## INTERNAL CONCEALMENT OF XENOBIOTICS

Jane M. Prosser

Internal concealment of illicit xenobiotics is a significant concern for local and international police efforts as well as medical and public health practitioners. There are two distinct categories of concealment colloquially known as “body stuffers” and “body packers.” The term *body stuffer* refers to individuals who hide xenobiotics in a body cavity or ingest them in an attempt to avoid discovery. The xenobiotics are concealed in an unplanned manner and are often poorly wrapped. The term *body packer* refers to individuals who conceal xenobiotics, typically in large quantities, in a premeditated fashion almost exclusively for the purposes of international smuggling.

**BODY PACKERS**

Internal concealment of xenobiotics for the purpose of smuggling was first reported in Canada in 1973. A 21-year-old man presented with a small bowel obstruction as a result of swallowing a condom filled with hashish. He had swallowed the condom to transport it into Canada after a trip to Lebanon.<sup>21</sup> Internal xenobiotic smuggling subsequently became a worldwide problem as increased surveillance at international borders made conventional transportation of illegal xenobiotics more difficult. Improved detection of smugglers also increased the number of patients brought to the attention of health care providers. Unfortunately, in attempts to evade enhanced detection, pregnant women and children as young as 6 years of age have been used as body packers.<sup>7,13,16</sup>

Airline and airport personnel are trained to identify people who may be body packers. Suspicious behavior includes not eating or drinking on the airplane, abnormal behavior while going through customs, and overt signs of xenobiotic toxicity.<sup>82,94</sup>

**Composition of Packages**

Body packers typically swallow large numbers of well-prepared packages, each filled with substantial amounts of xenobiotic. Although ingestion is common, packets are also sometimes concealed by insertion into the vagina and rectum.<sup>22,99</sup> The most frequently smuggled cargo is either heroin or cocaine, but other xenobiotics are also reported (Table SC5-1). Body packers often swallow 50 to 100 packages, and ingestion of as many as 500 is reported.<sup>100</sup> Each package typically contains from 0.5 to 10 g of xenobiotic. Therefore, one person may carry as much as 1.5 kg of xenobiotic.<sup>89</sup> Lethal doses of cocaine and heroin are not well characterized. For reference, death from cocaine toxicity is reported after ingestion of as little as 2 to 3 g,<sup>77</sup> and the lethal dose of oral heroin in an opioid-naïve person is above 300 mg.<sup>30</sup> As such, each packet should be considered to contain a potentially lethal dose.

**TABLE SC5-1** Xenobiotics Associated With Internal Concealment

Cannabis <sup>58,89</sup>
Cocaine powder and liquid <sup>20,78</sup>
Crack cocaine <sup>78</sup>
Hashish and hashish oil <sup>72</sup>
Heroin <sup>31,49</sup>
Methamphetamine <sup>40,58</sup>
Methylenedioxymethamphetamine (ecstasy) <sup>92</sup>
Prescription drugs <sup>79</sup>
Oxycodone <sup>7</sup>

A number of materials have been used for xenobiotic packaging. Some, such as latex, are used as wrappers. Others such as carbon paper and aluminum foil are used to change the radiodensity and decrease the likelihood of detection with diagnostic and forensic imaging studies. Packages have been made using plastic bags, plastic wrap, condoms, finger cots, balloons, cellophane, wax, tape, rubber gloves, surgical ligatures, paraffin, and fiberglass.<sup>11,32,39,62,73</sup>

Initial reports suggested a high rate of complications caused by packaging failure.<sup>62</sup> However, advances in the technology of packet construction have decreased rates of rupture.<sup>73</sup> A typical packet in current use is composed of a core of compacted xenobiotic covered by several layers of latex and encased in an outer wax coating.<sup>94</sup> More recently, the transport of xenobiotic in liquid form was reported.<sup>10,68</sup>

Important historical details include the number and contents of packets, the type of wrapping, the time of ingestion, and any associated symptoms. Body packers, as well as those financing and receiving the packages, generally know exactly how many packets are being carried. However, the individual are often reluctant to give an accurate clinical history to the health care provider or legal authorities.

**Bioavailability**

The oral bioavailability of cocaine hydrochloride is approximately 30% to 40%, which is similar to intranasal administration.<sup>26,104</sup> Rectal and vaginal bioavailability of cocaine hydrochloride and the oral, rectal, and vaginal bioavailability of crack cocaine have not been studied.

Oral exposure to heroin results in rapid first-pass metabolism to morphine<sup>34</sup> and can be considered a morphine prodrug.<sup>26,46</sup> The peak concentrations after 10 mg of oral heroin are similar to those expected from 10 mg of oral morphine.<sup>7</sup> The rectal bioavailability of morphine has a 1:1 ratio with oral administration. Although heroin is rectally bioavailable,<sup>81</sup> one study examining the bioavailability after rectal suppository administration in two opioid-dependent patients found it to be approximately 50% less than the oral bioavailability.<sup>36</sup>

**Clinical Manifestations**

Body packers undergoing medical examination may be asymptomatic, may have classic cocaine or opioid toxidromes, may have a mixed presentation, or may present with life-threatening manifestations of xenobiotic toxicity or mechanical bowel obstruction or perforation. Physical examination should be thorough, with a focus on findings related to these clinical manifestations (Chaps. 36 and 75).

When packets are too large to pass or malaligned, obstruction occurs at any point in the gastrointestinal (GI) tract. Individuals carrying packets containing opioids appear to be at higher risk of GI obstruction, even with intact packets.<sup>33</sup> The reason for this is unclear, but it may be related to microperforation of the package or contamination of the outside of the package during manufacture, resulting in opioid-induced GI stasis. Patients with a history of abdominal surgery also appear to be at increased risk of obstruction.<sup>19,44</sup> GI perforation and peritonitis can result if the obstruction is untreated.<sup>19</sup> Dysphagia,<sup>14</sup> esophageal perforation and mediastinitis,<sup>44,47</sup> gastric ulcers,<sup>66</sup> gastric hemorrhage,<sup>23,44</sup> esophageal obstruction,<sup>52</sup> hematochezia,<sup>96</sup> incarcerated hernias,<sup>90</sup> uterine ischemia,<sup>14</sup> and septic shock<sup>33</sup> have resulted after packet rupture.

### Laboratory Evaluation

Drug screening results are difficult to interpret. Although generally, a positive result should raise concern for a ruptured packet, positive results may also be due to external contamination of the packet during preparation from a microperforation or from prior xenobiotic utilization. Thus, some patients with packets that appear externally intact will have a positive urine drug screen.<sup>33,63</sup> The rate of positive screens in asymptomatic patients is reported to be as great as 52% to 72%.<sup>20,23</sup> Screening typically correlates closely with the drug carried,<sup>32</sup> but it is potentially misleading in that some patients transporting any xenobiotic will ingest opioids for the purpose of slowing GI transit time.<sup>69</sup> Additionally, some patients carry a combination of xenobiotics, known as “double breasting.”<sup>33</sup>

A subsequent urine drug screen is particularly useful in the setting of a patient with an initially negative screening result. An initially negative result that later becomes positive suggests a ruptured packet and is an indication for very close monitoring or surgical removal. This is of particular concern in the setting of a cocaine body packer when a change from a negative to a positive screening result might indicate the potential for a precipitous decline.

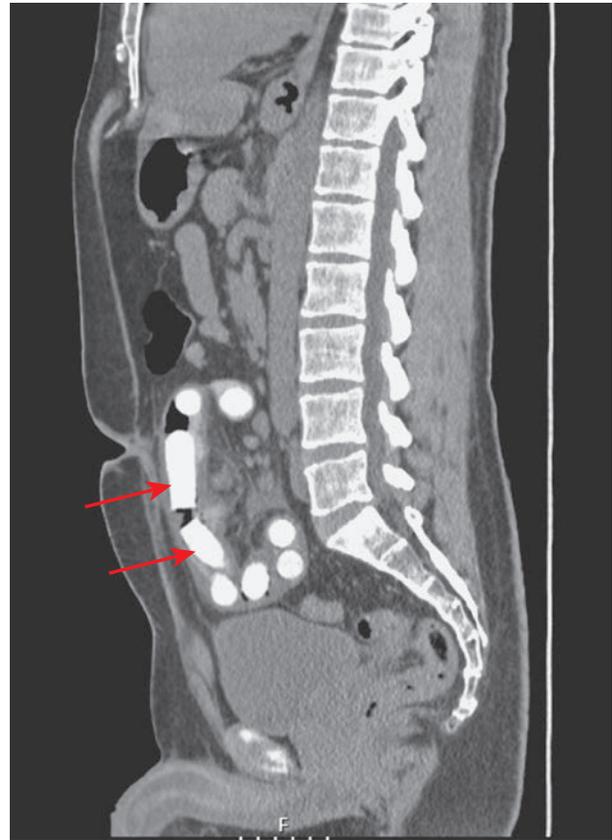

### Radiographic Evaluation

All suspected body packers should undergo radiographic evaluation. Abdominal radiographs have a detection sensitivity of 75% to 95%, but this success in recognition varies based on the number of packets and their methodology of construction.<sup>11,61,98</sup> Packets can be visualized as multiple radiodense foreign bodies (Fig. 8–8). The “double-condom sign” is a lucent ring surrounding the packet and results from air trapped between layered wrappings.<sup>74</sup> The “rosettelike” sign results from the air trapped in the knot when the condom or balloon is tied.<sup>87</sup> Caution must be used when interpreting plain radiographic studies. In one series, 19% of patients had false-negative radiographs, with one patient subsequently passing 135 packets.<sup>62</sup> False-positive results are also reported because of constipation,<sup>51</sup> intraabdominal calcifications,<sup>95</sup> and bladder stones.<sup>105</sup> Oral contrast administration is suggested by some to increase the sensitivity of plain radiography.<sup>31,43,60</sup>

Computed tomography (CT) scanning has a higher sensitivity than plain radiography,<sup>38,54,85</sup> with sensitivities reported to range from 96% to 100% (Figs. SC5–1 and SC5–2).<sup>1,29,107</sup> Although abdominal radiography is frequently used in airports as an initial screening test, CT is preferred in the hospital given this higher sensitivity. Noncontrast CT is the preferred modality because contrast may obscure packets.<sup>75</sup> Although likely to identify patients with multiple packets, a false-negative contrast CT scan after whole-bowel irrigation (WBI) was reported in a body packer who subsequently passed a single packet per rectum.<sup>37</sup> Retrospective review of the CT could not identify the packet. Recent studies suggest that even low-dose CT scans are quite accurate.<sup>83</sup> One study found a difference in Hounsfield units (HU) between packets containing cocaine (–219 HU) and heroin (–520 HU), suggesting that CT scanning can also potentially distinguish among package contents. However, other authors report a lack of utility of this measurement because of variations in drug formulation, compression, and packing materials.<sup>56,102</sup> Smaller slice size may aid in detection of smaller packets and use of lung windows in addition to traditional abdominal windows may also improve detection rates.<sup>5,6</sup> Ingestion of liquid cocaine can result in “jigsaw” pattern describing the interface of gas between packets visualized on CT scan.<sup>68</sup>

Ultrasonography may be another useful screening tool to reduce radiation exposure, particularly for evaluation of women of childbearing age. However, its utility has only been evaluated in a few small case series.<sup>12,42,64</sup> In one series of patients arrested on suspicion of body packing at an international airport, ultrasound examination correctly identified 40 of 42 body packers with positive plain radiographs. The two false-negative results occurred when packets were located low in the rectum.<sup>67</sup> Although potentially useful as a screening tool, particularly for patients in whom CT has increased risk, such as pregnant patients, it cannot definitively exclude packets.

Magnetic resonance imaging (MRI) is used less commonly than CT. However, MRI is able to detect the presence of packets, although it is less reliable in determining the number of packets.<sup>41</sup> Magnetic resonance imaging

**FIGURE SC5–1.** Computed tomography (sagittal view) of the abdomen showing packets in the intestine. (Used with permission from *The Fellowship in Medical Toxicology*, New York University School of Medicine, New York City Poison Center.)

**FIGURE SC5–2.** Computed tomography (coronal view) of the abdomen showing packets associated with free air (lower two arrows) caused by bowel perforation. (Used with permission from *The Fellowship in Medical Toxicology*, New York University School of Medicine, New York City Poison Center.)

may be useful for diagnosis in cases when there is concern about radiation exposure.<sup>6</sup> Pregnant women have been used as body packers because of hesitation from customs officials and health care providers to obtain radiographs. However, the average radiation dose of 100 millirads from an abdominal radiograph is much less than the threshold thought to induce fetal malformations. Abdominal radiography, ultrasonography, and MRI may be useful screening tools in pregnant women who are suspected body packers because none presents significant risk to fetuses. When considering CT, as in any situation, practitioners must ensure that patient's health and safety are the foremost concerns, and in each case, the risk of exposure to radiation must be weighed against the risks of undiagnosed internal concealment of xenobiotics.

## Management

All patients suspected of internal concealment of drugs should be closely monitored during evaluation. This should include blood pressure, heart rate, pulse oximetry, and continuous carbon dioxide monitoring, as well as direct visualization of the patient.

Gastrointestinal decontamination is a vital element in the management of body packers. Initially, surgical intervention was thought to be necessary in all body packers secondary to perceived high rates of toxicity and death.<sup>28,89</sup> The incidence of life-threatening complications has decreased due in part to both better packaging<sup>62,73</sup> and to increased rates of detection of asymptomatic carriers. Currently, a more conservative nonsurgical approach is suggested for asymptomatic patients<sup>94</sup> and is supported by a several large series (Fig. SC5-3).<sup>3,4,9,11,20,62,82,98,100</sup>

Treatment with activated charcoal (AC) is frequently suggested based on the fact that cocaine and heroin are both well adsorbed to AC.<sup>59</sup> However, there are no data showing actual benefit. Furthermore, AC may be detrimental if contamination of the peritoneal cavity occurs after GI rupture or during surgery or if it obscures visualization should endoscopy become indicated. Therefore, the risks and benefits must be weighed in each patient. Activated charcoal is of questionable value for cocaine packers given the higher risk of the need for surgical intervention. Also, it is not likely to improve the

outcome of symptomatic heroin body packers because these patients can be successfully managed with opioid antagonists and mechanical ventilation. Despite these risks and given the potential benefit of AC, we feel the use of AC is reasonable.

The utility of WBI to enhance elimination is generally accepted but has not been rigorously evaluated. There is a theoretical concern that polyethylene glycol could increase the water solubility of heroin should rupture occur<sup>98</sup> and that it may decrease the adsorption of cocaine to AC should AC be given.<sup>59</sup> Given the lack of in vitro data to support these risks<sup>25</sup> and its generally accepted benefit, WBI is recommended to decrease intestinal transit time (Antidotes in Depth: A2). We recommend not to perform orogastric lavage because packets are too large to fit through holes in the lavage tube.

Cathartics are sometimes recommended for GI decontamination. Although oil-based cathartics were frequently used in the past,<sup>11,61</sup> a non-oil-based medication such as magnesium citrate is preferred. Paraffin oil may dissolve some packet wrappers, potentially resulting in drug toxicity.<sup>101</sup> Use of promotility xenobiotics, such as metoclopramide and erythromycin, is reported,<sup>97</sup> but these are unlikely to add significantly to the use of WBI. Enemas and manual disimpaction should be avoided or used with great caution because packet rupture may occur.<sup>48,55</sup>

Treatment of symptomatic patients depends on the nature of the xenobiotic ingested. Patients manifesting opioid toxicity should be treated with the opioid antagonist naloxone by intravenous bolus and infusion and mechanical ventilation if necessary. Opioid antagonists also improve GI motility (Antidotes in Depth: A4). Surgical decontamination is generally not indicated for opioid poisoning because optimal medical therapy should be adequate.

Rupture of a cocaine packet, however, is a life-threatening emergency that requires aggressive medical and surgical therapy (Chap. 75). Benzodiazepines or other sedative-hypnotics such as propofol are recommended as temporizing measures, but surgical intervention for packet removal should be performed emergently in body packers with *any* sign of cocaine or amphetamine toxicity. Indications for surgery include, but are not limited to only hypertension, tachycardia, agitation or other alteration in mental status, myocardial ischemia, bowel ischemia, seizures, respiratory distress but also to the transition of a urine drug screen result from negative to positive.

Surgical removal of the packets is also the therapy of choice in the case of mechanical obstruction from any xenobiotic-containing packet.<sup>39,71,86</sup> Surgical removal may not be definitive; in one series, 6 of 70 patients were found to have retained packets postoperatively.<sup>19</sup> Also, emergent surgical removal is associated with a high rate of postoperative infection and fascial dehiscence for reasons that are not well understood.<sup>18,19,86</sup> Endoscopy<sup>80,83,98</sup> and proctoscopy<sup>35</sup> have been used successfully for removal of packets. However, caution must be used because attempted endoscopic removal can cause packet rupture and resultant toxicity.<sup>89</sup> Endoscopic removal should be reserved for cases in which a few packets are retained after failure of conservative management.

It is essential to ensure the passage of all packets before discharging a patient from medical care. Packets are reported to remain even in patients with clear rectal effluent after WBI.<sup>43</sup> After negative abdominal radiographs are obtained, a confirmatory study should be done using CT. However, these modalities do not have 100% sensitivity, and retained packets may be present.<sup>37</sup> It is therefore recommended that patients be observed for 24 hours after the passage of three packet-free stools<sup>11</sup> and negative confirmatory CT. Complete GI decontamination must be ensured before releasing the patient from close medical observation.

## BODY STUFFERS

Body stuffers usually present for health care when they are taken into custody by law enforcement officers. Typically, the person has hastily ingested the xenobiotic or inserted it into the rectum or vagina to hide the evidence from the police. Because the person was not planning to conceal the xenobiotic, the xenobiotic is likely unwrapped, as in the case

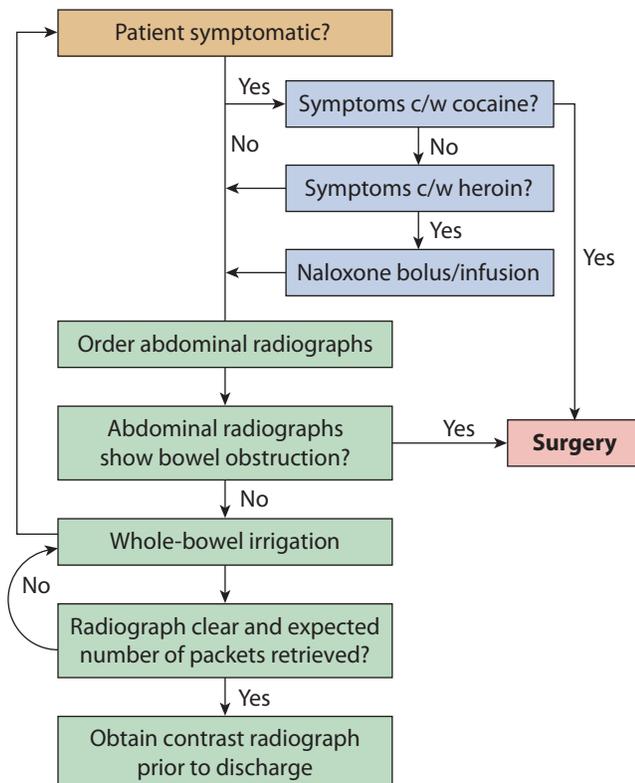

FIGURE SC5-3. Algorithm for managing cocaine or heroin body packers.

of crack cocaine “rocks,”<sup>65</sup> or poorly wrapped in materials intended for distribution.

Pertinent historical information includes time of ingestion, xenobiotic, amount ingested, packaging, and symptoms consistent with xenobiotic ingestion. Unfortunately, an accurate history is often difficult to obtain. Patients who are recent arrestees are prone to anticipate a secondary gain of delay to incarceration by reporting the ingestion of drugs; alternatively, some individuals deny ingestion to avoid prosecution. Complicating the clinical picture is the possibility that law enforcement officers may assume internal concealment of illicit substances when they are unable to find a substance after the arrest.

### Composition of Packages

Because xenobiotics are typically transported locally in plastic bags, condoms,<sup>88</sup> balloons,<sup>15</sup> glassine envelopes, aluminum foil,<sup>79</sup> or crack vials,<sup>43</sup> these are the most frequently reported wrappers. Reported amounts vary from one dose to up to 30 packages of unspecified dose.<sup>49</sup> Cocaine, either in crack rocks or the hydrochloride salt form, are most commonly ingested,<sup>78</sup> but other xenobiotics are also reported (Table SC5-1). Typically, the xenobiotics are ingested although other routes of exposure include the external auditory canal, rectum, and vagina.<sup>53,57,93</sup>

The importance of obtaining a precise history related to packaging material is highlighted by an *in vitro* study examining the effects of packet construction, medium used for dissolution, and pH on release of cocaine from drug packets. Cocaine was released almost immediately from paper packaging and least readily from condoms. Cellophane packing led to intermediate concentrations compared with paper and condom wrappers. When packets were double or triple wrapped in cellophane, decreased concentrations were noted. All packets released more xenobiotic in an acidic medium.<sup>2</sup>

### Clinical Manifestations

After oral ingestion of drug packets or crack rocks, toxicity is most frequently absent or mild.<sup>49,50</sup> However, although most case series report low rates of complications, both significant toxicity and death occur.<sup>27,45,50,69</sup> The time of onset of clinical effects in body stuffers is typically within several hours.<sup>1,49,50</sup> After the ingestion of cocaine in crack vials, the onset of toxicity was delayed by 3 to 4 hours.<sup>43</sup>

Most body stuffers reported in the literature had symptom onset within 6 hours of ingestion. Initial effects can occur 6 hours after ingestion; however, in nearly all reported cases, these patients displayed some manifestations at the time of initial medical contact. Two exceptions are noted in the literature. A 50-year-old woman reported ingesting xenobiotics at the time of incarceration. Seven hours later, a prison physician noted normal pulse and mental status, and she was placed in her cell to be observed by staff members every half hour. Prison staff documentation noted that she was “correct” and sat up 30 minutes before being found dead in the cell 11 hours after the time of ingestion. Postmortem examination revealed an open cocaine packet in the intestine.<sup>70</sup> A patient who placed methamphetamine in a plastic bag with a small hole in an attempt to create a sustained-release mechanism presented for abdominal pain 10 hours later. This patient remained without findings of methamphetamine intoxication until 42 hours after ingestion.<sup>40</sup>

### Laboratory Evaluation

Laboratory xenobiotic testing is difficult to interpret in body stuffers because these patients are often habitual substance users. Thus, a positive drug screen result could be equally indicative of either prior use or current toxicity or both. Likewise, a negative result does not exclude recent ingestion or leaking packages. One study of 50 suspected body stuffers found that urine drug screening correctly classified the presence or absence of packets only 57% of the time.<sup>61</sup> Several authors report toxicity or death occurring in the presence of a negative urine screen result despite symptoms consistent with packet contents.<sup>33,40</sup> One explanation is that patients may die of drug toxicity before substantial urinary excretion occurs.

### Radiographic Evaluation

Although detection of stuffed xenobiotics is possible by diagnostic imaging studies, the sensitivity is very poor.<sup>24,49,61</sup> Plastic bags, crack vials, and staples (enclosing plastic bags) are rarely visualized.<sup>49</sup> In one series of patients with crack vial ingestions, only 2 of 23 of abdominal radiographs were positive<sup>43</sup> in patients who subsequently passed vials. In two other series of cocaine body stuffers, all plain radiographs were negative.<sup>50,88</sup> Computed tomography scanning may identify some packets missed on radiographs, but the sensitivity has not been investigated and missed packets are reported with CT scanners as well.<sup>24</sup> Therefore, imaging is not likely to be clinically useful in these patients.

### Management

Body stuffers who exhibit xenobiotic toxicity should be managed according to standard principles for managing that xenobiotic or suspected xenobiotic (Chaps. 36 and 75).

Patients with GI complaints should be evaluated for ileus or obstruction. Removal of packets has been performed by endoscopy<sup>17,49,76</sup> but is useful only for a small number of packets because each package requires an additional passage of the endoscope. Endoscopy should be used with extreme caution because it may cause packet rupture with subsequent toxicity or aspiration of the packet with airway obstruction.<sup>89</sup> Bronchoscopic removal of pieces of a balloon wrapping in the airway was successful in one patient after attempted orogastric lavage led to balloon aspiration.<sup>15</sup> Use of colonoscopy<sup>82</sup> is also reported but carries a risk of rupture similar to that associated with upper endoscopy. The need for surgical intervention was reported in only one case. This patient presented with a complaint of epigastric pain 3 days after ingesting a large plastic bag filled with 15 to 20 smaller bags of cocaine. He showed no signs of cocaine toxicity but required surgical removal because the bag was still retained in the stomach 4 days postingestion.<sup>24</sup>

Management of asymptomatic body stuffers has not been rigorously evaluated. Treatment with AC and WBI is often advocated for high-risk patients. Although these methods have not been proven to reduce morbidity or mortality, they offer theoretical benefits.<sup>43,49,50,88</sup> Activated charcoal may reduce the absorption of liberated xenobiotic because both heroin and cocaine are well adsorbed to AC. Given this theoretical benefit, a dose of AC is recommended in an awake and cooperative patient. WBI may reduce intestinal transit time, leading to earlier passage of packets. However, it may provide additional solvent and enhance the leakage and absorption of poorly wrapped packets. Therefore, WBI is unlikely to offer any clinical benefits and is not recommended unless life-threatening amounts of xenobiotic (in packages) are ingested.

A therapeutic endpoint has not been established in part because packages are often not recovered from body stuffers. Review of more than 1,000 published cases of body stuffers, involving a variety of packaging methods, reveals only a few cases in which onset of toxicity occurred more than 6 hours after ingestion (when the time of ingestion is reported) and was not present at the time of initial medical evaluation. There are several cases reported when onset of symptoms occurred between 8 and 10 hours postingestion of “crack rocks”; however, in all of these cases (except in the two cases noted earlier), symptoms were present at the time of initial health care contact.<sup>17,76</sup> A methamphetamine body stuffer presented in a delayed manner after ingesting a homemade delayed-release preparation.<sup>103</sup> A retrospective review after cocaine body stuffing supported the safety of a 6-hour observation period, finding that no life-threatening complications occurred in 106 patients.<sup>67</sup> Another case series of patients with reported exposure to heroin, cocaine, and other unknown substances also supported the safety of a 6-hour observation period.<sup>106</sup>

Management strategies should consider the potential dose ingested, time since ingestion, and therapy administered. Because the vast majority of patients remain asymptomatic or develop symptoms shortly after medical contact, it is reasonable to observe asymptomatic patients for 6 hours.

Because rare patients may have more delayed presentations, patients who have ingested large, potentially lethal doses or those who refuse AC should be observed for longer periods of time in a closely monitored setting. Multiple stools devoid of packages or a lack of symptoms after 24 hours are reasonable end points for monitoring these patients.

## LEGAL PRINCIPLES

Because clinical errors have the potential for life-threatening consequences, it is essential to evaluate patients within the context of their unique medical, social, ethical, and legal settings. It is important to remember there may be significant motivation to deny ingestion altogether or conceivably secondary gain from overreporting the dose to delay incarceration. Often, patients refuse medical care either as an assertion of innocence or over concerns that evidence produced might be incriminatory.

In the United States, patients have a legal right to refuse care if they are competent to do so. This includes body stuffers and body packers who are under arrest. Patients with decisional capacity cannot be forced to take AC, WBI, any other form of therapy or diagnostic procedure. In this scenario, lower risk procedures may be acceptable to patients over more definitive tests; for example, a pregnant woman suspected of body packing may be agreeable to ultrasonography over CT scan given its lower risk. If in police custody, however, the individual may be kept in the hospital for an extended observation period. This strategy maintains the patient's medical autonomy and ensures clinical stability. If signs of life-threatening toxicity subsequently develop, the patient will most likely have lost decisional capacity, and therapy and management can proceed as medically necessary.

If a body packer who is not in legal custody presents for medical care, physicians face an ethical dilemma. Calling the authorities is a violation of the patient's right to confidentiality. However, possession of large amounts of drugs may theoretically endanger the hospital staff because criminal elements expect drug delivery. Consultation with hospital legal counsel, risk management, and the ethics committee are recommended in this situation (Chap. 138).

## SUMMARY

- Patients with intestinal concealment of xenobiotic present diagnostic, therapeutic, ethical, and medicolegal challenges.
- History, laboratory, and radiologic studies must be interpreted with caution.
- Conservative management is preferred for asymptomatic body packers with vigilant observation.
- Management strategies should focus on the needs of each individual patient and the xenobiotic ingested.
- A complex patient physician relationship is common and must be effectively transformed into a trusting relationship to ensure reliable and high-quality care.

# PREVENTION, TREATMENT, AND HARM REDUCTION APPROACHES TO OPIOID OVERDOSES

Daniel Schatz and Joshua D. Lee

## INTRODUCTION

Opioid-related deaths rates in the United States continue to rise. A decades-long US prescription drug epidemic persists, driven by high rates of per capita opioid analgesic dispensing, and is now paired with a growing availability of illicit heroin, fentanyl, and fentanyl derivatives. Rates of opioid use disorders, opioid treatment admissions, opioid-related emergency department (ED) and hospital admissions, and overdose mortality have all steadily increased since 1990.<sup>8</sup> In 2012, the Centers for Disease Control and Prevention (CDC) reported that for every unintentional overdose death related to an opioid analgesic, 9 people were admitted for substance abuse treatment, 35 visited EDs, 161 reported drug abuse or dependence, and 461 reported nonmedical uses of opioid analgesics.<sup>10</sup> Recent federal and state reform efforts seek to bolster a public health response to opioid use disorders and overdose deaths.<sup>14,50</sup> The availability and dissemination of core evidence-based interventions that treat and prevent overdose events and fatalities, however, has not kept pace with the number of persons using, suffering harm, and dying from opioids.

Evidence for, and policies supporting core community-based overdose interventions, which are harm reduction education and counseling, and naloxone distribution and administration, are reviewed here. Overdose outcomes associated with opioid use disorder treatment, including opioid use disorder treatments with agonist (methadone, buprenorphine) and antagonist (naltrexone) pharmacotherapies and counseling-only modalities, are addressed. Larger policy efforts and national practice guidelines with important implications for overdose prevention, including state prescription monitoring requirements and recently published CDC guidelines for the use of opioid analgesia for nonmalignant chronic pain are emphasized.

## EPIDEMIOLOGY

### Overdose Rates

Opioid use in the US has grown steadily since the 1990s, largely because of widespread and routine opioid analgesic prescribing. As of 2014, of 47,055 total US unintentional poisoning deaths, 18,893 were attributed to opioid analgesics and 10,574 to heroin.<sup>9</sup> Heroin availability and related problems appear to be accelerating, and heroin “markets” have expanded to all large US metropolitan areas as well as a substantial proportion of rural counties. More recently, novel opioids, such as U-47700 and W-18, and illicit fentanyl analogs, such as carfentanil, have entered street heroin formulations. This appears to drive local micro-epidemics and significant increases in overdose death rates.<sup>13,35</sup>

### Risk Factors

“Opioid overdose” generally refers to oversedation, hypoventilation, and anoxia stemming from an excessive dose of an opioid agonist alone or in combination with other central nervous system depressants. Established risk factors for opioid overdose include:<sup>48,49</sup>

- Persons with opioid dependence, particularly after periods of reduced use, resulting in loss of tolerance (after detoxification, release from incarceration, cessation of recovery treatment)
- People who inject opioids
- People who use prescription opioids, particularly those taking higher doses

- People who use opioids in combination with other sedating xenobiotics
- People who use opioids and have medical conditions such as HIV, liver or lung disease or depression
- Household members, including children, of people in possession of opioids (including prescription opioids)
- People with obstructive sleep apnea

Primary and secondary prevention efforts may target any or all of these risk factors, such as increased access to evidence-based treatments and harm reduction interventions at release from correctional facilities; public and medical practice regulatory reforms designed to lower rates and doses of opioid prescribing for painful conditions; or reducing the coadministration of other substances, particularly benzodiazepines, alcohol, and cocaine.

## NALOXONE AND HARM REDUCTION APPROACHES TO OVERDOSE PREVENTION AND OVERDOSE REVERSAL

Naloxone administration is the principal overdose intervention taught to at-risk opioid users, persons in treatment, and family members, as well as first responders. Naloxone pharmacokinetics and naloxone efficacy for overdose are discussed in Chapter 36, Antidotes in Depth: A4, and Special Considerations: SC5.

### Community-Based Effectiveness

Most opioid overdoses occur in the setting of a bystander and often in a private location.<sup>23,39</sup> Because of the time-dependent nature of the development of hypoxic brain injury as well as the rapidity and effectiveness of naloxone, many educational initiatives aim to reach those most likely to be in first contact with the patient. Education generally consists of overdose prevention; rapid recognition; and appropriate response, including timely administration of naloxone, rescue breathing or cardiopulmonary resuscitation, recovery positioning, and emergency medical services (EMS) activation. Despite variability in education duration (10 minutes to 1 hour) and educator qualifications,<sup>11</sup> the feasibility of naloxone programs was demonstrated in a variety of populations, including laypersons.<sup>24</sup> Although no randomized controlled trial exists, several cohort studies demonstrate effectiveness of community-based opioid overdose programs in the rates of opioid-related deaths. A prospective cohort study in Massachusetts found adjusted opioid overdose death rate ratios of 0.54 and 0.73 for communities with high degrees of opioid overdose program implementation (more than 100 participants per 100,000 population) and low degrees of implementation (1–100 participants per 100,000 population), respectively, compared with communities without any overdose program.<sup>47</sup> A Chicago-based study observed a 10% to 20% reduction in heroin overdose-related deaths after implementation of a naloxone education program.<sup>29</sup> In a meta-analysis, 11 of 18 programs reported 100% survival rates after naloxone administration; the remaining programs showed survival rates varying from 83% to 96%. The reduced survival rates were thought to be due to unknown outcomes, which may have included death, and time to administration of naloxone.<sup>11</sup>

### Controversies Regarding Naloxone

Although naloxone has proven efficacy, both under ideal conditions and in the community, controversy still exists. One common objection to increasing

the supply of naloxone is that it will allow users to feel more comfortable with drug use, ultimately leading to paradoxical increased use and risk-taking behavior. Such effects have been seen following previous public health safety projects, such as seatbelt use and football helmets.<sup>1,37</sup> However, this has not occurred in communities where naloxone programs were initiated. In fact, several communities where naloxone programs exist observed decreased drug use.<sup>29,46</sup> Another common concern is that when naloxone is given, there is no perceived need to activate 911, a critical component of overdose response. Activation of EMS has had mixed results despite pre- and postnaloxone education.<sup>11</sup> In one study, 71% cited “fear of police involvement” as the primary reason for not activating 911, and 20% thought medical intervention was unnecessary.<sup>6</sup> In New York City, EMS was activated 74% of the time by naloxone-trained laypersons,<sup>38</sup> which is similar to a 68% activation rate in a prior New York City study involving those without naloxone education.<sup>45</sup> Another concern is the inappropriate administration of naloxone by laypersons, especially if under the influence of an opioid or other xenobiotic, but studies have shown that trained laypersons are able to recognize opioid overdose and safely and appropriately administer naloxone.<sup>5</sup>

### Policies Regarding Naloxone

Many reforms and efforts are being undertaken to increase the availability, prescribing, and administration of naloxone. One target for reform is decreasing the liability concern at the prescriber and dispensing levels. In an effort to lower these barriers, many states have given prescribers immunity or are allowing third-party or standing prescriptions (ie, prescribing to someone other than the patient). Many states have expanded administration regulations to include nonmedical providers or laypersons. Although the laws regarding prescribing naloxone vary from state to state, many are moving toward pharmacist dispensing without a prescription (“behind the counter”) or non-prescription availability without personal identification, although this latter ability falls under federal jurisdiction. Good Samaritan laws, which exist in almost all states, are an effort to increase administration of naloxone and activation of EMS by laypersons without fear of legal repercussions.<sup>31</sup> More recently, the Comprehensive Addiction and Recovery Act of 2016 (CARA 2016) put forth measures to increase the availability and training of naloxone use to first responders.<sup>50</sup>

### Safe Injection Sites and Medical Heroin Interventions

Although controversial and to date prohibited in the United States, safe injection sites are becoming more prevalent internationally.<sup>34</sup> Heroin-assisted treatment (HAT) appears to be an effective intervention in terms of higher treatment retention both in European<sup>16,25</sup> and Canadian studies.<sup>41</sup> The Vancouver-based North American Opioid Medication Initiative (NAOMI) trial<sup>41</sup> randomized 226 adult current and chronic heroin injectors with a history of prior methadone maintenance to (1) injectable diacetylmorphine (DAM, heroin) or hydromorphone or (2) methadone maintenance treatment. Retention in the treatment arm (HAT) was 87.8% compared with 54.1% for methadone. Eleven overdoses occurred in the 115 patients randomized to HAT across more than 70,000 injection events versus no overdoses on methadone; 10 of these received naloxone, and all events resolved without any further negative sequela.<sup>33</sup> Increased patient satisfaction<sup>26</sup> and higher self-reported health-related quality of life<sup>18</sup> likely contributed to the increased HAT retention rates. Importantly, HAT was also associated with lower self-reported rates of criminal activity and superior cost-effectiveness.<sup>32</sup>

### Opioid Treatment as Overdose Prevention

Opioid use disorder treatment is itself intended to reduce illicit opioid use and prevent harm and death. Treatment effects associated with methadone, buprenorphine, and to some extent naltrexone include prevention of overdoses; reduced rates of communicable disease transmission and injection drug use; improved function and quality of life; and lower health and societal costs, including reduced criminal behavior and incarceration. The direct impact of opioid treatments on overdose event rates, however, can be difficult when examining individual or aggregate clinical trial results or when looking at overall ecologic trends, as opposed to estimating effects on overall

crude mortality rates. There are also crucial differences in medication-based treatments and counseling-only approaches; the later likely contribute to higher rates of overdose after relapse.

### Methadone and Buprenorphine

Mu opioid receptor agonist maintenance treatments with methadone (a full agonist) or buprenorphine (a partial agonist) are both the basic evidence-based, first-line treatments for an active opioid use disorders.<sup>30</sup> An active opioid user, who is tolerant to opioids, can be inducted onto either medication and thereafter titrated to and maintained on a maintenance dose that blocks or partly blocks the activity of further administered opioids. Maintenance opioid therapy allows the patient to retain acceptable levels of energy, cognition, and daily function, with reduced cravings and urges for illicit opioids. Buprenorphine maintenance can be delivered in an office-based setting, and both opioids can be used as directly observed therapy in a licensed opioid treatment program (or methadone maintenance program). Buprenorphine and methadone treatment can be blended with specialty addiction treatment in detoxification units; residential rehabilitation centers; or as part of intensive outpatient therapy, in which either medication can be combined with more intensive counseling. Systematic reviews, meta-analyses, and epidemiologic studies consistently find associations between exposure and retention in methadone maintenance with lower mortality rates compared with opioid-dependent individuals who discontinue such treatment.<sup>7,12,43,51</sup> Overdose rates fell in France and Baltimore, MD, during recent periods of methadone and buprenorphine treatment expansion.<sup>3,22,42</sup> Despite these clear trends favoring a treatment effect, individual randomized treatment trials have typically not been designed or powered to specifically estimate effects on overdose rates, making precise estimates of agonist treatment effects on opioid overdoses unavailable.<sup>27,28</sup>

### Extended-Release Naltrexone

Extended-release naltrexone (XR-NTX) is a more recently Food and Drug Administration–approved (2010) therapy for opioid use disorder, specifically for the prevention of opioid relapse after detoxification.<sup>2</sup> The extended-release, monthly, intramuscular depot formulation is designed to improve adherence to naltrexone therapy. Previously, naltrexone was approved and available as a daily oral tablet, which had limited or no effectiveness because of nonadherence. Extended-release naltrexone is an opioid relapse-prevention approach to treatment; a patient must be detoxified and opioid free at the time of induction. The naltrexone blockade then renders usual doses of opioid analgesics or heroin ineffective and noneuphoric. The pivotal efficacy of the NTX trial had no overdose events (fatal or nonfatal) in either the XR-NTX or placebo arms.<sup>20</sup> A subsequent XR-NTX effectiveness trial focused on a forensic adult outpatient population and found a lower rate of a combined fatal and nonfatal overdose outcome among XR-NTX participants compared with the treatment-as-usual control arm.<sup>21</sup>

### Counseling-Only Treatments

Contrary to opioid pharmacotherapy treatments, detoxifying from opioids and graduation to further residential or outpatient counseling-only modalities elevates the acute risk of overdose.<sup>44</sup> There are some practical advantages to counseling-only opioid addiction treatments. There are minimal requirements for a licensed medical provider or prescriber to be a member of the program staff, which is often composed primarily of addiction counselors. Patient preference for a “drug-free” recovery is respected. There is some evidence of effectiveness for various psychosocial counseling approaches for long-term recovery versus no treatment or drop-outs.<sup>40</sup> However, many studies show opioid relapse, overdose, and death occur at higher rates in counseling-only treatments over both the short and long terms compared with medication maintenance approaches.<sup>51</sup> Furthermore, acutely weaning and lowering the tolerance of an opioid-dependent user in a controlled environment (eg, jail, hospital, detoxification facility, inpatient rehabilitation), followed by return to the community, is an important overdose risk factor and arguably worse for patients than no treatment and continued illicit opioid use.<sup>44</sup> Counseling-only approaches to opioid treatment continue to be

widespread and in many parts of the United States and rapid access is essential to prevent recurrent overdoses. Increasing rates of medication treatment is a leading public health concern.<sup>14</sup> Recent federal initiatives to expand the availability of opioid treatment medications recognize that counseling-only approaches to the opioid overdose epidemic are inadequate and potentially counterproductive.

### Opioid Policies and Practice Reforms in the United States

Currently, extensive attention is being paid to the opioid epidemic and overdose rates by lawmakers and administrators at local, state, and federal levels. Overall efforts to reduce the volume and supply of opioid analgesics have important implications for overdose prevention. Prescriber practice reforms and regulatory efforts aimed at reducing individual opioid analgesic prescribing, state prescription monitoring programs, and the recent Drug Enforcement Agency upscheduling of hydrocodone to a Class II controlled substance may all contribute to lower opioid prescribing and overdose rates.<sup>17,19,36</sup> More peripherally, states with regulated medical marijuana and cannabis legalization laws report lower rates of opioid overdose.<sup>4</sup> These findings could represent unmeasured confounders, such as provider or payor policies, or an intriguing hypothesis that among chronic pain patients or the general population, increased cannabis use reduces exposure to opioids. An overriding public health aim regarding opioid use is to reduce harm and limit overdose risk, and these types of policies will require continuous evaluation and revision. The routine prescription of potent opioid analgesics for non-malignant chronic pain by US providers should end as described in the 2016 CDC practice guidelines.<sup>15</sup>

### SUMMARY

- The US opioid and opioid overdose epidemic has recently generated unprecedented media, policy, and patient advocacy attention. Drug poisonings in the US, the majority of which are now opioid related, are a leading cause of preventable death in young adults, and in comparison, now exceed the number of US annual automobile-related fatalities or breast cancer deaths.
- Preventing death in the setting of an overdose event involves immediate and sustained reversal of opioid agonist mediated hypoxia, hypoventilation, and oversedation, which is accomplished with basic life support, naloxone administration, and the activation of EMS.
- There is evidence that regional public health and harm reduction efforts to increase naloxone availability and training in overdose recognition and reversal are effective. Widespread expansion of these programs remains warranted.
- Secondary prevention of overdose events among opioid-dependent persons also hinges on improved and expanded access to evidence-based treatments for opioid use disorders, principally methadone and buprenorphine maintenance.
- Primary prevention of overall opioid use is of critical importance, given that a majority of opioid overdose deaths remain linked to prescription analgesics, and most current heroin users have initiated opioid use with opioid medications.
- Practice guidelines regarding both the management of acute and chronic pain are increasingly adamant that opioid analgesia should be used selectively in as few patients as possible, limited in dose and duration, and not as a primary treatment of chronic pain.

= 1.1–2.2 mmol/L

## HISTORY AND EPIDEMIOLOGY

The Ancient Egyptians recognized the pain-relieving effects of concoctions made from myrtle and willow leaves. Hippocrates was among the first reported to use willow bark and leaves from the *Salix* species to relieve fever, but it was not until 1829 that the glycoside salicin was extracted from the willow bark and used as an antipyretic. Seven years later, salicylic acid was isolated, and by the late 1800s, it was being used to treat gout, rheumatic fever, and elevated body temperature. The less irritating acetylated salicylate compound was first synthesized in 1833, and in 1899, acetylsalicylic acid was commercially introduced as aspirin by Bayer. With that, the modern era of aspirin therapy and salicylate toxicity began.

The American Association of Poison Control Centers (AAPCC) National Poison Data System (NPDS) collects and reports annual exposure data in the United States. Analgesics, which include both aspirin and acetaminophen (APAP), continue to rank first among pharmaceuticals most frequently reported in human exposures (Chap. 130). Salicylate toxicity and fatalities have long been a major toxicological concern. From the 1950s to 1970s, salicylates were the leading cause of fatal childhood poisoning. The association with Reye syndrome, safer packaging, and the increased use of nonsteroidal antiinflammatory drugs (NSAIDs), APAP, and other alternatives to aspirin decreased the incidence of unintentional salicylate poisoning. In the annual 2015 NPDS review of fatalities, 18 cases of death were documented from single substance acetylsalicylic acid exposures and another 31 fatalities included acetylsalicylic acid as part of the exposure (Chap. 130).<sup>93</sup> A query of the same NPDS database for single-agent aspirin poisoning deaths occurring from 2008 to 2012 yielded 83 cases in which death was coded as a direct consequence of aspirin poisoning.<sup>45</sup> Despite decline in general use, it is still imperative that clinicians are adept at early recognition and swift management of patients with salicylate overdose.

Aspirin and other salicylate-containing products continue to be some of the most common prescription and nonprescription xenobiotics used by the general public. Since landmark trials demonstrated the inhibition of platelet function by aspirin in the 1970s, its use became the standard of care for cardiovascular disease prevention and treatment. Subsequent investigations demonstrated potential benefits of aspirin in primary and secondary prevention of myocardial infarction, colon cancer, and transient ischemic attack. Its antiinflammatory properties continue to make it an active investigational xenobiotic for cancer.<sup>1</sup> Thus salicylates continue to be readily available and will continue to lead to significant morbidity and mortality in overdose.

## PHARMACOLOGY

Aspirin and other salicylates have analgesic, antiinflammatory, and antipyretic properties, a combination of traits shared by all of the NSAIDs (Chap. 35). Most of the beneficial effects of NSAIDs result from their inhibition of cyclooxygenase (COX). This enzyme enables the synthesis of prostaglandins, which in turn mediate inflammation and fever.<sup>110,136</sup> Contributing to the antiinflammatory effects and independent of the effects on prostaglandins, salicylates and other NSAIDs also directly inhibit neutrophils.<sup>10</sup> There are two types of salicylic acid esters, phenolic esters such as aspirin and carboxylic acid esters, including methyl salicylate, phenyl salicylate, and glycosalicylate.<sup>27</sup> Most of the studies of salicylate metabolism involve aspirin.<sup>27</sup> There is an implicit assumption that all members of the salicylate class have similar properties after being converted to salicylic acid.

Salicylates and NSAIDs are purportedly most effective in treating the pain accompanying inflammation and tissue injury. Such pain is elicited by prostaglandins liberated by bradykinin and other cytokines. Fever is also mediated by cytokines such as interleukins (IL-1 $\beta$ , IL-6),  $\alpha$  and  $\beta$  interferons, and tumor necrosis factor- $\alpha$ , all of which increase synthesis of prostaglandin E<sub>2</sub>. In turn, this inflammatory mediator increases cyclic adenosine monophosphate (cAMP), which triggers the hypothalamus to elevate the body temperature set point, resulting in increased heat generation and decreased heat loss.<sup>116</sup>

Because platelets cannot regenerate COX-1, a daily dose of as little as 30 mg of aspirin inhibits COX-1 for the 8- to 12-day lifespan of the platelet.<sup>116</sup> Adverse effects of aspirin and some NSAIDs related to alteration of COX include gastrointestinal (GI) ulcerations and bleeding, interference with platelet adherence,<sup>117</sup> and a variety of metabolic and organ-specific effects described later in this chapter.

To achieve an antiinflammatory effect for patients with chronic conditions such as rheumatoid arthritis, in the past, salicylates were prescribed in doses sufficient to achieve a serum salicylate concentration between 15 and 30 mg/dL, which is considered the therapeutic range. Concentrations higher than 30 mg/dL are typically associated with signs and symptoms of toxicity.

## PHARMACOKINETICS

Aspirin is rapidly absorbed from the stomach. The pK<sub>a</sub> of aspirin is 3.5, and the majority is nonionized (ie, acetylsalicylic acid) in the strongly acidic stomach (pH 1–2).<sup>27,59</sup> Although absorption of acetylsalicylate is less efficient in the small bowel because of its higher pH, it is substantial and rapid due to the large surface area of the small intestine increases the solubility of acetylsalicylate.<sup>90,91</sup> After ingestion of therapeutic doses of immediate-release acetylsalicylate, therapeutic serum concentrations are achieved in 30 minutes, and maximum concentrations are often attained in less than 1 hour.<sup>27</sup>

The plasma half-life of acetylsalicylate is about 15 minutes because it is rapidly hydrolyzed to salicylate. The apparent half-life for salicylate is about 2 to 3 hours at antiplatelet doses and increases to 12 hours at antiinflammatory doses demonstrating dose dependent elimination.<sup>95</sup> Aspirin undergoes biotransformation in the liver and is then eliminated by the kidneys. The apparent volume of distribution (V<sub>d</sub>) increases from 0.2 L/kg at low concentrations to 0.3 to 0.5 L/kg at higher concentrations.<sup>78,79,127</sup>

## TOXICOKINETICS

In overdose, several factors contribute to variable pharmacokinetics and present very challenging obstacles to effectively managing patients poisoned with salicylates. The dose contributes to the magnitude and duration of toxicity,

but other important factors include the formulation, rate of gastric emptying, alterations in gastric pH (eg, proton pump inhibitors, H<sub>2</sub> antagonists) bezoar formation, hepatic and renal function, and both the serum and urine pH.

There is a decrease in protein (albumin) binding from 90% at therapeutic concentrations to less than 75% at toxic concentrations caused by saturation of protein binding sites.<sup>2,12,34</sup> Salicylates have substantially longer apparent half-lives at toxic concentrations than at therapeutic concentrations, varying from 2 to 4 hours at therapeutic concentrations to as long as 20 hours at toxic concentrations.<sup>29,79</sup> The dosage form of salicylates (eg, effervescent, enteric coated) influences the absorption rate.<sup>115,118,145</sup> Therapeutic doses of enteric-coated tablets produce peak serum concentrations at 4 to 6 hours after ingestion, and in overdose, the reported peak is delayed up to 24 hours after ingestion.<sup>35,145</sup> Delayed absorption of immediate-release aspirin results from salicylate-induced pylorospasm or pharmacobezoar formation.<sup>12,115,122</sup>

Salicylates are conjugated with glycine and glucuronides in the liver and are eliminated by the kidneys. Approximately 10% of salicylates are excreted in the urine as free salicylic acid, 75% as salicylic acid, 10% as salicylic phenolic glucuronides, 5% as acylglucuronides, and 1% as gentisic acid (Fig. 37-1).<sup>116</sup> As the concentration of salicylates increases, two of the five pathways of elimination—those for salicylic acid and the salicylic phenolic glucuronide—become saturated and exhibit zero-order kinetics. As a result of this saturation, overall salicylate elimination changes from first-order kinetics to zero-order kinetics (Chap. 9).<sup>78,79</sup> In a healthy adult, these altered saturation kinetics typically occur after as little as 1 to 2 g of acute aspirin ingestion.<sup>79</sup>

When administered chronically, a small increase in dosage or a small decrease in metabolism or elimination results in substantial increases in

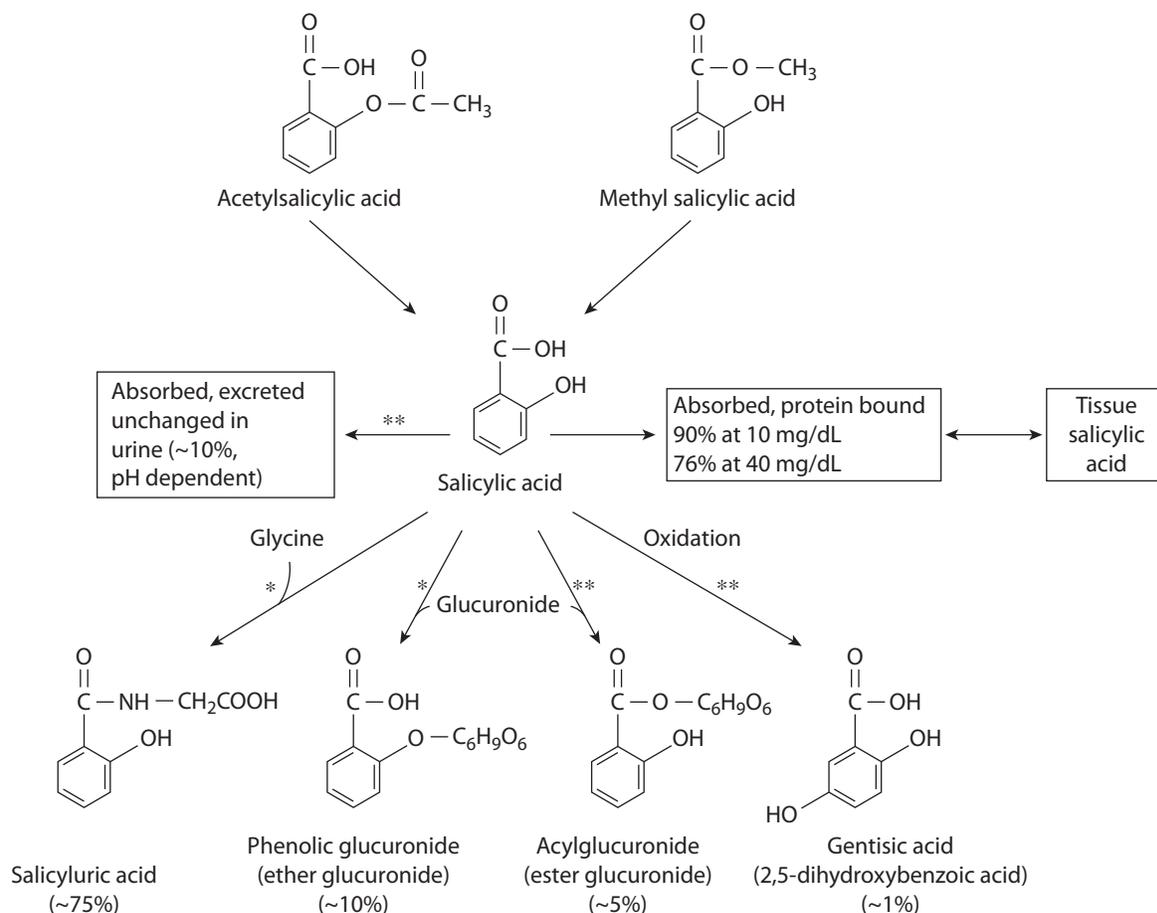

serum salicylate concentrations and the risk of toxicity.<sup>69</sup> At very high serum concentrations, salicylate elimination again resembles first-order elimination as an increasing fraction undergoes renal clearance.

