determined by both the concentration of compound A and the duration of exposure. Compound A is also conjugated, and its breakdown products are nephrotoxic.

### Technical Issues

Extensive clinical experience with several million patients who were exposed to sevoflurane and 4,000 closely studied volunteers failed to demonstrate

nephrotoxicity.<sup>34</sup> Higher concentrations of compound A are generated during low-flow anesthesia, use of high concentrations of sevoflurane, and increased temperature conditions. A high fresh-gas flow rate dilutes the concentration of compound A. Concern that higher compound A concentrations are generated when a low fresh-gas flow rate (eg,  $<2\text{ L/min}$ ) is used in a closed circuit led to the current sevoflurane package labeling, which warns against fresh-gas flow rates below  $2\text{ L/min}$  in a circle absorber system.<sup>18</sup>

Some controversy exists regarding the safety of low-flow sevoflurane anesthesia. Although there have been no clinical reports of sevoflurane-induced nephrotoxicity as measured by changes in blood urea nitrogen (BUN), serum creatinine, or creatinine clearance, clinical data demonstrate transient nephrotoxicity when more subtle measurements of glomerular and tubular function are used.<sup>18,20,22</sup> For example, when young, healthy patients without underlying kidney disease were anesthetized with low-flow sevoflurane for a mean of 6.7 hours, transient but statistically significant increases in urinary glucose and protein excretion were documented without any changes in BUN, creatinine, or creatinine clearance.<sup>22</sup> The clinical significance of such transient abnormalities in kidney function is uncertain. Regardless, it seems prudent to avoid the practice of low-flow sevoflurane in patients with CKD until clinical data document safety. Newer carbon dioxide absorbents that are free of strong alkali are now available to decrease compound A generation.

## INHALATION ANESTHETIC-RELATED CARBON MONOXIDE POISONING

### Pharmacology

Desflurane and isoflurane contain a difluoromethoxy moiety that can be degraded to carbon monoxide (CO). This process occasionally results in toxic exposure to patients. Carboxyhemoglobin levels as high as 36% were reported from intraoperative desflurane degradation.<sup>8</sup> Although there was no evidence of patient harm in this case, morbidity or mortality could occur at this level in patients (Chap. 122). The true incidence of carbon monoxide exposure during clinical anesthesia is unknown. Routine detection of intraoperative carbon monoxide exposure is now possible using multiwavelength pulse cooximeters, but these devices are not widely adopted, and conventional pulse oximeters used in ORs cannot detect carbon monoxide (Chaps. 28 and 122).<sup>9</sup>

Carbon monoxide production is inversely proportional to the water content of  $\text{CO}_2$  absorbents. Soda lime (a granular mixture of calcium, sodium, and potassium hydroxide) is the most frequently used  $\text{CO}_2$  absorbent. It is sold wet (13%–15% water by weight) but may dry with high gas-inflow rates, reducing its effectiveness at removing CO. Higher concentrations of carbon monoxide are most apt to be present during the first case after a weekend because of drying of  $\text{CO}_2$  absorbent from a continuous inflow of dry oxygen if the anesthesia machine was not in use.<sup>19</sup>

Other factors influence the concentration of carbon monoxide resulting from anesthetic degradation, including temperature (higher temperature increases carbon monoxide formation), type of absorbent, choice of anesthetic, and concentration of anesthetic. Strong alkalis, such as potassium and sodium hydroxide, initiate the reaction that forms carbon monoxide.

Mass spectrometry (available in some ORs) cannot directly detect carbon monoxide because its molecular weight is equivalent to that of nitrogen, a gas usually present in much greater amounts. In addition, detection of carbon monoxide by fragmentation products is not possible by mass spectrometry because  $\text{CO}_2$  is present in greater amounts and has similar fragmentation products.

Unfortunately, the diagnosis of carbon monoxide poisoning during anesthesia is difficult because the main clinical features of toxicity are masked by anesthesia, and no routinely available means can identify carbon monoxide within the breathing circuit or detect when the  $\text{CO}_2$  absorbent is desiccated. Delayed neurologic sequelae from intraoperative carbon monoxide poisoning are typically missed on the anesthesiologist's postoperative patient evaluation because the delayed manifestations may develop days following the procedure.<sup>61</sup>

The product label of desflurane and isoflurane advises that the  $\text{CO}_2$  absorbent should be replaced when a practitioner suspects the absorbent

is desiccated. However, this warning fails to account for the lack of a reliable method of actionable data to determine when the absorbent is fully or partially desiccated.

If an anesthetic machine is found with the fresh-gas flow on at the beginning of the day, a reasonable practice is to replace the absorbent. Newer CO<sub>2</sub> absorbents that are less likely to degrade anesthetics are now available. These newer absorbents have decreased amounts of strong bases.

### LONG-TERM USE OF HALOGENATED ANESTHETICS IN INTENSIVE CARE UNITS

Halogenated anesthetics have been used since the 1990s in ICUs for long-term sedation of patients receiving mechanical ventilation and more recently as part of the treatment for patients with refractory status epilepticus. Use is limited by concerns regarding atmospheric pollution, but also ambient ICU air, and high costs (because of a lack of rebreathing systems in the ICU). The development of anesthetic-conserving devices for use with ICU ventilators has addressed these issues. Potential advantages include more rapid wake-up and shorter times to extubation with minimal risk of toxicity.<sup>35</sup>

Clinical studies report the use of isoflurane and sevoflurane for ICU sedation. In one study, 19 patients were mechanically for more than 24 hours in the ICU with sevoflurane used for sedation.<sup>35</sup> Toxic effects of sevoflurane were not found even though serum fluoride concentrations often exceeded 50 μmol/L (the concentration suggested to be the nephrotoxic threshold).<sup>14</sup>

Isoflurane is being used as a first-choice for long-term sedation during mechanical ventilation in some ICUs. Experimental models demonstrate that isoflurane is potentially neurotoxic, primarily through induction of neuronal apoptosis. In rats, isoflurane substantially decreases local glucose utilization in various brain regions, including the thalamus. Reversible psychomotor dysfunction was reported in 3.6% of 335 patients who received isoflurane for more than 12 hours as a primary sedative during mechanical ventilation in a general ICU.<sup>5</sup> Psychomotor dysfunction occurred in 42% of patients aged 4 years or younger but in only 1.3% of patients older than 4 years.

Isoflurane is an alternate treatment for patients with refractory status epilepticus. Reversible MRI abnormalities developed in two patients who received inhaled isoflurane for a prolonged time (35 and 85 days).<sup>21</sup> Serial MRIs demonstrated the development of hyperintense T2 signals involving the medulla, cerebellar cortex, deep cerebellar nuclei, thalamus, and hypothalamus bilaterally. These abnormalities improved after discontinuation of the isoflurane.

### CHRONIC EXPOSURE TO WASTE ANESTHETIC GASES

Waste anesthetic gases are defined as inhalation gases and vapors that are released into work areas associated with or adjacent to the administration of a gas or volatile liquid for anesthetic purposes. Because anesthesia machines are not airtight and consist of hundreds of parts, it is inevitable that clinical personnel will be exposed to waste anesthetic gases. Exposure to waste anesthetic gas produces short- and long-term effects. Common short-term effects are lethargy and fatigue in staff members who are exposed to significant quantities of waste anesthetic gas. Chronic long-term effects correlate with the concentration of gas and duration of exposure. Animal studies demonstrate that exposure to high concentrations of nitrous oxide and halogenated xenobiotics can cause cellular, mutagenic, carcinogenic, and teratogenic effects.

The US government has been involved with the regulation and management of waste anesthetic gas since 1970. The OR environment in the United States is highly regulated and monitored, but exposure limits vary in other countries and can exceed the concentrations permitted in the United States. Even in a modern working environment with low-leakage anesthesia machines, scavenging systems, and high room ventilation exchange rates, exposure to inhalational anesthetics could not be kept below acceptable threshold concentrations in all cases. However, a cause-and-effect relationship between human exposure to waste anesthetic gases and

poor reproductive outcomes could not be identified in an analysis requested by the American Society of Anesthesiologists.<sup>12</sup>

Dentists and dental assistants are often exposed to greater concentrations of waste anesthetic gases than are individuals working in well-ventilated ORs. An epidemiologic survey compared 15,000 dentists who used nitrous oxide in their practices with 15,000 dentists who did not.<sup>11</sup> A 1.2- to 1.8-fold increase in hepatic, kidney, and neurologic disease was found in the dentists and their chair-side assistants who were chronically exposed to trace concentrations of nitrous oxide. For those with heavy office use of nitrous oxide, a fourfold increase in the incidence of neurologic complaints compared with the nonexposed group was observed. Female dental assistants who were exposed to nitrous oxide had a two- to threefold increase in spontaneous abortion rates, reduced fertility, and a higher rate of congenital abnormalities in their offspring.<sup>11</sup>

### ABUSE OF HALOGENATED VOLATILE ANESTHETICS

Fatal or life-threatening complications occur when halogenated inhalational anesthetics are used for nonanesthetic purposes such as suicide attempts, mood elevation, and topical treatment of herpes simplex labialis.

When ingested, halothane, a volatile liquid, usually produces gastroenteritis with vomiting followed by depressed levels of consciousness, hypotension, hypothermia, shallow breathing, respiratory failure, and bradycardia with varying degrees of heart block and extrasystoles. A depressed level of consciousness is attributed to large amount halothane that is absorbed from gastric mucosa, which also causes systemic vasodilation resulting in hypotension and hypothermia.<sup>16,60</sup> The diagnosis should be suspected when these features occur in a patient with the sweet or fruity odor of halothane on the breath. If suspected, nasogastric lavage is recommended to remove the remainder of halothane that is still in the stomach. Case reports have used ice-cold saline for hourly gastric lavage with success. The gastric aspirate also smelled of halothane.<sup>60</sup> Supportive care, including mechanical ventilation, fluid and electrolyte resuscitation, inotropic support, electrolytes correction, antidysrhythmics, normothermia, and antibiotics, should be provided. Full recovery can occur without permanent organ injury.

Intravenous injections of halothane may occur as a suicide attempt or unintentionally during anesthesia induction. A young patient who was found unconscious and hypotensive with ARDS after self-administered IV injection of halothane was unable to be resuscitated.<sup>7</sup> A 16-year-old girl received an unintentional IV injection of 2.5 mL of halothane during anesthesia induction.<sup>52</sup> She became unconscious and apneic within 30 seconds but began to awaken within 2 to 3 minutes. Four hours later, she developed ARDS but subsequently made a full recovery.

Transient coma and apnea probably are secondary to a halothane bolus reaching the brain on its first pass through the bloodstream. Redistribution then occurs, explaining the rapid awakening. The ARDS that develops after injection of halothane most likely results from a direct toxic effect of high concentrations of the hydrocarbon on the pulmonary vasculature. After injection, the anesthetic likely travels as a bolus during the first passage through the pulmonary circulation because of its poor solubility in blood.

Hospital personnel are involved in most reported cases of halothane abuse by inhalation.<sup>49</sup> Inhalation of halothane produces a pleasurable sensation similar to that described with other inhaled hydrocarbons, such as the solvents in glue and paint (Chap. 81). Death may result from upper airway obstruction after loss of consciousness or from dysrhythmias. Death occurred in a student nurse anesthetist suggested to have applied a full 250-mL bottle of enflurane over 3 hours to "cold sores" on her lower lip.<sup>31</sup>

### SUMMARY

- Inhalational anesthetics remain a popular choice for maintenance of anesthesia due to their safety profile and titratability. Toxicity is uncommon when properly administered and monitored.
- Health care practitioners who use inhaled anesthetics should be knowledgeable about their pharmacology and potential toxicity.

- Nitrous oxide abuse, typically in the form of “whippets,” is common and can lead acutely to life-threatening hypoxia. It causes bone marrow suppression and disabling polyneuropathy with chronic abuse. Treatment is supportive in acute setting, and patients with long-term hematologic and neurologic sequelae are treated with vitamin B<sub>12</sub>, methionine, and folic acid.
- Halothane, an older halogenated hydrocarbon, is no longer used in North America but is still in widespread use around the world and is associated with fulminant hepatitis.
- Sevoflurane is associated with production of compound A, which can cause renal tubular necrosis; however, it is not shown to cause acute kidney injury in vivo.
- Abuse of halogenated volatile anesthetics is rare; treatment is supportive.

### HISTORY AND EPIDEMIOLOGY

*Curare* is the generic term for the resinous arrowhead poisons used to paralyze hunted animals.<sup>116</sup> The curare alkaloids are derived from the bark of the *Strychnos* vine, and the most potent alkaloids, the toxiferines, are derived from *Strychnos toxifera*. Fortunately for the hunters who used curare, ingestion of their prey did not cause paralysis. Sir Walter Raleigh discovered the use of curare in Guyana in 1595, and he was the first person to bring curare to Europe. Curare played a pivotal role in the discovery of the mechanism of neuromuscular transmission. In 1844, Claude Bernard placed a small piece of dry curare under the skin of a live frog and observed that the frog became limp and died.<sup>8</sup> He performed an immediate autopsy and discovered that the heart was beating. Because direct muscle stimulation produced contraction but nerve stimulation did not, Bernard concluded that curare paralyzed the motor nerves. He later observed, however, that bathing the isolated nerve did not affect neuromuscular transmission, leading him to conclude: “Curare must act on the terminal plates of motor nerves.”<sup>18</sup> Curare was used by Nobel Laureate physiologists Charles Sherrington, John Eccles, and Bernard Katz to further elucidate neuromuscular physiology. Its first clinical use was described in 1878 when Hunter used curare to treat patients with tetanus and seizures.<sup>116</sup> In 1932, Raynard West used curare to reduce the muscular rigidity of hemiplegia.<sup>116</sup>

Curare (d-tubocurarine) was introduced into clinical anesthesia in 1943 by Harold Griffith and Enid Johnson.<sup>43</sup> Endotracheal intubation during general anesthesia was not common those days, so d-tubocurarine was administered in a dose that spared the diaphragm and maintained spontaneous ventilation. It was not until 1954 when Henry Beecher found that patients receiving d-tubocurarine had a sixfold increase in respiratory-related anesthesia mortality that artificial ventilation and reversal of residual d-tubocurarine became a routine practice.<sup>9</sup> Use of d-tubocurarine spanned almost 40 years until it was replaced by superior nondepolarizing neuromuscular blockers that caused less histamine release and hypotension.

Around the same time in the 1950s that curare gained popularity in the operating room, succinylcholine also came to clinical use to facilitate orotracheal intubation.<sup>9</sup> In the nonmedical world, succinylcholine carried a reputation of being the “person poison.”<sup>33</sup> This came to media attention when a high-profile killing case involving an anesthesiologist Dr. Carl Coppolino and his mistress were accused of murdering his wife and the mistress’s husband in 1966 and 1967, respectively, by injecting succinylcholine.<sup>77</sup> In 1983, shortly after Dr. Michael Swango began his internship at Ohio State University Hospital, patients began dying inexplicably, and he was relieved of his duties.<sup>109</sup> Following switching residencies and jobs for 14 years, prosecutors secured Swango’s guilty plea for the murder of three victims. The toxicological analysis of the 7-year-old remains of Thomas Sammarco revealed succinylcholine in the liver and gallbladder and its metabolite succinylmonocholine in multiple organs, which assisted in the conviction.

With the advent of new modalities of drug delivery, toxicologists must be attuned to possible malicious intent. Emergency personnel responding to a 911 call observed the widow removing an insulin pump reservoir from her dead husband’s body with the stated intent to donate the costly equipment.<sup>5</sup> A natural cause of death was presumed, yet surprisingly, forensic analysis revealed etomidate and laudanosine (a metabolite of atracurium) in the victim’s liver.

Understanding the pharmacokinetics and pharmacodynamics of the depolarizing and nondepolarizing neuromuscular blockers (NDNMBs) is critical to maximizing benefit while minimizing toxicity.

### MECHANISM OF NEUROMUSCULAR TRANSMISSION AND BLOCK

The purpose of a NMB is to selectively and reversibly inhibit signal transmission at the skeletal neuromuscular junction (NMJ). All NMBs possess at least one positively charged quaternary ammonium moiety that binds to the postsynaptic nicotinic acetylcholine (nACh) receptor at the NMJ, inhibiting its normal activation by acetylcholine (ACh). The nACh receptor is a ligand-gated ion channel that consists of 4 different protein subunits in a pentameric structure surrounding a central channel. The nACh receptor found in human skeletal muscle is present in 2 primary forms: a mature type found at the NMJ ( $\alpha_1\beta\epsilon\delta$ ) or as a fetal (immature) type found on muscle at extra-junctional regions of the muscle fiber ( $\alpha_1\beta\gamma\delta$ ). **Figure 66–1** provides an overview normal neuromuscular transmission and excitation–contraction coupling.

Skeletal muscle paralysis can occur by several mechanisms. For example, tetrodotoxin blocks voltage-sensitive sodium channels, preventing action potential conduction in the motor neuron (Chap. 39). On the other hand, botulinum toxin blocks ACh release from the presynaptic neuron by inhibiting the binding of ACh-containing vesicles to the neuronal membrane in the region of the synaptic cleft (Chap. 38). Modulation of postsynaptic ACh receptor activity at the NMJ may produce paralysis by one of two mechanisms: depolarizing (phase I block) and nondepolarizing (phase II block). Succinylcholine is the only depolarizing neuromuscular blocker (DNMB) in current clinical use. High doses of nicotine also cause a depolarizing block. All other drugs discussed are NDNMBs.

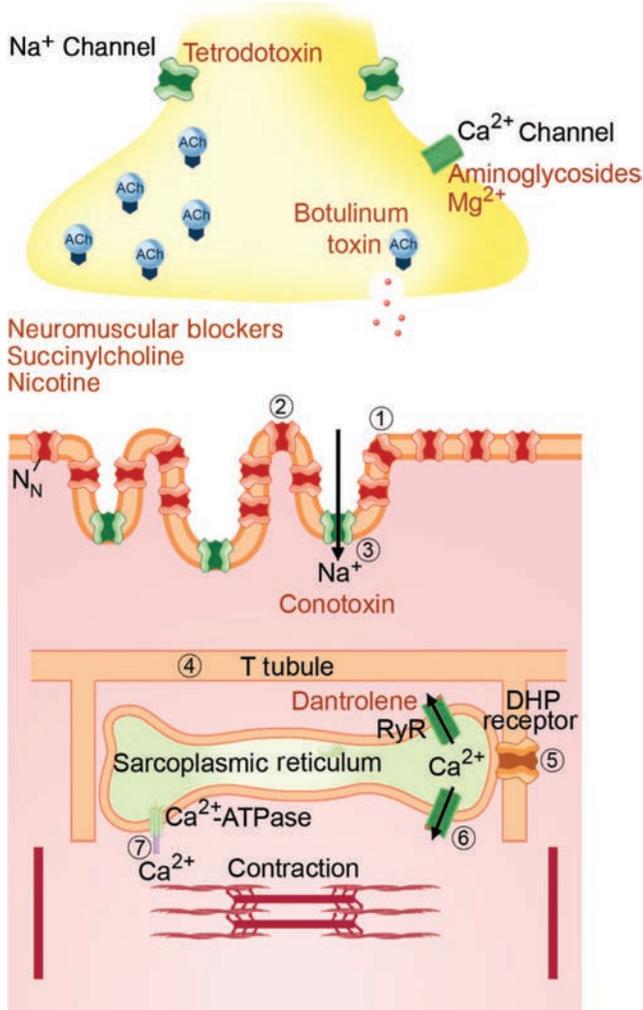

The process of DNMB requires several steps. First, two molecules of succinylcholine must bind to each  $\alpha$  site of the nACh receptor. This action causes a prolonged open state of the nACh receptor ion channel. The initial depolarization generates a muscle action potential and usually causes brief contractions (fasciculations). In contrast to ACh, succinylcholine is not hydrolyzed efficiently by acetylcholinesterase (AChE) located in the synaptic cleft. Thus, the effect of succinylcholine lasts much longer than ACh. Succinylcholine persistence at the ACh receptor causes a sustained local muscle endplate depolarization that, in turn, causes the voltage-gated sodium channel in the perijunctional region to remain in a prolonged inactive state, inducing a desensitization block. The muscle is temporarily refractory to presynaptic release of further ACh (phase I block).

The NDNMBs cause skeletal muscle paralysis by competitively inhibiting the effects of ACh and thus preventing muscle depolarization. One molecule of an NDNMB bound to a single nACh receptor (also on the  $\alpha$  site) is sufficient to competitively inhibit normal channel activation. Because the NDNMBs do not block voltage-gated sodium channels on the skeletal muscle membrane, direct electrical stimulation with a current sufficient to cause membrane depolarization will still elicit a muscular contraction. The NDNMBs are classified by duration of action as ultra-short, short, intermediate, and long. They are also classified by chemical structure as either a synthetic benzyloquinolinium or an aminosteroid (**Table 66–1**).

The NDNMBs also block nACh receptors on the prejunctional nerve terminal and inhibit ACh-stimulated ACh production and release by blocking local autoregulation of available ACh.<sup>98</sup> This effect reduces the available pool of ACh and augments the extent of neuromuscular block.<sup>11</sup>

### PHARMACOKINETICS

The NMBs are highly water soluble and relatively insoluble in lipids. Thus, they are rapidly distributed in the extracellular space and very slowly permeate lipid membranes such as the gut, placenta, and the normal blood–brain

**FIGURE 66-1.** Excitation–contraction coupling in skeletal muscle. At the neuromuscular junction, acetylcholine (2) released from the presynaptic nerve terminal crosses the 50-nm synaptic cleft to reach the nicotinic acetylcholine (nACh) receptor (1). When an agonist simultaneously occupies both receptor sites, this ion channel opens, becoming nonselectively permeable to monovalent cations, resulting in an influx of  $\text{Na}^+$  and an efflux of  $\text{K}^+$ . This produces local membrane depolarization (endplate potential), which in turn opens voltage-gated  $\text{Na}^+$  channels (3). A depolarization of sufficient amplitude generates a propagated muscle action potential (MAP), which is conducted along the muscle membrane and down the transverse (T) tubules (4). In the T tubule, the MAP triggers a voltage-gated calcium channel (7) and the dihydropyridine receptor (5), which then activates the skeletal muscle ryanodine receptor/channel (6). To allow the fastest activation of mammalian skeletal muscle, calcium diffusion is not necessary for activation of the type 1 ryanodine receptor (RyR-1); instead, there is a direct electrical (protein) linkage between the dihydropyridine (DHP) receptor and the ryanodine receptor.<sup>33</sup> Active ATPase-driven calcium reuptake terminates muscle contraction. Many factors influence the activity of the RyR-1 channel, including  $\text{Ca}^{2+}$ ,  $\text{Mg}^{2+}$ , and xenobiotics such as inhalational anesthetics that accelerate  $\text{Ca}^{2+}$  release in persons susceptible to malignant hyperthermia. Antagonists such as conotoxin are red and agonists such as nicotine are green.

barrier. For this reason, they are devoid of central nervous system (CNS) effects. Because these drugs distribute in the extracellular space, their dose is based on ideal body mass. Thus, in obese patients, estimation of drug requirement based on total body mass results in the administration of an excessive dose.

The speed of onset of an NMB is inversely related to its molar potency (ie,  $\text{ED}_{95}$  expressed as moles NMB drug per kilogram body weight).<sup>59,60</sup> Stated differently, the greater the affinity of the NDNMB for the ACh receptor, the fewer molecules per kilogram of tissue are required to produce a given degree of ACh receptor occupancy. Atracurium is the only NDNMB that does not

follow this generalization because it is a mixture of 10 isomers, each having a unique receptor affinity (cisatracurium consists of only one isomer).

In general, small, fast-contracting muscles such as the extraocular muscles are more susceptible to neuromuscular block than are larger, slower muscles such as the diaphragm. This is the so-called *respiratory-sparing effect*. After an intravenous (IV) bolus of NDNMB, paralysis of the diaphragm is coincident with paralysis of laryngeal muscles because high tissue perfusion results in rapid drug distribution and diffusion into the NMJ of all tissues.<sup>25</sup> However, recovery from NMB is fastest for the diaphragm and intercostal muscles; intermediate for the large muscles of the trunk and extremities; and slowest for the adductor pollicis, larynx, pharynx, and extraocular muscles.<sup>25</sup>

## COMPLICATIONS OF NEUROMUSCULAR BLOCKERS

Complications associated with the use of NMBs include (1) problems associated with the care of a paralyzed patient (eg, inability to secure a definitive airway, undetected hypoventilation resulting from ventilator or airway problems, impaired ability to monitor neurologic function, unintentional patient awareness, peripheral nerve injury, deep vein thrombosis, and skin breakdown); (2) immediate side effects; and (3) delayed effects occurring after prolonged drug exposure.<sup>85,86</sup>

### Consciousness

Even though NMBs do not affect consciousness, misconceptions about these drugs persist.<sup>73</sup> The pupillary light reflex, an important indicator of midbrain function, is preserved in healthy subjects who receive NDNMBs because pupillary function is mediated by muscarinic cholinergic receptors, for which the NMBs have no affinity.<sup>42</sup>

### Histamine Release

Neuromuscular blockers may elicit dose- and injection rate-related nonimmunologic (non-IgE-mediated) histamine release from tissue mast cells by an uncertain mechanism (Table 66-1). The NMBs most commonly associated with histamine release are atracurium and succinylcholine.<sup>81</sup>

### Anaphylaxis

Anaphylactic reactions are rare, with an incidence of 1 in 3,500 to 1 in 20,000 and up to 60% are related to NMBs.<sup>81</sup> Part of this variability is due to difficulty in determining the exact exposures in the operative setting when numerous xenobiotics and, blood products NMBs are administered simultaneously. Rocuronium and succinylcholine are the two most cited offenders among all NMB-associated anaphylaxis.<sup>66,115</sup>

### Control of Respiration

At subparalyzing doses, NDNMBs blunt the peripheral hypoxic ventilatory response (HVR) but not the ventilatory response to hypercapnia.<sup>30,31</sup> Hypoxic ventilatory response returns to normal when chemical paralysis is completely reversed. Hypoventilation resulting from blunting of the HVR, especially when combined with the residual effects of other xenobiotics used during anesthesia such as opioids or inhalational anesthetics, causes delayed respiratory failure after general anesthesia.

### Autonomic Side Effects

Nicotinic ACh receptors found in autonomic ganglia, similar to those at the NMJ, are pentamers composed of  $\alpha$  and  $\beta$  subunits. In general, they are less susceptible to block by NMBs.<sup>74</sup> There is one notable exception. At the same dose that produces neuromuscular block, tubocurarine also blocks nACh receptors at the parasympathetic ganglia, causing tachycardia, and at the sympathetic ganglia, blunting the sympathetic response.<sup>102</sup> In combination with tubocurarine-related histamine release, the sympathetic block causes significant hypotension, particularly in patients with heart failure or hypovolemia.<sup>11</sup> This is an important reason why tubocurarine is no longer available in the United States.

The muscarinic receptors ( $M_1$ – $M_5$ ) are members of the seven-transmembrane G-protein-coupled receptor family. As such, they are structurally unique and mostly unaffected by NMBs. At clinical doses, pancuronium

**TABLE 66-1** Pharmacology of Selected Neuromuscular Blockers

Generic Name	Class	Duration	Initial Dose (mg/kg) <sup>a,b</sup>	Onset (min) <sup>c</sup>	Clinical Duration (min) <sup>d</sup>
Succinylcholine	Depolarizer	Ultrashort	0.6–1	1–1.5	3–7
Atracurium	Nondepolarizer, benzylisoquinolinium	Intermediate	0.4	2–4	20–40
Cisatracurium		Intermediate	0.1	2–4	20–40
Pancuronium	Nondepolarizer, aminosteroid	Long	0.1	3–6	60–90
Rocuronium		Intermediate	0.6	1.5–3	30–40
Vecuronium		Intermediate	0.1	2–4	20–40
	Renal Excretion (%) <sup>e</sup>	Biliary Excretion (%) <sup>f</sup>	Metabolite	Histamine Release	Effect on Heart Rate
Succinylcholine	<10	Minimal	Succinic acid	Minimal	Bradycardia (rare)
Atracurium	5–10	Minimal	Laudanosine	Minimal	No
Cisatracurium	10–20	Minimal	Laudanosine	No	No
Pancuronium	40–60	10–20	3-Desacetyl-pancuronium <sup>g</sup>	No	Tachycardia
Rocuronium	10–20	50–70	No	No	Tachycardia at high dose
Vecuronium	15–25	40–70	3-Desacetyl-vecuronium <sup>h</sup>	No	No

<sup>a</sup>Cisatracurium is labeled as milligram of base per milliliter. Other drugs are labeled and packaged as milligram of salt per milliliter. <sup>b</sup>Typical initial dose is approximately  $2 \times ED_{50}$  (mg/kg). <sup>c</sup>Onset is time from bolus to 100% block. <sup>d</sup>Clinical duration is time from drug injection until 25% recovery of single twitch height. <sup>e</sup>Percent renal excretion in the first 24 h of unchanged drug; if high, associated with prolongation of clinical effect. <sup>f</sup>Percent biliary excretion in first 24 h of unchanged drug; if high, associated with prolongation of clinical effect. <sup>g</sup>Active metabolite.

elicits dose- and injection rate-related increases in heart rate, blood pressure, cardiac output, and sympathetic tone.<sup>26,103,110</sup> This is attributed to a selective block of parasympathetic transmission at the cardiac muscarinic receptors, an atropine-like effect,<sup>103</sup> block of presynaptic (feedback) muscarinic receptors at sympathetic nerve terminals, and perhaps an indirect norepinephrine-releasing effect at postganglionic fibers.<sup>26</sup>

Dysrhythmias such as bradycardia, junctional rhythms, ventricular dysrhythmias, and asystole occur rarely after use of succinylcholine. Dysrhythmias most likely result from stimulation of the cardiac muscarinic receptors and can be prevented by pretreatment with 15 to 20 mcg/kg of IV atropine. Bradycardia is uncommon, but it may be especially severe in children during anesthetic induction when large or repeated doses of succinylcholine are given.

### INTERACTIONS OF NEUROMUSCULAR BLOCKERS WITH OTHER XENOBIOTICS AND PATHOLOGIC CONDITIONS

The NMBs have significant interactions with many xenobiotics and coexisting medical conditions. These interactions affect the neuromuscular system at any level from the CNS to the muscle itself (Table 66-2).<sup>94,114</sup>

In most neuromuscular diseases, such as muscular dystrophy, Guillain-Barré syndrome, myasthenia gravis, and postpolio syndrome, the sensitivity to NDNMB is increased, so a small dose of NMB produces a profound degree of block.<sup>2,13,45</sup> However, persons with myasthenia gravis typically demonstrate resistance to the effects of succinylcholine.<sup>2,13</sup> In individuals with myopathy in whom the specific cause is not yet known, succinylcholine should be avoided because of the possible sensitivity to malignant hyperthermia (MH), hyperkalemia, or rhabdomyolysis. In place of succinylcholine, a short-acting NDNMB can be used to lessen the chance of prolonged weakness.

Many pathologic conditions potentiate the duration or intensity of NDNMB, such as respiratory acidosis, hypokalemia, hypocalcemia, hypermagnesemia, hypophosphatemia, hypothermia, shock, and liver or kidney failure.<sup>97</sup> Alternatively, acute sepsis and inflammatory conditions are associated with mild resistance to the effect of NDNMB.<sup>88</sup>

### PHARMACOLOGY OF SUCCINYLCHOLINE

Succinylcholine is a bis-quaternary ammonium ion composed of two molecules of ACh joined end to end at the acetate groups.<sup>28</sup> After a conventional IV induction dose of 1 mg/kg, typical plasma concentrations are approximately 62 mcg/mL.<sup>90</sup>

Succinylcholine is hydrolyzed primarily by plasma cholinesterase (PChE, also known as pseudocholinesterase or butyrylcholinesterase; BChE, EC 3.1.1.8) and to a slight extent by alkaline hydrolysis. Hydrolysis is a two-step reaction; first succinylmonocholine and choline are formed, and then succinic acid and choline are formed. The latter two are normal products of intermediary metabolism. The first reaction is approximately six times faster than the second reaction. Less than 3% of the administered dose is excreted unchanged in the urine.<sup>40</sup> After an IV bolus, the plasma succinylcholine concentration increases abruptly, and there is a rapid onset of NMJ block. Later, the plasma succinylcholine concentration undergoes a rapid decline as a result of drug redistribution to extravascular tissues and hydrolysis in plasma. Finally, succinylcholine leaves the NMJ to reenter the plasma as a result of reversal of the concentration gradient.<sup>39,55</sup>

At an induction dose of 1 mg/kg IV, succinylcholine theoretically increases cerebral blood flow, cortical electrical activity, intracranial pressure (ICP),<sup>61</sup> and intraocular pressure, but the clinical implication is unclear. Most data come from small nonrandomized studies involving ICP, and results are mixed. In addition, there has not been sufficient evidence that supports routine use of NDMBs as a pretreatment for succinylcholine.

### TOXICITY OF SUCCINYLCHOLINE

The important adverse drug reactions associated with succinylcholine include anaphylaxis, prolonged drug effect, hyperkalemia, acute rhabdomyolysis in patients with muscular dystrophy, MH in susceptible patients, masseter spasms or trismus in patients with congenital myopathies, and cardiac dysrhythmias. This is especially relevant for children who present with undiagnosed or a cyclically subtle myopathy.