Free salicylic acid is filtered through the glomerulus and is both passively reabsorbed and actively secreted from the proximal tubules. More than 30% of an ingested salicylate dose is eliminated in alkaline urine and as little as 2% in acidic urine.<sup>140</sup> Salicylate conjugates (glycine and glucuronides) are filtered and secreted by the proximal tubules; salicylate conjugates are not reabsorbed across renal tubular cells because of limited lipid solubility, and the amount eliminated depends on the glomerular filtration rate and proximal tubule secretion but not urine pH. Protein-binding abnormalities, urine and plasma pH variations, and delayed absorption all influence both the maximum salicylate concentration and the rate of decline.<sup>91,115</sup>

### Other Forms of Salicylate

#### Topical Salicylate, Methyl Salicylate (Oil of Wintergreen), and Salicylic Acid

Topical salicylates, which are used as keratolytics (salicylic acid) or as rubefacients ( $\leq 30\%$  methyl salicylate), are rarely responsible for salicylate poisoning when used in their intended manner because absorption through normal skin is very slow. However, particularly in children, extensive application of topical preparations containing methyl salicylate result in poisoning.<sup>15,143</sup> After 30 minutes of contact time, only 1.5% to 2.0% of a dose is absorbed, and even after 10 hours of contact with the methyl salicylate, only 12% to 20% of the salicylate is systemically absorbed.<sup>15</sup> Heat, occlusive dressings, young age, inflammation, certain body areas with enhanced absorption, and psoriasis may increase topical salicylate absorption.<sup>18,133,137</sup> In one case report, scrotal exposure to methyl salicylate caused significant salicylate toxicity with a delayed diagnosis.<sup>133</sup> In a study of healthy volunteers, a profound effect of

**FIGURE 37-1.** Salicylic acid metabolism. At excessive doses, the four mechanisms of salicylic acid metabolism are overloaded, leading to increased tissue binding, decreased protein binding, and increased excretion of unconjugated salicylic acid. Asterisk (\*) indicates Michaelis-Menten kinetics; double asterisk (\*\*) indicates first-order kinetics.

transdermal absorption of methyl salicylate was demonstrated from exercise and heat exposure, with a threefold increase in the systemic availability of salicylate.<sup>26</sup>

Ingestion of methyl salicylate is potentially disastrous because 1 mL of 98% oil of wintergreen contains an equivalent quantity of salicylate as 1.4 g of aspirin. The minimum toxic salicylate dose of approximately 150 mg/kg body weight can almost be achieved with 1 mL of oil of wintergreen, which represents 140 mg/kg of salicylates for a 10-kg child. In Hong Kong, medicated oils containing methyl salicylate accounted for 48% of acute salicylate poisoning cases treated in one hospital.<sup>17</sup> Methyl salicylate is rapidly absorbed from the GI tract, and much, but not all, of the ester is rapidly hydrolyzed to free salicylate. Despite rapid and complete absorption, serum concentrations of salicylates are much less than predicted after ingestion of methyl salicylate containing cream compared with oil of wintergreen.<sup>143</sup> Vomiting is common, along with abdominal discomfort. The onset of symptoms usually occurs within 2 hours of ingestion.<sup>18</sup> Patients with methyl salicylate toxicity have died in less than 6 hours, emphasizing the need for early determinations of salicylate concentrations in addition to frequent testing after such exposures.

Clinicians should be aware of the danger associated with powder formulations of salicylate that are simply mixed with water or juice before ingestion. In a small retrospective study, these powder formulations appeared less likely to have delayed peak serum salicylate concentrations compared with tablet formulations.<sup>120</sup>

### Bismuth Subsalsicylate

Bismuth subsalsicylate, which is available in several nonprescription formulations, releases salicylate in the GI tract, where it is subsequently absorbed. Each milliliter of common liquid preparations of bismuth subsalsicylate contains 8.7 mg of salicylic acid.<sup>40</sup> After a large therapeutic dose (60 mL), peak salicylate concentrations reach 4 mg/dL at 1.8 hours after ingestion.<sup>40</sup> Patients with diarrhea and infants with colic using large quantities of bismuth subsalsicylate are at increased risk for developing salicylate toxicity.<sup>138</sup> Chronic use should also raise concerns for bismuth toxicity (Chap. 87).

## PATHOPHYSIOLOGY

Aspirin has a pKa of 3.5, but as mentioned earlier, it is rapidly hydrolyzed to salicylic acid, which has a pKa of 2.97. Salicylic acid at physiologic pH exists predominantly in a charged (ionized) state (Chap. 9). But in overdose, as the serum pH falls, more salicylate shifts toward a nonionized (uncharged) salicylic acid form that readily permeates across lipid bilayers and cell membranes. This is an important effect in that it allows salicylic acid to enter cells exerting its toxic effects across a wide variety of organs and is discussed later as a target for management.

### Acid–Base and Metabolic Effects

Salicylate interferes with the citric acid cycle, which limits production of adenosine triphosphate (ATP).<sup>67</sup> It also uncouples oxidative phosphorylation, causing accumulation of pyruvic and lactic acids and releasing energy as heat (Chap. 11).<sup>73</sup> Salicylate induced increases in fatty acid metabolism generates ketone bodies, including  $\beta$ -hydroxybutyric acid, acetoacetic acid, and acetone. Toxic concentrations of salicylate impair renal hemodynamics, leading to the accumulation of inorganic acids. The net result of all of these metabolic processes is an anion gap metabolic acidosis in which the unmeasured anions include salicylate and its metabolites, lactate, ketoacids, and inorganic acids (Chap. 12).

The salicylate effect on glucose metabolism is variable and depends on the severity and phase of toxicity. Salicylate administration in mice increases glycogenolysis and results in hyperglycemia.<sup>125</sup> Early adrenergic effects of acute salicylate toxicity stimulate epinephrine and glucagon release, enhancing glycogenolysis as well as gluconeogenesis. But salicylate inhibits alanine and aspartate aminotransferase, and both enzymes provide key amino acid substrates for gluconeogenesis. Hypoglycemia also results from

the combined effect of increased energy demands, depletion of glycogen stores, and decreased gluconeogenesis.<sup>112</sup>

Salicylate-poisoned mice had dramatic increases in serum lactate concentration compared with control mice, likely because of increased glycogenolysis and anaerobic glycolysis to compensate partly for the energy loss caused by uncoupling of oxidative phosphorylation, (Chap. 11).<sup>56,89</sup> There was also a marked increase in oxygen consumption in mice even with low salicylate concentrations, highlighting the importance of salicylate-induced uncoupling of oxidative phosphorylation which is the cause of increased body temperature.<sup>57</sup> Several investigations examined the etiology of uncoupling of oxidative phosphorylation in salicylate poisoning. By using intact or fragmented mitochondria, it was demonstrated that increasing concentrations of salicylate result in decreased phosphate uptake and a concomitant decrease in the phosphate/oxygen (P/O) ratio.<sup>89,101</sup> The impaired P/O ratio demonstrates the inefficiency of ATP production by illustrating that the rate of phosphate incorporation into ATP per molecule falls despite oxygen consumed during oxidative phosphorylation. Salicylates reduce lipogenesis by blocking the incorporation of acetate into free fatty acids and increase peripheral fatty acid metabolism as an energy source. This salicylate-induced increased fatty acid metabolism generates ketones, including  $\beta$ -hydroxybutyric acid, acetoacetic acid, and acetone.

### Neurologic Effects

The central nervous system (CNS) effects are the most visible and most consequential clinical effects in salicylate-poisoned patients. With increasing CNS salicylate concentrations, neuronal energy depletion likely develops as salicylate uncouples neuronal and glial oxidative phosphorylation.<sup>89</sup> Several other mechanisms also likely contribute to the neurotoxic effects of salicylates. Salicylate also causes release of apoptosis-inducing factor (AIF) or cytochrome C, triggers p38 mitogen-activated protein kinase, and activates glial caspase-3, which are responsible for programmed neuronal cell apoptosis.<sup>113</sup> It is likely that in addition to severe cellular acidosis, these effects lead to neuronal dysfunction and ultimately cerebral edema.

Salicylate poisoning reportedly produces clinical discordance between serum and cerebrospinal fluid (CSF) glucose concentrations.<sup>112</sup> Despite normal serum glucose concentrations, CSF glucose concentration decreased 33% in salicylate-poisoned mice compared with control mice.<sup>134</sup> In other words, the rate of CSF glucose use exceeded the rate of supply even in the presence of a normal serum glucose concentration. This hypoglycorrhachia demonstrates that altered glucose metabolism and transport plays a role in the deleterious neurologic effects of the neuroglycopenia resulting from salicylate poisoning. Salicylate-poisoned mice have lower CSF glucose concentrations than control mice but can maintain similar concentrations of ATP by enhanced glycolysis. Administration of dextrose in these salicylate-poisoned mice suppressed clinical signs of toxicity underlying the importance of providing supplemental glucose despite normal serum concentrations as discussed later in the management of toxicity.<sup>134</sup>

### Hepatic Effects

Hepatic injury from either acute or chronic overdose of salicylate is rare. Although the hepatocyte is the location of its toxic effects on several metabolic pathways such as glycogenolysis and the Krebs cycle, other concurrent coingestants and causes should be evaluated if there is a clinically significant elevation of aminotransferases or bilirubin concentration or signs of acute liver failure.<sup>148</sup>

An unavoidable historical link exists between the hepatic encephalopathy in Reye syndrome and aspirin. A buildup of fatty acids in the hepatocyte resulting in microvesicular steatosis is characteristic of Reye syndrome. This occurs through salicylate depletion of intrahepatocyte coenzyme A (Co-A), in which fatty acids entering the hepatocyte cytoplasm cannot be transported into the mitochondria for  $\beta$ -oxidation. Although this mechanism is only suggestive in the relationship between aspirin and Reye syndrome, it is clear from epidemiologic evidence that aspirin is an essential cofactor among others in the development of this syndrome.<sup>48</sup>

### Otolaryngologic Effects

The molecular mechanism of salicylate ototoxicity is not completely understood but appears to be multifactorial. Inhibition of cochlear COX by salicylate increases arachidonate, enabling calcium flux and neural excitatory effects of *N*-methyl-D-aspartic acid (NMDA) on cochlear spinal ganglion neurons.<sup>107,108,121</sup> Also, the prevention of prostaglandin synthesis interferes with the Na<sup>+</sup>, K<sup>+</sup>-adenosine triphosphatase (ATPase) pump in the stria vascularis, and the vasoconstriction decreases cochlear blood flow.<sup>13,16,38,64</sup> Membrane permeability changes cause a loss of outer hair cell turgor in the organ of Corti, which impairs otoacoustic emissions.<sup>107,109</sup> A more complete description of the pathophysiology of salicylate-induced ototoxicity and sensorineural alterations as well as comparisons with the patterns of other ototoxic xenobiotics is found in Chap. 25.

### Pulmonary Effects

Salicylates have very potent stimulatory effects on respiratory drive via several mechanisms. Direct stimulation of the medullary respiratory neurons produces hyperpnea and tachypnea even at therapeutic concentrations. In fact, in a human trial, salicylates decreased the number and duration of apneic events in patients with sleep apnea.<sup>103</sup> Increased sensitivity to PCO<sub>2</sub> and pH further increases ventilation. Carotid body and peripheral arterial chemoreceptor stimulation also contribute to salicylate-induced hyperventilation.<sup>87</sup>

Some patients with either acute or chronic salicylism develop acute respiratory distress syndrome (ARDS). It is often a sign of severe and advanced toxicity and can be lethal. One study<sup>114</sup> that summarized data from nearly 400 consecutive cases of salicylate toxicity reported in the literature<sup>4,54,132,141</sup> concluded that ARDS occurred in approximately 7% of cases. The development of ARDS in salicylate poisoning is associated with a history of cigarette smoking, chronic overdose, metabolic acidosis, and neurologic symptoms at the time of arrival.<sup>97</sup>

Although the exact etiology of salicylate-induced ARDS is unclear, as with other causes, ARDS results from increased pulmonary capillary permeability and subsequent exudation of high-protein edema fluid into the interstitial or alveolar spaces.<sup>60</sup> Adrenergic excess in salicylate poisoning may injure the hypothalamus, leading to a shift in blood from the systemic to the pulmonary circulation because of a loss of left ventricular compliance with left atrial and pulmonary capillary hypertension (Chap. 16). Additionally, the resulting hypoxia produces pulmonary arterial hypertension and a local release of vasoactive substances, worsening ARDS.<sup>61</sup> Unventilated salicylate-poisoned sheep were more likely to develop ARDS compared with a mechanically ventilated control group, suggesting that the mechanical stress of prolonged and severe hyperventilation is a significant contributing factor to this complication.<sup>83</sup>

### Gastrointestinal Effects

Salicylate disrupts the mucosal barrier that normally protects the gastric lining from the extremely acidic contents of the stomach. Gastrointestinal injuries leading to ulcers or bleeding are among the most common adverse effects from therapeutic use of aspirin, but in acute overdose, the most common manifestations result from local gastric irritation presenting with nausea and vomiting. Emesis is triggered both by local mucosal irritation and central stimulation of the chemoreceptor trigger zone.<sup>11</sup> Hemorrhagic gastritis, decreased gastric motility, and pylorospasm result from the direct gastric irritant effects of salicylates.<sup>118</sup>

### Renal Effects

The kidneys play a major role in the excretion of salicylate and its metabolites. Although some believe that salicylates are nephrotoxic, the majority of experimental evidence does not strongly support this notion.<sup>25,36,102</sup> Most of the adverse renal effects historically associated with salicylates occurred with use of combination products such as aspirin-phenacetin-caffeine tablets and were likely caused by the phenacetin.<sup>36</sup> Renal papillary necrosis and chronic interstitial nephritis, initially characterized by reduced tubular function and reduced concentrating ability, rarely occur in adults using salicylates unless they have chronic illnesses that already compromise renal function.

Volume losses in patients with salicylate toxicity that develop from hyperventilation and hyperthermia also cause prerenal acute kidney injury (AKI). The kidneys also respond to salicylate poisoning by excreting an increased solute load, including large quantities of bicarbonate, sodium, potassium, and organic acids.<sup>5</sup> Rarely, salicylates also induce a Fanconilike syndrome with generalized proximal tubular dysfunction characterized by glucosuria (despite normal serum glucose), proteinuria, aminoaciduria, and uric acid wasting.<sup>135</sup>

### Hematologic Effects

The hematologic effects of salicylate poisoning include hypoprothrombinemia and platelet dysfunction.<sup>100</sup> The platelet dysfunction, caused by irreversible acetylation of COX-1 and COX-2, prevents the formation of thromboxane A<sub>2</sub>, which is normally responsible for platelet aggregation. Although the platelets are numerically and morphologically intact, they are unresponsive to thrombogenic stimulation. At supratherapeutic doses, salicylate decreases the plasma concentration of the  $\gamma$ -carboxyglutamate containing coagulation factors and an accumulation of microsomal substrates for vitamin K-dependent carboxylase in the liver and lung.<sup>119</sup> The result of this interruption of vitamin K cycling is similar to that of warfarin,<sup>99</sup> leading to hypoprothrombinemia (factor II) as well as decreases in factors VII, IX, and X (Chap. 58).

## CLINICAL MANIFESTATIONS OF SALICYLATE POISONING

The following sections describe the typical clinical manifestations that follow toxic exposures to salicylates. The natural course of acute ingestions begins with nonspecific GI symptoms, early tachypnea caused by direct central respiratory stimulation, development of an anion gap metabolic acidosis, and several minor neurologic sequelae. As the acidosis worsens, clinical effects progress and invariably evolve to severe CNS toxicity. Hyperthermia, cerebral edema, coagulopathy, ARDS, and severe acidemia are the gravest clinical consequences and are often preterminal events. Cerebral edema is often seen at autopsy in those who succumb to salicylate toxicity.

The earliest signs and symptoms of salicylate toxicity, which include nausea, vomiting, diaphoresis, and tinnitus, typically develop within 1 to 2 hours of acute ingestion.<sup>13,46</sup> But the type of salicylate-containing preparation, comorbidities, coingestants, and compromise in renal or hepatic function potentially delay the onset of symptoms up to 24 hours after exposure.<sup>118</sup> Case reports of enteric-coated aspirin tablet ingestions demonstrate delays in symptom onset and time to initial detectable salicylate concentration, with peak salicylate concentrations reported to occur 2 to 3 days after initial exposure.<sup>32,145</sup>

### Acute Salicylate Poisoning

Salicylates are extremely irritating to the GI mucosa; early vomiting after ingestion are a warning sign of a potentially clinically significant ingestion. Emesis occurs both by direct GI irritation and from salicylate-induced stimulation of the chemoreceptor trigger zone.<sup>11</sup> Pylorospasm, delayed gastric emptying, and decreased GI motility complicate toxicity by altering absorption kinetics. Hemorrhagic gastritis also occurs, likely as a consequence of severe emesis and alteration of protective mucosal GI barriers.

The initial evaluation of a patient suspected of salicylate poisoning must start with a thorough assessment of the respiratory rate and depth. Subtle tachypnea or hyperpnea should not be overlooked because if missed, they will delay the initiation of appropriate laboratory analysis and management. Direct central stimulation of the respiratory center increases minute volume ventilation, determined by the product of respiratory rate and tidal volume. A primary respiratory alkalosis predominates initially, although an anion gap metabolic acidosis begins to develop early in the course of salicylate toxicity. By the time a symptomatic adult patient presents to the hospital after a salicylate overdose, a mixed acid-base disturbance is often prominent.<sup>46</sup> This latter finding includes two primary processes, respiratory alkalosis and metabolic acidosis, and is discernible by arterial blood gas (ABG) or venous blood gas (VBG) and serum electrolyte analyses. In one study of 66 salicylate-poisoned adults, 22% had respiratory alkalosis, and 56% had mixed respiratory alkalosis and metabolic acidosis.<sup>46</sup>

**TABLE 37-1** Progressive Acid-Base Stages of Salicylate Poisoning

<b>Early:</b> Respiratory alkalosis, alkalemia, and alkaluria
<b>Intermediate:</b> Respiratory alkalosis, metabolic acidosis, alkalemia, and aciduria
<b>Late:</b> Metabolic acidosis with either a respiratory alkalosis or respiratory acidosis, acidemia, and aciduria

On presentation, salicylate-poisoned adults who demonstrate respiratory acidosis should alert the clinician to the fact that systemic toxicity is severe. This patient will likely be late in the clinical course of poisoning and have salicylate induced ARDS, fatigue from hyperventilating for a prolonged period of time, or CNS depression (from either salicylate itself or coingestants). These broad variations of clinical toxicity can be divided into three general time frames based on rapidly available laboratory testing. The progressive stages salicylate poisoning are demonstrated in **Table 37-1**.

Mixed overdoses are common; in one study, one-third of patients with a presumed primary salicylate overdose took other xenobiotics.<sup>46</sup> Benzodiazepines, barbiturates, alcohol, and cyclic antidepressants all blunt the centrally induced hyperventilatory response to salicylates, resulting in either actual respiratory acidosis ( $PCO_2 >40$  mm Hg) or metabolic acidosis without some respiratory compensation ( $PCO_2 <40$  mm Hg but inappropriately high for the concomitant degree of metabolic acidosis). In both adults and children, the development of respiratory acidosis occurs as salicylate poisoning progresses. The combination of metabolic and respiratory acidosis in a salicylate poisoning results in severe and worsening acidemia that is an exceedingly grave situation and almost invariably is a preterminal event.<sup>105</sup>

When clinical and radiographic manifestations of ARDS are observed in the setting of salicylate toxicity, the following conditions should be considered: aspiration pneumonitis, viral and bacterial infections, neurogenic ARDS, and salicylate-induced ARDS (Chap. 28).<sup>61,68</sup> In 111 consecutive patients with peak salicylate concentrations above 30 mg/dL, ARDS occurred in 35% of patients older than 30 years of age and none of the 55 patients younger than 16 years of age. The average arterial blood pH was 7.37 in the six adult patients with ARDS and 7.46 in the 30 adults without ARDS. There was no significant difference in salicylate concentrations, which were approximately 57 mg/dL in both groups.<sup>141</sup> In a 2-year review of all salicylate deaths in Ontario, Canada, 59% of 39 autopsies revealed pulmonary pathology, mostly “pulmonary edema” (ARDS).<sup>86</sup>

Although hyperventilation is centrally mediated, patients may develop a spectrum of CNS abnormalities that includes confusion, agitation, and lethargy and then ultimately seizures and coma. Human and animal evidence suggests that hypoglycorrhachia despite euglycemia contributes to the neurotoxic effects. Stupor, coma, and delirium may be reversed by the administration of dextrose in children and adults with salicylate toxicity and normal serum glucose concentrations. In one report, a child underwent lumbar puncture, and CSF analysis demonstrated no detectable glucose despite a normal peripheral glucose.<sup>24</sup> The most severe neurologic clinical findings are likely associated with the development of cerebral edema and portend a poor prognosis. Excluding effects on ventilation, signs of neurologic toxicity, even if mild, should be of great concern.

Tinnitus, a subjective sensation of ringing or hissing with or without hearing loss, loss of absolute acoustic sensitivity, and alterations of perceived sounds are the three effects resulting from exposure to large doses of salicylates.<sup>16</sup> The pattern of salicylate-induced auditory sensorineural alterations is different than that of other ototoxic xenobiotics.<sup>16</sup> Tinnitus is a demonstrable manifestation of CNS toxicity even without alterations in mental status. As CNS salicylate concentrations increase, tinnitus is rapidly followed by diminished auditory acuity that sometimes leads to deafness.<sup>13</sup> As acute toxicity progresses, other CNS effects include vertigo, hyperactivity, agitation, delirium, hallucinations, lethargy, seizures, and stupor. Coma is rare and is generally a late finding occurring in severe acute poisoning or mixed overdoses.<sup>4,147</sup>

Paratonia, extreme muscle rigidity, is reported in severe salicylate poisoning pre- and postmortem, and the rigidity, it was unresponsive to

**TABLE 37-2** Differential Characteristics of Acute and Chronic Salicylate Poisoning

	<i>Acute</i>	<i>Chronic</i>
Age	Younger	Older
Etiology	Overdose usually intentional	Therapeutic misadventures; iatrogenic
Diagnosis	Easily recognized (absent coingestion)	Frequently unrecognized
Other diseases	None	Underlying disorders (especially chronic pain conditions)
Suicidal ideation	Typical	Atypical
Serum concentrations	Marked elevation	Intermediate elevation
Mortality	Uncommon when recognized and properly treated	More common due to delayed recognition

succinylcholine in a single case report.<sup>86,111</sup> Decreased ATP production, impaired glycolysis, increased lactate, and uncoupling of muscular oxidative phosphorylation likely contribute to this phenomenon. This excess neuromuscular activity leads to rhabdomyolysis acute tubular necrosis and, most concerning, hyperthermia, which is typically a preterminal condition.<sup>77,89,90</sup>

### Chronic Salicylate Poisoning

Chronic salicylate poisoning most typically occurs in older adults as a result of unintentional overdosing on salicylates used for primary and secondary prevention of cardiovascular disorders and osteoarthritis in addition to analgesia and as an antipyretic.<sup>5,30,69</sup> (**Table 37-2**). Presenting signs and symptoms of chronic salicylate poisoning can be similar to those of acute toxicity and include nausea and vomiting, hearing loss and tinnitus, dyspnea and hyperventilation, tachycardia, hyperthermia, and neurologic manifestations (eg, confusion, delirium, agitation, hyperactivity, slurred speech, hallucinations, seizures, coma).<sup>4,33,76</sup> Although there is considerable overlap with acute salicylate poisoning, the slow, insidious onset of chronic poisoning in older adults frequently causes delayed recognition of the true cause of the patient’s presentation.<sup>4,46,75</sup>

On occasion, ill patients who have chronic salicylate poisoning are misdiagnosed as having delirium, dementia, or encephalopathy of undetermined origin; or diseases such as sepsis (fever of unknown origin), alcoholic ketoacidosis, respiratory failure, or cardiopulmonary disease.<sup>4,6,21,37</sup> Unfortunately, many of the signs and symptoms of chronic salicylate toxicity were mistakenly attributed to the illness for which the salicylates were administered.<sup>21,129</sup> In one report, despite an extensive evaluation during a first hospitalization for ARDS, chronic salicylism was not diagnosed until a second hospitalization for the same respiratory symptoms.<sup>23</sup> This case highlights the need to include chronic salicylism in the differential for ARDS with or without neurologic symptoms.

In a study of 73 consecutive adults hospitalized with salicylate poisoning, 27% were not correctly diagnosed for as long as 72 hours after admission.<sup>4</sup> In this group, 60% of the patients had a neurologic consultation before the diagnosis of salicylism was established. When diagnosis is delayed in older adults, the morbidity and mortality associated with salicylate poisoning are high. The mortality rate was reported to be as high as 25% in the 1970s,<sup>4</sup> and there are no data to suggest that survival after delayed diagnosis is substantially better today.

### EVALUATION AND DIAGNOSTIC TESTING

The most commonly reported route of exposure is from the acute ingestion of aspirin, which, as mentioned earlier, has a very short serum half-life of about 15 minutes during which time it is rapidly converted to salicylate. The symptoms of toxicity are due to the systemic effects of salicylate and not the parent compound. Systemic toxicity is concerning after the following exposures: ingestions of 150 mg/kg or 6.5 g of aspirin, whichever is less; ingestion of greater than a lick or taste of oil of wintergreen (98% methyl

salicylate) by children younger than 6 years of age; and more than 4 mL of oil of wintergreen by patients 6 years of age and older.<sup>22</sup> These patients as well as those with significant topical exposures and signs of toxicity should be promptly evaluated for salicylate toxicity.

The initial approach to a patient suspected of salicylate toxicity should include a serum salicylate concentration. It is very important to recognize that other laboratory assays such as an ABG or VBG, electrolytes to determine anion gap, the presence of serum or urine ketones, and a lactate concentration are often sufficient to uncover an unrecognized salicylate poisoning. It also is important to evaluate renal and hepatic function because dysfunction in either will exacerbate toxicokinetic effects in patients with acute or chronic exposures.

Elevated anion gaps are caused by increases in unmeasured anions that are primarily salicylate but also related to increases in lactic acid, ketoacids, and daily endogenous dietary acids. Contributing factors to the rise in the anion gap discussed earlier include volume loss from vomiting, AKI, and increased metabolic energetic production.

Several studies demonstrate that empiric serum salicylate concentrations are not required as part of a general toxicologic evaluation in patients with acute self-poisoning. Routine salicylate testing is likely unnecessary without a history of salicylate ingestion, an inability to obtain a valid history (altered mental status), or clinical features of salicylate poisoning.<sup>19,51,144</sup> One retrospective study also demonstrated that screening for salicylism is not needed in the absence of an elevated anion gap.<sup>124</sup> Although an anion gap metabolic acidosis is likely found in most cases of salicylate toxicity, severe salicylism is rarely reported to falsely elevate serum chloride, bringing the anion gap closer to a normal range.<sup>62</sup>

One explanation for the falsely elevated chloride concentrations comes from laboratory misinterpretation of salicylate ions for chloride ions that leads to a falsely lowered anion gap.<sup>70</sup> Additionally, a renal tubular acidosis can occur in salicylate poisoning, resulting in metabolic acidosis with a normal anion gap.<sup>142</sup> Several case reports demonstrate low or normal anion gaps in patients with significant salicylate toxicity; therefore, a normal anion gap should not rule out salicylate poisoning.<sup>8,70</sup>

Although it is wise to curtail empiric testing, clinicians should likely err on the side of ordering a salicylate concentration if there is any clinical concern because the morbidity and mortality are significantly increased with delays in recognition and management. Many of the signs and symptoms of salicylate toxicity are vague and often mistakenly attributed to another illness with disastrous consequences. In the review of all salicylate deaths in Ontario, Canada, in 1983 and 1984, the author noted that in six of the 23 (26%) patients who arrived alert, no salicylate determination was identified in the medical record, and that probably neither the diagnosis nor the severity of the salicylate poisoning was recognized.<sup>86</sup>

### Salicylate Analysis

Serum salicylate concentrations are relatively easy to obtain in most hospital laboratories today. Several methods are available for determining serum salicylate concentrations. The Trinder assay was once the most popular method for the measurement of salicylate in serum by using spectrophotometric analysis. Trinder's reagent contains mercuric chloride and hydrochloric acid used to precipitate serum proteins. The measured absorbance at 540 nm of a ferric ion-salicylate complex allows for accurate determination of the serum salicylate concentration. Historically, there have been several bedside urine qualitative test (ie, mercuric chloride, ferric chloride) used to assess for the presence of salicylate. Both the Trinder reaction and the bedside tests have limited utility today in modern centers because of poor specificity and chemical hazards and are no longer permissible in the United States under the federal Clinical Laboratory Improvement Amendments (CLIA).

Serum salicylate concentrations are commonly reported in mg/dL in the United States, but confusion can arise because values can also be reported in mg/L and mcg/mL. Reporting salicylate concentrations as mg/L when the clinician is accustomed to receiving results as mg/dL or inadvertently reporting actual mg/L (before internal laboratory conversion) produces

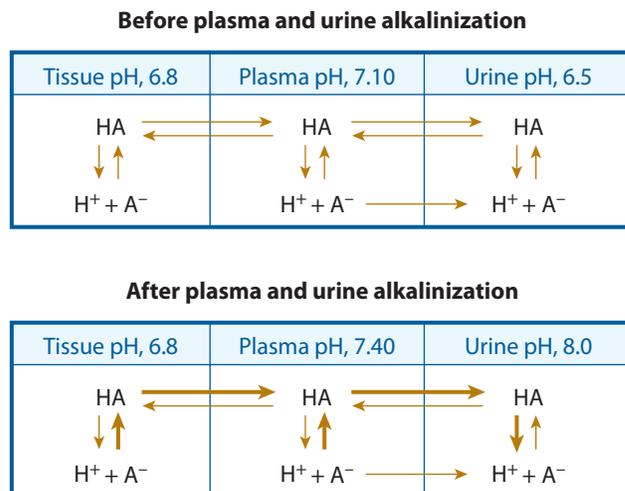

erroneous results. Such misinterpretations<sup>52</sup> suggest a toxic salicylate concentration in a patient whose serum salicylate concentration is actually within the therapeutic range (eg, "165 mg/L" instead of "16.5 mg/dL"). Most errors can be identified before initiation of aggressive therapy, such as hemodialysis (HD), by determining whether the reported salicylate concentration is consistent with the clinical presentation and ABG or VBG results and, when time permits, repeating the salicylate determination with appropriate consideration for methodology and conversion calculations.<sup>52</sup> Using the earlier example, a patient with a serum salicylate concentration of 165 mg/dL would undoubtedly show clinical signs of salicylate toxicity and have a profound acid-base abnormality, but a patient with a concentration of 165 mg/L would likely be asymptomatic.

It should also be noted that several clinical scenarios and xenobiotic exposures are recognized to cause false-positive or falsely elevated true salicylate concentrations. Depending on the assay, medications that reportedly interfered with accurate salicylate measurement include thioridazine, promethazine, prochlorperazine, chlorpromazine, *N*-acetylcysteine, and cysteamine.<sup>9</sup> Significantly falsely elevated serum salicylate concentrations are well recognized after diflunisal overdose.<sup>31,128</sup> Hyperbilirubinemia can create clinically significant false-positive results in neonates and adults.<sup>9,14</sup> Interestingly, hyperlipidemia can also cause significant interference and false elevation of serum salicylate concentrations.<sup>20</sup> If there is concern for false salicylate concentrations, clinicians should contact laboratory personnel, who often have information regarding instrument-specific recognized interferences for each assay as published by the manufacturer. Several techniques are used to determine a true salicylate concentration in the setting of a known interference. One of the most sensitive and specific assays now available is an automated immunoassay based on specific antisalicylate antiserum with fluorescence polarization immunoassay (FPIA) detection technology.<sup>9</sup>

### Interpretation of Serum Salicylate Concentrations and Correlation with Toxicity

The recommended therapeutic concentration of salicylate is 10 to 30 mg/dL, but this varies by indication. Antiinflammatory dosing usually is advised to be on the higher end of this spectrum, but analgesic effects occur as low as 5 to 10 mg/dL. Serum concentrations above 30 mg/dL are usually not found unless there is a supratherapeutic, acute, or chronic toxic exposure. Initial salicylate concentrations do not correlate with severe outcomes in salicylate poisoning.<sup>123</sup>

The correlation of serum salicylate concentrations and clinical toxicity is often poor and dependent on several factors. A concurrent arterial or venous blood pH should be determined when a serum salicylate concentration is obtained because in the presence of acidemia, more salicylic acid leaves the blood and enters the CSF and other tissues (Fig. 37-2), increasing

**FIGURE 37-2.** Rationale for alkalinization. Alkalinization of the plasma with respect to the tissues and alkalinization of the urine with respect to plasma shifts the equilibrium to the plasma and urine and away from the tissues, including the brain. This equilibrium shift results in "ion trapping."<sup>129</sup>

the toxicity. A decreasing serum salicylate concentration is difficult to interpret in isolation because it may reflect either an increased tissue distribution with increasing toxicity or an increased clearance with decreasing toxicity. Clinical correlation is required. For example, a decreasing serum salicylate concentration accompanied by a decreasing or low blood pH should be presumed to reflect a serious or worsening situation, not a benign or improving one. Patients with chronic toxicity demonstrate more significant clinical effects at lower concentrations compared with acute toxicity given the increased distribution over time into tissue compartments and specifically the CNS.

Although impractical clinically, salicylate concentrations in the CSF are likely the most accurate measure of toxicity, directly correlating with death in a rat model.<sup>57</sup> Animals that were lethally poisoned with salicylate were comatose and died from seizures. The time to death after salicylate administration varied greatly as did the blood, muscle, and liver salicylate concentrations. However, regardless of the time of death and the concentrations in blood, muscle, or liver, all animals died with a consistently narrow range of CSF salicylate concentrations.<sup>57</sup> Inhalation of CO<sub>2</sub> (lowering serum pH) in a rat resulted in a precipitous decrease in serum salicylate concentrations, which returned to baseline rapidly after the discontinuation of CO<sub>2</sub>.<sup>56</sup> This suggests that the salicylate redistributed into tissue during the period of induced respiratory acidosis and reequilibrated after its correction. After administration of radiolabeled salicylate to cats, autoradiographs of the brain visually and objectively documented the profound effect that acidemia has on the distribution of salicylate into the brain.<sup>49</sup>

Before serum assays were readily available, physicians who prescribed aspirin would advise patients to take repeated doses until tinnitus occurred and then “back off” a little to maintain this “steady state.” Tinnitus and the subsequent reversible hearing loss typically occur at serum salicylate concentrations of 20 to 45 mg/dL.<sup>13,16,94</sup> This prompted investigations into whether salicylate-induced tinnitus could be used as an indicator of serum salicylate concentration and toxicity. Unfortunately, some patients with therapeutic concentrations of salicylates had tinnitus, and many with higher or toxic concentrations had no tinnitus. In a study of 94 patients with salicylate concentrations above 30 mg/dL on one or more occasions, tinnitus only correlated with serum salicylate concentrations in 30%; 55% had no tinnitus, although audiologic testing results were usually abnormal regardless of the patient’s perception of presence or absence of tinnitus.<sup>53</sup> Thus, although symptomatic ototoxicity is a helpful warning sign of salicylate toxicity when present, it is too nonspecific and too insensitive to serve as an indicator of serum salicylate concentrations. Severe outcomes in salicylate poisoning were associated with increased respiratory rate, older age, and lactate concentrations above 2.25 mmol/L.<sup>123</sup>

## MANAGEMENT

The management of patients with salicylate poisoning is aimed at supporting vital signs and organ function, preventing or limiting ongoing exposure from the gut or skin, and enhancing elimination of salicylate that has already entered the systemic circulation. It is imperative to understand that there is no true antidote for salicylate toxicity; no xenobiotic can combat the clinical toxicity demonstrated in consequential exposures. Hemodialysis, as discussed later, aims to remove salicylate from the tissues but may not correct severe organ toxicity such as ARDS or cerebral edema and can therefore not guarantee survival after severe toxicity occurs.<sup>41,88</sup> Rather, all therapies are better at preventing tissue injury than treating it.

It is imperative to understand that the primary toxicity of salicylate is on the CNS, and the amount of salicylate in the brain is a function of pH with acidemia enhancing CNS penetration of the drug. Management strategies strive to create concentration gradients and pH conditions that favor exit of salicylate from the CNS and other tissues and enhanced renal elimination.

### Gastrointestinal Decontamination and Use of Activated Charcoal

The use of orogastric lavage and activated charcoal (AC) is discussed in Chap. 5 and Antidotes in Depth: A1. Their effects on the absorption and

elimination of salicylates have been extensively studied. In vitro studies demonstrate that each gram of AC maximally adsorbs approximately 550 mg of salicylic acid.<sup>80,96</sup> In humans, AC reduces the absorption of therapeutic doses of aspirin by 50% to 80%, effectively adsorbing aspirin released from enteric-coated and sustained-release preparations in addition to immediate-release tablets.<sup>80</sup> Presumably, the sooner AC is given after salicylate ingestion, the more effective it will be in reducing absorption. A 10:1 ratio of AC to ingested salicylate appears to result in maximal efficacy but is often impractical given the fact that ingestions of salicylate often reach 20- to 30-g amounts or more. Although peak serum concentrations are markedly decreased from predicted concentrations, aspirin desorption from the aspirin-AC complex in the alkaline milieu of the small bowel potentially diminishes the impact of AC on total absorption.<sup>43,84,96</sup> The addition of a cathartic to the initial dose of AC was abandoned for most xenobiotics, but a benefit of adding sorbitol to AC in preventing salicylate absorption was demonstrated in one study.<sup>71</sup>

Repetitive or multiple-dose AC (MDAC) is recommended to achieve desired ratios of AC to salicylate (and probably limits desorption), which reportedly reduces the concentration of initially absorbed salicylate to only 15% to 20%.<sup>43</sup> Multiple dose activated charcoal prevents absorption of unabsorbed salicylates over that achieved by single-dose AC.<sup>7,55,58</sup> Thus, the use of MDAC to decrease GI absorption of salicylates is recommended, particularly if a pharmacobezoar or extended-release preparation is suspected, barring contraindications (Antidotes in Depth: A1).

The value of MDAC in enhancing salicylate elimination through GI dialysis is considered controversial by some.<sup>3,63</sup> In one volunteer study of a 2,800-mg dose of aspirin followed by 25 g of AC at 4, 6, 8, and 10 hours after ingestion, the total amount of salicylate excreted from the body increased by 9% to 18% but was not considered statistically significant.<sup>72</sup> Efficacy is likely greater in an overdose situation, when more unbound salicylate is available because of decreased protein binding. However, in another study of the effects of MDAC on the clearance of high-dose intravenous (IV) aspirin in a porcine model, MDAC did not enhance the clearance of salicylates under conditions when the venous bicarbonate was kept at 15 mEq/L or less and urine pH kept at 7.5 or less.<sup>63</sup> In contrast to the findings of both of these studies, two children with salicylate overdoses were successfully treated with MDAC given every 4 hours for 36 hours, but it is unclear whether the predominant role of MDAC was to prevent absorption or enhance elimination.<sup>139</sup> Overall, the administration of two to four properly timed doses of AC is recommended. The administration of AC or MDAC must be balanced against risks of vomiting and aspiration, especially in patients with altered mental status and unprotected airways (Chap. 5).

In theory, whole-bowel irrigation (WBI) with polyethylene glycol electrolyte lavage solution (PEG-ELS) in addition to AC reduces absorption, particularly for enteric-coated aspirin preparations.<sup>131</sup> However, in an experimental model, WBI and MDAC did not increase the clearance of absorbed salicylate.<sup>84</sup>

### Fluid Replacement

There is a need to differentiate between restoration of fluid and electrolyte balance in salicylate-poisoned patients and increasing the fluid load presented to the kidneys in an attempt to achieve “forced diuresis.” Fluid losses in patients with salicylate poisoning are prominent, especially in children, and can be attributed to hyperventilation, vomiting, fever, a hypermetabolic state, polyuria, cathartic administration, and perspiration.<sup>5,130</sup> For all of these reasons, the patient’s volume status must be adequately assessed and corrected if necessary along with any glucose and electrolyte abnormalities. As in other cases, accurate management of volume status in poisoned patients may require invasive or noninvasive monitoring of central venous pressures, especially in patients with cardiac disease, ARDS, or AKI.

Increasing fluids beyond restoration of fluid balance to achieve forced diuresis is a practice that was inappropriately promoted in the past. Although forced diuresis theoretically increases renal tubular flow and reduces the urine tubular cell diffusion gradient for reabsorption, renal excretion of salicylate depends much more on urine pH than on flow rate, and use of forced diuresis under any circumstances is not effective regardless of whether

diuretics, osmotic agents, or large fluid volumes are used to achieve the diuresis.<sup>104</sup> Although renal salicylate clearance varies in direct proportion to flow rate, its relation to pH is logarithmic.<sup>66,75</sup> In summary, although fluid imbalance must be corrected, forced diuresis does little more than oral fluids to enhance elimination over a 24-hour period<sup>104</sup> and subjects the patient to the hazards of fluid overload and is therefore not recommended.

### Serum and Urine Alkalinization

The cornerstone of the management of patients with salicylate toxicity is to shift salicylate out of the brain and tissues into the serum, where elimination through the kidneys can then occur. Alkalinization of the serum with respect to the tissues and alkalinization of the urine with respect to the serum accomplishes this goal by facilitating the movement and “ion trapping” of salicylate into the serum and the urine (Fig. 37–2). Alkalinization of the serum by a substance that does not easily cross the blood–brain barrier such as intravenously administered sodium bicarbonate reduces the fraction of salicylate in the nonionized form and increases the pH gradient with the CSF. This both prevents entry and helps remove salicylate from the CNS.<sup>49,55–57,129</sup>

Serum alkalinization with IV sodium bicarbonate is recommended for all symptomatic patients whose serum salicylate concentrations exceed the therapeutic range and for clinically suspected cases of salicylism until a salicylate concentration and simultaneously obtained blood pH are available to guide treatment. Patients on therapeutic regimens of salicylates who feel well with salicylate concentrations of 30 to 40 mg/dL and who do not manifest toxicity do not require intervention.

Alkalinization is typically achieved with a bolus of 1 to 2 mEq/kg of sodium bicarbonate IV followed by an infusion of 3 ampules of sodium bicarbonate (132 mEq) in 1 L of 5% dextrose in water administered at 1.5 to 2.0 times the maintenance fluid range. Urine pH should be maintained at 7.5 to 8.0, and hypokalemia must be corrected (see later discussion) to achieve maximum urinary alkalinization. The volume load should remain modest while previous losses are repleted (Antidotes in Depth: A5).

Oral bicarbonate administration should never be substituted for IV bicarbonate to achieve alkalinization because the oral route potentially increases salicylate absorption from the GI tract by enhancing dissolution. Hyperventilation alone should not be relied on, and IV sodium bicarbonate should be used for alkalinization.

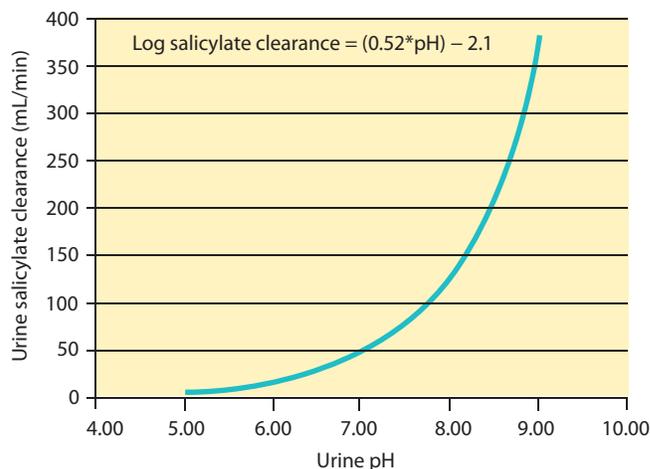

### Urine Alkalinization

Because salicylic acid is a weak acid ( $pK_a$  of 2.97), it is ionized in an alkaline milieu and theoretically can be “trapped” there. This occurs because there is no specific uptake mechanism in the kidney for salicylate ion, and passive reabsorption of a charged molecule is very limited. Thus, alkalinization of the urine (defined as a pH of 7.5 or greater) with sodium bicarbonate results in enhanced excretion of the ionized salicylate ion (Fig. 37–2).

Alkalinization of the urine is recommended as a first-line treatment for patients with moderately severe salicylate poisoning who do not meet the criteria for HD.<sup>106,134</sup> It is also recommended for salicylate-poisoned patients who require HD while preparations are being made to perform HD. Although salicylic acid is almost completely ionized within physiologic pH limits, small changes in pH obtained by alkalinization have substantial changes in the relative amount of salicylate in the charged form.

Regardless of the reason for the change in serum pH, renal excretion of salicylate is very dependent on urinary pH.<sup>66,104,140</sup> Alkalinization increases free salicylate secretion from the proximal tubule but does not affect renal elimination of salicylate conjugates. Alkalinizing the urine from a pH of 5 to 8 logarithmically increased renal salicylate clearance from 1.3 to 100 mL/min (Fig. 37–3).<sup>66,92</sup> Assuming an overdose  $V_d$  of 0.5 L/kg, this increased clearance would decrease the salicylate half-life from 310 to 4 hours. However, in reality, alkalinizing the urine from a pH of 5 to 8 has a more modest effect on serum salicylate clearance.<sup>104</sup>

Although the administration of acetazolamide, a noncompetitive carbonic anhydrase inhibitor, results in the formation of bicarbonate rich

**FIGURE 37–3.** The relationship between urine pH and urine salicylate clearance. This curve was adapted from a logarithmic relationship determined by Kallen in patients with salicylate poisoning. It illustrates the need to substantially increase urine pH above 7 to impact elimination.<sup>66</sup>

alkaline urine, it also causes a metabolic acidosis and acidemia.<sup>42,55,56</sup> This latter effect of acetazolamide is usually self-limited and mild but nevertheless increases the concentration of freely diffusible nonionized molecules of salicylic acid, thereby increasing the  $V_d$  and most probably enhancing the penetrance of salicylate into the CNS.<sup>56,79</sup>

Hypokalemia is a common complication of salicylate poisoning and sodium bicarbonate therapy and can prevent urinary alkalinization unless corrected. In the presence of hypokalemia, the renal tubules reabsorb potassium ions in exchange for hydrogen ions, preventing urinary alkalinization. If urinary alkalinization cannot be achieved easily, hypokalemia, excretion of organic acids, and salt and water depletion are the likely reasons for failure. Calcium concentrations should be monitored because decreases in both ionized<sup>30</sup> and total serum calcium<sup>44</sup> are also complications of bicarbonate therapy.

### Glucose Supplementation

As discussed earlier, salicylate poisoning significantly alters glucose metabolism, transport, and relative requirements. Clinically, this is relevant in that the presence of a normal serum glucose concentration may not be reflective of a normal CSF glucose concentration. The neurotoxicity of salicylism could be partly caused by this hypoglycorrhachia. Dextrose administration alone has reversed acute delirium associated with salicylate toxicity.<sup>23,24,69,74</sup> It is therefore recommended to liberally administer dextrose to all patients with altered mental status in salicylate toxicity regardless of their serum glucose concentration. A bolus of 0.5 to 1 g/kg of dextrose with additional doses or even continuous infusion is recommended for patients being treated for severe salicylate toxicity.

### Extracorporeal Removal

Indications for HD include severe salicylate poisoning, altered mental status, ARDS requiring supplemental oxygen, standard therapy is deemed to be failing regardless of the salicylate concentration, salicylate concentrations above 100 mg/dL, and salicylate concentrations above 90 mg/dL with impaired renal function<sup>65</sup> (Table 37–3). It is reasonable when a patient cannot tolerate the increased solute load that results from alkalinization or large-volume infusions necessary. Failure to tolerate such therapy can be anticipated if the patient has initial symptoms that are consistent with severe salicylate toxicity or has a history of congestive heart failure or chronic kidney disease.

In most instances, intermittent HD is the preferred method but hemoperfusion (HP) and continuous renal replacement therapies are appropriate when no HD is available.<sup>65</sup> Hemodialysis will not only clear the salicylate but also rapidly correct fluid, electrolyte, and acid–base disorders that will not be corrected by HP alone. The combination of HD and HP in series is feasible and theoretically may be useful for treating patients with severe or

**TABLE 37–3** Indications for Hemodialysis in Patients with Salicylate Poisoning**General Recommendation**

- Intermittent hemodialysis is the preferred modality.

**Indications**

ECTR is recommended if *any* of the following are met:

- Salicylate concentration  $\geq 100$  mg/dL ( $\geq 7.2$  mmol/L)
- Salicylate concentration  $\geq 90$  mg/dL ( $\geq 6.5$  mmol/L) in the presence of impaired kidney function
- Altered mental status
- New hypoxemia requiring supplemental oxygen
- If standard therapy (eg, supportive measures, bicarbonate) fails and:
  - Salicylate concentration  $\geq 90$  mg/dL ( $\geq 6.5$  mmol/L)
  - Salicylate concentration  $\geq 80$  mg/dL ( $\geq 5.8$  mmol/L) in the presence of impaired kidney function
  - If the systemic pH is  $\leq 7.20$

**Hemodialysis should be continued until**

- There is clear clinical improvement is apparent *and*
- Salicylate concentration  $< 19$  mg/dL (1.4 mmol/L) *or*
- Hemodialysis was performed for a period of at least 4–6 h when salicylate concentrations are not readily available

Modified with permission from Juurlink DN, Gosselin S, Kielstein JT, et al. Extracorporeal Treatment for Salicylate Poisoning: Systematic Review and Recommendations From the EXTRIP Workgroup. *Ann Emerg Med*. 2015 Aug;66(2):165–181.

mixed overdoses,<sup>28</sup> but it is rarely used. A rapid reduction of serum salicylate concentrations in severely poisoned patients was described with the use of continuous renal replacement therapy, a technique that may be valuable for patients who are too unstable to undergo HD or when HD is unavailable (Chap. 6).<sup>146</sup> There is only one published clinical experience with sustained low-efficiency dialysis for salicylate toxicity, which demonstrated similar clearance rates to other continuous extracorporeal therapies.<sup>81</sup> Exchange transfusion is recommended in neonates when HD is unavailable.<sup>65</sup>

While the patient is awaiting HD, alkalinization of serum and urine is recommended using sodium bicarbonate therapy. During HD, it is unnecessary to continue bicarbonate therapy because it will be provided by HD. It is prudent to reinstitute bicarbonate therapy after HD is completed, especially if patients are still symptomatic or serum salicylate concentrations are pending.

Nephrology consultation should be sought early and liberally to anticipate and prevent avoidable morbidity and mortality. Despite the well-recognized benefit of extracorporeal removal of salicylates in severe toxicity, delays in initiating HD remain a potentially preventable cause of death despite repeated calls over many years for prompt HD for patients with salicylate poisoning.<sup>41,88</sup>

In Table 37–3, impaired kidney function can be defined as advanced chronic kidney disease, AKI, when baseline not available, elevated creatinine of greater than 2 mg/dL in adults or 1.5 mg/dL in older adults, children with no baseline creatinine concentration, a serum creatinine greater than twice the upper limit of normal for age and sex or the presence of oligo- or anuria for more than 6 hours, regardless of serum creatinine concentration.<sup>65</sup>

The initiation of HD should not be considered definitive treatment because patients often still have a significant GI burden of salicylate, resulting in continued absorption. Even with early and multiple runs of HD, patients may still succumb to this poisoning, particularly if salicylate is still being absorbed from the GI tract into the blood.<sup>88</sup>

**Sedation, Intubation, and Mechanical Ventilation Risks**

Salicylate-poisoned patients have a significantly increased minute ventilation rate brought about by both tachypnea and hyperpnea, often exceeding 20 to 30 L/min. Any decrease in minute ventilation increases the PCO<sub>2</sub> and decreases the pH. This shifts salicylate into the CNS, exacerbating toxicity. Thus, extreme caution must be used with chemical sedation, intubation, and initiation of mechanical ventilation.

Although induced hyperventilation may effectively increase the blood pH in certain patients, endotracheal intubation followed by assisted ventilation

of a salicylate-poisoned patient poses particular risks if it is not meticulously performed. Although early endotracheal intubation to maintain hyperventilation will aid in the management of patients whose respiratory efforts are faltering, health care providers must maintain appropriate hypocarbia through hyperventilation. Ventilator settings that result in an increase in the patient's PCO<sub>2</sub> relative to premechanical ventilation will produce relative respiratory acidosis even if serum pH remains in the alkalemic range.

In a search of a poison control center database of patients with salicylate poisoning between 2001 and 2007, seven patients were identified with salicylate concentrations above 50 mg/dL who had both premechanical ventilation and postmechanical ventilation data. All seven had postmechanical ventilation pH values below 7.4, and five of the six for whom recorded PCO<sub>2</sub> values were available had postmechanical ventilation PCO<sub>2</sub> values above 50 mm Hg, suggesting substantial hypoventilation. Two of the seven patients died after intubation, and one sustained neurologic injury. Inadequate mechanical ventilation of patients with salicylate poisoning was associated with respiratory acidosis, a decrease in the serum pH, and an abrupt clinical deterioration.<sup>126</sup> Even when achieved, however, respiratory alkalosis sustained by hyperventilation (assisted or unassisted) alone should never be considered a substitute for use of either sodium bicarbonate (to achieve both alkalemia and alkaluria) or HD (when indicated).

If sedation is required, although there is no clear choice of preferred sedative, the goals are to minimize respiratory depression and use the minimum amount required for desired sedation. If intubation is deemed necessary, which it often is in severe toxicity or multidrug ingestions, the following steps should be taken to optimize before, during, and after intubation conditions. The goal should be to maintain or exceed minute ventilation rates that were present before intubation. Before intubation, an attempt should be made to optimize serum alkalization by administering a 2-mEq/kg bolus of sodium bicarbonate. Preparations should be made to minimize the time the patient will spend with apnea or decreased ventilation by considering an awake intubation. The provider most experienced in intubation should be present as well as any adjunct materials to increase first-pass success. An intensivist, respiratory technician, or other mechanical ventilator expert should be consulted to help match preintubation minute ventilation. After mechanical ventilation has begun, frequent blood gas monitoring should be obtained and ventilator settings adjusted as needed.<sup>126</sup> One report suggested the use of ketamine for awake intubation, thereby minimizing the hypoventilation associated with rapid-sequence intubation.<sup>39</sup>

If mechanical ventilation has already occurred or is planned in patients with salicylate toxicity, emergent nephrology consult is indicated for HD if not previously obtained.<sup>126</sup> In a retrospective single poison control center investigation of patients<sup>85</sup> in which symptoms, severity, and indications for HD cannot be reliably obtained,<sup>50</sup> patients who had salicylate concentrations above 50 mg/dL and were intubated demonstrated high rates of mortality when no HD was performed; in 56 cases, the overall survival rate was 73.2%, but without HD and a peak salicylate concentration above 50 mg/dL, only 56% survived, and no patients survived without HD when above 80 mg/dL.

**Serum Salicylate Concentration and pH Monitoring**

Careful observation of the patient, correlation of the serum salicylate concentrations with blood pH, and repeat determinations of serum salicylate concentrations every 2 to 4 hours are essential until the patient is clinically improving and has a low serum salicylate concentration in the presence of a normal or high blood pH. In all cases, after a presumed peak serum salicylate concentration is reached, at least one additional serum concentration should be obtained several hours later. Analyses should be obtained more frequently in managing seriously ill patients to assess the efficacy of treatment and the possible need for HD.

**Pediatric Considerations**

The predominant primary respiratory alkalosis that initially characterizes salicylate poisoning in adults either does not occur or is often transient in young children.<sup>47,129</sup> This likely results from the limited ventilatory reserve of

small children that prevents the same degree of sustained hyperpnea as occurs in adults. The typical acidemia noted in seriously poisoned children led some investigators in the past to incorrectly suggest that pediatric salicylate poisoning produces only metabolic acidosis. Although after a significant salicylate exposure, some children present with a mixed acid–base disturbance and a normal or high pH, most present with acidemia,<sup>47</sup> suggesting the need for more urgent intervention because the protective effect of alkalemia on CNS penetration of salicylate is already lost. Although not routinely recommended, exchange transfusion effectively removes large quantities of salicylate in infants too small to undergo emergent HD without extensive delays.<sup>82</sup>

## Pregnancy

Considered a rare event, salicylate poisoning during pregnancy poses a particular hazard to fetuses because of the acid–base and hematologic characteristics of fetuses and placental circulation. Salicylates cross the placenta and are present in higher concentrations in a fetus than in the mother. The respiratory stimulation that occurs in the mother after toxic exposures does not occur in the fetus, which has a decreased capacity to buffer acid. The ability of a fetus to metabolize and excrete salicylates is also less than in the mother. In addition to its toxic effects on the mother, including coagulation abnormalities, acid–base disturbances, tachypnea, and hypoglycemia, repeated exposure to salicylates late in gestation displaces bilirubin from protein binding sites in the fetus, causing kernicterus.

A case report described fetal demise in a woman who claimed to ingest 50 aspirin tablets per day for several weeks during the third trimester of pregnancy. This raises concerns that a fetus is at greater risk from salicylate exposures than is the mother. The need for emergent delivery of near-term fetuses of salicylate-poisoned mothers should be evaluated on a case-by-case basis (Chap. 30).<sup>98</sup>

## SUMMARY

- The clinical presentation of a patient with a salicylate overdose is best characterized by an early onset of nausea, vomiting, abdominal pain, tinnitus, and lethargy.
- The combination of a primary respiratory alkalosis and a primary metabolic acidosis with net alkalemia constitutes the classic early acid–base abnormality of salicylate poisoning in the adult.
- Initial efforts in managing patients with salicylate poisoning include restoration of intravascular volume, the provision of dextrose, the use of AC to limit absorption, and urinary alkalization to enhance renal elimination of salicylate.
- Hemodialysis is indicated in patients with significant salicylate toxicity (eg, altered mental status, ARDS, AKI, or the inability to administer sodium bicarbonate) and significantly elevated salicylate concentrations.
- It is essential to maintain alkalemia to prevent CNS penetration of salicylate. As such, sedation and mechanical ventilation can be rapidly lethal if they impair minute ventilation, causing a rise in PCO<sub>2</sub> and a fall in pH.

## SODIUM BICARBONATE

Paul M. Wax and Ashley Haynes

## INTRODUCTION

Sodium bicarbonate is a nonspecific antidote that is effective in the treatment of a variety of poisonings by means of a number of distinct mechanisms (Table A5-1). However, the support for its use in these settings is predominantly based on animal evidence, case reports, and consensus.<sup>13</sup> It is most commonly used in toxicology as a treatment for patients with cyclic anti-depressant (CA) and salicylate poisonings. Sodium bicarbonate also has a role in the treatment of phenobarbital, chlorpropamide, and chlorophenoxy herbicide poisonings and wide-complex tachydysrhythmias induced by Na<sup>+</sup> channel blocking type IA and IC antidysrhythmics and cocaine. Correcting the life-threatening acidemia induced by cyanide, methanol, and ethylene glycol metabolism and enhancing formate elimination are other important indications for sodium bicarbonate.

## PHARMACOLOGY

Sodium bicarbonate has a molecular weight of 84 Da. It is supplied in solution at approximately pH 8.0 (pH limits range from 7.0 to 8.5). The onset of action of intravenous (IV) sodium bicarbonate is rapid with a duration of action of 8 to 10 minutes.<sup>3</sup> Sodium bicarbonate increases plasma bicarbonate and buffers excess hydrogen ion.<sup>35</sup> In normal individuals, the distribution volume for bicarbonate salts is approximately twice the extracellular fluid (ECF) volume.<sup>46,103</sup> The apparent bicarbonate space (ABS) proportionally increases in severe acidemia, leading to higher bicarbonate requirements.<sup>41</sup> Canine studies demonstrated that this effect is not due to the acidemia per se but due to the tight correlation of extracellular bicarbonate concentrations with the ABS.<sup>1</sup> Low bicarbonate concentrations increase the apparent volume of distribution in a highly dynamic manner.<sup>1</sup> Human studies, in which the ABS is described by the equation  $ABS = (0.36 + 2.44/[HCO_3^-]) \times \text{weight (kg)}$  appear to support this concept.<sup>90</sup>

## ALTERED INTERACTION BETWEEN XENOBIOTIC AND SODIUM CHANNEL

The most important role of sodium bicarbonate in toxicology is the ability to reverse potentially fatal cardiotoxic effects of myocardial Na<sup>+</sup> channel blockers such as CAs and other type IA and IC antidysrhythmics.<sup>19</sup> Its mechanism of action in these cases results from both an increase in [Na<sup>+</sup>] and a change in the proportion of the Na<sup>+</sup> channel blocker that is ionized, resulting in an altered distribution away from its channel.<sup>95</sup> Use of sodium bicarbonate for myocardial Na<sup>+</sup> channel blocker overdose developed as an extension of sodium lactate use in the treatment of patients with toxicity from type IA antidysrhythmics. Noting similarities in electrocardiographic (ECG) findings between hyperkalemia and quinidine toxicity (ie, QRS widening), investigators in the 1950s began to use sodium lactate (which is rapidly metabolized in the liver to sodium bicarbonate) to treat quinidine

and procainamide toxicity.<sup>6,12,111</sup> In a canine model, quinidine-induced ECG changes and hypotension were consistently reversed by infusion of sodium lactate.<sup>11</sup> Clinical experience confirmed this benefit.<sup>12</sup> Similar efficacy in the treatment of patients with procainamide cardiotoxicity was also reported.<sup>111</sup>

The introduction of CAs during the 1960s yielded reports of conduction disturbances, dysrhythmias, and hypotension occurring in overdose. Extending the use of sodium lactate for the type I antidysrhythmics to CA poisoning, uncontrolled observations in the 1970s showed a decrease in mortality rate from 15% to less than 3%.<sup>42</sup> In 1976, sodium bicarbonate was successful in a pediatric series of CA-induced dysrhythmias.<sup>20</sup> In this series, 9 of 12 children who developed multifocal premature ventricular contractions, ventricular tachycardia, or heart block reverted to normal sinus rhythm with sodium bicarbonate therapy alone. An early canine experiment of amitriptyline-poisoning demonstrated resolution of dysrhythmias upon blood alkalization to a blood pH above 7.40.<sup>20</sup>

An improved understanding of the mechanism and utility of sodium bicarbonate came from a series of animal experiments during the 1980s. In amitriptyline-poisoned dogs, sodium bicarbonate reversed conduction disturbances and ventricular dysrhythmias and suppressed ventricular ectopy.<sup>74</sup> When comparing sodium bicarbonate, respiratory alkalemia (hyperventilation), hypertonic (3%) sodium chloride, and lidocaine, both sodium bicarbonate and hyperventilation proved most efficacious in reversing ventricular dysrhythmias and narrowing QRS prolongation.

In desipramine-poisoned rats, the isolated use of either hypertonic sodium chloride or sodium bicarbonate was effective in decreasing QRS duration.<sup>80</sup> Both sodium bicarbonate and hypertonic sodium chloride also increased mean arterial pressure, but hyperventilation or direct intravascular volume repletion with mannitol did not. In further studies both in vivo and on isolated cardiac tissue, alkalization and increased sodium concentration improved CA effects on cardiac conduction.<sup>95,96</sup> Although respiratory alkalemia and hypertonic sodium chloride each independently improved conduction velocity, this effect was greatest when sodium bicarbonate was administered.

Another study on amitriptyline-poisoned rats demonstrated that treatment with hypertonic sodium bicarbonate was associated with shorter QRS interval, longer duration of sinus rhythm, and increased survival rates.<sup>57</sup> Sodium bicarbonate works independently of initial blood pH. Animal studies show that cardiac conduction improves after treatment with sodium bicarbonate or hypertonic sodium chloride in both normal and academic animals.<sup>80</sup> Clinically, CA-poisoned patients who were already alkalemic responded to repeat doses of sodium bicarbonate.<sup>71</sup>

Although several authors suggested that the efficacy of sodium bicarbonate is modulated via a pH-dependent change in plasma protein binding that decreases the proportion of free drug,<sup>21,62</sup> further study failed to support this hypothesis.<sup>83</sup> The administration of large doses of a binding protein  $\alpha_1$ -acid glycoprotein (AAG) (to which CAs show significant affinity) to desipramine-poisoned rats only minimally decreased cardiotoxicity. Although the addition of AAG increased the concentrations of total desipramine and protein-bound desipramine in the serum, the concentration of active free desipramine did not decline significantly. A redistribution of CA from peripheral sites prevented lowering of free desipramine concentration.<sup>83</sup> The persistence of other CA-associated toxicities, antimuscarinic effects and seizures, also argues against changes in protein-binding modulating toxicity. In vitro

**TABLE A5-1 Sodium Bicarbonate: Mechanisms, Site of Action, and Uses in Toxicology**

Mechanism	Site of Action	Uses
Alters interaction between the xenobiotic and Na <sup>+</sup> channel	Heart	β-Adrenergic antagonists with MSA
		Amantadine
		Bupropion
		Carbamazepine
		Chloroquine
		Citalopram
		Cocaine
		Cyclic antidepressants
		Dimenhydrinate
		Diphenhydramine
		Disopyramide
		Encainide
		Flecainide
		Fluoxetine
		Hydroxychloroquine
		Lamotrigine
		Mesoridazine
		Orphenadrine
		Procainamide
		Propafenone
		Propoxyphene
		Quinidine
		Quinine
Thioridazine		
Venlafaxine		
Alters xenobiotic ionization leading to altered tissue distribution	Retina	Formic acid
	Brain	Phenobarbital
		Salicylates
Alters xenobiotic ionization leading to enhanced xenobiotic elimination	Kidneys	Chlorophenoxy herbicides
		Chlorpropamide
		Diffunisal
		Fluoride
		Formic acid
		Methotrexate
		Phenobarbital
		Salicylates
		Uranium
		Corrects life-threatening acidemia
Ethylene glycol		
Metformin		
Methanol		
Increases xenobiotic solubility	Kidneys	DAMPA
		Methotrexate
Neutralization	Lungs	Chlorine gas, HCl
Maintenance of chelator effect	Kidneys	Dimercaprol (BAL)—metal
Prevents ferriheme release from myoglobin	Kidneys	Drug-induced rhabdomyolysis
Shifts potassium into cells		Drug-induced hyperkalemia

BAL = British anti-Lewisite; DAMPA = methotrexate metabolite 4-amino-4-deoxy-10-methylpteroic acid; MSA = membrane-stabilizing activity acebutolol, betaxolol, carvedilol, metoprolol, oxprenolol, propranolol.

studies performed in plasma protein-free bath further substantiate sodium bicarbonate's efficacy independent of plasma protein binding.<sup>95</sup>

Sodium bicarbonate has a crucial antidotal role in myocardial Na<sup>+</sup> channel blocker poisoning by increasing the number of open Na<sup>+</sup> channels, thereby partially reversing fast Na<sup>+</sup> channel blockade. This decreases QRS prolongation and reduces life-threatening cardiovascular toxicity such as ventricular dysrhythmias and hypotension.<sup>74,80,95</sup> The animal evidence supports two distinct and additive mechanisms for this effect: a pH-dependent effect and a sodium-dependent effect. The pH-dependent effect increases the fraction of the more freely diffusible nonionized xenobiotic. Both the ionized xenobiotic and the nonionized forms are able to bind to the Na<sup>+</sup> channel, but assuming myocardial Na<sup>+</sup> channel blockers act like local anesthetics, it is estimated that 90% of the block results from the ionized form. Increase the nonionized fraction limits the quantity of xenobiotic available to bind to the Na<sup>+</sup> channel. The sodium-dependent effect increases the availability of Na<sup>+</sup> ions to pass through the open channels. Decreased ionization should not significantly decrease the rate of CA elimination because of the small contribution of renal pathways to overall CA elimination (<5%). Sodium displaces flecainide and likely other Na<sup>+</sup> channel blocking drugs from the channel itself.<sup>88</sup>

Although anecdotal accounts support the efficacy of sodium bicarbonate in treating CA cardiotoxicity in humans,<sup>50</sup> these reports are uncontrolled observations; controlled studies are unavailable. In one of the largest retrospective observational studies involving 91 patients who received sodium bicarbonate after CA overdose, QRS complex widening corrected in 39 of 49 patients who had QRS durations above 120 ms, and hypotension corrected within 1 hour in 20 of 21 patients who had systolic blood pressures below 90 mm Hg.<sup>51</sup> Use of sodium bicarbonate was not associated with any complications in this study.

Prospective validation of treatment criteria for use of sodium bicarbonate after CA overdose have not been performed. Recommended indications are conduction delays (QRS complex duration above 100 ms or a right bundle branch block), wide-complex tachydysrhythmias, and hypotension.<sup>63</sup> Because studies demonstrate a critical threshold QRS complex duration (160 ms or greater) at which ventricular dysrhythmias significantly increase in propensity,<sup>16</sup> it seems reasonable that narrowing the QRS complex duration through use of sodium bicarbonate or hyperventilation prevents the development of dysrhythmias. Practice patterns vary considerably with regard to the use of sodium bicarbonate when the QRS complex duration is below 160 ms.<sup>100</sup> Although sodium bicarbonate has no proven efficacy in either the treatment or prophylaxis of CA-induced seizures, seizures often produce acidemia, which rapidly increases the risks of conduction disturbances and ventricular dysrhythmias.<sup>107</sup> Administering sodium bicarbonate when the QRS complex duration is 100 ms or greater establishes a theoretical margin of safety in the event the patient suddenly deteriorates without adding significant demonstrable risk. When the QRS complex duration is below 100 ms, given the minimal risk of seizures or dysrhythmias, we recommend not to administer prophylactic sodium bicarbonate.<sup>101</sup> In patients exhibiting a type I Brugada ECG pattern (right bundle branch block with downsloping ST segment elevation in V1–V3) and QRS complex widening after CA ingestion, sodium bicarbonate administration narrows the QRS complex. Depending on the nature of the patient's intrinsic channel and degree of acquired channelopathy, the unmasked Brugada pattern may or may not reverse (Chap. 15).<sup>9,56,65</sup>

Because cardiotoxicity often worsens during the first few hours after ingestion, we recommend sodium bicarbonate therapy be initiated immediately if the QRS interval is greater than 100 ms. Because CA-induced hypotension responds to sodium bicarbonate, we recommend hypotension be treated with prompt sodium bicarbonate therapy. In CA-poisoned patients who present with altered mental status or seizures without QRS complex widening or hypotension, we recommend not to give sodium bicarbonate.

Because the potential benefits of alkalinization in CA overdose usually outweigh the risks, we recommend sodium bicarbonate be administered regardless of whether the patient has an acidemic or normal pH.

The time to resolution of conduction abnormalities during continuous bicarbonate infusion varies significantly, ranging from several hours to several days.<sup>64,101</sup> Potential ongoing or delayed absorption because of antimuscarinic CA properties, CA pharmacologic preparations, coingestants, and other factors may play into this. In a case of poisoning from modified-release amitriptyline, sodium bicarbonate was required on multiple occasions over 110 hours after the initial ingestion to reverse ongoing Na<sup>+</sup> channel conduction disturbances.<sup>75</sup> It is reasonable to discontinue sodium bicarbonate infusion upon hemodynamic improvement and resolution of cardiac conduction abnormalities and altered mental status, although controlled data supporting such an approach are lacking.

Sodium bicarbonate is useful in treating patients with cardiotoxicity from other myocardial Na<sup>+</sup> channel blockers that present with widened QRS complexes, dysrhythmias, and hypotension. Isolated case reports provide the bulk of the evidence in these situations. The utility of sodium bicarbonate in treating patients with type IA and IC antidysrhythmics, diphenhydramine, quinine, cocaine, and others is demonstrated.<sup>15,30,33,91,93,102,111</sup>

Use of sodium bicarbonate in the treatment of patients with overdoses of amantadine, a xenobiotic with multiple myocardial channel effects, was suggested, but concurrent hypokalemia limits its use.<sup>98</sup> Although the usefulness of sodium bicarbonate in reversing QRS complex widening is occasionally observed during fluoxetine and citalopram overdose,<sup>22,34,43</sup> Na<sup>+</sup> channel disturbances are uncommon in most cases of selective serotonin reuptake inhibitor (SSRI) overdose. Routine use of alkalinization therapy in SSRI toxicity is not recommended, as it might risk worsening QT interval prolongation by promoting hypokalemia. It is reasonable to administer sodium bicarbonate in the management of patients with other ingestions associated with type IA–like cardiac conduction abnormalities and dysrhythmias, such as carbamazepine, lamotrigine, and the phenothiazines thioridazine and mesoridazine.<sup>47</sup> Case reports regarding bupropion toxicity have been mixed, with some demonstrating no response to sodium bicarbonate,<sup>2,32,112</sup> but others support its use.<sup>38</sup> The reported lack of efficacy of sodium bicarbonate in reversing QRS complex prolongation caused by bupropion poisoning is due to prolongation of QRS complex by an alternate mechanism.<sup>112</sup> Bupropion contributes to QRS prolongation because of reduction of cardiac intercellular coupling (ie, inhibition of gap junction communication), as opposed to Na<sup>+</sup> channel blockade.<sup>25</sup> Given that the potential benefit may outweigh the risks, it is reasonable to use sodium bicarbonate in the setting of bupropion toxicity.

Cocaine, a local anesthetic with membrane-stabilizing properties resembling other type I antidysrhythmics, causes similar conduction disturbances. In several canine models of cocaine toxicity, sodium bicarbonate successfully reversed cocaine-induced QRS complex prolongation<sup>107,78</sup> and improved myocardial function.<sup>113</sup> Of interest, sodium loading by itself failed to produce a benefit. Similar findings were demonstrated in cocaine-treated guinea pig hearts.<sup>114</sup> Patients with cocaine-induced cardiotoxicity responded to treatment with sodium bicarbonate.<sup>55,77,110</sup> In many of these cases, simultaneous treatment with sedation, active cooling, and hyperventilation confounds the interpretation of the benefit of sodium bicarbonate; however, given its mechanism of action, we recommend its use.

## ALTERED XENOBIOTIC IONIZATION TO ALTER DISTRIBUTION AND ENHANCE ELIMINATION

### Salicylates

Although there is no known specific antidote, judicious sodium bicarbonate use is recommended in the treatment of salicylate toxicity. Through its ability to alter the concentration gradient of the ionized and nonionized fractions of salicylates, sodium bicarbonate decreases tissue (eg, CNS) concentrations of salicylates and enhances urinary elimination of salicylates.<sup>86</sup>

Salicylate is a weak acid with a pK<sub>a</sub> of 3.0. As pH increases, the ionized proportion increases. Because of the presence of polar groups, ionized molecules penetrate lipid-soluble membranes less efficiently than do nonionized molecules. Consequently, when the ionized forms predominate, weak

acids such as salicylates accumulate in an alkaline milieu, such as an alkaline urine (Fig. 37-2).<sup>68,105</sup>

Although alkalinizing the urine to increase salicylate elimination is an important intervention in the treatment of patients with salicylate poisoning, increasing the serum pH in patients with severe salicylism proves even more consequential by protecting the brain from a lethal central nervous system (CNS) salicylate burden. In these patients, using sodium bicarbonate to “trap” salicylate in the blood by keeping it out of the brain decreases the likelihood of clinical deterioration. Salicylate lethality is directly related to primary CNS dysfunction, which in turn corresponds to a “critical brain salicylate concentration.”<sup>49</sup> At physiologic pH, at which a very small proportion of the salicylate is in the nonionized form, a small change in pH is associated with a significant change in amount of nonionized molecules. For example, whereas at a pH of 7.40, 0.004% of the salicylate molecules are in the nonionized form, at a pH of 7.20, 0.008%, of the salicylate is in the nonionized form. In experimental models, lowering the blood pH produced a shift of salicylate into the tissues.<sup>23</sup> Hence, acidemia in patients with significant salicylate poisonings is devastating. In salicylate-poisoned rats, increasing the blood pH with sodium bicarbonate produced a shift in salicylate out of the tissues and into the blood.<sup>48</sup> This change in salicylate distribution did not result from enhanced urinary excretion because occlusion of the renal pedicles failed to alter these results.

Enhancing the elimination of salicylate by trapping ionized salicylate in the urine is also beneficial. Salicylate elimination at therapeutic concentrations is predominantly through first-order hepatic metabolism. At these low concentrations, without alkalinization, only approximately 10% to 20% of salicylate is eliminated unchanged in the urine. With increasing concentrations, enzyme saturation occurs (Michaelis-Menten kinetics); thus, a larger percentage of elimination occurs as unchanged free salicylate. Under these conditions, in an alkaline urine, urinary excretion of free salicylate becomes even more significant, accounting for 60% to 85% of total elimination.<sup>44,89</sup> The relationship between salicylate clearance and urine pH— $\log(\text{Salicylate clearance}) = [(0.52 \times \text{pH}) - 2.1]$ <sup>54</sup>—would suggest that increasing urine pH from 5.0 to 8.0 could increase the amount of salicylate cleared by almost 40-fold.

The exact mechanism of pH-dependent salicylate elimination has generated controversy. The pH-dependent increase in urinary elimination initially was ascribed to “ion trapping,” which is the filtering of both ionized and nonionized salicylate while reabsorbing only the nonionized salicylate.<sup>99</sup> However, limiting reabsorption of the ionizable fraction of filtered salicylate cannot be the primary mechanism responsible for enhanced elimination produced by sodium bicarbonate.<sup>66</sup> Because the quantitative difference between the percentage of molecules trapped in the ionized form at a pH of 5.0 (99% ionized) and a pH of 8.0 (99.999% ionized) is small, decreases in tubular reabsorption cannot fully explain the rapid increase in urinary elimination seen at a pH above 7.0.

“Diffusion theory” offers a reasonable alternative explanation. Fick’s law of diffusion states that the rate of flow of a diffusing substance is proportional to its concentration gradient. At a higher urinary pH, a greater proportion of secreted nonionized molecules quickly becomes ionized upon entering the alkaline environment, and more salicylate (ie, nonionized salicylate) must pass from the peritubular fluid into the urine in an attempt to reach equilibrium with the nonionized fraction. In fact, as long as nonionized molecules are rapidly converted to ionized molecules in the urine, equilibrium in the alkaline milieu will never be achieved. The concentration gradient of peritubular nonionized salicylates to urinary nonionized salicylates continues to increase with increasing urinary pH. Hence, increased tubular diffusion, not decreased reabsorption, probably accounts for most of the increase in salicylate elimination observed in the alkaline urine.<sup>66</sup>

We recommend sodium bicarbonate in the treatment of salicylate poisoning for most patients with evidence of significant systemic toxicity. Relative contraindications to sodium bicarbonate use include severe acute kidney injury (AKI) or chronic kidney disease (CKD) and acute respiratory distress syndrome.<sup>54</sup> Dosing recommendations depend on the acid–base

considerations. We recommend alkalinization be started with a continuous sodium bicarbonate infusion of 150 mEq in 1 L of dextrose in water (D<sub>5</sub>W) at 150 to 200 mL/h (or about twice the maintenance requirements in a child). Continued titration with sodium bicarbonate over 4 to 8 hours is recommended until the urinary pH reaches 7.5 to 8.0.<sup>106,108</sup> For patients with low serum bicarbonate, IV administration of 1 to 2 mEq of sodium bicarbonate per kilogram of body weight is recommended.<sup>108</sup> The addition of the dextrose is important because salicylate toxicity causes hypoglycemia.<sup>108</sup> Achieving a urinary pH of 8.0 is difficult but is the goal. Fastidious attention to the patient's changing acid–base status is required. Blood pH should not rise above 7.55 to prevent complications of alkalemia, although some clinicians would accept a ceiling of 7.60, depending on the risk–benefit circumstances.<sup>51,61,97,100</sup> In hypokalemic patients, the kidneys preferentially reabsorb potassium in exchange for hydrogen ions. Urinary alkalinization will be unsuccessful as long as hydrogen ions are excreted into the urine. Thus, concurrent potassium supplementation to achieve and maintain normokalemia is required to alkalinize the urine.<sup>115</sup>

### Phenobarbital

Although cardiopulmonary support is the most critical intervention in the treatment of patients with severe phenobarbital overdose, sodium bicarbonate is a useful adjunct to general supportive care. The utility of sodium bicarbonate is particularly important considering the long plasma half-life (~100 hours) of phenobarbital. Phenobarbital is a weak acid (pK<sub>a</sub> of 7.24) that undergoes significant renal elimination. As in the case of salicylates, alkalinization of the blood and urine reduces the severity and duration of toxicity. In a study of mice, the median anesthetic dose for mice receiving phenobarbital increased by 20% with the addition of sufficient sodium bicarbonate to increase the blood pH from 7.23 to 7.41, demonstrating decreased tissue concentrations associated with increased pH.<sup>109</sup> Animal evidence extrapolated to humans suggests that phenobarbital-poisoned patients in deep coma might develop a respiratory acidosis secondary to hypoventilation, with the acidemia enhancing the phenobarbital transfer into the brain, thus worsening CNS and respiratory depression. Alternatively, increasing the pH with bicarbonate, ventilatory support, or both would enhance the phenobarbital efflux from brain, thus lessening toxicity. Given phenobarbital's relatively high pK<sub>a</sub>, significant urinary phenobarbital accumulation is evident only when urinary pH is increased above 7.5.<sup>14</sup> As the pH approaches 8.0, a threefold increase in urinary elimination occurs. The urine-to-serum ratio of phenobarbital, although much higher in alkaline urine than in acidic urine, remains less than unity, thereby suggesting less of a role for tubular secretion than in salicylate poisoning.

Clinical studies examining the role of alkalinization in phenobarbital poisoning are inadequately designed. Many are poorly controlled and fail to examine the effects of alkalinization, independent of coadministered diuretic therapy. In one uncontrolled study with phenobarbital overdoses, a 59% to 67% decrease in the duration of unconsciousness in patients occurred in patients administered alkali compared with nonrandomized control participants.<sup>70</sup> In other older studies, treatment with sodium lactate and urea reduced mortality and frequency of tracheotomy to 50% of control participants, enhanced elimination, and shortened coma.<sup>60,73</sup> In a later human volunteer study, urinary alkalinization with sodium bicarbonate in addition to hydration was associated with a decrease in phenobarbital elimination half-life from 148 to 47 hours.<sup>39</sup> However, this beneficial effect was less than the effect achieved by multiple-dose activated charcoal (MDAC), which reduced the half-life to 19 hours. In a nonrandomized study of phenobarbital-poisoned patients comparing urinary alkalinization alone, MDAC alone, and both methods together, both the phenobarbital half-life decreased most rapidly and the clinical course improved most rapidly in the group of patients who received MDAC alone.<sup>69</sup> Interesting, the combination approach proved inferior to MDAC alone but was better than alkalinization alone. The authors speculated that when both treatments were used together, the increased ionization of phenobarbital resulting from sodium bicarbonate infusion might have decreased the efficacy of MDAC. Although these studies suggest that

MDAC is more efficacious than urinary alkalinization in the treatment of phenobarbital-poisoned patients, in patients with contraindications to MDAC, it is reasonable to alkalinize the urine.

We do not currently recommend sodium bicarbonate therapy in the treatment of patients with ingestions of other barbiturates, such as pentobarbital and secobarbital, which either have a pK<sub>a</sub> above 8.0 or are predominantly eliminated hepatically.

### Methotrexate

Urinary alkalinization with sodium bicarbonate in addition to hydration is routinely used during high-dose methotrexate cancer chemotherapy to achieve a urine pH of 7.0 or greater prior to methotrexate administration.<sup>105</sup> Methotrexate is predominantly eliminated unchanged in the urine. Unfortunately, methotrexate, as well as its metabolites DAMPA (4-amino-4-deoxy-10-methylpteroic acid) and 7-hydroxymethotrexate, are poorly water soluble in acidic urine. Under these conditions, tubular precipitation of the methotrexate occurs, leading to AKI and decreased elimination, increasing the likelihood of methotrexate toxicity. Administration of sodium bicarbonate (as well as intensive hydration) during high-dose methotrexate infusions increases methotrexate solubility and the elimination of methotrexate and its metabolites.<sup>29,94</sup> Formal studies in which chemotherapy was dosed per body surface have included bicarbonate infusions up to 200 mL/m<sup>2</sup>/h for 8 hours with 5.4 gm/m<sup>2</sup> commencing 1 hour before methotrexate infusion.<sup>87</sup> In practice, alkalinization is typically maintained with intravenous sodium bicarbonate 50–150 mEq/L to achieve adequate urine flow and alkalinization until leucovorin administration ceases. In the setting of methotrexate toxicity, it is reasonable to provide sodium bicarbonate 150 mEq in 1 L of dextrose in water (D<sub>5</sub>W) at 150 to 250 mL/h, in a manner similar to salicylate toxicity until methotrexate has cleared.

### Chlorophenoxy Herbicides

Alkalinization is recommended in the treatment of patients with poisonings from weed killers that contain chlorophenoxy compounds, such as 2,4-dichlorophenoxyacetic acid (2,4-D) or 2-(4-chloro-2-methylphenoxy) propionic acid (MCP),<sup>85</sup> Poisoning results in muscle weakness, peripheral neuropathy, coma, hyperthermia, and acidemia. These compounds are weak acids (pK<sub>a</sub> of 2.6 and 3.8 for 2,4-D and MCP, respectively) that are excreted largely unchanged in the urine. In an uncontrolled case series of 41 patients poisoned with a variety of chlorophenoxy herbicides, 19 of whom received sodium bicarbonate, alkaline diuresis significantly reduced the half-life of each by enhancing renal elimination.<sup>36</sup> In one patient, resolution of hyperthermia and metabolic acidosis and improvement in mental status were associated with a transient elevation of serum concentration, perhaps reflecting chlorophenoxy compound redistribution from the tissues into the more alkalemic blood. The limited data suggest that the increased ionized fractions of the weak-acid chlorophenoxy compounds produced by alkalinization is trapped in both the blood and the urine as demonstrated both with salicylates and phenobarbital. Although data are limited to case reports, it is reasonable to administer sodium bicarbonate because of evidence that its use shortens the duration of effect.

### CORRECTION OF LIFE-THREATENING METABOLIC ACIDOSIS

Some toxins cause an accumulation of acid byproducts leading to metabolic acidosis. Unchecked, metabolic acidosis leading to acidemia has important physiologic consequences. These are complex and depend on multiple other factors as well, including compensatory mechanisms, with the most severe effects involving the cardiovascular system.<sup>31</sup> When blood pH decreases from 7.40 to 7.20, cardiac output increases because of increased catecholamine concentrations, but when below 7.10 to 7.20, a decrease in cardiac output ensues.<sup>58</sup> Other cardiovascular effects include increased propensity for dysrhythmias, decreased systemic vascular tone, and pulmonary vasoconstriction.<sup>58</sup> The respiratory system suffers from increased respiratory stimulus and increased work of breathing. Additionally, 2,3-DPG (2,3-diphosphoglycerate) decreases, leading to a rightward shift of the oxygen dissociation curve and

decreased release of oxygen to the tissues. Further consequences include cerebral vasodilation, hyperkalemia, hypercalcemia, increased renal oxygen demand and diuresis, decreased splanchnic perfusion with delayed gastric emptying, impaired platelet aggregation, and coagulopathy.<sup>31,58</sup>

Treatment of metabolic acidosis is largely aimed at treating the underlying cause. However, because the effects of persistent acidemia are severe, sodium bicarbonate is reasonable to administer to correct the acidemia in toxic alcohols and metformin toxicity.

### Toxic Alcohols

Sodium bicarbonate has two important roles in treating patients with toxic alcohol ingestions. As an immediate temporizing measure, it is reasonable to consider administration of sodium bicarbonate to treat the life-threatening acidemia associated with methanol and ethylene glycol ingestions. In rats poisoned with ethylene glycol, the administration of sodium bicarbonate alone resulted in a fourfold increase in the median lethal dose.<sup>17</sup> Clinically, titrating the endogenous acid with bicarbonate greatly assists in reversing the consequences of severe acidemia, such as hemodynamic instability and multiorgan dysfunction.

The second role of bicarbonate in the treatment of toxic alcohol poisoning involves its ability to favorably alter the distribution and elimination of certain toxic metabolites.<sup>92</sup> In cases of methanol poisoning, the proportion of ionized formic acid is increased by administering bicarbonate, thereby trapping formic acid in the blood compartment.<sup>53,67</sup> Consequently, decreased visual toxicity results from removal of the toxic metabolite from the eyes. In cases of formic acid ( $pK_a$  of 3.7) ingestion, sodium bicarbonate decreases tissue penetration of the formic acid and enhances urinary elimination.<sup>72</sup>

Early treatment of acidemia with sodium bicarbonate is recommended in cases of methanol and ethylene glycol poisoning.<sup>46,59</sup> Sodium bicarbonate therapy should be administered to toxic alcohol-poisoned patients with an arterial pH below 7.30.<sup>7,8</sup> More than 400 to 600 mEq of sodium bicarbonate may be required in the first few hours.<sup>52</sup> In cases of ethylene glycol toxicity, sodium bicarbonate administration worsens hypocalcemia, so the serum calcium concentration should be monitored. Combating the acidemia, however, is not the mainstay of therapy, and concurrent administration of IV fomepizole or ethanol and evaluation for hemodialysis are almost always indicated.

### Metformin

Metformin toxicity, either from overdose or therapeutic use in the setting of AKI or CKD, causes severe, life-threatening metabolic acidemia with an elevated lactate concentration. The use of high-dose sodium bicarbonate to correct the metabolic acidosis, as well as extracorporeal removal of the metformin, is recommended in these cases.<sup>26,45</sup> Although an exact threshold for initiating sodium bicarbonate is not well-defined, it would be reasonable to initiate this in severe acidosis, similar to that of other causes of acidosis (pH <7.10, serum bicarbonate <10 mmol/L).<sup>58</sup>

## NEUTRALIZATION

### Chlorine Gas

Nebulized sodium bicarbonate serves as a useful adjunct in the treatment of patients with pulmonary injuries resulting from chlorine gas inhalation.<sup>5,27</sup> Inhaled sodium bicarbonate neutralizes the hydrochloric acid that is formed when the chlorine gas reacts with the water in the respiratory tree. Although oral sodium bicarbonate is not recommended for neutralizing acid ingestions because of the problems associated with the exothermic reaction and production of carbon dioxide in the relatively closed gastrointestinal tract, the rapid exchange of air in the lungs with the environment facilitates heat dissipation. In a sheep model of chlorine inhalation, animals treated with 4% nebulized sodium bicarbonate solution demonstrated a higher  $PO_2$  and lower  $PCO_2$  than did the 0.9% sodium chloride treated animals.<sup>28</sup> There was no difference, however, in 24-hour mortality rate or pulmonary histopathology. In a retrospective review, 86 patients with chlorine gas inhalation were treated with nebulized sodium bicarbonate.<sup>18</sup> Sixty-nine patients were sent

home from the emergency department, 53 of whom had clearly improved. In a more recent study, 44 patients who were diagnosed with reactive airway dysfunction syndrome after an acute exposure to chlorine gas were randomized to receive either nebulized sodium bicarbonate (4 mL of 4.2% sodium bicarbonate solution) or nebulized placebo.<sup>5</sup> Both groups also received IV corticosteroids and inhaled  $\beta_2$ -adrenergic agonists. Compared with the placebo group, the nebulized sodium bicarbonate group had significantly higher forced expiratory volume in 1 second ( $FEV_1$ ) values at 120 and 240 minutes and scored significantly higher on a posttreatment quality of life questionnaire. In patients experiencing reactive airway symptoms, it is reasonable to treat with a nebulized solution of 4 mL of 3.75% to 4.2% sodium bicarbonate solution in addition to humidified oxygen and inhaled  $\beta_2$ -adrenergic agonists. Nebulized sodium bicarbonate failed to demonstrate a benefit in the treatment of chloramine gas exposure.<sup>79</sup>

## OTHER INDICATIONS

Adverse effects and safety concerns are associated with the dissociation of the dimercaprol (British anti-Lewisite {BAL}) metal binding that occurs in acid urine. Because dissociation of the BAL-metal chelate occurs in acidic urine, it is recommended to alkalinize the urine of patients receiving BAL with hypertonic sodium bicarbonate to a pH of 7.5 to 8.0 to prevent renal liberation of the metal.<sup>24</sup>

Sodium bicarbonate provides a renal protection benefit after exposure to depleted uranium. Animal studies suggest that sodium bicarbonate in conjunction with a chelator such as deferiprone accelerates uranium excretion and reduces uranium nephrotoxicity and thus it is reasonable to administer.<sup>40</sup>

## ADVERSE EFFECTS AND SAFETY ISSUES

The use of sodium bicarbonate has associated risks. Excessive alkalemia (with adverse effects upon respiratory physiology), hypernatremia, fluid overload, hypokalemia, and hypocalcemia occur.<sup>37,61,80,89,99</sup> The package insert urges caution in patients with congestive heart failure, severe renal insufficiency, and preexisting edema with sodium retention.<sup>4</sup> Regarding its use to treat salicylism, early on, patients with pure respiratory alkalosis often have alkaluria and alkalemia and do not require urinary alkalization. Young children who rapidly develop metabolic acidosis often require alkalization but should be at less risk for complications of this therapy.<sup>76</sup> However, because hypertonic sodium bicarbonate causes hypernatremia, decreased cerebrospinal fluid pressure, and possible intracranial hemorrhage in children younger than 2 years of age, the 4.2% solution is preferred in these patients.<sup>4</sup> Extravasation causes local tissue damage.<sup>4</sup> Dobutamine and norepinephrine are incompatible with sodium bicarbonate solutions, and calcium solutions cause precipitation.

## PREGNANCY AND LACTATION

According to the Food and Drug Administration (FDA), sodium bicarbonate is a Category C drug. The World Health Organization rates sodium bicarbonate as compatible with breastfeeding.

## DOSING AND ADMINISTRATION

For the treatment of QRS complex prolongation in the setting of myocardial sodium channel poisoning, we recommend administration of 1 to 2 mEq/kg of sodium bicarbonate IV as a bolus over a period of 1 to 2 minutes.<sup>81</sup> Greater amounts, totaling as much as 35 mEq/kg over hours of resuscitation, are sometimes required to treat patients with recurrent unstable ventricular dysrhythmias.<sup>84</sup> Similar boluses should be repeated as needed to achieve a blood pH of 7.50 to 7.55.<sup>82,104</sup> Because sodium bicarbonate has a brief duration of effect, a continuous infusion usually is required after the initial IV boluses. The treatment endpoint is the narrowing of the QRS interval. Excessive alkalemia (pH >7.55) and hypernatremia should be avoided. To prepare a sodium bicarbonate infusion, three 50-mL ampules of 8.4% or 7.5% solution should be placed in 1 L of 5%  $D_5W$  and run at twice maintenance with frequent evaluation of the QRS duration, potassium concentration, and pH, depending on the fluid requirements and blood pressure of the patient. Frequent evaluation of

the fluid status should be performed to avoid precipitating pulmonary edema. An optimal duration of therapy has not been established.

For the treatment of patients with salicylate poisoning, sodium bicarbonate should be administered by bolus or infusion using the dosing strategies described earlier to achieve a serum pH of 7.45–7.55, until the with a goal of a urinary pH of 8.0. Careful and frequent monitoring of the urinary pH and serum potassium concentration is critical to ensure optimal treatment. In salicylate-poisoned patients with altered mental status, aggressive administration of sodium bicarbonate is required to ensure that the serum pH is greater than at least 7.40 to 7.45 although not exceed pH 7.55.

## FORMULATIONS

The most commonly used sodium bicarbonate preparations are an 8.4% solution (1 M) containing 1 mEq each of sodium and bicarbonate ions per milliliter (calculated osmolarity of 2,000 mOsm/L) and a 7.5% solution containing 0.892 mEq each of sodium and bicarbonate ions per milliliter (calculated osmolarity of 1,786 mOsm/L). Fifty-milliliter ampules of the 8.4% and 7.5% solutions therefore contain 50 and 44.6 mEq of sodium bicarbonate, respectively. The common infant formulation is a 4.2% solution packaged as a 10-mL injectable ampule. This yields 5 mEq per container (0.5 mEq each of sodium and bicarbonate ions per milliliters). According to the package insert, the FDA-approved indications for sodium bicarbonate include the “treatment of certain drug intoxications, including barbiturates (where dissociation of the barbiturate-protein complex is desired), in poisoning by salicylates or methyl alcohol, and in hemolytic reactions requiring alkalization of the urine to diminish nephrotoxicity of blood pigments. Urinary alkalization is also used in methotrexate therapy to prevent nephrotoxicity.”

## SUMMARY

- Sodium bicarbonate remains an important treatment of a wide variety of xenobiotic exposures.
- Sodium bicarbonate is effective in patients poisoned by myocardial sodium channel blockers by providing sodium through its effects on drug ionization and subsequent diffusion from the sodium channel binding site.
- Sodium bicarbonate is effective for salicylates, phenobarbital, methotrexate, and other weak acids because of its ability to “ion trap” in blood or urine compartments and mitigate target organ accumulation.
- Nebulized sodium bicarbonate administration is reasonable in neutralizing inhaled acids such as chlorine gas.

# BOTULISM

Howard L. Geyer

### HISTORY AND EPIDEMIOLOGY

Botulism, a potentially fatal neuroparalytic illness, results from exposure to botulinum neurotoxin (BoNT), which is produced by the bacterium *Clostridium botulinum* and other *Clostridium* species. The earliest cases of botulism were described in Europe in 1735 and were attributed to improperly preserved German sausage; the name of the disease alludes to this association because *botulus* is the Latin word for *sausage*. Emile van Ermengem identified the causative organism in 1897 and named it *Bacillus botulinum*; it was later renamed *Clostridium botulinum*.<sup>25</sup> These gram-positive, spore-forming bacteria produce eight serotypes of BoNT, denoted A through H.<sup>88,134</sup>

In adults, most cases result from ingestion of toxin in contaminated food, but in infants, most cases result from consumption of bacterial spores that proliferate and produce toxin in the gastrointestinal (GI) tract. Less common forms of botulism include wound botulism, in which spores are inoculated into a wound and locally produce toxin, and inhalational botulism caused by aerosolized BoNT, which potentially can be used as a weapon of bioterrorism.

Botulism outbreaks occur throughout the world<sup>149</sup> and have been reported from such diverse areas as Uganda,<sup>179</sup> Iran,<sup>137</sup> Japan,<sup>128</sup> Thailand,<sup>96</sup> Pakistan,<sup>93</sup> Australia,<sup>113</sup> France,<sup>1</sup> Portugal,<sup>103</sup> Poland,<sup>58</sup> Greenland,<sup>82</sup> Chile,<sup>12</sup> and Canada.<sup>123</sup> In 2016, a total of 150 laboratory-confirmed cases and 10 probable cases of botulism were reported to the US Centers for Disease Control and Prevention (CDC).<sup>39</sup> Foodborne botulism constituted 14% of cases, infant botulism 73% of cases, and wound botulism 12%. In this analysis, toxin type A accounted for 83% of cases of foodborne botulism, with the remainder split between type A and type B (27% each). Toxin type A was responsible in at least 88% of cases of wound botulism, and infant botulism was caused by toxin type A in 36% and to toxin type B in 59% of cases. Two deaths from foodborne botulism were reported in 2016.<sup>39</sup> The case fatality rate has improved for all botulism toxin types, probably caused by increasing awareness of the condition and consequent earlier diagnosis, appropriate and early use of antitoxin, and better and more accessible life support techniques.

In the past 50 years, home-processed food has accounted for 65% of outbreaks, with commercial food processing constituting only 7% of reported cases; in the remaining outbreaks, the origin is unknown.<sup>45</sup> Common home-canning errors responsible for botulism include failure to use a pressure cooker and allowing food to putrefy at room temperature. Minimally processed foods such as soft cheeses lack sufficient quantities of intrinsic barriers to BoNT production, such as salt and acidifying agents.<sup>143</sup> These foods become high-risk sources of botulism when refrigeration standards are violated. The US Food and Drug Administration (FDA) continuously reviews recommendations for appropriate measures to process such foods.<sup>168,169</sup>

Awareness of evolving trends and unusual presentations or locations of botulism permits the establishment of preventive education programs. Outbreaks of botulism have been associated with specialty foods consumed by different ethnic groups, such as chopped garlic in soy oil by Chinese in Vancouver, British Columbia,<sup>123,163</sup> unviscerated salted fish—called *kapchunka*—eaten by Russian immigrants in New York City;<sup>36,167</sup> and the same fish—called *faseikh*—eaten in Egypt.<sup>182</sup> The incidence of botulism is high in Alaska where traditional foods include fermented fish and fish eggs, seal, beaver, and whale; between 2001 and 2014, one-third of cases of foodborne botulism in the United States occurred in Alaska. Approximately 90% of toxin type E outbreaks have occurred in Alaska because of home-processed fish or meat

from marine animals,<sup>52,107,181</sup> and one incident occurred in New Jersey.<sup>37</sup> In the 1990s, three cases of botulism involved members of a Native American church after they ingested a ceremonial tea made from the buttons of dried, alkaline-ground peyote cactus that were stored for 2 months in a water-filled refrigerated jar. The resultant alkaline and anaerobic milieu presumably fostered the growth of toxin from naturally occurring spores.<sup>83</sup> In 1996, eight cases of foodborne botulism in Italy were linked to mascarpone cream cheese eaten either alone or in tiramisu contaminated with BoNT type A.<sup>14</sup> Other outbreaks have been linked to mushrooms bottled in a restaurant,<sup>38</sup> home-canned bamboo shoots,<sup>44,47</sup> home-pickled eggs,<sup>48</sup> commercial carrot juice,<sup>40</sup> commercially processed chili sauce,<sup>41</sup> home-prepared tofu,<sup>42,49</sup> improperly stored potato soup,<sup>51</sup> and improperly jarred pesto.<sup>31</sup>

Larger outbreaks are especially concerning. In April 2015, 29 patients in Ohio developed botulism (25 laboratory-confirmed cases and 4 probable cases) after consuming home-canned potatoes at a church potluck meal; one died of respiratory failure.<sup>114</sup> In June 2016, 31 male inmates in a medium-security federal correctional institution in Mississippi developed botulism after drinking “pruno,” an illicit alcohol made by the prisoners;<sup>115</sup> similar preparations were responsible for four prior outbreaks in prisons in California, Utah, and Arizona.<sup>43,180,186</sup> Twenty-four patients were hospitalized and nine required mechanical ventilation, but none died. This botulism outbreak was the largest in the United States since 1978, when 32 people were affected after eating at a New Mexico country club.<sup>35</sup>

Among cases attributed to commercial food processing, vegetables (peppers, beans, mushrooms, tomatoes, and beets, with or without meat) were thought to be the causative agents in approximately 70%, meat in 17%, and fish in 13% of cases.<sup>45</sup> Although only 4% of foodborne botulism is associated with food purchased in restaurants, restaurant-related outbreaks usually affect large numbers of individuals.<sup>107</sup>

Of 29 laboratory-confirmed cases of foodborne botulism in 2016, there were three multi-case outbreaks, each involving two or three patients.<sup>39</sup> Among hundreds of reports of botulism from 1975 to 1988 involving more than 400 persons, approximately 70% involved only one person, 20% involved two persons, and only 10% involved more than two persons, yielding a mean of 2.7 cases per outbreak.<sup>185</sup> Single affected patients were more severely ill, with 85% requiring intubation compared with only 42% requiring intubation in multi-person outbreaks, presumably because diagnosis in the index case leads to more rapid therapeutic intervention for associated cases.

Infant botulism is more common in certain geographic areas than in others presumably because of higher concentrations of botulinum spores in soil. Raw honey is a potential source of spores.<sup>124</sup> Most affected infants are younger than 6 months of age. Of 128 confirmed cases reported in 2014, most were from California (38%), New Jersey (8%), Maryland (7%), Pennsylvania (6%), or Texas (5%). The median age was 17 weeks (range, 2–54 weeks), and 46% were female. No US deaths from infant botulism were reported in 2014.<sup>39</sup> With appropriate support and treatment, a favorable outcome is achieved in the majority of cases.

In 2016, 24 cases of wound botulism were confirmed in the United States; 15 of these cases occurred in California. Age ranged from 25 to 68 years, with a median of 45 years, and 29% were women. Patients continue to be almost exclusively injection drug users.<sup>39</sup>

In ways unimaginable when the first edition of this book was published, medical and public health realities associated with terrorism in the 21st

century unfortunately have resulted in increased relevance of botulism to medical practitioners (Chaps. 126 and 127). The advent of therapeutic BoNT injections has raised other concerns regarding potential adverse consequences.<sup>10</sup>

## BACTERIOLOGY

The genus *Clostridium* comprises a group of four spore-forming anaerobic gram-positive bacillary species that produce eight different neurotoxic proteins. *C. botulinum* produces all BoNT serotypes A through H, *C. baratii* produces toxin type F, *C. butyricum* produces toxin type E, and *C. argentinense* (sometimes considered a subgroup of *C. botulinum*) produces toxin type G.<sup>88</sup> Some strains produce two different toxin types. Most cases of botulism result from BoNT types A, B, E, or F.<sup>39,65,170</sup> Reports of cases caused by BoNT type F have increased in recent years in parallel with improved ability of laboratories to detect *C. baratii* and other clostridial species producing toxin type F. The seven types A to G were recognized for over 40 years until in 2014 when a new toxin was identified in an infant with botulism and was designated type H.<sup>21</sup>

Clostridial species are ubiquitous, and the bacteria and spores are present in soil, seawater, and air.<sup>160</sup> Genomic sequence analysis shows that multiple toxin subtypes exist within each of the eight main types A through H; for example, there are eight subtypes of type A, designated A1 through A8.<sup>88</sup> In the United States, toxin type A is found in soil west of the Mississippi;<sup>106</sup> type B is found east of the Mississippi, particularly in the Allegheny range; and type E is found in the Pacific northwest and the Great Lakes states.<sup>46,160</sup> Toxin types A and B typically are found in poorly processed meats and vegetables. Toxin type E is commonly found in raw or fermented marine fish and mammals. Toxin types C and D cause disease in birds and mammals. Toxin type G has not been associated with naturally occurring disease. Although the different botulinum toxins differ in the cellular molecules they target, their ultimate pathophysiology and clinical syndromes are identical.

All botulinum spores are dormant and highly resistant to damage. They withstand boiling at 212°F (100°C) for hours, although they usually are destroyed by 30 minutes of moist heat at 248°F (120°C). Factors that promote germination of spores in food are pH greater than 4.5, sodium chloride content less than 3.5%, and low nitrite concentration. Most viable organisms produce toxin in an anaerobic milieu with temperatures greater than 80.6°F (27°C), although some strains produce toxins even when conditions are not optimal. Clostridia produce toxin type E at temperatures as low as 41°F (5°C). To prevent spore germination, acidifying agents such as phosphoric or citric acid are added to canned or bottled foods that have a low acid content, such as green beans, corn, beets, asparagus, chili peppers, mushrooms, spinach, figs, olives, and certain nonacidic tomatoes. Unlike the spores, the toxin itself is heat labile and is destroyed by heating to 176°F (80°C) for 30 minutes or to 212°F (100°C) for 10 minutes. At high altitudes, where the boiling point of water may be as low as 202.5°F (94.7°C), boiling for a full 30 minutes is prudent to ensure that the toxin is destroyed. Under high-altitude conditions, pressure cooking at 13 to 14 lb of pressure often is necessary to achieve appropriate temperatures to destroy the toxin in a timely fashion.