**TABLE 66–2** Effect of Prior Administration of Xenobiotics on Subsequent Response to Succinylcholine or Nondepolarizing Neuromuscular Blockers

<i>Xenobiotic</i>	<i>Response to Succinylcholine</i>	<i>Response to Nondepolarizer</i>	<i>Comments</i>
Aminoglycosides (eg, amikacin, gentamicin)	Potentiates	Potentiates	Dose-related decrease in presynaptic ACh release. Decrease postjunctional response to ACh. Partially reversible with calcium administration. The ability of neostigmine to reverse this effect is unpredictable.
Anticholinesterase, peripherally acting: neostigmine, edrophonium	Prolongs succinylcholine (except edrophonium)	No effect	Neostigmine, pyridostigmine, and physostigmine inhibit plasma AChE and prolong succinylcholine block. Edrophonium does not inhibit plasma cholinesterase.
Anticholinesterase, centrally acting: donepezil	Potentiates	No effect	Inhibits AChE (junctional $\gg$ plasma); long half-life (70 h).
$\beta$ -Adrenergic antagonist: propranolol	Potentiates in cats, effects in humans uncertain	Potentiates	When given alone, unmasks myasthenic syndrome. Blocks ACh binding at postsynaptic membrane. Reversal of block with neostigmine causes severe bradycardia.
$\beta$ -Adrenergic antagonist: esmolol	? Mild prolongation	Slows onset of rocuronium	Competes for PChE or red blood cell cholinesterase.
Botulinum toxin	?	Early potentiation, delayed resistance	Subclinical systemic denervation leads to hypersensitivity.
Calcium channel blockers	Potentiates	Potentiates	Causes calcium channel block pre- and postjunctionally. Verapamil has local cholinesterase inhibitor effect on nerve. Inhibits block reversal of NDNMBs by cholinesterase inhibitors.
Carbamazepine	?	Inhibits, shortened duration	Chronic therapy causes resistance to NDNMB, except for atracurium.
Cardioactive steroids	More prone to cardiac dysrhythmias	Pancuronium increases catecholamines and causes dysrhythmias	
Dantrolene	?	Potentiates	Blocks excitation–contraction coupling by blocking ryanodine receptor channel in sarcoplasmic reticulum of skeletal muscle.
Furosemide <10 mcg/kg 1–4 mg/kg	Potentiates or inhibits	Potentiates or inhibits	Biphasic dose response in cats; protein kinase inhibition at low doses and phosphodiesterase inhibition at high doses. Diuretic-related hypokalemia potentiates pancuronium in cats.
Glucocorticoids	?	Inhibits	Chronic steroid use induces resistance to pancuronium and decrease plasma cholinesterase activity by 50%. Steroids $\pm$ NDNMB associated with myopathies.
Inhalational anesthetics: isoflurane	Potentiates	Potentiates	Decrease CNS activity and potentiates NMB in anesthetic doses: dependent fashion (postsynaptic and muscle effects). Halothane causes less muscle relaxation than isoflurane.
Lidocaine	Potentiates	Low dose potentiates block; high dose inhibits nerve terminals and blocks ACh binding site at postsynaptic membrane.	The fast Na <sup>+</sup> channel blockers decrease action potential propagation, ACh release, postsynaptic membrane sensitivity, and muscle excitability. Weak inhibitor of PChE. This potentially is observed with all local anesthetic, but practically lidocaine one that is intravenously administered.
Lithium	Prolongs onset and duration	Prolongs effect of pancuronium	Inhibits synthesis and release of ACh. Lithium alone causes myasthenic reaction.
Magnesium	Potentiates; blocks fasciculations	Potentiates or prolongs blocks	Decreases prejunctional ACh release, postjunctional membrane sensitivity, and muscle excitability.
NDNMB: pancuronium, vecuronium, rocuronium	“Precurarization” with NDNMB shortens the onset and decreases side effects of succinylcholine; pancuronium increases block duration.	Chronic NDNMB induces resistance to their effect; mixing different NDNMBs causes greater than additive effects, especially combining pancuronium with tubocurarine or metocurine.	Prior NDNMB inhibits plasma PChE and prolongs mivacurium and succinylcholine block. Rank order: pancuronium > vecuronium > atracurium. Heterozygote for atypical PChE develops phase II block when given succinylcholine and pancuronium.
Organic phosphorus compounds	Potentiates	?	Irreversible PChE inhibitor. Which totally blocks enzyme activity.
Phenelzine (MAOI)	Prolongs	?	Decreases PChE activity.
Phenytoin	?	Resistant, shortened duration	Acutely, potentiates NDNMB paralysis. With chronic use (except for atracurium), phenytoin induces resistance to NDNMB and increases metabolism. This increases the initial dose and decreases the repeat dosing interval.
Polypeptide antibiotics: polymyxin	Potentiates	Potentiates	Causes severe weakness and induces postsynaptic neuromuscular block. Neostigmine increases block.

(Continued)

**TABLE 66–2** Effect of Prior Administration of Xenobiotics on Subsequent Response to Succinylcholine or Nondepolarizing Neuromuscular Blockers (Continued)

Xenobiotic	Response to Succinylcholine	Response to Nondepolarizer	Comments
Succinylcholine	Small initial dose of succinylcholine are used to limit muscular fasciculations.	Pancuronium and vecuronium slightly prolonged by prior succinylcholine.	
Theophylline		Inhibits	The combination of pancuronium and theophylline increases cardiac dysrhythmias.
Cyclic antidepressants (CA)			The combination of pancuronium and CA cause cardiac dysrhythmias due to sympathetic effects.

ACh = acetylcholine; AChE = acetylcholinesterase; CNS = central nervous system; MAOI = monoamine oxidase inhibitor; NDNMB = nondepolarizing neuromuscular blocker; NMB = neuromuscular blocker; NMJ = neuromuscular junction; PChE = plasma cholinesterase.

## PROLONGED EFFECT

The effects of succinylcholine last for several hours if metabolism is significantly slowed because of decreased PChE concentration, abnormal PChE activity (genetic variant or drug inhibition), or a phase II block.<sup>20</sup> Acquired PChE deficiency is caused by hepatic disease, malnutrition, plasmapheresis, or pregnancy.<sup>20</sup> Inactivation of PChE results from fluoride poisoning, organic phosphorus compounds, or carbamates. However, even with only 20% to 30% of normal PChE activity, the clinical duration of succinylcholine is less than doubled.<sup>35</sup>

Many genetic variants of PChE are known. The most common atypical PChE (atypical type, homozygous; incidence 1:3,000) can be assayed by its resistance to inhibition by the local anesthetic dibucaine.<sup>95</sup> A history of uneventful exposure to succinylcholine *excludes* the possibility of atypical PChE except in the case of hepatic transplantation. Dibucaine inhibits the ability of normal PChE to hydrolyze benzoylcholine by more than 70% (ie, dibucaine number >70), heterozygous atypical PChE by 40% to 60%, and homozygous atypical PChE by 30% or less. Dibucaine number is an effective method of identifying patients at increased risk for prolonged neuromuscular blockade from succinylcholine. The lower the number, the greater likelihood there will be prolonged neuromuscular blockade from atypical reasonable PChE activity. Fresh-frozen plasma or PChE concentrates are infused to hasten recovery in the case of a genetic enzyme defect or an acquired PChE deficiency. However, to avoid the risks of transfusion, it is best to provide supportive care, simply keep the patient sedated, intubated, and ventilated until the drug is metabolized. In this setting, spontaneous reversal usually occurs within 3 to 4 hours, although in rare cases, full recovery requires up to 12 hours.<sup>20</sup> When the duration of succinylcholine is very prolonged, blood samples should be drawn for measurement of PChE concentration and activity.

Prolonged nondepolarizing block also occurs when unusually large IV doses of succinylcholine (3–5 mg/kg) are given over minutes.<sup>68</sup> This is called *phase II block*, and it can be partially reversed by neostigmine.

Interestingly, pseudocholinesterase is also involved in metabolism of cocaine. Plasma cholinesterase catalyzes the hydrolysis of cocaine, and low PChE concentrations are associated with increased risk of cocaine toxicity.<sup>24,51,92</sup> There have been few small studies demonstrating that exogenously administered PChE degrades cocaine more quickly and is theoretically able to treat cocaine-induced toxicity.<sup>16,75,78,105</sup>

## HYPERKALEMIA

Succinylcholine 1 mg/kg IV typically causes a transient serum K<sup>+</sup> concentration increase of approximately 0.5 mEq/L within minutes of administration both in normal individuals and in persons with kidney failure. The acute

hyperkalemic response to succinylcholine is greatly exaggerated with coexisting myopathy or proliferation of extrajunctional muscle ACh receptors. However, the mortality rate is highest (approaching 30%) when rhabdomyolysis is present.<sup>44</sup> Severe, precipitous, potentially life-threatening hyperkalemia also occurs after succinylcholine administration in several conditions associated with proliferation of ACh receptors. These conditions include denervation caused by head or spinal cord injury, stroke, neuropathy, prolonged use of NDNMBs because of muscle pathology direct trauma, crush or compartment syndrome, or muscular dystrophy; critical illness due to hemorrhagic shock, neuropathy, myopathy, or prolonged immobility; thermal burn or cold injury; and sepsis lasting several days. After a neurologic injury, susceptibility to hyperkalemia begins within 4 to 7 days and persist for an extended period of time. In patients who have been in the intensive care unit (ICU) for more than 1 week, succinylcholine should be avoided altogether because of the risk of hyperkalemic cardiac arrest, which is associated with a mortality rate of at least 19%.<sup>7,10,44</sup> Severe hyperkalemia can be mitigated, but not prevented, by a small dose of an NDNMB (10%–30% ED<sub>95</sub> of the NDNMB or 5%–15% of the intubation dose). This dose should be sufficient to prevent succinylcholine-induced muscle fasciculations.<sup>106</sup>

Severe or even fatal hyperkalemia is reported in a few patients who received succinylcholine immediately after exsanguinating hemorrhage or massive trauma. The mechanism for this condition differs from that after neurologic injury because of inadequate time for proliferation of extrajunctional ACh receptors. Succinic acid, a tricarboxylic acid cycle intermediate that is also a metabolite of succinylcholine, facilitates activation of voltage-gated sodium channels in a dose-dependent fashion, increasing skeletal muscle excitability.<sup>46</sup> In hemorrhagic shock, accumulation of succinic acid as a result of cell breakdown and anaerobic metabolism possibly augments the potassium-releasing effect of succinylcholine.

## RHABDOMYOLYSIS

Severe hyperkalemia rarely occurs in the absence of a clinical history that readily discloses an obvious risk factor, with one important exception. Acute or delayed onset of rhabdomyolysis, hyperkalemia, ventricular dysrhythmias, cardiac arrest, and death are reported in apparently healthy children who were subsequently found to have an undiagnosed myopathy.<sup>64</sup> Since March 1995, a black box warning on the package insert has stated that succinylcholine should be avoided in elective surgery in children, particularly in children younger than 8 years of age, because of the risk of a previously undiagnosed skeletal myopathy, especially Duchenne muscular dystrophy. Sudden cardiac arrest occurring immediately after succinylcholine administration should always be assumed to be caused by hyperkalemia. If fever, muscle rigidity, and elevated lactate concentration or metabolic and respiratory acidosis are

also present, the presumptive diagnosis of MH should prompt immediate therapy with dantrolene.

## MALIGNANT HYPERTHERMIA

Malignant hyperthermia is a syndrome characterized by extreme skeletal muscle hypermetabolism. It is most often initiated after exposure to an anesthetic that triggers a cycle of abnormal calcium release from the skeletal muscle sarcoplasmic reticulum and can have a variable presentation.<sup>100</sup> Malignant hyperthermia is observed in patients with underlying muscle diseases, such as muscular dystrophy and myotonia. It is also strongly linked to three rare genetic myopathies, central core disease, King Denborough syndrome, and multimimicore disease.

Although MH is linked with rare congenital myopathies, it typically affects individuals who are otherwise healthy.<sup>63</sup> It is inherited as an autosomal dominant trait with variable penetrance.<sup>76</sup> Triggering xenobiotics that can precipitate an attack of MH include succinylcholine and volatile inhalational anesthetics (the prototypical xenobiotic is halothane). In individuals considered MH susceptible, xenobiotics that can be administered safely include NDNMBs, nitrous oxide, propofol, ketamine, etomidate, benzodiazepines, barbiturates, opioids, and local anesthetics.

In human MH, there is a causal association with several unique defects involving a skeletal muscle receptor or regulatory protein, especially defects involving the voltage sensitive calcium release channel found in skeletal muscle; the type 1 ryanodine receptor (or RYR1, chromosome 19q13.1). Mutations of the RYR1 receptor are detected in 50% to 70% of patients with MH, and more than 200 different mutations are described<sup>12,50</sup> (Fig. 66–1). The structurally distinct type 2 ryanodine receptor (RYR2) is the primary type expressed in cardiac muscle, and this could explain why the myocardium is relatively spared in the early phase of MH (with the exception of an acute hyperdynamic response).<sup>99</sup> The existence of multiple mutations across multiple alleles means that genetic testing is not likely to prove useful in detecting all individuals who are MH susceptible or to exclude the risk of MH.

Although the prevalence of a genetic disorder associated with MH is between 1 in 3,000 and 1 in 8,500, the observed incidence of fulminant MH in patients exposed to general anesthesia when triggering anesthetic agents are used is 1 in 62,000 and 1 in 84,000.<sup>93,100</sup> Each year in the United States, there are an estimated 700 cases of MH.<sup>62</sup> Even in those who are MH susceptible after exposure to anesthesia with known triggers, clinical manifestations develop less than half the time. For this reason, a previous uneventful anesthetic exposure does not preclude development of MH on a subsequent exposure.<sup>4</sup> In the operating room, MH most often presents abruptly soon after initial exposure to a triggering anesthetic, although the onset of MH may be delayed several hours during the anesthesia<sup>84</sup> or occur as long as 12 hours after surgery. In addition, recrudescence of MH occurs within 24 to 36 hours after an initial episode in up to 25% of patients.

The immediate systemic manifestations of MH result from extreme skeletal muscle hypermetabolism. The uncontrolled release of calcium from the terminal cisternae of the sarcoplasmic reticulum causes skeletal muscle contraction. Although generalized muscular rigidity is a specific sign of MH, it is only observed in 40%; masseter spasm is a finding observed in 27% of MH patients.<sup>63</sup> Futile calcium cycling by sarcoplasmic  $\text{Ca}^{2+}$ -ATPase rapidly depletes intracellular adenosine triphosphate and leads to anaerobic metabolism. Clinically, MH presents as skeletal muscle hypermetabolism with an increase in cardiac output and sinus tachycardia; increased  $\text{CO}_2$  production causes hypercapnia; increased  $\text{O}_2$  consumption can cause: mixed venous  $\text{O}_2$  desaturation (below the normal value of 75%), arterial hypoxemia, anaerobic metabolism, metabolic acidosis, elevated lactate concentration, cyanosis, and skin mottling; and excess heat production that leads to a rapid increase in core temperature with hyperthermia.<sup>47</sup> Other clinical findings include tachycardia, cardiac dysrhythmias, hyperkalemia, rhabdomyolysis, and disseminated intravascular coagulopathy.

The earliest signs of MH include an early and rapid increase in  $\text{CO}_2$  production, causing an increase in arterial, venous, and end-tidal  $\text{CO}_2$ , followed

by or associated with tachycardia; tachypnea; hypertension or labile blood pressure; and skeletal and jaw muscle rigidity. Despite the name of the syndrome, hyperthermia is not a universal finding in MH, and moreover, it may be a late sign.<sup>113</sup> Acute potassium release from skeletal muscle cells produce life-threatening hyperkalemia. Subsequent rhabdomyolysis exacerbates the elevation of potassium by causing acute kidney injury. In late-stage MH, cardiac decompensation results from hyperkalemia, heart failure, vascular collapse, or myocardial ischemia (especially with coexisting coronary artery disease).

The differential diagnosis of MH includes antipsychotic malignant syndrome, propofol infusion syndrome, serotonin toxicity, thyroid storm, pheochromocytoma, baclofen withdrawal, tetanus, meningitis, poisoning by salicylates, amphetamines, cocaine, or antimuscarinics, unintentional intraoperative hyperthermia, environmental heat stroke, and transfusion reactions (Chap. 29). Of note, early septic shock is also associated with hypermetabolism, increased cardiac output, and fever; however, in contrast to MH, early septic shock is associated with an elevated mixed venous  $\text{O}_2$  saturation (typically >75%).

Rarely, MH is triggered by severe exercise in a hot climate, IV potassium (which depolarizes the muscle membrane), antipsychotics, or infection.<sup>23,54</sup> There is of a possible link between MH and exertional heat illness (EHI) or exertional rhabdomyolysis (eg, a patient with exertional rhabdomyolysis who at a later time develops MH).<sup>14,15</sup> There is no evidence that patients with heat-related illness have MH, even if, on occasion, some patients appear to improve following many interventions including dantrolene. Furthermore, a presumptive diagnosis of heat-related illness does not necessarily exclude the diagnosis of MH, and one must maintain clinical suspicion for possible MH, especially because environmental factors can be a sole precipitating factor in the absence of anesthetics.<sup>50</sup>

One theory of the pathogenesis of MH suggests that MH-triggering xenobiotics interact with an abnormal RYR1 channel, causing it to stay in a prolonged open state and leading to rapid efflux of calcium from the skeletal muscle sarcoplasmic reticulum into the myoplasm. Succinylcholine prolongs muscle depolarization, leading to an elevated myoplasmic calcium concentration. This action initiates the voltage sensitive calcium release channel of the sarcoplasmic reticulum.<sup>44</sup> However, not all cases of MH can be explained by an RYR1 mutation.<sup>36</sup> For example, MH is also associated with defects in the CACNA1S protein that encodes a subunit of the skeletal muscle L-type calcium channel (known as the dihydropyridine receptor) and possibly with certain disorders of sodium channels (observed in the myotonic disorders).<sup>36,83</sup>

The antidote for MH is dantrolene, and the key aspects of MH therapy are rapid initial diagnosis, discontinuation of triggering anesthetics, active cooling, and immediate therapy with dantrolene (within minutes). By partially blocking calcium release from skeletal muscle sarcoplasmic reticulum, dantrolene rapidly reverses the signs and symptoms of hypermetabolism (Antidotes in Depth: A24). The precise mechanism of dantrolene activity is not known, but it modulates several calcium pathways.<sup>50</sup> Before the introduction of dantrolene, the mortality rate of MH was 64%.<sup>62</sup> When patients with acute MH are treated immediately with dantrolene, removal of triggering agents, and supportive measures (volume resuscitation, active cooling, control of hyperkalemia), the mortality rate is less than 5%.<sup>62</sup> Factors associated with an increase in mortality rate are a muscular body habitus, development of disseminated intravascular coagulation, and a longer duration of anesthesia before the peak in end-tidal carbon dioxide.<sup>62</sup> Even if administration is delayed for hours or days, dantrolene still improves survival after an acute episode of MH. Patients with significant dysrhythmias can be treated with standard antidysrhythmics; however, calcium channel blockers must *not* be given with dantrolene because they precipitate hyperkalemia and severe hypotension<sup>101</sup> (Table 66–3).

Persons who have experienced a possible episode of MH or have a positive family history should be referred to the Malignant Hyperthermia Registry and may be considered for muscle biopsy or genetic sequencing of the *RYR1* gene. The muscle biopsy is considered to be the gold standard, but patients must

TABLE 66–3 Therapy for Malignant Hyperthermia (MH)<sup>a</sup>**Acute Phase Treatment of MH**

1. Call for help. Immediately summon experienced help when MH is suspected. Call MH hotline, 800-644-9737.
2. Discontinue triggers: volatile inhalational anesthetics and succinylcholine.
3. Hyperventilate with 100% O<sub>2</sub> with flow  $\geq$  10 L/min and monitor end-tidal CO<sub>2</sub>.
4. Halt procedure as soon as possible and continue sedation and analgesia with nontriggering agents: opioids and benzodiazepines.
5. Administer dantrolene, initial IV bolus of 2.5 mg/kg followed by additional boluses (every 15 minutes), until signs of MH are controlled (tachycardia, rigidity, increased end-tidal CO<sub>2</sub>, hyperthermia). Typically, a total dose of 10 mg/kg IV controls symptoms, but occasionally 30 mg/kg is required.
  - Dantrium/Revonto:<sup>b</sup> Each 20-mg vial is reconstituted by adding 60 mL of sterile water.
  - Ryanodex: Each 250-mg vial is reconstituted by adding 5 mL of sterile water.
6. Monitor core temperature closely (tympanic membrane, nasopharynx, esophagus, rectal, or pulmonary artery) and actively cool the patient with core temperature  $>39^{\circ}\text{C}$  (immersion in ice-water slurry is preferred, cooling by peritoneal or gastric lavage, surface cool or surface cooling techniques are also reasonable).
7. Hyperkalemia is common and should be treated aggressively with hyperventilation, IV calcium gluconate (30 mg/kg up to 3 g) or chloride (10 mg/kg up to 1 g), sodium bicarbonate, IV dextrose, and insulin. Hypokalemia should be treated with caution because of the potential for rhabdomyolysis induced hyperkalemia.<sup>c</sup>
8. Sodium bicarbonate. 1–2 mEq/kg (up to 50 mEq/kg) is reasonable if blood gas values have not yet been obtained or if clinically indicated.
9. Monitor continuously: ECG, pulse oximetry, end-tidal CO<sub>2</sub>, core temperature, CVP, urine output; and serially measure: arterial and mixed venous blood gases, metabolic profile (especially potassium), calcium, CBC, coagulation indices, and creatine kinase.
10. Dysrhythmias usually respond to dantrolene, cooling, and correction of acidosis and hyperkalemia. If dysrhythmias persist or are life threatening, standard antidysrhythmics are indicated, including amiodarone, magnesium, and procainamide.
  - Calcium channel blockers (verapamil or diltiazem) should not be used to treat dysrhythmias because they may cause hyperkalemia and cardiac arrest.
11. Ensure adequate urine output by restoration of intravascular volume followed by administration of mannitol or furosemide. Insert a urinary bladder catheter and consider central venous or pulmonary artery catheterization.
12. For emergency consultation, refer to the MHAUS at <http://www.mhaus.org/>. Call the MH Emergency Hotline:
  - Inside the United States or Canada, call 800-MH-HYPER (800-644-9737).
  - Outside the United States and Canada, call 001 315-464-7079.

**Postacute Phase Treatment of MH**

1. Observe the patient in an ICU setting for at least 24 h because recrudescence of MH occurs in 25% of cases, particularly after a fulminant case resistant to treatment. Observe for pulmonary edema, kidney failure, and compartment syndrome.
2. Administer dantrolene 1 mg/kg IV q4–6h or 0.25 mg/kg/h by infusion for at least 24 h after the episode.
3. Serially monitor arterial blood gases, metabolic profile, CBC, creatine kinase, calcium, phosphorus, coagulation indices, urine and serum myoglobin, and core body temperature until they return to normal values.
4. Counsel the patient and family regarding MH and further precautions.
  - For nonemergency patient referrals, contact the MHAUS at 800-644-9737, 1 North Main Street, PO Box 1069, Sherburne, NY 13460.
  - Report patients who have had an acute MH episode to the North American MH Registry of MHAUS at 888-274-7899.
  - Alert family members to the possible dangers of MH and anesthesia.
5. Recommend an MH medical identification tag or bracelet for the patient, which should be worn at all times.

<sup>a</sup>The guidelines may not apply to every patient and of necessity must be altered according to specific patient needs. <sup>b</sup>There are two formulation of dantrolene, Dantrium/Revonto and Ryanodex. <sup>c</sup>Sudden unexpected cardiac arrest in children: Children younger than about 10 years of age who experience sudden cardiac arrest after succinylcholine administration in the absence of hypoxemia and anesthetic overdose should be treated for acute hyperkalemia first. In this situation, calcium chloride should be administered along with means to reduce serum potassium. They should be presumed to have subclinical muscular dystrophy, and a pediatric neurologist should be consulted.

CBC = complete blood count; CVP = central venous pressure; ECG = electrocardiogram; ICU = intensive care unit; IV = intravenous; MHAUS = Malignant Hyperthermia Association of the United States.

Modified with permission from Malignant Hyperthermia Association of the United States (mhaus.org).

travel to an authorized testing center for biopsy. There are currently four centers in the United States and one center in Canada. A fresh tissue specimen is placed in a tissue bath perfused with Krebs solution, and halothane or caffeine is added. According to the North America Malignant Hyperthermia Group, an MH-susceptible individual is one who demonstrates a positive muscle contraction in response to either halothane or caffeine. On the other hand, genetic testing can be performed. Additional information regarding testing options can be found on the website of the Malignant Hyperthermia Association of the United States ([www.mhaus.org](http://www.mhaus.org)).

**MUSCLE SPASMS**

Masseter muscle rigidity was observed in 0.3% to 1.0% of children when general anesthesia was induced with succinylcholine and halothane (a technique now obsolete) and currently is much less frequently encountered. Masseter muscle rigidity is clinically significant because it will complicate airway management and herald the onset of MH.<sup>91</sup>

When administered to persons genetically predisposed to myotonia, succinylcholine precipitates tonic muscular contractions, ranging from trismus (which prevents orotracheal intubation) to severe generalized myoclonus and chest wall rigidity (which prevent ventilation).<sup>32</sup> Because the myotonic contractions are independent of neural activity, they cannot be aborted by an NDNMB. Usually the contractions are self-limited, but occasionally they will be life threatening if an airway cannot be established and hypoxemia ensues.

**PHARMACOLOGY OF NONDEPOLARIZING NEUROMUSCULAR BLOCKERS**

Table 66–1 summarizes the pharmacology and toxicity of the NDNMBs.<sup>53,79,80,86</sup> Whereas atracurium is composed of 10 different isomers, each having its unique pharmacokinetic and pharmacodynamic profile, cisatracurium contains only the 1R-*cis* and 1'R-*cis* isomers. Both atracurium and cisatracurium exhibit organ-independent elimination and are rapidly metabolized

by spontaneous (nonenzymatic) temperature- and pH-dependent Hoffmann degradation and, to a lesser extent, by ester hydrolysis. The latter is catalyzed by nonspecific plasma esterases distinct from the PChE that hydrolyzes succinylcholine. In addition, significant drug metabolism or elimination occurs in the liver and kidney.<sup>34</sup>

**TOXICITY OF NONDEPOLARIZING NEUROMUSCULAR BLOCKERS**

The most important toxic effects of the NDNMBs are accumulation of laudanosine and persistent weakness. In general, limiting the drug dose and monitoring the drug effect with a portable nerve stimulator reduce the incidence of prolonged weakness.

**Laudanosine**

Metabolism of atracurium and cisatracurium generates laudanosine, which crosses the blood–brain and placental barriers and may cause neuroexcitation but lacks any neuromuscular blocking activity.<sup>29</sup> Metabolism of each atracurium molecule generates one molecule of laudanosine.<sup>89</sup> Cisatracurium is an improvement over atracurium because it produces one-third as much laudanosine (and is three times more potent).<sup>38,58</sup>

In the CNS, laudanosine has an inhibitory effect at the  $\gamma$ -aminobutyric acid, nACh, and opioid receptors. At high serum concentrations in experimental animals, laudanosine causes dose-related neuroexcitation, myoclonic activity (>14 mcg/mL), and generalized seizures (>17 mcg/mL).<sup>17,38</sup> In humans, the toxic serum laudanosine concentration is unknown, and seizures directly attributable to atracurium are not reported even after prolonged infusion in the ICU.<sup>38,117</sup> In ICU patients who received a 72-hour infusion of atracurium (1 mg/kg/h), the highest serum laudanosine concentrations (10–20 mcg/mL) were observed in patients with impaired glomerular filtration rate.<sup>69</sup> Laudanosine is excreted primarily in the bile, and its elimination is prolonged in patients with liver disease, biliary obstruction, and kidney disease.<sup>96</sup>

**Persistent Weakness Associated with Nondepolarizing Neuromuscular Blockers**

Short-term blockade with a NDNMB usually resolves promptly upon discontinuation. When an NDNMB is administered for more than 48 hours, there is a risk that weakness will persist longer than anticipated based on the kinetics of drug elimination. In addition, critical illness is associated with dysfunction of the peripheral nerve, NMJ, and muscle (Table 66–4). For instance, in the ICU, persistent weakness is observed in 68% to 100% of patients with sepsis or multiorgan failure<sup>22,37,112</sup> and in 20% to 30% of patients who receive NDNMB for only 48 to 72 hours.<sup>71</sup> Persistent weakness is multifactorial and associated with illness severity; sepsis; acute respiratory distress syndrome; multiorgan failure; hyperglycemia; NDNMB; use of systemic corticosteroids;

muscle injury; thermal injury, and electrolyte, endocrine, and nutritional disorders.<sup>21,27,49,70</sup> Many xenobiotics given to patients in the ICU can cause weakness by themselves or potentiate the effects of NDNMB.<sup>52,94</sup> Progressive weakness and acute respiratory failure are even described after discharge from the ICU and will be life threatening if not immediately recognized.<sup>65</sup> Patients who develop persistent weakness have a 2.5- to 3.5-fold increase in ICU mortality and ICU stay.<sup>71</sup>

**PHARMACOLOGIC REVERSAL OF NEUROMUSCULAR BLOCKADE**

**Acetylcholinesterase Inhibitors**

Termination of NMB effect initially results from drug redistribution and later from drug elimination, metabolism, or chemical antagonism. Pharmacologic antagonism of a partial NDNMB is achieved by giving a reversal agent that inhibits junctional AChE and thereby increases ACh at the NMJ. This increase in ACh can overcome the competitive inhibition caused by residual NDNMB. The commonly used anti-ChEs are polar molecules that possess a quaternary ammonium (Table 66–5). Neostigmine and pyridostigmine are hydrolyzed by ChE and form short-lived carbamyl complexes (half-life, 15–20 minutes) with the esteratic site of the enzyme.<sup>6</sup> In contrast, edrophonium is not hydrolyzed by ChE; rather, it forms an electrostatic interaction and a hydrogen bond with the cationic site of ChE that is both competitive and reversible. Neostigmine and pyridostigmine, but not edrophonium, inhibit PChE and thus prolong the effects of xenobiotics metabolized by this enzyme, such as succinylcholine.<sup>35</sup>

The most common and troublesome clinical side effect of ChE inhibition is bradycardia, which usually is prevented by coadministration of an antimuscarinic such as atropine.<sup>19</sup> Bradycardias are severe and lead to nodal or idioventricular rhythm, complete heart block, or even asystole.<sup>72</sup> These side effects occur more frequently in patients with preexisting bradycardia and those receiving chronic  $\beta$ -adrenergic antagonist therapy. They are not necessarily prevented by prior administration of atropine.<sup>108</sup> Other problems that result from excess ChE inhibition are hypersalivation, lacrimation, bronchospasm, increased bronchial secretions, abdominal cramping from intestinal hyperperistalsis, and increased bladder tone. After general anesthesia, use of anti-ChE pharmacologic reversal increases the incidence of nausea, vomiting, and abdominal cramps.<sup>57</sup> Because atropine crosses the blood–brain barrier, it may produce central anticholinergic syndrome.

**Sugammadex**

Sugammadex (Bridion) is a selective NDNMB binder that was developed specifically for rapid and complete reversal of neuromuscular blockage induced by rocuronium and vecuronium (Fig. 66–2). Approved by the European Union in 2008 for use, the US Food and Drug Administration initially rejected

TABLE 66–4 Acute Neuromuscular Pathology Associated With Critical Illness or Nondepolarizing Neuromuscular Blockers				
	Critical Illness Polyneuropathy	Residual Neuromuscular Block	Disuse (Cachectic) Myopathy	Critical Illness Myopathy
Sensory	Moderate to severe, distal > proximal	Normal	Normal	Normal
Motor	Symmetric weakness, lower > upper extremity, proximal > distal or diffuse, respiratory failure	Diffuse symmetric weakness, respiratory failure	Diffuse weakness, proximal > distal	Symmetric weakness, proximal > distal or diffuse, respiratory failure
Creatine phosphokinase	Normal	Normal	Normal	Elevated in $\leq$ 50%
Electrodiagnostic studies (EMG, NCV)	Axonal degeneration of motor > sensory, reduced sensory and motor compound action potentials, normal NCV	Fatigue at NMJ assessed by fade on repetitive nerve stimulation	Normal EMG and NCV	Myopathic changes, muscle membrane inexcitability, normal NCV
Muscle biopsy	Denervation atrophy	Normal	Atrophy of type 2 fibers, no myosin loss, no necrosis	Atrophy of type 2 fibers, myosin loss, mild myonecrosis, no inflammatory infiltration

Crosses blood–brain barrier	No	Yes	

sugammadex because of concerns of hypersensitivity and allergic reactions but it was approved in December 2015.

Sugammadex reverses the effect of steroidal NMBs by directly binding to the steroidal NMB at 1:1 ratio to form sugammadex–NMB complex, thus preventing the binding of NMBs to the nicotinic receptors. Although sugammadex can bind to all steroidal NMBs, its affinity is greatest for rocuronium followed by vecuronium and least with pancuronium.<sup>87</sup> Administration of IV sugammadex results in rapid removal of NMB from plasma, which facilitates the movement of NMBs from the NMJ into plasma through a concentration gradient effect, where they bind to any free remaining sugammadex. Thus, sugammadex can reverse any depth of neuromuscular blockade in a dose-dependent fashion. After the sugammadex–NMB complex is formed, it is eliminated through biliary (75%) and renal (25%) clearance and excreted via the urine (65%–97%).<sup>48</sup> In addition, the sugammadex–NMB complex is inert and does not cause any muscarinic effect. There are some concerns over hypersensitivity and allergic reactions, which occurred in 0.3% of healthy volunteers, which delayed its approval in the United States. A particular precaution for sugammadex exists on utilizing women on hormonal

**FIGURE 66-2.** Sugammadex encapsulating a molecule of rocuronium. (Reproduced with permission from Hemmerling TM, Zaouter C, Geldner G, et al. Sugammadex—a short review and clinical recommendations for the cardiac anesthesiologist. *Ann Card Anaesth.* 2010;Sep-Dec;13(3):206-216.)

contraceptives. In vitro studies indicate sugammadex binds to progesterone and decreases the concentration. Administration of sugammadex is considered to be equivalent to missing a dose (or doses) of an oral contraceptive. Therefore, patients must be counseled regarding the use additional non-hormonal or back-up method of contraception for the subsequent 7 days if they received the sugammadex and are receiving hormonal contraceptives.

The doses of sugammadex based on actual body weight are:<sup>1</sup>

- 2 mg/kg for shallow blockade: if spontaneous recovery has been reached up to the reappearance of the second twitch to train-of-four stimulation after rocuronium and vecuronium blockade
- 4 mg/kg for profound blockade: if 1 or 2 posttetanic counts and response to train-of-four stimulation after rocuronium and vecuronium blockade
- 16 mg/kg for immediate reversal: 3 minutes after administration of 1.2 mg/kg of rocuronium. Immediate reversal of vecuronium is unstudied.

Sugammadex is not effective for nonsteroidal NMBS such as mivacurium, atracurium, and cisatracurium. Therefore, if neuromuscular blockade needs to be reestablished after sugammadex, succinylcholine or one of the nonsteroidal neuromuscular blockers should be used. In the meantime, supportive management is continued with establishing a definitive airway and mechanical ventilation.

### CHOICE OF REVERSAL

Choice of reversal between sugammadex versus acetylcholinesterase inhibitor is complex. Although sugammadex has been available in Europe since 2008, experience has been limited in the United States due to availability and cost, largely because of its very recent approval.

Sugammadex offers two major advantages: rapid reversal and lack of cholinergic side effects. Its disadvantages include a lack of affinity for nonsteroidal NDNMB and a variable affinity for steroidal NMB (rocuronium > vecuronium >> pancuronium). Thus, it is unlikely to replace acetylcholinesterase inhibitors completely. In routine anesthesia care, rapid reversal of NDNMB is rarely needed, and the anticholinergic effects are well tolerated when administered with an antimuscarinic. However, there are clearly situations when rapid reversal of an NDNMB with sugammadex can be beneficial such as difficult airway management, brief surgical procedures that require deep neuromuscular blockade, patients with cardiac comorbidities who do not tolerate dysrhythmias from AChE inhibition, and pediatric patients in whom neuromuscular blockade have been avoided because of unknown myopathy.