Foods contaminated with *C. botulinum* toxin types A and B often look or smell putrefied because of the action of proteolytic enzymes.<sup>81</sup> In contrast, because toxin type E organisms are saccharolytic and not proteolytic, foods contaminated with toxin type E typically look and taste normal.<sup>17</sup>

## PHARMACOKINETICS AND TOXICOKINETICS

BoNT is the most potent toxin known. The LD<sub>50</sub> for mice is 3 million molecules injected intraperitoneally. The human oral lethal dose is 1 mcg.<sup>147</sup>

Foodborne botulism results from ingestion of preformed BoNT from food contaminated with *Clostridium* spores. The toxin is complexed to associated proteins (hemagglutinins and a nontoxic nonhemagglutinin)<sup>88</sup> that protect it from the acidic and proteolytic environment in the stomach. In the intestine, the alkaline pH dissociates the toxin from the associated proteins, allowing for subsequent absorption into the bloodstream.<sup>121</sup> Because the toxin is often demonstrated only in the stool, determining the percentage of the

toxin actually absorbed is difficult.<sup>64,67</sup> The median incubation period for all patients is 1 day, but it ranges from 0 to 7 days for toxin type A, 0 to 5 days for toxin type B, and 0 to 2 days for toxin type E.<sup>185</sup>

Infant botulism does not result from ingestion of preformed BoNT but rather from ingestion of *C. botulinum* spores, which germinate in the GI tract and produce toxin. The immaturity of the bacterial flora in the infant GI tract facilitates colonization by the organisms. Adults with altered GI tracts (eg, those who have undergone gastric bypass or are taking proton pump inhibitors or H<sub>2</sub> antagonists) also rarely develop botulism in the same way, with the onset of symptoms typically following ingestion by 1 or 2 months. Cases of foodborne infant botulism associated with home-canned food have been reportedly extremely rarely.<sup>6,105</sup>

In wound botulism, spores proliferate in a wound or abscess and locally elaborate toxin. The incubation period is typically less than 2 weeks, but delays as long as 51 days are reported.<sup>86</sup>

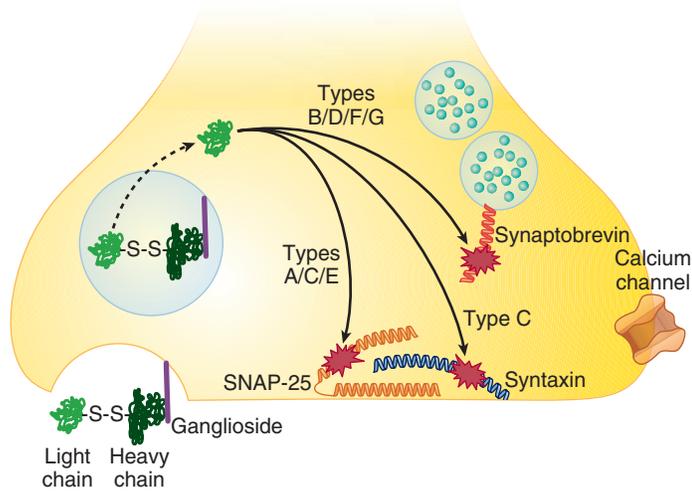

The duration of action of the BoNT types varies depending on the components of the neurotransmitter release apparatus that are disrupted (see Pathophysiology). It is unclear whether the persistence of clinical effect results from the individual cleavage target, the intraneuronal biological half-life of the toxin, or both. Current evidence indicating intraneuronal toxin metabolism or elimination is inadequate.

## PATHOPHYSIOLOGY

Botulinum neurotoxin is produced as a protein consisting of a single polypeptide chain with a molecular weight of 900 kDa, which includes a 750-kDa nontoxic protein and a 150-kDa neurotoxic component. To become fully active, the single-chain polypeptide 150-kDa neurotoxin must undergo proteolytic cleavage to generate a dichain structure consisting of a 100-kDa heavy chain linked by a disulfide bond to a 50-kDa light chain. The dichain form of the molecule is responsible for all clinical manifestations.<sup>29,84</sup> Both the single polypeptide chain toxin and the dichain form are resistant to GI degradation.<sup>108</sup>

The ingested toxin binds to serotype-specific receptors on the mucosal surfaces of gastric and small intestinal epithelial cells, where endocytosis is followed by transcytosis, permitting release of the toxin on the serosal (basolateral) cell surface.<sup>100,142</sup> The dichain form travels intravascularly to peripheral cholinergic nerve terminals, where it binds rapidly and irreversibly to the cell membrane and is taken up by endocytosis. The heavy chain is responsible for cell-specific membrane binding to acetylcholine-containing neurons (Fig. 38–1). Botulinum neurotoxin use dual host receptors to achieve their high affinity; whereas BoNT A binds a ganglioside and synaptic vesicle glycoprotein 2, BoNT B uses synaptotagmin. This mechanism allows rapid toxin entry via synaptic vesicles. The subsequent acidification of the synaptic vesicle lumen triggers the heavy chain N-terminal domain to form a channel to facilitate translocation of the light chain into the cytosol.<sup>97</sup>

When inside the cell, the light chain acts as a zinc-dependent endopeptidase to cleave presynaptic membrane polypeptides that are essential components of the soluble *N*-ethylmaleimide-sensitive factor attachment receptor (SNARE) apparatus that subserves acetylcholine exocytosis, thereby inhibiting release.<sup>147</sup> Botulinum neurotoxin types specifically cleave different proteins belonging to the SNARE family, and these differences are one possible reason for their variable toxicity.<sup>155</sup> SNARE proteins targeted by proteolysis include vesicle-associated membrane protein (VAMP) called synaptobrevin which is localized on synaptic vesicles, syntaxin found on the presynaptic membrane, and synaptosomal-associated protein (SNAP)-25, which is attached to syntaxin and to the presynaptic membrane. Toxin types A and E cleave SNAP-25; types B, D, F, and G act on VAMP/synaptobrevin; and type C cleaves both syntaxin and SNAP-25 (Fig. 38–1).<sup>100</sup> All BoNT types impair transmission at acetylcholine-dependent synapses in the peripheral nervous system, but cholinergic synapses in the central nervous system are not thought to be affected. Very high concentrations of BoNT also impair release of other neurotransmitters, including norepinephrine and serotonin.<sup>80</sup> Botulinum neurotoxin also exerts effects via mechanisms other than cleavage of SNARE proteins, possibly including apoptosis or gene expression.<sup>112</sup>

**FIGURE 38–1.** Botulinum toxins consist of two peptides linked by disulfide bonds. The heavy chain is responsible for specific binding to acetylcholine (ACh)-containing neurons. After binding to the cell surface, the entire complex undergoes endocytosis and subsequent translocation of the light chain into the nerve cell cytoplasm. The light chain contains a zinc-requiring endopeptidase that cleaves soluble *N*-ethylmaleimide sensitive factor (NSF) attachment protein receptor (SNARE) proteins belonging to the docking–fusion complex required for neuroexocytosis of ACh. These proteins may be associated with the synaptic vesicles (v-SNARE) or with their targets on the presynaptic membrane (t-SNARE). Botulinum neurotoxin types A and E proteolyze the t-SNARE protein known as synaptosomal-associated protein (SNAP)-25, and BoNT type C cleaves both SNAP-25 and syntaxin, which is attached to SNAP-25 and to the presynaptic membrane. Botulinum neurotoxin types B, D, F, and G target the v-SNARE protein VAMP/synapto synaptobrevin. As a result of cleavage of these components of the docking complex by the endopeptidase, ACh is not released and neuromuscular transmission is impaired.

## CLINICAL MANIFESTATIONS

### Foodborne Botulism

Although botulism is the most dreaded of all food poisonings, the initial phase of the disease often is so subtle that it goes unnoticed. Botulism frequently is misdiagnosed on the first visit to a health care provider.<sup>32</sup> When GI effects are striking and food poisoning is suspected, the differential diagnosis should include other acute poisonings, such as metals; plants; mushrooms; and the common bacterial, viral, and parasitic agents discussed in Chap. 39.

The onset of symptoms typically occurs the day after ingestion. Early GI signs and symptoms of botulism include nausea, vomiting, abdominal distension, and pain. A time lag (from 12 hours to several days but usually not more than 24 hours) typically occurs before neurologic signs and symptoms appear. Common findings include diplopia (often horizontal); blurred vision with impaired accommodation; and bilaterally symmetric flaccid paralysis, which typically begins in cranial muscles and descends to the limbs. Constipation caused by smooth muscle involvement is frequent, and urinary retention and ileus also occur. Anticholinergiclike effects such as dry mouth, dysphagia, and dysarthria or dysphonia (manifested by a nasal quality to the voice) occur, and many patients exhibit fixed mydriatic pupils with ptosis. Deep tendon reflexes are usually reduced or absent. Hypotension and bradycardia sometimes develop, but temperature regulation is normal.

Severe weakness of respiratory muscles necessitates intubation and mechanical ventilation. Approximately 67% of botulism patients with toxin type A require intubation compared with 52% of patients with toxin type B and 39% with toxin type E.<sup>185</sup>

Importantly, mental status and sensation remain normal. These findings, along with the absence of tachycardia, distinguish botulism from the anticholinergic syndrome, which shares many initial features with botulism.

The differential diagnosis of botulism includes a variety of toxicologic and nontoxicologic conditions (Table 38–1). All of these disorders have weakness as a prominent feature, but many are readily differentiated from botulism based on their time course or a history of exposure. The most difficult and frequently encountered diagnostic challenge is differentiating

**TABLE 38–1A** Toxicologic Differential Diagnosis of Botulism

<i>Xenobiotic Exposure</i>	<i>Typical Associated Findings</i>
Aminoglycosides	Paralysis (usually in a patient with myasthenia gravis or other neuromuscular disorders)
Anticholinergics	Mydriasis, vasodilation, fever, tachycardia, ileus, dry mucosa, urinary retention, altered mental status
Batrachotoxin (eg, poison dart frog)	Paralysis almost instantaneous, cardiac arrest
Buckthorn ( <i>Karwinskia humboldtiana</i> )	Rapidly progressive ascending paralytic neuropathy with quadriplegia
Carbon monoxide	Headache, nausea, altered mental status, tachypnea, elevated carboxyhemoglobin level
Conotoxin (cone snails)	Burning, itching, and edema at site of sting; circumoral paresthesias; nausea; facial muscle paralysis, ptosis, sialorrhea; respiratory and cardiac arrest
Depolarizing and nondepolarizing neuromuscular blockers (eg, curare, succinylcholine, rocuronium, vecuronium)	Paralysis without sedation or sensory involvement
Diphtheria	Exudative pharyngitis, cardiac manifestations, hypotension, demyelinating neuropathy with cranial nerve involvement (late)
Bungarotoxin (Elapids: kraits, coral snakes, sea snakes)	Cramps, fasciculations, tremor, salivation, nausea, vomiting followed by bulbar palsy and paralysis including slurred speech, diplopia, ptosis, dysphagia, dyspnea, respiratory compromise
Organic phosphorus compounds, carbamates	Salivation, lacrimation, urination, defecation, miosis, fasciculations, bronchorrhea, delayed neuropathy
Paralytic shellfish poisoning (saxitoxin, neosaxitoxin)	Incubation <1 h, dysesthesias, paresthesias, dysphagia, respiratory paralysis
Tetrodotoxin (pufferfish, blue-ringed octopus, Taricha newts)	Nausea, diarrhea; circumoral paresthesias, dizziness, hypotension, bradycardia When severe: hypersalivation, cyanosis, diaphoresis, dysphagia, anarthria.
Thallium	Alopecia, painful ascending sensory neuropathy, constipation, cranial neuropathy, Mees lines

**TABLE 38–1B** Nontoxicologic Differential Diagnosis of Botulism

Condition	Typical Associated Findings
Electrolyte abnormalities	
• Hyperkalemia	Fatigue, dyspnea, palpitations, nausea, vomiting, paresthesias
• Hypokalemia	Fatigue, exercise intolerance, myalgia, dyspnea, palpitations or dysrhythmia
• Hypermagnesemia	Hyporeflexia, facial paresthesias, respiratory depression, hypotension, bradycardia, ileus, diffuse flushing, nausea, vomiting
Encephalitis	Fever, altered mental status, seizures; CSF showing elevated protein and pleocytosis
Food “poisoning” (other bacterial)	Rapid onset of disease; absence of cranial nerve findings
Guillain-Barré syndrome or acute inflammatory demyelinating polyneuropathy (and Miller Fisher variant)	Areflexia, paresthesias, ataxia, CSF showing elevated protein without pleocytosis, slowed nerve conduction velocity; ophthalmoparesis in Miller Fisher syndrome
Hypokalemic periodic paralysis	Proximal muscle weakness; no cranial nerve involvement or sensory findings
Inflammatory or infectious myelopathy and polyradiculopathy	Complete (transverse) or incomplete spinal syndrome with paraparesis or sensory level or sensory signs; possible sphincter dysfunction or back pain; may be preceded by viral illness; CSF pleocytosis and elevated protein
Lambert-Eaton myasthenic syndrome	Neoplasm (especially small cell lung cancer), limb weakness exceeding ocular or bulbar weakness, increased strength after sustained contractions; postexercise facilitation on repetitive nerve stimulation; antibodies to voltage-gated calcium channels
Myasthenia gravis	Aggravation of fatigue with exercise, fluctuating weakness, acetylcholine receptor or muscle-specific (MuSK) antibodies, positive edrophonium test, decremental response on high-frequency repetitive nerve stimulation
Poliomyelitis	Fever, GI symptoms, asymmetric weakness; CSF showing elevated protein and pleocytosis
Polymyositis	Insidious onset; proximal limb weakness; dysphagia; muscle tenderness sometimes present; elevated creatine kinase, aldolase, C-reactive protein, and ESR; fibrillations and sharp waves on electromyography
Stroke	Asymmetric weakness, abnormal brain imaging
Tetanus	Rigidity; cranial nerves usually normal
Tick paralysis ( <i>Dermacentor</i> spp)	Rapidly evolving paralysis, ptosis, absence of paresthesias; normal CSF analysis, presence of an embedded tick with resolution upon removal

CSF = cerebrospinal fluid; ESR = erythrocyte sedimentation rate; GI = gastrointestinal.

between botulism and the Miller Fisher variant of Guillain-Barré syndrome (Table 38–2). Because physicians so rarely encounter botulism (especially compared with other much more common disorders in the differential diagnosis), initiation of appropriate management often is significantly delayed. The index case of an epidemic or an isolated case often is misdiagnosed at a stage when the risk of morbidity and mortality still could be substantially diminished. This is particularly true of toxin type E botulism, which typically initially causes much more prominent GI signs than neurologic signs.<sup>17</sup>

### Infant Botulism

First described in California in 1976, several thousand cases of infant botulism have now been confirmed across the world,<sup>9,85,90</sup> from all inhabited continents except Africa.<sup>70</sup> Interestingly, 95% of reported cases occur in the United States.<sup>56,130</sup> In 2016, 47 of 150 laboratory-confirmed cases occurred in California.<sup>39</sup> Aggressive surveillance and educational efforts have been practiced in that state since 1976, which may help to explain the disproportionate distribution of reported cases.<sup>8</sup>

**TABLE 38–2** Differentiating Botulism from Guillain-Barré Syndrome

	Botulism	Guillain-Barré Syndrome	Miller Fisher Variant of Guillain-Barré Syndrome
Fever	Absent (except in wound botulism)	Occasionally present	Occasionally present
Pupils	Dilated or unreactive (50%)	Normal	Normal
Ophthalmoparesis	Present (early)	May be present (late)	Present (early)
Paralysis	Descending	Ascending (classically, but not necessarily)	Descending
Deep tendon reflexes	Diminished	Absent	Absent
Ataxia	Absent	Often present	Present
Paresthesias	Absent	Present	Present
CSF protein	Normal	Elevated (late)	Elevated (late)

CSF = cerebrospinal fluid.

Infant botulism is the most common form of botulism in the United States, and virtually all cases are caused by BoNT type A or B. Affected children are younger than 1 year (median, 15 weeks) and characteristically have normal gestation and birth. The first signs of infant botulism are constipation; difficulty with feeding, sucking, and swallowing; a feeble cry; and diffusely decreased muscle tone (“floppy baby”).<sup>50</sup> The hypotonia is particularly apparent in the limbs and neck. Ophthalmoplegia, loss of facial grimacing, dysphagia, diminished gag reflex, poor anal sphincter tone, and respiratory failure are often present, but fever does not occur. Mydriasis typically is present. The differential diagnosis of infant botulism initially includes salt and water depletion, failure to thrive, sepsis, and a viral syndrome. Because the toxin in infant botulism is absorbed gradually as it is produced, the onset of clinical manifestations commonly is less abrupt than in severe cases of foodborne botulism, which are caused by large amounts of preformed toxin absorbed over a brief period of time.

Infant botulism results from ingestion of *C. botulinum* organisms in food or following the inhalation or ingestion of organism-laden aerosolized dust. Many cases occur near construction sites or soil disruption for other reasons, or in children of parents who work in construction, farming, plant nursery, or plumbing.<sup>63</sup> A number of factors determine a child's susceptibility to development of botulism. Although bile acids and gastric acid in the GI tract inhibit clostridial growth in older children and adults, gastric acidity is reduced in the infant during the first few months of life.<sup>109</sup> Also, some infants are deficient in immunologic mechanisms for spore control, resulting in a permissive environment for spore germination and toxin development within their GI tracts with subsequent absorption. Approximately 70% of infant botulism cases occur in breastfed infants, even though only 45% to 50% of all infants are breastfed. Formula-fed infants are rapidly colonized by *Coliforme* spp, *Enterococcus* spp, and *Bacteroides* spp, which inhibit *C. botulinum* proliferation; conversely, the absence of these typical organisms in breastfed infants facilitates *C. botulinum* multiplication.<sup>85</sup>

Epidemiologic studies in Europe found that ingestion of honey was associated with 59% of cases of infant botulism.<sup>15</sup> When *C. botulinum* spores were isolated from honey implicated in cases of infant botulism, the same toxin type was isolated from the infant and, as expected, no preformed toxin was isolated from the honey.<sup>9</sup> It is possible that pollen and nectar carried by worker bees results in contamination of honey with spores of *Clostridia* found in soil.<sup>124</sup> In addition, the oxidative metabolism of *Bacillus alvei*, another common contaminant of honey, may promote spore germination by creating an anaerobic microenvironment.<sup>121</sup> Honey is the only food generally considered likely to be a risk factor for infant botulism,<sup>9</sup> although a 2001 report from the United Kingdom implicated an infant formula.<sup>28</sup>

Previous studies suggested a correlation between the presence of both *C. botulinum* organisms and toxin and sudden infant death syndrome (SIDS).<sup>8,161</sup> However, in a prospective study of 248 infants with SIDS, *C. botulinum* was not found in the stool cultures of any of the children.<sup>33</sup>

Patients with infant botulism must be managed in the hospital, preferably in a pediatric intensive care unit, at least for the first week, when the risk of respiratory arrest is greatest. In one study, approximately 80% of children with botulism required intubation for reduced vital capacity on pulmonary function testing, and 25% of these children had frank respiratory compromise.<sup>148</sup> In a group of 57 affected infants aged 18 days to 7 months managed during the decade ending in the mid-1980s, 77% were intubated, and 68% required mechanical ventilation. In the subsequent decade, investigators from the same institution found that 37 of 60 (62%) infants required endotracheal intubation (for a mean duration of 21 days).<sup>4</sup> The apparent decrease in intubations and complications was ascribed to better understanding of disease progression and closer observation of patients. However, a similar study at another institution revealed that 13 of 24 (54%) infants admitted between 1985 and 1994 required ventilatory support, compared to 15 of 20 (75%) infants admitted in the subsequent decade.<sup>171</sup> All but one patient in this study required nasogastric feeding. In one series, younger patients were more likely to require mechanical ventilation.<sup>127</sup> Airway complications of intubation such as stridor, granuloma formation, and subglottic

stenosis are common, yet tracheotomy is infrequently required.<sup>4</sup> The survival rate in infant botulism is approximately 98% and most patients are discharged home from the hospital.<sup>127,148</sup>

## Wound Botulism

The first recorded case of wound botulism occurred in 1943 and was reported in 1951.<sup>59</sup> The classic presentation of wound botulism involves a motor vehicle crash resulting in a deep muscle laceration, crush injury, or compound fracture treated with open reduction. The wound typically is dirty and associated with inadequate débridement, subsequent purulent drainage, and local tenderness, although in some cases, the wound appears clean and uninfected. Four to 18 days later, cranial nerve palsies and other neurologic findings typical of botulism appear.<sup>119</sup> Other manifestations characteristic of food-related botulism, such as GI symptoms, usually are absent.

In wound botulism, an abscess, sinusitis, or other tissue infection harbors the Clostridial organisms. Recognition of botulism as a potential complication of wound infections is essential for appropriate early and aggressive therapy. In one analysis, fever was present in only 7% of patients with wound botulism.<sup>77</sup>

The CDC identified 24 cases of wound botulism in the United States in 2014.<sup>39</sup> Botulinum neurotoxin type A accounted for 88% of the cases.<sup>39</sup> Use of heroin, particularly subcutaneous injection (“skin popping”) of black tar heroin, is associated with an increased risk of wound botulism.<sup>53,132,183</sup> This association appears to be related, at least in part, to the physical characteristics of black tar heroin such as its viscosity, its potential to facilitate anaerobic growth and spore germination, and its ability to devitalize tissue or inhibit wound resolution.<sup>20</sup> Wound botulism also is reported in association with subcutaneous,<sup>138</sup> intravenous,<sup>164</sup> and intranasal<sup>98,139</sup> cocaine use. The first case of wound botulism with BoNT type E was reported in 2007, affecting a drug user in Sweden.<sup>13</sup>

## Adult Intestinal Colonization Botulism

Although GI colonization is the typical pathogenic mechanism responsible for infant botulism, it is rare in adults. Prior to 1997, only 15 cases were reported.<sup>79,117</sup> Patients invariably have anatomic or functional GI abnormalities. Risk factors favoring organism persistence and *C. botulinum* colonization include achlorhydria (surgically or pharmacologically induced), previous intestinal surgery, and probably recent antibiotic therapy. These factors compromise the gastric and bile acid barrier, gut flora, and motility, thus allowing spore germination, altered bacterial growth, and toxin development.

Cases of adult infectious botulism are reported in patients with Crohn disease after ileal bypass surgery,<sup>79</sup> jejunioileal bypass for obesity,<sup>73,116</sup> gastroduodenostomy,<sup>116</sup> vagotomy and pyloroplasty,<sup>116</sup> and necrotic volvulus.<sup>107</sup> In such hosts, botulism results from the ingestion of food contaminated with *C. botulinum* organisms and no preformed toxin, with intraluminal elaboration of toxin occurring in vivo.<sup>56</sup>

In one case of adult intestinal colonization botulism, a high concentration of endogenously produced antibody to toxin type A was identified.<sup>79</sup> This finding highlights a distinct characteristic of this form of botulism, because endogenous antitoxin immunity does not develop in patients with foodborne botulism.<sup>147</sup>

## Iatrogenic Botulism

Botulinum toxins are used therapeutically in the treatment of a variety of disorders. Three preparations of BoNT type A are available in the United States: onabotulinumtoxinA (Botox), abobotulinumtoxinA (Dysport), and incobotulinumtoxinA (Xeomin). Botulinum neurotoxin type B is available as rimabotulinumtoxinB (Myobloc). All are approved by the FDA for treatment of cervical dystonia and upper limb spasticity; onabotulinumtoxinA is also approved for lower limb spasticity. OnabotulinumtoxinA and incobotulinumtoxinA are also indicated for treatment of blepharospasm. Additionally, onabotulinumtoxinA is approved for strabismus, chronic migraine, severe axillary hyperhidrosis inadequately managed by topical therapies, and detrusor overactivity associated with a neurologic condition. All three formulations of BoNT type A are approved for cosmetic purposes. Botulinum

neurotoxin is also used off-label for a variety of neurologic and non-neurologic conditions. In Japan and the United Kingdom, a preparation of BoNT type F is available.<sup>154</sup> Some studies suggest that animals receiving BoNT type F have more transient and reversible weakness than that associated with types A and B.<sup>26</sup>

A 2016 practice guideline update by the American Academy of Neurology assessed the level of evidence of the four BoNT products for various neurologic indications. Based on the evidence, the authors issued Level A recommendations (denoting an intervention that should be offered) for treatment of cervical dystonia with abobotulinumtoxinA or rimabotulinumtoxinB; treatment of upper limb spasticity with abobotulinumtoxinA, incobotulinumtoxinA, or onabotulinumtoxinA; treatment of lower limb spasticity with abobotulinumtoxinA or onabotulinumtoxinA; and treatment of chronic migraine with onabotulinumtoxinA.<sup>159</sup>

Botulinum neurotoxin is thought to exert its therapeutic effect in most cases by temporarily weakening muscles whose overactivity results in the clinical condition. Doses range widely depending on the size of the muscles to be treated, the severity of the muscular contraction, and the commercial preparation of the toxin. The injected toxin blocks the local neuromuscular junction by inhibiting release of acetylcholine. The “chemodenervated” muscles recover within 2 to 4 months as nerve transmission is restored through sprouting of new nerve endings and formation of functional connections at motor endplates,<sup>2,147</sup> necessitating repeated injections of BoNT for sustained clinical efficacy.

Doses of BoNT are measured in functional units corresponding to the median intraperitoneal lethal dose (LD<sub>50</sub>) in female Swiss-Webster mice weighing 18 to 20 g.<sup>131</sup> The units of each marketed pharmaceutical are distinctly different, which has led to inadvertent overdosing.<sup>175</sup> The potential for confusion is substantial when switching between products because their relative potencies are quite different.<sup>125,144,151</sup> Attempts to establish precise lethal doses of BoNT are complicated by the lack of human data, use of varying formulations of toxin by different investigators, changes in manufacturing processes, and factual errors in the published literature.<sup>29</sup> One group of investigators estimated that “lethal amounts of crystalline type A toxin for a 70-kg human would be approximately 0.09 to 0.15 mcg intravenously or intramuscularly, 0.70 to 0.90 mcg inhalationally, and 70 mcg orally,”<sup>10</sup> but it is unclear whether these values can be applied reliably to any currently available commercial product.

In a series of 139 patients with cervical dystonia randomized to treatment with BoNT type A or BoNT type B, no difference in efficacy was found between serotypes; the groups were also equivalent in frequency of adverse effects such as neck pain and neck weakness, but dry mouth and dysphagia were more common in the group treated with BoNT type B.<sup>57</sup>

After repeated injections of therapeutic doses of BoNT, patients develop neutralizing antibodies that would limit the subsequent efficacy of the toxins; this prompts switching to a different toxin type. In 1998, the formulation of Botox was changed to reduce the amount of potentially antigenic protein from 25 ng of neurotoxin complex protein per 100 units to 5 ng of complex protein per 100 units, and studies in patients with cervical dystonia demonstrate a sixfold lower rate of development of anti-BoNT antibodies with the newer formulation.<sup>89</sup> For Xeomin, the protein content is 0.6 ng per 100 units; Dysport contains 4.35 ng of protein per 500-unit vial (ie, 0.87 ng per 100 units).

Although one early marketing assumption was that the neurotoxin does not diffuse from the injection site, BoNT can diffuse into adjacent tissues and produce local adverse effects.<sup>141</sup> Systemic manifestations are of concern when an inadvertent, excessive, or misdirected dose of toxin is administered or in the setting of a neuromuscular disorder that may be previously undiagnosed, as in one case in which injection of BoNT type A unmasked Lambert-Eaton myasthenic syndrome (LEMS).<sup>66</sup> In addition, a number of studies demonstrate that even appropriately injected doses result in neuromuscular junction abnormalities throughout the body, occasionally producing autonomic dysfunction without muscle weakness.<sup>75,101,126</sup> Several cases of iatrogenic botulismlike symptoms, including diplopia and severe generalized muscle weakness with widespread electromyographic (EMG) abnormalities,

resulted from therapeutic or cosmetic use of intramuscular BoNT injections.<sup>18,24,69,172,187</sup> A 2008 report raised the possibility that BoNT type A undergoes retrograde axonal transport and transcytosis to afferent neurons,<sup>5</sup> suggesting a potential mechanism for such generalized effects. However, the reproducibility and clinical significance of these findings have yet to be established.

In a much publicized case from late 2004, four patients in Florida developed paralysis after being injected with BoNT type A. An FDA investigation revealed that these patients were injected by an unlicensed physician who obtained raw toxin (not approved for medical purposes) and administered it at a dose 2,000 to 100,000 times greater than that used in clinical practice.<sup>3</sup> These events were not believed to be relevant to the use of approved pharmaceutical BoNT. In February 2008, the FDA issued an Early Communication stating that it was reviewing safety data on BoNT after receiving reports of hospitalization or death in patients injected with these therapies, mostly in children treated for spasticity associated with cerebral palsy.<sup>173</sup> In 2009, the FDA mandated changes to the prescribing information for the BoNT products, requiring a Boxed Warning highlighting the possibility of potentially life-threatening effects distant from the injection site; a Risk Evaluation and Mitigation Strategy, including a medication guide to help patients understand the risks and benefits of the botulinum neurotoxin; and changes of the drug names to underscore differences between the potencies of the individual products and the lack of interchangeability among them.<sup>175</sup>

### Inhalational Botulism

Inhaled BoNT is estimated to be 100 times more potent than ingested BoNT; a single gram of toxin, if disseminated evenly, could kill more than 1 million people.<sup>10</sup> A 1962 report from West Germany described three veterinary workers who inhaled BoNT type A from the fur of animals they were handling; on the third day after exposure, they developed mucus in the throat, dysphagia, and dizziness, and on the next day, they developed ophthalmoparesis, mydriasis, dysarthria, gait dysfunction, and weakness.<sup>10</sup> Use of aerosolized BoNT as a bioweapon has been attempted by terrorists in Japan, and both the Soviet Union and Iraq developed BoNT as part of biological warfare programs (Chap. 127).<sup>10,61,188</sup>

### DIAGNOSTIC TESTING

The CDC case definition for foodborne botulism is established in a patient with a neurologic disorder manifested by diplopia, blurred vision, bulbar weakness, or symmetric paralysis in whom:

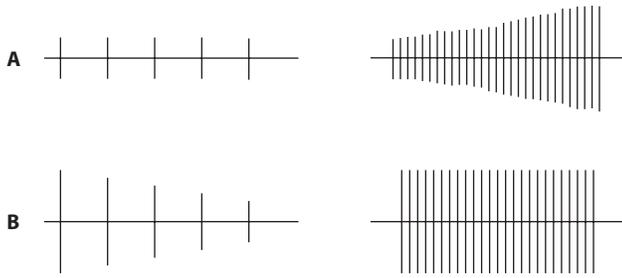

- Botulinum neurotoxin is detected in serum, stool, or implicated food samples or
- *C. botulinum* is isolated from stool or
- A clinically compatible case is epidemiologically linked to a laboratory-confirmed case of botulism<sup>46</sup>

Routine laboratory studies, including cerebrospinal fluid analysis, are normal in patients with botulism but are usually performed to exclude other etiologies. Specific tests can be helpful in diagnosing botulism.

### Edrophonium Testing

Edrophonium is a rapidly acting cholinesterase inhibitor of short duration that is useful in the diagnosis of myasthenia gravis. It is occasionally used to differentiate myasthenia gravis from botulism. This drug inhibits the metabolism of acetylcholine located in synapses, permitting continued binding with the reduced number of postsynaptic acetylcholine receptors in myasthenia gravis.

A syringe containing 10 mg of edrophonium is prepared, and then a test dose of 1 to 2 mg is administered intravenously. A positive result (ie, supportive of myasthenia gravis) consists of dramatic improvement in the strength of weak muscles within 30 to 60 seconds and lasting 3 to 5 minutes. If there is no effect, the remainder of the edrophonium is given and the same effect sought. Ideally, a second syringe is filled with saline and the test performed

**FIGURE 38-2.** Schematic representations of repetitive nerve stimulation at low (5/sec) and high (50/sec) frequencies. In botulism (**A**), stimulation produces a small muscle action potential that is facilitated (increases in amplitude) by repetitive stimulation at higher frequencies. This effect (which, although classic, is not found in all cases of botulism) results from increased acetylcholine release with high-frequency stimulation because of intracellular calcium accumulation. In contrast, myasthenia gravis (**B**) is associated with a normal muscle action potential amplitude and a decremental response at low-frequency stimulation with a normal response at high-frequency stimulation. Myasthenia gravis, a disorder of the muscle endplate, produces this decremental response at low frequencies because the natural reduction in acetylcholine response with subsequent stimulation falls below threshold.

under double-blind conditions to ensure accurate assessment and remove the potential of a placebo effect.

Because release of acetylcholine is impaired in botulism, preventing its catabolism with an anticholinesterase medication typically has little clinical benefit, but a weaker effect is occasionally observed if some neurons maintain the ability to release acetylcholine. Thus, in rare cases, early in the course of botulism, injection of edrophonium results in limited improvement in strength, but this is far less dramatic than the improvement that occurs in patients with myasthenia gravis.<sup>136</sup>

### Electrophysiologic Testing

In all forms of botulism, sensory nerve action potentials are normal. Motor potentials in severely affected muscles typically are reduced in amplitude, but conduction velocity is not affected. Repetitive nerve stimulation at high frequencies would be expected to result in an increment of the amplitude of the motor potential, given the presynaptic localization of the defect, but this finding is neither sensitive nor specific; it also is more common in disease caused by BoNT type B than with type A.<sup>55,110</sup> A marked incremental response with high-frequency repetitive stimulation is more likely to suggest LEMS than botulism. Likewise, a decremental response to low-frequency repetitive nerve stimulation is characteristic of LEMS but is not consistently present in botulism.<sup>110</sup>

The needle EMG examination in botulism is characterized by low-amplitude, short-duration motor unit action potentials (MUAPs) caused by blockade of neuromuscular transmission in many muscle fibers (Fig. 38-2).

Polyphasic MUAPs are also common. Recruitment is usually normal but is reduced in severely affected muscles if all muscle fibers of a motor unit are blocked. Spontaneous activity, including positive sharp waves and fibrillation potentials, is often seen. Single-fiber EMG is useful in demonstrating abnormal neuromuscular transmission; for patients who cannot control voluntary muscle activation (eg, as infants), stimulated jitter analysis is proposed but is not universally available.<sup>129,177</sup>

Although these electrodiagnostic abnormalities support the diagnosis of botulism, there are no pathognomonic electrophysiologic findings. Nerve conduction studies and EMG are most useful for excluding alternative diagnoses, including Guillain-Barré syndrome and other neuropathies (both demyelinating and axonal), poliomyelitis, myasthenia gravis, and myopathies. Occasionally, muscle biopsy is necessary to exclude a myopathic process.<sup>110</sup>

### Laboratory Testing

If foodborne botulism is suspected, samples of serum, stool, vomitus, gastric contents, and suspected foods should be subjected to anaerobic culture (for *C. botulinum*) and mouse bioassay (for BoNT) (Table 38-3). A list of the patient's medications should accompany each sample to exclude other xenobiotics that might interfere with the assay (eg, pyridostigmine) or be toxic to the mice. The serum samples must be collected before initiation of antitoxin therapy. When wound botulism is considered, serum, stool, exudate, debrided tissue, and swab samples should be collected. For infant botulism, feces and serum samples also should be obtained. In infants who are constipated, an enema with nonbacteriostatic sterile water will facilitate collection. All enema fluid and stool should be sent for analysis. The specimens should be refrigerated (not frozen) and examined as soon as possible after collection. Detailed information on specimen collection and examination is available online from the CDC (<https://www.cdc.gov/botulism/pdf/bot-manual.pdf>).<sup>45</sup>

In the mouse lethality assay, which remains the gold standard for diagnosis, the sample (serum, stool, or food) is injected intraperitoneally into mice, which are then observed for development of signs of botulism. Control mice are injected with the sample as well as antitoxin. This test is very sensitive, with a detection limit of 0.01 ng/mL of sample eluate. However, it is laborious and expensive, and a positive result is often delayed for several days, reducing its usefulness in early diagnosis of botulism.<sup>104</sup> Alternative methods for detecting BoNT, including immunologic methods (eg, enzyme-linked immunosorbent assay, endopeptidase assays, and analysis of synaptic activity in neuronal cell cultures) have been used successfully.<sup>23,135,140,158</sup>

*Clostridium botulinum* can be cultured under strict anaerobic conditions. Stool specimens are incubated anaerobically and then subcultured on egg yolk agar to assess for lipase production, although this test is not specific as other clostridia also produce lipase. Various protocols using polymerase chain reaction and probe hybridization to detect and identify *C. botulinum* are described but are not widely applied in clinical practice.<sup>94,104</sup>

**TABLE 38-3** Epidemiologic and Laboratory Assessment of Botulism<sup>a</sup>

Classification	Foodborne	Infant	Wound	Adult Intestinal Colonization
BoNT type	A, B, E, F, G in humans; C, D in animals	A, B, C, F, H	A, B	A
Route	Ingestion of toxin	Ingestion of bacteria and spores	Wound, abscess (sinusitis)	Ingestion of bacteria and spores
Specimens	Stool: positive for bacteria/spores and toxin	Stool: positive for bacteria/spores and toxin for up to 8 wk after recovery	Wound site: Gram stain, aerobic and anaerobic cultures; positive for bacteria/spores	Stool: positive for bacteria/spores and toxin
BoNT in serum	Yes	Yes (but low sensitivity)	Yes	Yes
Bacteria/spores <sup>a</sup> in food	Yes	Yes	Not applicable	Yes
BoNT in food	Yes	No	Not applicable	No

<sup>a</sup>"Bacteria/spores" refers to *C. botulinum*.

BoNT = botulinum toxin.

## MANAGEMENT

### Supportive Care

Respiratory compromise is the usual cause of death from botulism. To prevent or treat this complication, hospital admission of the patient and of all individuals with suspected exposure is mandatory. Careful continuous monitoring of respiratory status using parameters such as vital capacity, peak expiratory flow rate, negative inspiratory force (NIF), pulse oximetry, end-tidal CO<sub>2</sub>, and the presence or absence of a gag reflex is essential to determine the need for intubation if a patient begins to manifest signs of bulbar paralysis.<sup>148</sup> The NIF is the most reliable, readily obtainable test for determining the need for intubation. When suspicion of botulism is high and the vital capacity is less than 20 mL/kg or the NIF is poorer than -30 cm H<sub>2</sub>O, intubation is generally indicated.<sup>102,118</sup>

Reverse Trendelenburg positioning at 20 to 25 degrees with cervical support has been suggested to be beneficial by enhancing diaphragmatic function. In theory, this approach would reduce the risk of aspiration while decreasing the pressure of abdominal viscera on the diaphragm, with resultant improvement in ventilatory effort. However, its clinical application to seriously ill patients has not been validated.<sup>10</sup>

In addition to attention to respiratory issues, patients require nutrition (enteral or parenteral), prompt recognition and treatment of secondary infections, and prophylaxis against deep vein thromboses.

### Gastrointestinal Decontamination

Removal of the spores and toxin from the gut should be attempted. Although most patients present after a substantial time delay, the bacteria or BoNT (or both) can still be present hours or even days later. Activated charcoal is recommended as a routine part of supportive care because in vitro it adsorbs BoNT type A and probably also the other BoNT types.<sup>76</sup> Gastric lavage or emesis should be initiated only for an asymptomatic person who has very recently ingested a known contaminated food. If a cathartic is chosen, sorbitol is preferable because other cathartics such as magnesium salts potentially exacerbate neuromuscular blockade. Theoretically, whole-bowel irrigation has a role in decontamination, particularly if there is concern about initiating emesis, but interventions other than activated charcoal have not been evaluated under these circumstances.

### Wound Care

Thorough wound débridement is the most critical aspect in the management of wound botulism and should be performed promptly.<sup>86,107</sup> Antibiotic therapy alone is inadequate, as evidenced by several case reports of disease despite antibiotic therapy. Penicillin G is one of many drugs with excellent in vitro antimicrobial efficacy against *C. botulinum* and is useful for wound management.<sup>165</sup> However, penicillin has no role in the management of botulism caused by preformed toxin nor does it prevent gut spores from germinating. For these reasons, penicillin is not considered useful in infant and adult infectious botulism, and it is not by itself adequate for wound botulism. We recommend against using medications that interfere with neuromuscular transmission, such as aminoglycoside<sup>146</sup> and fluoroquinolone antibiotics<sup>91</sup> and clindamycin.<sup>150</sup>

### Guanidine, Dalfampridine, and 3,4-Diaminopyridine

Guanidine is no longer recommended for treatment of botulism because its merits were not substantiated.<sup>68,92</sup> (See previous editions of this text for a more extensive discussion.) Several studies<sup>145</sup> and case reports<sup>62</sup> have proposed that dalfampridine (4-aminopyridine) and 3,4-diaminopyridine are effective in improving neuromuscular transmission by enhancing acetylcholine release from the motor nerve terminal. In a rat BoNT type A model of botulism, 3,4-diaminopyridine restored neuromuscular function and enhanced animal survival.<sup>156</sup> Results in humans have been mostly disappointing,<sup>60,157</sup> but given the promising animal data and the apparent response in some patients,<sup>74</sup> along with the effectiveness in patients with LEMS, further investigative efforts may prove fruitful. Dalfampridine (Ampyra) is

FDA approved to improve walking in patients with multiple sclerosis, but its potential to induce seizures at therapeutic doses limits its clinical usefulness. The fact that 3,4-diaminopyridine does not substantially cross the blood-brain barrier, resulting in limited central nervous system manifestations, makes this xenobiotic appropriate for further investigation, but cannot be recommended for routine use at the current time.

### Botulinum Antitoxin

Since the 1960s, passive immunization with antitoxin has been used to neutralize unbound BoNT. In the United States, botulinum antitoxin (BAT) is available for adults and children older than 1 year through the CDC, the Alaska Division of Public Health, and the California Department of Public Health. State public health officials can obtain the antitoxin through the CDC by calling 770-488-7100. In 2013, the FDA approved a heptavalent BAT containing equine-derived antibody to botulinum toxin types A through G. It currently is the only BAT available in the United States for the treatment of botulism in adults and for cases of infant botulism caused by nerve toxins other than types A and B.<sup>174</sup>

Because of the rarity and severity of botulism, randomized controlled studies of antitoxin in humans are neither feasible nor ethical. The current heptavalent BAT was shown to increase survival in guinea pig and rhesus macaque animal models.<sup>22</sup> In a CDC analysis of an open-label observational study involving 109 patients with suspected or confirmed botulism, treatment with BAT within 2 days of symptom onset was associated with a shorter length of hospitalization (13.7 days less), shorter duration in intensive care unit (6.6 days less), and shorter duration of mechanical ventilation (11.8 days less) compared with patients treated later.<sup>22</sup> Because of the benefit of earlier treatment, physicians should contact their state health department at the time the diagnosis of botulism is first suspected to expedite obtaining antitoxin from the CDC.

In a review of 132 cases of type A foodborne botulism from 1984 (when only trivalent antitoxin was available), a lower fatality rate and a shorter course of illness were demonstrated for patients who received the antitoxin, even after controlling for age and incubation period.<sup>166</sup> The earlier a patient received antitoxin, the shorter was the clinical course. In addition, no respiratory arrests occurred more than 5 hours after antitoxin was administered. Two studies on the use of antitoxin in the presence of wound botulism demonstrated that the longer the delay to antitoxin administration, the more prolonged the requirement for ventilatory support and the poorer the outcome.<sup>54</sup>

Serum, stool, and gastric aspirate samples should be collected before administration of antitoxin. In adults (17 years and older), the entire vial of botulinum antitoxin should be given intravenously as a 1:10 vol/vol dilution in 0.9% sodium chloride at rate of 0.5 mL/min for 30 minutes, optionally increasing to 1 mL/min for 30 minutes and then 2 mL/min if tolerated. In children 1 to 17 years of age, the dose and infusion rate are modified based on body weight; in infants (younger than 1 year), the dose is 10% of the adult dose and infusion rate is based on body weight.<sup>22</sup> Premedication with corticosteroids and antihistamines is reasonable in children and in patients with a suspected history of reaction to equine-derived products. Epinephrine and diphenhydramine should be readily available to treat anaphylaxis or hypersensitivity reactions.<sup>22</sup> The overall rate of adverse reactions, including hypersensitivity and serum sickness,<sup>27</sup> to equine-derived BATs is reported as 9% to 17%, with an incidence of anaphylaxis as high as 1.9%.<sup>17,120</sup> However, because BAT is despeciated, the risk of such reactions likely is lower.

The antitoxin neutralizes only unbound toxin; consequently, it can prevent paralysis but does not affect already paralyzed muscles.<sup>72</sup> Because of the potential lethality of foodborne botulism, the antitoxin should be given to patients in whom the diagnosis is suspected; treatment should not be delayed while awaiting laboratory confirmation of the diagnosis. In the event of a potential outbreak of foodborne botulism, asymptomatic individuals should be closely monitored for early signs of illness so that antitoxin can be administered promptly<sup>153</sup> (Antidotes in Depth: A6).

### Treatment of Infant Botulism

Similar to adults, infants with botulism require intensive care, with meticulous monitoring for respiratory compromise and autonomic dysfunction.<sup>133</sup> Constipation can be severe.

In October 2003, the FDA licensed human-derived botulism antitoxin antibodies as botulism immune globulin (BabyBIG) for treatment of infant botulism types A and B.<sup>7</sup> A randomized trial of 122 cases of infant botulism showed that treatment with intravenous botulism immune globulin significantly reduced the length of hospital stay and intensive care, duration of mechanical ventilation and tube or intravenous feeding, and cost of hospitalization relative to placebo without causing serious adverse effects.<sup>11,71</sup> Similar results were seen in a 2007 retrospective chart review.<sup>176</sup> BabyBIG is available from the California Department of Health Services Infant Botulism Treatment and Prevention Program (510-231-7600; <http://www.infantbotulism.org>).<sup>34</sup>

### Prevention

Measures used to prevent infant botulism include limiting exposure to spores by thoroughly washing foods and objects that might be placed in a child's mouth. In addition, honey should not be given to infants younger than 6 months of age.

Vaccination strategies are under investigation, including several recombinant vaccines that have shown promise in protecting against botulism in animal and human trials.<sup>19,160</sup> Future approaches may include treatments that inhibit BoNT trafficking or promote toxin clearance or acetylcholine potentiation, among other mechanisms.<sup>16,95</sup>

### PROGNOSIS

The prolonged and variable period of recovery that occurs after exposure to BoNT is directly related to the extent of neuromuscular blockade and neurogenic atrophy as well as the regeneration rates of nerve endings and presynaptic membranes.<sup>111</sup> If the patient has excellent respiratory support during the acute phase and receives adequate parenteral nutrition, residual neurologic disability may not occur. Although the initial course sometimes is protracted, near-total functional recovery can follow within several months to 1 year. Common long-term sequelae include dysgeusia, dry mouth, constipation, dyspepsia, arthralgia, exertional dyspnea, tachycardia, and easy fatigability.

The status of 13 patients who survived a toxin type B botulinum outbreak was characterized 2 years later by persistent dyspnea and fatigue, although surprisingly, pulmonary function test results had returned to normal in all patients.<sup>184</sup> Inspiratory muscle weakness persisted in 4 of 13 patients. Maximal oxygen consumption and maximal workload during exercise were diminished in all patients, and all had more rapid shallow breathing and a higher dyspnea score than controls. The reasons for premature exercise termination may be multifactorial. Although persistent respiratory muscle weakness may be an explanation, most dyspnea and fatigue appeared to be related to reduced cardiovascular fitness, leg fatigue, and diminished nutrition.<sup>184</sup>

A 2007 case-control series reported long-term outcomes in 217 adults with foodborne botulism in the Republic of Georgia. Six patients died; the remaining 211 were interviewed a median of 4.3 years after onset of disease. They were significantly more likely than control participants to report ongoing fatigue, dizziness, weakness, dry mouth, difficulty lifting things, and difficulty breathing with moderate exertion.<sup>78</sup>

### PREGNANCY

At least eight cases of botulism occurring during pregnancy are reported.<sup>30</sup> None of the neonates had neurologic evidence of botulism, though two (one with a heroin-abusing mother) had complications apparently unrelated to the botulism.<sup>122,162</sup> The large molecular weight of the neurotoxin (150 kDa) makes passive diffusion through the placenta unlikely, and experimental results in rabbits attest that this does not take place.<sup>87</sup> Appropriate care of

the affected mother and preparation for maternal complications of delivery appear to ensure the best potential outcome for the infant.

All commercially available BoNT products are FDA Pregnancy Category C. Published case reports regarding therapeutic use of BoNT during pregnancy mostly describe uncomplicated births, although two miscarriages have been reported. In a review of 137 prospective pregnancies in the Allergan safety database of women treated with onabotulinumtoxinA during pregnancy or within 3 months before pregnancy, 79% resulted in live births, of which 2.7% were associated with fetal defects. These prevalence rates are said to be similar to those in the general population.<sup>30</sup>

It is unknown whether BoNT is excreted in breast milk.

### EPIDEMIOLOGIC AND THERAPEUTIC ASSISTANCE

Whenever botulism is suspected or proven, the local health department should be contacted. The health department should report to the CDC Emergency Operations Center at 770-488-7100. The CDC can provide or facilitate diagnostic, consultative, and laboratory testing services, access to BAT, and assistance in epidemiologic investigations. All foods that are potentially responsible for the illness should be refrigerated and preserved for epidemiologic investigation. The merits of this surveillance and antitoxin release system were demonstrated in Argentina,<sup>178</sup> where the CDC assisted in establishing nation-specific principles, including local stocking of antitoxin and establishing mechanisms for distribution, emergency identification, response, and laboratory confirmation of suspected cases. Expansion of this system to other nations will enhance worldwide botulism surveillance for foodborne botulism and for potential terrorist dissemination of BoNT.<sup>152</sup>

### SUMMARY

- Most cases of botulism in the United States affect infants younger than 6 months of age. Because of an epidemiologic association, honey should not be given to babies younger than 1 year of age.
- Most cases of foodborne botulism relate to food processed at home under improper conditions.
- Treatment of botulism should not be delayed while awaiting laboratory confirmation in patients presenting with diplopia, blurred vision, bulbar weakness, or symmetric paralysis.
- BabyBIG, a botulism immune globulin, is available for treatment of infant botulism types A and B, and there is a heptavalent BAT against serotypes A through G for infants with botulism caused by other BoNT types and for noninfants. Treatment should not be delayed while laboratory diagnosis is pending.

# BOTULINUM ANTITOXIN

Silas W. Smith and Howard L. Geyer

## INTRODUCTION

Antidotal therapies for adult and infant *Clostridium botulinum* infection are available as equine- and human-derived immunoglobulin antitoxins. Antitoxins are beneficial for most clinical forms of botulism, although their utility is restricted to limiting disease progression rather than to reversing clinical manifestations.

## HISTORY

Beginning in the 1930s, a formalin-inactivated toxoid against botulinum neurotoxin was first tested in humans, and in 1946, a bivalent (against types A and B) formaldehyde-inactivated toxoid was deployed by the Department of Defense as prophylaxis for at-risk individuals during the US Offensive Biological Warfare Program.<sup>56,65</sup> Before 1999, an equine trivalent antitoxin (BAT-ABE) was used to treat botulism.<sup>13</sup> From 1999 to 2010, equine-derived, licensed bivalent botulinum antitoxin AB (BAT-AB) and investigational monovalent serotype E botulinum antitoxin (BAT-E) were available in the United States as immunoglobulin preparations. Patients with presumed wound botulism received BAT-AB. BAT-AB and BAT-E antitoxins were coadministered to patients with foodborne botulism. On March 13, 2010, equine heptavalent botulinum antitoxin (H-BAT, NP-018), an investigational new drug sponsored by the Centers for Disease Control and Prevention (CDC), replaced licensed bivalent BAT-AB and investigational BAT-E.<sup>16</sup> Effective November 30, 2011, the CDC also stopped providing the investigational pentavalent (ABCDE) botulinum toxoid (PBT) for vaccination of workers at risk for occupational exposure.<sup>17</sup> Botulism Immune Globulin Intravenous (Human) (BIG-IV), or BabyBIG was created by the California Department of Health Services (CDHS) in 1991 to treat infants affected by type A or type B botulism; it received Food and Drug Administration (FDA) approval in 2003.<sup>2,27</sup> On March 22, 2013, the FDA approved H-BAT, equine Botulism Antitoxin Heptavalent (A, B, C, D, E, F, G), which is currently available.

## PHARMACOLOGY

### Chemistry and Preparation

A toxoid is an inactivated form of a bacterial toxin. An antitoxin is an antibody or antibody fragment capable of neutralizing a toxin. Multiple injections of formalin-inactivated toxoid are required over months to effectively immunize horses against botulinum toxin and to produce equine-derived antitoxins.<sup>37</sup> The resultant antitoxin immunoglobulin requires several purification and preparation steps.<sup>30</sup> Heptavalent botulism antitoxin is produced by pooling plasma from horses immunized with seven specific botulinum toxoid types (A–G) followed by pepsin digestion and blending of the seven unique serotype antitoxins into a heptavalent product.<sup>11</sup> The antitoxin potencies for botulism serotypes A to G in H-BAT are provided in [Table A6–1](#). By convention, 1 IU of BAT neutralizes 10,000 mouse intraperitoneal median lethal doses (MIPLD<sub>50</sub>) of toxin types A, B, C, D, and F and 1,000 MIPLD<sub>50</sub> of toxin type E (the IU for type G remains undefined).<sup>15</sup> As the equine H-BAT is “despeciated” by pepsin enzymatic cleavage to remove the Fc fragment portion, the resultant product is composed of 90% or greater Fab and F(ab')<sub>2</sub> immunoglobulin fragments and less than 2% intact immunoglobulin G (IgG).<sup>16</sup> This decreases the risk of immediate hypersensitivity reactions and serum sickness.

Human whole IgG BIG-IV was formerly produced from pooled adult plasma collected from human donors immunized multiple times with

PBT (A–E).<sup>45,61</sup> The current purified immunoglobulin is derived from cold ethanol precipitation of pooled adult plasma from persons who were immunized with a recombinant botulinum vaccine for serotypes A and B (rBV A/B) followed by a number of purification steps to inactivate and/or remove infectious agents.<sup>34</sup> The reconstituted product (2 mL containing 50 ± 10 mg immunoglobulin in each milliliter) is primarily IgG, with trace amounts of IgA and IgM, and contains greater than or equal to 15 IU/mL anti-type A toxin activity and greater than or equal to 4 IU/mL anti-type B toxin activity; antibody titers against botulinum neurotoxins C, D, and E are undetermined.<sup>27,34</sup>

### Mechanism of Action

Current antitoxins (whether equine or human derived) bind to and neutralize free botulinum toxin.<sup>13</sup> Thus, antitoxins are ineffective against toxin bound to presynaptic acetylcholine release sites, toxin endocytosed by peripheral neuronal cells, and intracellular botulinum toxin light chain endopeptidase activity.<sup>9</sup> Affected presynaptic endplates must regenerate to regain function.

### Pharmacokinetics and Pharmacodynamics

Antidotal antibody fragments {eg, (F(ab')<sub>2</sub>, F(ab')}, and single-chain variable fragments (scFvs)} demonstrate shortened half-lives in vivo compared with whole immunoglobulins.<sup>39</sup> Improved renal clearance and uptake by vascular endothelium and surrounding tissues contributes to this effect.<sup>50</sup> Although linking fragments to polyethylene glycol (PEG) can extend the half-life,<sup>19</sup> this methodology remains investigational. Half-lives for antitoxin types A, B, and E were 6.5, 7.6, and 5.3 days, respectively, in a patient provided whole intact IgG trivalent antitoxin.<sup>29</sup> Because H-BAT contains primarily Fab and F(ab')<sub>2</sub> immunoglobulin fragments and minimal intact whole IgG, administration of H-BAT antitoxin yields shorter half-lives which are on the order of hours ([Table A6–1](#)). These half-lives generally increase in a nonlinear fashion when two vials were administered ([Table A6–1](#)). The total volume of distribution ranges from 1,465 mL (anti-D) to 14,172 mL (anti-E) and tends to increase with multiple vials.<sup>12</sup> The more rapid clearance of Fab and F(ab')<sub>2</sub> fragments compared with whole IgG, infrequently necessitates repeat H-BAT dosing in patients with wound or intestinal colonization or other cases in which in situ botulinum toxin production continues after antitoxin clearance.<sup>16</sup> Indeed, recurrence of paralysis was reported after H-BAT therapy in a patient with persistent type F intestinal colonization.<sup>24</sup> Given the neutralization parameters provided by each IU of BAT as indicated previously, the antitoxin in H-BAT would offset a total amount of toxin ranging from 5.1 × 10<sup>6</sup> MIPLD<sub>50</sub> of botulinum E toxin to 4.5 × 10<sup>7</sup> MIPLD<sub>50</sub> of botulinum A toxin ([Table A6–1](#)).<sup>54</sup> These values would be anticipated to provide significant neutralization, because patient serum botulinum toxin concentrations in foodborne botulism are usually less than 10 MIPLD<sub>50</sub>/mL and rarely exceed 32 MIPLD<sub>50</sub>/mL using a plasma volume of 3,000 mL reported previously.<sup>3,29,53</sup> However, in isolated outbreaks, botulinum toxin concentrations in adult serum samples collected less than 18 hours after exposure are reported to be as high as 160 MIPLD<sub>50</sub>/mL.<sup>5</sup> Other extremely rare cases have yielded human serum botulinum toxin concentrations of type A of 1,800 MIPLD<sub>50</sub>/mL.<sup>54</sup> Nevertheless, even with these elevated exposures, the reported H-BAT maximum concentration values<sup>12</sup> after single-vial administration are anticipated to sufficiently neutralize 26,900 MIPLD<sub>50</sub>/mL of botulinum A toxin, 19,000 MIPLD<sub>50</sub>/mL of botulinum B toxin, 22,600 MIPLD<sub>50</sub>/mL of botulinum C toxin, 8,100 MIPLD<sub>50</sub>/mL of botulinum D toxin, 940 MIPLD<sub>50</sub>/mL of botulinum E toxin, and 23,700 MIPLD<sub>50</sub>/mL of botulinum F toxin ([Table A6–1](#)).

TABLE A6-1 Botulinum Antitoxin Parameters

	Antitoxin Serotype						
	A	B	C	D	E	F	G
<b>Heptavalent Botulinum Antitoxin (H-BAT)</b>							
Antitoxin potency (IU per vial)	4,500	3,300	3,000	600	5,100	3,000	600
Anticipated neutralization (MIPLD <sub>50</sub> )	$4.5 \times 10^7$	$3.3 \times 10^7$	$3.0 \times 10^7$	$6.0 \times 10^6$	$5.1 \times 10^6$	$3.0 \times 10^7$	Undefined
Maximum concentration values (IU/mL), one-vial administration	2.69	1.90	2.26	0.81	0.94	2.37	0.59
Maximum concentration values (MIPLD <sub>50</sub> /mL)	$2.69 \times 10^4$	$1.90 \times 10^4$	$2.26 \times 10^4$	$8.1 \times 10^3$	$9.4 \times 10^2$	$2.37 \times 10^4$	Undefined
Maximum concentration values (IU/mL), 1-vial administration	6.23	4.28	4.89	1.60	1.75	4.29	1.19
Maximum concentration values (MIPLD <sub>50</sub> /mL)	$6.23 \times 10^4$	$4.28 \times 10^4$	$4.89 \times 10^4$	$1.60 \times 10^4$	$1.75 \times 10^3$	$4.29 \times 10^4$	Undefined
Half-life (h), one-vial administration	8.64	34.2	29.6	7.51	7.75	14.1	11.7
Half-life (h), two-vial administration	10.2	57.1	45.6	7.77	7.32	18.2	14.7
Volume of distribution, one-vial administration	3,637	9,607	6,066	1,465	14,172	3,413	2,372
Volume of distribution, two-vial administration	3,993	14,865	8,486	1,653	11,596	4,334	3,063
<b>Botulism Immune Globulin Intravenous (Human) (BabyBIG-IV)</b>							
Potency (IU/mL) <sup>a</sup>	15	4					
Anticipated neutralization (MIPLD <sub>50</sub> )	$1.5 \times 10^5$	$4 \times 10^4$					
Half-life (days)	28	28					
<b>Bivalent botulinum antitoxin AB (BAT-AB) (for historical comparison)</b>							
Antitoxin potency (IU)	7,500	5,500					
<b>Monovalent serotype E botulinum antitoxin (BAT-E) (for historical comparison)</b>							
Antitoxin potency (IU)					5,000		
<b>Equine trivalent antitoxin (BAT-ABE) (for historical comparison)</b>							
Antitoxin potency (IU)	7,500	5,500			8,500		

<sup>a</sup>The reconstituted vial contains a total of 2 mL.

MIPLD<sub>50</sub> = mouse intraperitoneal median lethal dose.

Data from references 12, 24, 27, 32, 34, 49, and 54.

A second vial would provide even greater protection (Table A6-1). This might be warranted in particularly severe exposures because circulating neutralizing antibody concentrations and botulinum toxin interactions are nonlinear and lead to a more efficacious, disproportional increase in botulinum toxin neutralization when antibody concentrations are increased.<sup>38,53</sup> Although anticipating or interpreting absolute neutralization efficacy is inexact because of numerous factors, one study that measured four patients' serum antitoxin concentrations after trivalent antitoxin (BAT-ABE) administration determined that the patients' measured antitoxin titers would retain the capability to neutralize 1,500, 1,000, and 12 times the anticipated toxin concentrations of types A, B, and E, respectively.<sup>29</sup>

A new botulinum neurotoxin "type H" recovered from a naturally occurring infant botulism case raised concern because it was unable to be neutralized by available monovalent botulinum neurotoxin types (A-G) or a heptavalent antitoxin product.<sup>6,21</sup> Botulinum neurotoxin "type H" shares sequence homology with the botulinum neurotoxin type A1 heavy chain binding domain and the botulinum neurotoxin F5 light chain enzymatic domain. Subsequent mouse bioassay and neuronal cell-based assays demonstrated that commercial H-BAT provides complete neutralization of botulinum neurotoxin "type H" at exposures of 100 MIPLD<sub>50</sub>/mL and complete neutralization with a single exception at 2,000 MIPLD<sub>50</sub>/mL.<sup>38</sup> Given that

serum botulinum toxin concentrations in foodborne botulism rarely exceed 32 MIPLD<sub>50</sub>/mL, one H-BAT vial is anticipated to be sufficient to treat most botulism type H cases and bivalent strain cases (a strain that produces dual, distinct botulinum neurotoxins).<sup>29,38</sup>

The half-life of BIG-IV is approximately 28 days.<sup>34</sup> BabyBIG Lot 2 anti-A titers were 0.5371 ± 0.2134 IU/mL on day 1 after administration, declining to 0.0193 ± 0.0141 IU/mL by week 20.<sup>34</sup> Because 1 IU neutralizes 10,000 mouse intraperitoneal median lethal doses (MIPLD<sub>50</sub>) of botulinum toxin A, this yields approximate neutralization titers of 5,370 MIPLD<sub>50</sub>/mL on day 1 and 193 MIPLD<sub>50</sub>/mL by week 20.<sup>15,34</sup> Thus, a single infusion is anticipated to neutralize all botulinum toxin that might be absorbed from an infant's colon for several months.<sup>4</sup>

### Related Agents

To properly interpret earlier botulism studies, it is important to recall that the previously available, equine BAT-AB antitoxin contained 7,500 IU of anti-A antitoxin and 5,500 IU of anti-B antitoxin.<sup>49</sup> Monovalent serotype E botulinum antitoxin contained 5,000 IU of antitoxin. Trivalent antitoxin (BAT-ABE), contained 7,500 IU anti-A, 5,500 IU anti-B, and 8,500 IU anti-E antitoxins.<sup>32</sup> Investigational, whole and fragment-derived monoclonal antibodies that are raised in murine and equine species against type A and B are also being explored.<sup>37,39</sup> Investigational PBT vaccine, combining individual

monovalent toxoids, was initially manufactured by Parke Davis more than 50 years ago and was subsequently produced by the Michigan Department of Public Health under contract from the US Army.<sup>26,55</sup>

The US Department of Defense Medical Countermeasure Systems-Joint Vaccine Acquisition Program (MCS-JVAP) manages the development pipeline for the lead replacement vaccine—recombinant botulinum vaccine (rBV A/B)—which is intended to protect adults 18 to 55 years old against botulism type A (subtype A1) and type B (subtype B1).<sup>28,52</sup> Other monoclonal antibodies, small peptides and peptide mimetics, receptor mimics and antagonists, endosome modulators, and endopeptidase inhibitors are being explored for botulism treatment.<sup>1</sup>

### ANTITOXIN ROLE IN ADULT BOTULISM

Rigorous adult morbidity and mortality studies are difficult to perform because the rarity of botulism, varied exposure and presentation, delayed recognition when bound toxin is no longer scavengable by antitoxin, and inconsistent clinical care. Given the delay involved in confirmatory testing by the CDC or public health laboratories, which could decrease the window of opportunity for antitoxin reversal potential, the decision to administer H-BAT is often made on the basis of empirical clinical and epidemiologic grounds. Earlier disease recognition and an organized public health approach consisting of surveillance, emergency notification, stocking, a release and distribution system, and laboratory confirmation appear to be responsible for decreasing morbidity and increasing survival after typical foodborne botulism.<sup>51,64</sup> Simian experiments demonstrate reduced mortality with antitoxin administration.<sup>43</sup> Early antitoxin administration appears to be a critical factor affecting clinical course and outcome. In a 1963 type E outbreak, all three patients who died failed to receive antitoxin, but three of five who received BAT survived.<sup>35</sup> Trivalent equine antitoxin decreased the fatality rate of botulinum A poisoning in a case series of 132 patients from 1973 to 1980.<sup>59</sup> The mortality rate was 10% in patients receiving antitoxin within 24 hours after onset, 15% in those who received antitoxin more than 24 hours after onset, and 46% in those without antitoxin administration. Age over 60 years and being an index patient conferred a greater mortality risk; a shorter incubation period of less than 36 hours (a likely measure of toxin dose) increased duration of hospitalization, mechanical ventilation, and time to sustained improvement.<sup>59</sup> The case-fatality rate was 3.5% in patients with type E botulism who were provided antitoxin and 28.9% for untreated control participants from previous years, although the utilization of supportive measures was uncontrolled.<sup>33</sup> In a retrospective review of 29 patients admitted between 1991 and 2005 with type A and a single case of type B wound botulism, a delay in antitoxin administration correlated with increased length of intensive care unit (ICU) stay.<sup>44</sup> In 20 patients with type A wound botulism treated from 1991 to 1998, those who received antitoxin within 12 hours of presentation required mechanical ventilation 57% of the time for a median duration of 11 days compared with those who failed to receive antitoxin within 12 hours in whom 85% required mechanical ventilation for a median duration of 54 days.<sup>48</sup> Again, a shorter time to presentation heralded more severe disease (respiratory failure). A third wound botulism series (types A and B) with seven patients confirmed the importance of early therapy. Those receiving antitoxin more than 8 days from symptom onset or not at all (1 case) had worse outcomes compared with those receiving it within 4 days of symptom onset, including need for persistent mechanical ventilation (40%), bedridden (100%), inability to discharge to home setting (100%), and prolonged hospital course.<sup>18</sup> In an uncontrolled, retrospective review of 205 cases of foodborne botulinum (predominantly type E) in Canada from 1985 to 2005, patients receiving antitoxin experienced a median hospital length of stay of 5 days, which was significantly shorter than the group that did not receive antitoxin (median length of stay, 11 days).<sup>36</sup>

An earlier despeciated heptavalent botulism immune globulin (dBIG), which was prepared by the University of Minnesota under US Army contract, was deployed in the 1991 Egyptian type E botulism outbreak.<sup>30</sup> In a 2006 Thailand type A outbreak, a heptavalent antitoxin was administered to 20 patients 5 days after toxin ingestion when respiratory failure was already

present. Mechanical ventilation and hospital duration were shorter compared with a historical study, and there were no deaths in those receiving antitoxin.<sup>68</sup> In a 2011 Utah prison botulism outbreak caused by potato-based pruno (prison-brewed alcohol), H-BAT was administered to eight patients a median of 12 hours after emergency department (ED) arrival and 73.3 hours after exposure.<sup>67</sup> Three patients required intubation; all survived.<sup>67</sup> Heptavalent botulism antitoxin was used in a separate prison botulism outbreak in Arizona in 2012 in eight inmates who also had consumed potato-based pruno.<sup>70</sup> Incubation periods ranged from 10 to 67 hours. All patients received antitoxin within 24 hours of hospital admission, seven required intubation and percutaneous endoscopic gastrostomies, and none died.<sup>70</sup> In the largest US botulism outbreak in nearly 40 years, which resulted from home-canned potato salad at a church potluck meal, 25 of 29 confirmed or probable cases received heptavalent botulinum antitoxin (H-BAT); 11 required intubation and mechanical intubation; and 1 patient died of respiratory failure shortly after arriving at the ED.<sup>40</sup>

The absolute time frame for efficacy remains undetermined. In 109 patients treated under the CDC open-label protocol, H-BAT administration within 2 days after symptom onset (compared with longer than 2 days) was associated with clinically significant, shorter mean durations of hospitalization (12.4 versus 26.1 days), ICU utilization (9.2 versus 15.8 days), and mechanical ventilation (11.6 versus 23.4 days).<sup>12</sup> However, circulating toxin can persist for long periods in patients with foodborne botulism. One study reported toxin detection in almost 20% of serum specimens taken greater than or equal to 10 days after toxin ingestion.<sup>69</sup> Furthermore, persistent, viable organisms or spores were present in stools 40% of the time at 10 days or more after toxin ingestion. A review of laboratory-confirmed botulism cases in Alaska from 1959 to 2007 demonstrated that toxin could be recovered in patients' sera up to 11 days after ingestion, but no serum specimens collected after antitoxin administration tested positive.<sup>23</sup> In one case, toxin was detected in serum 12 days after the onset of descending paralysis.<sup>22</sup> Another patient in a multinational foodborne outbreak had toxin detected at 25 days after symptom onset.<sup>54</sup> Other isolated cases detail detectable circulating toxin as late as 3.5 weeks after contaminated food consumption.<sup>20</sup> Botulinum toxin-associated ileus can result in conditions conducive for continued absorption and prolonged toxin exposure. In other scenarios, contaminated wounds and orthopedic hardware can harbor *Clostridia* species despite antibiotic therapy.<sup>60</sup> Collectively, these factors suggest that H-BAT could still provide clinical benefit in patients with delayed presentations or disease recognition, in whom gastrointestinal or circulating toxin presents a persistent risk. Indeed, one report documented improvement when H-BAT was administered 48 hours after admission and many days after consumption of type-unspecified, botulism-contaminated canned corn.<sup>31</sup> Clinically significant improvement (weaning from mechanical ventilation and resumption of feeding) was documented in a case of BIG-IV administered 13 days after onset of infant botulism.<sup>10</sup> Botulin antitoxins are also provided in cases of iatrogenic botulism.<sup>57</sup> In two patients with cosmetic iatrogenic botulism type A, administration of monovalent type A antitoxin as late as 7 and 9 days after the onset of weakness and bulbar symptoms improved symptoms.<sup>25</sup> Based on these limited data, it would be reasonable to provide BAT in delayed scenarios.

Botulism poisoning does not appear to induce protective immunity or decrease morbidity or mortality associated with subsequent exposure in food or wound botulism.<sup>7,13,71</sup> Thus, retreatment with antitoxin is required upon reexposure or in recurrent cases.

### ANTITOXIN ROLE IN INFANT BOTULISM

BabyBIG is approved for treatment of patients younger than 1 year of age with infant botulism caused by toxin type A or B. BabyBIG is no longer derived from human donors vaccinated with PBT (A–E), only those immunized with recombinant botulinum vaccine of serotypes A and B. Thus, H-BAT is required to treat infants with non-type A or B botulism. In a double-blind and subsequent open-label trial, treatment with BabyBIG-IV significantly reduced the overall length of hospital and intensive care stay, the duration of mechanical ventilation, tube and intravenous (IV) feeding, and the cost

of hospitalization.<sup>24</sup> A retrospective review of 67 ICU patients with type A or B botulinum toxin from 1976 to 2005 found clinically significant decreases in length of hospital stay, ICU stay, and mechanical ventilation in patients who received BabyBIG-IV and those who did not.<sup>62</sup> Another retrospective review of patients with type A or B botulinum toxin from 1985 to 2005 reported a significant decrease in length of stay a reduced need for nasogastric feeding and duration of tracheal intubation in infants treated with botulism immune globulin.<sup>71</sup>

Bivalent BAT-AB and other equine derived products were rarely used in infants because of concern for anaphylaxis, lifelong hypersensitivity, and unclear efficacy.<sup>15</sup> However, in situations when BabyBIG-IV was unavailable because of lack of access or cost, BAT-AB treatment within 5 days of symptom onset significantly reduced overall hospital and ICU stays, duration of mechanical ventilation, tube feedings, and incidence of sepsis.<sup>63</sup>

## ADVERSE EFFECTS AND SAFETY ISSUES

Despite purification, inactivation, and filtration measures, potential transmission of bloodborne infectious agents from animal or human donors (pooled equine or human plasma) may still occur. Treatment with whole equine-derived antitoxins risks hypersensitivity reactions and serum sickness.<sup>49</sup> Early rates of adverse reactions during the first decade during which BAT was available (1967–1977) ranged from 9% to 21%.<sup>8,42</sup> The reported rates of anaphylaxis and serum sickness were 1.9% and 3.7%, respectively.<sup>8</sup> However, the doses of antitoxin were larger than those subsequently used. Heptavalent botulism antitoxin despeciation further decreases, but does not eliminate this risk. Heptavalent botulism immune globulin (dBIG) produced adverse reactions in 10 of 45 patients when used in one botulism type E outbreak.<sup>30</sup> These included nine “mild” reactions (local skin reactions, 6; pruritus, 1; urticaria, 1; shivering, 1) and one episode of “suggested serum sickness” without additional detail. The incidence of adverse effects of dBIG was similar to other internationally available antitoxins.<sup>30</sup> Healthy participants administered H-BAT in clinical trials (56 total, of whom 20 received two vials) reported headache, pruritus, nausea, and urticaria at rates of 9%, 5%, 5%, and 5%, respectively.<sup>12</sup> Two moderate allergic reactions required treatment. Eleven subjects produced anti-BAT antibodies. The open-label CDC observation study revealed adverse reactions in 10% of 228 assessable patients: pyrexia (4%), rash (2%), chills (1%), nausea (1%), and edema (1%).<sup>12</sup> There were no immediate hypersensitivity reactions, one cardiac arrest, and one episode of serum sickness. Heptavalent botulism antitoxin contains maltose, which can interfere with certain non-glucose-specific blood glucose monitoring systems and falsely elevated glucose readings.<sup>12</sup>

Hypersensitivity reactions might also occur to human BIG-IV, although this was not reported in clinical trials.<sup>34</sup> Human BIG is contraindicated in patients with a prior history of severe reactions to other human immunoglobulin preparations.<sup>34</sup> Patients with selective immunoglobulin A deficiency have the potential to develop antibodies to immunoglobulin A and could have anaphylactic reactions to subsequent administration of blood products that contain immunoglobulin A. The most commonly reported adverse reaction was a mild, transient erythematous rash on the face or trunk. Kidney function should be assessed and monitored; if compromised, BabyBIG-IV is administered at minimum concentration and rate of infusion. The prescribing information warns of adverse events from immune globulin therapy, including aseptic meningitis, hemolytic anemia, thrombosis, transfusion-related acute lung injury, and hyperviscosity, although these are unreported with the Human BIG-IV immune globulin product.<sup>34</sup> Administration of live-virus vaccines (ie, measles, mumps, rubella, and varicella) utilization should be delayed for 3 or more months after BabyBIG-IV treatment because of concerns of loss of immunization efficacy.

## PREGNANCY AND LACTATION

Although there is limited information regarding H-BAT use in pregnancy, whole equine bivalent and trivalent antitoxins have been previously administered without apparent harm to the mother or the fetus.<sup>14,41,46,47,58</sup> Pregnancy is not a contraindication to H-BAT. Given the morbidity and mortality of

botulism, maternal treatment benefits would presumably exceed risks of harm, although all decisions are ultimately made on a case-by-case basis. The breast milk distribution of heptavalent botulism antitoxin is unknown.

## DOSING AND ADMINISTRATION

Close monitoring; medications, including epinephrine, diphenhydramine, and corticosteroids; therapeutic modalities; and practitioners who are capable of diagnosing and treating anaphylactic or anaphylactoid reactions (including intubation competence) should be immediately available before and during antitoxin administration.

### Botulism Antitoxin Heptavalent (A, B, C, D, E, F, and G)

Unlike prior equine-derived products, H-BAT does not require routine sensitivity testing before administration. In patients at risk for hypersensitivity reactions—those with previous therapy with an equine-derived antivenom or antitoxin or a history of hypersensitivity to horses, asthma, or hay fever—H-BAT administration is begun at the lowest rate achievable (<0.01 mL/min) and monitored.<sup>12</sup> Three separate dosing strategies are recommended for adults, pediatric patients (1–17 years of age), and infants younger than 1 year of age. The adult dose is one vial. The vial is diluted 1:10 in 0.9% sodium chloride and administered intravenously via an optional 15-micron in-line filter. Barring any infusion-related safety concerns, the initial rate is 0.5 mL/min for the first 30 minutes, which is increased to 1 mL/min for the next 30 minutes and then to 2 mL/min until completion of the infusion. For pediatric patients, the dose is a percentage of the adult (one vial) dose calculated according to the dosing rule summarized in the package insert. For pediatric patients with a body weight of 30 kg or less, the percentage of the adult dose to administer is equal to twice the body weight (in kilograms); for patients with a body weight greater than 30 kg, the percentage of the adult dose to administer equals the weight (in kilograms) + 30.<sup>12</sup> This rule yields the recommended percentages of the adult dose to administer for pediatric weight intervals from 10 to greater than 55 kg reproduced in the package insert.<sup>12</sup> Without ever exceeding the adult rates, the infusion is initiated at a rate of 0.01 mL/kg/min for the first 30 minutes, which is increased 0.01 mL/kg/min every 30 minutes, to a maximum infusion rate of 0.03 mL/kg/min until completion. Infants (younger than 1 year of age) receive 10% of the adult dose regardless of body weight. The infusion is initiated at a rate of 0.01 mL/kg/min for the first 30 minutes, which is increased 0.01 mL/kg/min every 30 minutes, to a maximum infusion rate of 0.03 mL/kg/min until completion.

### Botulism Immune Globulin Intravenous (Human)

The lyophilized product is reconstituted with 2 mL of Sterile Water for Injection USP, to obtain a 50 mg/mL human BIG-IV solution. The vial should not be shaken because this causes foaming. Infusion should begin within 2 hours of reconstitution. A dedicated IV line using low volume tubing and a constant infusion pump are used to provide 75 mg/kg (1.5 mL/kg of reconstituted 50-mg/mL BIG-IV solution). The BIG-IV solution can be “piggybacked” into a preexisting line if it contains Sodium Chloride Injection USP, 2.5% dextrose in water, 5% dextrose in water, 10% dextrose in water, or 20% dextrose in water (with or without added sodium chloride). If a preexisting line must be used, BIG-IV should not be diluted more than 1:2 with any of these solutions.<sup>34</sup> Human BIG-IV is administered at an initial rate of 25 mg/kg/h (0.5 mL/kg/h of reconstituted 50-mg/mL BIG-IV solution) for the first 15 minutes, which is then increased to 50 mg/kg/hr (1 mL/kg/hr of reconstituted 50 mg/mL BIG-IV solution), for a total infusion time of 97.5 minutes at the recommended dose.

### Other Immunoglobulins

In regions where whole, equine-derived antitoxins are still available, it is important to note that these products required sensitivity testing and potential desensitization, and the package inserts should be consulted for specific procedural details for dosing and administration, particularly because titers and volumes may differ by brand.<sup>49</sup> For prophylaxis, the recommended dose of BAT-AB for an individual ate food suspected of being infected with *C. botulinum* depends on the amount of food eaten and is 1,500 to 7,500 IU of anti-type A and 1,100 to 5,500 IU of anti-type B intramuscularly (20%–100%

of one vial). This initial therapy was followed in 12 to 24 hours by the injection of a second vial if any signs or symptoms of botulism developed.<sup>49</sup> In addition, 1,000 IU to 5,000 IU (20% to 100% of one vial) of investigational anti-type E, based on the estimated ingested quantity of botulinum toxin, was used for type E outbreaks.<sup>66</sup> The BAT-AB and BAT-E treatment doses were one vial of antitoxin diluted 1:10 (vol/vol) in 0.9% sodium chloride solution and administered slowly intravenously over 30 to 60 minutes.<sup>32,49</sup> Subsequent doses could be provided intravenously every 2 to 4 hours if progression of clinical findings occurs. The BAT-AB and BAT-E are administered separately.

## FORMULATION AND ACQUISITION

Heptavalent botulism antitoxin is supplied in either 20-mL or 50-mL single-dose vials. Despite variable vial filling of 10 to 22 mL/vial, the amount of A to G antitoxin contained per vial is fixed: more than 4,500 IU of anti-A, more than 3,300 IU of anti-B, more than 3,000 IU of anti-C, more than 600 IU of anti-D, more than 5,100 IU of anti-E, more than 3,000 IU of anti-F, and more than 600 IU of anti-G.<sup>12</sup> The bulk material contains approximately 30 to 70 mg/mL of protein. Heptavalent botulism antitoxin contains 10% maltose and 0.03% polysorbate 80. Heptavalent botulism antitoxin is stored frozen at or below 5°F (−15°C) until used. Thawed H-BAT must be maintained at 36° to 46°F (2°–8°C) and used within 36 months or until 48 months from the manufacture date, whichever occurs earliest. Heptavalent botulism antitoxin should not be refrozen. Frozen H-BAT can be thawed in a refrigerator at 36° to 46°F (2°–8°C) over approximately 14 hours. Rapid thawing can be achieved by placing at room temperature for 1 hour followed by a water bath at 98.6°F (37°C) until thawed. Reconstituted H-BAT may be stored refrigerated for use within 8 to 10 hours.

BabyBIG is formulated as a single-use, solvent-detergent-treated, sterile vial containing 100 ± 20 mg of lyophilized immunoglobulin (primarily IgG with trace amounts of IgA and IgM), stabilized with 5% sucrose and 1% albumin (human), without preservative and supplied with 2 mL of Sterile Water for Injection USP for reconstitution.<sup>27,34</sup>

Bivalent BAT-AB, which may be available outside of the United States, must be maintained at 2° to 8°C (35°–46°F) and not frozen. It contains phenol 0.4% as a preservative.

Clinicians who suspect botulism should immediately call their local or state health department's emergency 24-hour telephone service to request release of BAT and comply with legal reporting requirements; a single case is considered a public health emergency. When local and state public health authorities are unavailable, the CDC Emergency Operations Center telephone contact is 770-488-7100. The CDC controls H-BAT distribution from stocks located throughout a national network of decentralized Quarantine Stations. The California Infant Botulism Treatment and Prevention Program (510-231-7600) maintains the supply of BabyBIG for infant botulism treatment. The Biomedical Advanced Research and Development Authority (BARDA) within the US Department of Health and Human Services has obtained approximately 120,000 H-BAT doses for the Strategic National Stockpile (SNS), with anticipated completion of delivery of 80,000 additional doses by 2018.<sup>65</sup> The CDC released 50 doses of H-BAT from the SNS to Ohio during a large outbreak from home-canned potato salad.<sup>40</sup>

## SUMMARY

- In conjunction with frequent clinical assessments and aggressive supportive care of respiratory, gastric, and urinary function, BAT decreases morbidity and mortality after typical foodborne or wound botulism.
- Preliminary data suggest that early administration of licensed H-BAT decreases duration of hospitalization, ICU utilization, and mechanical ventilation.
- Licensed BabyBIG-IV provides effective treatment for infant botulism.
- Early consultation with local and state health departments, the CDC Emergency Operations Center (770-488-7100), or a regional poison control center (or other comparable agencies in other parts of the world) should occur to rapidly access effective therapeutic modalities and diagnostic tests for botulism.

## FOOD POISONING

Laura J. Fil and Michael G. Tunik

Each year in the United States known foodborne pathogens are responsible for approximately 30.7 million illnesses, 228,144 hospitalizations, and 2,612 deaths.<sup>47</sup> It is estimated that foodborne illness costs an annual burden to the American society of 36 billion dollars, which is estimated to be an average cost burden per illness of \$3,630.<sup>143</sup> Worldwide food distribution, large-scale national food preparation and distribution networks, limited food regulatory practices, and corporate greed place everyone at risk. Food poisoning causes morbidity and mortality by one or more of the following mechanisms: (bacteria, viruses and parasites) that can be transmitted in food; toxins that are produced by organisms, can be consumed in food; and xenobiotics can be inadvertently or purposefully used to contaminate food and ultimately be ingested.

This chapter is organized into four major types of food poisoning: foodborne poisoning with neurologic effects, food poisoning with gastrointestinal (GI) symptoms, foodborne poisoning with anaphylaxislike effects, and food poisoning used for bioterrorism.

### HISTORY AND EPIDEMIOLOGY

In the United States, viruses are the most responsible cause of foodborne outbreaks (82%) followed by bacteria (12%), and parasites (6%). Norovirus was the most common cause of single, confirmed etiology outbreaks (54%). The bacteria that caused the largest number of food poisonings were *Salmonella* spp, *Clostridium perfringens*, *Staphylococcus aureus* enterotoxin, and *Shigella* spp. The estimated annual number of episodes of foodborne pathogen related illness, hospitalization and death in the United States is shown in Table 39-1.<sup>48</sup>

Globally, researchers estimated foodborne pathogens were found to cause 582 million cases of illnesses annually. The leading cause of foodborne illness was norovirus (125 million cases) followed by campylobacter (96 million). Most important, around 43% of the disease burden from contaminated food occurred in children younger than 5 years of age, who make up 9% of the population.<sup>110</sup>

In the past decade, large numbers of people have also had food poisoning because of purposeful placement of chemicals in food.<sup>51</sup>

Many foodborne illnesses result in long-term sequelae to the GI, immune, nervous, respiratory, renal, cardiovascular, endocrine, and hepatic systems.<sup>14</sup>

### FOODBORNE POISONING WITH NEUROLOGIC SYMPTOMS

The differential diagnosis of patients with foodborne poisoning presenting with neurologic symptoms is vast (Tables 39-2 and 39-3). The sources of many of these cases are ichthyosarcotoxic, involving toxins from the muscles, viscera, skin, gonads, and mucous surfaces of the fish; rarely, toxicity follows consumption of the fish blood or skeleton. Most episodes of poisoning are not species specific, although particular forms of toxicity from Tetraodontiformes (puffer fish), Gymnothoraces (moray eel), and newts (*Taricha* and other species) are recognized.

In cases of ciguatera poisoning, the major symptoms usually are neurotoxic, and the GI symptoms are minor. Knowing where the fish was caught often helps establish a diagnosis, but refrigerated transport of foods and rapid worldwide travel can complicate the assessment. Travelers to Caribbean, Pacific, and Canary islands, as well as those traveling within the United States, have experienced ciguatera poisoning.<sup>119,155</sup> In geographically disparate regions of Canada,<sup>161</sup> individuals have experienced domoic acid poisoning caused by ingestion of cultivated mussels from Prince Edward Island.

In the differential diagnosis of foodborne poisons presenting with neurologic findings, activities other than eating must always be considered. In

particular, sport divers often perform their activities in high-risk areas such as Florida, California, and Hawaii and often during the high-risk periods from May through August. In the process, they may sustain a sting from a stingray tail, or laceration (from a deltoid or pectoral fin spine of a lionfish or stonefish) that can cause consequential marine toxicity (Chap. 116). Scientists have found that the chance of encountering numerous bacterial pathogens harmful to both human and marine life was cut in half near seagrass meadows. Swimmers and divers can limit disease by choosing waters rich in seagrass meadows.<sup>165</sup>

### Ciguatera Poisoning

Ciguatera poisoning is one of the most commonly reported forms of vertebrate fishborne poisonings in the United States, accounting for almost half of the reported cases.<sup>85</sup> Ciguatoxins are lipid soluble, polyether compounds consisting of 13 to 14 rings fused by ether linkages into a rigid ladder-like structure (Fig. 39-1). Ciguatera poisoning is endemic to warm water, bottom-dwelling reef fish living around the globe between 35° North and 35° South latitude, which includes tropical areas such as the Indian Ocean, the South Pacific, and the Caribbean. Hawaii and Florida report 90% of all cases occurring in the United States, most commonly from May through August.<sup>125</sup> The incidence and geographical distribution of ciguatera are increasing because of increased fish trade and consumption, international tourism, and climate changes.

**TABLE 39-1** Estimated Annual Number of Episodes of Illness, Hospitalizations and Death Caused by Pathogens Transmitted Commonly by Food in the United States (2014)<sup>48</sup>

Pathogen	Total Mean Episodes	Total Mean Hospitalizations	Total Mean Deaths
<b>BACTERIA</b>			
<i>Bacillus cereus</i>	62,623	20	0
<i>Campylobacter</i> spp.	1,322,137	13,240	119
<i>Clostridium botulinum</i>	56	42	9
<i>Clostridium perfringens</i>	969,342	439	26
STEC O157*	96,534	3,268	31
<i>Listeria monocytogenes</i>	1,662	1,520	266
<i>Salmonella</i> spp.	1,229,007	23,128	452
<i>S. enterica</i>	5,752	623	0
<i>Shigella</i> spp.	494,908	5,491	38
<i>Staphylococcus</i> spp.	241,994	1,067	6
<i>Streptococcus</i> Group A	11,257	1	0
<i>Vibrio vulnificus</i>	207	202	77
<i>Vibrio parahaemolyticus</i>	44,950	129	5
<i>Yersinia enterocolitica</i>	116,706	637	34
<b>PARASITES</b>			
<i>Cryptosporidium</i> spp.	748,123	210	46
<i>Giardia intestinalis</i>	1,221,564	225	34
<i>Trichinella</i>	162	6	0
<b>VIRUSES</b>			
Astrovirus	3,090,384	17,430	5
Hepatitis A	35,769	2,255	171
Norovirus	20,865,958	56,013	571
Rotavirus	3,090,384	69,721	32

\*STEC = shiga toxin producing *Escherichia coli*.

**TABLE 39–2 Differential Diagnosis of Possible Foodborne Poisoning Presenting with Neurologic Findings<sup>a</sup>**

Anticholinergic poisoning
Bacterial food poisoning
Botulism
Dinoflagellates (brevetoxin, saxitoxin)
Marine food poisoning (ciguatoxin, tetrodotoxin)
Metals (arsenic, lead, mercury)
Monosodium glutamate
Mushrooms ( <i>Amanita</i> spp, <i>Gyromitra</i> spp)
Organic phosphorus compounds

<sup>a</sup>Altered mental status, motor weakness, and sensory changes.

More than 500 fish species have caused human cases of ciguatera poisoning, with the barracuda, sea bass, parrot fish, red snapper, grouper, amber jack, kingfish, and sturgeon the most common sources. The common factor is the comparably large size of the fish involved.

Large fish (1.5–3.0 kg or more) become vectors of ciguatera poisoning in accordance with complex feeding patterns inherent in aquatic life. This traditional teaching is challenged by a recent study. The lack of relationship between toxicity and size observed for most of the species and families from the six islands in French Polynesia suggests that fish size cannot be used as an efficient predictor of fish toxicity.<sup>75</sup> Ciguatoxin is found in blue-green algae, protozoa, and the free algae dinoflagellates. These plankton members of the phylum Protozoa are single-celled, motile, flagellated, pigmented organisms thriving through photosynthesis. Photosynthetic dinoflagellates such as *Gambierdiscus toxicus* and bacteria within the dinoflagellates are the origins of ciguatoxin.<sup>66,97,130</sup> Dinoflagellates are the main nutritional source for small herbivorous fish, which, in turn, are the major food source for larger carnivorous fish, thereby increasing the ciguatoxin concentrations in the flesh, adipose tissue, and viscera of larger and larger fish.<sup>12</sup>

Ciguatoxin is heat stable, lipid soluble, acid stable, odorless, and tasteless. When purified, the toxin is a large (molecular weight, 1,100 Da) complex ester that does not harm the fish but is stored in its tissues.<sup>125,131</sup> The molecule binds to voltage-sensitive sodium channels in diverse tissues and increases the sodium permeability of the channel.<sup>191</sup> The ciguatoxins cause hyperpolarization and a shift in the voltage dependence of channel activation, which opens the sodium channels. Ciguatoxins bind selectively to a particular binding site on the neuron's voltage-sensitive sodium channel protein.<sup>129</sup>

Multiple ciguatoxins are identified in the same fish, perhaps explaining the variability of symptoms and differing severity.<sup>130</sup> People can be affected after eating fresh or frozen fish that was prepared by all common methods: boiling, baking, frying, stewing, or broiling. The appearance, taste, and smell of the ciguatoxic fish are usually unremarkable. The majority of symptomatic episodes begin 2 to 6 hours after ingestion, 75% within 12 hours, and 96% within 24 hours.<sup>12</sup> Symptoms include acute onset of diaphoresis; headaches, abdominal pain with cramps, nausea, or vomiting; profuse watery diarrhea; and a constellation of dramatic neurologic symptoms.<sup>209</sup> A sensation of loose or painful teeth is reported. Typically, peripheral dysesthesias and paresthesias predominate. Watery eyes, tingling, and numbness of the tongue, lips, throat, and perioral area occur. A strange metallic taste is frequently reported as is a reversal of temperature discrimination, the pathophysiology of which remains to be elucidated.<sup>34</sup> Myalgias, most often in the lower extremities; arthralgias; ataxia; and weakness are commonly experienced.<sup>12</sup>

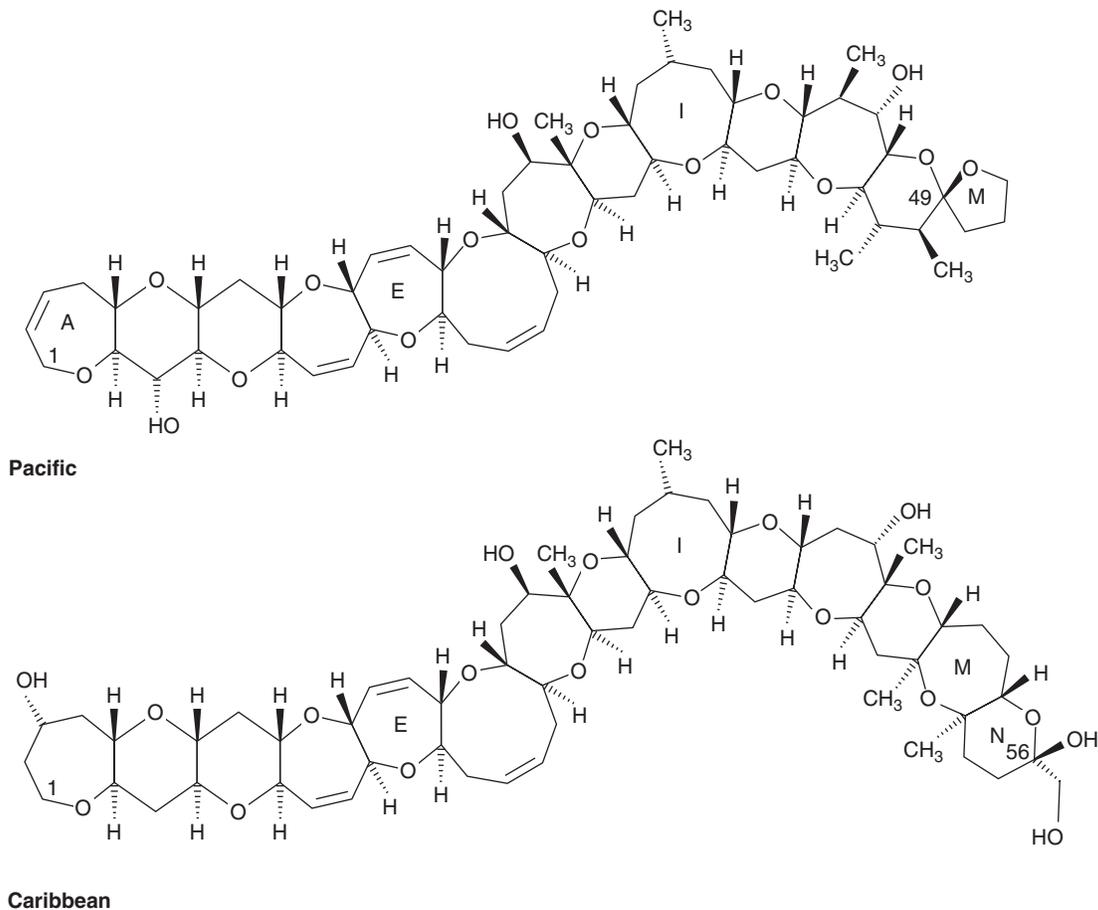

Dysuria<sup>81</sup> and symptoms of dyspareunia and vaginal and pelvic discomfort are reported to occur in some women after sexual intercourse with men who are ciguatoxic and whose semen contains the toxin.<sup>118</sup> Vertigo, seizures, and visual disturbances (eg, blurred vision, scotomata, and transient blindness) are reported.

Bradycardia and orthostatic hypotension are described.<sup>77</sup> The GI symptoms usually subside within 24 to 48 hours; however, cardiovascular and neurologic symptoms typically persist for several days to weeks, depending

**TABLE 39–3 Foodborne Neurologic Toxicity (Primary Presenting Symptoms)**

Disease	Toxin	Toxin Source and Mechanism**	Onset	Duration	Findings	Therapy	Diagnosis
Ciguatera	Ciguatoxin	Large reef fish: amber jack, barracuda, snapper, parrot, sea bass, moray **Increased sodium channel permeability	2–24 h	Days-weeks	Paresthesias, nausea; vomiting, diarrhea, temperature reversal	Mannitol, amitriptyline	Clinical, mouse bioassay, immunoassay
Tetrodotoxin	Tetrodotoxin	Puffer fish, <i>fugu</i> , blue-ringed octopus, newts, horseshoe crab Dinoflagellate **Blocks sodium channel	Minutes to hours	Days	Paresthesias, respiratory depression, hypotension	Respiratory support	Clinical
Neurotoxic shellfish poisoning	Brevetoxin	Mussels, clams, scallops, oysters, <i>Ptychodiscus brevis</i> : "red tide" **Increased sodium channel permeability	15 min to 18 h	Days	Bronchospasm, temperature reversal, nausea; vomiting, diarrhea, paresthesias	Bronchodilators	Clinical, mouse bioassay of food, HPLC
Paralytic shellfish poisoning	Saxitoxin	Mussels, clams, scallops, oysters, <i>Protogonyaulax catanella</i> , <i>Protogonyaulax tamarensis</i> **Decreases sodium channel permeability	30 min	Days	Respiratory depression, paresthesias, nausea, vomiting, diarrhea	Respiratory support	Clinical, mouse bioassay of food, HPLC
Amnesic shellfish poisoning	Domoic acid	Mussels, possibly other shellfish; <i>Nitzschia pungens</i> **Excitatory neurotoxicity	15 min to 38 h	Years	Amnesia, nausea; vomiting, diarrhea, paresthesias, respiratory depression	Respiratory support	Clinical, mouse bioassay of food, HPLC
Botulism	Botulinum toxin	Home-canned foods, honey, corn syrups, <i>Clostridium botulinum</i> **Binds presynaptically, blocks acetylcholine release	12–72 h	Weeks	Vomiting, diarrhea, respiratory depression, initial cranial nerve paralysis followed by a symmetric descending paralysis of the motor and autonomic nerves	Antitoxin, respiratory support	Clinical, immunoassay, serologic, bacteriologic

HPLC = high-pressure liquid chromatography.

**FIGURE 39-1.** The structure of Pacific and Caribbean ciguatoxins. Source: Food and Agriculture Organization of the United Nations. 2004, *Marine Biotoxins*; FAO Food and Nutrition Paper 80. <http://www.fao.org/docrep/007/y5486e/y5486e00.htm>. Reproduced with permission.

on the amount of toxin ingested. Delayed effects include protracted itching and hiccoughs. Ciguatoxin is transmitted in breast milk<sup>23</sup> and can cross the placenta.<sup>159</sup>

Although deaths are reported, internationally, none have been documented in the United States.<sup>85</sup> When it occurs, death is a result of respiratory paralysis and seizures not managed with adequate life support. One study showed that the main contributory factors associated with death were the consumption of ciguatoxin-rich fish parts (viscera and head) in larger amounts, ingestion of the ciguatoxic fish species (eg, barracuda, sea bass, red snapper, grouper), ingestion of reef fish collected after storms, and ultimately individual susceptibility.<sup>52</sup>

The Food and Drug Administration (FDA) and Ciguatoxin (CTX) fish testing procedure is performed in an analytical laboratory setting and uses a two-tiered protocol involving: (1) *in vitro* mouse neuroblastoma (N2a) cell assay as a semiquantitative screen for toxicity consistent with CTX mode of action and (2) liquid chromatography tandem-mass spectrometry (LC-MS/MS) for molecular confirmation of CTX. To date, there is no commercially available, rapid, cost-effective, fish-testing product that has been demonstrated by independent investigations to provide CTX detection in seafood with adequate reliability or accuracy.

Laboratory testing is not readily available, and it often takes days to weeks to receive the result. A useful approach to diagnosis and management includes laboratory testing to exclude other possible etiologies and determine the need for, or extent of, specific therapeutic interventions.

Initial treatment for victims of ciguatoxin poisoning includes standard supportive care for a toxic ingestion.<sup>209</sup> In most patients, elimination of the toxin is accelerated if vomiting (40%) and diarrhea (70%) have occurred. Administration of activated charcoal has benefit for patients who are not vomiting. In patients with significant GI fluid loss through vomiting,

diarrhea, or both, intravenous (IV) fluid and electrolyte repletion are essential. The orthostatic hypotension responds to IV fluids and  $\alpha$ -adrenergic agonists. Symptomatic bradycardia is treated with atropine.<sup>73</sup>

Intravenous mannitol is reported to alleviate neurologic and muscular dysfunctional symptoms associated with ciguatera; however, GI symptoms are not ameliorated.<sup>158,160</sup> An *in vivo* study showed that there was no change in neuronal swelling when ciguatera-poisoned cells were treated with mannitol but did show some prevention of the membrane depolarization and repetitive firing of action potentials induced by ciguatera.<sup>19</sup> Despite these findings, one prospective randomized control trial, mannitol failed to produce any greater improvement in symptoms than did IV normal saline solution. This study is a randomized double-blinded control trial to answer this question. Most of the previous data on the use of mannitol in ciguatera poisoning was either obtained in an uncontrolled or randomized but nonblinded fashion or is the result of case reports.<sup>179</sup> Mannitol should be used with caution because it causes hypotension. Vascular reexpansion and cardiovascular stability should be initial treatment priorities. Mannitol works by inhibiting the ciguatoxin-induced opening of sodium channels on the neuron membranes or reducing the neural edema via an osmotic gradient and is recommended in the hemodynamically stable patient. The search for a treatment for ciguatera poisoning that has minimal side effects and is easily accessible is ongoing. Two cases were reported of symptomatic patients exposed to ciguatera who were successfully treated with pregabalin.<sup>30</sup> There is limited evidence for the efficacy of pregabalin.<sup>30</sup>

Admission to the hospital for cautious supportive care is essential when the diagnosis is uncertain or when volume depletion or any consequential manifestations are present (Tables 39-2 and 39-3). The etiology of the symptoms must be rapidly identified to provide specific therapy, if available. Diaphoresis is a common clinical finding and an important factor in the

differential diagnosis. Late in the course of ciguatera poisoning, amitriptyline 25 mg orally twice daily helps alleviate symptoms,<sup>27</sup> which have been reported to persist up to 1 year. Patients recovering from ciguatera should avoid alcohol and nuts for 3 to 6 months if their consumption exacerbates symptoms.

### Ciguateralike Poisoning

Moray, conger, and anguillid eels carry a ciguatoxinlike neurotoxin in their viscera, muscles, and gonads that does not affect the eel itself. The toxin is a complex ester that is structurally very similar to ciguatoxin and is heat stable.<sup>154</sup> Individuals who eat these eels can infrequently manifest neurotoxic symptoms similar to ciguatoxin or show signs of cholinergic toxicity, such as hypersalivation, nausea, vomiting, and diarrhea. Shortness of breath, mucosal erythema, and cutaneous eruptions also occur. These findings are present in addition to the neurotoxic symptoms.<sup>90</sup> Management is supportive. Death is related to the complications of neurotoxicity, such as seizures and respiratory paralysis.

### Shellfish Poisoning

Healthy mollusks living between 30° North and 30° South latitude ingest and filter large quantities of dinoflagellates. These dinoflagellates are the major source of available ocean food during the “non-R” months (May through August) in the northern hemisphere. During this time, these dinoflagellates are responsible for the “red tides” that occur from California to Alaska, from New England to the St. Lawrence, and across the west coast of Europe.<sup>137</sup> The number of toxic dinoflagellates in these “red tides” is often so overwhelming that birds and fish die, and humans who walk along the beach experience respiratory symptoms caused by aerosolized toxin.<sup>140</sup>

Ingestion of shellfish, including oysters, clams, mussels, and scallops, contaminated by dinoflagellates or algae causes neurotoxic, paralytic, and amnesic syndromes. The dinoflagellates most frequently implicated are *Karenia brevis* (originally named *Gymnodinium breve* in 1948, renamed *Ptychodiscus brevis* in 1979, and reclassified again to the current nomenclature in 2000). The diatoms causing neurotoxic shellfish poisoning (NSP) include *Protogonyaulax catanella* and *Protogonyaulax tamarensis*, which cause paralytic shellfish poisoning, and *Nitzschia pungens*, the diatom implicated in amnesic shellfish poisoning. Proliferation of these diatoms cause a red tide, but shellfish poisoning occurs even in the absence of this extreme proliferation.

*Paralytic shellfish poisoning* is caused by saxitoxin. Saxitoxin blocks the voltage-sensitive sodium channel in a manner identical to tetrodotoxin (TTX; see later). The shellfish implicated usually are clams, oysters, mussels, and scallops, but poisoning has occurred through consumption of crustaceans, gastropods, and fish. In the summer of 2013, a saxitoxin outbreak was identified among 31 individuals in the who consumed green mussels in the Philippines. The symptoms in these individuals ranged from circumoral and extremity numbness to dizziness and lightheadedness. One adult and one child died secondary to cardiorespiratory arrest.<sup>56</sup>

The higher the number of affected shellfish consumed, the more severe the symptoms. Symptoms usually occur within 30 minutes of ingestion. Neurologic effects predominate and include paresthesias and numbness of the mouth and extremities, a sensation of floating, headache, ataxia, vertigo, muscle weakness, paralysis, and cranial nerve dysfunction manifested by dysphagia, dysarthria, dysphonia, and transient blindness. Gastrointestinal symptoms are less common and include nausea, vomiting, abdominal pain, and diarrhea. Fatalities occur as a result of respiratory failure, usually within the first 12 hours after symptom onset. Muscle weakness often persists for weeks.

Treatment is supportive. Early intervention for respiratory failure is indicated. Orogastric lavage and cathartics were used to remove unabsorbed toxin from the GI tract and were not efficacious and thus are not recommended.<sup>31,127,145,183</sup> Activated charcoal is reasonable if vomiting has not occurred. Antibodies against saxitoxin have reversed cardiorespiratory failure in animals,<sup>16</sup> but this therapy is not yet available for humans. Assays for saxitoxin include a mouse bioassay, enzyme-linked immunosorbent assay (ELISA), and high-performance liquid chromatography (HPLC). High-performance liquid chromatography is demonstrated to result in

good interlaboratory accuracy,<sup>203</sup> but the differences in saxitoxin derivatives make standardization of an analytic test difficult.<sup>11,121</sup>

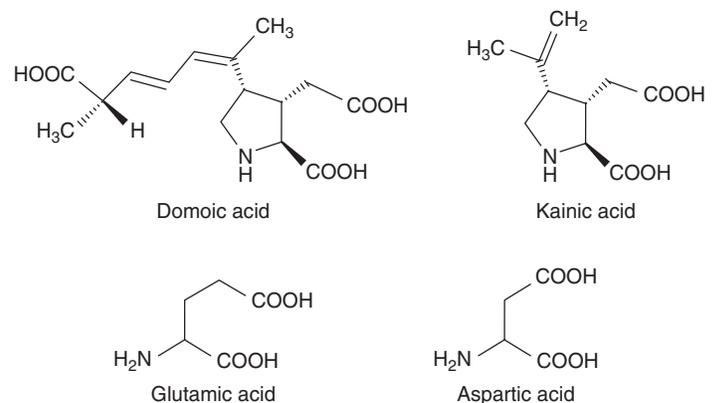

*Neurotoxic shellfish poisoning* is caused by brevetoxin. Brevetoxin, which is produced by *K. brevis* (previously *Gymnodium brevis*, and subsequently *P. brevis*), is a lipid-soluble, heat-stable polyether toxin similar to ciguatoxin. It acts by stimulating sodium flux through the sodium channels of both nerve and muscle.<sup>8,35</sup> Similar to paralytic shellfish poisoning, the shellfish implicated usually are clams, oysters, mussels, and other filter feeders. Neurotoxic shellfish poisoning is characterized by gastroenteric manifestations with associated neurologic symptoms. Gastrointestinal symptoms include abdominal pain, nausea, vomiting, diarrhea, and rectal burning. Neurologic features include paresthesias, reversal of hot and cold temperature sensation, myalgias, vertigo, and ataxia. Other effects include headache, malaise, tremor, dysphagia, bradycardia, decreased reflexes, and mydriasis. Paralysis does not occur. Bradycardia and mydriasis are not commonly present in an individual patient. The incubation period is 3 hours (range, 15 minutes–18 hours). Gastrointestinal and neurologic symptoms appear simultaneously. Other manifestations of brevetoxin poisoning include mucosal irritation, cough, and bronchospasm, which occur when *P. brevis* is aerosolized by wave action during red tides. The duration of effects averages 17 hours (range, 1–72 hours).<sup>145</sup>

Brevetoxins are identified by mouse bioassay; ELISA; and, more recently, antibody radioimmunoassay and reconstituted sodium channels. (Reconstitution is when a purified membrane protein is incorporated into a membrane bilayer and the reconstituted channel is then used as a tool for the measurement of specific toxin binding.<sup>163,200</sup>) Treatment is supportive, and severe respiratory depression is very uncommon. Therapy includes removal of the patient from the environment and the administration of bronchodilators. An antagonist to brevetoxin named brevenal has been discovered and is in the early research phase as a potential therapy.<sup>82</sup> Neurotoxic shellfish poisoning is not fatal.