## DIAGNOSTIC TESTING

Quantitative methods for analysis of blood and tissue NDNMB and metabolite concentrations using high-performance liquid chromatography and mass spectrometry are described.<sup>56,104</sup>

Succinylcholine and succinylmonocholine can be assayed by gas chromatography and mass spectrometry in blood, urine, or the site of intramuscular injection.<sup>90,107</sup> Less than 3% of administered succinylcholine and 10% of its metabolite succinylmonocholine are excreted in the urine. However, both the parent drug and the metabolite undergo spontaneous hydrolysis, especially in alkaline conditions.<sup>111</sup> Historically, detection of succinylcholine was difficult because of its rapid hydrolysis. However, techniques for detecting this parent compound in tissues even after embalming are described.<sup>41</sup> Because succinic acid is also a product of normal intermediary metabolism, assay of this metabolite is not useful for positive identification of prior succinylcholine exposure.<sup>82</sup> Surprisingly, the presence of succinylmonocholine in forensic samples also cannot prove prior exposure to succinylcholine. Succinylmonocholine in concentrations of 0.01 to 0.20 mcg/g has been detected in tissues of six autopsy cases with no history of succinylcholine exposure.<sup>67</sup>

## SUMMARY

- Succinylcholine is the only DNMB in current clinical use. Its immediate adverse effects include dose- and rate-related histamine release and modulation of autonomic tone.
- Acute and potentially fatal hyperkalemia occurs after succinylcholine administration; in patients with certain myopathies such as Duchenne muscular dystrophy; or after stroke, spinal cord injury, neuropathy, prolonged immobility, or crush syndrome.
- In MH, acute onset of severe hypermetabolism causing acidosis, rhabdomyolysis, hyperkalemia, and death occurs if treatment with dantrolene and aggressive cooling is not rapidly administered. One vial of Ryanodex, the newer formulation of dantrolene, contains the initial 2.5 mg/kg dose for patients up to 100 kg, whereas the older formulation requires mixing of 12.5 vials to provide the same dose.
- The most important complications associated with use of NDNMBs are undetected hypoventilation and prolonged drug effect.
- In most neuromuscular diseases, sensitivity to NDNMB is increased and fatal hyperkalemia is a potential result.
- Reversal of nonsteroidal NDNMB can be achieved with acetylcholinesterase inhibitors, and steroidal NDNMB can be achieved with acetylcholinesterase inhibitors or sugammadex.
- Choice of reversal depends on availability, cost, and indications. The main advantage of sugammadex is rapid reversal of selected steroidal NDNMB without cholinergic effects.

## DANTROLENE SODIUM

Caitlin J. Guo and Kenneth M. Sutin

**INTRODUCTION**

Dantrolene produces relaxation of skeletal muscle without causing complete paralysis. It is the only therapy proven to be effective for both treatment and prophylaxis of malignant hyperthermia (MH).<sup>8</sup> Malignant hyperthermia is a rare life-threatening condition that is triggered by the use of either an inhalational anesthetic or succinylcholine. It is a syndrome of hypermetabolism involving the skeletal muscle, which overwhelms the ability of the body to supply oxygen, remove carbon dioxide, and regulate body temperature and can quickly lead to circulatory collapse if untreated. Typical signs include severe hyperthermia, increased CO<sub>2</sub> production and oxygen consumption, hemodynamic instability, mixed respiratory and metabolic acidosis, hyperkalemia, muscle rigidity, and rhabdomyolysis.

**HISTORY**

Dantrolene was first synthesized in 1967.<sup>33</sup> Four years later, it was used in oral form to treat skeletal muscle spasticity secondary to neurologic disorders.<sup>6</sup> The ability of intravenous (IV) dantrolene to rapidly reverse MH was first reported in swine in 1975<sup>11</sup> and subsequently in humans in 1982.<sup>16</sup> The delay from dantrolene discovery to clinical use was in part due to the difficulty encountered in formulating a parenteral (water-soluble) solution of the lipid-soluble drug.

**PHARMACOLOGY**

Dantrolene is a hydantoin derivative that is structurally similar to local anesthetics and anticonvulsants but possess neither property.<sup>17,37</sup> It is highly lipophilic and relatively insoluble in water. Widespread use had to wait until there was a suitable IV preparation. Today mannitol is added to the lyophilized dantrolene to improve solubility. In plasma, dantrolene is bound to plasma proteins, especially albumin. Oral dantrolene exhibits variable absorption by the small intestine, bioavailability is up to 70%, and peak blood concentrations are achieved 3 to 6 hours after ingestion.<sup>17</sup>

Quantitative analysis of dantrolene and its metabolites were performed using reverse-phase, high-performance liquid chromatography.<sup>1</sup> After a 2.4-mg/kg IV dose, the mean serum dantrolene concentration was 4.2 mcg/mL.<sup>8</sup> This concentration produced a 75% reduction in twitch contraction of skeletal muscle.<sup>8</sup> The therapeutic plasma concentration in humans is estimated at 2.8 to 4.2 mcg/mL.<sup>8</sup>

Dantrolene is metabolized in the liver by 5-hydroxylation of the hydantoin ring or by reduction of the nitro group to an amine.<sup>37</sup> Up to 20% of administered dantrolene is excreted in the urine as the 5-hydroxydantrolene, which is an active metabolite that is half as potent as the parent drug.<sup>37</sup> In adults, the elimination half-lives are 6 to 9 hours for dantrolene and 15.5 hours for the 5-hydroxydantrolene metabolite.<sup>37</sup> In one study of children ages 2 to 7 years, the dantrolene elimination half-life was 10 hours, and that for 5-hydroxydantrolene was 9 hours.<sup>18</sup>

At therapeutic concentrations, dantrolene inhibits binding of [<sup>3</sup>H]ryanodine to the ryanodine receptor type 1 (RYR-1) receptor on

sarcoplasmic reticulum membrane of skeletal muscle,<sup>24</sup> causing a dose-dependent inhibition of both the steady and peak components of calcium release.<sup>34</sup> This reduces the free myoplasmic calcium concentration and thereby directly inhibits excitation-contraction coupling.<sup>20</sup> Dantrolene causes skeletal muscle weakness but not complete paralysis, which may be related to its low water solubility. This plateau effect (achieved at a plasma concentration of 4.2 mcg/mL) produces a 75% reduction of skeletal muscle twitch contraction and a 42% reduction in hand grip strength.<sup>8</sup> Dantrolene does not change the electrical properties or excitation of nerve excitation-contraction coupling at the neuromuscular junction (NMJ), or skeletal muscle, and it does not alter sarcoplasmic calcium reuptake. Dantrolene does not bind to the cardiac ryanodine receptor (RYR-2) and thus does not have any direct cardiac effects.<sup>10,36,39</sup> In animal models, the combination with verapamil use is associated with a significant decrease in cardiac function, although this has not been described in humans.<sup>21,30</sup> Dantrolene also stabilizes adverse ventricular electrophysiological characteristics and ventricular dysrhythmias in rat models of chronic β-adrenergic receptor activation.<sup>19</sup>

**ROLE IN MALIGNANT HYPERTHERMIA AND OTHER HYPERTHERMIAS**

Dantrolene is indicated for treatment of skeletal muscle hypermetabolism characteristic of MH after an acute episode of MH to prevent recrudescence. Long-term oral dantrolene therapy is used rarely to treat chronic spasticity.<sup>15</sup> Historically, dantrolene was used prophylactically in MH-susceptible individuals; however, current practice is simply to avoid exposure to triggers of MH during anesthesia in potentially susceptible patients.

It is reasonable to administer dantrolene for patients with severe hypermetabolism when the diagnosis of MH cannot be excluded with certainty, especially when there is coexisting respiratory and metabolic acidosis, coagulopathy, hyperthermia, or rhabdomyolysis.<sup>7</sup> In typical fulminant MH, the diagnosis is not subtle, and the course of treatment is obvious once the diagnosis is considered. This is not true when the clinical presentation is atypical. Atypical clinical presentations of MH in the presence or absence of triggering anesthetics are reported, especially in MH-susceptible individuals.

Dantrolene use is reported in hyperthermic syndromes other than MH, including antipsychotic malignant syndrome,<sup>25</sup> heat stroke,<sup>2</sup> serotonin toxicity,<sup>12</sup> monoamine oxidase inhibitor interaction or overdose,<sup>13</sup> methylenedioxymethamphetamine ("ecstasy") overdose,<sup>22,27</sup> intrathecal baclofen withdrawal,<sup>14</sup> and thyroid storm.<sup>5</sup> Given the lack of evidence-based support for these conditions, dantrolene therapy is not recommended for indications other than MH. However, given that (1) the differential diagnosis of a hyperthermic syndrome does not necessarily exclude (and often includes) that of MH, (2) the definitive diagnosis of a hyperthermic syndrome may be subtle or delayed, and (3) MH may occur simultaneously with another hyperthermic syndrome,<sup>23</sup> it is reasonable to give dantrolene when MH cannot be specifically excluded because its use may be lifesaving and response to standard cooling measure is not rapidly effective. It bears emphasis that dantrolene provided for hyperthermia does not substitute for aggressive cooling and resuscitation.

**ADVERSE EFFECTS AND SAFETY ISSUES**

The alkaline pH of the reconstituted dantrolene causes pain at the injection site and thrombophlebitis in 9% of patients.<sup>3</sup> Unintended extravasation can cause tissue necrosis, highlighting that dantrolene should only be given through a

central vein or a large peripheral vein. There is no evidence to suggest allergic cross-reactivity with dantrolene in patients with prior phenytoin allergy.

When given to healthy persons or for MH prophylaxis or treatment, dantrolene causes skeletal muscle weakness in 15% to 22%, and diaphragm weakness (dyspnea) is noted.<sup>3,38</sup> In healthy volunteers, dantrolene 2.5 mg/kg does not reduce respiratory rate, vital capacity, or peak expiratory flow rate.<sup>8</sup> However, in patients with diminished respiratory reserve (eg, end stage pulmonary disease, preexisting neuromuscular disease), dantrolene is reported to precipitate respiratory failure.<sup>3,17</sup> Dantrolene also causes gastrointestinal distress, nausea, and vomiting. Other reported side effects include dizziness, somnolence, disorientation, ptosis, blurred vision, and dysphagia.<sup>3,8,38</sup> Uncommonly, compartment syndrome is observed, and even though likely secondary to MH or trauma, it is associated with dantrolene administration.<sup>3</sup>

Dantrolene and verapamil should not be used in combination because of the risk of hyperkalemia and hypotension; however, the mechanistic details of this drug interaction remain unclear.<sup>17,26,30</sup> Intravenous calcium salts are safe to administer with dantrolene if needed, such as for the treatment of cardiac dysrhythmias or hyperkalemia (during an episode of MH).

When dantrolene is given orally for more than 2 months to treat skeletal muscle spasticity, there is a 1.8% risk of dose- and duration-related chronic hepatitis, including elevated aminotransferase concentrations and hyperbilirubinemia<sup>35</sup> that it is not always fully reversible after dantrolene is discontinued.<sup>4</sup>

## PREGNANCY AND LACTATION

Dosing during pregnancy is based on total body weight. Dantrolene rapidly crosses the placenta and is slowly excreted in breast milk.<sup>32</sup> The elimination half-life in neonates is about 20 hours.<sup>32</sup> At the concentrations achieved in serum or breast milk, there are no reports of significant adverse neonatal effects, although there is a potential for neonatal respiratory depression. However, it is suggested that breastfeeding only resume 48 hours after the last dose of dantrolene.<sup>9</sup> Dantrolene carries a Pregnancy Category C designation because embryo lethality in rabbits and decreased pup survival in rats were observed at doses seven times the human oral dose.<sup>28</sup>

## FORMULATION

There are currently two formulations of dantrolene, Dantrium or Revonto, and Ryanodex. Approved by the US Food and Drug Administration in 2014, Ryanodex<sup>29,31</sup> offers significant advantages over the older formulations.

Dantrium and Revonto are long-standing formulations of dantrolene, they are supplied as a sterile lyophilized powder in a 70-mL vial that contains 20 mg of dantrolene sodium and 3,000 mg of mannitol. After addition of 60 mL of sterile water to each vial, each vial is shaken for approximately 20 seconds and until the solution becomes clear. The final solution is isotonic and has a pH of approximately 9.5. Caution must be taken to avoid extravasation. The extreme alkalinity of the reconstituted solution also can corrode glass and thus must not be transferred into a glass bottle for prophylactic infusion.

Ryanodex is supplied as a sterile nanocrystalline powder suspension containing 250 mg of dantrolene sodium (or 12.5 times more dantrolene per vial than the older formulations) and 125 mg of mannitol. Each vial of Ryanodex is reconstituted with 5 mL of preservative-free sterile water. It is not compatible with dextrose-containing solutions nor 0.9% sodium chloride because they may cause precipitation. The reconstituted vial is shaken for 10 seconds until a uniform orange color suspension forms. Ryanodex can be administered by IV bolus into a free running infusion line of either 0.9% sodium chloride or 5% dextrose solution. Because of the extreme alkalinity of the reconstituted solution (pH of 10.5), care must be taken to prevent extravasation into surrounding tissue and possible tissue necrosis.

A single vial of Ryanodex is sufficient to provide a loading dose for a patient weighing up to 100 kg, and it can be mixed and administered in less than 1 minute. For the older dantrolene formulations, a 100-kg patient requires 12.5 vials to be prepared and in a much larger volume of sterile water, a process that could take 15 to 20 minutes and multiple providers to mix and administer.

Of note, each vial of Ryanodex contains 125 mg of mannitol compared with 3,000 mg of mannitol in the older formulations. The additional mannitol may not be required because the volume of water used to dilute Ryanodex is much less than for the older formulations.

## DOSING AND ADMINISTRATION

The initial dose of dantrolene for treatment of acute MH is an IV bolus of 2.5 mg/kg in the adults and children.<sup>18</sup> Depending on the formulation, for a typical adult, the initial dose may require multiple bottles of dantrolene to be simultaneously reconstituted. The newer formulation provides 250 mg dantrolene per vial, and the older formulation provides 20 mg per vial. Initial dosing probably should be determined by total body weight given that dantrolene is lipophilic; however, its pharmacokinetics in obesity are not determined.<sup>8</sup> Redosing of 2.5 mg/kg IV is recommended every 15 minutes until the signs of hypermetabolism are reversed or until a total dose of approximately 10 mg/kg has been administered. Occasionally, doses in excess of 10 mg/kg are required; however, alternative diagnosis should be considered in such cases. The key point is that the total dose of dantrolene is determined by titration to a metabolic endpoint and resolution of skeletal muscle hypermetabolism. When an effective dose of dantrolene is given, signs of muscle hypermetabolism usually start to normalize within 30 minutes.<sup>16</sup>

After successful termination of the acute episode of hypermetabolism, it is recommended that dantrolene therapy be continued for at least 24 hours to prevent reoccurrences, with bolus dosing at 1 mg/kg IV every 4 to 6 hours or 0.25 mg/kg/h IV as a continuous infusion. After 24 hours, dantrolene can be discontinued or the interval doses increased to every 8 or 12 hours if the patient has achieved metabolic stability and is clinically improving. The Malignant Hyperthermia Association of the United States (MHAUS) has similar recommendations for postexposure.

## SUMMARY

- Dantrolene is the only specific antidote to treat malignant hyperthermia.
- Dantrolene should be stocked whenever MH-triggering xenobiotics are used.
- Dantrolene is primarily eliminated by the liver and about 20% is excreted in the urine as an active metabolite, that is half potent as the parent drug.
- Dantrolene is lipophilic, crosses the placenta and is excreted in breast milk.
- The initial dose of dantrolene for treatment of acute MH is an IV bolus of 2.5 mg/kg in adults and children, which is repeated every 15 minutes until clinical signs of hypermetabolism are corrected.
- The Malignant Hyperthermia Association of the United States maintains a website, [www.mhaus.org](http://www.mhaus.org); a toll-free hotline for MH emergencies, 800-MH-HYPER (644-9737); and a national MH registry.

## G. Psychotropic Medications

# ANTIPSYCHOTICS

David N. Juurlink

### HISTORY AND EPIDEMIOLOGY

The development of antipsychotic drugs dramatically altered the practice of psychiatry and eventually, medical care in general. Before the introduction of chlorpromazine in 1950, patients with schizophrenia were treated with nonspecific sedatives such as barbiturates or chloral hydrate. Agitated patients were housed in large “mental institutions” and often placed in physical restraints, and thousands underwent surgical disruption of the connections between the frontal cortices and other areas of the brain (leucotomy). By 1955, approximately 500,000 patients with mental health disorders were institutionalized in the United States. The advent of antipsychotic drugs in the 1950s revolutionized the care of these patients. These drugs, originally termed *major tranquilizers* and subsequently *neuroleptics*, dramatically reduced the characteristic hallucinations, delusions, thought disorders and paranoia—the “positive” symptoms of schizophrenia.

Shortly after the introduction of these drugs, it became apparent that they were capable of causing significant toxicity after overdose, a common occurrence in patients with mental illness. Moreover, they were also associated with a host of adverse effects during routine therapeutic use, particularly involving the endocrine and nervous systems. The latter includes the extrapyramidal syndromes (EPS), a constellation of disorders that are relatively common, sometimes irreversible, and occasionally life threatening.

The search for new drugs led to the development of multiple antipsychotics in several distinct chemical classes. These drugs exhibited varying potencies and markedly different adverse effect profiles. The novel antipsychotic clozapine was first synthesized in 1959 but did not enter widespread clinical use until the early 1970s. Clozapine was unusual because it conferred a relatively low risk of EPS and was often effective in patients who had not responded well to other antipsychotics. Moreover, unlike other antipsychotic drugs available at the time, it often improved the “negative” symptoms of schizophrenia, such as avolition, alogia, and social withdrawal, symptoms that, although often less outwardly apparent than the positive symptoms, result in significant disability. Reports of life-threatening agranulocytosis led to the withdrawal of clozapine from the market in 1974, although it was reintroduced in 1990 with stringent monitoring requirements.<sup>8,56</sup> However, clozapine’s unique therapeutic and pharmacologic properties led to its characterization as an *atypical* antipsychotic, the forerunner and prototype of many other second-generation antipsychotics that have now largely supplanted the earlier drugs in clinical practice.

Most antipsychotic toxicity occurs through one of two mechanisms. After overdose, antipsychotic toxicity is dose dependent and reflects an extension of the drug’s effects on neurotransmitter systems and other biologic processes. The features of antipsychotic overdose are therefore generally predictable based on an understanding of the drug’s pharmacology. Unpredictable (idiosyncratic) adverse effects also occur in the context of therapeutic use. These toxicities result from individual susceptibility, which may in part have a genetic basis, and are less reliably correlated with the antipsychotic dose. In both types of toxicity, the severity of illness ranges from minor to life threatening, depending on variety of other factors, including concomitant drug exposures, comorbidity, and access to medical care.

The true incidences of antipsychotic overdose and adverse effects are not known with certainty. Some patients never seek medical attention, and others are misdiagnosed. Even among those who seek medical attention and are correctly diagnosed, notification of poison control centers or other

adverse event reporting systems is discretionary and incomplete (Chap. 130). With these limitations in mind, a few observations can be made.

In 2015, poison control centers in the United States were contacted about more than 2.17 million human exposures involving potential poisons.<sup>92</sup> Antipsychotic exposures are reported together with sedative-hypnotics, but these collectively represented 151,433 exposures (5.84% of all exposures). The vast majority of poison control center calls involving antipsychotic drugs pertain to intentional overdoses in patients 20 years or older, most of whom have a good outcome. However, these drugs were associated with more fatalities than any other group ( $n = 401$  deaths), although the extent to which they played a causal role in death is unclear. Importantly, poison control center data underestimate the annual incidence of poisoning and mortality associated with antipsychotic drugs and likely identify only a small minority of adverse drug reactions involving these drugs (Chap. 130).

Although all antipsychotics exhibit significant toxicity in overdose, a substantial body of clinical experience and some observational data suggest that the low-potency, first-generation antipsychotics such as thioridazine, chlorpromazine, and mesoridazine are associated with greater toxicity than other antipsychotics.<sup>18,20</sup> Inferences regarding the relative toxicity of the antipsychotics derived from aggregated data should be extrapolated to individual patients with caution.<sup>18,42</sup>

### PHARMACOLOGY

#### Classification

Antipsychotics are classified in several ways, according to their chemical structures, their receptor binding profiles, or as *typical* or *atypical* antipsychotics. Table 67-1 outlines the taxonomy of some of the more commonly used antipsychotics. Classification by chemical structure was most useful before the 1970s, when phenothiazines and butyrophenones constituted most of the antipsychotics in clinical use. At present, however, the spectrum of available antipsychotics and their structural heterogeneity renders this scheme of little use to clinicians. It is worth noting, however, that the phenothiazines exhibit a high degree of structural similarity to the tricyclic antidepressants (TCAs) (Fig. 67-1) and share many of their manifestations in overdose. The phenothiazines are further classified according to the nature of the substituent on the nitrogen atom at position 10 of the center ring as aliphatic, piperazine, or piperidine compounds.

Of greater clinical utility is the classification of antipsychotics according to their binding affinities for various receptors (Table 67-2). However, by far the most widely used classification system categorizes antipsychotics as either *typical* or *atypical*. Typical (also called *traditional*; *conventional*; or, increasingly, *first-generation*) antipsychotics dominated the first 40 years of antipsychotic therapy. They were subcategorized according to their affinity for the D<sub>2</sub> receptor as either low potency (exemplified by thioridazine and chlorpromazine) or high potency (exemplified by haloperidol).

The concept of atypicality has evolved over time with the introduction of new antipsychotics<sup>110,130</sup> and connotes different features to pharmacologists and clinicians. From a clinical perspective, atypical (*second-generation*) antipsychotics treat both the positive and negative symptoms of schizophrenia, are less likely than traditional drugs to produce EPS at clinically effective doses, and cause little or no elevation of the serum prolactin concentration.<sup>66</sup> From a pharmacologic perspective, many atypical antipsychotics also inhibit the activity of serotonin at the 5-HT<sub>2A</sub> receptor. Some antipsychotics are

TABLE 67-1 Classification of Commonly Used Antipsychotics

Classification	Antipsychotic	Usual Daily Adult Dose (mg)	Volume of Distribution (L/kg)	Half-Life (Range, h)	Protein Binding (%)	Active Metabolite	
<b>Typicals</b>							
Butyrophenones	Droperidol	1.25–30	2–3	2–10	85–90	N	
	Haloperidol	1–20	18–30	14–41	90	Y

	Thiothixene	5–30	NR	12–36	>90	NR	
	Zuclopentixol	20–100	10	20	NR	NR	
<b>Atypicals</b>							
Benzamides	Amisulpride	50–1,200	5.8	12	16	N	
	Raclopride	3–6	1.5	12–24	NR	N	
	Remoxipride	150–600	0.7	3–7	80	Y	
	Sulpiride	200–1,200	0.6–2.7	4–11	14–40	N	
Benzepines	Dibenzodiazepine	Clozapine	50–900	15–30	6–17	95	Y
	Dibenzoxazepine	Loxapine <sup>a</sup>	20–250	NR	2–8	90–99	Y
	Thienobenzodiazepine	Olanzapine	5–20	10–20	21–54	93	N
	Dibenzothiazepine	Quetiapine	150–750	10	3–9	83	N
<b>Indoles</b>							
Benzisoxazole	Risperidone	2–16	0.7–2.1	3–20	90	Y	
	Paliperidone	1–12 mg (IM 25–150 monthly)	7	23	74	N	
	lloperidone	12–14	30–36	18–33	96	Y	
Imidazolidinone	Sertindole	12–24	20–40	24–200	99	Y	
	Benzisothiazole	Ziprasidone	40–160	2	4–10	99	N
Lurasidone		20–160	80–90	29–37	99	Y	
Dibenzo-oxepino pyrroles	Asenapine	5–20	20–25	13–39	95	N	
Quinolinones	Aripiprazole	10–30	5	47–68	99	Y	

<sup>a</sup>Loxapine's atypical profile is lost at doses >50 mg/d; it is sometimes therefore categorized as a typical antipsychotic. <sup>b</sup>For hydrochloride salt; enanthate and decanoate have ranges of 3–4 days and 5–12 days, respectively.

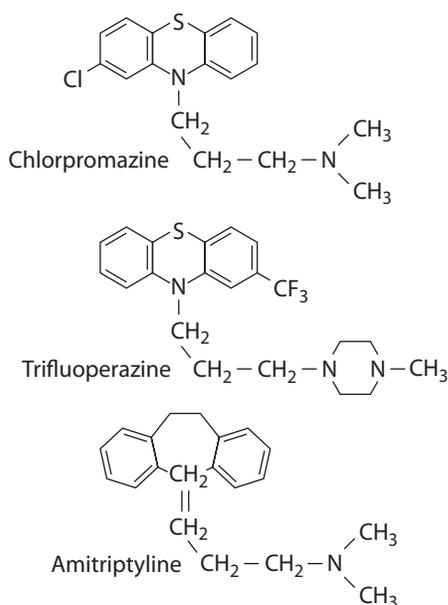

IM = intramuscular; N = no; NR = not reported; Y = yes.

Data from references 9, 11, 14, 39, 62, 70, and 86.

classified as third generation, reflecting the property of antagonism (or partial antagonism) of D<sub>2</sub> receptors with agonist at 5-HT<sub>1A</sub> receptors.<sup>96</sup>

More than two dozen atypical antipsychotics are now in clinical use or under development. Despite their considerably higher cost, they have largely supplanted traditional antipsychotics because of their effectiveness in treating the negative symptoms of schizophrenia and their somewhat more favorable adverse effect profile in addition to the perception that they cause fewer

long-term adverse effects than conventional antipsychotics—a belief that may result, in part, from the use of higher doses of older drugs in studies comparing the tolerability of typical and atypical antipsychotics.<sup>55</sup> Controversy exists regarding the superiority of these drugs over first-generation antipsychotics, and it is worth noting that the use of the newer antipsychotics for indications other than schizophrenia is extremely common, including their use as adjunctive treatment for depression, eating disorders, attention

**FIGURE 67-1.** Structural similarity between phenothiazines and cyclic antidepressants.

deficit hyperactivity disorder, insomnia, posttraumatic stress disorder, personality disorders, and Tourette syndrome.<sup>81</sup> However, the most extensive off-label use of atypical antipsychotics is for the management of agitation associated with cognitive impairment in older adults.

### Mechanisms of Antipsychotic Action

Of the many contemporary theories of schizophrenia, the most enduring has been the *dopamine hypothesis*.<sup>123</sup> First advanced in 1967 and supported by in vivo data,<sup>1</sup> this theory posits that the “positive symptoms” of schizophrenia result from excessive dopaminergic signaling in the mesolimbic and mesocortical pathways.<sup>88</sup> This hypothesis arose in part from the observation that hallucinations and delusions could be produced in otherwise normal individuals by drugs that augment dopaminergic transmission, such as cocaine and amphetamine, and that these effects could be blunted by dopamine antagonists.

There are at least five subtypes of dopamine receptors (D<sub>1</sub> through D<sub>5</sub>), but schizophrenia principally involves excess signaling at the D<sub>2</sub> subtype,<sup>123</sup> and antagonism of D<sub>2</sub> neurotransmission is the *sine qua non* of antipsychotic activity. Antipsychotics have different binding profiles at this receptor, reflected by the dissociation constant (K<sub>d</sub>), which in turn reflects release of the drug from the receptor. For example, the receptor releases clozapine and quetiapine more rapidly than it does any other drugs.<sup>121,123</sup>

Dopamine receptors are present in many other areas of the central nervous system (CNS), including the nigrostriatal pathway (substantia nigra, caudate and putamen, which collectively govern the coordination of movement), tuberoinfundibular pathway, hypothalamus and pituitary, and area postrema of the medulla, which contains the chemoreceptor trigger zone (CTZ). Antipsychotic-related blockade of D<sub>2</sub> neurotransmission in these areas is associated with many of the beneficial and adverse effects of these drugs. For example, whereas D<sub>2</sub> antagonism in the CTZ alleviates nausea and vomiting, blockade of hypothalamic D<sub>2</sub> receptors increases pituitary prolactin release, resulting in gynecomastia and galactorrhea. Blockade of nigrostriatal D<sub>2</sub> receptors underlies many of the movement disorders associated with antipsychotic therapy.<sup>136,150</sup>

**TABLE 67-2** Clinical and Toxicologic Manifestations of Selected Antipsychotics

	$\alpha_1$ -Adrenergic Antagonism	Muscarinic Antagonism	Fast Sodium Channel ( $I_{Na}$ ) Blockade	Delayed Rectifier ( $I_{Kr}$ ) Blockade

Antipsychotics interfere with signaling at other receptors to varying degrees, including muscarinic receptors,  $H_1$  histamine receptors, and  $\alpha$ -adrenergic receptors. The extent to which these receptors are blocked at therapeutic doses can be used to predict the adverse effect of each antipsychotic profile.<sup>22</sup> For example, those that antagonize muscarinic receptors at clinically effective doses (most notably the aliphatic and piperidine phenothiazines as well as clozapine, loxapine, olanzapine, and quetiapine) often produce anticholinergic effects during routine use and can produce pronounced anticholinergic manifestations after overdose (Table 67-2). Similarly, blockade of peripheral  $\alpha_1$ -adrenergic receptors by the aliphatic and piperidine phenothiazines, clozapine, risperidone, paliperidone, iloperidone, and others increases the risk of postural hypotension during therapy and clinically important hypotension after overdose. In contrast, haloperidol overdose, for example, is characterized by neither antimuscarinic effects nor hypotension.

Several antipsychotics also block voltage-gated fast sodium channels ( $I_{Na}$ ). Although this effect is of little consequence during therapy, in the setting of overdose this can slow cardiac conduction (phase 0 depolarization) and impair myocardial contractility. This effect, most notable with the phenothiazines, is both rate and voltage dependent and is therefore more pronounced at faster heart rates and less negative transmembrane potentials.<sup>19</sup> Blockade of the delayed rectifier potassium current ( $I_{Kr}$ ) can produce prolongation of the QT interval, creating a substrate for development of torsade de pointes.<sup>94</sup> Prolongation of the QT interval is sometimes evident during maintenance therapy, particularly in patients with previously unrecognized repolarization abnormalities or additional risk factors for QT interval prolongation. This effect may partially explain the dose-dependent increase in risk of sudden cardiac death among patients treated with typical and atypical antipsychotic drugs.<sup>108,109</sup>

Several antipsychotics exhibit a relatively high degree of antagonism at the 5-HT<sub>2A</sub> receptor, which imparts two important therapeutic properties: (1) greater effectiveness for the treatment of the negative symptoms of schizophrenia and (2) a significantly lower incidence of extrapyramidal side effects. Some antipsychotics produce unique effects through effects at other receptors. For example, loxapine and clozapine inhibit the presynaptic reuptake of catecholamines and antagonize  $\gamma$ -aminobutyric acid (GABA)<sub>A</sub> receptors,<sup>129</sup> which may explain the apparent increase in the occurrence of seizures with overdose of these antipsychotics.<sup>105</sup> A more detailed description of the pharmacology of the most commonly used second-generation antipsychotics is warranted in light of their increasing role in therapy.

Clozapine, a dibenzodiazepine, binds to dopamine receptors ( $D_1$ – $D_3$ ) and serotonin receptors (5-HT<sub>1A/1C</sub>, 5-HT<sub>2A/2C</sub>, 5-HT<sub>3</sub>, and 5-HT<sub>6</sub>) with moderate to high affinity.<sup>8,106,114</sup> It also antagonizes  $\alpha_1$ -adrenergic,  $\alpha_2$ -adrenergic, and  $H_1$  histamine receptors. It has the highest binding affinity of any atypical antipsychotic at  $M_1$  muscarinic receptors.<sup>113</sup> Despite this feature, clozapine paradoxically activates the  $M_4$  genetic subtype of the muscarinic receptor and frequently produces sialorrhea during therapy.<sup>112</sup>

Olanzapine, a thienobenzodiazepine, binds with high affinity to serotonin (5-HT<sub>2A/2C</sub>, 5-HT<sub>3</sub>, and 5-HT<sub>6</sub>) and dopamine receptors ( $D_1$ ,  $D_2$ , and  $D_4$ ), although its potency at  $D_2$  receptors is lower than that of most traditional antipsychotics.<sup>70,114</sup> It is an exceptionally potent  $H_1$  antagonist, binding more avidly than pyrilamine, which is a widely used antihistamine. It is also has a high affinity for  $M_1$  receptors and is a relatively weak  $\alpha_1$  antagonist.