*Amnesic shellfish poisoning* is caused by domoic acid, which is produced by the diatom *N. pungens*. Domoic acid is structurally similar to glutamic acid, kainic acid, and aspartic acid (Fig. 39–2). Because of this structural similarity, domoic acid interacts with the glutamate receptors on nerve cell terminals. Glutamate is the principal neuroexcitatory transmitter in the brain and is necessary for synaptic transmission (Chap. 13). However, excessive glutamate is associated with neurodegeneration, seizures, and apoptosis.<sup>124</sup>

The most extensively documented human outbreak occurred in Canada in 1987, when 107 individuals who had consumed mussels harvested from cultivated river estuaries on Prince Edward Island were affected.<sup>161</sup> Other human outbreaks have occurred due to a similar diatom—*Pseudonitzschia australis*—which has been isolated in shellfish from other areas.<sup>74</sup> Pelican deaths caused by domoic acid-laden anchovies were reported in 1991 and Canada instituted monitoring for domoic acid after this outbreak.<sup>197</sup> The death of 400 sea lions in California in 1998 was linked to domoic acid from the same diatom.<sup>180</sup>

Amnesic shellfish poisoning is characterized by GI symptoms of nausea, vomiting, abdominal cramps, diarrhea, and neurologic symptoms of memory loss and, less frequently, coma, seizures, hemiparesis, ophthalmoplegia,

**FIGURE 39–2.** Comparison of the chemical structures of domoic acid, kainic acid, glutamic acid, and aspartic acid.<sup>121</sup>

purposeless chewing, and grimacing. Other signs and symptoms include hemodynamic instability and cardiac dysrhythmias. Symptoms typically begin 5 hours (range, 15 minutes–38 hours) after ingestion of mussels. The mortality rate is 2%, with death most frequently occurring in older patients, who experience more severe neurologic symptoms. Ten percent of victims have long-term antegrade memory deficits, as well as motor and sensory neuropathy. Postmortem examinations revealed neuronal damage in the hippocampus and amygdala.<sup>195</sup> Animal studies show that domoic acid can cross the placenta.<sup>138</sup>

### Tetrodotoxin Poisoning

This type of fish poisoning involves only the order Tetraodontiformes. Although this order of fish is not restricted geographically, it is eaten most frequently in Japan, California, Africa, South America, and Australia.<sup>90</sup> Cases also occurred in Florida and New Jersey, as well as Europe, the Mediterranean, and Bangladesh. Approximately 100 freshwater and saltwater species exist in this order, including a number of pufferlike fish such as the globe fish, balloon fish, blowfish, and toad fish.<sup>147</sup> Tetrodotoxin (TTX) found in these fish is also isolated from the blue-ringed octopus<sup>71</sup> and the gastropod mollusk<sup>211</sup> and are responsible for fatalities from ingestion of horseshoe crab eggs.<sup>102</sup> Certain TTX-containing newts (*Taricha*, *notophthalmus*, *triturus*, and *cynops*), particularly *Taricha granulosa*, found in Oregon, California, and southern Alaska, are reportedly fatal when ingested. Most newts and salamanders with bright colors and rough skins contain toxins.<sup>28</sup> In Japan, *fugu* (a local variety of puffer fish) is considered a delicacy, but special licensing is required to prepare this exceedingly toxic fish. In 1989, the US FDA legalized the importation of puffer fish. However, before exportation from Japan, the fish must be laboratory tested and certified by two Japanese organizations to be free of TTX.<sup>49</sup>

Tetrodotoxin is a heat-stable, water-soluble nonprotein found mainly in the fish skin, liver, ovary, intestine, and possibly muscle.<sup>90,175</sup> The ovary has a high concentration of the toxin and is most poisonous if eaten during the spawning season. Tetrodotoxin is detected by mouse bioassay. It is unstable when heated to 212°F (100°C) in acid, distinguishing it from saxitoxin. Tetrodotoxin from fish is detected using fluorescent spectrometry<sup>11</sup> or from the urine of poisoned patients using a combination of immunoaffinity chromatography and fluorometric HPLC.<sup>105</sup>

Similar to saxitoxin, TTX is produced by marine bacteria and likely accumulate in animals higher on the food chain that consume these bacteria.<sup>151</sup> Accumulation of toxins, primarily in the skin, of two species of Asian puffer fish is documented. Whether this accumulation of toxin is simply an evolutionary adaptation, to remove a toxic substance, or one that has evolutionary advantages of protection is unclear.<sup>150</sup>

Neurotoxicity is produced by inhibition of sodium channels and blockade of neuromuscular transmission. The sodium channel is blocked from the external surface of the neuron by the TTX molecule, which contains a guanidinium group that fits into the external orifice of the sodium channel. This causes external “plugging” of the sodium channel, although the gating mechanism remains functional.<sup>148,149</sup>

Effects of TTX poisoning typically occur within minutes of ingestion. Headache, diaphoresis, dysesthesias, and paresthesias of the lips, tongue, mouth, face, fingers, and toes evolve rapidly. Buccal bullae and salivation develop. Dysphagia, dysarthria, nausea, vomiting, and abdominal pain ensue. Generalized malaise, loss of coordination, weakness, fasciculations, and an ascending paralysis (with risk of respiratory paralysis) occur in 4 to 24 hours. Other cranial nerves are involved. In more severe toxicity, hypotension is present. In some studies, the mortality rate approaches 50%.<sup>186</sup>

Therapy is supportive. Removal of the toxin and prevention of absorption are the essential measures. Supportive respiratory care emphasizing airway protection, including intubation, if necessary, is extremely important. Neostigmine, a cholinesterase inhibitor, is proposed as a therapy for tetrodotoxigenicity. The theory is that increasing acetylcholine at the neuromuscular junction combats TTX effects at the motor end plate and motor axon. Although this sounds promising, a recent literature review found the data insufficient to make an evidence-based recommendation.<sup>132</sup>

### *Clostridium botulinum*

In 2015, the CDC reported 39 cases of laboratory-confirmed foodborne botulism and 141 cases of infant botulism.<sup>50</sup> Home-canned fruits and vegetables, as well as commercial fish products, are among the common foods causing botulism. The incubation period usually is 12 to 36 hours; typical signs and symptoms include some initial GI symptoms followed by malaise, fatigue, diplopia, dysphagia, and rapid development of small muscle incoordination.<sup>122</sup> In botulism, the toxin is irreversibly bound to the structures within the nerve terminal, where it impairs the presynaptic release of acetylcholine.<sup>115</sup> A patient's survival depends on rapidly diagnosing botulism and immediate initiation of aggressive respiratory therapy. Establishing the diagnosis early makes it possible to treat the “sentinel” or index patient and also others who consumed the contaminated food with antitoxin before their developing signs and symptoms (Chap. 38 and Antidotes in Depth: A6). The differential diagnosis of botulism includes myasthenia gravis, atypical Guillain-Barré syndrome, tick-induced paralysis, and certain chemical ingestions (Tables 39–1 and 39–2).

## PREVENTION OF MARINE FOODBORNE DISEASE

Careful evaluation of the symptoms and meticulous reporting to local and state health departments, as well as to the US Centers for Disease Control and Prevention (CDC), will allow for more precise analysis of epidemics of poisoning from contaminated or poisonous food or fish. Many states and countries have developed rigorous health codes with regard to harvesting certain species of fish in certain areas at certain times.

Some examples of actions taken by state, federal, and foreign health agencies in controlling epidemics of seafood-borne food poisoning are the following: The health code of Miami, Florida, prohibits the sale of barracuda and warns against eating filets from large and potentially toxic fish containing ciguatoxin. A 3,230-km stretch of the Massachusetts coastline was noted to be unsafe for shellfish harvesting because of a red tide bloom. The National Oceanic and Atmospheric Administration's Fisheries Service along with the FDA declared a health emergency and confiscated shellfish harvested in this area and prohibited the marketing, export, and serving of shellfish.<sup>33</sup> The Japanese closely regulate preparation and selling of the puffer fish (*fugu*), requiring that preparers receive special training and licensing. The sale of *fugu* is now also permitted under strict control in the United States as well. The Canadian government identifies and registers the location and time of harvesting of mussels, and mussels are tested for the presence of domoic acid.<sup>74,161</sup>

### Less Common Poisonings

#### Echinoderms

The sea urchin usually causes toxicity by contact with its spinous processes, but this Caribbean delicacy is also toxic upon ingestion. When the sea urchin is prepared as food, the venom-containing gonads should be removed because they contain an acetylcholine-like substance that causes the cholinergic syndrome of profuse salivation, abdominal pain, nausea, vomiting, and diarrhea.

#### Haff Disease

The consumption of cooked seafood can potentially lead to a syndrome of myalgias and rhabdomyolysis. This syndrome is termed Haff disease, after an outbreak occurred in the 1920s in approximately 1,000 persons living along the Koenigsberg Haff, an inlet of the Baltic Sea. The actual etiology of Haff disease is unknown, but it is suspected that the causative agent is similar to a palytoxin (potent vasoconstrictor). Treatment is hydration with intravenous fluids.<sup>63</sup>

## FOOD POISONING ASSOCIATED WITH DIARRHEA

The initial differential diagnosis for acute diarrhea involves several etiologies: infectious (bacterial, viral, parasitic, and fungal), structural (including surgical), metabolic, functional, inflammatory, toxin induced, and food induced. The differential diagnosis is described in greater detail in Chap. 18.

An elevated temperature is caused by invasive organisms, including *Salmonella* spp, *Shigella* spp, *Campylobacter* spp, invasive *E. coli*, *Vibrio parahaemolyticus*, and *Yersinia* spp, as well as some viruses. Episodes of acute gastroenteritis not typically associated with fever are caused by organisms producing toxins, including *S. aureus*, *Bacillus cereus*, *Clostridium perfringens*, enterotoxigenic *E. coli*, and viruses.<sup>4</sup>

Fecal leukocytes typically are found in patients with invasive shigellosis, salmonellosis, *Campylobacter* enteritis, typhoid fever, invasive *E. coli* colitis, *V. parahaemolyticus*, *Yersinia enterocolitica*, and inflammatory bowel disease. In all of these conditions, except typhoid fever, the leukocytes are primarily polymorphonuclear; in typhoid fever, they are mononuclear. No stool leukocytes are noted in cholera, viral diarrheas, noninvasive *E. coli* diarrhea, or nonspecific diarrhea.<sup>95</sup>

The timing of diarrheal onset after exposure or the incubation period is useful in differentiating the cause. Extremely short incubation periods of less than 6 hours are typical for *Staphylococcus* spp, *B. cereus* (type I), enterotoxigenic *E. coli*,<sup>4,134,194</sup> and preformed enterotoxins, as well as roundworm larval ingestions. Intermediate incubation periods of 8 to 24 hours are found with *C. perfringens*, *B. cereus* (type II enterotoxin), enteroinvasive *E. coli*,<sup>64,142</sup> and *Salmonella*. Longer incubation periods occur in other bacterial causes of acute gastroenteritis (Table 39–4).

The three most likely etiologies of diarrhea are infectious, xenobiotics (chemicals found in an organism, not normally present, frequently a pollutant or contaminant), and foodborne. These three etiologies are not mutually exclusive. The differential diagnosis must be established among these groups. When the time from exposure to onset of symptoms is brief, all of the nonbacterial infectious etiologies (viral, parasitic, fungal, and algal), except

for upper GI invasion by roundworm larvae, can be eliminated and the possibility of a bacterial etiology with enterotoxin production becomes more likely (Table 39–4).<sup>4,24</sup>

### Epidemiology

Epidemiologic analysis is of immediate importance, particularly when GI diseases strike more than one person in a group. The questions raised in Table 39–5 should be answered.<sup>174</sup> If available, an infectious disease consultant or infection control officer should be called for assistance. Alternatively, assistance from state and local health departments should be sought. Often, only the CDC or state health department has the resources to investigate and confirm a presumptive diagnosis in an outbreak. Sophisticated techniques such as toxin detection, matching the organism in the food by phage type with a food handler, matching an organism by phage type with other persons, isolating 10 or more organisms per gram of implicated food,<sup>64,68</sup> or polymerase chain reaction (PCR) identification of bacterial or plasmid DNA are potentially useful, although generally not possible using the laboratory and personnel available in most hospitals.<sup>32,39,83</sup> Structural, metabolic, and functional causes often can be eliminated. As in these diseases, neither a significant grouping of cases nor a limited clinical history is characteristic. Foodborne parasites such as *Trichinella spiralis* (trichinosis), *Toxoplasma gondii* (toxoplasmosis), and *G. lamblia* (giardiasis) must be considered, although acute GI symptoms are not usually prominent.

### Salmonella Species

*Salmonella enterica* infections are of great concern in the United States. Two particular outbreaks define very special problems. In the 1980s, recurrent

**TABLE 39–4** Foodborne Infections: Gastrointestinal (Time of Onset and Primary Presenting Symptom)

Etiology	Symptoms						Source	Pathogenesis	Therapy
	Onset	A	V	Di	Dy	F			
<i>Staphylococcus</i> spp	2–6 h	+	+	+	–	–	Prepared foods: meats, pastries, salads	Heat-stable enterotoxin	Fluid and electrolyte resuscitation
<i>Bacillus cereus</i>									
Type I	1–6 h	+	+	+	–	–	Fried rice	Heat-labile toxin	Fluid and electrolyte resuscitation
Type II	12 h	+	–	+	–	–	Meats, vegetables	Heat-labile toxin	
Anisakiasis	1–12 h	+	+	–	–	–	Raw fish, sushi, (Eustrongyloides), minnows, salmon, cod, herring, squid, tuna	Intestinal larvae	Endoscopy, laparotomy removal
<i>Clostridium perfringens</i>	8–24 h	+	±	+	±	–	Poultry, heat-processed meats	Heat-labile enterotoxin	Fluid and electrolyte resuscitation
<i>Salmonella</i> spp	8–24 h	±	±	+	±	+	Poultry, egg	Bacteria, endotoxin (bacteremia)	Antibiotics
<i>Escherichia coli</i>									
Enterotoxigenic	<6 h	+	±	+	–	+	Enteric contact		Fluid and electrolyte resuscitation
Invasive	24–72 h	+	–	+	+	+	Raw produce	Bacteria (invasive)	Antibiotics
Hemorrhagic	24–72 h	+	+	+	+	±	Under cooked beef, unpasteurized milk	Shiga toxin heat stable	Fluid and electrolyte resuscitation and hematologic (blood transfusion) support
<i>Vibrio cholerae</i>	24–72 h	±	±	+	–	±	Water, food enteric contact	Heat labile enterotoxin	Fluid and electrolyte resuscitation, antibiotics
<i>Shigella</i> spp	24–72 h	+	±	+	+	±	Institutional food handler, household, preschool, enteric contact	Endotoxin Shiga toxin	Antibiotics
<i>Campylobacter jejuni</i>	1–7 d	+	+	+	±	+	Milk, poultry, unchlorinated water	Bacteria, heat labile enterotoxin	Antibiotics
<i>Yersinia</i> spp	1–7 d	+	+	+	±	+	Pork, milk, pets	Bacteria, enterotoxin	Antibiotics

A = abdominal pain; Di = diarrhea; Dy = dysentery; F = fever; V = vomiting.

TABLE 39–5 Epidemiologic Analysis of Gastrointestinal Disease

1. Is the occurrence of the disease in a large group significant enough to be consistent with foodborne disease (two or more cases)?
2. Is the symptomatology in affected individuals well defined and similar?
3. Are the onset, time, and duration of illness similar among affected group members (incubation)?
4. What are the possible modes of transmission (eg, contact, food, water)?
5. Is there a relationship between the time of exposure of the group and the mode of transmission?
6. Do attack rates differ for age, gender, or occupation?
7. Can it be determined which foods were served and to whom? Can the items that were not eaten by those who did not become ill be identified?
8. What is the food-specific attack rate?
9. How was the food procured? How was it stored?
10. Was cooking technique adequate?
11. Was personal hygiene acceptable?
12. Was there animal contamination?

outbreaks associated with grade A eggs or food containing such eggs occurred. In the past, such outbreaks of *Salmonella* enteritis were attributed to infection of the egg with *Salmonella* (from the GI tract of the chicken) through cracks in the shell. More recently, outbreaks involved noncracked, nonsoiled eggs.<sup>144</sup> In these cases, presumably, the *Salmonella* has infected the eggs before the shell was formed. In either case, people who consume raw or undercooked eggs are at most risk for *Salmonella* enteritis. Raw eggs are standard ingredients of chocolate mousse, hollandaise sauce, eggnog, Caesar salads, and homemade ice cream. Whole, partially cooked eggs are problematic when eaten sunny side up or poached.<sup>45</sup> The second group of outbreaks was associated with raw milk,<sup>164</sup> which has become very popular in certain communities. Inadequate microwave cooking also causes small outbreaks.<sup>68</sup> These outbreaks are of great concern because they frequently involve multiple drug-resistant *Salmonella* infections.<sup>58</sup> Drinking pasteurized milk is not absolutely protective. An outbreak of salmonellosis resulting in more than 16,000 culture-proven cases was traced to one Illinois dairy. The probable cause of the outbreak was a transfer line connecting raw and pasteurized milk containment tanks.<sup>171</sup>

The contamination of food that is widely distributed places thousands at risk. An outbreak of *Salmonella* food poisoning from peanut butter caused 529 confirmed illnesses in 48 states and Canada, 116 hospitalizations, and possibly 8 deaths.<sup>44</sup> The CDC estimates that the proportion of *Salmonella* infections that are confirmed by laboratory testing is 3% of the total, so that the estimated magnitude of infected people affected by this type of contamination incident is more than 15,000 individuals annually. News reports state that the peanut butter contamination with *Salmonella* was suspected; however, the peanut butter was then nationally distributed before confirmatory testing resulted.<sup>93,94</sup> The ethical and public health implications of maintaining meticulous standards are highlighted by this epidemic.

Additional concern developed over the widespread use of antibiotics in animal feed, responsible for meats, poultry, and manure-fertilized vegetables now frequently containing resistant bacterial strains to which virtually the entire population is exposed.<sup>58,171</sup>

The diagnosis of *Salmonella* infection is made through culture of the stool. The treatment of *Salmonella* is fluid and, electrolyte resuscitation, and antibiotics (ciprofloxacin or alternatively azithromycin).<sup>112</sup>

## FOODBORNE POISONING ASSOCIATED WITH MULTIORGAN SYSTEM DYSFUNCTION

The hemolytic uremic syndrome (HUS) is frequently caused by a bacterial gastroenteritis. The most commonly responsible organism is *E. coli* O157:H7.<sup>87</sup> Other bacteria and xenobiotics cause the same findings. Typical laboratory findings in HUS include microangiopathic hemolytic anemia, thrombocytopenia, and acute kidney injury (AKI).

Hemolytic uremic syndrome begins with a prodrome of diarrhea 90% of the time. The diarrhea lasts for 3 to 4 days and frequently becomes bloody.

Abdominal pain caused by colitis is common, and vomiting, altered mental status (irritability or lethargy), pallor, and low-grade fever frequently occur. At presentation, many patients have oliguria or anuria, and 10% of children have a generalized seizure at HUS onset.<sup>182</sup>

Hemolytic uremic syndrome is frequently associated with enterohemorrhagic *E. coli* (EHEC) or *E. coli* O157:H7 with postdiarrheal HUS.<sup>29,136,156,157,169,206</sup> Food products from cattle (ground beef, milk, yogurt, cheese) and water contaminated with fecal material are EHEC sources.<sup>62,139</sup> Contaminated water used in gardens and unpasteurized apple cider have caused bloody diarrhea and HUS as a result of EHEC.<sup>18,57</sup>

Enterohemorrhagic *E. coli*, including *E. coli* O157:H7, produces a toxin similar to that produced by *Shigella dysenteriae* type I, referred to as Shiga-like toxin (SLT) or verotoxin.<sup>24</sup> The proposed mechanism for SLT damage is intestinal absorption, bloodstream access to renal glomerular endothelium, intracellular adsorption via glycolipid receptors, ribosomal inactivation, and cell death.<sup>193</sup> In animal models, organ damage is more severe if endothelial cells have high concentrations of globotriaosylceramide receptors, which have a high binding affinity for Shiga toxin. Other organs with these receptors include the kidney, GI, and central nervous systems, which explain the pattern of organ damage in children with HUS. Endothelial cell damage and other pathologic processes, including platelet and leukocyte activation, triggering of the coagulation cascade, and the production of cytokines, occur.<sup>104,202</sup> Types of SLT exist as SLT-1, SLT-2, and additional variants of SLT-2 structure are identified.<sup>20</sup>

Detection of *E. coli* O157:H7 through stool culture early in the course of disease is useful. The recovery of organisms decreases after the first week of illness.<sup>193</sup> *Escherichia coli* O157:H7 almost always produces SLT; therefore, if stool cultures are negative, enzyme immunoassay (EIA) and PCR tests can be used to detect SLT in the stool when *E. coli* can no longer be identified by culture.<sup>32</sup>

Treatment of HUS should focus on meticulous supportive care, with fluid and electrolyte balance the priority. Dialysis should be instituted early for azotemia, hyperkalemia, acidemia, and fluid overload. Red blood cells and platelet transfusions are required. It is reasonable to treat hypertension with short-acting calcium channel blockers (nifedipine 0.25–0.5 mg/kg/dose orally) and seizures with benzodiazepines. Plasmapheresis was in nondiarrheal HUS and in recurrent HUS after renal transplantation. Anti-SLT-2 antibodies protected mice from SLT-2 toxicity, but IV immunoglobulin with SLT-2 activity did not improve outcome in children with HUS. A double-blind, placebo-controlled study on the use of synthetic SLT receptors attached to an oral carrier found that mortality or serious morbidity of HUS syndrome did not change as a result.<sup>199</sup>

The mortality rate from HUS with good supportive care is approximately 5%; another 5% of victims have end-stage kidney disease or cerebral ischemic events and chronic neurologic impairment. Prolonged anuria (longer than 1 week), oliguria (longer than 2 weeks), or severe extrarenal disease serve as markers for higher mortality and morbidity.<sup>162</sup>

There is some evidence that early treatment with antibiotics increases the risk of development HUS in children with *E. coli* O157:H7 infections.<sup>187</sup> An earlier meta-analysis and randomized trial did not find this association.<sup>166,172</sup> Because of this concern, it is not typically recommended to treat patients with clinical or epidemiologic presentations consistent with *E. coli* O157:H7 infections (crampy abdominal pain, bloody diarrhea, regional outbreak) until a definitive pathogen can be identified.<sup>196</sup>

Approximately 10% of the cases of HUS are not caused by SLT-producing bacteria or streptococci and are classified as atypical. Atypical HUS has a poor prognosis, with death rates as high as 25% and progression to end-stage kidney disease in half of the patients.<sup>153</sup>

Strategies to prevent the spread of *E. coli* O157:H7 and subsequent HUS include public education on the importance of thorough cooking of beef to a “well-done” temperature of 170°F (77°C), pasteurization of milk and apple cider, and thorough cleaning of vegetables. Public health measures include education of clinicians to consider *E. coli* O157:H7 in patients with bloody diarrhea and ensuring the routine capability of microbiology laboratories to culture *E. coli* O157:H7 and provide for EIA or PCR determination of SLT.

Public health departments should provide active surveillance systems to identify early outbreaks of *E. coli* O157:H7 infection.

### Staphylococcus Species

In cases of suspected food poisoning with a short incubation period, the physician should first assess the risk for staphylococcal causes. The usual foods associated with staphylococcal toxin production include milk products and other proteinaceous foods, cream-filled baked goods, potato and chicken salads, sausages, ham, tongue, and gravy. Pie crust can act as an insulator, maintaining the temperature of the cream filling and occasionally permitting toxin production even during refrigeration.<sup>6</sup> A routine assessment must be made for the presence of lesions on the hands or nose of any food handlers involved. Unfortunately, carriers of enterotoxigenic staphylococci are difficult to recognize because they usually lack lesions and appear healthy.<sup>96</sup> A fixed association between a particular food and an illness would be most helpful epidemiologically but rarely occurs clinically. Factors such as environment, host resistance, nature of the agent, and dose make the results surprisingly variable.

Although patients with staphylococcal food poisoning rarely have significant temperature elevations, 16% of 2,992 documented cases in a published review had a subjective sense of fever.<sup>96</sup> Abdominal pain, nausea followed by vomiting, and diarrhea dominate the clinical findings. Diarrhea does not occur in the absence of nausea and vomiting. The mean incubation period is 4.4 hours with a mean duration of illness of 20 hours. Two staphylococcal enterotoxin food poisoning incidents involving large numbers of people are reported. At a public event in Brazil in 1998, half of the 8,000 people who attended had nausea, emesis, diarrhea, abdominal pain, and dizziness within hours of consuming food. Of the ill patients, 2,000 overwhelmed the capacity of local emergency departments; 396 (20%) were admitted, including 81 to intensive care units; and 16 young children and older adults died.<sup>185</sup> In another report, 328 individuals became ill with symptoms of diarrhea, vomiting, dizziness, chills, and headache after eating cheese or milk.<sup>182</sup> In both reports, staphylococcus enterotoxin was found in the food consumed.

Most enterotoxins are produced by *S. aureus* coagulase-positive species. The enterotoxins initiate an inflammatory response in GI mucosal cells and lead to cell destruction. The enterotoxins also result in sudden effects on the emesis center in the brain and diverse other organ systems. Discrimination of unique *S. aureus* isolates from those found in foodborne outbreaks is established using restriction fragment length polymorphism analysis by pulsed-field gel electrophoresis and PCR techniques.<sup>207</sup> The illness usually lasts for 24 to 48 hours. The treatment is supportive care with hydration and electrolyte repletion.<sup>188</sup>

### Bacillus cereus

Another foodborne toxin that produces GI effects is associated with eating reheated fried rice. *Bacillus cereus* type I is the causative organism, and bacterial overgrowth and toxin production causes consequential early onset nausea and vomiting.<sup>2</sup> Infrequently, this toxin causes liver failure.<sup>135</sup> *Bacillus cereus* type II has a delayed onset of similar GI effects including diarrhea.<sup>76</sup> The diagnosis of *B. cereus* infection is made through culture of the stool. The treatment of *B. cereus* is fluid and electrolyte resuscitation, and antibiotics (including ciprofloxacin or vancomycin).<sup>25</sup>

### Campylobacter jejuni

*Campylobacter jejuni* is a major cause of bacterial enteritis. The organism is most commonly isolated in children younger than 5 years and in adults 20 to 40 years of age. *Campylobacter* enteritis outbreaks are more common in the summer months in temperate climates. Although most cases of *Campylobacter* enteritis are sporadic, outbreaks are associated with contaminated food and water. The most frequent sources of *Campylobacter* spp in food are raw or undercooked poultry products<sup>70</sup> and unpasteurized milk.<sup>189</sup> Birds are a common reservoir, and small outbreaks are associated with contamination of milk by birds pecking on milk-container tops.<sup>189</sup> Contaminated water supplies are also frequent sources of *Campylobacter enteritis* involving large numbers

of individuals.<sup>22</sup> *Campylobacter jejuni* is heat labile; cooking of food, pasteurization of milk, and chlorination of water prevent human transmission.

The incubation period for *Campylobacter* enteritis varies from 1 to 7 days (mean, 3 days). Typical symptoms include diarrhea, abdominal cramps, and fever. Other symptoms include headache, vomiting, excessive gas, and malaise. The diarrhea contains gross blood, and leukocytes are frequently present on microscopic examination.<sup>95</sup> Illness usually lasts 5 to 6 days (range, 1–8 days). Rarely, symptoms last for several weeks. Severely affected individuals present with lower GI hemorrhage, abdominal pain mimicking appendicitis, a typhoidlike syndrome, reactive polyarthritis (Reiter syndrome), or meningitis. Guillain-Barré is associated with the disease with an incidence of less than 1 in 1,000 cases.<sup>3</sup> The organism is detected using PCR identification techniques.<sup>79</sup> Treatment is supportive and consists of volume resuscitation and antibiotics for the more severe cases.<sup>4</sup>

### Group A Streptococcus

Bacterial infections not usually associated with food or food handling are nevertheless occasionally transmitted by food or food handling. Transmission of streptococci in food prepared by an individual with streptococcal pharyngitis is demonstrated.<sup>60</sup> A Swedish food handler caused 153 people to become ill with streptococcal pharyngitis when his infected finger wound contaminated a layer cake served at a birthday party.<sup>9</sup>

### Yersinia enterocolitica

*Yersinia enterocolitica* causes enteritis most frequently in children and young adults. Typical clinical features include fever, abdominal pain, and diarrhea, which usually contains mucus and blood.<sup>10,192,204</sup> Other associated findings include nausea, vomiting, anorexia, and weight loss. The incubation period is 1 to 7 days or more. Less common features include prolonged enteritis, reactive polyarthritis, pharyngeal and hepatic involvement, and rash. *Yersinia* is a common pathogen in many animals, including dogs and pigs. Sources of human infection include milk products, raw pork products, infected household pets, and person-to-person transmission.<sup>26,89,123</sup> The diagnosis is based on cultures of food, stool, blood, and, less frequently, skin abscesses, pharyngeal cultures, or cultures from other organ tissues (mesenteric lymph nodes, liver). *Yersinia* is identified by PCR.<sup>103</sup> Patients receiving the chelator deferoxamine (Antidotes in Depth: A7) frequently acquire *Yersinia* infections because the deferoxamine-iron complex acts as a siderophore for organism growth. Therapy is usually supportive, but patients with invasive disease (eg, bacteremia, bacterial arthritis) should be treated with IV antibiotics. Fluoroquinolones and third-generation cephalosporins are highly bacteriocidal against *Yersinia* spp.

### Listeria monocytogenes

Listeriosis transmitted by food usually occurs in pregnant women and their fetuses, older adults, and immunocompromised individuals using corticosteroids or with malignancies, diabetes mellitus, kidney disease, or HIV infection.<sup>17,41,43,178</sup> Typical food sources include undercooked chicken and unpasteurized milk as well as soft cheeses such as feta, queso fresco, queso blanco, queso panela, blue cheese, and brie. Individuals at risk should avoid the usual sources and should be evaluated for listeriosis if typical symptoms of fever, severe headache, muscle aches, and pharyngitis develop. Treatment with IV ampicillin and aminoglycoside, or trimethoprim-sulfamethoxazole is indicated for systemic *Listeria* infections.

### Xenobiotic-Induced Diseases

In addition to the aforementioned saxitoxin, tetrodotoxin, domoic acid, and ciguatoxin, many other xenobiotics contaminate our food sources. Careful assessment for possible foodborne pesticide poisoning is essential. For example, aldicarb contamination has occurred in hydroponically grown vegetables and watermelons contaminated with pesticides.<sup>86</sup> Eating malathion-contaminated chapatti and wheat flour resulted in 60 poisonings, including a death in one outbreak<sup>54</sup> (Chap. 110). Insecticides, rodenticides, arsenic, lead, or fluoride preparations can be mistaken for a food

ingredient. These poisonings usually have a rapid onset of signs and symptoms after exposure.

The possibility of unintentional acute metal salt ingestion must also be evaluated. This type of poisoning most typically occurs when very acidic fruit punch is served in metal-lined containers. Antimony, zinc, copper, tin, or cadmium in a container are dissolved in an acidic food or juice medium.

### Mushroom-Induced Disease

Some species produce major GI effects. *Amanita phalloides*, the most poisonous mushroom, usually causes GI symptoms as well as hepatotoxic effects with a delay to clinical manifestations. The rapid onset of symptoms suggests some of the gastroenterotoxic mushrooms, but this is not always true as in the case of *Amanita smithiana*, which has an early GI phase followed later by acute kidney injury (Chap. 117).

### Intestinal Parasitic Infections

The popularity of eating raw fish, or sushi, led to an increase in reported intestinal parasitic infections. Etiologic agents are roundworms (*Eustrongyloides anisakis*) and fish tapeworms (*Diphyllobothrium* spp). Symptoms of anisakiasis are either upper intestinal (occur 1–12 hours after eating) or lower intestinal (delayed for days or weeks). Typical symptoms include nausea, vomiting, and severe crampy abdominal pain; with intestinal perforation, severe pain, rebound, and guarding occur. A dietary history of eating raw fish is needed to establish diagnosis and therapy. Visual inspection of the larvae (on endoscopy, laparotomy, or pathologic examination) is useful. Treatment of intestinal infection involves surgical or laparoscopic removal. *Anisakis simplex* and *Pseudoterranova decipiens* are Anisakidae that are found in several types of consumed raw fish, including mackerel, cod, herring, rockfish, salmon, yellow fin tuna, and squid. Reliable methods of preventing ingestion of live anisakid larvae are freezing at  $-4^{\circ}\text{F}$  ( $-20^{\circ}\text{C}$ ) for 60 hours or cooking at  $140^{\circ}\text{F}$  ( $60^{\circ}\text{C}$ ) for 5 minutes.<sup>38,111,133,170,176,210</sup>

Diphyllobothriasis (fish tapeworm disease) is caused by eating uncooked fish such as herring, salmon, pike, and whitefish that harbor the parasite. The symptoms are less acute than with intestinal roundworm ingestions and usually begin 1 to 2 weeks after ingestion.<sup>37</sup> Signs and symptoms include nausea, vomiting, abdominal cramping, flatulence, abdominal distension, diarrhea, and megaloblastic anemia due to vitamin B<sub>12</sub> deficiency. The diagnosis is based on a history of ingesting raw fish and on identification of the tapeworm proglottids in stool. Treatment with niclosamide, praziquantel, or paromomycin usually is effective.<sup>42</sup>

### Monosodium Glutamate

This clinical presentation is misnamed “Chinese restaurant syndrome” because it results from the ingestion of monosodium glutamate (MSG), which has multicultural use in the preparation of many foods. Monosodium glutamate (regarded as “safe” by the FDA) can cause other acute and bizarre neurologic symptoms. Affected individuals present with a burning sensation of the upper torso, facial pressure, headache, flushing, chest pain, nausea and vomiting, and, infrequently, life-threatening bronchospasm<sup>4</sup> and angioedema.<sup>190</sup> The intensity and duration of symptoms are generally dose related but with significant variation in individual responses to the amount ingested.<sup>177,212</sup> Monosodium glutamate causes “shudder attacks” or a seizure-like syndrome in young children. Absorption is more rapid after fasting, and the typical burning symptoms rapidly spread over the back, neck, shoulders, abdomen, and occasionally the thighs. Gastrointestinal symptoms are rarely prominent and symptoms can usually be prevented by prior ingestion of food. When symptoms do occur, they tend to last approximately 1 hour. Monosodium glutamate is also marketed as an effective flavor enhancer.<sup>15</sup> Many sausages and canned soups contain large doses of MSG.

There is evidence that humans have a unique taste receptor for glutamate.<sup>114</sup> This explains its ability to act as a flavor enhancer for foods. Glutamate is also an excitatory neurotransmitter that can stimulate central nervous system neurons through activation of glutamate receptors and be the explanation for some of the neurologic symptoms described with ingestion.<sup>213</sup>

Animal studies in which MSG was administered perorally in doses similar to average human intake or intake of extreme users showed that MSG led to disturbances in metabolism affecting insulin, fatty acids, and triglycerides in serum. Monosodium glutamate also affected several genes implicated in adipocytes differentiation. It elevated aminotransferase concentrations and bile synthesis and led to oxidative stress in the liver and to pathological changes in ovaries and fallopian tubes. These more recent findings will lead to further understanding of MSG and its safety in long-term use.<sup>100</sup>

### Anaphylaxis and Anaphylactoid Presentations

Some foods and foodborne toxins cause allergic or anaphylactoidlike manifestations,<sup>106</sup> also sometimes referred to as “restaurant syndromes”<sup>181</sup> (Table 39–6). The similarity of these syndromes complicates a patient’s future approach to safe eating. Isolating the precipitant is essential so that the risk can be effectively assessed. Manufacturers of processed foods should provide an unambiguous listing of ingredients on package labels. Sensitive

TABLE 39–6 Symptoms of Foodborne Toxicity

	Onset	Symptoms or Signs	Cause	Therapy
Anaphylaxis (anaphylactoid)	Minutes to hours	Urticaria, angioedema, bronchospasm, hypotension, cardiorespiratory arrest	Allergens—nuts, eggs, milk, fish, shellfish, peanuts, soy	Oxygen, epinephrine, $\beta_2$ -adrenergic agonist, corticosteroids, fluid and electrolyte resuscitation, H <sub>1</sub> , H <sub>2</sub> histamine antagonists, avoidance
Monosodium glutamate (MSG)	Minutes	Flushing, hypotension, palpitations, facial pressure, headaches, rhinitis, bronchospasm, shivering	Flavor enhancer of foods	Oxygen, $\beta_2$ -adrenergic agonists, fluid and electrolyte resuscitation, avoidance
Metabisulfites	Minutes	Flushing, hypotension, bronchospasm	Preservative in wines, salad (bars), fruit juice, shrimp	See Anaphylaxis; avoidance
Scombroid	Minutes to hours	Flushing, hypotension, urticaria, headache, pruritus, gastrointestinal symptoms	Large fish—poorly refrigerated; tuna, bonito, albacore, mackerel, mahi mahi (histamine)	Histamine (H <sub>1</sub> , H <sub>2</sub> ) antagonists
Tyramine	Minutes to hours	Headache, hypertension	Wines, aged cheeses that contain tyramine (INH or MAOI) increases risk	Avoidance
Tartrazine	Hours	Urticaria, angioedema, bronchospasm	Yellow coloring food additive	See Anaphylaxis; avoidance

INH = isoniazid; MAOI = monoamine oxidase inhibitor.

individuals (or in the cases of children, their parents) must be rigorously attentive.<sup>173,215</sup> Those who experience severe reactions should make sure that epinephrine and antihistamines are always available immediately. Attempts to prevent allergic reactions to dairy products by avoiding dairy-containing foods may fail. Nondairy foods are still periodically processed in equipment used for dairy products or contain flavor enhancers of a dairy origin (eg, partially hydrolyzed sodium caseinate), both of which cause morbidity and mortality in allergic individuals.<sup>78</sup> Individuals with known food allergies do not always carry prescribed autoinjectable epinephrine syringes, in some cases from a belief that the allergen is easily identifiable and avoidable.<sup>106</sup> Food additives that cause anaphylactic or anaphylactoid reactions include antibiotics, aspartame, butylated hydroxyanisole, butylated hydroxytoluene, nitrates or nitrites, sulfites, and paraben esters.<sup>128</sup> Regulation of these preservatives is limited, and xenobiotics such as sulfites are so ubiquitous that predicting which guacamole, cider, vinegar, fresh or dried fruits, wines, or beers contain these sensitizing xenobiotics may be impossible.

### Scombroid Poisoning

Scombroid poisoning originally was described with the Scombridae fish (including the large dark-meat marine tuna, albacore, bonito, mackerel, and skipjack). However, the most commonly ingested vectors identified by the CDC are nonscombroid fish, such as mahi mahi and amber jack. All of the implicated fish species live in temperate or tropical waters. Ingestion of bluefish and tilapia is associated with scombroid poisoning.<sup>67,152</sup> The incidence of this disease is probably far greater than was originally perceived. This type of poisoning differs from other fishborne causes of illness in that it is entirely preventable if the fish is properly stored after removal from the water.

Scombroid poisoning can result from eating cooked, smoked, canned, or raw fish. The implicated fish all have a high concentration of histidine in their dark meat. *Morganella morganii*, *E. coli*, and *Klebsiella pneumoniae*, commonly found on the surface of the fish, contain a histidine decarboxylase enzyme that acts on a warm (not refrigerated), freshly killed fish, converting histidine to histamine, saurine, and other heat-stable substances. Although saurine was suggested as the causative toxin, chromatographic analysis demonstrates that histamine is found as histamine phosphate and saurine is merely histamine hydrochloride.<sup>72,146</sup> The term *saurine* originated from saury, a Japanese dried fish delicacy often associated with scombroid poisoning. The extent of spoilage usually correlates with histamine concentrations. Histamine concentrations in healthy fish are less than 0.1 mg/100 g fish meat. In fish left at room temperature, the concentration rapidly increases, reaching toxic concentrations of 100 mg/100 g fish within 12 hours.

The appearance, taste, and smell of the fish are usually unremarkable.<sup>7</sup> Rarely, the skin has an abnormal “honeycombing” character or a pungent, peppery taste that is a clue to its toxicity. Within minutes to hours after eating the fish, the individual experiences numbness, tingling, or a burning sensation of the mouth; dysphagia; headache; and, of particular significance for scombroid poisoning, a unique flush characterized by an intense diffuse erythema of the face, neck, and upper torso.<sup>107</sup> Rarely, pruritus, urticaria, angioedema, or bronchospasm ensues. Nausea, vomiting, dizziness, palpitations, abdominal pain, diarrhea, and prostration may develop.<sup>55,61,80,107,141</sup>

The prognosis is good with appropriate supportive care and parenteral antihistamines such as diphenhydramine. Histamine (H<sub>1</sub>)-receptor antagonists such as cimetidine or ranitidine are also reasonable to administer because they can also be useful in alleviating GI symptoms.<sup>21</sup> Toxic substance removal using orogastric suctioning or adsorption from the gut by activated charcoal are reportedly used, but no randomized trials demonstrate benefit over treatment with antihistamines. Inhaled  $\beta_2$ -adrenergic agonists and epinephrine are necessary if bronchospasm is prominent. Although rare, another concern with scombroid toxicity is coronary vasospasm.<sup>5,59</sup> Patients usually show significant improvement within a few hours.

Elevated serum or urine histamine concentrations can confirm the diagnosis but are clinically unnecessary. If any uncooked fish remains, isolation of causative bacteria from the flesh is suggestive but not diagnostic. A capillary electrophoretic assay makes rapid histamine detection possible.<sup>96</sup>

Histamine concentrations greater than 50 mg/100 g fish meat are considered hazardous by the FDA; in Europe, the concentrations are 100 to 200 mg/100 g.<sup>99</sup> Research demonstrates that human subjects can tolerate up to 180 mg of pure histamine orally without noticeable effects.<sup>5</sup> Isoniazid increases the severity of the reaction to scombroid fish by inhibiting enzymes that metabolize histamine.<sup>99,201</sup>

Patients should be reassured that they are not allergic to fish if other individuals experience a similar reaction while eating the same fish at the same time or if any remaining fish can be preserved and tested for elevated histamine concentrations. If this information is not available, then an anaphylactic reaction to the fish cannot be excluded. Table 39–6 represents the differential diagnosis of flushing, bronchospasm, and headache. Because many people often consume alcohol with fish, alcohol is an independent variable.

The differential diagnosis of the scombrototoxic flush apart from a disulfiramlike reaction includes ingestion of niacin or nicotinic acid, pheochromocytoma and carcinoid syndrome. The history and clinical evolution usually establish the diagnosis quickly.

### Global Food Distribution: Illegal Food Additives

The United States imports food from all over the world, year round. Approximately 19% of the food consumed in the United States is imported. An analysis of outbreak data from 1996 to 2014 shows 195 outbreak investigations implicated an imported food, resulting in about 11,000 illnesses, about 1,000 hospitalizations, and 19 deaths. The number of outbreaks associated with an imported food has increased from an average of 3 per year (1996–2000) to an average of 18 per year (2009–2014).<sup>84</sup> Xenobiotics are given to animals to increase their health and growth. Clenbuterol, a  $\beta_2$  agonist, was administered to cattle raised for human consumption. Clenbuterol causes toxicity in humans who eat contaminated animal meat. Tachycardia, tremors, nausea, epigastric pain, headache, muscle pain, and diarrhea were present in 50 poisoned patients. Other findings included hypertension, hypokalemia, and leukocytosis.<sup>168</sup> No deaths are reported. The use of antibiotics,  $\beta_2$  agonists, and other growth enhancers continues, despite safety concerns and laws against their use, because these practices increase yield and profit.

The globalization of food supplies and international agricultural trade has created a new global threat—the apparent purposeful contamination of food for profit. In 2008, almost 300,000 children in China were affected by melamine contamination of milk. Of these, 50,000 were hospitalized, and 6 reported deaths occurred.

The melamine-contaminated milk was sold in China as powdered infant formula, with more than 22 brands containing melamine. The contamination was not limited to China because melamine has been found in candy, chocolate, cookies, and biscuits sold in the United States, likely because of the adulteration of milk used in preparation of these products.

Melamine is a non-nutritious, nitrogen-containing compound, usually used in glues, plastics, and fertilizers. To increase profits, milk sold in China was previously diluted, causing protein malnutrition in children. Because the nitrogen content of milk (a surrogate measure for protein content) is now carefully monitored to detect dilution and to prevent another episode of malnutrition, melamine was added to increase the measured nitrogen content and hide the dilution. This purposeful addition of melamine is suspected to be the cause of the melamine contamination of powdered milk in China.

Melamine and its metabolite cyanuric acid are excreted in the kidneys. Kidney stones containing melamine and uric acid were found in 13 children with acute kidney injury who had consumed melamine containing milk formula.<sup>88,205</sup> Both melamine and cyanuric acid appear necessary to cause kidney stones in animals. The combination alone caused renal crystals in cats.<sup>164</sup> Melamine found in wheat gluten was added to pet food in 2007 resulted in thousands of complaints and dozens of suspected animal deaths in the United States.

The melamine milk contamination is one of the largest reported deliberate food adulteration incidents. It affected about 300,000 Chinese infants and young children and caused 6 deaths.<sup>51,101</sup>

In India, 22 children were killed after becoming poisoned when eating their school lunch. It was discovered that the cooking oil was being kept in a container previously used for monocrotophos, a water-soluble organophosphate.<sup>92,126</sup>

Food products from all over the world find their way into our foods. Increased vigilance by the agencies responsible for food safety, both in countries where the food originates and in countries that import the food, is needed to prevent other events such as the melamine contaminations. Chapter 2 discusses numerous other foodborne toxicologic outbreaks.

### Vegetables and Plants

Plants and vegetables produce clinical signs and symptoms that are associated with diverse presentations often are involved in food poisoning.<sup>91,108,109,115,117</sup> Edible plants and plant products that are poorly cooked or prepared or contaminated result in poisoning. Extensive discussion of this is found in Chap. 118. The development of genetically modified plants has led many to be concerned about both the long- and short-term health effects. Currently, animal data are being collected, and no definitive conclusions about health effects have been made.

### FOOD POISONING AND BIOTERRORISM

The threat of terrorist assaults is discussed in Chaps. 126 and 127. The use of food as a vehicle for intentional contamination with the intent of causing mass suffering or death has already occurred in the United States.<sup>46,113,198</sup> In the first report, 12 laboratory workers had GI signs and symptoms, primarily severe diarrhea, after consuming food purposefully contaminated with *Shigella dysenteriae* type II served in a staff break room.<sup>113</sup> Four workers were hospitalized; none had reported long-term sequelae. This *Shigella* strain rarely causes endemic disease. Nevertheless an identical strain, identified by pulsed-field gel electrophoresis, was found in eight of the 12 symptomatic workers, as well as in the pastries served in the break room and in the laboratory stock culture of *S. dysenteriae*. This finding suggests purposeful poisoning of food eaten by laboratory personnel. The person responsible and the motive remain unknown.

The second case series describes a large community outbreak of food poisoning caused by *Salmonella typhimurium*.<sup>198</sup> The outbreak occurred in the Dalles, Oregon, area during the fall of 1984; a total of 751 people developed *Salmonella* gastroenteritis. The outbreak was traced to the intentional contamination of restaurant salad bars and coffee creamer by members of a religious commune using a culture of *S. typhimurium* purchased before the outbreak of food poisoning. A criminal investigation found a *Salmonella* culture on the religious commune grounds that contained *S. typhimurium* identical to the *Salmonella* strain found in the food poisoning victims. It was identified by using antibiotic sensitivity, biochemical testing, and DNA restriction endonuclease digestion of plasmid DNA. Only after more than 1 year of investigation was this *Salmonella* outbreak linked to terrorist activity. Reasons for the delay in identifying the outbreak as a purposeful food poisoning included (1) no apparent motive; (2) no claim of responsibility; (3) no pattern of unusual behavior in the restaurants; (4) no disgruntled restaurant employees identified; (5) multiple time points for contamination indicated by epidemic exposure curves, suggesting a sustained source of contamination and not a single act; (6) no previous event of similar nature as a reference; (7) the likeliness of other possibilities (eg, repeated unintentional contamination by restaurant workers); and (8) fear that the publicity necessary to aid the investigation might generate copycat criminal activity.

Publication of the event was delayed by almost 10 years out of fear of unintentionally encouraging copycat activity. On the other hand, use of biological weapons by the Japanese cult Aum Shinrikyo appears to have motivated authorities to release this publication in the hopes of quickly identifying similar deliberate food poisoning patterns in the future.

A third report describes a disgruntled employee who contaminated 200 lb of meat at a supermarket with a nicotine-containing insecticide.<sup>46</sup> Ninety-two people became ill, and four sought medical care. Signs and symptoms included vomiting, abdominal pain, rectal bleeding, and one case of atrial tachycardia.

There are multiple reports of deliberate food poisoning with tetramine.<sup>53,214</sup> In one particular case of human greed, a Chinese restaurant owner poisoned the food in his neighbor's restaurant with tetramine. Tetramine or tetramethylenedisulfotetramine is a highly lethal neurotoxic rodenticide, once used worldwide, now illegal in the United States. The snack shop owner caused hundreds to become ill and 38 deaths by spiking his competitor's breakfast offerings (fried dough sticks, sesame cakes, and sticky rice balls). Tetramethylenedisulfotetramine is an odorless and tasteless white crystal that is water soluble. The mechanism of action is noncompetitive irreversible binding to the chloride channel on the  $\gamma$ -aminobutyric acid receptor complex, which blocks the influx of chloride and alters the neurons potential. It is referred to as a "cage convulsant" because of its globular structure. Severe toxicity presents with tachycardia, dysrhythmias, agitation, status epilepticus, and coma. Immediate or early treatment with sodium-(RS)-2,3-dimercaptopropane-1-sulfonate (DMPS) and pyridoxine (vitamin B<sub>6</sub>) (A15) appears to be effective in a mouse model.<sup>13,65,208</sup>

The capacity of foodborne xenobiotics that are easy to obtain and disperse to infect large numbers of people is clearly exemplified by two specific outbreaks: (1) the purposeful *Salmonella* outbreak in Oregon and (2) the apparently unintentional *Salmonella* outbreak that resulted in more than 16,000 culture-proven cases traced to contamination in an Illinois dairy. The probable cause of the outbreak was a contaminated transfer pipe connecting the raw and pasteurized milk containment tanks.<sup>171</sup> These events emphasize the vulnerability of our food supply and the importance of ensuring its safety and security.

### PREVENTION OF FOODBORNE ILLNESS

The incidence of foodborne disease has increased over the years and has resulted in a major public health problem on the global level. The current methods for detecting foodborne pathogens are inefficient. This has led to the research and development of rapid detection methods.

The three major types of rapid detection methods are biosensor-based, nucleic acid-based, and immunological-based methods. Biosensor detection methods use an analytical device that contains a bioreceptor and transducer. The transducer converts the biological interactions into a measurable electrical signal. Examples of biosensor based methods are optical, electrochemical, and mass-based biosensors. Nucleic acid-based detection methods work by detecting specific DNA or RNA in the pathogen. An example of this test is the PCR, immunological-based methods detect foodborne pathogens based on antibody-antigen interactions, whereby a particular antibody binds to the specific antigen. An example of an immunological based detection method is ELISA.

In general, the rapid detection methods are more efficient and sensitive than the conventional detection methods. Rapid detection methods may be a very useful way of preventing foodborne disease in the future. Currently, implementing special equipment and training personnel along with high costs have thwarted comprehensive application of rapid detection methods at this time.<sup>120</sup>

### SUMMARY

- The diverse etiologies of food poisoning involve almost all aspects of toxicology.
- Our concerns center around the natural toxicity of plants or animals, the contamination of which can occur in the field, during factory processing, subsequent transport and distribution, or during home preparation or storage.
- Whether these events are intentional or unintentional, they alter our approaches to general nutrition and society.
- Issues in food safety include the governmental role in food preparation and protection, bacteria such as *Salmonella* and *E. coli* O157:H7, prions in Creutzfeldt-Jacob disease (bovine encephalopathy), and genetically altered materials such as corn.
- Future discussions of food poisonings and interpretations of the importance of these problems may dramatically alter our food sources and their preparation and monitoring.