Risperidone, a benzisoxazole derivative, has high affinity for several receptors, including serotonin receptors (5-HT<sub>2A/2C</sub>),  $D_2$  receptors, and  $\alpha_1$  and  $H_1$  receptors.<sup>70,112,114</sup> It has no appreciable activity at  $M_1$  receptors. Its primary metabolite (9-hydroxyrisperidone) is nearly equipotent as the parent compound at  $D_2$  and 5-HT<sub>2A</sub> receptors.<sup>70</sup> Paliperidone is the major active metabolite of risperidone and is available orally and as a long-acting parenteral preparation that exhibits a similar receptor binding profile.<sup>86</sup>

Quetiapine, a dibenzothiazepine, is a weak antagonist at  $D_2$ ,  $M_1$ , and 5-HT<sub>1A</sub> receptors, but it is a potent antagonist of  $\alpha_1$ -adrenergic and  $H_1$  receptors.<sup>70</sup> At least 2 of its 11 metabolites are pharmacologically active, but they circulate at low concentrations and likely contribute little to the quetiapine's

clinical effects. A considerable proportion of fatalities involving antipsychotics reported to North American Poison Control Centers involve quetiapine, usually in combination with other drugs.<sup>16</sup>

Ziprasidone, a benzothiazole derivative, is an antagonist at  $D_2$  and several serotonin (5-HT<sub>2A/2C</sub>, 5-HT<sub>1D</sub>, and 5-HT<sub>7</sub>) receptors, but it also displays agonist activity at 5-HT<sub>1A</sub> receptors.<sup>70,71,114</sup> Its  $\alpha_1$  antagonist activity is particularly strong, with a binding affinity approximately one 10th that of prazosin. In addition, it is a strong inhibitor of the delayed rectifier channel ( $I_{Kr}$ ) and can significantly prolong repolarization.<sup>71,83</sup>

Lurasidone is an active metabolite of risperidone. It exhibits high affinity for  $D_2$  and 5-HT<sub>2A</sub> receptors, as well as for 5-HT<sub>1A</sub> and 5-HT<sub>7</sub>, but low affinity  $\alpha_1$  adrenergic receptors and no appreciable affinity for muscarinic or  $H_1$  receptors.<sup>86</sup>

Aripiprazole, a quinolinone derivative, is a novel antipsychotic that binds avidly to  $D_2$  and  $D_3$  receptors as well as 5-HT<sub>1A</sub>, 5-HT<sub>2A</sub>, and 5-HT<sub>2B</sub> receptors.<sup>93,114</sup> Some evidence suggests that its efficacy in the treatment of schizophrenia and its lower propensity for EPS relates to partial agonist activity at dopamine  $D_2$  receptors.<sup>91</sup> Aripiprazole acts as a partial agonist at 5-HT<sub>1A</sub> receptors but is an antagonist at 5-HT<sub>2A</sub> receptors. Its principal active metabolite, dehydroaripiprazole, has affinity for  $D_2$  receptors and thus has pharmacologic activity similar to that of the parent compound.<sup>93</sup>

Like aripiprazole, bifeprunox is a partial agonist at  $D_2$  and 5-HT<sub>1A</sub> receptors. It is characterized as a third-generation antipsychotic and has no appreciable affinity for serotonin 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub>, muscarinic, or  $H_1$  receptors.<sup>31,96,122</sup>

Amisulpride is a substituted benzamide derivative that preferentially blocks dopamine receptors in limbic rather than striatal structures. At low doses, it blocks presynaptic  $D_2$  and  $D_3$  receptors with high affinity, thereby accentuating dopamine release, and at high doses, it blocks postsynaptic  $D_2$  and  $D_3$  receptors. It has no appreciable affinity for serotonergic, histaminergic, adrenergic, and cholinergic receptors.<sup>86</sup>

Sertindole is a second-generation antipsychotic recently reintroduced into the market after being voluntarily withdrawn in 1998 over concerns about its effects on the QT interval. It binds to striatal  $D_2$  receptors, although less avidly than olanzapine, and exhibits antagonism at 5-HT<sub>2A</sub> and  $\alpha_1$  adrenergic receptors.<sup>68,102,128</sup> It is estimated that between 3.1% and 7.8% of patients receiving sertindole develop QT intervals greater than 500 ms.<sup>148</sup>

Asenapine is a second-generation antipsychotic administered sublingually because of its high first-pass metabolism. It acts as an antagonist at multiple dopamine, 5-HT, histamine, and  $\alpha$ -adrenergic receptors but has no appreciable activity at muscarinic receptors or on the QT interval.<sup>28,29</sup>

## PHARMACOKINETICS AND TOXICOKINETICS

With a few exceptions, the antipsychotics have similar pharmacokinetic characteristics regardless of their chemical classification. Most are lipophilic; have a large volume of distribution; and with the exception of asenapine, are generally well absorbed, although some antipsychotics with prominent anticholinergic effects are likely to exhibit delayed absorption. Plasma concentrations generally peak within 2 to 3 hours after a therapeutic dose but can be delayed after overdose.

Most antipsychotics are substrates for one or more isoforms of the hepatic cytochrome (CYP) enzyme system. For example, haloperidol, perphenazine, thioridazine, sertindole, and risperidone are extensively metabolized by the CYP2D6 system, which is functionally absent in approximately 7% of white patients and overexpressed in 1% to 25% of patients, depending on ethnicity.<sup>53</sup> These polymorphisms influence the tolerability and efficacy of treatment with these antipsychotics during therapeutic use<sup>15,32,33,65,142</sup> but are unlikely to significantly alter the severity of acute antipsychotic overdose.

Drugs that inhibit CYP2D6 (eg, paroxetine, fluoxetine, and bupropion) can increase concentrations of these antipsychotics, increasing the risk of adverse effects. In contrast, metabolism of clozapine and asenapine is primarily mediated by CYP1A2, and increased clozapine concentrations follow exposure to CYP1A2 inhibitors such as fluvoxamine, macrolide, or fluoroquinolone antibiotics or upon smoking cessation because the polycyclic aromatic hydrocarbons in cigarette smoke induce CYP1A2.<sup>38</sup> The kidneys play a relatively small

role in the elimination of antipsychotics, and dose adjustment is generally not necessary for patients with chronic kidney disease.

## PATHOPHYSIOLOGY AND CLINICAL MANIFESTATIONS

Table 67–3 lists the adverse effects of antipsychotics. Some of these effects develop primarily following overdose, but others occur during the course of therapeutic use.

### Adverse Effects During Therapeutic Use

**The Extrapyramidal Syndromes.** The EPSs (Table 67–4) are a group of disorders that share the common feature of abnormal muscular activity. Among the typical antipsychotics, the incidence of EPS appears to be highest with the more potent antipsychotics such as haloperidol and flupenthixol and lower with less potent antipsychotics such as chlorpromazine and thioridazine. Atypical antipsychotics are associated with an even lower incidence of EPS. Although the physiologic mechanisms for this observation are not fully understood, several hypotheses have been put forth, including 5-HT<sub>2A</sub> antagonism, rapid dissociation from the D<sub>2</sub> receptor, and a lower degree of nigrostriatal dopaminergic hypersensitivity during chronic use.<sup>66,67,84</sup> However, it is important to note that EPS occur during treatment with any antipsychotic, regardless of typicality or potency.

**Acute Dystonia.** Acute dystonia is a movement disorder characterized by sustained involuntary muscle contractions, often involving the muscles of the head and neck, including the extraocular muscles and the tongue, but occasionally involving the extremities. These contractions are sometimes referred to as *limited reactions*, reflecting their transient nature rather than

their severity. All of the currently available antipsychotics are associated with the development of acute dystonic reactions.<sup>136</sup> Spasmodic torticollis, facial grimacing, protrusion of the tongue, and oculogyric crisis are among the more common manifestations. Laryngeal dystonia is a rare but potentially life-threatening variant that is easily misdiagnosed because it presents with throat pain, dyspnea, stridor, and dysphonia rather than the more characteristic features of dystonia.<sup>40</sup>

Acute dystonia typically develops within a few hours of starting of treatment but may be delayed in onset for several days. Left untreated, dystonia resolves slowly over several days after the offending antipsychotic is withdrawn. Risk factors for acute dystonia include male gender, young age (children are particularly susceptible), a previous episode of acute dystonia, and recent cocaine use.<sup>137,150</sup> Although the reaction often appears dramatic and sometimes is mistaken for seizure activity, it is rarely life threatening. Of note, xenobiotics other than antipsychotics sometimes cause acute dystonia, particularly metoclopramide, the antidepressants, some antimalarials, histamine H<sub>2</sub> receptor antagonists, anticonvulsants, and cocaine.<sup>137</sup>

**Treatment of Acute Dystonia.** Acute dystonia is generally more distressing than serious, but rare cases compromise respiration, necessitating supplemental oxygen and, occasionally, assisted ventilation.<sup>40,137</sup> The response to parenteral anticholinergics is generally rapid and dramatic, and benztropine is recommended as the first-line treatment (2 mg intravenously or intramuscularly in adults or 0.05 mg/kg in children). Diphenhydramine is often more readily available, and it is also reasonable to use (50 mg intravenously or intramuscularly in adults, or 1 mg/kg in children). Parenteral benzodiazepines such as lorazepam (0.05–0.10 mg/kg intravenously or intramuscularly) or diazepam (0.1 mg/kg intravenously) can be used for patients who do not respond to anticholinergics but can also be effective as initial therapy. It is important to recognize that additional doses of anticholinergics are often necessary because the duration of action of most antipsychotics exceeds that of either benztropine or diphenhydramine.<sup>30</sup> We recommend that patients in whom acute dystonia jeopardizes respiration be observed for at least 12 to 24 hours after initial resolution.

**Akathisia.** Akathisia (from the Greek phrase “not to sit”) is characterized by a feeling of restlessness, anxiety, or sense of unease, often in conjunction with the objective finding of an inability to remain still. Patients with akathisia frequently appear uncomfortable or fidgety. They typically rock back and forth while standing or repeatedly cross and uncross their legs while seated. Akathisia is sometimes misinterpreted as a manifestation of the underlying psychiatric disorder rather than an adverse effect of drug therapy.

Akathisia is common and often reduces adherence to therapy. Like acute dystonia, akathisia tends to occur relatively early in the course of treatment and coincides with peak antipsychotic concentrations in plasma.<sup>150</sup> The incidence appears highest with typical, high-potency antipsychotics and lowest with atypical antipsychotics. Although most cases develop within days to weeks after initiation of treatment or an increase in dose, a delayed-onset (tardive) variant is also recognized.

The pathophysiology of akathisia is incompletely understood but appears to involve antagonism of postsynaptic D<sub>2</sub> receptors in the mesocortical pathways.<sup>84,136</sup> Interestingly, a similar phenomenon is described in patients after the initiation of treatment with antidepressants, particularly the selective serotonin reuptake inhibitors.<sup>7,78</sup>

**Treatment of Akathisia.** Akathisia can be difficult to treat. A reduction in the antipsychotic dose is a reasonable initial intervention. If this fails or is impractical, substitution of another (generally atypical) antipsychotic drug or treatment with lipophilic  $\beta$ -adrenergic antagonists such as propranolol lessen akathisia. In the absence of good data, the choice of intervention should be guided by individual patient considerations.<sup>76,104</sup> Benzodiazepines produce short-term relief, and anticholinergics such as benztropine or procyclidine lessen akathisia in some patients but are more likely to be effective for akathisia induced by antipsychotics with little or no intrinsic anticholinergic activity.<sup>21,77</sup>

TABLE 67–3 Adverse Effects of Antipsychotics

Central nervous system	Somnolence, progressing to coma Respiratory depression with loss of airway reflexes Hyperthermia Seizures Extrapyramidal syndromes Central anticholinergic syndrome
Cardiovascular	
Clinical	Tachycardia Hypotension (orthostatic or resting) Myocardial depression
Electrocardiographic	QRS complex prolongation Right deviation of terminal 40 ms of frontal plane axis QT interval prolongation Torsade de pointes Nonspecific repolarization changes
Endocrine	Amenorrhea, oligomenorrhea, or metrorrhagia Breast tenderness and galactorrhea
Gastrointestinal	Impaired peristalsis Dry mouth <sup>a</sup>
Genitourinary	Urinary retention Ejaculatory dysfunction Priapism
Ophthalmic	Mydriasis or miosis; visual blurring
Dermatologic	Impaired sweat production Cutaneous vasodilation

<sup>a</sup>An exception is clozapine, which can cause sialorrhea.

TABLE 67-4 The Extrapyramidal Syndromes

Disorder	Time of Maximal Risk	Features	Postulated Mechanism	Suggested Treatments
Akathisia	Hours to days	Restlessness and general unease; inability to sit still	Mesocortical D <sub>2</sub> antagonism	Dose reduction, trial of alternate drug, propranolol, benzodiazepines, anticholinergics
Dystonia	Hours to days	Sustained, involuntary muscle contraction, including torticollis, blepharospasm, oculogyric crisis	Imbalance of dopaminergic or cholinergic transmission	Anticholinergics, benzodiazepines
Neuroleptic malignant syndrome	2–10 days	Many (Table 67-5): altered mental status, motor symptoms, hyperthermia, autonomic instability, catatonia, mutism	D <sub>2</sub> antagonism in striatum, hypothalamus, and mesocortex	Cooling, benzodiazepines, supportive care, bromocriptine, amantadine, or other direct-acting dopamine agonist
Parkinsonism	Weeks	Bradykinesia, rigidity, shuffling gait, masklike facies, resting tremor	Postsynaptic striatal D <sub>2</sub> antagonism	Dose reduction, anticholinergics, dopamine agonists
Tardive dyskinesia	3 months to years	Late-onset involuntary choreiform movements, buccolingual masticatory movements	Excess dopaminergic activity	Recognize early and stop offending drug; addition of other antipsychotic; cholinergics

Data from references 104 and 136.

**Parkinsonism.** Antipsychotics occasionally produce a parkinsonian syndrome characterized by rigidity, akinesia or bradykinesia, and postural instability. It is similar to idiopathic Parkinson disease, although the classic “pill-rolling” tremor is often less pronounced.<sup>104</sup> The syndrome typically develops during the first few months of therapy, particularly with high-potency antipsychotics. It is more common among older women, and in some patients, it represents iatrogenic unmasking of latent Parkinson disease. Parkinsonism results from antagonism of postsynaptic D<sub>2</sub> receptors in the striatum.<sup>136</sup>

**Treatment of Drug-Induced Parkinsonism.** The risk of drug-induced parkinsonism is minimized by using the lowest effective dose of antipsychotic. The addition of an anticholinergic often attenuates symptoms at the expense of additional side effects. This strategy is often effective in younger patients, although the routine use of prophylactic anticholinergics is not recommended. A dopamine agonist such as amantadine is sometimes added, particularly in older patients who may be less tolerant of anticholinergics, but this may aggravate the underlying psychiatric disturbance and is not generally recommended.<sup>82</sup>

**Tardive Dyskinesias.** The term *tardive dyskinesia* was coined in 1952 to describe the delayed onset of persistent orobuccal masticatory movements occurring in a three women after several months of antipsychotic therapy.<sup>136</sup> The adjective *tardive*, meaning delayed, was used to distinguish these movement disorders from the Parkinsonian movements described earlier. The incidence of tardive dyskinesia in younger patients is approximately 3% to 5% per year but rises considerably with age. A prospective study of older patients treated with high-potency typical antipsychotics identified a 60% cumulative incidence of tardive dyskinesia after 3 years of treatment.<sup>61</sup> Potential risk factors for tardive dyskinesia include alcohol use, affective disorder, prior electroconvulsive therapy, diabetes mellitus, and various genetic factors.<sup>136</sup>

Several distinct tardive syndromes are recognized, including the classic orobuccal lingual masticatory stereotypy, chorea, dystonia, myoclonus, blepharospasm, and tics. It is generally accepted that the atypical antipsychotics are associated with a lower incidence of tardive dyskinesia and other drug-related movement disorders. However, whether this is true of all atypical antipsychotics is unclear. Among the atypical antipsychotics, clozapine is associated with the lowest incidence of tardive dyskinesia and risperidone with the highest incidence (when higher doses are used), but the reasons for this are uncertain.<sup>132,133,136</sup>

**Treatment of Tardive Dyskinesia.** Tardive dyskinesia is highly resistant to the usual pharmacologic treatments for movement disorders. A recent systematic review of various treatment options concluded that none was supported by good evidence, including dose reduction, switching between antipsychotics, anticholinergics, benzodiazepines,  $\beta$ -adrenergic antagonists, buspirone,

calcium channel blockers, or vitamin E.<sup>12</sup> Consequently, no firm guidance can be offered regarding the management of tardive dyskinesia, which should be guided by individual patient considerations. Despite the absence of good data, a recent review proposed strategies for management of tardive dyskinesia, beginning with primary prevention (avoidance of antipsychotic therapy where possible and use of the lowest effective dose).<sup>141</sup> Tetrabenazine, an inhibitor of vesicular monoamine transporter type 2 (VMAT2), was suggested as the first-line treatment, although it is expensive and may cause somnolence, depression, or parkinsonism.<sup>4</sup> Valbenazine, a recently approved VMAT2 inhibitor with a longer half-life, appears to be better tolerated than tetrabenazine.<sup>59</sup> For focal tardive dyskinesia (cervical or oromandibular, for example), the same review suggested botulinum toxin injections.

**Neuroleptic Malignant Syndrome.** Neuroleptic malignant syndrome (NMS) is a potentially life-threatening emergency. First described in 1960 in patients treated with haloperidol, this syndrome is now associated with virtually every antipsychotic.<sup>35</sup> The reported incidence of NMS ranges from 0.2% to 1.4% of patients receiving antipsychotics,<sup>2,24,131</sup> but less severe episodes may go undiagnosed or unreported. As a result, much of what is known about the epidemiology and treatment of NMS is speculative and based on case reports and case series. Most cases of NMS are diagnosed in young adulthood, with the frequency of diagnosis diminishing gradually thereafter.<sup>46</sup>

The pathophysiology of NMS is incompletely understood but involves abrupt reductions in central dopaminergic neurotransmission in the striatum and hypothalamus, altering the core temperature “set point”<sup>48</sup> and leading to impaired thermoregulation and other manifestations of autonomic dysfunction. Blockade of striatal D<sub>2</sub> receptors contributes to muscle rigidity and tremor.<sup>13,26,138</sup> In some cases, a direct effect on skeletal muscle may play a role in the pathogenesis of hyperthermia, but the thermoregulation of NMS is principally a centrally mediated phenomenon.<sup>48</sup> Altered mental status is multifactorial and reflects one or more of hypothalamic and spinal dopamine receptor antagonism, a genetic predisposition, or the direct effects of hyperthermia and other drugs.<sup>50</sup> Although NMS most often occurs during treatment with a D<sub>2</sub> receptor antagonist, withdrawal of dopamine agonists sometimes produces an indistinguishable syndrome. The latter typically occurs in patients with long-standing Parkinson disease who abruptly change or discontinue treatment with dopamine agonists such as levodopa/carbidopa, amantadine,<sup>43</sup> or bromocriptine.<sup>13</sup> The resulting disorder is sometimes referred to as the Parkinsonian-hyperpyrexia syndrome, and mortality rates of up to 4% are reported.<sup>95</sup> Hospitalization for aspiration pneumonia, a common occurrence in older patients with Parkinson disease, is a particularly high-risk setting for this complication and is particularly dangerous because the cardinal manifestations of NMS are easily misattributed to the combined effects of pneumonia and the underlying movement disorder.

The vast majority of NMS cases occur in the context of therapeutic use of antipsychotics rather than after overdose. Postulated risk factors for the development of NMS include young age, male gender, extracellular fluid volume contraction, use of high-potency antipsychotics, depot preparations, cotreatment with lithium, multiple drugs in combination, and rapid dose escalation.<sup>2,25,75,97</sup> One large observational study<sup>97</sup> suggests that treatment with high-potency first-generation antipsychotics is associated with a more than 20-fold increase in the risk of NMS, although this may partly reflect heightened suspicion of the disorder in patients receiving those drugs. The mortality rate of NMS associated with first-generation antipsychotics is estimated at approximately 16%, and the rate associated with second-generation antipsychotics is estimated at 3%.<sup>135</sup>

The manifestations of NMS include the tetrad of altered mental status, muscular rigidity (classically described as “lead pipe”), hyperthermia, and autonomic dysfunction. These findings appear in any sequence, although a review of 340 NMS cases found that mental status changes and rigidity usually preceded the development hyperthermia and autonomic instability.<sup>139</sup> Occasionally, rigidity is not present when creatine kinase concentrations are elevated but emerges thereafter.<sup>98</sup> Signs typically evolve over a period of several days, with the majority occurring within 2 weeks of antipsychotic initiation. However, it is important to recognize that NMS occurs even after prolonged use of an antipsychotic, particularly after a dose increase, the addition of another antipsychotic, or the development of intercurrent illness. It is also worth noting that the clinical course of NMS often fluctuates, sometimes waxing and waning dramatically over a few hours.

There are no universally accepted criteria for the diagnosis of NMS, and more than a dozen sets of criteria have been proposed.<sup>3,24,37,75</sup> The operating characteristics of these criteria have not been formally evaluated, in part because of the absence of a gold standard. An international group published the results of a Delphi consensus panel regarding the diagnosis of NMS (Table 67–5).<sup>47</sup> A recent validation exercise suggested that an aggregate cut-off score of 74 (of a possible 100) was associated with the highest degree of agreement between expert-generated criteria and *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision, criteria (sensitivity,

69.6%; specificity, 90.7%).<sup>49</sup> However, the authors caution that in the absence of a biological reference standard, this scoring system should be used adjunctively with current clinical standards for the diagnosis of NMS.

It may be difficult to distinguish NMS from other toxin-induced hyperthermia syndromes, such as those associated with anticholinergics (antimuscarinics) (Chap. 49) and the serotonergics (Chap. 69), all of which share common features of elevated temperature, altered mental status, and neuromuscular abnormalities. The most important differentiating feature is the medication history, with dopamine antagonists, antimuscarinic drugs, and direct or indirect serotonin agonists (often in combination) as the most likely etiologies, respectively. The time course of the illness also helps to differentiate among the disorders. Whereas serotonin toxicity and the antimuscarinic syndrome tend to develop rapidly after exposure to causative xenobiotics, NMS typically develops more gradually, often waxing and waning over several days or more. Occasionally, clinicians must attempt to differentiate NMS from other disorders in the absence of a reliable medication history. The physical examination is of some utility in this regard.<sup>103</sup> Although NMS is classically characterized by “lead-pipe” rigidity, the presence of ocular or generalized clonus is more suggestive of serotonin toxicity, particularly when accompanied by shivering and hyperreflexia, findings not typical of NMS. Because skeletal muscle contraction occurs through nicotinic rather than muscarinic transmission, patients with the antimuscarinic syndrome generally have few muscular abnormalities. However, such patients are sometimes resistant to physical restraint, giving the appearance of increased muscle tone.

**Treatment of Neuroleptic Malignant Syndrome: General Measures.** Treatment recommendations are largely based on general physiologic principles, case reports, and case series. Therapy should be individualized according to the severity and duration of illness and the modifying influences of comorbidity.<sup>13,111,140</sup> The provision of good supportive care is the cornerstone for treatment of NMS. It is essential to recognize the condition as an emergency and to withdraw the offending xenobiotic immediately. When NMS ensues after abrupt discontinuation of a dopamine agonist such as levodopa, the drug should be reinstated promptly. Most patients with suspected NMS should be admitted to an intensive care unit. Supplemental oxygen should be administered, and assisted ventilation is necessary in cases of respiratory failure, which result from one or more of central hypoventilation, loss of protective airway reflexes, rigidity of the chest wall muscles or oversedation.

The hyperthermia associated with NMS is multifactorial in origin and, when present, warrants aggressive treatment. Antipyretics are not effective. Immersion of patients with severe drug-induced hyperthermia (>106°F) in an ice-water bath has been shown to rapidly lower body temperature (Chaps. 29 and 75).<sup>74</sup> Despite the absence of good data in patients with NMS, we recommend ice-water immersion in patients with severe hyperthermia given the urgency with which it should be corrected. Other strategies include active cooling blankets; the placement of ice packs in the groin and axillae; or evaporative cooling, which can be accomplished by removing the patient's clothing and exposing the patient to cooled water or towels immersed in ice water while maintaining continuous air circulation with the use of fans. Although often used,<sup>145</sup> these approaches are inferior to ice water immersion and are not recommended unless immersion is impractical or unsafe.

Hypotension should be treated initially with isotonic crystalloid followed by vasopressors if necessary. Maintenance of intravascular volume and adequate renal perfusion are recommended to reduce the incidence of myoglobinuric acute kidney injury in patients with high creatine kinase concentrations. Tachycardia does not require specific treatment, but hemodynamically significant bradycardia necessitates transcutaneous or transvenous pacing. Venous thromboembolism is a major cause of morbidity and mortality in patients with NMS, and prophylactic doses of low-molecular-weight heparin are reasonable in patients who likely will be immobilized for more than 12 to 24 hours.

**Pharmacologic Treatment of Neuroleptic Malignant Syndrome.** Benzodiazepines are the most widely used pharmacologic adjuncts for treatment of

**TABLE 67–5 Suggested Diagnostic Criteria for the Neuroleptic Malignant Syndrome**

Criterion	Priority Score
Exposure to a dopamine antagonist or withdrawal of a dopamine agonist in previous 72 hours	20
Hyperthermia (>100.4°F or 38.0°C on at least two occasions, measured orally)	18
Rigidity	17
Mental status alteration (reduced or fluctuating level of consciousness)	13
Creatine kinase elevation (at least four times the upper limit of normal)	10
Sympathetic nervous system lability, defined as at least two of: Blood pressure elevation (SBP or DBP ≥25% above baseline) Blood pressure fluctuation (≥20% DBP change or ≥25% SBP change in 24 hours) Diaphoresis Urinary incontinence	10
Hypermetabolic state (defined as heart rate increase ≥25% above baseline and respiratory rate increase ≥50% above baseline)	5
Negative workup for other toxic, metabolic, infectious, or neurologic causes	7

DBP = diastolic blood pressure; SBP = systolic blood pressure.

Data from Fryml L, Williams KR, Pelic CG, et al. The role of amantadine withdrawal in 3 cases of treatment-refractory altered mental status. *J Psychiatr Pract.* 2017 May;23(3):191-199.

NMS and are recommended as first line-therapy. Dantrolene and bromocriptine are not well studied, and their incremental benefit over good supportive care is debated.<sup>111,116</sup> Benzodiazepines are frequently used in the management of NMS because of their rapid onset of action, which is particularly important when patients are agitated or restless. They attenuate the sympathetic hyperactivity that characterizes NMS by facilitating GABA-mediated chloride transport and producing neuronal hyperpolarization, in a fashion analogous to their beneficial effects in cocaine toxicity.<sup>50</sup> The primary disadvantage of benzodiazepines is that they will cloud the assessment of the patient's mental status.

Dantrolene reduces skeletal muscle activity by inhibiting ryanodine receptor type 1 calcium release channels, interfering with calcium release from the sarcoplasmic reticulum.<sup>69</sup> In theory, this should reduce body temperature and total oxygen consumption and lessen the risk of myoglobinuric acute kidney injury. The role of dantrolene in NMS is controversial because the available literature is limited to case reports and case series with varying conclusions. Moreover, unlike malignant hyperthermia (in which the use of dantrolene is unquestioned), the muscle rigidity of NMS is principally a centrally mediated process. Nevertheless, several reports describe rapid, dramatic reductions in rigidity and temperature after its administration.<sup>17,53,72</sup> Dantrolene is not recommended as a routine treatment in patients with NMS but is reasonable in those with prominent muscular rigidity or rhabdomyolysis, in light of its potential benefits and relative safety.<sup>13</sup> It can be given by mouth or nasogastric tube (50–100 mg/d) or by intravenous (IV) infusion (2–3 mg/kg/d, or up to 10 mg/kg/d in severe cases). Bromocriptine is a centrally acting dopamine agonist given orally or by nasogastric tube at dosages of 2.5 to 10 mg three or four times daily. The rationale for its use rests in the belief that reversal of antipsychotic-related striatal D<sub>2</sub> antagonism will ameliorate the manifestations of NMS. It is recommended in patients with moderate to severe NMS, but other dopamine agonists anecdotally associated with success may be used instead, including ropinirole, levodopa,<sup>100,127</sup> and amantadine.<sup>44,60,131</sup> Of note, dopaminergics are associated with exacerbation of underlying psychiatric illness.

When these medications are used, they should be tapered slowly after the patient improves to minimize the likelihood of recrudescence of NMS. In severe cases with prominent rigidity it is reasonable to use dantrolene and a dopamine agonist should be used in combination with benzodiazepines.

**Electroconvulsive Therapy.** Electroconvulsive therapy (ECT) is reported to dramatically improve the manifestations of NMS, presumably by enhancing central dopaminergic transmission. In one report, five patients received an average of 10 ECT treatments, and resolution generally occurred after the third or fourth session.<sup>99</sup> Whether this result represents a true effect of ECT or simply the natural course of NMS with good supportive care alone is not clear. As with drug therapies for NMS, the effectiveness of ECT remains unproven, but its use seems reasonable in patients with severe, persistent, or treatment-resistant NMS as well as those with residual catatonia or psychosis after resolution of other manifestations.<sup>13,100</sup>

**Adverse Effects on Other Organ Systems.** Sedation, dry mouth, and urinary retention occur commonly with antipsychotics, particularly during the initial period of therapy. These effects occur most commonly with antipsychotics that exhibit antihistaminic and antimuscarinic activity. All antipsychotics lower the seizure threshold, but seizures are uncommon during therapeutic use. Because hypothalamic dopamine inhibits hypophyseal prolactin release, hyperprolactinemia and galactorrhea can occur. All antipsychotics are associated with a host of metabolic derangements, including weight gain, dyslipidemia, and steatohepatitis. The metabolic syndrome appears most commonly in association with clozapine, olanzapine, and chlorpromazine therapy.<sup>34</sup> Rare but dramatic instances of glucose intolerance, including fatal cases of diabetic ketoacidosis, are also described.<sup>6,54,107,134</sup> The mechanism of this is incompletely understood, but it is not adequately explained by the weight gain associated with antipsychotic therapy because glucose disturbances often develop shortly after therapy is instituted. The risk of hyperglycemia appears greatest during

the initial weeks of antipsychotic therapy.<sup>79</sup> Other idiosyncratic reactions reported with use of antipsychotics include photosensitivity, skin pigmentation and cholestatic hepatitis (particularly with the phenothiazines), myocarditis, and agranulocytosis (the latter occurs with many antipsychotics, most notably clozapine, occurring in up to 2% of patients).<sup>90</sup> Most of these conditions result from an immunologically based hypersensitivity reaction and develop during the first month of therapy. Finally, an increasing number of reports associate antipsychotic drugs with venous thromboembolism.<sup>52,63</sup> This may partially explain the high incidence of thromboembolic disease found in patients with NMS (see later).

### Acute Overdose

Antipsychotic overdose produces a spectrum of toxic manifestations involving multiple organ systems, but the most serious toxicity involves the CNS and cardiovascular system. Some of these manifestations are present to a minor degree during therapeutic use, although they tend to be most pronounced during the early period of therapy and dissipate with continued use.

Depressed level of consciousness is a common and dose-dependent feature of antipsychotic overdose, ranging from somnolence to coma. It may be associated with impaired airway reflexes, but significant respiratory depression is uncommon in the absence of other factors. Many antipsychotics, including several of the atypicals, are potent muscarinic antagonists and produce anticholinergic features in overdose.<sup>10,22,27</sup> Peripheral manifestations include tachycardia, decreased production of sweat and saliva, flushed skin, urinary retention, diminished bowel sounds, and mydriasis, although miosis also occurs. These findings may be present in isolation or coexist with central manifestations, including agitation, delirium, psychosis, hallucinations, and coma, some of which may be mistakenly attributed to the underlying psychiatric illness.

Mild elevations in body temperature are common and reflect impaired heat dissipation as a result of impaired sweating, as well as increased heat production in agitated patients. Hyperthermia should always prompt a search for other features of NMS. Tachycardia is a common finding in patients with antipsychotic overdose and reflects reduced vagal tone and, with some antipsychotics, a compensatory response to hypotension. Bradycardia is distinctly uncommon, and although it may be a preterminal finding, its presence should prompt a search for alternative causes, including ingestion of negative chronotropic drugs such as  $\beta$ -adrenergic antagonists, calcium channel blockers, cardioactive steroids, and opioids. Hypotension is a common feature of antipsychotic overdose and is generally caused by peripheral  $\alpha_1$ -adrenergic blockade and, particularly with the phenothiazines, reduced myocardial contractility.

The electrocardiographic (ECG) manifestations of antipsychotic overdoses vary, sometimes exhibiting similarities to those of cyclic antidepressant toxicity (Chaps 15 and 68). These include prolongation of the QRS complex and a rightward deflection of the terminal 40 ms of the QRS complex, typically manifesting as a tall, broad terminal positive deflection of the QRS complex in lead aVR. These changes reflect blockade of the inward sodium current ( $I_{Na}$ ). Prolongation of the QT interval results from blockade of the delayed rectifier potassium current ( $I_{Kr}$ ), creating a substrate for development of torsade de pointes and other ventricular dysrhythmias.<sup>94</sup> This situation is sometimes evident during maintenance therapy and may underlie the apparent increase in sudden cardiac death among users of antipsychotic drugs.<sup>108,109</sup>

### DIAGNOSTIC TESTS

The diagnosis of antipsychotic poisoning is supported by the clinical history, the physical examination, and a limited number of adjunctive tests. Both the clinical and ECG findings are nonspecific and shared by other drug classes, including TCAs, skeletal muscle relaxants, carbamazepine, and first-generation antihistamines such as diphenhydramine. Moreover, the absence of typical ECG changes does not exclude a significant antipsychotic ingestion, particularly early after overdose, and at least one additional ECG is recommended in the following 2 to 3 hours.

Abdominal radiography sometimes reveals densities in the gastrointestinal tract because some solid dosage forms of phenothiazines are radiopaque. However, these tests are neither sensitive nor specific, and they are not recommended in the absence of another indication.

Plasma concentrations of antipsychotics are not widely available, do not correlate well with clinical signs and symptoms, and do not help guide therapy. Comprehensive urine drug screens using high-performance liquid chromatography, gas chromatography–mass spectrometry, or tandem mass spectrometry can detect antipsychotics, but these tests are available at only a few hospitals and in most instances provide only a qualitative result and are not recommended. Urine immunoassays for TCAs occasionally produce a false-positive result in the presence of phenothiazines.<sup>5,115</sup>

## MANAGEMENT

The care of a patient with an antipsychotic overdose should proceed with the recognition that other drugs, particularly other psychotropics, may have been coingested and can confound both the clinical presentation and management. Regularly encountered coingestants include other psychotropic drugs such as antidepressants, sedative–hypnotics, opioids, anticholinergic agents, valproic acid, and lithium, as well as ethanol and nonprescription analgesics such as acetaminophen and aspirin.

Supportive care is the cornerstone of treatment for patients with antipsychotic overdose. Supplemental oxygen should be administered if hypoxia is present. Intubation and ventilation are rarely required for patients with single xenobiotic ingestions but may be necessary for patients with very large overdoses of antipsychotics or coingestion of other CNS depressants. Patients with altered mental status should receive thiamine, as well as parenteral dextrose if hypoglycemia is present. Naloxone is recommended based on clinical grounds (Antidotes in Depth: A4). All symptomatic patients should undergo continuous cardiac monitoring. An ECG should be recorded upon presentation and reliable venous access obtained. Asymptomatic patients with a normal ECG 6 hours after overdose are at exceedingly low risk of complications and generally do not require ongoing cardiac monitoring. Symptomatic patients and those with an abnormal ECG should have continuous monitoring for a minimum of 24 hours.

### Gastrointestinal Decontamination

Gastrointestinal decontamination with activated charcoal (1 g/kg by mouth or nasogastric tube) is recommended for patients who present within a few hours of a large or multidrug overdose and have no contraindications. Although this intervention is time sensitive, many antipsychotics exhibit significant antimuscarinic activity and slow gastric emptying, thereby increasing the likelihood that activated charcoal will be beneficial. Although it is unknown whether activated charcoal improves clinically important outcomes,<sup>64</sup> a Bayesian analysis of pharmacokinetic data from a series of quetiapine overdoses concluded that activated charcoal use led to a 35% reduction in the fraction of quetiapine absorbed.<sup>57</sup> Orogastric lavage and whole-bowel irrigation likely will not improve clinical outcomes and should be used rarely in the management of patients with antipsychotic overdose.