## INTRODUCTION AND HISTORY

Obesity is a worldwide epidemic, and the United States has the largest proportion of a national population of overweight and obese individuals. According to the World Health Organization, 67.3% of the US population older than 18 years of age has a body mass index (BMI) of 25 or greater. The only country that has a larger proportion is the United Arab Emirates.<sup>135</sup> The majority of countries in the world have demonstrated a doubling to quadrupling of those with obesity in the past 30 years.<sup>61</sup> Some estimates predict that nearly 38% of the world's adult population will be overweight and 20% will be obese by 2030.<sup>61,66</sup> Even more alarming, the incidence of obesity in children between the ages of 6 and 19 years has tripled in the past 30 years. In one systematic review, there was a strong association between childhood obesity and adult obesity. Eighty percent of obese adolescents were obese into adulthood.<sup>117</sup> Although there are conflicting data, it is clear that obesity results in excess mortality.<sup>39,40</sup> In 2009, the Centers for Disease Control and Prevention reported more than 110,000 deaths caused by obesity in the United States. Mortality is a proven increase for every 5 kg/m<sup>2</sup> higher than a BMI of greater than 25 kg/m<sup>2</sup> with a reduction of median survival of 8 to 10 years in those with a BMI between 40 and 45 kg/m<sup>2</sup>.<sup>103</sup> Obesity is linked to numerous health risks, including type 2 diabetes, hypertension, coronary heart disease,<sup>10,18</sup> metabolic syndrome,<sup>133</sup> fatty liver, and low back pain.<sup>114</sup> Obesity is considered a leading preventable health risk, second only to cigarette smoking with a large economic impact costing upward of \$147 billion annually.<sup>21</sup>

Americans spend upward of \$60 billion per year on weight loss therapies. Pharmacologic interventions typically result in a 5% to 10% weight loss, although a return to baseline upon drug cessation is common.<sup>32,109</sup> Surgical interventions consistently achieve substantial weight loss, causing up to a 30% reduction in weight, but they are associated with numerous and varied complications.<sup>26</sup>

One of the earliest accounts of weight loss therapy dates back to 10th century Spain. King Sancho I, who was obese, underwent successful treatment with a “theriaca” thought to contain plants and possibly opioids, administered with wine and oil. In addition, he was closely supervised and treated by a physician.<sup>60</sup>

Weight loss xenobiotics (Table 40–1) are available as prescription medications (lorcaserin, phentermine, phentermine/topiramate, bupropion/naltrexone, phendimetrazine, orlistat, and liraglutide), nonprescription dietary supplements (*Citrus aurantium*, chitosan, *Garcinia cambogia*, caffeine), and nonprescription diet aids (orlistat). Numerous other prescription medications, including thyroid medications and metformin, have been used on an off-label basis for weight loss. Numerous xenobiotics are promoted as weight loss aids, many with no proven efficacy and some with serious toxicity.

The history of dieting xenobiotics is checkered. A number of weight loss therapies were withdrawn or banned by the Food and Drug Administration (FDA) because of serious adverse health effects (Table 40–2). Phenylpropanolamine (PPA),<sup>27</sup> fenfluramine/phentermine,<sup>27</sup> and sibutramine<sup>63</sup> were withdrawn from the US market. The endocannabinoid receptor inverse agonist (rimonabant) never reached the US market but was withdrawn in Europe

after its use was associated with serious dysphoria.<sup>106</sup>  $\gamma$ -Hydroxybutyric acid (GHB) and its congeners were initially sold as dietary supplements (Chap. 80) and promoted to body builders as a means to “convert fat into muscle” as a result of increasing growth hormone. Because of toxicity and its association with drug-facilitated sexual assault, GHB is strictly controlled as a Schedule I drug, with limited availability as a schedule III drug for narcolepsy (sodium oxybate; Xyrem). Clenbuterol is a long-acting  $\beta_2$ -adrenergic agonist. Because of the stimulant properties and lipolytic effects, clenbuterol is abused by body builders and others as a stimulant and anorectic.<sup>57,138</sup> Despite at least one meta-analysis demonstrating that that  $\beta$ -human chorionic gonadotropin ( $\beta$ -HCG) was without efficacy in the treatment of obesity,<sup>75</sup> injectable beta-HCG continues to be sold for weight loss, with the potential for significant harm.<sup>74</sup>

Since 2012, the prescription pharmaceutical market has developed, and the FDA approved numerous new medications. Phentermine/topiramate, lorcaserin, bupropion/naltrexone, liraglutide, and orlistat are all available in the United States. Pharmacologically different, they show modest promise, at best in the weight loss drug armamentarium. There is ongoing research both for existing and novel pharmaceutical approaches for weight loss and will likely be presented to the FDA for new drug approval or labeling changes to include weight loss. Despite numerous innovative pharmacologic approaches and advancements, there will likely be no perfect, ideal weight loss drug.

## PHARMACOLOGY

The hypothalamus is the key site in the brain that regulates food intake, energy expenditure, satiety, and metabolism. It also integrates endocrine signaling to meet the energy demand.<sup>83</sup> The hormonal endocrine regulation of appetite continues to be extensively investigated. Dieting xenobiotics can be divided into classes based on one or more of the following mechanisms or action: (1) appetite suppression (*anorectics*), (2) alteration of food absorption or elimination, or (3) increased energy expenditure. Sympathomimetics, serotonergics, dinitrophenol, and bupropion/naltrexone all work pharmacologically on the hypothalamus to induce weight loss. Dinitrophenol is a mitochondrial uncoupler, thereby resulting in an increasing energy expenditure.<sup>71</sup> Glucagon-like peptide-1 (GLP-1) agonists, such as liraglutide, act on the hypothalamus and suppress appetite.<sup>17</sup>

Endocannabinoid receptor antagonists bind to CB1 endocannabinoid receptors in the brain and in the intestines, liver, pancreas, adipose tissue, and skeletal muscle. Antagonizing central CB1 receptors has a negative effect on the reward pathway in the mesolimbic system as well as decreasing appetite via the hypothalamus.<sup>30</sup> Leptin is secreted from fat proportionate to the amount of lipids contained in the adipocyte, with women secreting more leptin than men. Leptin acts on the hypothalamus to decrease food intake, enhancing the metabolic rate and energy expenditure. Ghrelin is secreted by the stomach, and concentrations increase after fasting and just before meals. Ghrelin stimulates the hypothalamus and stimulates food intake. Glucagon-like peptide-1 enhances glucose-induced insulin secretion while suppressing glucagon release (Fig. 40–1).<sup>17,33</sup> Most humans have metabolically active brown adipose tissue containing both brown and beige adipocytes. Under conditions of obesity, there appears to be inhibition of brown and beige adipocytes. Although very early in research, beige adipocytes may be a potential therapeutic target for obesity.<sup>115</sup>

## SYMPATHOMIMETICS

Although controversial, certain sympathomimetic amines still carry official indications for short-term weight reduction (Table 40–3). Sympathomimetic amines share a  $\beta$ -phenylethylamine parent structure and include phentermine,

TABLE 40–1 Weight Loss Xenobiotics

Drug or Supplement <sup>a</sup>	Mechanism of Action	Regulation Status, DEA Schedule	Adverse Effects or Contraindications <sup>b</sup>
<b>Sympathomimetics</b>			
Bitter orange extract ( <i>Citrus aurantium</i> )	Contains synephrine and octopamine; increases thermogenesis and lipolysis	Dietary supplement	Hypertension, cerebral ischemia, myocardial ischemia, prolonged QT interval
Bupropion/naltrexone	Increased release of norepinephrine; synergistic effect of midbrain dopamine	Nonscheduled prescription drug	Tachycardia; hypertension; seizures Opioid withdrawal in tolerant patients
Diethylpropion	Increased release of norepinephrine and dopamine	Schedule IV	Dry mouth, tremor, insomnia, headache, agitation, palpitations, hypertension, stroke, dysrhythmias; contraindications: monoamine oxidase inhibitor use within 14 days, glaucoma, hyperthyroidism
Guarana ( <i>Paullinia cupana</i> )	Contains caffeine, which may increase thermogenesis	Dietary supplement	Nausea, vomiting, insomnia, diuresis, anxiety, palpitations
Mazindol	Increased release of norepinephrine and dopamine	Schedule IV	Dry mouth, tremor, insomnia, headache, agitation, palpitations, hypertension, stroke, dysrhythmias; contraindications: monoamine oxidase inhibitor use within 14 days, glaucoma, hyperthyroidism
Phentermine	Increased release of norepinephrine and dopamine	Schedule IV	Similar to diethylpropion
Phentermine/topiramate	Increased release of norepinephrine and dopamine (phentermine); exact mechanism of action for topiramate remains speculative	Schedule IV	Phentermine: similar to diethylpropion Topiramate: central nervous system depression; ataxia; non-anion gap metabolic acidosis; kidney stones Contraindication: first trimester pregnancy
Raspberry ketone	Structurally similar to synephrine; increases thermogenesis and lipolysis	Dietary supplement	Nausea, vomiting, insomnia, hypertension, tachycardia, anxiety, palpitations
<b>Serotonergics</b>			
Lorcaserin (Belviq)	Selective agonist at 5-HT <sub>2c</sub>	Schedule IV	Dizziness, headache, nausea; serotonin toxicity possible after overdose
<b>GLP-1 Agonists</b>			
Albiglutide Dulaglutide Exenatide Liraglutide	GLP-1 analog	Nonscheduled prescription medication	Nausea, diarrhea Potential: hypoglycemia
<b>GI Agents</b>			
Chitosan	Insoluble marine fiber that binds dietary fat	Dietary supplement	Decreased absorption of fat-soluble vitamins Contraindications: shellfish allergy
Orlistat	Inhibits gastric and pancreatic lipases	Prescription and nonprescription medication	Abdominal pain, oily stool, fecal urgency or incontinence; fat-soluble vitamin loss Contraindications: cholestasis, chronic malabsorption
<b>Fibers and Other Supplements</b>			
Chromium picolinate	Improves blood glucose and lipids; produces fat loss (unproven)	Dietary supplement	Dermatitis, hepatitis, possibly mutagenic in high doses
<i>Garcinia cambogia</i>	Increases fat oxidation (unproven)	Dietary supplement	None reported
Glucomannan	Expands in stomach to increase satiety	Dietary supplement	GI obstruction with tablet form Contraindications: abnormal GI anatomy

<sup>a</sup>Trade names and botanical names are given in parentheses. <sup>b</sup>All xenobiotics are contraindicated during pregnancy and lactation.

GI = gastrointestinal; GLP-1 = glucagon-like peptide-1; MAOI = monoamine oxidase inhibitor; 5-HT<sub>2c</sub> = serotonin receptor.

diethylpropion, and mazindol, which are Schedule IV drugs and carry warnings that advise prescribers to limit use to only a few weeks. Phentermine/topiramate extended release (Qsymia) is indicated for long-term use.<sup>5,9</sup> Regardless of their source and legal status, sympathomimetics generally share a spectrum of toxicity and produce adverse effects similar to amphetamines (Chap. 73). Both PPA and ephedra were popular

sympathomimetics used in weight loss products, and were both fraught with significant toxicity and are no longer available. Reported toxicity associated with PPA generally results from hypertension.<sup>95</sup> A comprehensive review of more than 100 case reports of adverse drug effects involving PPA revealed 24 intracranial hemorrhages, 8 seizures, and 8 fatalities between 1965 and 1990.<sup>71</sup> Ephedra (*Ephedra sinica*), or Ma-huang, is a

TABLE 40–2 High-Risk Xenobiotics Unapproved or Withdrawn by the US Food and Drug Administration

Drug or Supplement <sup>a</sup>	Mechanism of Action	Regulation Status, DEA Schedule, or Withdrawal Date	Adverse Effects or Contraindications
Amphetamine	Increased release of norepinephrine and dopamine	Schedule II	Sympathomimetic effects, psychosis, dependence
Benzphetamine	Increased release of norepinephrine and dopamine	Schedule III	Sympathomimetic effects, psychosis, dependence
Caffeine	$\beta_2$ -Adrenergic agonist activity; increased energy expenditure	Never approved	Nausea, vomiting, tachycardia, wide pulse pressure, hypokalemia, hyperglycemia, anion gap metabolic acidosis
Clenbuterol	$\beta_2$ -Adrenergic agonist activity	Never approved	Tachycardia, headache, nausea, vomiting; may be prolonged
Dexfenfluramine	Promotes central serotonin release and inhibits its reuptake	Withdrawn September 1997	Valvular heart disease, primary pulmonary hypertension
Dieter's teas (senna, cascara, aloe, buckthorn)	Stimulant laxative herbs that promote colonic evacuation	FDA required label warning, June 1995	Diarrhea, vomiting, nausea, abdominal cramps, electrolyte disorders, dependence
Dinitrophenol	Alters metabolism by uncoupling oxidative phosphorylation	Never approved; available on the Internet	Hyperthermia, cataracts, hepatotoxicity, skin rash, peripheral neuropathy
Ephedra sinica (Ma-huang)	Increased release of NE and dopamine	Banned by FDA, April 2004	Sympathomimetic effects, psychosis
Fenfluramine	Increased release and decreased reuptake of serotonin	Withdrawn September 1997	Valvular heart disease, primary pulmonary hypertension
Guar gum	Hygroscopic polysaccharide swells in stomach, producing early satiety	Banned by FDA, July 1990	Esophageal and small bowel obstruction, fatalities
$\beta$ -Human chorionic gonadotrophin	Unknown	Never approved	Coronary artery dissection
LipoKinetix (sodium usniate, norephedrine, 3,5-diiodothyronine, yohimbine, caffeine)	Unknown	FDA warning, November 2001	Acute hepatitis
Phendimetrazine	Increased release of NE and dopamine	Schedule III	Sympathomimetic effects, psychosis
Phenylpropanolamine	$\alpha_1$ -Adrenergic agonist	Withdrawn November 2000	Sympathomimetic effects, headache, hypertension, myocardial infarction, intracranial hemorrhage
Rimonabant	Endocannabinoid receptor inverse partial agonist	Never approved in the United States; withdrawn from European market in 2011	Anxiety, nausea, diarrhea, dizziness; increased suicidality and depression
Salicylate (willow bark)	Uncoupler of oxidative phosphorylation	Never approved	Nausea, vomiting, tinnitus, tachycardia, altered mental status, anion gap metabolic acidosis (see chapter)
Sibutramine	Inhibits reuptake of serotonin and norepinephrine	Withdrawn October 2010	Increase in cardiovascular toxicity; increase in nonfatal myocardial infarction; increase in nonfatal stroke

<sup>a</sup>Trade names or botanical names as appropriate are given in parentheses.

DEA = Drug Enforcement Administration; FDA = Food and Drug Administration; NE = norepinephrine.

plant that contains six sympathomimetic amines, known collectively as *ephedra alkaloids*. The FDA banned ephedra-containing products in 2004 because of cases of serious cardiovascular toxicity<sup>54</sup> and acute hepatitis.<sup>86</sup>

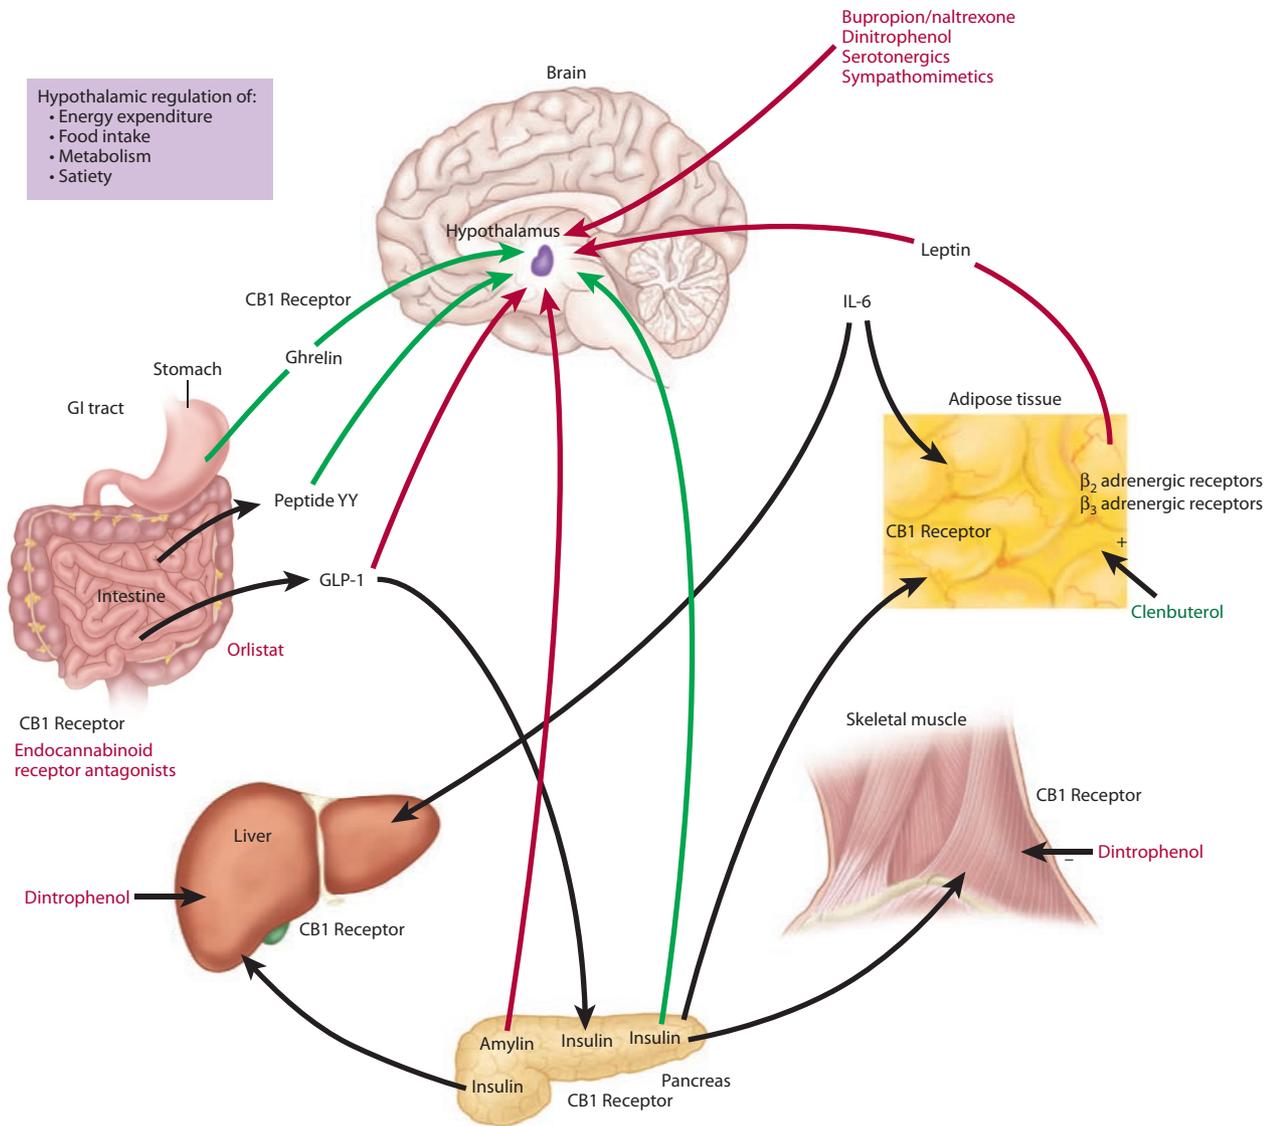

### Pharmacology

Sympathomimetic amines that act at  $\alpha$ - and  $\beta$ -adrenergic receptors are clinically effective in promoting weight loss but have numerous side effects that limit their clinical use. Soon after its introduction as a pharmaceutical for nasal congestion in the 1930s, the prototype sympathomimetic drug amphetamine (Fig. 40–2) was noted to cause weight loss (Chap. 73). The weight loss effect of amphetamine was also readily apparent in early animal studies, although tolerance to the anorectic effects was also noted.<sup>125</sup> The primary mechanism of action of the weight loss effects of

sympathomimetics is central nervous system (CNS) stimulation, resulting from increased release of norepinephrine and dopamine.<sup>121</sup> The effects include direct suppression of the appetite center in the hypothalamus and reduced taste and olfactory acuity, leading to decreased interest in food. Increased energy and euphoriant effects of the stimulants also contribute to weight loss. However, tachyphylaxis occurs, and the rate of weight loss diminishes within a few weeks of initiating therapy.<sup>35</sup> Significant side effects and abuse potential severely limit the therapeutic use of this class.

### Adverse Effects

The absence of polar hydroxyl groups from a sympathomimetic amine increases its lipophilicity; therefore, unsubstituted or predominantly alkyl group substituted compounds such as amphetamine, ephedrine, and PPA

Mechanisms of Weight Loss	Examples of Drugs
Amylin analogs	▪ Pramlintide
CB1 receptor antagonism	▪ Rimonabant
GI absorption	▪ Acarbose ▪ Laxatives ▪ Orlistat
GLP-1 analogs	▪ Albiglutide ▪ Dulaglutide ▪ Exenatide ▪ Liraglutide
Hypothalamic regulation	▪ Bupropion/Naltrexone ▪ Dinitrophenol ▪ Ephedrine ▪ Lorcaserin ▪ Phentermine ▪ Sibutramine

**FIGURE 40-1.** Endocrine and neuroendocrine pathways of obesity and weight loss regimens. Systems regulating food ingestion and energy balance are interconnected and regulated. The hypothalamus regulates food intake, satiety, energy expenditure, and metabolism. Adipose tissue functions for glucose uptake and conversion; lipogenesis and lipolysis;  $\beta$  oxidation of fatty acids; and release of leptin, adiponectin, and interleukin-6 (IL-6), all of which regulate energy balance. CB1 = endocannabinoid receptor; GI = gastrointestinal; GLP-1 = glucagon-like peptide 1; Red text: Suggests a negative effect or antagonist effect; Green text: Suggests a positive effect or agonist effect; Red arrow: promotes satiety; Green arrow: increases hunger; Black arrow: normal cause/effect and + if promotes positive effects and - if promotes negative effects.

**TABLE 40–3** Defining Overweight and Obesity in the United States

Age	Overweight	Obese
2–19 y of age	BMI between 85th and 95th percentiles <sup>a</sup>	BMI ≥95th percentile <sup>a</sup>
≥20 y of age	BMI ≥25 but <30	BMI ≥30

<sup>a</sup>From the Centers for Disease Control and Prevention's sex-specific body mass index (BMI) for age growth charts

Data from Ogden CL, Flegal KM. Changes in terminology for childhood overweight and obesity. *Natl Health Stat Report*. 2010 Jun 25;(25):1-5.

have greater CNS activity. Mild cardiovascular and CNS stimulant effects include headache, tremor, sweating, palpitations, and insomnia. More severe effects that may occur after overdose of sympathomimetic amines include anxiety, agitation, psychosis, seizures, palpitations, and chest pain.<sup>127,129</sup>

Hypertension is common after overdose and occasionally after therapeutic use. Patients present with confusion and altered mental status as a result of hypertensive encephalopathy. Reflex bradycardia after exposure to xenobiotics with predominantly  $\alpha$ -adrenergic agonist effects often accompanies the hypertension and provides a clue to the diagnosis. Children are at especially high risk for hypertensive episodes because of the relatively significant dose per kilogram of body weight from even a single tablet. Other manifestations include chest pain, palpitations, tachycardia, hypertension, syncope, coronary vasospasm, mania, psychosis, and convulsions.<sup>94</sup>

Clinically significant hypertension should be treated with a rapid acting, easily titratable vasodilator such as nicardipine or phentolamine. Analogous to the management of cocaine toxicity, we recommend against the use of  $\beta$ -adrenergic antagonists avoided because the resultant unopposed  $\alpha$ -adrenergic agonist effects may lead to greater vasoconstriction and hypertension.<sup>4</sup> Agitation, tachycardia, and seizures should be treated initially with benzodiazepines.

### Herbal Sympathomimetic Products

Since ephedra was banned, herbal weight loss supplements have been reformulated. Many now contain an extract of bitter orange (*Citrus aurantium*), a natural source of the sympathomimetic amine synephrine, often in combination with caffeine, guarana, theophylline, willow bark (containing salicylates), diuretics, and other constituents. The dried fruit peel of bitter orange

is a traditional remedy for gastrointestinal (GI) ailments. The predominant constituents, *p*-synephrine (Fig. 40–2) and octopamine, are structurally similar to epinephrine and norepinephrine. The isomer *m*-synephrine (phenylephrine) is used extensively as a vasopressor and nasal decongestant. Although the physiologic actions of synephrine are not fully characterized, it appears to interact with amine receptors in the brain and acts at peripheral  $\alpha_1$ -adrenergic receptors, resulting in vasoconstriction and increased blood pressure.<sup>44,124</sup> Some evidence indicates that synephrine also has both  $\beta_2$  and  $\beta_3$ -adrenergic agonist activity,<sup>19,82,105</sup> which could increase lipolysis.  $\beta_3$ -Adrenergic agonists have remarkable antiobesity effects in rodents;<sup>137</sup> however, effects in humans are not as profound.

Nearly 2% of 4,140 Californians surveyed had used a *C. aurantium*-containing product several times a week. Despite the study of more than 350 participants that concluded that *C. aurantium* did not produce changes in blood pressure or heart rate and was without significant adverse effects,<sup>123</sup> there are numerous case reports describing toxicity. Tachydysrhythmias,<sup>38</sup> cerebral ischemia,<sup>13</sup> QT prolongation,<sup>88</sup> and myocardial infarction<sup>82,91</sup> are all reported.

Raspberry ketone, 4-(4-hydroxyphenyl)-2-butanone, is promoted to induce weight loss and is available as a supplement. Structurally similar to synephrine, its purported effects on weight loss are similar. The amount of raspberry ketone in a typical dose of a dietary supplement is equal to the amount derived from 40 kg of raspberries. The effect on weight loss and adipose tissue remains unclear.<sup>85,94</sup> There has been only one report of toxicity described in the literature, and clinical effects are consistent with other sympathomimetics.<sup>126</sup>

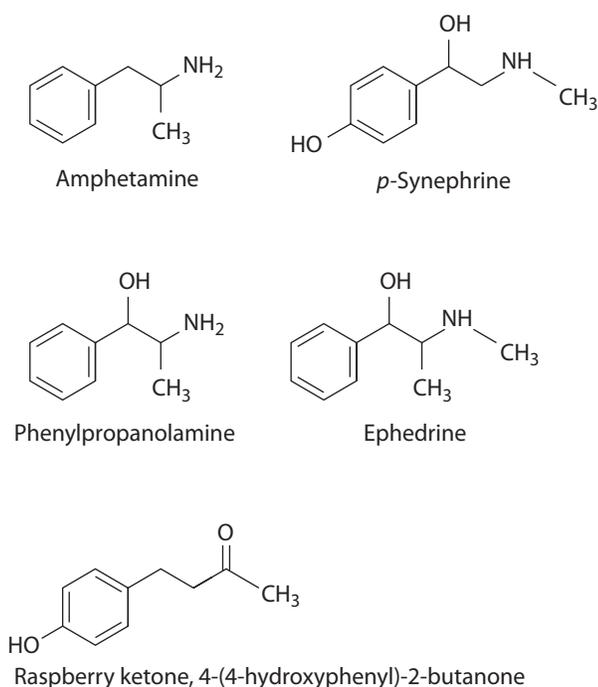

### Phentermine/Topiramate

Phentermine is a sympathomimetic that retains an FDA indication for short-term weight loss. It increases release of norepinephrine, which serves as an appetite suppressant via the effects on the hypothalamus. Topiramate is available for a variety of conditions, including seizure disorders and migraine headaches. Weight loss is a demonstrated side effect of topiramate when used for these indications.<sup>67</sup> The mechanism of weight loss induced by topiramate remains speculative and is likely a combination of decreased caloric intake, increased energy expenditure, and decreased energy efficiency.<sup>5,45</sup>

Phentermine/topiramate controlled release (Qsymia) is approved for long-term management of weight loss. If, within 24 weeks of therapy initiation, there is less than a 5% decrease in body weight, therapy should be terminated.<sup>25</sup> The clinical trials evaluating the efficacy of phentermine/topiramate were short-term studies performed in approximately 4,000 patients.<sup>5,9,45</sup> In all of these trials, there was a substantial decline in body fat (upward of 10%) as well as improvement in other metabolic parameters, including lipid control and glucose regulation. Cardiovascular effects reveal mild increases in heart rate at therapeutic dosing.<sup>129</sup> There appears to be an increased risk of congenital malformations, particularly orofacial clefts, when this drug was taken during the first trimester of pregnancy.<sup>43</sup> Topiramate is a carbonic anhydrase inhibitor, and electrolyte abnormalities, including hyperchloremia, hypokalemia, and decreased bicarbonate resulting in non-anion gap metabolic acidosis are commonly associated with use.<sup>113</sup> Overdose of topiramate causes CNS depression, ataxia, seizures and laboratory abnormalities noted above.<sup>14</sup> Although there have been no documented cases of overdose of this combination product, its toxicity can be extrapolated from the known toxicities of the individual components.

### SEROTONERGICS

Xenobiotics that affect central release and reuptake of serotonin are approved for a number of indications, including depression, anxiety, nicotine dependency, migraine headache, and premenstrual dysphoric syndrome. Serotonin is believed to have a role in appetite suppression, which is due to the effect on the hypothalamic serotonin 5-HT<sub>2C</sub> receptor, as well as the 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub>, and 5-HT<sub>6</sub> receptors.<sup>52,53</sup> Serotonin receptor effects also enhance energy expenditure. Use of serotonin agonists for weight loss is associated with

**FIGURE 40–2.** Sympathomimetic amines formerly and currently used for weight loss.

cardiac valvulopathy (5-HT<sub>2B</sub> receptor), hallucinations (5-HT<sub>2A</sub> receptor), and pulmonary hypertension (5-HT<sub>1B</sub>), and serotonin toxicity. The serotonergics dexfenfluramine (Redux), fenfluramine (Pondimin), and sibutramine were all removed from the US market because of significant cardiac toxicity.<sup>1,15,63</sup>

Lorcaserin (Belviq) is a selective agonist at the 5-HT<sub>2C</sub> receptor.<sup>36,79</sup> This novel selectivity for the 5-HT<sub>2C</sub> receptor results in weight loss with a decreased incidence of toxicity compared with other serotonergics.<sup>53</sup> Lorcaserin neither stimulates the release of norepinephrine, dopamine, or serotonin, nor does it inhibit the reuptake of these neurotransmitters.<sup>53</sup>

Lorcaserin 10 mg twice daily resulted in a significant reduction in body fat after 52 weeks of therapy in 3,182 participants that was maintained for 1 year.<sup>120</sup> No increase in the incidence of cardiac valvulopathy was demonstrated in the 2-year follow-up in the participants receiving lorcaserin.<sup>120</sup> A recent study<sup>80</sup> described 44 patients with exposures to lorcaserin, 30 of whom had unintentional exposures.<sup>14</sup> There were no major adverse outcomes or death reported, and the majority of adverse events included agitation or irritability, diaphoresis, drowsiness, tachycardia, and muscle rigidity consistent with serotonergic toxicity. Management of the toxic effects mediated by serotonin receptors should address the specific clinical effects. Benzodiazepines are recommended for tachycardia and hypertension that occurs in the setting of psychomotor agitation. Rapid identification and management of serotonin toxicity are essential to prevent associated morbidity and mortality (Chap. 69).

## XENOBIOTICS THAT ALTER FOOD ABSORPTION, METABOLISM, AND ELIMINATION

### Fat Absorption Blockers

Orlistat was approved by the FDA in 1999 for treatment of obesity. It is also available as nonprescription medication. Orlistat abuse should be assessed in patients presenting with related adverse events. Orlistat is the only FDA-approved drug that alters the absorption, distribution, and metabolism of food. Orlistat is a potent inhibitor of gastric and pancreatic lipase, thus reducing lipolysis and increasing fecal fat excretion.<sup>20</sup> The drug is not systemically absorbed but exerts its effects locally in the GI tract. It inhibits hydrolysis of dietary triglycerides and reduces absorption of the products of lipolysis, monoglycerides, and free fatty acids. Several clinical trials demonstrate that orlistat reduces GI fat absorption by as much as 30%.<sup>140</sup> When taken in association with a calorie-restricted diet, weight loss of approximately 10% body weight can be achieved in 1 year.<sup>118</sup>

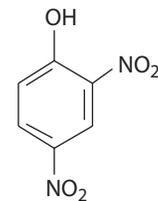

Orlistat should be taken only in conjunction with meals that have a high fat content; it should not be consumed in the absence of food intake. Adverse effects correlate with the amount of dietary fat consumption and include abdominal pain, oily stool, fecal incontinence, fecal urgency, flatus, and increased defecation. Systemic effects are rare because of the lack of systemic absorption.<sup>37,94</sup> Liver toxicity manifesting as cholestatic, jaundice, and centrilobular necrosis are reported,<sup>84,107</sup> although the mechanism is unknown. In a cohort of nearly 16,000 patients in England, there were reports of aminotransferase elevations but no cases of serious hepatotoxicity. Two of the cases were deemed as causally related to orlistat, and one had evidence of initial aminotransferase elevation and elevation on rechallenge.<sup>97</sup> Concomitant use of natural fibers (6 g of psyllium mucilloid dissolved in water) is proposed reduce the GI side effects of orlistat. Because orlistat reduces absorption of fat-soluble food constituents, daily ingestion of a multivitamin supplement containing vitamins A, D, and K, and β-carotene is advised to prevent resultant deficiency. Pancreatitis<sup>3</sup> and oxalate nephropathy<sup>117</sup> are rarely reported after orlistat use. There are no reported intentional overdoses of orlistat. There are limited data regarding unintentional pediatric exposure to orlistat, and the toxicity appears to be limited to mild GI effects.<sup>92</sup> In overdose and/or misuse, treatment should be responsive to clinical manifestations.

### Dietary Fibers

Glucosaminan, a dietary fiber consisting of glucose and mannose, is derived from konjac root, a traditional Japanese food. Edible forms of glucosaminan include konjac jelly and konjac flour, which are mixed with liquid before

ingestion. Purified glucosaminan is available in capsule form and is found in various proprietary products marketed for weight loss. On contact with water, glucosaminan swells to approximately 200 times its original dry volume, turning into a viscous liquid. It lowers blood cholesterol and glucose concentrations and decreases systolic blood pressure,<sup>7,129</sup> but significant weight loss benefits are not demonstrated.<sup>68</sup> Following several reports of esophageal obstruction, glucosaminan tablets were withdrawn from the market in Australia in 1985.<sup>55</sup> Serious adverse effects are not described with encapsulated glucosaminan, presumably because slower dissolution allows for GI transit before expansion. Glucosaminan capsules are available as a nutritional supplement in the United States, although adequate safety and efficacy studies have not been published.

### Dinitrophenol

Dinitrophenol

One of the earliest attempts at a pharmaceutical treatment for obesity was 2,4-dinitrophenol (DNP), which was popularized as a weight loss adjuvant in the 1930s.<sup>49,98</sup> This chemical, which is used in dyes, wood preservatives, herbicides, and explosives, was never approved as a pharmaceutical. Dinitrophenol was legally available as a dietary supplement before enactment of the US Federal Food, Drug, and Cosmetic Act of 1938 and thus remained legal. Dinitrophenol is readily available in capsules or tablets and can be purchased online.<sup>59,98</sup> By increasing metabolic energy expenditure, it reportedly produces weight loss of 1 to 2 lb per week in doses of 200 to 300 mg per day.<sup>25,46,49</sup> Dinitrophenol increases metabolic work by uncoupling oxidative phosphorylation in the mitochondria. Through this mechanism, the hydrogen ion gradient that facilitates adenosine triphosphate (ATP) synthesis is disrupted, and ATP production is arrested, although oxidative metabolism in the citric acid cycle continues (Chap. 11). This mechanism results in inefficient substrate utilization, and the resulting energy loss is dissipated as heat. This wastes calories but also increases temperature and, occasionally, life-threatening hyperthermia occurs.<sup>79</sup> In fact, DNP was reportedly administered to Russian soldiers during World War II to keep them warm during winter battles.<sup>49</sup> Symptoms related to DNP toxicity include malaise, rashes, headache, diaphoresis, thirst, peripheral neuropathy,<sup>100</sup> and dyspnea. Acute toxic effects include hyperthermia, hepatotoxicity, agranulocytosis, respiratory failure, coma, and death.<sup>59,70,138</sup> Delayed-onset cataracts were a frequent and serious complication of DNP use.<sup>11</sup>

Epidemic use of DNP occurred in Texas in the 1980s when industrial DNP was used at a physician's weight loss center. The physician distributed DNP under the trade name Mitcal. The fatality of a wrestler after an intentional overdose in 1984 led a Texas court to prohibit the practice.<sup>70</sup> Dinitrophenol continues to reappear as a weight loss treatment,<sup>98</sup> and cases of serious toxicity are reported.<sup>46,49</sup> Management should emphasize rapid cooling (Chap. 29). Benzodiazepines should also be used as an adjunct therapy for management of agitation and seizures.

### Endocannabinoid Receptor Antagonists and Inverse Agonists

In the past 15 years, the endocannabinoid system (ECS) and its involvement in weight loss sparked excitement and potential for novel xenobiotics. Endocannabinoids, which are the natural ligand for the cannabinoid receptor, have diverse effects on metabolic functions.<sup>58</sup> The ECS contributes to the regulation of food intake, body weight, and energy balance, and it may have a role in inflammation and neuropathic pain.<sup>64,108,132,136</sup> It has long been known that tetrahydrocannabinol, the active principle in marijuana (*Cannabis sativa*), stimulates appetite and is an effective antiemetic<sup>22,96</sup> (Chap. 74).

Several CB1 receptor antagonists and inverse agonists showed promise in both animal and human studies of weight loss. Rimonabant was approved for therapeutic use in Europe, and clinical trials in the United States were performed. Clinical studies note that these xenobiotics showed a significant and sustained reduction in body weight.<sup>104</sup> There was also improvement in insulin resistance with a decline in plasma leptin, insulin, and free fatty acid concentrations, presumably caused by the upregulation of the peripheral ECS system in diabetes.<sup>56,106</sup> In the clinical trials, there was a significant increase in adverse events, including anxiety and depression in the rimonabant groups. This led to a delay in the FDA approval of this product for therapeutic use. Shortly after approval in Europe, it became evident that the effects of anxiety and depression were far greater than initially expected. Rimonabant was never approved by the FDA, and other phase III studies, including those involving other endocannabinoid receptor inverse agonists (eg, taranabant), were terminated early because of a range of dose-related GI, nervous, psychiatric, cutaneous, and vascular side effects.<sup>6,102</sup> Rimonabant was removed from the European market after only 2 years.<sup>81</sup> Centrally acting CB1 antagonists proved to have an unfavorable risk–benefit relationship. However, peripherally acting CB1 antagonists have promise for weight loss, and further research is ongoing.<sup>34,51</sup> Current animal research uses AM4113, a central CB1 neutral antagonist for weight loss as well as nicotine dependence apparently without the psychiatric effects.<sup>50</sup> It remains unclear what role that CB1 receptor antagonists will play in the weight loss drug therapeutics.

### Naltrexone/Bupropion

Bupropion/naltrexone (Contrave) was FDA approved in late 2014.<sup>131</sup> The mechanisms by which naltrexone/bupropion cause weight loss is incompletely understood.<sup>131</sup> Proopiomelanocortin (POMC)-producing neurons in the hypothalamus are stimulated with bupropion, and naltrexone inhibits the opioid-mediated POMC autoinhibition. This combination of stimulation and inhibition of the negative feedback loop on POMC neurons is believed to facilitate ongoing weight loss. Additionally, it is believed that there is synergism with naltrexone and bupropion in midbrain dopamine areas resulting in decreased food intake, presumably through modulation of mesolimbic reward systems.<sup>48,65,132</sup> The synergistic effect has shown good results in sustainable weight loss.<sup>48,131</sup>

The FDA mandated a clinical trial evaluating cardiovascular risk of naltrexone SR 32 mg/bupropion SR 360 mg in participants with underlying cardiovascular risk factors. The study reported less than a twofold increase in cardiovascular risk. However, it was terminated before completion, and it is impossible to confirm the lack of increased cardiovascular toxicity in susceptible patients.<sup>90,111</sup>

Adverse events from this product result from the known toxicity of each individual xenobiotic. Naltrexone is generally expected to be safe and well tolerated in opioid-naïve patients; however, it will cause prolonged opioid withdrawal symptoms in opioid-tolerant patients and will significantly reduce the efficacy of opioids if they are required<sup>141</sup> (Antidotes in Depth: A4). Bupropion toxicity is well described in the literature. Seizures occur with bupropion doses greater than 450 mg/day.<sup>28,112</sup> The amount of bupropion available in this formulation is of particular concern as is the potential for misuse or overdose. Bupropion toxicity is discussed in detail in Chap. 69.

### Liraglutide

Glucagon-like peptide-1 is produced in the brain and distal intestine. During a meal, GLP-1 concentrations increase and remain elevated for several hours. Glucagon-like peptide-1 inhibits food intake, inhibits glucagon secretion, decreases gastric acid secretion, and delays gastric emptying.<sup>17</sup> Glucagon-like peptide-1 analogs have been FDA-approved pharmaceuticals for type 2 diabetes for several years with only one agent receiving weight loss as an approved indication for use. There are currently four GLP-1 analogs available in the United States (liraglutide, exenatide, dulaglutide, and albiglutide).

Liraglutide (Saxenda), a GLP-1 analog, previously on the US market for the treatment of type 2 diabetes, received FDA approval in late 2014 for weight loss. Liraglutide (3 mg) resulted in at least a 5% reduction of body

weight in 63.2% of study participants compared with 27.1% in the control group. A total of 33.1% of participants demonstrated a greater than 10% reduction in body weight compared with 10.6% of control participants over the 56-week study period.<sup>100</sup> The drug was well tolerated with nausea and diarrhea being the most common adverse events.<sup>29,100</sup> In the participants who had adverse events during the clinical trials, nausea was reported in 40% of the participants, diarrhea in 20%, and vomiting in 16%.<sup>100</sup>

Although there are no documented overdoses of the 3-mg liraglutide formulation, there have been many reports of overdose with the other, lower doses formulations used in type 2 diabetes. In one case of intentional overdose of 72-mg liraglutide, mild GI toxicity predominated, and significant hypoglycemia was absent.<sup>87</sup> An inadvertent dosing error of 18 mg/day for 7 months in a 67-year-old male patient with type 2 diabetes only resulted in nausea, vomiting, and diarrhea.<sup>12</sup>

### Alternative Pharmaceutical Approaches

In an attempt to find the “perfect” therapeutic alternative for weight loss, there is a desire to use currently approved xenobiotics for weight loss. Similar to topiramate, xenobiotics that are known to cause weight loss at therapeutic doses such as metformin, bupropion, and zonisamide continue to be investigated for both labeled and off-label use. Combination therapy aimed at multiple systems may prove efficacious. Although these xenobiotics provide a beneficial weight loss, each of them has its own inherent toxicities. Metformin can cause a metabolic acidosis with elevated lactate concentration, particularly in patients with underlying kidney dysfunction and after large intentional overdoses (Chap. 47). Zonisamide, an adjunct antiepileptic that is not used commonly, is associated with adverse events, including CNS depression and hypersensitivity (Chap. 48).<sup>89,139</sup>

### HYPOCALORIC DIETS AND CATHARTIC OR EMETIC ABUSE

Starvation, as well as abuse of laxatives, syrup of ipecac, diuretics, and anorectics, has led to morbidity and mortality, often in young patients.<sup>28,112</sup> The potential for fad diets and laxative abuse should be evaluated in young people with unexplained salt and water depletion, syncope, hypokalemia, and metabolic alkalosis. A variety of extreme calorie-restricted diets resulting in profound weight loss were very popular in the late 1970s, but reports of a possible association between these diets and sudden death followed.<sup>100</sup> Myocardial atrophy was a consistent finding on autopsy. Torsade de pointes and other ventricular dysrhythmias may have occurred as a result of hypokalemia,<sup>141</sup> and protein-calorie malnutrition is proposed as a cause of death.<sup>29,87,100</sup>

After the negative reports and FDA warnings, the enthusiasm for liquid protein diets waned. Several current diets (Atkin’s plan, South Beach diet) advocate intake of high protein, high fat, and low carbohydrates while allowing unlimited amounts of meat, fish, eggs, and cheese. Lack of carbohydrates induces ketosis, which results in salt and water depletion, giving the user the appearance of rapid weight loss. With rehydration and resumption of a normal diet, weight gain generally occurs. In addition, salt and water depletion causes orthostatic hypotension and ureterolithiasis. Atherosclerosis and hypercholesterolemia occur as a result of substitution of high-calorie, high fat foods for carbohydrates. Despite the rapid initial weight loss with these diets, when carbohydrates are reintroduced, weight gain occurs rapidly and significantly.<sup>32</sup> Regardless of the type of diet, there is no clinically relevant weight loss or maintenance of weight loss over the long term.<sup>41,47,72</sup>

Dieter’s teas that contain combinations of herbal laxatives, including senna and *Cascara sagrada*, can produce profound diarrhea, salt and water depletion, and particular hypokalemia. They are associated with sudden death, presumably as a result of cardiac dysrhythmias. Despite FDA warnings of the dangers of these weight loss regimens, dieter’s teas remain available in retail stores that sell nutritional supplements and are easily accessible to adolescents.

Chronic laxative use can result in an atonic colon (“cathartic bowel”) and development of tolerance, with the subsequent need to increase dosing to achieve catharsis.<sup>87</sup> Various test methods can be used to detect laxative abuse. Phenolphthalein can be detected as a pink or red coloration to stool

or urine after alkalinization. Colonoscopy reveals the benign, pathognomonic “melanosis coli,” the dark staining of the colonic mucosa secondary to anthraquinone laxative abuse. The combination of misuse or abuse of laxatives in conjunction with orlistat has the potential to cause severe diarrhea and subsequent fluid and electrolyte imbalances. Now that orlistat is readily available, there is a greater likelihood of being added to prescription weight loss regimens with or without the providers knowledge.<sup>83</sup> Syrup of ipecac was chronically used to induce emesis by patients with eating disorders, such as bulimia nervosa, leading to the development of cardiomyopathy, subsequent dysrhythmias, and death.<sup>42,93</sup> Emetine, a component of syrup of ipecac, was the alkaloid responsible for the severe cardiomyopathy. In 2003, an FDA advisory committee recommended that the nonprescription drug status of syrup of ipecac be rescinded because of its use by patients with bulimic disorders. Syrup of ipecac is no longer produced in the United States.

## OTHER HERBAL REMEDIES

Several herbal approaches for weight loss have resulted in serious toxicity. In France, germander (*Teucrium chamaedrys*) supplements taken for weight loss resulted in seven cases of hepatotoxicity.<sup>72</sup> A “slimming regimen” first prescribed in a weight loss clinic in Belgium produced an epidemic of progressive kidney disease, known as Chinese herb nephropathy, when botanical misidentification led to the substitution of *Stephania tetrandra* with the nephrotoxic plant *Aristolochia fangji*.<sup>128</sup> The toxic constituent, identified as aristolochic acid, is implicated in numerous cases of kidney failure and urothelial carcinoma.<sup>77</sup> A case of profound digitalis toxicity occurred with a laxative regimen contaminated with *Digitalis lanata*.<sup>119</sup> Contamination of herbal products remains a concern today because of the lack of standardization of manufacturing processes. Until regulation of herbal products is improved and manufacturing practices worldwide are standardized, sporadic reports of herb-related toxicity likely will continue (Chap. 43).

## FUTURE TARGETS FOR XENOBIOTIC DEVELOPMENT

Despite all of the advances in pharmacotherapy and surgical interventions, success remains limited. The ideal therapeutic intervention has yet to be identified, and combination therapy needs to be addressed rigorously with caution. Ongoing investigation into the mechanisms and pathways that mediate appetite and energy balance continues. The hormonal endocrine regulation has provided promise and remains an area for future investigation and drug development.<sup>84</sup> Based on history, it is impossible to predict if any of these investigations will result in the creation and approval of new pharmaceutical agents available in the weight loss drug armamentarium.

## NONPHARMACOLOGIC INTERVENTIONS

Although not a specific toxicologic concern, surgical and other nonpharmacologic interventions are included in the management of obesity. Vagus nerve stimulators have been studied and do show a reduction in body fat.<sup>8,73</sup>

Surgical interventions to manage obesity have increased in frequency over the past years and may provide a long-term solution for obesity. In 2013, there were approximately 460,000 surgical procedures performed.<sup>78</sup> Roux-en-Y gastric bypass, laparoscopic adjustable banding, and biliary-pancreatic diversion with duodenal switch are the most commonly described techniques.<sup>2,8,78</sup>

Sleeve gastrectomy is easier than Roux-en-Y and has been associated with fewer adverse events and similar efficacy.<sup>78</sup> The long-term body weight reduction is significantly better in bariatric surgery compared with standard medical treatment,<sup>16,31,62,78</sup> however, there are significant postoperative complications that do occur. The health of these patients is of particular concern because absorption of vitamins, minerals, and drugs is altered.<sup>26,68,101,110</sup> The pharmacokinetic properties of existing and newly initiated medications of orally administered medications are altered.<sup>101,110</sup> Evaluation of drug properties should be examined closely before initiation in this patient population. Despite the risks of the surgical procedures, the Centers for Medicare and Medicaid Services (CMS) agree that surgical intervention is necessary for

patients with a BMI of 35 or greater who have at least one comorbidity and have been unsuccessful with medical treatment for obesity.

## SUMMARY

- Obesity is a major health concern and a significant cause of preventable diseases and sequelae. Unproven weight loss modalities are associated with treatment failure and the potential for significant adverse events.
- Typical pharmaceutical weight loss strategies include:
  - Sympathomimetics
    - Tachyphylaxis occurs within weeks
    - Hypertension; tachycardia; anxiety
    - Cerebral ischemia; myocardial ischemia
  - Serotonergics
    - Dizziness, headache, nausea
    - Serotonin toxicity possible after overdose
  - GLP-1 analogs
    - Nausea, vomiting, diarrhea
    - Hypoglycemia possible after overdose
  - GI agents (orlistat)
    - Abdominal pain, nausea, vomiting, fecal incontinence, fat-soluble vitamin loss
  - Risks from caloric restriction, laxatives, unapproved therapies include:
    - Dinitrophenol: hyperthermia; high anion gap metabolic acidosis, and death
    - Beta-HCG: coronary artery dissection
    - Clenbuterol: tachycardia, wide pulse pressure hypotension, hypokalemia, anion gap metabolic acidosis
    - Laxatives or calorie restrictions: electrolyte disturbances; atonic colon
- Some common themes exist. Combination drug therapy likely provides the best weight loss, and toxicity from proven and unproven treatments remains a significant concern.
- Clinicians should be aware of the lack of regulation of most available diet remedies and should report adverse events involving these products to poison control centers and to the FDA MedWatch system so that appropriate regulatory actions can be taken to prevent further instances of toxicity.

## ATHLETIC PERFORMANCE ENHANCERS

Susi U. Vassallo

### HISTORY AND EPIDEMIOLOGY

Interest in extraordinary athletic achievement fuels the modern-day science of performance enhancement in sports. The desire to improve athletic performance in a scientific manner is a relatively recent development. At one time, the focus on maximizing human physical and mental potential centered on the importance of manual work and military service. The role of sport was inconsequential, except for its potential in improving military preparedness.<sup>95</sup> Today, “sports doping” refers to the use of a prohibited xenobiotic to enhance athletic performance. The word *doping* comes from the Dutch word *doop*, a viscous opium juice used by the ancient Greeks.<sup>32,128</sup>

Controversy surrounding the systematic use of performance enhancing xenobiotics by the participating athletes has marred many sporting events. Since the International Olympic Committee (IOC) began testing during the 1968 Olympic games, prominent athletes have been sanctioned and stripped of their Olympic medals because they tested positive for banned xenobiotics. However, from a public health perspective, the use of performance-enhancing xenobiotics among athletes of all ages and abilities is a far more serious concern than the highly publicized cases involving world-class athletes. The majority of studies on the epidemiology of performance enhancing xenobiotics have investigated androgenic anabolic steroid use. *Androgenic* means masculinizing, and *anabolic* means tissue building. An *anabolic process* stimulates protein synthesis, promotes nitrogen deposition in lean body mass, and decreases protein breakdown. Studies of high school students document that 6.6% of male seniors have used anabolic steroids, and 35% of these individuals were not involved in organized athletics.<sup>35</sup> Others find rates of androgenic steroid use begins at age 10 years old and ranges from 3% to 19% of all adolescents.<sup>102,114,156,174,229</sup>

### PRINCIPLES

Performance enhancers are classified in several ways. Some categorize performance enhancers according to the expected effects. For example, some xenobiotics increase muscle mass; others decrease recovery time, increase energy, or mask the presence of other xenobiotics. However, many xenobiotics frequently have several expected and unexpected effects. For example, diuretics are used to mask the presence of other xenobiotics by producing dilute urine, or they are used to reduce weight. Clenbuterol is an anabolic xenobiotic, but it also is a stimulant because of its  $\beta_2$ -adrenergic agonist effects. Depending on the xenobiotic, it is used either during training to improve future performance or during competition to improve immediate results or for weight loss.<sup>32</sup>

According to the 2017 World Anti-Doping Agency (WADA) World Anti-Doping Code, a xenobiotic or method constitutes doping and can be added to the Prohibited List if it is a masking xenobiotic or if it meets two of the following three criteria: it enhances performance, its use presents a risk to the athlete’s health, and it is contrary to the spirit of sport<sup>1</sup> (Table 41–1).