### Treatment of Cardiovascular Complications

Vital signs should be monitored closely. Hypotension most often results from peripheral  $\alpha$ -adrenergic blockade and is most likely to occur with older, low-potency antipsychotics such as thioridazine.<sup>91</sup> Hypotension should be treated initially with appropriate titration of 0.9% sodium chloride. If vasopressors are required, direct-acting agonists such as norepinephrine or phenylephrine are recommended over dopamine, which is an indirect agonist and likely will be ineffective. Vasopressin or its analogs should be used with great caution in patients who have coingested a negative inotropic drug such as a  $\beta$ -adrenergic antagonist or calcium channel blocker. Continuous blood pressure monitoring may be warranted in such cases.

Progressive prolongation of the QRS complex is uncommon and reflects sodium channel blockade and slowing of phase 0 depolarization in the His-Purkinje system. This is usually associated with reduced cardiac output

and malignant ventricular dysrhythmias. Much of what is known about the treatment of sodium channel blocker toxicity derives from the cyclic antidepressant literature, with treatment recommendations extended to sodium channel blocking antipsychotic drugs by analogy. Sodium bicarbonate (1–2 mEq/kg) is the first-line therapy for ventricular dysrhythmias and is recommended for patients with dysrhythmias or QRS complex greater than 0.12 seconds (Antidotes in Depth: A5 and Chap. 68). At least two mechanisms underlie the beneficial effects of sodium bicarbonate, sodium channel blockade is partially overcome by an increase in extracellular sodium, and the binding of antipsychotics to the sodium channel is less extensive binding at higher pH values.

Repeated boluses of bicarbonate are recommended to achieve a target blood pH of no greater than 7.5, although we recommend continuous infusions.<sup>125</sup> If the patient is intubated, hyperventilation is recommended only if sodium bicarbonate is unavailable. If significant conduction abnormalities or ventricular dysrhythmias persist despite the use of sodium bicarbonate, lidocaine (1–2 mg/kg, followed by continuous infusion) is a reasonable second-line antidysrhythmic. Although lidocaine is also a sodium channel blocker, it exhibits rapid on/off sodium channel binding with preferential binding in the inactivated state and reportedly lessens the cardiotoxicity associated with antipsychotic drug overdose.<sup>124</sup> Class IA antidysrhythmics (procainamide, disopyramide, and quinidine), class IC antidysrhythmics (propafenone, encainide, and flecainide), and class III antidysrhythmics (amiodarone, sotalol, and bretylium) can aggravate cardiotoxicity and are contraindicated. When administering sodium bicarbonate to patients with antipsychotic overdose, caution must be taken to avoid hypokalemia because many of these antipsychotics block cardiac potassium channels, thereby prolonging the QT interval. Hypokalemia and hypomagnesemia exacerbate this blockade, potentially leading to torsade de pointes and other lethal dysrhythmias, particularly in patients with overdoses involving amisulpride or ziprasidone.

Sinus tachycardia related to anticholinergic activity should not be treated unless it is associated with active ischemia, which, although uncommon, may complicate antipsychotic overdose in patients with existing coronary disease. If symptomatic sinus tachycardia requires emergent treatment, a short-acting  $\beta$ -adrenergic antagonist such as esmolol is recommended. Prolongation of the QT interval requires no specific treatment other than monitoring and correction of potential contributing causes such as hypokalemia and hypomagnesemia. After torsade de pointes has resolved spontaneously resolved or after cardioversion, intravenous magnesium sulfate is recommended to lessen the likelihood of recurrence, taking care to prevent hypotension, which is dose and rate dependent. Overdrive pacing with isoproterenol or transcutaneous or transvenous pacing is recommended if the patient does not respond to magnesium; however, magnesium is preferred because pacing may worsen rate-dependent sodium channel blockade.

Most antipsychotics exhibit a high degree of lipophilicity in addition to significant cardiovascular toxicity. Considerable enthusiasm has emerged for the use of intravenous lipid emulsion (ILE) therapy for patients with significant cardiac toxicity from lipophilic drugs (Antidotes in Depth: A23). The rationale for this therapy rests, in part, in the concept that highly lipophilic drugs selectively partition into the exogenous lipid, minimizing toxicity at the biophase. This treatment has been extensively studied in animal models of bupivacaine toxicity,<sup>36,143,144</sup> but published experience with antipsychotic drugs is limited to a handful of case reports.<sup>41,85,87,151</sup> Recently published evidence-based recommendations on the use of ILE in acute poisoning note the very low quality of evidence supporting the intervention for most poisonings.<sup>45</sup> As a result, it is reasonable to give ILE only in cases of not rapidly treatable cardiovascular collapse after antipsychotic overdose. Dosing for ILE is not well established, but a reasonable protocol begins with 20% lipid emulsion given as a bolus of 1.5 mL/kg (Antidotes in Depth: A23). Extracorporeal circulatory support is associated with survival in severe quetiapine overdose; however, this is only an option in selected centers. This intervention, when available, in critically ill patients unresponsive to other therapies is reasonable but therefore not routinely recommended at this time.<sup>73</sup>

## Treatment of Seizures

Seizures associated with antipsychotic overdose are generally short-lived and often require no pharmacologic treatment. Multiple or refractory seizures should prompt a search for other causes, including hypoglycemia and ingestion of other proconvulsant xenobiotics. When treatment is necessary, benzodiazepines such as lorazepam or diazepam generally suffice, although phenobarbital is a reasonable second-line therapy. Although phenytoin is part of the standard algorithm for status epilepticus, it is of limited effectiveness for xenobiotic-induced seizures.<sup>126</sup> Patients with refractory seizures should respond to propofol infusion or general anesthesia. Finally, seizures abruptly lower serum pH and thereby increase the cardiotoxicity of antipsychotics by enhancing binding to the sodium channel; therefore, an ECG should be obtained after resolution of seizure activity.

## Treatment of the Central Antimuscarinic Syndrome

Many of the older and newer generation antipsychotics have pronounced anticholinergic properties. Case reports and observational studies suggest that the cholinesterase inhibitor physostigmine (Antidotes in Depth: A11) can safely and effectively ameliorate the agitated delirium associated with the central antimuscarinic (anticholinergic) syndrome by indirectly increasing synaptic acetylcholine levels.<sup>26,118-120</sup> Although benzodiazepines control agitation, they further impair alertness, obfuscating the assessment of mental status and increasing the risk of complications.<sup>23</sup>

Physostigmine has been used successfully in patients with antipsychotic overdose,<sup>23,117,120,146,147</sup> but it should be used with caution. It should not be used in patients with ventricular dysrhythmias, any degree of heart block, or prolongation of the QRS complex. If physostigmine is used, it is recommended to be given in 0.5-mg increments every 3 to 5 minutes, with close observation. If bradycardia, bronchospasm, or bronchorrhea develops, these can be treated with glycopyrrolate 0.2 to 0.4 mg IV. Atropine is often more widely available and is a reasonable alternative to glycopyrrolate but it crosses the blood-brain barrier and is likely to aggravate delirium. The effects of physostigmine are transient, typically ranging in duration from 30 to 90 minutes, and additional doses are often necessary. Of note, physostigmine does not prevent other complications of antipsychotic overdose, particularly those involving the cardiovascular system.

Other commonly used cholinesterase inhibitors, such as edrophonium, neostigmine, and pyridostigmine, should not be used to treat anticholinergic delirium because they do not cross the blood-brain barrier. Case reports involving other anticholinergics suggest that cholinesterase inhibitors used for treatment of dementia (eg, tacrine, donepezil, and galantamine) are reasonable alternatives to physostigmine for patients able to take medications orally.<sup>58,89,101</sup>

## Enhanced Elimination

No pharmacologic rationale supports the use of multiple-dose charcoal or manipulation of urinary pH to increase the clearance of antipsychotics. One volunteer study found that urinary acidification may increase remoxipride elimination,<sup>149</sup> but this practice is impractical and possibly dangerous. Because most antipsychotics exhibit large volumes of distribution and extensive protein binding (Table 67-1), extracorporeal removal is unwarranted and should be performed only if the patient has coingested other xenobiotics amenable to extracorporeal removal.

## SUMMARY

- Over the past decade, the atypical antipsychotics have largely supplanted traditional antipsychotics, which were associated with greater toxicity in overdose and a higher incidence of extrapyramidal reactions. Consequently, atypical antipsychotics are now implicated in the majority of overdoses.
- With both typical and atypical antipsychotics, significant toxicity can occur either during the course of therapy or after overdose. Of the various toxicities that arise during therapeutic use, NMS is the most dangerous. Its manifestations are protean, and it may be difficult to

recognize. Altered mental status, muscle rigidity, hyperthermia, and autonomic instability are its hallmarks, but the diagnosis should be considered in any unwell patient treated with antipsychotics, particularly in the 2 weeks after a change in therapy or in a patient with another stressor such as severe intercurrent illness or general anesthesia. Treatment of NMS is largely supportive and often involves the use of benzodiazepines. Dopamine agonists such as bromocriptine and ropinirole are recommended in patients with moderate to severe NMS, while dantrolene is recommended only in those with severe muscle rigidity or rhabdomyolysis. Electroconvulsive therapy is anecdotally associated with dramatic clinical improvement.

- The principal manifestations of antipsychotic overdose involve the CNS and cardiovascular system. Depressed mental status, hypotension, and anticholinergic signs are nonspecific features that support the diagnosis of, particularly in conjunction with typical ECG findings of sodium channel blockade and QT interval prolongation, although these vary considerably among the available antipsychotic drugs.
- Most fatalities after antipsychotic overdose occur in cases involving coingestion of other CNS depressants or cardiotoxic medications.
- Supportive care is the mainstay of therapy for patients with antipsychotic overdose, although selective use of nonspecific antidotes, such as activated charcoal, sodium bicarbonate, or physostigmine, may improve outcomes in selected patients. Particularly severe or refractory cardiovascular toxicity may warrant a trial of ILE or extracorporeal life support, although these interventions are not well studied in the context of antipsychotic drug overdose.

# CYCLIC ANTIDEPRESSANTS

Matthew Valento and Erica L. Liebelt

## HISTORY AND EPIDEMIOLOGY

The term *cyclic antidepressant* (CA) refers to a group of pharmacologically related xenobiotics used for treatment of depression, neuralgic pain, migraines, enuresis, and attention deficit hyperactivity disorder (ADHD). Most CAs have at least three rings in their chemical structure. They include the traditional tricyclic antidepressants (TCAs) imipramine, desipramine, amitriptyline, nortriptyline, doxepin, trimipramine, protriptyline, and clomipramine, as well as other cyclic compounds such as the tetracyclic, maprotiline and the dibenzoxapine amoxapine, antidepressants.

Imipramine was the first TCA used for treatment of depression in the late 1950s. However, the synthesis of iminodibenzyl, the “tricyclic” core of imipramine, and the description of its chemical characteristics date back to 1889. Structurally related to the phenothiazines, imipramine was originally developed as a hypnotic for agitated or psychotic patients and was serendipitously found to alleviate depression. From the 1960s until the late 1980s, the TCAs were the major pharmacologic treatment for depression in the United States. However, by the early 1960s, cardiovascular and central nervous system (CNS) toxicities were recognized as major complications in patients with TCA overdoses. The newer CAs developed in the 1980s and 1990s were designed to decrease some of the adverse effects of older TCAs, improve the therapeutic index, and reduce the incidence of serious toxicity. The epidemiology of CA poisoning has evolved significantly in the past 30 years, resulting in great part from the introduction of the selective serotonin reuptake inhibitors (SSRIs and SSNRIs) and other newer antidepressants for the treatment of depression. Although the use of CAs for depression has decreased, other medical indications, including chronic pain, sleep disorders, obsessive-compulsive disorder, and, particularly in children, enuresis and ADHD, have emerged, resulting in their continued use.<sup>19,87</sup> The antidepressants are a leading cause of drug-related self-poisonings in the developed world, primarily because of their ready availability to people with depression or chronic pain who by virtue of their diseases are at high risk for overdose. However, despite the increase in SSRI use and overdose, patients with TCA overdoses continue to have a higher incidence of hospitalization and fatality than do those with SSRI overdose and continue to be among the leading xenobiotics associated with fatality reported to poison control centers (Chap. 130).

Despite the emergence of the SSRIs in the early 1990s, TCAs are still frequently prescribed by pediatric office-based practices for many of the conditions noted earlier. Since the October 2004 US Food and Drug Administration boxed warning about the increased risk of suicidal behavior associated with antidepressant use, several reports describe significant declines in antidepressant dispensing in children compared with historical trends.<sup>25</sup> Nevertheless, CA poisoning likely will continue to be among the most lethal unintentional drug ingestions in younger children because only one or two adult-strength pills can produce serious clinical effects in young children.

## PHARMACOLOGY

The TCAs are classified into tertiary and secondary amines based on the presence of a methyl group on the propylamine side chain (Table 68–1). The tertiary amines amitriptyline and imipramine are metabolized to the secondary amines nortriptyline and desipramine, respectively, which themselves are marketed as antidepressants. In therapeutic doses, the CAs produce similar pharmacologic effects on the autonomic system, CNS, and cardiovascular system. However, they can be distinguished from each other by their relative potencies and side effect profiles.<sup>124</sup>

At therapeutic doses, CAs inhibit presynaptic reuptake of norepinephrine or serotonin, functionally increasing the amount of these neurotransmitters

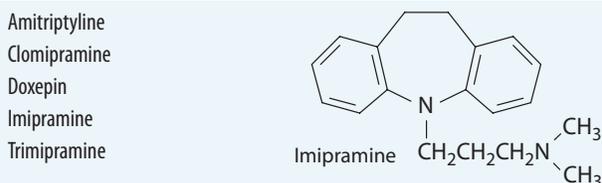

at CNS receptors. Whereas the tertiary amines, especially clomipramine, are more potent inhibitors of serotonin reuptake, the secondary amines are more potent inhibitors of norepinephrine reuptake. Although these pharmacologic actions formed the basis of the monoamine hypothesis of depression in the 1960s, antidepressant actions of these drugs appear to be much more complex.

The “receptor sensitivity hypothesis of antidepressant drug action” postulates that after chronic CA administration, alterations in the sensitivity of various receptors are responsible for antidepressant effects. Chronic CA administration alters the number or function of central  $\beta$ -adrenergic and serotonin receptors. In addition, CAs modulate glucocorticoid receptor gene expression and cause alterations at the genomic level of other receptors.<sup>8</sup> All of these actions likely play a role in the antidepressant effects of CAs.

Additional pharmacologic mechanisms of CAs are responsible for their side effects with therapeutic dosing and clinical effects after overdose. All of the CAs are competitive antagonists of the muscarinic acetylcholine receptors, although they have different affinities. The CAs also antagonize peripheral  $\alpha_1$ -adrenergic receptors. The most prominent effects of CA overdose result from binding to the cardiac sodium channels, which is also described as a membrane-stabilizing effect (Fig. 68–1) (Chap. 15). The TCAs are potent inhibitors of both peripheral and central postsynaptic histamine receptors.

TABLE 68–1 Cyclic Antidepressants—Classification by Chemical Structure

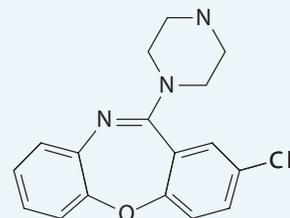

### Tertiary Amines

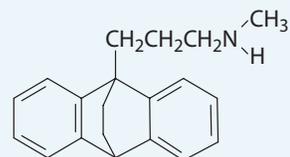

### Secondary Amines

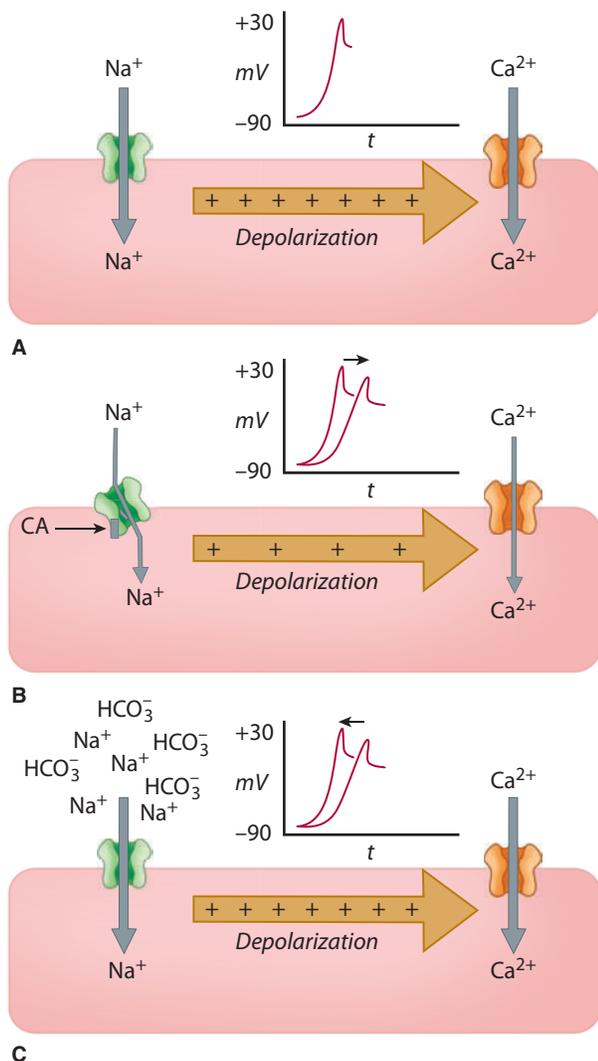

### Amoxapine

### Maprotiline

**FIGURE 68-1.** Effects of cyclic antidepressants (CAs) on the fast sodium channel. (A) Sodium depolarizes the cell, which both propagates conduction, allowing complete cardiac depolarization, and opens voltage-dependent  $\text{Ca}^{2+}$  channels, producing contraction. (B) CAs and other sodium channel blockers alter the conformation of the sodium channel, slowing the rate of rise of the action potential, which produces both negative dromotropic and inotropic effects. (C) Raising the  $\text{Na}^+$  gradient across the affected sodium channel speeds the rate of rise of the action potential, counteracting the drug-induced effects. Raising the pH removes the CA from the binding site on the  $\text{Na}^+$  channel. See Fig. 68-3 for the effects noted on the electrocardiograph.

Finally, the CAs interfere with chloride conductance by binding to the picrotoxin site on the  $\gamma$ -aminobutyric acid (GABA)-chloride complex.<sup>112</sup>

Amoxapine is a dibenzoxazepine CA derived from the active antipsychotic loxapine. Although it has a three-ringed structure, this drug has little similarity to the other tricyclics. It is a potent norepinephrine reuptake inhibitor, has no effect on serotonin reuptake, and blocks dopamine receptors. Maprotiline is a tetracyclic antidepressant that predominantly blocks norepinephrine reuptake. Both of these CAs have a slightly different toxic profile than the traditional TCAs.<sup>59,61,124</sup>

## PHARMACOKINETICS AND TOXICOKINETICS

In therapeutic dosing, the CAs are rapidly and almost completely absorbed from the gastrointestinal (GI) tract, with peak concentrations 2 to 8 hours after administration of a therapeutic dose. They are weak bases (high  $\text{pK}_a$ ). In overdose, the decreased GI motility caused by anticholinergic effects and ionization in gastric acid delay CA absorption. Because of extensive first-pass metabolism by the liver, the oral bioavailability of CAs is

low and variable, although metabolism saturates in overdose, increasing bioavailability.

The CAs are highly lipophilic and possess large and variable volumes of distribution (15–40 L/kg). They are rapidly distributed to the heart, brain, liver, and kidney, in which the tissue to plasma ratio generally exceeds 10:1. The octanol/water partition coefficient ( $\log P$ ) is an often cited measure of lipid-solubility with the  $\log D$  representing  $\log P$  at physiological pH—a more representative measure. Some examples of  $\log D$  values for CAs are amitriptyline, 3.96; nortriptyline, 2.86; imipramine, 2.06; desipramine, 1.05; and doxepin, 2.93.

Less than 2% of the ingested dose is present in blood several hours after overdose, and serum CA concentrations decline biexponentially. The CAs are extensively bound to  $\alpha_1$ -acid glycoprotein (AAG) in the plasma, although differential binding among the specific CAs is observed.<sup>2</sup> Changes in AAG concentration or pH can alter binding and the percentage of free or unbound drug.<sup>94,106</sup> Specifically, a low blood pH (which often occurs in a severely poisoned patient) increases the amount of free drug, making it more available to exert its effects. This property serves as one basis for alkalization therapy (see later).

The CAs undergo demethylation, aromatic hydroxylation, and glucuronide conjugation of the hydroxy metabolites. The tertiary amines imipramine and amitriptyline are demethylated to desipramine and nortriptyline, respectively. The hydroxy metabolites of both tertiary and secondary amines are pharmacologically active and contribute to toxicity. The glucuronide metabolites are inactive.

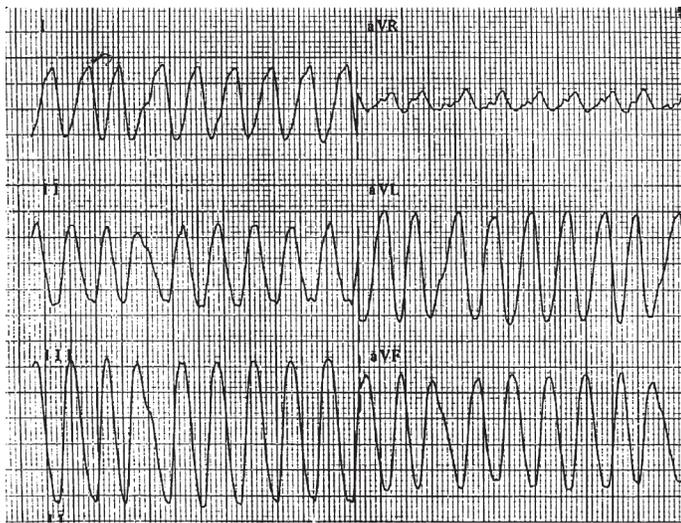

Genetically based differences in the activity of the CYP2D6, which are responsible for hydroxylation of imipramine and desipramine, account for wide interindividual variability in metabolism and steady-state serum concentrations.<sup>18</sup> “Poor metabolizers” are reported to recover more slowly from an overdose or demonstrate toxicity with therapeutic dosing, which is a major risk factor for attaining high serum CA concentrations.<sup>47,116</sup> The metabolism of CAs is also influenced by concomitant ingestion of ethanol and other xenobiotics that induce or inhibit CYP2D6 (Chap. 11 and Appendix). Increased plasma CA concentrations in older adult patients are likely because of decreased renal clearance.<sup>100</sup>

Elimination half-lives for therapeutic doses of CAs vary from 7 to 58 hours (54–92 hours for protriptyline), with even longer half-lives in older adults. The half-lives are also prolonged following overdose as a result of saturable metabolism. A small fraction (15%–30%) of CA elimination occurs through biliary and gastric secretion. The metabolites are then reabsorbed in the systemic circulation, resulting in enterohepatic and enterohepatic recirculation and reducing their fecal excretion. Finally, less than 5% of CAs are excreted unchanged by the kidney.

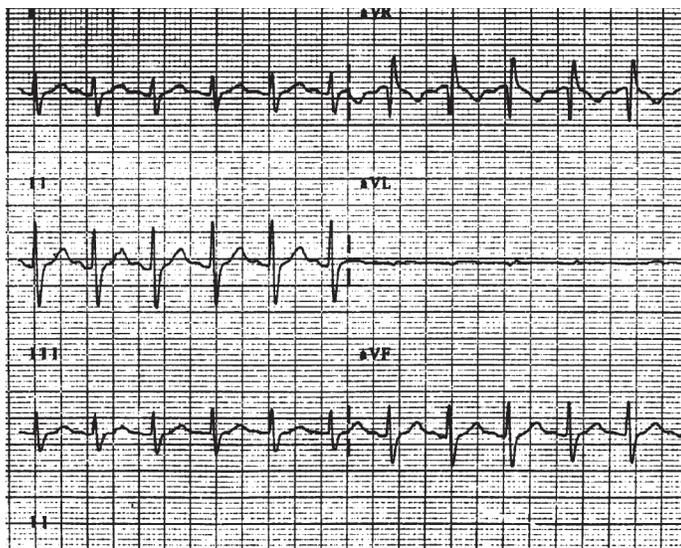

## PATHOPHYSIOLOGY

The CAs slow the recovery from inactivation of the fast sodium channel, slowing phase 0 depolarization of the action potential in the distal His-Purkinje system and the ventricular myocardium (Figs. 68-1 and 15-2 and Chap. 15). Impaired depolarization within the ventricular conduction system slows the propagation of ventricular depolarization, which manifests as prolongation of the QRS complex on the electrocardiogram (ECG) (Figs. 68-2 and 68-3). The right bundle branch has a relatively longer refractory period, and it is affected disproportionately by xenobiotics that slow intraventricular conduction. This slowing of depolarization results in a rightward shift of the terminal 40 ms (T40-ms) of the QRS axis and the right bundle branch block pattern that is noted on the ECG of patients who are exposed to or overdose with a CA.<sup>126</sup>

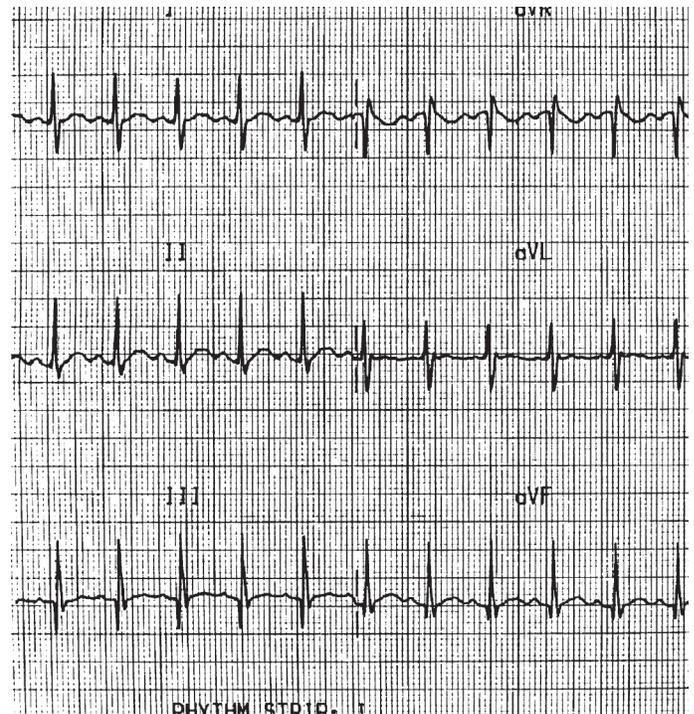

Because CAs are weakly basic, they are increasingly ionized as the ambient pH falls and less ionized as the pH rises. Changing the ambient pH therefore alters their binding to the sodium channel. This probably occurs because 90% of the binding of CA to the sodium channel occurs in the ionized state, alkalizing the blood facilitates the movement of the CA away from the hydrophilic sodium channel and into the lipid membrane (Antidotes in Depth: A5).

B

C

**FIGURE 68-2.** (A) Electrocardiograph (ECG) shows a wide-complex tachycardia with a variable QRS complex duration (minimum, 220 ms). (B) ECG 30 minutes after presentation following sodium bicarbonate administration shows narrowing of the QRS complex duration to 140 ms and an amplitude of the R in  $aV_R$  of 6.0 mm. (C) ECG 9 hours after presentation shows further narrowing of the QRS complex to 80 ms and decrease in the amplitude of the R in  $aV_R$  to 4.5 mm. (Reproduced with permission from Liebelt EL. Targeted management strategies for cardiovascular toxicity from tricyclic antidepressant overdose: the pivotal role for alkalinization and sodium loading. *Pediatr Emerg Care.* 1998 Aug;14(4):293-298.)

Sinus tachycardia is caused by the antimuscarinic, vasodilatory (reflex tachycardia), and sympathomimetic effects of the CAs. Wide-complex tachycardia most commonly represents aberrantly conducted sinus tachycardia rather than ventricular tachycardia. However, by prolonging anterograde conduction, nonuniform ventricular conduction can result, leading to reentrant ventricular dysrhythmias.

Electrophysiologic studies in a canine model demonstrate that prolongation of the QRS complex duration is rate dependent, a characteristic effect of the Vaughn Williams class IA antidysrhythmics (Chap. 57). Furthermore, pharmacologic induction of bradycardia prevents or narrows wide-complex tachycardia by allowing time for recovery of the sodium channel from inactivation.<sup>4,103</sup> However, because bradycardia adversely affects cardiac output, induction of bradycardia is not recommended.

A Brugada ECG pattern, specifically type 1 or “coved” pattern, is rarely associated with CA overdose. The Brugada syndrome originates from a structural change in the myocardial sodium channel that results in functional sodium channel alterations similar to those caused by the CAs.<sup>11,83</sup> It is possible that this small cohort of patients have subclinical Brugada syndrome that was uncovered by the CA (Chap. 15).

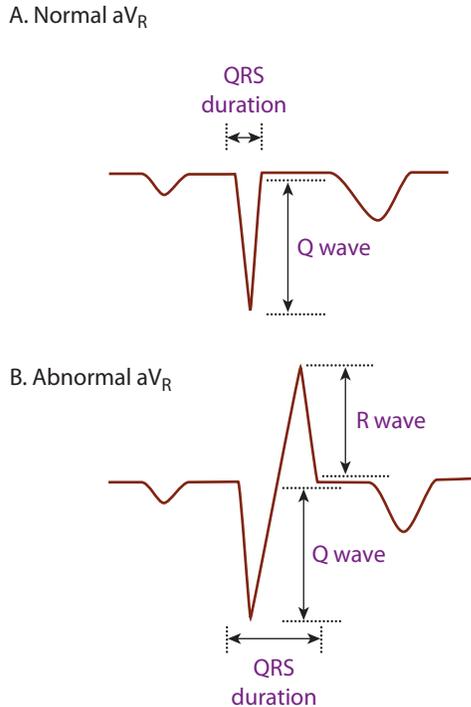

Prolongation of the QT interval also occurs in the setting of both therapeutic use and overdose of CAs. This apparent prolongation of repolarization results primarily from slowed depolarization (ie, QRS complex prolongation)

rather than altered repolarization.<sup>99</sup> Although QT interval prolongation predisposes to the development of torsade de pointes, this dysrhythmia is uncommon in patients with CA poisoning where tachycardia is prominent.

Hypotension is caused by direct myocardial depression secondary to altered sodium channel function, which disrupts the subsequent excitation-contraction coupling of myocytes and impairs cardiac contractility. Peripheral vasodilation from  $\alpha$ -adrenergic blockade by CAs also contributes prominently to postural hypotension. In addition, downregulation of adrenergic receptors blunts the physiologic response to catecholamines.<sup>82</sup>

Agitation, delirium, and depressed sensorium are primarily caused by central anticholinergic and antihistaminic effects. Details regarding the exact mechanism of CA-induced seizures remain elusive. Cyclic antidepressant-induced seizures may result from a combination of an increased concentration of monoamines (particularly norepinephrine), muscarinic antagonism, neuronal sodium channel alteration, and GABA inhibition.<sup>84</sup>

Acute respiratory distress syndrome (ARDS) occurs in the setting of CA overdose. In one study, amitriptyline exposure caused dose-related vasoconstriction and bronchoconstriction in isolated rat lungs.<sup>115</sup> Many substances implicated in ARDS, such as platelet-activating factor and protein kinase activation, were important in mediating amitriptyline-induced impairment of lung function in this experimental model. Another animal model demonstrated that acute amitriptyline poisoning causes dose-dependent rises in

**FIGURE 68-3.** (A) Normal QRS complex in lead aVR. (B) Abnormal QRS complex in a patient with cyclic antidepressant (CA) poisoning. The R wave in lead aVR is measured as the maximal height in millimeters of the terminal upward deflection in the QRS complex. In this example, the QRS complex duration is prolonged, indicating significant CA poisoning.

pulmonary artery pressure, pulmonary edema, and sustained vasoconstriction that could be attenuated by either calcium channel inhibition or a nitric oxide donor.<sup>72</sup>

## CLINICAL MANIFESTATIONS

The toxic profile is qualitatively the same for all of the first-generation TCAs but is slightly different for some of the other CAs.<sup>124</sup> The progression of clinical toxicity is unpredictable and often rapid. Patients commonly present to the emergency department (ED) with minimal apparent clinical abnormalities, only to develop life-threatening cardiovascular and CNS toxicity within hours.

The CAs have a narrow therapeutic index, meaning that a small increase in serum concentration over the therapeutic range results in toxicity. Acute ingestion of 10 to 20 mg/kg of most CAs causes significant cardiovascular and CNS manifestations (therapeutic dose, 2–4 mg/kg/d). Thus, in adults, ingestions of more than 1 g of a CA is usually associated with life-threatening effects. In a series of children with unintentional TCA exposure, all patients with reported ingestions of more than 5 mg/kg manifested clinical toxicity.<sup>78</sup>

## Acute Toxicity

Most of the reported toxicity from CAs derives from patients with acute ingestions, especially in patients who are chronically taking the medication. Clinical manifestations of these two cohorts do not appear to be different, and most studies do not distinguish between them.

## Acute Cardiovascular Toxicity

Cardiovascular toxicity is primarily responsible for the morbidity and mortality attributed to CAs. Refractory hypotension caused by myocardial depression is the most common cause of death from CA overdose.<sup>20,114</sup> Hypoxia, acidosis, volume depletion, seizures, or concomitant ingestion of other cardiodepressant or vasodilating drugs exacerbate hypotension and predispose to ventricular dysrhythmia.<sup>69,118</sup>

The most common dysrhythmia observed after CA overdose is sinus tachycardia (rate, 120–160 beats/min in an adult), and this finding is present in most patients with clinically significant TCA poisoning. The ECG typically

demonstrates intraventricular conduction delay that manifests as a rightward shift of the T40-ms QRS complex axis and a prolongation of the QRS complex duration. These findings can be used to identify and risk stratify patients with CA poisoning (see Diagnostic Testing). Prolongation of the PR interval, QRS complex, and QT interval can occur in the setting of both therapeutic and toxic amounts of TCAs.<sup>74</sup>

Wide-complex tachycardia is the characteristic potentially life-threatening dysrhythmia observed in patients with severe toxicity (Fig. 68–2). Ventricular tachycardia is often difficult to distinguish from the aberrantly conducted sinus tachycardia that occurs more commonly. In the former cases, the preceding P wave may not be apparent because of prolonged atrioventricular conduction, widened QRS interval, or both. Ventricular tachycardia occurs most often in patients with prolonged QRS complex duration or hypotension.<sup>69,118</sup> Fatal dysrhythmias are rare because ventricular tachycardia and fibrillation occur in only approximately 4% of all cases.<sup>41,92</sup> Both the Brugada type I ECG pattern and torsade de pointes are uncommon with acute TCA overdose.

## Acute Central Nervous System Toxicity

Altered mental status and seizures are the primary manifestations of CNS toxicity. Delirium, agitation, or psychotic behavior with hallucinations most likely result from antagonism of muscarinic and histaminergic receptors. These alterations in consciousness usually are followed by lethargy, which is followed by rapid progression to coma. The duration of coma is variable and does not necessarily correlate with or occur concomitantly with ECG abnormalities.<sup>61</sup>

Seizures usually are generalized and brief, most often occurring within 1 to 2 hours of ingestion.<sup>28</sup> The incidence of seizures is similar to ventricular tachycardia and occurs in an estimated 4% of patients presenting with overdose and 13% of fatal cases.<sup>128</sup> Status epilepticus is uncommon. Abrupt deterioration in hemodynamic status, namely hypotension and ventricular dysrhythmias, often develops during or within minutes after a seizure.<sup>28,69,118</sup> This rapid cardiovascular deterioration likely results from seizure-induced acidemia that exacerbates cardiovascular toxicity. The risk of seizures in patients with CA overdoses is increased in those undergoing long-term therapy or who have other risk factors such as history of seizures, head trauma, or concomitant drug withdrawal.<sup>110</sup> Myoclonus and extrapyramidal symptoms also occur in CA-poisoned patients, and cerebellitis is reported.<sup>119</sup>

Cessation of CAs produces a drug discontinuation syndrome in some patients, which is typified by GI and somatic distress, sleep disturbances, movement disorders, and mania.<sup>37</sup>

## Other Clinical Effects

Anticholinergic effects can occur early or late in the course of CA toxicity. Pupils are dilated and poorly reactive to light. Other anticholinergic effects include dry mouth, dry flushed skin, urinary retention, and ileus. Although prominent, these findings are typically inconsequential.

Reported pulmonary complications include ARDS, aspiration pneumonitis, and multisystem organ failure. Acute respiratory distress syndrome results from aspiration, hypotension, pulmonary infection, and excessive fluid administration, along with the primary toxic effects of CAs.<sup>107,109</sup> Bowel ischemia, pseudoobstruction, and pancreatitis are reported in patients with CA overdose.<sup>80</sup>

Death directly caused by CA toxicity usually occurs in the first several hours after presentation and is secondary to refractory hypotension in patients who reach health care facilities. Late deaths (>1–2 days after presentation) usually are secondary to other factors such as aspiration pneumonitis, ARDS from refractory hypotension, or infection.<sup>21</sup>

## Chronic Toxicity

Chronic CA toxicity usually manifests as exaggerated side effects, such as sedation and sinus tachycardia or is identified by supratherapeutic drug concentrations in the blood in the absence of an acute overdose.<sup>39</sup> Unlike patients with chronic theophylline and aspirin poisoning, chronic CA toxicity does not appear to cause life-threatening effects.

A sparse literature describes the clinical course of this cohort. However, a case report described chronic amitriptyline overdose in a child (15 mg/kg a day for 1 month) that resulted in status epilepticus and significant cardiac conduction abnormalities but normal neurologic outcome.<sup>26</sup> Genetic analysis showed two copies of wild-type alleles for the genes responsible for CYP2D6 activity, concluding the patient was not a “rapid metabolizer.” Several possible protective mechanisms are presented by the authors that further illustrate the complexity of this drug, its metabolism, and toxicity. These include a unique pharmacogenomics profile that yields an abnormal receptor profile or metabolic pathway (eg, polymorphism in the gene for myocardial fast sodium channels), another xenobiotic causing a beneficial drug–drug interaction, and the protective effect from other drugs the patient was taking—guanfacine and clonidine—adrenergic medications that may have offered some protective effect from the  $\alpha$ -adrenergic blockade caused by amitriptyline.

Several reports describe sudden death in children taking therapeutic doses of CAs.<sup>96,98,117</sup> Prolongation of the QT interval with resultant torsade de pointes, advanced atrioventricular conduction delays, blood pressure fluctuations, and ventricular tachycardia are postulated mechanisms, although whether any of these effects contributed to the deaths is unknown. Prospective studies using 12-lead ECG, 24-hour ECG recording, and Doppler echocardiography in children receiving therapeutic doses of CAs have failed to find any significant cardiac abnormalities when compared to children not taking CAs.<sup>14,31</sup> However, it is recommended that CAs not be initiated or continued in any child with a resting QT interval greater than 450 ms or with a bundle branch block.<sup>34</sup> This is an ongoing area of research because it becomes problematic in making decisions about pharmacotherapy interventions.

### Unique Toxicity from “Atypical” Cyclic Antidepressants

Although the incidence of serious cardiovascular toxicity is lower in patients with amoxapine overdoses, the incidence of seizures is significantly greater than with the traditional CAs.<sup>61,71</sup> Moreover, seizures are more frequent, or status epilepticus occurs.<sup>83</sup> Similarly, the incidences of seizures, cardiac dysrhythmias, and duration of coma are greater with maprotiline toxicity compared with the CAs.<sup>59</sup>

## DIAGNOSTIC TESTING

Diagnostic testing for patients with CA poisoning primarily relies on indirect bedside tests (ECG) and other qualitative laboratory analyses. Quantification of CA concentration provides little help in the acute management of patients with CA overdose but provides adjunctive information to support the diagnosis.

### Electrocardiography

The ECG provides important diagnostic information and predicts clinical toxicity after a CA overdose. Toxicity results in distinctive and diagnostic ECG changes that allows early diagnosis and targeted therapy even when the clinical history and physical examination are unreliable.

A rightward T40-ms axis shift is a sensitive indicator of drug presence.<sup>22,86,126</sup> A terminal QRS complex vector between 130 degrees and 270 degrees discriminated between 11 patients with positive toxicology screens for CAs and 14 patients with negative toxicology screen results.<sup>86</sup> In one report, the positive and negative predictive values of this ECG parameter for CA ingestions were 66% and 100%, respectively, in a population of 299 general overdose patients. A retrospective study reported that a CA-poisoned patient was 8.6 times more likely to have a T40-ms axis greater than 120 degrees than was a non-CA-poisoned patient.<sup>126</sup> This parameter was a more sensitive indicator of CA-induced altered mental status but not necessarily of seizure or dysrhythmia. An abnormal terminal rightward axis is easily estimated by observing a negative deflection (terminal S wave) in leads I and  $aV_L$  and a positive deflection (terminal R wave) in lead  $aV_R$  (Fig. 68–3).

The maximal limb lead QRS complex duration is an easily measured ECG parameter that is a sensitive indicator of toxicity. A landmark investigation reported that 33% of patients with a limb lead QRS complex duration greater than or equal to 100 ms developed seizures, and 14% developed ventricular dysrhythmias.<sup>16</sup> No seizures or dysrhythmias occurred in those patients

whose QRS complex duration remained less than 100 ms. There was a 50% incidence of ventricular dysrhythmias among patients with a QRS complex duration greater than or equal to 160 ms. No ventricular dysrhythmias occurred in patients with a QRS complex duration less than 160 ms. Subsequent studies confirmed that a QRS complex duration greater than 100 ms is associated with an increased incidence of serious toxicity, including coma, need for intubation, hypotension, seizures, and dysrhythmias, making this ECG parameter a useful indicator of toxicity.<sup>22,66</sup>

Evaluation of lead  $aV_R$  on a routine ECG is also reported to predict toxicity (Figs. 68–2 and 68–3). When prospectively studied, 79 patients with acute CA overdoses demonstrated that the amplitude of the terminal R wave and R/S wave ratio in lead  $aV_R$  ( $RaV_{Rr}$ ,  $R/SaV_{Rr}$ ) were significantly greater in patients who developed seizures and ventricular dysrhythmias.<sup>66</sup> The sensitivity of  $RaV_{Rr} = 3$  mm and  $R/SaV_{Rr} = 0.7$  in predicting seizures and dysrhythmias was comparable to the sensitivity of a QRS complex duration greater than 100 ms.

The type 1 Brugada pattern is similar to a right bundle branch block (rSR'), with downsloping ST elevations (“coved”) in the right precordial leads (V1–V3) (Chap. 15 and Fig. 15–12).<sup>11,83</sup> This pattern is neither highly sensitive nor specific for CA toxicity, and it is reported in patients with cocaine and phenothiazine toxicity as well as those on class IA antidysrhythmic therapy. In one series of more than 400 patients with CA overdose, a significant increase in adverse outcomes (ie, seizures, widened QRS complex duration, and hypotension) was identified in those patients with a Brugada ECG pattern compared with those who did not have the pattern.<sup>11</sup> However, there were no deaths or dysrhythmias in the nine patients with this pattern.

Serial ECGs are recommended because the ECG changes are dynamic. Electrocardiograph parameters should always be interpreted in conjunction with the clinical presentation, history, and course during the first several hours to assist in decision making regarding interventions and disposition.<sup>67</sup>

### Laboratory Tests

Determination of serum CA concentrations has limited utility in the immediate evaluation and management of patients with acute overdoses. In one study, serum drug concentrations failed to accurately predict the development of seizures or ventricular dysrhythmias.<sup>16</sup> The pharmacologic properties of CAs—namely, large volumes of distributions, prolonged absorption phase, long distribution half-lives, pH-dependent protein binding, and the wide interpatient variability of terminal elimination half-lives—explain the limited value of serum concentrations in this situation. Any concentration above the therapeutic range (50–300 ng/mL, including active metabolites) is associated with adverse effects and is an indication to decrease or discontinue the medication.

Although CA concentrations greater than 1,000 ng/mL usually are associated with significant clinical toxicity such as coma, seizures, and dysrhythmias, life-threatening toxicity occurs in patients with serum concentrations of less than 1,000 ng/mL.<sup>16,62</sup> Serious toxicity at lower concentrations probably results from a number of factors, including the timing of the specimen in relation to the ingestion and the limitations of measuring the concentration in blood and not the affected tissue. Quantitative concentrations usually cannot be readily obtained in most hospital laboratories. However, qualitative screens for CAs using an enzyme-multiplied immunoassay test are available at many hospitals. Unfortunately, false-positive results occur with many drugs such as carbamazepine, cyclobenzaprine, thioridazine, diphenhydramine, quetiapine, and cyproheptadine (Chap. 7). Thus, the presence of a CA on a qualitative assay should not be relied on to confirm the diagnosis of CA poisoning in the absence of corroborating historical or clinical evidence, and obtaining these laboratory results is not recommended.

An ultra-pressure liquid chromatography tandem mass spectrometry (UPLC-MS) assay capable of quantifying nine CA drugs in less than 5 minutes was recently validated, although its clinical application is limited because it is not currently widely available.<sup>68</sup>

Quantitative concentrations are helpful in determining the cause of death in suspected overdose patients. Concentrations reported in lethal overdoses typically range from 1,100 to 21,800 ng/mL. However, it should be noted that CA concentrations increase more than fivefold because of postmortem

redistribution (Chap. 140).<sup>5</sup> Measurement of liver CA concentration or the parent-to-metabolite drug ratio provide additional information in the post-mortem setting.

## MANAGEMENT

Any person with a suspected or known ingestion of a CA requires immediate evaluation and treatment (Table 68–2). The patient should be attached to a cardiac monitor, and intravenous access should be secured. Early intubation is recommended for patients with CNS depression or hemodynamic instability because of the potential for rapid clinical deterioration. A 12-lead ECG should be obtained for all patients. Laboratory tests, including concentrations of glucose and electrolytes, should be performed for all patients with altered mental status, as well as blood gas analysis to both assess the degree of acidemia and guide alkalinization therapy. Aggressive interventions for maintenance of blood pressure and peripheral perfusion must be performed early to avoid irreversible damage. Both children and adults receiving cardiopulmonary resuscitation have recovered successfully despite periods of asystole exceeding 90 minutes.<sup>24,27,86,111</sup> The options for GI decontamination are discussed in the following section.

**TABLE 68–2 Treatment of Cyclic Antidepressant (CA) Toxicity**

Toxic Effect	Treatment
Sinus rhythm with a QRS complex >100 ms	Sodium bicarbonate: 1–2 mEq/kg IV boluses at 3- to 5-min intervals to reverse the abnormality or to a target serum pH $\leq 7.55$ Sodium bicarbonate: 150 mEq in 1 L of D <sub>5</sub> W continuous infusion at twice maintenance rate up to target serum pH $\leq 7.55$ Controlled ventilation (if clinically indicated for hypoventilation)
Wide-complex tachycardia or ventricular tachycardia	Sodium bicarbonate: 1–2 mEq/kg IV boluses at 3- to 5-min intervals to reverse the abnormality or to a target serum pH $\leq 7.55$ Sodium bicarbonate: 150 mEq in 1 L of D <sub>5</sub> W continuous infusion at twice maintenance rate up to target serum pH $\leq 7.55$ Correct hypoxia, acidemia, hypotension Lidocaine for refractory dysrhythmias despite sodium bicarbonate administration: 1 mg/kg slow IV bolus followed by infusion of 20–50 mcg/kg/min Hypertonic saline (3% sodium chloride): 1–2 mEq/kg bolus Magnesium sulfate 25–50 mg/kg (maximum 2 g) IV over 2 min
Torsade de pointes	DC cardioversion followed by Magnesium sulfate or Overdrive pacing (caution because of rate dependence of CA)
Hypotension	0.9% sodium chloride boluses (up to 30 mL/kg) Correct hypoxia, acidemia Sodium bicarbonate: 1–2 mEq/kg IV boluses at 3- to 5-min intervals to reverse the abnormality or to a target serum pH $\leq 7.55$ Sodium bicarbonate: 150 mEq in 1 L of D <sub>5</sub> W continuous infusion at twice maintenance rate up to target serum pH $\leq 7.55$ Norepinephrine in standard titrated doses
Seizures	Benzodiazepines Secure airway with intubation if necessary Correct hypoxia, acidemia Continuous infusion of midazolam or propofol if benzodiazepines fail Neuromuscular paralysis or general anesthesia with EEG monitoring if all other measures fail
Refractory poisoning	If standard therapies fail, ILE for cardiac arrest Extracorporeal mechanical circulation (ECMO, cardiopulmonary bypass); no evidence to support hemodialysis or hemoperfusion

DC = direct current; D<sub>5</sub>W = dextrose 5% in water; ECMO = extracorporeal membrane oxygenation; EEG = electroencephalography; ILE = intravenous lipid emulsion; IV = intravenous.

## Gastrointestinal Decontamination

The benefits of orogastric lavage for CA toxicity are not substantiated by controlled trials. The potential benefits of removing significant quantities of a highly toxic drug must be weighed against the risks of the procedure (Chap. 5).<sup>17</sup> The anticholinergic actions of some CAs decrease spontaneous gastric emptying, allowing unabsorbed drug to remain in the stomach for several hours. However, because of the potential for rapid deterioration of mental status and seizures, orogastric lavage should not be performed on patients without a protected airway. As such, this procedure should be limited to patients presenting shortly after ingestion (within 2 hours) who have already undergone endotracheal intubation for depressed mental status or other clinical toxicity. Endotracheal intubation should not be performed for the sole purpose of GI decontamination. Orogastric lavage in young children with unintentional ingestions of CAs may be associated with more risk and impracticalities, such as the inadequate hole size of pediatric tubes, and less benefit given the amount of drug usually ingested.

Activated charcoal (AC) is recommended in all patients presenting within 2 hours of ingestion with a normal mental status, and in patients with altered mental status and a protected airway. Irrespective of age, an additional dose of AC several hours later is reasonable in a seriously poisoned patient in whom unabsorbed drug may still be present in the GI tract or in the case of desorption of CAs from AC. It is important to monitor for the development of an ileus to prevent abdominal complications from additional doses of AC.<sup>80</sup>

## Wide-Complex Dysrhythmias, Conduction Delays, and Hypotension

The mainstay of therapy for treating wide-complex dysrhythmias and for reversing conduction delays and hypotension is the combination of serum alkalinization and sodium loading. Increasing the extracellular concentration of sodium, or sodium loading, overwhelms the effective blockade of sodium channels, presumably through gradient effects (Fig. 68–1). Controlled in vitro and in vivo studies in various animal models demonstrate that hypertonic sodium bicarbonate effectively reduces QRS complex prolongation, increases blood pressure, and reverses or suppresses ventricular dysrhythmias caused by CAs.<sup>89,102–104</sup> These studies showed a clear benefit of hypertonic sodium bicarbonate compared with hyperventilation, hypertonic sodium chloride, or nonsodium buffer solutions. A systematic review of all animal and human studies revealed that alkalinization therapy was the most beneficial therapy for consequential dysrhythmias and shock<sup>15</sup> (Antidotes in Depth: A5).

The optimal dosing and mode of administration of hypertonic sodium bicarbonate and the indications for initiating and terminating this treatment are unsupported by controlled clinical studies. Instead, the information is extrapolated from animal studies, clinical experience, and an understanding of the pathophysiologic mechanisms of CA toxicity. A bolus, or rapid infusion over several minutes, of hypertonic sodium bicarbonate (1–2 mEq/kg) is recommended initially.<sup>76,108</sup> Additional boluses every 3 to 5 minutes are recommended until the QRS complex duration narrows and the hypotension improves (Fig. 68–2). Blood pH should be carefully monitored after several bicarbonate boluses, aiming for a target pH of no greater than 7.50 or 7.55. Because CAs redistribute from the tissues into the blood over several hours, it is reasonable to begin a continuous sodium bicarbonate infusion to maintain the pH in this range. Although diluting sodium bicarbonate in 5% dextrose in water and infusing it slowly renders it less able to increase the sodium gradient across the cell, the beneficial effects of pH elevation still warrant its use after the patient is stabilized. No evidence supports prophylactic alkalinization in the absence of cardiovascular toxicity (eg, QRS complex duration < 100 ms). In addition, alkalinization inevitably decreases in potassium and ionized calcium, which result in QT interval prolongation and potentially contribute to other dysrhythmias. Hypertonic sodium chloride (3% NaCl) reverses cardiotoxicity in several animal studies,<sup>49,77,89</sup> and numerous reports and extensive clinical experience support its efficacy in humans.<sup>15,50,51,79</sup> However, the dose of hypertonic saline for CA poisoning has never been evaluated in humans for safety or efficacy, and the dose suggested by animal studies (up to 15 mEq/kg) exceeds the amount that most clinicians

would consider safe (1–2 mEq/kg). Hypertonic sodium chloride is associated with a hyperchloremic metabolic acidosis, an undesired effect that highlights one benefit of hypertonic sodium bicarbonate. However, it is reasonable to administer hypertonic saline in situations in which alkalinization with sodium bicarbonate is not possible. Sodium acetate is a possible alternative treatment if sodium bicarbonate is unavailable, although this cannot be given as a rapid bolus because high acetate concentrations result in hypotension.<sup>85</sup>

Hyperventilation of an intubated patient is a more rapid and easily titratable method of serum alkalinization but is not as effective as sodium bicarbonate in reversing cardiotoxicity.<sup>55,76</sup> Simultaneous hyperventilation and sodium bicarbonate administration may result in profound alkalemia and should be performed only with extreme caution and careful monitoring of serum pH. Hyperventilation without bicarbonate administration is a reasonable alternative in patients with ARDS or congestive heart failure in whom administration of large quantities of sodium is contraindicated.

Alkalinization and sodium loading with hypertonic sodium bicarbonate and or hypertonic saline along with controlled ventilation (if clinically indicated) should be administered to all CA overdose patients presenting with major cardiovascular toxicity. Indications include conduction delays (QRS complex >100 ms) and hypotension. It is imperative to initiate treatment until CA toxicity is excluded because of the risk of rapid and precipitous deterioration. Although commonly assumed, it is unclear whether the failure of the QRS complex to narrow with sodium bicarbonate treatment excludes CA toxicity.

It is also unclear whether alkalinization and sodium loading are effective for reversing the Brugada pattern. The sparse available literature is equivocal.<sup>12,83</sup> It is prudent to administer sodium bicarbonate in the presence of a presumed CA-induced Brugada pattern, especially with concomitant signs of other CA toxicity.

Alkalinization should be continued for at least 12 to 24 hours after the ECG has normalized because of the redistribution of the drug from the tissue. However, the time observed for resolution or normalization of conduction abnormalities is extremely variable, ranging from several hours to several days, despite continuous bicarbonate infusion.<sup>67</sup> We recommend stopping alkalinization when the patient's mental status improves and there is improvement, but not necessarily normalization, of abnormal ECG findings.

### Antidysrhythmic Therapy

Lidocaine is the antidysrhythmic most commonly advocated for treatment of CA-induced dysrhythmias, although no controlled human studies demonstrate its efficacy.<sup>93</sup> Because lidocaine has sodium channel blocking properties, some investigators argue against its use in CA poisoning.<sup>1</sup> These theoretical concerns are not well supported in the literature, and the class IB antidysrhythmic channel binding kinetics may prove favorable. Lidocaine should be used for ventricular dysrhythmias not responsive to sodium bicarbonate therapy. Although limited data also suggest that the IB antidysrhythmic phenytoin prevents or reverses conduction abnormalities,<sup>44,75</sup> these data were poorly controlled for other confounding factors, such as blood pH and sodium bicarbonate administration; they had very small numbers; and, in some, the cardiotoxicity was not severe. Because phenytoin exacerbates ventricular dysrhythmias in animals and fails to protect against seizures, its use is no longer recommended.<sup>10,21</sup>

The use of class IA (quinidine, procainamide, disopyramide, and moricizine) and class IC (flecainide, propafenone) antidysrhythmics is absolutely contraindicated because they have similar pharmacologic actions to CAs and thus will worsen the sodium channel inhibition and exacerbate cardiotoxicity. Class III antidysrhythmics (amiodarone, bretylium, and sotalol) prolong the QT interval and, although unstudied, are contraindicated as well (Chap. 57).

Because magnesium sulfate has antidysrhythmic properties, it may be beneficial in the treatment of ventricular dysrhythmias. Animal studies of the effects of magnesium on CA-induced dysrhythmias yield conflicting results.<sup>56,57</sup> However, successful use of magnesium sulfate in the treatment of refractory ventricular fibrillation after TCA overdose is reported.<sup>24,27,58,101</sup> A case control study suggested that magnesium sulfate and sodium bicarbonate

resulted in lower fatality incidence and shorter intensive care unit (ICU) stay compared to sodium bicarbonate alone.<sup>29</sup> When dysrhythmias fail to reverse after alkalinization, sodium loading, and a trial of lidocaine and then magnesium sulfate is reasonable.

Slowing the heart rate in the presence of CAs allows more time during diastole for CA unbinding from sodium channels and results in an improvement in ventricular conduction.<sup>3,4,104</sup> This abolishes the reentry mechanism for dysrhythmias and was one rationale for the past use of physostigmine and propranolol. However, results from animal studies and limited clinical reports fail to show a clear benefit from these interventions. Propranolol terminated ventricular tachycardia in an animal model but also caused significant hypotension and death.<sup>103</sup> In one case series, patients developed severe hypotension or had a cardiac arrest shortly after receiving a  $\beta$ -adrenergic antagonist.<sup>36</sup> The combined negative inotropic effects of  $\beta$ -adrenergic antagonists and CAs, along with the significant cardiac and CNS effects reported with physostigmine use, do not support their use in the management of CA-induced tachydysrhythmias.

### Hypotension

Standard initial treatment for hypotension should include volume expansion with isotonic saline or sodium bicarbonate. Hypotension unresponsive to these therapeutic interventions necessitates the use of inotropic or vasopressor support and possibly extracorporeal cardiovascular support.

No controlled human trials are available to guide the use of vasopressor therapy. The pharmacologic properties of CAs complicate the choice of a specific agent. Specifically, CA blockade of neurotransmitter reuptake theoretically could result in depletion of intracellular catecholamines, blunting the effect of dopamine, which is dependent on the release of endogenous norepinephrine for its inotropic activity. This pharmacologic effect and limited clinical data suggest that a direct-acting vasopressor such as norepinephrine is more efficacious than an indirect-acting catecholamine such as dopamine.<sup>32,120,121,123</sup>

Based on the available data, pharmacologic effects, theoretical concerns, and experience, norepinephrine (0.1–0.2 mcg/kg/min) is recommended for hypotension that is unresponsive to volume expansion and hypertonic sodium bicarbonate therapy. Central venous pressure measurement can guide the choice of additional vasopressor or inotropic agents, especially in the presence of other cardiodepressant drugs.

If these measures fail to correct hypotension, extracorporeal life support measures are reasonable, if available. Extracorporeal membrane oxygenation, extracorporeal circulation, and cardiopulmonary bypass are successful adjuncts for refractory hypotension and life support when maximum therapeutic interventions fail.<sup>42,52,60,111,125</sup> These modalities can provide critical perfusion to the heart and brain and maintain metabolic function while giving the body time to redistribute and eliminate the CA by maintaining hepatorenal blood flow.

### Additional Therapies

Intravenous lipid emulsion (ILE) is reported to be effective in reversing cardiovascular toxicity caused by several lipophilic drugs, including amitriptyline and clomipramine. Its utilization and effectiveness appear logical given their pharmacological properties—log D and log P—octanol/water partition coefficient discussed previously.

Several controlled animal studies have demonstrated improved survival in clomipramine-induced cardiovascular collapse when ILE is given either as pretreatment or resuscitation in comparison with saline controls and sodium bicarbonate infusion.<sup>45,46</sup> Other animal studies failed to demonstrate any benefit or have shown poor results compared with standard therapies.<sup>7,70,95,122</sup> Case series and case reports demonstrate clinical improvement when ILE was administered for cardiovascular collapse or instability refractory to other therapies.<sup>38,45,54,63,105</sup> The dosing and timing of administration are variable as well as other concomitant therapies, making it difficult to reach any definitive conclusions regarding its effectiveness. In addition, significant adverse reactions and complications are noted, including ARDS, pancreatitis, and interference with laboratory assays. A recent extensive review by the Lipid

Emulsion Workgroup found only one randomized control trial of ILE utilization on CA-poisoned patients, which found no difference in time to ECG improvement, mortality, or hospitalization length compared with standard therapy.<sup>53,64</sup> There is no evidence to promote ILE use for non-life-threatening toxicity.<sup>43</sup> Given the current available data, ILE is reasonable for cardiac arrest after CA poisoning and for refractory hypotension or cardiac dysrhythmias if other interventions fail but should not be used as a first-line therapy and should not delay efforts to achieve sodium loading and serum alkalization in patients with cardiovascular toxicity (Antidotes in Depth: A23).<sup>97</sup>

Successful use of vasopressin for intractable hypotension caused by CA toxicity, unresponsive to  $\alpha$ -receptor agonists and pH manipulation, is described.<sup>9</sup> The vasoconstrictive effects of this drug may provide benefit in the setting of vasodilatory shock. Data are insufficient to recommend vasopressin as a first-line therapy for CA toxicity, and its use should be restricted to hypotension refractory to other treatments.

### Central Nervous System Toxicity

Seizures caused by CAs usually are brief and often stop before treatment can be initiated. Recurrent seizures, prolonged seizures (>2 minutes), and status epilepticus require prompt treatment to prevent worsening acidosis, hypoxia, and development of hyperthermia and rhabdomyolysis. Benzodiazepines are effective as first-line therapy for seizures. If this therapy fails, either a barbiturate or propofol is recommended. Propofol controls refractory seizures resulting from amoxapine toxicity.<sup>81</sup> Failure to respond to barbiturates or propofol should prompt the use of neuromuscular paralysis and general anesthesia with continuous electroencephalographic monitoring. Phenytoin is contraindicated for seizures because data not only demonstrate a failure to terminate seizures but also suggest enhanced cardiovascular toxicity.<sup>921</sup>

Use of flumazenil in a patient with known or suspected CA ingestion is contraindicated. Several case reports of patients with CA overdoses describe seizures after administration of flumazenil (Antidotes in Depth: A25).<sup>65</sup> Physostigmine was used in the past to reverse the acute CNS toxicity (Antidotes in Depth: A11). However, physostigmine is contraindicated because it precipitates seizures in acutely CA-poisoned patients increasing the risk of cardiac toxicity, causing bradycardia and asystole.<sup>91</sup>

### Enhanced Elimination

No specific treatment modalities have demonstrated clinical significant efficacy in enhancing the elimination of CAs. Some investigators propose multiple doses of AC to enhance CA elimination because of their small enterohepatic and enterogastric circulation.<sup>73</sup> Human volunteer studies and case series of patients with CA overdoses suggest that the half-life of CAs is decreased by multiple-dose activated charcoal (MDAC). Activated charcoal reduced the apparent half-life of amitriptyline to 4 to 40 hours in overdose patients compared with previously published values of 30 to more than 60 hours.<sup>117</sup> Changes in the severity or duration of clinical toxicity, however, were not reported. Other investigators showed that in human volunteers, MDAC reduced the half-life of therapeutic doses of amitriptyline approximately 20% compared with no AC administration. However, the methodologic flaws and equivocal findings of these studies and the lack of any positive outcome data for this intervention from additional studies do not provide evidence supporting its use in this setting.<sup>23,40</sup> Pharmacokinetic properties of CAs (large volumes of distribution, high plasma protein binding) weighed against the small increases in clearance and the potential complications of MDAC, such as impaction, intestinal infarction, and perforation, do not warrant its routine use.<sup>23,80</sup> One additional dose of AC is reasonable to decrease GI absorption in patients with evidence of significant CNS and cardiovascular toxicity if bowel sounds are present.

Measures to enhance urinary CA excretion have a minimal effect on total clearance. Urinary alkalization does not enhance, and may reduce, urinary clearance because of passive reabsorption of the nonionized CA from an alkaline urine.<sup>127</sup> Hemodialysis is ineffective in enhancing the elimination of CAs because of their large volumes of distribution, high lipid solubility, and extensive protein binding.<sup>48</sup> Redistribution of drug to the plasma and

a rebound effect would be expected after this procedure. Although several uncontrolled case reports and a case series described improvement in cardiotoxicity during hemoperfusion, this finding is likely coincidental.<sup>13,24,35</sup> Given these limitations, hemodialysis or hemoperfusion should not be performed for patients with CA toxicity.

### Hospital Admission Criteria

All patients who present with known or suspected CA ingestion should undergo continuous cardiac monitoring and serial ECG for a minimum of 6 hours. Recommendations in the older literature for 48 to 72 hours of ICU monitoring even for patients with minor CA ingestions stem from isolated case reports of late-onset dysrhythmias, CNS effects, and sudden deaths.<sup>90</sup> However, review of these cases shows inadequate GI decontamination, inadequate therapeutic interventions, and significant ongoing complications of overdose. Several retrospective studies demonstrate that late, unexpected complications in CA overdoses such as seizures, dysrhythmias, and death did not occur in patients who had few or no major signs of toxicity at presentation or a normal level of consciousness and a normal ECG for 24 hours.<sup>20,27,30,92</sup> The following previously proposed disposition algorithm, based on clinical signs and symptoms, is reasonable: If the patient is asymptomatic at presentation, undergoes GI decontamination, has normal ECGs, or has sinus tachycardia (with normal QRS complexes) that resolves and the patient remains asymptomatic in the health care facility for a minimum of 6 hours without any treatment interventions, the patient may be medically cleared for psychiatric evaluation or discharged home, as appropriate.<sup>6,118</sup>

A prospective study of 67 patients used the Antidepressant Overdose Risk Assessment (ADORA) criteria to identify patients who were at high risk for developing serious toxicity and proposed criteria for hospitalization.<sup>33</sup> In this study, the presence of QRS complex duration greater than 100 ms, cardiac dysrhythmias, altered mental status, seizures, respiratory depression, or hypotension on presentation to the ED (or within 6 hours of ingestion, if the time was known) was 100% sensitive in identifying patients with significant toxicity and subsequent complications. Criteria specific for ICU admission (other than patients requiring ventilatory and or blood pressure support), versus an inpatient bed with continuous cardiac monitoring, are less clear and probably are institution dependent.<sup>113</sup>

The disposition of patients with persistent isolated sinus tachycardia, prolonged QT interval with no concomitant altered mental status, or blood pressure changes is not clearly defined. Previous studies demonstrate that these two parameters alone are not predictive of subsequent clinical toxicity or complications.<sup>33,34</sup> In addition, the sinus tachycardia may persist for up to 1 week after ingestion. However, a study of isolated CA overdose patients reported that a heart rate greater than 120 beats/min and a QT interval greater than 480 ms were associated with an increased likelihood of major toxicity.<sup>22</sup> These patients are candidates for observation with continuous ECG monitoring and serial ECGs for 24 hours.

### Inpatient Cardiac Monitoring

The duration of cardiac monitoring in any patient initially exhibiting signs of major clinical toxicity depends on many factors. Certainly, the duration of CA cardiotoxicity and neurotoxicity may be prolonged, and using normalization of ECG abnormalities as an endpoint for therapy and discharge is problematic. Some studies document the variable resolution and normalization of QRS prolongation and T40-ms axis rotation.<sup>88,109</sup> Based on the available literature, patients admitted to the hospital for significant poisoning should be monitored for another 24 hours after termination of CA therapy, including alkalization, antidysrhythmics, and inotropics or vasopressors, after resolution of clinical toxicity.

### SUMMARY

- Cyclic antidepressant poisoning continues to be a cause of serious morbidity and mortality worldwide.
- The distinctive characteristics of these drugs cause significant CNS and cardiovascular toxicity, the latter being responsible for mortality as a result of overdose of these drugs. Cardiovascular toxicity ranges from

mild conduction abnormalities and sinus tachycardia to wide-complex tachycardia, hypotension, and asystole. Central nervous system toxicity includes delirium, lethargy, seizures, and coma.

- The ECG is a simple, readily available diagnostic test that can predict the development of significant toxicity, particularly seizures and dysrhythmias.
- Management strategies are based primarily on the pathophysiology of these drugs, namely, sodium channel blockade in the myocardium. Alkalinization and sodium loading with hypertonic sodium bicarbonate is the principal therapy for cardiovascular toxicity.
- Guidelines for observing or admitting patients to the hospital are based on initial clinical presentation or development of clinical effects and ECG changes.

## SEROTONIN REUPTAKE INHIBITORS AND ATYPICAL ANTIDEPRESSANTS

Christine M. Stork

### INTRODUCTION

In the United States, major depressive disorder is a leading cause of disability and affects 15.7 million American adults; representing 6.7% of all US adults in 2015.<sup>97</sup> Although major depressive disorder can develop at any age, a higher percentage of 15- to 25-year-old adults are found to have depression, and women are affected nearly twice as often as men. The exact etiology of depression and the mechanism by which increased serotonergic and norepinephrine neurotransmission modulates mood remain unclear. A complex interaction of genetics and altered serotonin neurotransmission along with alterations in brain-derived neurotrophic factor, neurotrophin-3, dopamine, norepinephrine, and excitatory neuronal pathways likely have a role in depressive disorders.<sup>119</sup> Although termed *selective serotonin reuptake inhibitors* (SSRIs), these antidepressants have complex pharmacologic effects and interact with a number of other receptors and neurotransmitters. The class of SSRIs includes citalopram, escitalopram (citalopram's active enantiomer), fluoxetine, fluvoxamine, paroxetine, and sertraline (Fig. 69-1). Atypical antidepressants extend the pharmacologic principles of SSRIs to achieve beneficial effects for patients with depression. The SSRIs and atypical antidepressants comprise the current standard for the treatment of depression.<sup>70</sup> The SSRIs also are used to treat anxiety disorders, insomnia, chronic pain, panic disorders, social phobia, fibromyalgia, migraine, obsessive-compulsive disorders, bipolar disorders, premenstrual syndrome, menopausal symptoms, nicotine dependence, attention deficit hyperactivity disorder (ADHD), posttraumatic stress disorder, sexual dysfunction, digestive system disorders, urinary system disorders, and bulimia nervosa.<sup>10,110,116,125</sup> They have excellent safety profiles compared with previous antidepressants such as monoamine oxidase inhibitors (MAOIs) and the cyclic antidepressants (Cas) (Chaps. 68 and 71). Similar to many xenobiotics, the appropriateness of their use, their effectiveness, and the associated morbidity and mortality have made their use increasingly controversial as the patient population, especially those at the extremes of age, and the comorbidity profiles of those using the SSRIs are expanding.

### HISTORY AND EPIDEMIOLOGY

Serotonin (5-hydroxytryptamine) got its name after its initial discovery as a vasoconstrictor. The SSRIs were initially marketed in the United States in the early 1980s and are today considered one of the first-line therapies for

treatment of major depressive disorders.<sup>54</sup> The SSRIs are as effective as the CAs and MAOIs for the treatment of major depression, have fewer significant adverse events associated with their therapeutic use, and are less problematic in overdose (Chaps. 68 and 71). An increased risk of suicidal behavior is reported with the use of many antidepressants compared with herbals or counseling alone in children and adults.<sup>65,92</sup> This may be related to delayed onset of therapeutic efficacy coupled with increased energy associated with the initiation of therapy.

### PATHOPHYSIOLOGY

Table 69-1 lists the pharmacology, therapeutic doses, and metabolism of the available SSRIs and atypical antidepressants. Modulation of serotonin and norepinephrine neurotransmission has a significant role in the treatment of depression.<sup>131</sup> There are seven widely known classes of serotonin receptors, with many containing subtype classifications (Chap. 13). The SSRIs selectively inhibit serotonin reuptake via the serotonin transporter (SERT) caused by p-trifluoromethyl or p-fluoro substitution present in many of these xenobiotics.<sup>161</sup> Serotonin transporter functions through conformational changes as it moves serotonin across the membranes. An increase in transport and in the related conformational change is also associated with an increase in cyclic guanosine monophosphate (cGMP) phosphorylation within the neuron. Serotonergic neurons are located almost exclusively in the median raphe nucleus of the brainstem, where they extend into and are in close proximity to norepinephrine neurons that are located primarily in the locus ceruleus<sup>9</sup> (Fig. 69-2). The interplay between norepinephrine and serotonin likely explains the effectiveness of antidepressants that do not directly modulate serotonin neurotransmission.

### PHARMACOKINETICS AND TOXICOKINETICS

The SSRIs display diverse elimination patterns and have numerous active metabolites, which substantially increase both the duration of therapeutic effectiveness and the duration during which drug interactions and adverse drug effects occur. These latter effects often persist even after the medication is discontinued (Table 69-1). Important pharmacokinetic and pharmacodynamic drug interactions are reported with therapeutic dosing (see Serotonin Toxicity). The SSRIs and their active metabolites are substrates

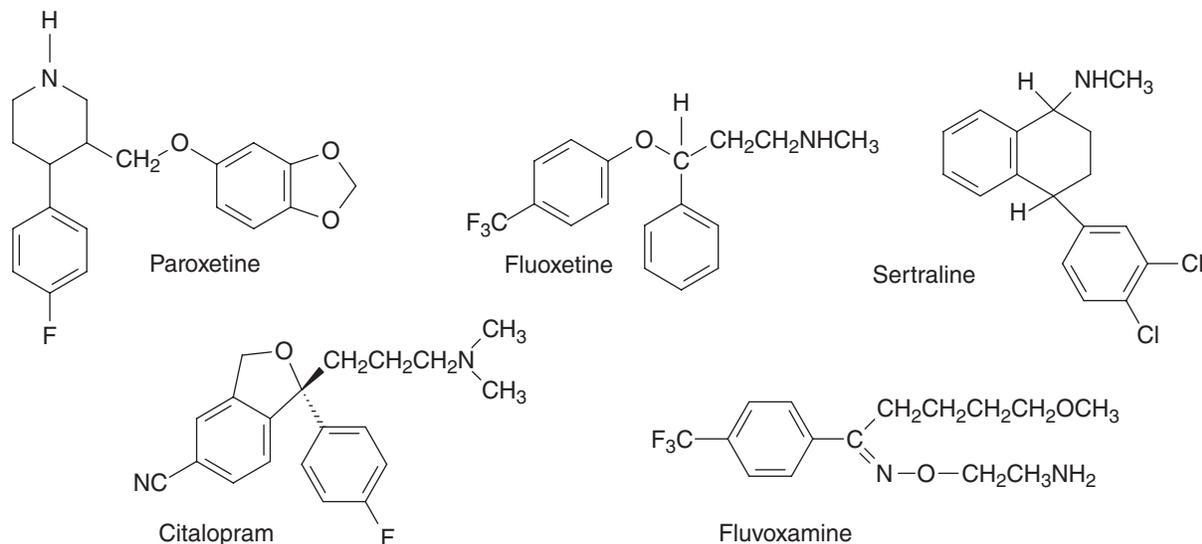

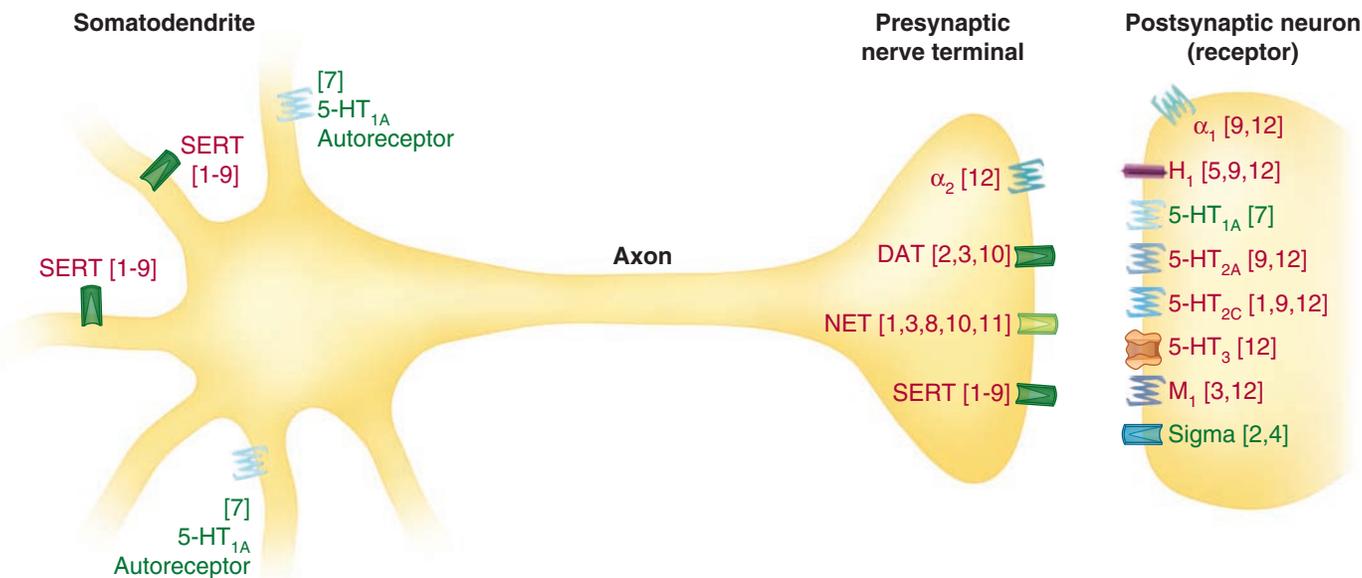

FIGURE 69-1. Structures of common selective serotonin reuptake inhibitors. Citalopram is shown as the S-enantiomer (escitalopram).

**TABLE 69–1 Drug Mechanism and Pharmacokinetic Data for Available Selective Serotonin Reuptake Inhibitors and Atypical Antidepressants<sup>a</sup>**

<i>Drug</i>	<i>Typical Daily Dose Range (mg)</i>	<i>t<sub>1/2</sub> (h)</i>	<i>Major Metabolic Mechanism</i>	<i>Major Active Metabolites</i>	<i>Major Active Metabolite t<sub>1/2</sub></i>	<i>Drug (d) or Metabolite (m) Inhibits CYP</i>
<b>SSRIs</b>						
Citalopram	20–60	33–37	2C19, 3A4, 2D6	Monodesmethylcitalopram, didesmethylcitalopram	59 h	None or unknown
Escitalopram	10–20	22–32	2C19, 3A4, 2D6	S(+)-Desmethylcitalopram	59 h	None
Fluoxetine	10–80	24–144	2C9, 2D6	Norfluoxetine	4–16 d	2D6 (d,m), 2C19 (d,m), 2D6 (d,m), 3A4 (m)
Fluvoxamine	100–300	15–23	1A2, 2D6	None	N/A	1A2, 2C9, 2C19, 3A4
Paroxetine	10–50	2.9–44	2D6	None	N/A	2D6
Sertraline	50–200	24	2C9, 2B6, 2C19, 2D6, 3A4	Desmethylsertraline	62–104 h	2C19 (d,m)
<b>SPARIs</b>						
Vilazodone	10–40	25	3A4, 2C19, 2D6	None	NA	None or unknown
Vortioxetine	5–20	66	2D6, 3A4	None	NA	None or unknown
<b>SARIs</b>						
Trazodone	50–600	3–9	2D6, 3A4 inhibitors may increase concentration	m-Chlorophenylpiperazine	?	None or unknown
Nefazodone	300–600	3.5	3A4	Triazoledione, hydroxynefazodone	10 hours	(m)3A4
<b>SNRIs</b>						
Desvenlafaxine	50	11	Conjugation, 2D6	None or unknown	N/A	None or unknown
Duloxetine	40–60	8–17	2D6, 1A2	None	N/A	2D6
Levomilnacipran	40–120	12	3A4, P-glycoprotein Minor: 2C19, 2C8 and 2D6	None	N/A	None or unknown
Milnacipran	25–200	6–8	Glucuronidation	None	N/A	None
Venlafaxine	75–375	3–4	2D6	O-desmethylvenlafaxine, depends on 3A4 and 2C19 for metabolism	10 h	None or unknown
<b>PSNR</b>						
Mirtazapine	15–45	20–40	3A4	Desmethylmirtazapine	Unknown	3A4 induction
<b>NDRI</b>						
Bupropion	150–450	9.6–20.9	2D6	Hydroxybupropion, erythrohydrobupropion, threohydrobupropion	24–37 h	2D6

<sup>a</sup>The volume of distribution for all these xenobiotics is large except for trazodone.

N/A = not applicable; NDRI = norepinephrine/dopamine reuptake inhibitor; PSNR = presynaptic serotonin and norepinephrine releaser; SARI = serotonin antagonist/partial agonist/reuptake inhibitor; SNRI = serotonin/norepinephrine reuptake inhibitor; SPARI = serotonin reuptake inhibitors/partial receptor agonists; SSRI = selective serotonin reuptake inhibitor.

**FIGURE 69–2.** Simplified sites of action of select serotonin and noradrenergic antidepressants. Xenobiotics in green numbers are agonists, and those in red numbers are antagonists. (A) All of the following inhibit the serotonin transporter (SERT) and affect other receptors: (1) fluoxetine blocks norepinephrine reuptake transporter (NET) (weak) and 5-HT<sub>2C</sub>; (2) sertraline blocks the dopamine reuptake transporter (DAT) (weak) and binds to the sigma receptor; (3) paroxetine blocks NET (weak) and the muscarinic receptor (M<sub>1</sub>) and inhibits nitric oxide synthase (NOS); (4) fluvoxamine binds to the sigma receptor; (5) citalopram has mild histamine receptor (H<sub>1</sub>) receptor inhibition and increases QTc prolongation at high doses; (6) escitalopram is a pure selective serotonin reuptake inhibitor (SSRI); (7) serotonin reuptake inhibitors/partial receptor agonists (SPARIs) include the partial 5-HT<sub>1A</sub> agonist vilazodone (buspirone; not a SERT); (8) serotonin/norepinephrine reuptake inhibitors (SNRIs), including venlafaxine, deslafaxine, and duloxetine, indirectly increase dopamine in the prefrontal cortex; and (9) serotonin antagonist/partial agonist/reuptake inhibitors (SARIs; trazodone) block 5-HT<sub>2A</sub>, 5-HT<sub>2C</sub>, H<sub>1</sub>, and  $\alpha_1$  receptor (dose dependent). (B) All of the following have no SERT inhibition but exhibit other effects: (10) norepinephrine/dopamine reuptake inhibitors (NDRIs; bupropion); (11) norepinephrine reuptake inhibitors (NRIs; atomoxetine); and (12) noradrenergic and specific serotonergic antidepressants (NASSAs; mirtazapine), which blocks central  $\alpha_2$  presynaptic receptors, 5-HT<sub>2A</sub>, 5-HT<sub>2C</sub>, 5-HT<sub>3</sub>, H<sub>1</sub>, M<sub>1</sub> (weak) and peripheral  $\alpha_1$  receptor (weak). The xenobiotics listed next to the receptors affect the receptors to varying degrees of potency.

for and potent inhibitors of CYP2D6 and other cytochrome P-450 metabolizing enzymes (CYPs).<sup>63</sup> For example, whereas fluoxetine, fluvoxamine, citalopram, venlafaxine, mirtazapine, paroxetine, sertraline, and vortioxetine are substrates for CYP2D6, paroxetine, norfluoxetine, and fluoxetine inhibit the same enzyme (Table 69–1). Fluvoxamine inhibits CYP1A2 and CYP2C19, nefazodone inhibits CYP3A4, and mirtazapine induces CYP3A4. The metabolism of trazodone, vilazodone, and vortioxetine is decreased after this same enzyme is inhibited.<sup>146</sup> The consequences of these interactions manifest when the metabolism of xenobiotics that rely on these enzymes for metabolic transformation is altered (Chap. 11).

## PATHOPHYSIOLOGY

The causes of depression and the mechanisms by which antidepressants ameliorate depressive symptoms are not well understood. Population-based studies demonstrate heritability in major depression, and a unique genotype was identified in the 5HT<sub>2A</sub> receptor in patients with seasonal affective disorder.<sup>42</sup> Mutations in the serotonin transporter are known to cause conformational changes as serotonin moves across the membrane.<sup>163</sup> These mutations also affect the regulation of cGMP-dependent signaling processes and are found to be associated with psychiatric disorders. The current postulated causes of depression include a disruption in function in the signal transduction cascade or events that occur thereafter that influences the regulation of neuronal ion channels, receptor modulation, neurotransmitter release, synaptic potentiation, and neuronal survival.<sup>23</sup> Multiple neurotransmitters are likely involved, including serotonin, norepinephrine, and dopamine. Further research evaluating the lesser known influences of  $\gamma$ -aminobutyric acid (GABA), excitatory amino acids, substance P antagonists, and antimuscarinic xenobiotics is ongoing. In addition to the direct pharmacologic effect of increasing synaptic concentrations of serotonin, antidepressants increase neurogenesis in the prefrontal cortex and glia in oligodendrocytes and activate complementary factors such as brain-derived neurotrophic factor and mitogen-activated protein kinase. The secondary effects, including conformational changes occurring

after exposure to these endogenous mediators, may explain previous research finding no difference in the concentration of serotonin-binding sites or serotonin receptor activity between depressed patients who respond to SSRIs and those who do not respond.<sup>24,134</sup> Unlike the CAs and other atypical antidepressants, the SSRIs have little direct interaction with cholinergic receptors, GABA receptors, sodium channels, or adrenergic reuptake (Table 69–2).

## CLINICAL MANIFESTATIONS

Most of the effects that occur after overdose are direct extensions of the pharmacologic activity of the SSRIs in therapeutic doses. Excess serotonergic stimulation is prominent and nonselective. Common signs and symptoms include drowsiness, tremor, nausea, and vomiting. Less commonly, central nervous system (CNS) depression and sinus tachycardia occur.<sup>13</sup> Seizures and changes on electrocardiography (ECG), including prolongation of the QRS complex and QT interval duration, are reported, but they rarely occur with most SSRIs, even after large overdoses (Table 69–3). Infrequently, SSRI overdose results in life-threatening effects with fatalities often associated with coadministration of other xenobiotics.

### Citalopram

Citalopram and its S(+)-enantiomer, escitalopram, cause QT interval prolongation in therapeutic doses in a linear, dose-related, and delayed manner.<sup>74,90</sup> In healthy adults, an increase of 8.5 ms occurred at a dose of 20 mg/day and 18.5 ms with a dose of 60 mg/day. The development of torsade de pointes is reported in therapeutic doses but only when concurrent xenobiotics are used or when there are electrolyte abnormalities. In large case series, patients are at risk for seizures and QT interval prolongation after ingestions exceeding 600 mg of citalopram or with serum concentrations more than 40 times the expected therapeutic concentrations.<sup>27,122,123</sup> Seizures were an early finding, occurring within 2 hours of ingestion, but the development of abnormalities on ECG were delayed for as long as 24 hours after ingestion.<sup>123</sup> Other case series report survival with seizures and significant QT interval prolongation

after a reported ingestion of 2.0 to 5.2 g of citalopram.<sup>13,64</sup> In 50 forensic cases, femoral blood citalopram concentrations were between 1.5 and 27 mcg/mL. Therapeutic concentrations identified at postmortem are reported to be up to 0.4 mcg/mL.<sup>129</sup>

Although the mechanisms are unclear, experimental models suggest that the didesmethylcitalopram metabolite of citalopram prolongs the QT interval by blocking I<sub>Kr</sub>, but high concentrations of both the parent drug and this metabolite result in seizures (Chaps. 15 and 57).<sup>19,160</sup> The elimination half-life of the *R*-enantiomer of citalopram exceeds that of the *S*-enantiomer.<sup>104</sup>

## MANAGEMENT

Treatment of patients with acute SSRI overdose is largely supportive. Dextrose and thiamine should be given when clinically indicated for patients who present with altered mental status. Although cardiac manifestations after SSRI overdose are rare, a 12-lead ECG should be obtained to identify other cardiotoxic drugs, such as the CAs, to which the patient might access (Chaps. 15, 67, and 68). We recommend that patients suspected of overdose with citalopram or escitalopram be attached to a cardiac monitor to exclude the possibility of delayed QT interval prolongation and subsequent risk for ventricular dysrhythmias.<sup>152</sup> After the patient is initially stabilized, oral activated charcoal (AC) (1 g/kg) is recommended to adsorb drug remaining in the gastrointestinal (GI) tract. Lowering of blood concentrations and reduction in risk for QT interval prolongation are demonstrated when AC is given within the first 4 hours after escitalopram and citalopram ingestion.<sup>49,50,59</sup> Patients with small unintentional overdoses of SSRIs other than citalopram and escitalopram are not expected to develop significant signs and symptoms of poisoning. Adults with well-defined unintentional ingestions of up to 100 mg of citalopram and 50 mg of escitalopram can be managed safely at home with close observation.<sup>112</sup> The dose at which children can be safely managed in the home is less well defined. Fatalities resulting from SSRIs are rare and most commonly occur after ingestions of multiple xenobiotics or are manifestations of drug interactions resulting from excess serotonergic

effects (see Serotonin Toxicity).<sup>57</sup> Forensic analysis of femoral blood samples is useful as corroborative data regarding death caused by SSRIs. In a forensic case study, blood concentrations in fatalities were higher concentrations than those found after purported therapeutic use of SSRIs.<sup>129</sup>

### ADVERSE EVENTS AFTER THERAPEUTIC DOSES

Adverse events commonly associated with therapeutic doses of SSRIs as well as with overdose include GI (anorexia, nausea, vomiting, diarrhea), sexual dysfunction, weight gain, sleep disturbance, and discontinuation reactions.<sup>44</sup> Less common adverse events include sedation, particularly after citalopram and paroxetine, which result from their weak antimuscarinic activity, and anxiety after fluoxetine treatment.<sup>93</sup> Serotonin activity inhibits platelet secretory response, platelet aggregation, and platelet plug formation.<sup>16</sup> Although the effect increases in SSRIs with increased potency, clinically consequential bleeding is rare and is significant only in patients concurrently taking other antiplatelet medications.<sup>1,87</sup> This effect is of potential benefit in patients at risk for cardiovascular events.<sup>6</sup> Other rarely reported adverse events include new-onset panic disorder, priapism, bradycardia, hepatotoxicity, and urinary incontinence.<sup>44</sup> Movement disorders, most commonly akathisia, parkinsonism, myoclonus, and dystonia, also occur after SSRI use.<sup>1,36,147</sup> These extrapyramidal adverse events appear to be related to the complex interplay between serotonergic and dopaminergic activity. Predisposing factors for the development of movement disorders include concomitant use of dopamine antagonists such as the antipsychotics.<sup>88</sup>

The use of SSRIs is associated with the syndrome of inappropriate antidiuretic hormone secretion (SIADH; Chap. 12), in which severe hyponatremia occurs rapidly. The effect appears to be serotonin mediated in animal models, with increased concentrations of serum cortisol, adrenocorticotropin, and vasopressin noted.<sup>51</sup> Rat studies demonstrate that stimulation of 5-HT<sub>1C</sub> and 5-HT<sub>2</sub> receptors increases antidiuretic hormone secretion.<sup>144,145</sup> However, human case control studies using water-loading tests have not confirmed defects in osmoregulated release of vasopressin through measurement of vasopressin concentrations after 3 to 11 months of paroxetine use.<sup>99</sup> A review of the literature identified increasing age, female sex, concurrent medications known to cause hyponatremia, low body weight, a previous history of hyponatremia, and excessive fluid intake as risk factors for hyponatremia.<sup>76,83,84</sup> Although reported to occur from 3 days to 4 months after initiation of therapy, a case-matched control study of 203 patients identified that SIADH occurs most frequently within the first 2 weeks of therapy.<sup>106</sup> Hyponatremia is also reported when switching from one SSRI to another.<sup>8</sup> Neither CYP2D6 genotype metabolizer status nor high serum concentrations predicts risk of hyponatremia.<sup>149</sup> Patients older than 40 years of age using SSRIs are at increased risk for bone fracture, presumably caused by a serotonergic effect on osteoblasts and osteoclasts.<sup>140</sup>

### Serotonin Toxicity

The most common severe adverse event associated with SSRIs is the development of serotonin toxicity. This was formerly referred to in life-threatening cases as *serotonin syndrome* and *serotonin behavioral or hyperactivity syndrome*. It was first described in patients treated with MAOIs who were given other xenobiotics that enhance serotonergic activity.<sup>30,115,143</sup> However, ingestion of an MAOI is not required for serotonin toxicity to develop, and its occurrence is unpredictable (Table 69–4).

### Pathophysiology

The pathophysiologic mechanism of serotonin toxicity is not completely understood but likely involves excessive selective stimulation and genetic variation of serotonin 5-HT<sub>2A</sub> and perhaps 5-HT<sub>1A</sub> receptors.<sup>32,109,113</sup> Initial animal models demonstrate that specific stimulation of 5-HT<sub>1A</sub> receptors results in serotonin toxicity even when 5-HT<sub>2A</sub> receptors were inactivated using a specific antagonist.<sup>35,113</sup> However, a subsequent animal study and a human retrospective case series showed that the potency of 5-HT<sub>2A</sub> agonist therapy was directly related to the development of the findings attributed to serotonin toxicity.<sup>56</sup> 5-HT<sub>1D</sub> receptors are not implicated in cases of serotonin toxicity.

**TABLE 69–4 Potential Causes of Serotonin Toxicity<sup>21</sup>**

#### *Inhibitors of Serotonin Metabolism*

Linezolid  
Methylene blue  
Monoamine oxidase inhibitors (nonselective)  
  Phenelzine, moclobemide, clorgyline, isocarboxazid  
Harmine and harmaline from Ayahuasca preparations, psychoactive beverage used for religious purposes in the Amazon and Orinoco River basins  
St. John's wort (*Hypericum perforatum*)  
Syrian rue (*Peganum harmala*)

#### *Blockers of Serotonin Reuptake*

Bupropion  
Clomipramine, imipramine  
Cocaine  
Dextromethorphan  
Fentanyl  
Meperidine  
Pentazocine  
SSRIs: all  
Milnacipran  
Tramadol  
Trazodone, nefazodone  
Venlafaxine

#### *Serotonin Precursors or Agonists*

L-Tryptophan  
Lysergic acid diethylamide (LSD)  
Tryptans (sumatriptan)

#### *Enhancers of Serotonin Release*

Substituted amphetamines and analogs: phenylethylamines, especially MDMA, cathinones, aminoindanes  
Methylone  
Bupirone  
Butylone  
Cocaine  
Lithium  
Mirtazapine

#### *Other*

Ginseng  
Lithium  
Ondansetron, granisetron, and metoclopramide  
Sibutramine  
Ritonavir  
Valproic acid

MDMA = 3,4-methylenedioxyamphetamine; SSRI = selective serotonin reuptake inhibitor.

Serotonin toxicity occurs most frequently after use of combinations of serotonergic xenobiotics (Table 69–4) but also occurs after high therapeutic dosing or overdoses of isolated serotonergic xenobiotics.<sup>34,68,81,117</sup> Interactions resulting in serotonin toxicity also occur while alternating serotonergic xenobiotic regimens, particularly when an insufficient time lag occurs before initiating the alternative therapy.<sup>95</sup> Residual pharmacologic effects, receptor downregulation or upregulation, and the presence of active metabolites are likely causative in these circumstances. For example, fluoxetine metabolism results in the active metabolite norfluoxetine, which has comparable pharmacologic effects and a half-life substantially longer than fluoxetine. The clearance of norfluoxetine takes approximately 2 weeks.

**TABLE 69–5** Diagnostic Criteria for Serotonin Toxicity**After Introduction of a Serotonergic Xenobiotic:**

Spontaneous clonus alone  
 Inducible or ocular clonus *plus* agitation or diaphoresis or hypertonicity with temperature >38°C (100.4°F)  
 Tremor with hyperreflexia

**Other Common Manifestations**

Diaphoresis and shivering  
 Diarrhea  
 Hyperthermia  
 Incoordination  
 Mental status changes  
 Myoclonus

Although sporadic reports occur, selective MAO subtype B (MAO-B) inhibitor xenobiotic combinations and triptans (5-HT<sub>1B/1D</sub> receptor agonists) can result in serotonin toxicity at therapeutic doses.<sup>43,45</sup>

**Manifestations**

Signs of serotonin toxicity include altered mental status, agitation, tachycardia, myoclonus, hyperreflexia, diaphoresis, tremor, diarrhea, incoordination, muscle rigidity, and hyperthermia (Table 69–5). The neuromuscular effects are often more prominent in the lower extremities. The clinical manifestations of serotonin toxicity are diverse, and minor manifestations are common after initiation of SSRI and atypical antidepressant therapy. In fact, a prospective study of depressed inpatients given clomipramine demonstrated that 16 of the 38 patients experienced manifestations consistent with serotonin toxicity, with 14 having spontaneous resolution within 1 week without discontinuation of therapy.<sup>91</sup> Life-threatening effects invariably result from hyperthermia caused by excessive muscle activity that is more prominent in the lower extremities. Sustained severe hyperthermia can lead to death through denaturation of essential protein and enzymatic function that ultimately results in an elevated lactate concentration and metabolic acidosis, rhabdomyolysis, renal and hepatic dysfunction, disseminated intravascular coagulation, or acute respiratory distress syndrome (Chap. 29).<sup>103,150</sup>

**Diagnosis**

Although fulminant life-threatening cases are easy to recognize, mild cases of serotonin toxicity are more difficult to distinguish from similarly appearing disorders from other causes. In an effort to determine diagnostic criteria, a study that included 38 cases of presumed serotonin toxicity suggested diagnostic criteria to include three of the following signs and symptoms—altered level of consciousness, agitation, myoclonus, hyperreflexia, diaphoresis, tremor, diarrhea, and incoordination—when other causes were excluded.<sup>150</sup> A modification, the Hunter Serotonin Toxicity Criteria, which included the variables of myoclonus, agitation, diaphoresis, hyperreflexia, hypertonicity, and fever, was validated in 473 patients and found to correlate best with a clinical toxicologic diagnosis of serotonin toxicity (Table 69–5).<sup>41</sup> Currently, no diagnostic test capable of determining whether a patient is experiencing serotonin toxicity is available. A single case report demonstrated increased urinary serotonin concentrations associated with serotonin toxicity.<sup>25</sup> There are likely genetic alterations of SERT or 5-HT<sub>2A</sub> receptors or polymorphisms of drug metabolism via CYP2D6 involved.<sup>47</sup> Mice with *SERT* gene deficiency showed increased serotonergic response when given serotonergic drugs. A T102C single-nucleotide polymorphism of the 5-HT<sub>2A</sub> was associated with SSRI adverse event–related drug discontinuation after initiation of paroxetine therapy, although this was unable to be validated after acute overdose.<sup>32,108</sup>

**Management**

Treatment of patients with serotonin toxicity begins with supportive care and focuses on decreasing core body temperature and muscle activity. Because

muscular rigidity is thought to be primarily responsible for hyperthermia and death, rapid, aggressive external cooling using ice water immersion if severe in conjunction with sedative hypnotics such as benzodiazepines are recommended to limit complications and mortality (Chap. 29). In severe cases, neuromuscular blockade with a definitive airway is a recommended approach to achieve rapid muscle relaxation. The time course of serotonin toxicity is variable and related to the time required to eliminate the offending xenobiotics. In most patients, the manifestations of serotonin toxicity resolve within 24 hours after the offending xenobiotic is removed. However, serotonin toxicity can be prolonged when it is caused by xenobiotics with long half-lives, protracted duration of effects, or active metabolites.

Animal models indicate that pretreatment with serotonin antagonists can prevent development of serotonin toxicity.<sup>113</sup> Several case reports suggest success after use of 4 mg of oral cyproheptadine, an antihistamine with nonspecific serotonin antagonist effects, including 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptors.<sup>62,89</sup> Patients who responded typically had no hyperthermia and only mild to moderate manifestations of serotonin toxicity. Evidence supports the use of cyproheptadine in this patient group. We currently recommend doses of 8 to 16 mg orally repeated hourly, as needed, to achieve muscle relaxation in more severe cases. Further research is warranted to determine the success of higher doses given to gain sufficient 5-HT<sub>2A</sub> antagonistic effects in more severely affected patients.<sup>56</sup> Other xenobiotics, such as methysergide, chlorpromazine, atypical antipsychotics, and propranolol, are anecdotally reported to be successful for the treatment of serotonin toxicity.<sup>21,56,66,133</sup> These therapies are not currently recommended.

**Differentiating Serotonin Toxicity from Neuroleptic Malignant Syndrome**

Many features overlap between serotonin toxicity and the neuroleptic malignant syndrome (NMS; Chap. 67). Although altered mental status, autonomic instability, and changes in neuromuscular tone that result in hyperthermia are common to both disorders: many differences are apparent. It is also clear that the implicated xenobiotics, time course, pathophysiology, and manifestations are distinct (Table 69–6).<sup>56</sup> Signs and symptoms of serotonin toxicity develop within minutes to hours after exposure to the offending xenobiotics, but NMS typically develops days to weeks after daily exposure.<sup>124</sup> In addition, after syndrome onset, even with the offending xenobiotics discontinued, NMS can persist for as long as 2 weeks. However, serotonin toxicity usually resolves

**TABLE 69–6** Comparison of Neuroleptic Malignant Syndrome (NMS) and Serotonin Toxicity

	NMS	Serotonin Toxicity
<b>Historical Diagnostic Clue</b>		
Inciting drug pharmacology	Dopamine antagonist	Serotonin agonist
Time course of initiation of symptoms after exposure	Days to weeks	Hours
Duration of symptoms	Days to 2 wk	Usually 24 h
<b>Symptoms</b>		
Altered mental status (depressed or confusion)	+++	+++
Altered mental status (agitation or hyperactivity)	+++	+++
Autonomic instability	+++	+++
Bradykinesia	+++	–
Gastrointestinal findings (diarrhea)	–	+++
Hyperthermia	+++	+++
Lead pipe rigidity	+++	+
Shivering	–	+++
Tremor, hyperreflexia, myoclonus	+	+++

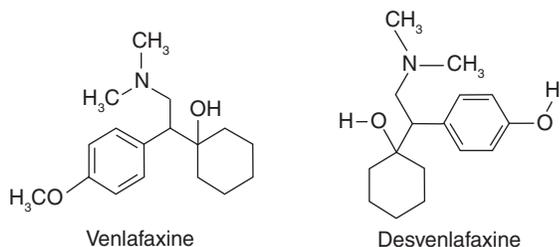

– = not found; + = rare finding; +++ = common finding.

within 24 hours and is directly correlated with the pharmacokinetic metabolic profile of the offending xenobiotic. A review of the literature indicates that patients presenting with serotonin toxicity are more likely to exhibit agitation, hyperactivity, clonus, myoclonus, ocular oscillations (opsoclonus), shivering, tremors, and lower limb hyperreflexia, but patients presenting with NMS were more likely to exhibit bradykinesia and lead pipe rigidity.<sup>56,121</sup>

### ATYPICAL ANTIDEPRESSANTS

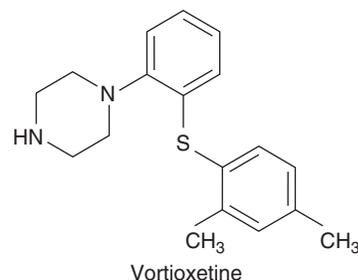

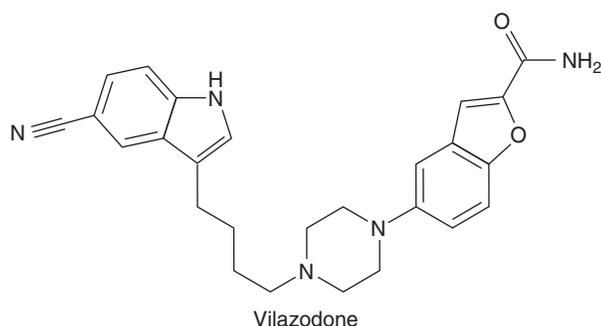

Atypical antidepressants are defined as not belonging strictly within a class of antidepressants. They are not SSRIs, CAs, or MAOIs. Most are derivatives of SSRIs and have additional pharmacologic effects that were selected in an attempt to decrease the undesirable side effects of traditional antidepressants.

#### Serotonin/Norepinephrine Reuptake Inhibitors: Venlafaxine, Desvenlafaxine, Duloxetine, Milnacipran, and Levomilnacipran

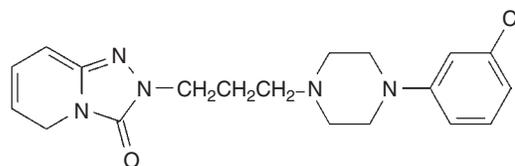

In addition to inhibiting serotonin reuptake, venlafaxine inhibits norepinephrine reuptake. Venlafaxine produces rapid downregulation of central  $\beta$ -adrenergic receptors, which results in a faster onset of antidepressant effect.<sup>137</sup> Patients with acute venlafaxine overdose present with nausea, vomiting, dizziness, tachycardia, CNS depression, hypotension, hypoglycemia, hyperthermia, hepatic toxicity (including zone 3 necrosis), rhabdomyolysis, and seizures.<sup>48,100,118,139</sup> Sodium and potassium channel blocking effects are rarely clinically apparent; however, prolongation of the QRS complex and QT interval can lead to ventricular tachycardia and death.<sup>18,132,156</sup> One report indicated a positive incremental association of clinical toxicity with a maximum measured serum venlafaxine concentration of 25.8  $\mu\text{mol/L}$ .<sup>102</sup> Although no clinical data regarding efficacy are available, we recommend sodium bicarbonate to attenuate the sodium channel blocking effects that lead to QRS complex prolongation (Antidotes in Depth: A5). In addition, GI decontamination with AC with or without whole-bowel irrigation (WBI) decreases serum concentrations and decreases the incidence of seizures in select patients, particularly after the ingestion of extended-release formulations.<sup>85,86</sup> Adverse events associated with chronic therapeutic doses of venlafaxine include alopecia, yawning, focal myositis, facial flushing, and dose-related increases in blood pressure.<sup>79,120</sup> Although limited information is available, venlafaxine appears to be more dangerous than SSRIs and the other serotonin/norepinephrine reuptake inhibitors (SNRIs)—desvenlafaxine, duloxetine, milnacipran, and levomilnacipran—after overdose.<sup>31,77,156</sup>

#### Serotonin Reuptake Inhibitors/Partial Receptor Agonists: Vilazodone and Vortioxetine

Vilazodone is an SSRI with additional 5-HT<sub>1A</sub> receptor agonism. Little information is available about vilazodone after overdose. After therapeutic doses, a case report suggested that vilazodone resulted in breakthrough seizures shortly after dose escalation in a patient with a seizure disorder who had been seizure free for 8 years.<sup>101</sup> However, in an analysis of published literature regarding therapeutic doses, only GI side effects occurred in more than 2,000 patients taking therapeutic doses.<sup>162</sup> A single report of a child with a reported ingestion of 37 mg/kg of vilazodone exhibited altered mental status, signs of serotonin toxicity, and a seizure.<sup>2</sup> Similarly, there is little information available regarding vortioxetine overdose, but it is anticipated to have effects similar to other SSRIs.

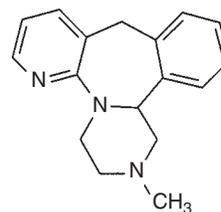

#### Serotonin Antagonist/Partial Agonist/Reuptake Inhibitors: Trazodone and Nefazodone

Trazodone is an antagonist at 5-HT<sub>2A</sub> and 5-HT<sub>2C</sub> receptors, a partial agonist at 5-HT<sub>1</sub> receptors, and a weak serotonin reuptake inhibitor. In addition, trazodone has  $\alpha$ -adrenergic antagonist activity and weak H<sub>1</sub> receptor antagonism. Central nervous system depression and orthostatic hypotension are the most common complications after acute overdose of trazodone.<sup>53</sup> Less common, seizures and cardiac conduction delays, such as QT interval prolongation and ventricular dysrhythmias, and death.<sup>29,39,126,138</sup> Trazodone is rarely reported to cause SIADH and cholestatic hepatitis.<sup>46,155,26,115,126</sup> Priapism, reported with therapeutic doses of trazodone, occurs occasionally after overdose.<sup>69</sup> Treatment is supportive and includes monitoring the ECG for conduction delays and the administration of fluids and vasopressors for hypotension if necessary.

Nefazodone is an antagonist at 5-HT<sub>2A</sub> receptors and  $\alpha$ -adrenergic receptors in addition to moderate inhibition of serotonin and norepinephrine reuptake.<sup>38</sup> Nefazodone is rarely used because of concerns of severe hepatic toxicity, including jaundice, hepatitis, and hepatocellular necrosis.<sup>28</sup> The most common manifestations seen after acute overdose include drowsiness, nausea, dizziness, and hypotension.<sup>15</sup> Treatment is similar to trazodone overdose.

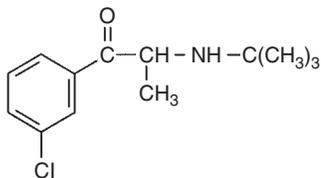

#### Presynaptic Serotonin and Norepinephrine Releaser: Mirtazapine

The mechanism of action of mirtazapine is unique. It is a central presynaptic  $\alpha_2$ -adrenergic inhibitor which increases neuronal norepinephrine and serotonin release.<sup>20</sup> Mirtazapine also blocks some subtypes of 5-HT receptors, including 5-HT<sub>2A</sub>, 5-HT<sub>2C</sub>, and 5-HT<sub>3</sub>. Finally, mirtazapine blocks H<sub>2</sub> receptors,

peripheral  $\alpha_1$  receptors, and muscarinic acetylcholine receptors.<sup>114</sup> The main effects that occur after acute mirtazapine overdoses include altered mental status, tachycardia, and hypothermia.<sup>96,157</sup> Large overdoses cause respiratory depression and prolongation of the QT interval.<sup>22,130</sup> Rare adverse reactions associated with the therapeutic use of mirtazapine causing serotonin toxicity, hepatitis, and reversible agranulocytosis are reported.<sup>71,75,111</sup>

### Norepinephrine/Dopamine Reuptake Inhibitor: Bupropion

The use of bupropion, especially extended-release formulations, is common for the treatment of depression. Bupropion is also frequently used in the treatment of smoking cessation therapy, weight loss, ADHD, and, occasionally, in compulsive eating disorders.<sup>4,52,98</sup> The pharmacologic mechanism of action of bupropion, a substituted cathinone ( $\beta$ -keto amphetamine) and its active metabolite, hydroxybupropion, include inhibition of reuptake of dopamine and, to a lesser extent, norepinephrine.<sup>7</sup> Chronic doses above 450 mg/day place patients at risk for seizures.<sup>37,80</sup> Frequent effects that occur after overdose include tachycardia, hypertension, GI symptoms, and agitation.<sup>12,14</sup> Large acute overdoses result in seizures (infrequently status epilepticus), QRS complex prolongation, and occasionally QT interval prolongation.<sup>12,77,78,153</sup> In some cases, effects were delayed for up to 10 hours, and seizures up to 24 hours, particularly after the ingestion of sustained-release preparations.<sup>148</sup> Effects can continue for up to 48 hours. Euphoria, hallucinations, and seizures are reported after nasal insufflation.<sup>72,128</sup> This is caused by extensive mucosal absorption, effectively bypassing first-pass hepatic metabolism.

It remains unclear whether seizures are caused by bupropion or its metabolite hydroxybupropion.<sup>37,141</sup> Elevated bupropion and hydroxybupropion concentrations are documented after seizures. The exact mechanism for seizures caused by hydroxybupropion is unclear at this time. Treatment, when required for seizures, should be supportive and includes judicious use of benzodiazepines. Significant cardiotoxicity and QRS complex prolongation are likely because of delayed and sustained elevation of serum bupropion serum concentration.<sup>3</sup> As assessed in animal studies, the mechanism is a deficiency in intracellular communication via gap junctions and therefore may not be responsive to sodium bicarbonate (Antidotes in Depth: A5).<sup>26</sup> Research is warranted to define the role of intravenous lipid emulsion (ILE) in life-threatening cases. Evidence-based recommendations suggest the use of ILE for life-threatening bupropion overdose after other therapies fail.<sup>60,142</sup> Intravenous lipid emulsion is not recommended in the situation of bupropion overdose without life-threatening cardiac toxicity. When a patient presents shortly after an overdose or the patient has taken a massive overdose, we recommend the use of multiple doses of AC with the addition of WBI if the airway is protected.

Other serious adverse events reported after chronic bupropion use include cholestatic and hepatocellular dysfunction and rhabdomyolysis, with isolated reports of chest pain, dystonia, trigeminal nerve dysfunction, mania, generalized erythrodermic psoriasis, erythema multiforme, dyskinesia, altered vestibular and sensory function, and serum sickness.<sup>5,33,36,58,61,82,94,154</sup>

### DRUG DISCONTINUATION SYNDROME

The term *drug discontinuation syndrome* is used to describe the physiologic manifestations that occur after abrupt antidepressant cessation. The distinction between a withdrawal syndrome and drug discontinuation syndrome is unclear, but it likely distinguishes the manifestations occurring after therapeutic use versus misuse, that is, alcohol or heroin withdrawal and SSRI discontinuation syndrome. Drug discontinuation syndromes

are commonly reported after abrupt discontinuation of all antidepressants, including SSRIs and atypical antidepressants.<sup>158</sup> Selective serotonin reuptake inhibitors cause a discontinuation syndrome that usually begins within 5 days after drug discontinuation and continues up to 3 weeks.<sup>67</sup> The most frequently reported symptoms include dizziness, lethargy, paresthesias, nausea, vivid dreams, irritability, and depressed mood.<sup>135</sup> The risk factors associated with development of a discontinuation syndrome are not fully clarified; however, in a given individual, a genetic polymorphism of the 5-HT<sub>1A</sub> receptor is hypothesized to play a role.<sup>107</sup> The syndrome is more common with SSRIs with shorter elimination half-lives (paroxetine > fluvoxamine > sertraline > fluoxetine). Of published cases, approximately 65% were attributed to paroxetine, approximately 20% to sertraline, and only 10% to fluoxetine and fluvoxamine.<sup>11,17</sup> Fluoxetine discontinuation syndrome occurs less frequently, at only 2 cases per 1 million prescriptions.<sup>127</sup> The long elimination half-life of fluoxetine and its active metabolite norfluoxetine probably decrease the incidence of discontinuation syndrome by providing a tapered effect after cessation. The discontinuation symptoms found with paroxetine were classified as mild to moderate in 20% to 40% of patients receiving 20 mg/day.<sup>11</sup>

Because of difficulty in distinguishing symptoms of discontinuation syndrome from underlying disease, some authors have proposed diagnostic criteria for the SSRI discontinuation syndrome.<sup>17</sup> All proposed criteria include discontinuation of the SSRI in concordance with CNS effects, GI distress, or anxiety.<sup>151</sup> The prominent CNS findings include dizziness; ataxia; vertigo; sensory abnormalities, including electric shocklike sensations and paresthesias; and behavior abnormalities, including aggression and impulsivity.

The biochemical basis of the discontinuation syndrome appears to be similar to tryptophan depletion, which results in an acute decrease in synaptic serotonin.<sup>40</sup> In fact, abrupt discontinuation versus drug taper was a noted risk factor for the discontinuation syndrome in paroxetine cases compared with drug taper.<sup>73</sup>

Treatment of patients exhibiting the discontinuation syndrome should include supportive care and resumption of the discontinued drug or administration of another SSRI if the implicated drug is contraindicated.<sup>159</sup> The drug then should be tapered at a rate that allows for improved patient tolerance. Many of the other antidepressants discussed in this chapter also result in discontinuation reactions. Symptoms appear similar to those reported after discontinuation of the SSRIs and are treated in a similar manner.<sup>159</sup>

Drug discontinuation syndrome is also identified to occur in neonates.<sup>55</sup> It is commonly referred to as the neonatal (serotonin) abstinence syndrome (NSAS). Neonatal (serotonin) abstinence syndrome is reported to occur after in utero exposure to SSRIs and other atypical antidepressants. The incidence of NSAS was reported to be as high as 30% in a cohort of neonates whose mothers were taking SSRIs.<sup>93</sup> Another literature review found an overall relative risk of 3 compared with those without exposure. In these cases, symptoms were generally confined to the CNS, respiratory system, and GI system and resolved over a 2-week period.<sup>105</sup>

### SUMMARY

- Acute overdose with SSRIs or atypical antidepressants are not usually life threatening, although seizures or cardiac toxicity occur.
- Monitoring is recommended for 24 hours for the delayed cardiotoxicity with citalopram or escitalopram.
- Monitoring is also recommended for 24 hours for delayed seizures after extended-release bupropion ingestion.
- Drug interactions and adverse drug events are associated with serotonin reuptake inhibitors and lead to acute life-threatening events, including serotonin toxicity.
- Serotonin toxicity can produce life-threatening hyperthermia and should be treated with aggressive cooling and sedation. Cyproheptadine is recommended for symptomatic patients and neuromuscular blockade is recommended for those with refractory hyperthermia.

# LITHIUM

Howard A. Greller

MW	= 6.94 Da
Lithium concentration (serum): Therapeutic concentration for bipolar depression	= 0.6–1.2 mEq/L (mmol/L)

## HISTORY AND EPIDEMIOLOGY

Lithium derives its name from *lithos*, the Greek word for stone, conferred to the element on its discovery in 1817 by the Swedish chemistry student Arfwedson. Lithium is a metal with no charge; lithium salts that are used therapeutically are monovalent cations. By the mid 19th century, lithium salts were used therapeutically for the treatment of gout, as well as mania and depression. The soft drink 7-Up originally contained lithium as its “active ingredient,” and during the 1930s and 1940s, it was used as a salt substitute (“Westal”) for patients with congestive heart failure until several cases of poisoning led to its discontinuation.<sup>7,17,61</sup> In 1949, Cade “rediscovered” the calming effects of lithium by initially injecting a combination of lithium carbonate and urea (believed a source of mania) into normally “frenetic” guinea pigs and noting the resulting sedation. He subsequently tested it on 10 patients with mania.<sup>46,59</sup> In 1954, Mogens Schou performed a randomized placebo controlled trial of lithium for mania, with promising results.<sup>59,204</sup> However, for 20 years, until reapproved in 1974, lithium was banned by the US Food and Drug Administration in response to multiple reports of toxicity.<sup>7,59</sup>

Lithium is considered the most effective long-term therapy for treatment and prevention of relapse of bipolar affective disorders.<sup>58,80,86,97,207,212</sup> It has a demonstrated antisuicidal effect<sup>57</sup> and the ability to improve both the manic and the depressive symptoms, as well as augment the therapeutic efficacy of other approaches that have failed to achieve symptom remission.<sup>17,51,60,86,92,97,130,135,142,159</sup> Lithium is also effective for compulsive gambling<sup>112,178</sup> and has shown promise for use in neurodegenerative disorders such as Alzheimer disease, ischemic stroke, amyotrophic lateral sclerosis, Huntington disease, multiple sclerosis, and traumatic brain injury.<sup>53,139,152,172,202,240,241</sup>

## PHARMACOLOGY

Lithium is the chemically simplest xenobiotic in the modern pharmacopeia. It has a complex mechanism of action that eludes complete explication after more than 50 years of clinical use and study. The exploration of the mechanism of action of lithium is tied to the understanding of the physiology of mood disorders. In the classic model of psychopharmacology, xenobiotics exert their effects through interaction with monoamine neurotransmission, primarily dopamine, norepinephrine, and serotonin, in addition to their secondary signaling systems, primarily G protein-coupled receptors.<sup>28</sup> Clinically, the therapeutic effects of lithium and similar mood-stabilizing pharmaceuticals become evident only after chronic administration, so their mechanism of action is unlikely solely the result of acute biochemical interactions.

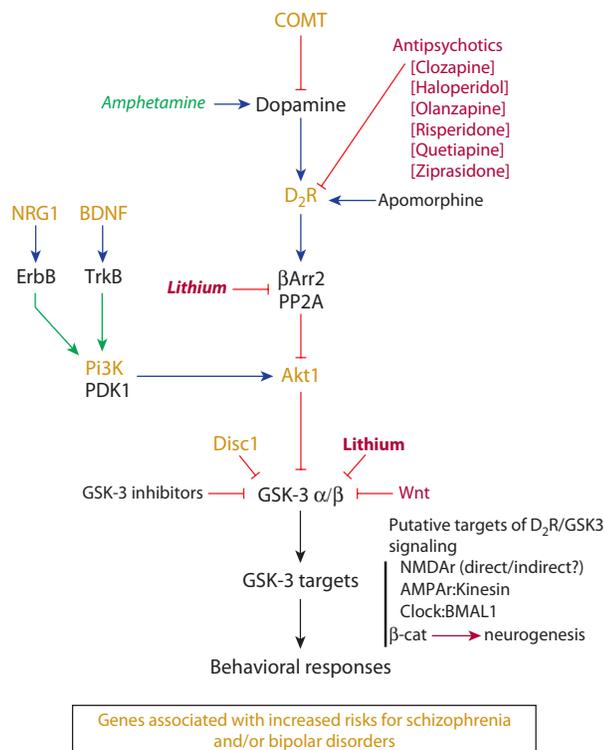

One of the central processes involved in the pathogenesis of mood disorders and schizophrenia, as well as the therapeutic effects of lithium, is interaction with the  $\beta$  form of the multifunctional enzyme glycogen synthase kinase 3 (GSK-3 $\beta$ ). Glycogen synthase kinase 3 is a serine/threonine kinase at the nexus of multiple signaling pathways. It is the central kinase involved in both neuronal cell survival (through interaction with Akt, a GSK-3 $\beta$ -modifying enzyme) as well as neurogenesis (through interaction with Wnt/ $\beta$ -catenin),<sup>161</sup> in addition to a number of significant processes, including gene transcription, neuronal function, synaptic plasticity, and the circadian cycle, as well as cellular structure, apoptosis, and cell death.<sup>30,52,120,132</sup> In fact, GSK-3 $\beta$  phosphorylates more than 100 substrates, with a suggestion of many more.<sup>30,52,187</sup>

Postmortem tissue from the ventral prefrontal cortex of patients with major depressive disorder showed elevated GSK-3 $\beta$  activity as well as decreased activity in Akt.<sup>121,122</sup> Glycogen synthase kinase 3 is inadequately inhibited in association with mood disorders and is inhibited in humans treated with lithium.<sup>120</sup> Overactivity of GSK-3 $\beta$  is associated with neuronal degeneration and sensitivity to apoptotic stimulation. Dysregulation of GSK-3 $\beta$  is implicated in tumor growth and the neurofibrillary tangles of Alzheimer disease.<sup>65,235</sup> It also is a key regulator of neuronal cell fate, with a proapoptotic effect in many settings.<sup>4,24,26,29,120,144,159,194</sup> It is involved in regulating the activity of Wnt/ $\beta$ -catenin, Jun, and cyclic adenosine monophosphate (cAMP) response element-binding protein (CREB), transcription factors important in embryonic patterning, cell proliferation, neuronal modeling and plasticity, neuronal signal transduction, memory consolidation, and cytoskeletal remodeling. Its other targets include transcription factors such as c-Jun, nuclear factor activated T cells, proteins bound to microtubules (Tau, microtubule-associated protein 1B, kinesin light chain), cell cycle mediators (cyclin D), and metabolic regulators (glycogen synthase, pyruvate dehydrogenase).<sup>161,185,187,197,224</sup> Hypoxia contributes to increased GSK-3 $\beta$  activity, which is counteracted or inhibited with mood-stabilizing drugs. Vascular depression, or depression after stroke, is an organic model of major depression.<sup>113,162</sup> The finding that this form of depression responds similarly to intervention with mood stabilizers lends further support to the GSK-3 $\beta$  hypothesis.<sup>82,94,109,182,234</sup>

Many older generation antipsychotics are known to affect GSK-3 $\beta$  signaling in mice.<sup>145</sup> Glucocorticoid synthase kinase (GSK-3 $\beta$ ) activity is regulated not only by first- and second-generation antipsychotics but also through serotonin (5-hydroxytryptamine or 5-HT) neurotransmission and activation of 5-HT<sub>2A</sub> receptors as well as through monoamine-affecting antidepressants that modify these neurotransmitters.<sup>23,24,26,27,29,31,143</sup> Atypical antipsychotics and antagonists of D<sub>2</sub> dopamine receptors, as well as antagonism of 5-HT<sub>2A</sub> serotonin receptors, exert some of their utility through inhibition of GSK-3 $\beta$  activity.<sup>29,30</sup> Lithium modulates dopamine neurotransmission both pre- and postsynaptically, reducing the functional output of the mesolimbic system. Abnormal functioning of this pathway results in mania in animal models.<sup>28,49</sup>

The link between neuropsychiatric illness and these centrally placed mediators of signaling comes from exploration of dopamine neurotransmission (Fig. 70–1). Scaffolding proteins, the  $\beta$ -arrestins, are traditionally associated with the termination of G protein-coupled receptor (GPCR) signaling and desensitization. After a receptor is stimulated, GPCRs are phosphorylated, leading to the  $\beta$ -arrestin recruitment that uncouples the receptor from the G protein and leads to GPCR internalization.  $\beta$ -Arrestins also act as scaffolds for the formation of a protein complex that allows for GPCRs to signal independently from G proteins.<sup>24,26,28,29,49</sup> Dopaminergic neurotransmission through GPCRs is mediated through a complex that involves Akt,  $\beta$ -arrestin2 ( $\beta$ Arr2) and protein phosphatase 2A (PP2A). Akt is a serine/threonine kinase that is additionally regulated through phosphatidylinositol-mediated signaling.<sup>30</sup> Akt activity results from an equilibrium between phosphorylation (activation) and dephosphorylation (inactivation).<sup>27</sup> Regulation of GSK-3 $\beta$  activity is achieved through phosphorylation of its *N*-terminal serine residue, leading to inhibition.<sup>144</sup> The Akt- $\beta$ Arr2-PP2A complex, when activated, dephosphorylates (deactivates) Akt, which leads to the activation of GSK-3 $\beta$  through loss of inhibition (loss of phosphorylation).<sup>25,27,30,67,82</sup>

Lithium is a direct inhibitor of GSK-3 $\beta$  that can also inhibit its activity indirectly through a mechanism involving Akt activation.<sup>26,27,54,120</sup> Lithium activates Akt by disrupting assembly of the Akt- $\beta$ Arr2-PP2A complex through displacement of the magnesium cofactor required for assembly.<sup>23,26,27,224</sup>

**FIGURE 70-1.** Regulation of GSK-3 (glycogen synthase kinase 3) and Akt (GSK-3 $\beta$ -modifying enzyme) signaling by psychoactive drugs and related network of gene products associated with mental disorders. Proteins labeled in orange are the product of genes associated with an increased risk of developing schizophrenia or bipolar disorders. Blue arrows indicate activation, and the red T arrows indicate inhibition. Black arrows indicate actions that can either activate or inhibit the function of specific substrates. Behavioral changes in dopaminergic responses have been reported in Akt1 and  $\beta$ -arrestin 2 knock out mice and in GSK-3 $\beta$ -HET mice. Growth factors, including neurotrophins, activate Akt, which phosphorylates, and inhibits GSK-3, allowing activation of downstream effectors to promote cell survival. Wnt (wingless-related integration site) inhibits GSK-3, stabilizing  $\beta$ -catenin, which activates Wnt target genes, and promotes neurogenesis.<sup>224</sup>  $\beta$ -cat =  $\beta$ -catenin; COMT = catechol-*O*-methyltransferase; D<sub>2</sub>R = D<sub>2</sub> dopamine receptor; Disc1 = disrupted-in-schizophrenia 1; NRG1 = neuregulin 1; PDK1 = phosphatidylinositol-dependent kinase 1; Pi3K = phosphatidylinositol 3-kinase. (Reproduced with permission from Beaulieu JM, Gainetdinov RR. *The physiology, signaling, and pharmacology of dopamine receptors. Pharmacol Rev.* 2011 Mar;63(1):182-217.)

Through disruption of this complex, which normally inactivates Akt, lithium promotes Akt activation, leading to increased phosphorylation and subsequent inactivation of GSK-3 $\beta$ . This is demonstrated in  $\beta$ -arrestin knockout mice, which, unable to create this complex, are resistant to the behavioral effects of lithium.<sup>27,30,82,120</sup> Thus, lithium demonstrates both direct and indirect mechanisms of GSK-3 $\beta$  inhibition.

Identification of the Akt- $\beta$ Arr2-PP2A signaling complex as a target of lithium lends credence to the use of lithium as an adjunct to enhance the action of atypical antipsychotics and antidepressants in poorly responsive subjects by acting through Akt-GSK-3 $\beta$  signaling.<sup>26,27,120</sup>

Inhibition of GSK-3 $\beta$  by lithium is thought to be neuroprotective by modifying the downstream targets and effectors of GSK-3 $\beta$  activity.<sup>4,23,27,82,109,182,196</sup> Lithium is implicated in the neuroprotective modulation of the bcl-2 gene, which is known for its role in preventing apoptosis and in downregulation of the proapoptotic protein p53. Lithium increases bcl-2 concentrations in cultured nervous tissue of both rats and humans.<sup>55,157</sup> Additional support comes from patients undergoing long-term therapy with either lithium or valproic acid (VPA) whose prefrontal cortex volumes are significantly greater than in untreated patients, suggesting a protective effect in humans.<sup>53,196</sup> Further evidence points toward a neuroprotective and neurotrophic effect of lithium with

evidence to support benefit in such diverse neurodegenerative conditions as Parkinson disease (in a mice model of Parkinson disease using *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine {MPTP}),<sup>239</sup> Huntington disease,<sup>152,202</sup> amyotrophic lateral sclerosis (ALS),<sup>79</sup> stroke and multiple sclerosis,<sup>23,53</sup> traumatic brain injury,<sup>139,240,241</sup> and Alzheimer disease.<sup>4,20,29,30,47,159,166</sup>

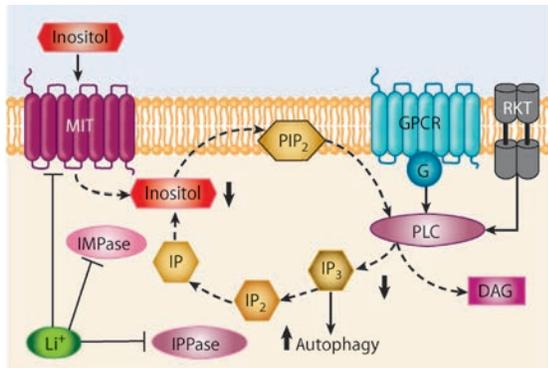

The interplay among lithium, GSK-3 $\beta$ , and the Akt pathway and all of its downstream targets is one major link between mood disorder and the effects of lithium. The other is the interaction between lithium and the Wnt pathway, also mediated through the interaction of lithium and GSK-3 $\beta$  (Fig. 70-1). Glucocyan synthase kinase (GSK-3 $\beta$ ) constitutively antagonizes Wnt signaling and must be inhibited for the pathway to function. Wnt modulates transcription through  $\beta$ -catenin signaling in the nucleus.  $\beta$ -Catenin is involved in a cycle of synthesis and destruction mediated through the  $\beta$ -catenin destruction complex, composed of scaffolding proteins, including axin and tumor suppressor adenomatous polyposis coli (APC). Wnt inhibits GSK-3 $\beta$ , stabilizing and promoting  $\beta$ -catenin signaling. Lithium, through its effects on GSK-3 $\beta$  does the same, enhancing cell survival. Wnt signaling removes APC from the complex and relocalizes the other components to the plasma membrane, leading to stabilization of  $\beta$ -catenin, allowing it to enter the nucleus and modulate transcription.<sup>197,224</sup>

It is unlikely that lithium has a single mechanism of action. Other mechanisms, such as the inhibition of inositol monophosphatases, contribute to its pleiotropic effects on behavior. Evidence has bridged the current molecular targets and downstream regulators of the effects of lithium with the classic proposed mechanism of action, the inositol-depletion hypothesis, one of the first proposed mechanisms of action of lithium.<sup>109</sup> Inositol is a six-carbon sugar that forms the backbone of a number of cellular signaling mechanisms. Lithium treatment results in a decreased myo-inositol (the most biologically active stereoisomer of inositol) concentration in the cerebral cortex.<sup>36,109,159</sup> Abnormalities in regional brain myo-inositol concentrations are found in patients with bipolar disorder. This theory is partially supported by experimental magnetic resonance spectroscopy data.<sup>213,238</sup> Myo-inositol is phosphorylated to form phosphatidyl inositol (PIP), which is further phosphorylated and combined with diacylglycerol (DAG) to form phosphatidyl 4,5-bisphosphate (PIP-2). Upon stimulation of a cell, GPCRs activate phospholipase C (PLC), which hydrolyzes PIP-2 to release the secondary messengers DAG and inositol 1,4,5-trisphosphate (IP3).<sup>37,108</sup> Each of these secondary messengers in turn initiates a cascade of events, including activation of protein kinase C, which is important for calcium homeostasis and neurotransmitter release,<sup>159,213</sup> as well as independent mobilization and regulation of intracellular calcium.<sup>181,196,213</sup> Many extracellular signals, including some serotonin receptor subtypes, neurotrophin signaling pathways, receptor tyrosine kinase pathways, and G protein-mediated signaling, activate PLC to exert their actions.<sup>96,186,187</sup>

Serial dephosphorylation of IP3 leads to regeneration of myo-inositol and recycling of the inositol pool. Two enzymes involved in this pathway are inhibited by lithium. The first enzyme, inositol 1,4-bisphosphate 1-phosphatase (IPPase), dephosphorylates the bisphosphate to inositol monophosphate (IMP). The second enzyme, inositol 1-monophosphatase (IMPase), dephosphorylates IMP to myo-inositol<sup>4</sup> (Fig. 70-2).

Lithium inhibits IMPase in an uncompetitive fashion by binding to the enzyme-substrate complex and preventing the release of phosphate. It performs this function by displacing a magnesium ion from the active site after hydrolysis similar to its effects on GSK-3 $\beta$ .<sup>54</sup> Uncompetitive inhibitors only bind to the enzyme-substrate complex, inhibiting the reaction at that point; the higher the concentration of the substrate, the more the enzyme is inhibited.<sup>82,102,154</sup> Uncompetitive inhibitor kinetics are related proportionally to the concentration of the enzyme-substrate complex and cannot be overcome by increasing the concentration of the substrate, unlike a competitive inhibitor.<sup>82,102,154</sup> The nature of the action of lithium serves as a regulator to preferentially block pathologic signaling caused by excessive myo-inositol while leaving the normal signaling intact. As described, IMPase is an important step in the cellular recycling of the inositol pool and is inhibited by lithium.

Myo-inositol is also generated de novo from glucose-6-phosphate by inositol synthase, which forms IMP. The inhibition of IMPase by lithium

**FIGURE 70-2.** The actions of lithium on inositol depletion and autophagy induction. Extracellular signal binding to its cell surface receptor, either G protein-coupled receptor (GPCR) or RTK, activates phospholipase C (PLC), which hydrolyzes the phospholipid phosphatidyl bisphosphate ( $\text{PIP}_2$ ) to yield second messengers inositol triphosphate ( $\text{IP}_3$ ) and diacylglycerol (DAG). Inositol triphosphate is recycled by enzymes inositol bisphosphate phosphatase (IPPase) and inositol monophosphatase (IMPase) and converted to inositol (mainly myo-inositol), which is required for  $\text{PIP}_2$  resynthesis. Lithium decreases intracellular inositol concentrations by directly inhibiting IPPase, IMPase, and myo-inositol transporter (MIT) that uptakes extracellular inositol. Decreased intracellular inositol concentrations are expected to subsequently reduce  $\text{PIP}_2$  and prevent the formation of  $\text{IP}_3$  and DAG, thus blocking transmembrane signaling and triggering the induction of autophagy. Lines with solid arrows represent stimulatory connections; lines with flattened ends represent inhibitory connections. Dashed lines represent pathways with reduced activity as a result of lithium treatment. IP = inositol monophosphate;  $\text{IP}_2$  = inositol bisphosphate. (Reproduced with permission from Chiu CT, Chuang DM. Molecular actions and therapeutic potential of lithium in preclinical and clinical studies of CNS disorders. *Pharmacol Ther.* 2010 Nov;128(2):281-304.)

subsequently leads to myo-inositol depletion by preventing the conversion of the newly synthesized IMP to myo-inositol. Valproic acid also inhibits inositol synthase, illustrating a potential mechanism for the synergy of these complementary mood stabilizers.<sup>71,141</sup> A third mechanism of intracellular diminution of inositol by lithium (as well as VPA and carbamazepine) is by reducing the activity and transcription of the sodium myo-inositol transporter, preventing the uptake of exogenous myo-inositol by the cell.<sup>109</sup>

The result of these effects is depletion of the inositol pool available to the cell, causing a series of events at different points in the signal transduction cascade that leads to differential gene transcription and expression. This sequence ultimately is responsible for some of the observed clinical effects of lithium on the central nervous system (CNS).<sup>209</sup> Experimental data using dextroamphetamine as a model for clinical mania demonstrate increased regional inositol signaling in the human brain that is attenuated by pretreatment with lithium, lending support to the hypothesis.<sup>34,95</sup>

The inositol depletion hypothesis, an original attempt to explain in molecular terms the therapeutic effects of lithium, does not fully elucidate nor replicate clinical disease or response to therapy. In vivo studies with more drastic inositol depletion than that which occurs from lithium therapy fail to replicate predicted behavioral patterns. Studies in knockout mice lacking various isoforms of inositol monophosphatase fail to replicate the antidepressant or antimanic effects of lithium. However, the model remains attractive, and the flaws may represent species variation with validity more in humans with bipolar disorder than the mouse model illustrates.<sup>23,159,209</sup> There is a synergy with the other proposed mechanisms of the effects of lithium. In a yeast model, GSK-3 $\beta$  is required for de novo inositol synthesis, and the loss of GSK-3 $\beta$  activity leads to inositol depletion. This finding links two of the targets of not only lithium but other mood stabilizers as well.<sup>11,64</sup>