Some of the prohibited xenobiotics are used to treat legitimate medical conditions of athletes.<sup>1</sup> Athletes with documented medical conditions requiring the use of a prohibited substance or method may request a therapeutic use exemption (TUE). For example, the use of an inhaled  $\beta$ -adrenergic agonist in low doses other than albuterol, salbutamol, or formoterol in an athlete with documented asthma requires a TUE.<sup>1</sup>

### ANABOLIC XENOBIOTICS

#### Anabolic Androgenic Steroids

Anabolic-androgenic steroids (AASs) increase muscle mass and lean body weight and cause nitrogen retention.<sup>148</sup> The androgenic effects of steroids are responsible for male appearance and secondary sexual characteristics such

**TABLE 41–1** Abbreviated Summary of World Anti-Doping Agency 2017 Prohibited List<sup>1</sup>

#### Substances (S) and Methods (M) Prohibited at All Times (In and Out of Competition)

- S0. Any pharmacological substance with no current approval for therapeutic use
- S1. Anabolic Agents
  - Anabolic androgenic steroids
  - Other anabolic agents
    - Clenbuterol
    - Selective androgen receptor modulators
- S2. Peptide Hormone, Growth Factors, Related Agents, and Mimetics
  - Erythropoiesis stimulation agents
  - Chorionic gonadotropin and luteinizing hormone
  - Corticotropins
  - Growth hormone
 Additional prohibited growth factors: affecting muscle, tendon or ligament protein synthesis/ degradation, energy utilization, regenerative capacity, or fiber type switching
- S3.  $\beta_2$ -Adrenergic Agonists
  - Except inhaled salbutamol, formoterol, and salmeterol with urinary concentration limits
- S4. Hormone Antagonists and Metabolic Modulators
  - Aromatase inhibitors
  - Selective estrogen receptor modulators
  - Antiestrogens
  - Myostatin modulators
  - Metabolic modulators
    - Insulins
    - Peroxisome proliferator activated receptor delta agonist and AMP activate protein kinase axis agonists
    - Meldonium
- S5. Diuretics and Other Masking Agents
  - Desmopressin, probenecid, plasma expanders, glycerol intravenous administration of albumin, dextran, hydroxyethyl starch, and mannitol
  - Exception: ophthalmic use of carbonic anhydrase inhibitors

#### Prohibited Methods

- M1. Manipulation of Blood and Blood Components
- M2. Chemical and Physical Manipulation
  - Tampering with samples
  - Intravenous infusions
- M3. Gene Doping: The transfer of polymers of nucleic acids or analogues, the use of normal or genetically modified cells

#### Substances (S) and Methods (M) Prohibited in Competition

In addition to the above, the following categories are prohibited only in competition:

- S6. Stimulants
- S7. Narcotics
- S8. Cannabinoids: natural (marijuana) or cannabimimetics eg, “spice,” JWH-018, JWH-073, HU-210
- S9. Glucocorticosteroids; all are prohibited when administered by oral, intravenous, intramuscular, or rectal routes

#### Substances Prohibited in Particular (P) Sports

- P1. Alcohol in competition. Detection by analysis of breath and or blood. Threshold is 0.10 g/L (air sports, archery, automobile, powerboating).
- P2.  $\beta$ -Adrenergic Antagonists

**TABLE 41–2 Synthetic Testosterone Derivatives/Anabolic Androgenic Steroids: Generic Nomenclature<sup>1</sup>**

17 $\alpha$ -Alkyl Derivatives (Oral)	17 $\beta$ -Ester Derivatives (Parenteral)	Testosterone Preparations (Topical)
Ethylestrenol	Boldenone	Buccal gel, sublingual
Fluoxymesterone	Nandrolone decanoate	Dermal gel, ointment
Methandrostenolone	Nandrolone	Transdermal reservoir patch
Methyltestosterone	phenpropionate	
Oxandrolone	Testosterone esters	
Oxymetholone	Testosterone cypionate	
Stanozolol	Testosterone enanthate	
	Testosterone ester combination	
	Testosterone propionate	
	Trenbolone	

as increased growth of body hair and deepening of the voice. Testosterone is the prototypical androgen, and most AASs are synthetic testosterone derivatives. The WADA categorizes AASs into two groups: exogenous, referring to substances that are not ordinarily capable of being produced by the body naturally, and endogenous, referring to those capable of being produced by the body naturally. As such, there is sometimes discordance in categorization schemes with other governing entities. In this chapter, the term *anabolic steroid* means any xenobiotic, chemically and pharmacologically related to testosterone, other than estrogens, progestins, corticosteroids, and dehydroepiandrosterone (DHEA).

In the 1970s and 1980s, federal regulation of anabolic steroids was under the direction of the Food and Drug Administration (FDA). Because of increasing media reports on the use of AASs in sports, particularly by high school students and amateur athletes, Congress enacted the Anabolic Steroid Control Act of 1990, which amended the Controlled Substances Act and placed anabolic steroids in Schedule III. Schedule III implies that a drug has a currently accepted medical use in the United States and has less potential for abuse than the drugs categorized as Schedule I or II. The Anabolic Steroid Control Act of 2004 added certain steroid precursors, such as androstenedione and dihydrotestosterone, to the list of controlled substances that are considered illegal without a prescription. However, DHEA is exempted. Possession of androstenedione or other metabolic precursors called *prohormone drugs* is considered a federal crime. Nevertheless, AASs are still available illicitly via the Internet from international marketers, veterinary pharmaceutical companies, and some legitimate US manufacturers (Table 41–2).

### Antiandrogens and Antiandrogens

In male athletes using androgens, avoiding the unwanted side effects of feminization, such as gynecomastia, or in female athletes, avoiding masculinization and features such as facial hair and deepening voice, requires manipulation of the metabolic pathways of androgen metabolism. Creating a xenobiotic that completely dissociates the desired from the unwanted effects has not been possible. However, xenobiotics with properties capable of manipulating metabolic pathways associated with undesirable side effects are divided into four main groups, all on the Prohibited List.

1. Aromatase inhibitors such as anastrozole and aminoglutethimide prevent the conversion of androstenedione and testosterone into estrogen.
2. The antiestrogen clomiphene blocks estrogen receptors in the hypothalamus, opposing the negative feedback of estrogen, causing an increase in gonadotropin-releasing hormone, thereby increasing testosterone release.
3. Selective estrogen receptor modulators (SERMs) such as tamoxifen and raloxifene bind to estrogen receptors and exhibit agonist or antagonist effects at the estrogen receptors. By indirectly increasing gonadotropin

release, SERMs restore endogenous testosterone production upon discontinuation of AASs.<sup>181</sup>

4. Selective androgen receptor modulators (SARMs) are nonsteroidal tissue selective *anabolic* xenobiotics. Selective androgen receptor modulators are neither aromatized nor substrates for 5 $\alpha$ -reductase, nor do they undergo the same metabolic pathways as testosterone. Therefore, they have fewer unwanted androgenic side effects compared with testosterone.<sup>77,212</sup>

### Administration

In the 1990s, approximately 50% of AASs were taken orally; the remainder were administered by intramuscular (IM) injection, with one-fourth of IM users sharing needles.<sup>57</sup> In the same era, one-third of the and syringes exchanged in a needle-exchange program in Wales were used for AAS injections.<sup>164</sup> Unlike therapeutically indicated regimens, which consist of fixed doses at regular intervals, athletes typically use AASs in cycles of 6 to 8 weeks.<sup>15</sup> For example, the athlete may use steroids for 2 months and then abstain for 2 months. This *cycling* of steroid use is based on the athlete's individual preferences and not on any validated protocol. *Stacking* implies combining the use of several AASs at one time, often with both oral and IM administration. To prevent *plateauing*, or developing tolerance, to any one AAS, some athletes use an average of five different AASs simultaneously on a cycle. The doses used are frequently hundreds of times in excess of scientifically-based therapeutic recommendations.<sup>5,228</sup> *Pyramiding* implies starting the AASs at a low dose, increasing the dose many times, and then tapering once again. Whereas fat-soluble steroids typically require several months to be totally eliminated, water-soluble steroids require only days to weeks to be cleared by the kidney. Water-soluble testosterone esters are used for "bridging therapy." *Bridging* refers to the practice of halting the administration of long-lasting alkylated testosterone formulations so that urine analyses at a specific time offer no evidence of use, but injections of shorter acting testosterone esters are used to replace the orally administered alkylated formulations. This strategy, which was used extensively in the German Democratic Republic, is documented in a review of the subject based on extensive research of previously classified records.<sup>69</sup> Clearance profiles for testosterone congeners were determined for each athlete. In general, the daily injection of testosterone esters was used when termination of the more readily detectable synthetic alkylated testosterone derivatives was necessary to avoid a positive doping test. These daily injections of testosterone propionate were halted 4 to 5 days before competition. Corrupt officials involved in doping were sure that the values would decrease to acceptable concentrations in time for the event based on the science of athletes' clearance of testosterone esters.<sup>69</sup>

### Clinical Manifestations of Anabolic-Androgenic Steroid Use

#### Cancer

An association between AAS use and the development of cancer is observed in experimental animals.<sup>183</sup> Testicular and prostatic carcinomas are reported in more frequent users of anabolic-androgenic steroids.<sup>64,75,182</sup> Hepatocellular carcinoma,<sup>101,157</sup> cholangiocarcinoma,<sup>15</sup> Wilms tumor, and renal cell carcinoma are also reported in young AAS users.<sup>34,173</sup> The relationship between the dose of AASs and cancer is unknown.

#### Cardiovascular

Cardiac complications include acute myocardial infarction, venous thromboembolism, and sudden cardiac arrest due to lethal dysrhythmias.<sup>11,67,90,97,143</sup> Autopsy examination of the heart often reveals biventricular hypertrophy, extensive myocardial fibrosis, and contraction-band necrosis.<sup>219</sup> Myofibrillar disorganization as well as hypertrophy of the interventricular septum and left ventricle are present.<sup>129</sup> Compared with nonusers, anabolic androgenic steroid users demonstrated reduced left ventricular systolic and diastolic function and more coronary artery plaque volume. There is a dose dependent association with the coronary atherosclerotic burden. Intense training and use of AASs impair diastolic function by increasing left ventricular wall thickness.<sup>16</sup> Animal models and in vitro myocardial cell studies show similar pathologic changes.<sup>50,113,144,211,218,219</sup> Doppler

echocardiography shows that several years after strength athletes discontinue using AASs, excessive concentric left ventricular hypertrophy remains. Growth hormone (GH) appears to potentiate the effects of AASs and further increase concentric remodeling of the left ventricle.<sup>106</sup> In addition to direct myocardial injury, vasospasm or thrombosis occurs.<sup>144</sup> Alkylated androgens lower the concentration of high-density lipoprotein (HDL) cholesterol and increases platelet aggregation.<sup>6,67</sup> Thromboembolic complications include pulmonary embolus,<sup>54,76</sup> stroke,<sup>109,110</sup> carotid arterial occlusion,<sup>121</sup> cerebral sinus thrombosis,<sup>118</sup> poststeroid balance disorder,<sup>29</sup> and popliteal artery entrapment.<sup>125</sup>

### Dermatologic and Gingival

Cutaneous side effects are common and include keloid formation, sebaceous cysts, comedones, seborrheic furunculosis, folliculitis, and striae.<sup>195</sup> Acne is associated with steroid use and sometimes is referred to as “gymnasium acne.”<sup>43,166</sup> A common triad of acne, striae, and gynecomastia occurs. The production of sebum is an androgen-dependent process, and dihydrotestosterone is active in sebaceous glands.<sup>15</sup> Gingival hyperplasia is reported.<sup>158</sup>

### Endocrine

Conversion of AASs to estradiol in peripheral tissues results in feminization of male athletes. Gynecomastia is sometimes irreversible. Anabolic androgenic steroids use causes negative feedback inhibition of gonadotropin-releasing hormone, luteinizing hormone, and follicle-stimulating hormone from the hypothalamus. This process results in testicular atrophy and decreased spermatogenesis, which is often reversible. In women, menstrual irregularities and breast atrophy are reported.<sup>15</sup>

### Hepatic

Hepatic subcapsular hematoma with hemorrhage is reported.<sup>194</sup> Peliosis hepatis, a condition of blood-filled sinuses in the liver that results in fatal

hepatic rupture, occurs most commonly with the use of alkylated androgens and often does not improve when androgen use is stopped.<sup>17,94,201,226</sup> This condition is not associated with the dose or duration of treatment.<sup>15,64,204</sup> Cyproterone acetate is a chlorinated progesterone derivative that inhibits 5 $\alpha$ -reductase and reportedly causes hepatotoxicity.<sup>15,74,79</sup>

### Infectious

Local complications from injection include septic joints,<sup>63</sup> cutaneous abscess,<sup>139,177</sup> and *Candida albicans* endophthalmitis.<sup>227</sup> Injection of AASs using contaminated needles has led to transmission of infectious diseases such as human immunodeficiency virus and hepatitis B and C.<sup>155,159,176,196,200</sup> Severe varicella is reported in a long-term AAS user.<sup>100</sup>

### Musculoskeletal

Supraphysiologic doses of testosterone, when combined with strength training, increase muscle strength and size.<sup>26</sup> The most common musculoskeletal complications of steroid use are tendon and ligament rupture.<sup>70,92,122,127</sup>

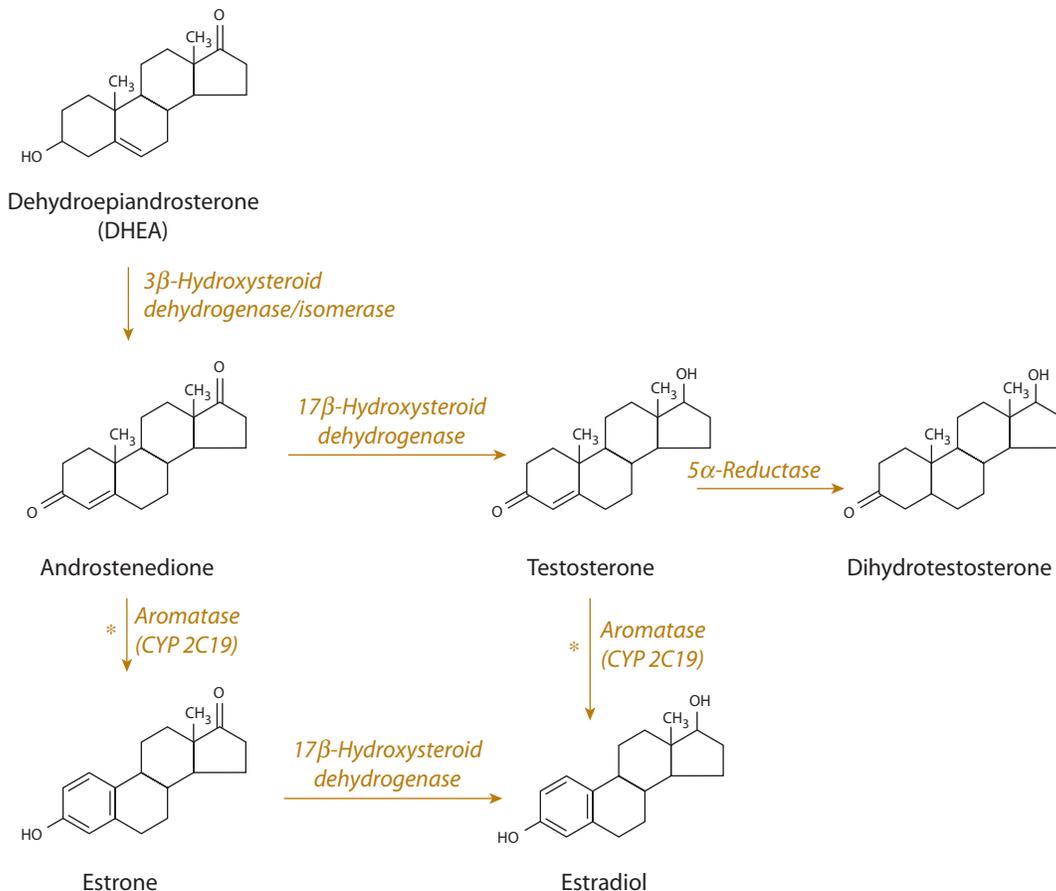

### Neuropsychiatric

Distractibility, depression or mania, delirium, irritability, insomnia, hostility, anxiety, mood lability, and aggressiveness (“roid rage”) may occur.<sup>21,71,170,171,210</sup> These neuropsychiatric effects do not appear to correlate with serum AAS concentrations.<sup>198,210</sup> Withdrawal symptoms from AAS include decreased libido, fatigue, and myalgias.<sup>108,230</sup>

### Specific Anabolic Xenobiotics

#### Dehydroepiandrosterone

Dehydroepiandrosterone (DHEA) is a precursor to testosterone (Fig. 41–1). Because it is produced endogenously, DHEA most commonly is not categorized as an AAS. However, DHEA is weakly anabolic and weakly androgenic. Although banned by the FDA in 1996, this xenobiotic subsequently

**FIGURE 41–1.** Metabolic pathway of the transformation of Dehydroepiandrosterone (DHEA) to androgens and estrogens. Anastrozole and aminoglutethimide inhibit aromatase (asterisk), thus blocking feminization after the utilization of androgens.

was marketed as a nutritional supplement and is available for purchase without a prescription.<sup>80</sup> Dehydroepiandrosterone is converted to androstenedione and then to testosterone by the enzyme 17 $\beta$ -hydroxysteroid dehydrogenase.<sup>96,128,131</sup> Administration of androstenedione in dosages of 300 mg/d increases testosterone and estradiol concentrations in some men and women.<sup>124</sup> Women with adrenal insufficiency given DHEA replacement at a dose of 50 mg/d orally for 4 months demonstrated increased serum concentrations of DHEA, androstenedione, testosterone, and dihydrotestosterone. Serum total and HDL cholesterol concentrations simultaneously decreased. Some women experienced androgenic side effects, including greasy skin, acne, and hirsutism.<sup>14</sup> Sense of well-being and sexuality increased in men and women after 4 months of treatment.<sup>14,149</sup> The neuropsychiatric effects of DHEA have been demonstrated in animals. Increased hypothalamic serotonin, anxiolytic effects, antagonism at the  $\gamma$ -aminobutyric acid type A (GABA<sub>A</sub>) receptor, and agonism at the *N*-methyl-D-aspartate receptor (NMDA) are demonstrated.<sup>14,132,145</sup>

### Clenbuterol

Clenbuterol is a  $\beta_2$ -adrenergic agonist that decreases fat deposition and prevents protein breakdown in animal models.<sup>10,41,93</sup> Clenbuterol is also a potent *nutrient partitioning agent*, a term implying it increases the amount of muscle and decreases the amount of fat produced per pound of feed given to cattle and other animals.<sup>71,180</sup> Clenbuterol increases the glycolytic capacity of muscle and causes hypertrophy, enhancing the growth of fast-twitch fibers (Chap. 63).<sup>133,232</sup> Use of clenbuterol in cattle farming is illegal in many countries. Nevertheless, the consumption of veal liver contaminated with clenbuterol has resulted in sympathomimetic symptoms and positive urine test results in affected individuals.<sup>186</sup> Clenbuterol is composed of a racemic mixture of (+) and (–) stereoisomers, eliminated in urine in approximately equal amounts. As clenbuterol accumulates in animal meat, stereoisomer ratios change over time, and (–) clenbuterol is depleted. By analyzing urinary ratios of clenbuterol stereoisomers, it is possible to differentiate administration of therapeutic clenbuterol preparations from inadvertent ingestion of clenbuterol in meat products.<sup>215</sup> The enantiomeric composition of clenbuterol from meat is different than the composition of clenbuterol from drugs. Analytic techniques relying on stereoselectivity can identify the source of the clenbuterol, whether it is ingested in meat or as a drug preparation. Tourists returning from Mexico and China are found to have traces of clenbuterol in their urine.<sup>161</sup>

## PEPTIDES AND GLYCOPROTEIN HORMONES

### Creatine

Creatine is an amino acid formed by combining the amino acids methionine, arginine, and glycine. It is synthesized naturally by the liver, kidneys, and pancreas. Creatine is found in protein-containing foods such as meat and fish. In its phosphorylated form, it is involved in the rapid resynthesis of adenosine triphosphate (ATP) from adenosine diphosphate (ADP) by acting as a substrate to donate phosphorus.<sup>208</sup> Because ATP is the immediate source of energy for muscle contraction, creatine is used by athletes to increase energy during short, high-intensity exercise.<sup>222</sup> Exceptional athletes have admitted to using creatine as part of their training nutritional regimen, leading to interest by athletes at all levels. Numerous studies demonstrate improved performance with creatine supplementation, particularly in sports requiring short, high-intensity effort.<sup>28,35,116,142,222</sup> Creatine is found in skeletal muscle and in the heart, brain, and kidneys. Two-thirds of creatine is stored primarily as phosphorylated creatine and the remainder as free creatine.<sup>18</sup> Consuming carbohydrates with creatine supplements increases total creatine and phosphorylated creatine stores in skeletal muscle.<sup>18</sup> This process explains why creatine is marketed in combination with carbohydrate. Human endogenous creatine production is 1 g/d, and normal diets containing meat and fish offer another 1 to 2 g/d as dietary intake. One to two grams of creatine is eliminated daily by irreversible conversion to creatinine.<sup>225</sup> Creatine is not currently on the WADA prohibited list 2017.<sup>1</sup>

Creatine supplementation is most commonly accomplished with creatine monohydrate. A dose of 20 to 25 g/d can increase the skeletal muscle total creatine concentration by 20%.<sup>87,98</sup> Creatine stores do not increase in some individuals despite creatine supplementation. Creatine uptake in skeletal muscle occurs via the creatine transporter proteins at the sarcolemma. Creatine transporter expression and activity, as well as exercise and training, influence the uptake of creatine and the effect of creatine loading on athletic performance.<sup>202,203,205</sup>

One adverse effect of creatine supplementation is weight gain, which is thought to result primarily from water retention.<sup>87,142</sup> However, evidence indicates that net protein increase is partially responsible for the weight gain associated with long-term creatine use.<sup>104</sup> Diarrhea was the most commonly reported side effect of creatine use in one study of 52 male college athletes. Other complaints were muscle cramping and dehydration, although many participants had no complaints.<sup>104</sup>

Creatine supplementation increases urinary creatine and creatinine excretion and may increase serum creatinine concentrations by 20%.<sup>87,105</sup> Long- and short-term creatine supplementation does not appear to have an adverse effect on kidney function.<sup>168,169</sup> One patient who had been taking creatine 5 g/d for 4 weeks developed interstitial nephritis that improved with cessation of creatine use. Whether ingestion of creatine caused the nephritis is unknown.<sup>115</sup> A young man with focal segmental glomerular sclerosis developed an elevated creatinine concentration and decreased glomerular filtration rate when creatine supplementation was started. The values returned to baseline upon cessation of creatine supplementation.<sup>175</sup> The possibility of developing decreased kidney function is a theoretical concern. Ingestion of large amounts of creatine results in formation of the carcinogenic substance *N*-nitrososarcosine, which induces esophageal cancer in rats.<sup>12,13</sup>

### Human Growth Hormone

Human growth hormone (hGH) is an anabolic peptide hormone secreted by the anterior pituitary gland. It stimulates protein synthesis and increases growth and muscle mass in children. Recombinant hGH (rhGH) became available in 1984. It is commonly used therapeutically for children with GH deficiency in daily doses of 5 to 26 mcg/kg body weight.<sup>223</sup>

Growth hormone secretion is stimulated by GH-releasing hormone and is inhibited by somatostatin. Growth hormone receptors are found in many tissues, including the liver. Binding of hGH to hepatic receptors causes secretion of insulinlike growth factor-1 (IGF-1), which has potent anabolic effects and is the mediator for many of the actions of hGH.

Release of hGH, which occurs mainly during sleep, occurs in a pulsatile manner. Exercise stimulates hGH release, and more intense exercise causes proportionately more hGH release.<sup>31,47,209</sup> Amino acids such as ornithine, L-arginine, tryptophan, and L-lysine increase hGH release through an unknown mechanism and often are ingested for this purpose.<sup>47,89</sup>

By causing nitrogen retention and increased movement of amino acids into tissue, hGH stimulates protein synthesis and tissue growth. The effects on increasing muscle mass and size are demonstrated in GH-deficient individuals. Some studies do not support an increase in strength secondary to the increase in muscle size in athletes,<sup>45,130</sup> but others demonstrate lean body mass, strength, and power increases. Growth hormone improves muscle and cardiac function, increases red blood cell (RBC) mass and oxygen-carrying capacity, stimulates lipolysis, normalizes serum lipid concentrations, and decreases subcutaneous fat. It also improves mood and sense of well-being.<sup>45,46,91,188,209,223</sup>

Growth hormone is used by athletes for its anabolic potential. As a xenobiotic of abuse, it is particularly attractive because laboratory detection is difficult. In one survey, 12% of people in gyms used hGH for body building.<sup>62</sup> In another survey of adolescents, 5% of 10th-grade boys had used hGH.<sup>179</sup> It may be sold illicitly as recombinant hGH.

Administration of hGH often cause myalgias, arthralgias, carpal tunnel syndrome, and edema. The effects of hGH on skeletal growth depend on the user's age. In preadolescents, excessive hGH cause increased bony growth and gigantism. In adults, excessive hGH cause acromegaly.<sup>217,219</sup> Growth

hormone causes glucose intolerance and hyperglycemia. Skin changes, such as increased melanocytic nevi and altered skin texture, occur.<sup>167</sup> Lipid profiles are adversely affected. High-density lipoprotein concentrations are decreased, a change associated with increased risk of coronary artery disease.<sup>233</sup> Because hGH must be given parenterally, there is risk of transmission of infection.<sup>130</sup> The illicit sale of cadaveric human pituitary-derived GH is associated with a risk of Creutzfeldt-Jakob disease.<sup>53</sup> Long-term users of hGH are at increased risk for prostate cancer because of the complications associated with IGF-1<sup>80</sup> (see later).

Testing for hGH is plagued by the difficulties inherent in testing for exogenous peptide doping in general—the identical amino acid sequences of both rhGH and hGH; the fluctuating, pulsatile secretion; short half-life; and variation in normal concentration depending on sleep as well as stress and exercise status. Unlike the ability to use the differing pattern of *N*-linked glycosylation in human erythropoietin (hEPO) produced in human kidneys to distinguish it from recombinant human erythropoietin (rhEPO) produced in hamsters, hGH has no *N*-linked glycosylation sites to facilitate differentiation.

The detection of GH relies primarily on the detection of hGH-dependent factors through which hGH exerts its effect, such as IGF-1 and IGF binding proteins, as well as other markers of bone growth and turnover, such as the *N*-terminal extension peptide of procollagen type III.<sup>8,172</sup> The isoform approach refers to the measurement of the various forms of GH. Whereas rhGH is primarily a 22-kDa monomeric form, pituitary hGH contains multiple isoforms. In athletes using rhGH, endogenous hGH with its multiple isoforms is suppressed through negative feedback on the pituitary. Therefore, the 22-kDa form characteristic of rhGH becomes predominant. The ratio of isoforms, as measured by immunoassay, changes.

### Insulinlike Growth Factor-1

Insulinlike growth factor-1 is a peptide chain structurally related to insulin. A recombinant form is available.<sup>84-86</sup> Parenteral administration of IGF-1 is approved for clinical treatment of dwarfism and insulin resistance. Children who develop antibodies to rhGH often respond to IGF-1.

The primary stimulus for release of IGF-1 is hGH, although insulin, DHEA, and nutrition play a role. The actions of IGF-1 can be classified as either anabolic or insulinlike.<sup>185</sup> The effects of GH are primarily mediated by IGF-1. Insulinlike growth factor-1 is produced in the liver and many other cell types. Insulinlike growth factor-1 binds principally to the type I IGF receptor, which has 40% homology with the insulin receptor and a similar tyrosine kinase subunit. Although IGF-1 also binds to insulin receptors, it has only 1% of insulin affinity for the insulin receptor and actually increases glucose utilization by causing the movement of glucose into cells, increasing amino acid uptake and stimulating protein synthesis.

Side effects are similar to those associated with use of GH and include acromegaly. Other effects include headache, jaw pain, edema, and alterations in lipid profiles. A potentially serious side effect of IGF-1 is hypoglycemia. High endogenous plasma IGF-1 concentrations are associated with an increased risk for prostate cancer.<sup>39</sup>

Few studies on the efficacy of IGF-1 in improving the conditioning of athletes are available. Insulinlike growth factor-1 is preferred by female athletes because it does not cause virilization.<sup>209</sup>

### Insulin

Insulin is used by body builders for its anabolic properties. Of 20 self-identified AAS users in a single gym, 25% who had no medical reason to take insulin reported using it to increase muscle mass.<sup>178</sup> These individuals stated that they had injected insulin from 20 to 60 times over the 6 months before the study.<sup>174</sup> Their practice was to inject 10 units of regular insulin and then eat sugar-containing foods after injection. As expected, hypoglycemia is reported in body builders using insulin.<sup>60,99,175</sup>

Insulin inhibits proteolysis and promotes growth by stimulating movement of glucose and amino acids into muscle and fat cells. It increases the synthesis of glycogen, fatty acids, and proteins (Chap. 47).<sup>49</sup>

### Meldonium

Meldonium inhibits the carnitine transporter type 2, thereby reducing L-carnitine biosynthesis and transport. Long-term meldonium treatment may be beneficial by improving energy metabolism during hypoxia. This is the benefit that athletes seek. Meldonium improves glucose utilization. In one high-profile case, the athlete said that she was using meldonium to treat her prediabetes state; however, it is a banned substance, and the athlete was sanctioned.<sup>48,126</sup>

### Human Chorionic Gonadotropin

In men, the glycoprotein hCG stimulates testicular steroidogenesis. In women, hCG is secreted by the placenta during pregnancy. It sometimes used by male athletes to prevent testicular atrophy during and after androgen administration.<sup>111</sup> Analysis of hCG in 740 urinary specimens of male athletes revealed abnormal concentrations in 21 individuals. This finding prompted the IOC ban on hCG use in 1987.<sup>111</sup> Presently, distinguishing exogenous hCG administration from hCG production in early pregnancy is under study.<sup>117</sup>

Very small amounts of hCG are normally present in men and nonpregnant women. Currently, measurement is made by immunoassay. The decision limit, the concentration at which the test result is considered positive, is set at 5 IU/mL urine. Trophoblastic tumors and nontrophoblastic tumors can increase hCG concentrations, and this possibility must be considered in the evaluation of elevated urinary hCG concentration.<sup>117</sup> Administration of hCG causes an increase in the total testosterone and epitestosterone produced.

## OXYGEN TRANSPORT

### Erythropoietin

Human erythropoietin is a hormone that, through a receptor-mediated mechanism, induces erythropoiesis by stimulating stem cells. Erythropoietin has been available since 1988 as rhEPO, and its use in international competition has been prohibited since 1990. Although hEPO is produced primarily by the kidneys, rhEPO is produced in hamsters;<sup>56</sup> this results in differing glycosylation patterns, an important piece in the laboratory detection of EPO in sports doping.

Because EPO increases exercise capacity and hemoglobin production, it is used by athletes, often with additional iron supplementation. The clinical effects of increased hemoglobin occur several days after administration.<sup>73,160</sup> Erythropoietin increases maximal oxygen uptake by 6% to 7%, an effect that lasts approximately 2 weeks after rhEPO administration is completed.<sup>59</sup>

Erythropoietin analogs such as darbepoetin are *erythropoiesis-stimulating proteins*, differing from EPO by five amino acids. Darbepoetin has a much longer half-life and can be injected weekly. Another protein, known as *synthetic erythropoiesis protein*, has a similar protein structure to EPO. The protein polymers created in this molecule have less immunogenicity, fewer biologic contaminants, and more predictable pharmacokinetics.<sup>162</sup>

Human EPO is secreted primarily by the kidney, although some is produced by the liver. The mean apparent half-lives of rhEPO are 4.5 hours after intravenous (IV) administration and 25 hours after subcutaneous administration.<sup>187</sup>

Erythropoietin enhances endothelial activation and platelet reactivity and increases systolic blood pressure during submaximal exercise.<sup>25,207</sup> These effects, in addition to the increase in hemoglobin, increase the risk of thromboembolic events, hypertension, and hyperviscosity syndromes.<sup>25,141,160</sup> Nineteen Belgian and Dutch cyclists died of uncertain causes between 1987 and 1990.<sup>58</sup> Increases in hematocrit subsequent to EPO use are believed to have contributed to these deaths.

An EPO overdose occurred in a patient who self-administered 10,000 units/d for an unknown period of time as a result of a dosing error. The patient presented to the hospital with confusion, a plethoric appearance, blackened toes, decreased pulses, and a hematocrit of 72%. Emergent erythropheresis was performed and resulted in rapid reduction of hematocrit and improvement in the patient's condition.<sup>231</sup> Another report of deliberate daily self-administration of an unknown dose of rhEPO resulted in a hematocrit of 70%. The patient was treated emergently with phlebotomy and IV hydration and improved.<sup>33</sup>

### Testing for Erythropoietin

Erythropoietin is directly measured by a monoclonal anti-EPO antibody test, which does not distinguish between endogenously produced and exogenously administered recombinant EPO. Therefore, tracking indirect methods of EPO detection are used, such as measurement of hemoglobin or hematocrit. The isoelectric focusing double immunoblotting detection strategy is the WADA-accredited strategy.<sup>42</sup>

Previously, some sports-governing bodies, such as the International Cycling Federation and the International Skiing Federation, selected a hematocrit of 50% in men and 47% in women as the action level above which an athlete may be disqualified for presumed EPO use. However, normal hematocrit values vary greatly among athletes. Several studies have shown that hematocrits above the action values of 50% in men and 47% in women are common in athletes. From 3% to 6% of athletes who did not use EPO had hematocrits greater than 50%.<sup>224</sup> Of athletes living and training at altitudes between 2,000 and 3,000 m above sea level, 20.5% had hematocrit values higher than 50%.<sup>224</sup> Other studies confirm the increased hematocrits of athletes training at altitudes of 1,000 to 6,000 m.<sup>23,190-192</sup>

Although many endurance athletes have increased blood volume, the hematocrit may be lowered because of the increased plasma volume, which exceeds the RBC volume. This dilutional pseudoanemia is sometimes called *sports anemia*.<sup>197</sup> Additionally, hematocrit measurements are affected by hydration status, posture (upright versus supine), and nutrition, and they demonstrate an approximately 3% diurnal variation.<sup>190</sup> Because of natural variations among individuals, postural effects, and the ease of manipulation through saline infusion, indirect detection of EPO use by hematocrit measurement is fraught with potential for error.<sup>160</sup>

Several methods have been studied to detect the use of rhEPO by athletes. The ratio between serum soluble transferrin receptors (sTfR) and ferritin was used as an indirect method for detection of EPO use. The sTfR is released from RBC progenitors. Erythropoietin stimulates erythropoiesis and causes an increase in sTfR and a decrease in ferritin.<sup>78</sup> Individuals with other causes of polycythemia or accelerated erythropoiesis also can exhibit increased ratios and be falsely accused of EPO use. An increased hematocrit with sTfR greater than 10 mcg/mL and sTfR-to-serum protein ratio greater than 153 has been proposed as an indirect measurement of EPO use.<sup>12</sup>

State-of-the-art detection of EPO doping is accomplished by two techniques: isoelectric focusing and immunoblotting performed on urine samples. The two isoforms of EPO, recombinant and endogenous, have different glycosylation patterns and glycan sizes, resulting in differing molecular charges.<sup>42,162</sup> An immunoblotting procedure takes advantage of these different net charges, and the proteins can be separated by their charges when they are placed in an electric field.<sup>123</sup> Subsequently, by isoelectric focusing, this method obtains an image of EPO patterns in the urine.<sup>123</sup> World Anti-Doping Agency considers a positive urine test result by this method definitive, even without the blood testing of indirect markers.<sup>42</sup>

Because of the structural similarity of darbepoetin to EPO, these detection techniques also are effective for darbepoetin.<sup>162</sup>

## STIMULANTS

### Caffeine

Caffeine is a central nervous system stimulant that causes a feeling of decreased fatigue and increases endurance performance (Chap. 63).<sup>61,163</sup> These changes may occur through several different mechanisms, including increased calcium permeability in the sarcoplasmic reticulum and enhanced contractility of muscle, phosphodiesterase inhibition and subsequent increased cyclic nucleotides, adenosine blockade leading to blood vessel dilation, and inhibited lipolysis.

### Amphetamines

The beneficial effects of amphetamines in sports result from their ability to mask fatigue and pain.<sup>51</sup> Initial studies done in soldiers showed that they could march longer and ignore pain when taking amphetamines

(Chap. 73).<sup>217</sup> In one study in college students, resting and maximal heart rate, strength, acceleration, and anaerobic capacity increased. However, although the perception of fatigue decreased, lactic acid continued to accumulate, and maximal oxygen consumption was unchanged.<sup>40</sup> Other studies show no significant effects on exercise performance.<sup>107</sup>

### Sodium Bicarbonate

Sodium bicarbonate loading, known as “soda loading,” has a long history of use in horse racing.<sup>19</sup> Sodium bicarbonate buffers the metabolic acidosis associated with an elevated lactate caused by exercise, thereby delaying fatigue and enhancing performance.<sup>81,199</sup>

During high-intensity exercise, metabolism becomes anaerobic, and lactic acid is produced. Intracellular acidosis is suggested to contribute to muscle fatigue by reducing the sensitivity of the muscle contractile apparatus to calcium.<sup>165</sup> Several studies demonstrated improved performance in running when sodium bicarbonate was ingested 2 to 3 hours before competition.<sup>44,184</sup> The study dose was 0.2 to 0.3 g/kg body weight of sodium bicarbonate, approximately 160 mEq of sodium bicarbonate per day. The effects of sodium bicarbonate are greatest when periods of exercise last longer than 4 minutes because anaerobic metabolism contributes more to total energy production and energy from aerobic metabolism diminishes.<sup>72,80,81</sup> Adverse effects of bicarbonate loading include diarrhea, abdominal pain, and the possibility of hypernatremia.

Contrary to this theory, an animal model demonstrated that intracellular acidosis associated with lactate production reversed muscle fatigue.<sup>7,165</sup> Previously, intracellular acidosis was thought to contribute to muscle fatigue by reducing the sensitivity of the muscle contractile apparatus to calcium, decreasing the force of muscle contraction. However, the mechanism of excitation-contraction is complex. Because it permeates membranes easily, chloride is an important ion in maintaining and stabilizing the muscle fiber resting membrane potential at normal pH. Because of this, a large sodium current is needed to overcome membrane stabilization and produce an action potential. In the case of intracellular acidosis, the permeability of the membrane to the chloride ion is reduced, the resting membrane potential is no longer stabilized, and less inward sodium influx is needed to produce an action potential. The excitability of the muscle T-tubule system is therefore increased by acidosis, protecting against muscle fatigue.<sup>165</sup>

## DIURETICS

The WADA bans nonmedical diuretic use.<sup>1</sup> Diuretics are used in sports in which the athlete must achieve a certain weight to compete in discrete weight classes. In addition to weight loss, body builders find that diuretic use gives greater definition to the physique as the skin draws tightly around the muscles.<sup>3</sup> In one report, a professional body builder attempted to lose weight using diuretics, including bumetanide and spironolactone as well as potassium supplements. He presented with hyperkalemia and hypotension (Chap. 12).<sup>3</sup> Diuretics also result in increased urine production, thereby diluting the urine and making the detection of other banned xenobiotics more difficult.<sup>36,52</sup>

## LABORATORY DETECTION

Enormous amounts of energy and money are expended to determine the presence or absence of performance-enhancing xenobiotics.<sup>213</sup> Analysis of samples on the international level is performed by a limited number of accredited laboratories. The majority of tests are performed on urine, with careful procedural requirements regarding handling of samples. Attention must be paid to proper storage of specimens because bacterial metabolism may increase urinary steroid concentrations.<sup>27,55</sup> Upon arrival of a sample at the testing laboratory, the integrity of the sample is checked, including the code, seal, visual appearance, density, and pH. Registration of the sample is completed, and the sample is divided into two aliquots. All testing is done on the first aliquot, and any positive results are confirmed on the second aliquot. The aliquots are commonly referred to as sample A and sample B. Sample preparation is difficult and time consuming.

The complexity of the laboratory testing and continuous attempts to evade detection is illustrated in the discovery of an AAS previously undetectable by standard sport doping tests of urine. In the following situation, there was no preexisting reference data for the unknown xenobiotic. In the summer of 2003, a used syringe was provided anonymously to the US antidoping authority. Through a painstaking process of analyses, a previously unrecognized chemical in the syringe was identified as a derivative of the AAS noretholone, a known reference compound, leading to the discovery, synthesis, and detection of tetrahydrogestrinone (THG), a new chemical unknown as a pharmaceutical or veterinary compound.<sup>38</sup> Doping control analysis is forever challenged by new xenobiotics.<sup>213</sup>

### Capillary Gas Chromatography–Mass Spectrometry

Capillary gas chromatography allows the determination of approximately 95% of all doping positive results. Gas chromatography typically is combined with mass spectrometry for detection of the majority of substances.<sup>153,213</sup> Analysis of the urine by gas chromatography–mass spectrophotometry (GC-MS) is the current standard for detection of AASs.<sup>36</sup> Such analysis relies on a large amount of previously derived reference data (Chap. 7).<sup>38</sup>

### Testosterone-to-Epitestosterone Ratio

Gas chromatography–mass spectrophotometry cannot distinguish endogenous testosterone from pharmaceutically derived exogenous testosterone. Therefore, other methods of detection are needed. One way of detecting the use of exogenous testosterone is to measure the testosterone-to-epitestosterone (T/E) ratio.<sup>221</sup> Epitestosterone is not a metabolite of testosterone, but it is a 17- $\alpha$  epimer, differing from testosterone only in the configuration of the hydroxyl group on C-17. Men produce 30 times more testosterone than epitestosterone; however, 1% of testosterone and 30% of epitestosterone are excreted unchanged in the urine. Therefore, the normal T/E ratio in the urine is about 1:1.<sup>206</sup>

A T/E ratio less than 4:1 is considered acceptable; a T/E ratio greater than 4:1 is considered evidence of doping using testosterone. To maintain a normal T/E ratio, athletes self-administer both testosterone and epitestosterone.<sup>37</sup>

The overall pattern of the T/E ratio over time is important. Athletes subjected to testing will have previous measurements of their T/E ratios on record with antidoping authorities, or additional tests may be obtained to establish a pattern of T/E ratios. These results are plotted against time. The mean, standard deviation, and confidence values are calculated.<sup>37</sup> The confidence values of three or more samples taken over months will be less than 60% unless the athlete is using testosterone.<sup>34</sup> Sudden variations in an athlete's pattern of T/E ratios over time is a cause for further testing.

A steroid profile is measured on all urine samples. It consists of the urinary concentrations of testosterone, epitestosterone, androsterone, etiocholanolone, 5 $\alpha$ -androstane-3 $\alpha$ ,17 $\beta$ -diol, and 5 $\beta$ -androstane-3 $\alpha$ ,17 $\beta$ -diol, together with the specific gravity of the urine sample. Further ratios are calculated to detect multiple forms of steroid doping.<sup>1</sup>

In one high-profile doping case in which the T/E ratio was elevated, the athlete suggested that ethanol consumption the previous night caused the elevated T/E ratio. In this regard, there is evidence that at very high doses; for example, 2 g/kg, ethanol increases the T/E ratio, although the T/E ratio did not exceed 6:1.<sup>45</sup> This effect of ethanol is more pronounced in women and is limited to 8 hours postingestion of ethanol. The mechanism of this effect of ethanol is that it increases the NADH-to-NAD<sup>+</sup> ratio, and many steroid oxidation–reduction reactions are dependent on the relative abundance of NADH to NAD<sup>+</sup>.<sup>65</sup> Ketoconazole inhibits testosterone synthesis and causes a decrease in the T/E ratio within 6 hours of administration.<sup>112</sup>

### Isotope Ratio Mass Spectrometry

Carbon is made up of six protons and six neutrons, giving it an atomic weight of 12 (<sup>12</sup>C). Sometimes carbon has an extra neutron, giving it an atomic weight of 13 (<sup>13</sup>C). Carbon is derived from carbon dioxide in the atmosphere. Warm climate plants, such as soy, process carbon dioxide differently than other plants, using different photosynthetic pathways for carbon dioxide fixation, causing the depletion of <sup>13</sup>C.<sup>189</sup> Pharmaceutical testosterone is made from plant sterols, primarily soy plants, and therefore has less <sup>13</sup>C isotope

than endogenous testosterone, made in the body from a typical human diet based in corn and not soy. This difference in isotope ratios is measured by isotope ratio mass spectrometry. An athlete's natural carbon makeup is determined by analysis of an endogenous reference compound such as the testosterone precursor cholesterol. Cholesterol may be called an "autostandard" because it represents the athlete's <sup>13</sup>C/<sup>12</sup>C ratio.<sup>24</sup> Finally, it is the difference between the ratio of the athlete's <sup>13</sup>C/<sup>12</sup>C ratio and an international standard ratio that is measured and reported.<sup>2</sup> Values are negative because both endogenous and pharmaceutical testosterone contain less <sup>13</sup>C than the international standard.<sup>88</sup>

### Insulin

Laboratory detection methods for insulin are not yet standardized and accredited by WADA. Therefore, athletes are not currently tested for insulin use. The technology for testing for insulin uses immunoaffinity purification followed by liquid chromatography–tandem mass spectrometry to identify analytes including urinary metabolites of insulin.<sup>216</sup> When insulin is modified to improve its receptor selectivity or give it other favorable properties, the change in molecular weight or amino acid profile from human insulin makes it detectable by GC-MS.<sup>216</sup>

### Masking Xenobiotics

Any chemical or physical manipulation done with the purpose of altering the integrity of a urine or blood sample is prohibited by WADA.<sup>1</sup> For example, use of IV fluids for dilution of the sample, or urine substitution, is prohibited. Some xenobiotics are added to the urine for the sole purpose of interfering with urine testing and are easily detected. Examples include "Klear," which is 90% methanol, and Golden Seal tea, which produces colored urine.<sup>32</sup> Other commercially available products include "Xtra Clean," which contains pyridinium chlorochromate, and "Urine Luck," which contains glutaraldehyde.

Niacin is used to alter urine test results, although there is no evidence it is effective for this purpose. There are reports of niacin toxicity, including skin reactions such as itching, flushing, and burning, when niacin is used for this purpose.<sup>146,147</sup> More serious effects, including nausea, elevated liver enzymes, hypoglycemia, and anion gap metabolic acidosis, are reported as a result of ingesting niacin in large amounts, in the 2.5 to 5.5 g range over 1 to 2 days.<sup>146,147</sup>

A significant issue in the analysis of urine for the presence of prohibited peptides such as rhEPO is the masking potential of proteases surreptitiously added to urine specimens slated for doping analysis. The proteases are packaged in "grains" known as protease granules or "rice grains" and placed in the urethra.<sup>212</sup> Upon urination for the purpose of providing a specimen for doping analysis, the grain flows with urine into the specimen cup. The proteases, including trypsin, chymotrypsin, and papain, quickly degrade renally excreted peptides, most notably EPO, making them undetectable. By the process of autolysis, proteases themselves become undetectable over time. In one report, urine with elevated protease concentrations greater than 15 mcg/mL underwent further analysis to identify urinary proteins such as albumin.<sup>212</sup> Normally, the presence of urinary proteins creates the image of a visible band by gel electrophoresis. However, the urine with elevated protease activity will demonstrate something called *trace of burning*, a term indicating an absence of proteins.<sup>214</sup>

In this report, suspicious specimens were subjected to further testing using liquid chromatography–mass spectrometry. After further molecular sequencing of derived proteins, human proteases can be distinguished from nonhuman proteases, such as bovine chymotrypsin or papain. The addition of a protease inhibitor to urine samples immediately after collection is suggested as a future strategy to limit the effectiveness of protease addition as a masking method.<sup>214</sup>

In approximately 15% of urine samples performed in antidoping laboratories, there is no endogenous or rhEPO detectable by immunoelectrophoresis.<sup>120</sup> Undetectable EPO occurs more commonly in competition, the "competition effect." This is due in part to circumstances unrelated to doping, such as physiological variation in EPO production, gender, and very low or very high urine

specific gravity. However, doping with exogenous EPO and inhibition of endogenous hEPO production or addition of proteases are other possible causes. Strenuous effort causes a shift in the isoforms of EPO, yielding a more basic isoelectric point, a result known as “effort” urine.<sup>119</sup> Urine samples deemed suspicious do not necessarily result in a positive doping test result.<sup>120,212</sup>

The list of prohibited masking xenobiotics includes diuretics; epitestosterone; probenecid; plasma expanders such as albumin, dextran, and hydroxymethyl starch; and  $\alpha$ -reductase inhibitors such as finasteride and dutasteride.<sup>1</sup> Probenecid blocks urinary excretion of the glucuronide conjugates of AAS.

### Gene Doping

The discovery of the genetic codes for some diseases has made gene therapy of medical conditions, such as muscular dystrophy, a reality. It is now conceivable that this technology can be used to enhance athletic performance. Gene doping is included on the WADA 2017 Prohibited List.<sup>1</sup> Gene doping is defined as “the non-therapeutic use of cells, genes, genetic elements, or of the modulation of gene expression, having the capacity to enhance athlete performance.”<sup>71</sup> For example, insertion of a gene sequence could produce a desired effect, such as large muscles or increased body production of potentially advantageous substances such as testosterone or GH. In animal models, genes for EPO lead to erythropoiesis, and genes for IGF-1 produce increased muscle size and strength.<sup>22</sup> Myostatin, which belongs to a family of proteins that control growth and differentiation of tissues in the body, inhibits skeletal muscle growth.<sup>103,193</sup> Mutations of the myostatin gene may result in muscle hypertrophy. In dogs, the athletic performance of racing whippets is enhanced in animals with a myostatin gene mutation.<sup>152</sup> In humans, a report of an extremely muscular baby born with a mutation in the myostatin gene illustrates the potential effect of gene alterations on athletic performance. The mother of this infant was a professional athlete, and other members of the family were known for their strength.<sup>193</sup> This was a natural genetic mutation. Transcription regulators such as AMP-activated protein kinase (AMPK) are exercise mimetics and increase muscle endurance when administered orally in animal models.<sup>83,154</sup> Influencing the expression of the transcription factor peroxisome proliferator-activated receptor- $\delta$  (PPAR- $\delta$ ), a nuclear hormone receptor hormone protein, leads to increased formation of slow twitch skeletal muscle. Angiotensin II receptor blockers such as telmisartan influence both the AMPK pathway and upregulate PPAR- $\delta$ , expression improving muscle performance.<sup>66</sup>

### Athlete’s Biological Passport

A significant development in the detection of blood transfusion, known as blood doping, is the development of a longitudinal record of an athlete’s RBC parameters called the *athlete’s biological passport*. This is individualized longitudinal monitoring that tests blood for markers of doping. Because of this record of athletes’ biomarkers, athletes are more sophisticated and use very small amounts of blood-boosting xenobiotics. Such blood manipulation causes changes in gene expression that may be detected. The detection of plasticizer metabolites from blood storage and alteration of gene expression resulting from infusion of autologous blood are proposed adjuncts to detection of autologous blood transfusion.<sup>150,151</sup> The observation of physiological parameters over time has made it easier to detect use of performance-enhancing agents.<sup>20</sup>

### Neurocognitive Enhancement

Improvement in brain function and mental agility is an element of performance enhancement receiving increasing study. Students report improving academic productivity as the motivation for use of stimulants. Those using methylphenidate and amphetamine have reported positive effects on working memory, delayed memory, and processing speed in learning. Whereas also limit cognitive flexibility. There is a wide dosing range for individual stimulants to increase cognitive performance. At this time, the effect of these xenobiotics on learning requires extensive study.<sup>140</sup>

Nutritional studies are reported to demonstrate the positive effects of fruit flavonoid supplementation. Blueberries and other berries in the diet

enhance are suggested to enhance memory both with acute and chronic diet inclusion in both animals and human subjects.<sup>9,30</sup>

Enhancement of neurocognitive performance using vitamins and minerals is a new area of study.

## PERFORMANCE ENHANCEMENT AND SUDDEN DEATH IN ATHLETES

Many unexpected deaths in certain groups of young competitors have occurred in the absence of obvious medical or traumatic causes. In some of these cases, the use of performance-enhancing drugs was linked to the deaths. The use of EPO, introduced in Europe in 1987, is suggested to have contributed to the large number of deaths in young European endurance athletes over the next several years.<sup>82</sup> In young healthy athletes experiencing cerebrovascular events or myocardial infarction, the temporal link between the use of cocaine, ephedrine, or performance enhancers such as AAS suggests a role for these xenobiotics as precipitants of these adverse events. Nevertheless, the leading cause of nontraumatic sudden death in young athletes is most often associated with cardiac anomalies. In autopsy studies of athletes in the United States with congenital sudden death, hypertrophic cardiomyopathy is the most common structural abnormality, accounting for more than one-third of the cardiac arrests followed by coronary artery anomalies.<sup>134-138</sup> In Italy, dysrhythmogenic right ventricular cardiomyopathy is implicated in one-fourth of these deaths.<sup>68,220</sup> Medical causes of sudden death other than cardiac causes include heat stroke (Chap. 29), sickle cell trait, and asthma.

## SUMMARY

- Although the press spotlights a few world-class athletes, the majority of individuals using performance-enhancing substances are not in the public view. Some individuals experience adverse consequences.
- Knowledgeable clinicians identify these health effects when they occur and educate susceptible individuals on the health risks of using performance-enhancing substances.
- Continuous development and refinement of antidoping laboratory methods broadly benefit our understanding of the physiology of exercise.
- WADA is the international body responsible for coordinating antidoping efforts nationally and internationally, and as such, the WADA Prohibited List sets the standard for methods and substances barred in sports.

## ESSENTIAL OILS

Lauren Kornreich Shawn

### INTRODUCTION

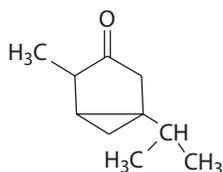

Essential oils are a class of volatile oils that are extracted through steam distillation or are cold pressed from the leaves, flowers, bark, wood, fruit, or peel of a single parent plant. The term *essential* refers to the essence of a plant rather than an indispensable component of the oil or a vital biologic function. These compounds are a mixture of complex hydrocarbons that give the oil its aroma and potential therapeutic properties and that occasionally cause toxicity. More than 500 essential oils exist and are typically categorized into five chemical groups: terpenes, quinines, substituted benzenes, aromatic/aliphatic esters, and phenols and aromatic/aliphatic alcohols.

### HISTORY AND EPIDEMIOLOGY

The potential for toxicity arises from several aspects of oil production, use, and regulation. These oils are not under regulation by the US Food and Drug Administration (FDA); therefore, there is no standard for manufacturing, leading to variability in active ingredients and adulterants with each producer. Furthermore, there is no standardized nomenclature for many of these herbs or for the exact chemical composition of a specific oil. Even with the strictest production guidelines, oils vary by the environment the plant was grown in and by part of the plant primarily used in production. Sometimes these differences are used to confer a particular property to the oil in terms of aroma or perceived therapeutic benefit.

Therapeutic use of essential oils can be traced back thousands of years in history to the ancient Greeks and ancient Egyptians, and it is also described in biblical writings. The first documents detailing an actual distillation process date back to the ninth century, when such oils were imported into Europe from the Middle East.<sup>185</sup> By the 16th century, concepts of separating fatty oils and essential oils from aromatic water became more defined, and oils were used frequently for fragrance, flavoring, and medicinal purposes. By the 19th century, these processes became industrialized, and specific chemicals could be identified and mass produced. Essential oils fell out of favor in the early 20th century as new medications and a desire for modernization developed. However, in the latter part of the 20th century, resurgence in interest and use of essential oils developed as many people deemed natural products to be safer and more environmentally benign. This chapter highlights some of the most commonly used oils for medicinal purposes that also have the greatest potential for toxicity.

### Absinthe

Thujone

### History

*Artemisia absinthium* is more commonly known as wormwood because of its use as an anthelmintic in ancient times. It is a member of the Compositae family, which also includes ragweed, chrysanthemums, marigolds, and daisies.<sup>164</sup> Absinthe is a liqueur composed of ethanol, oil of wormwood, and various other herbs, and it is known for its green color and bitter taste. It became a favorite among the artists and poets of Paris during the city's Belle Époque in the 19th century. Bohemian society enjoyed the drink by pouring

water on top of a sugar cube that was suspended over a glass of absinthe. The addition of sugar water not only made the drink more palatable but also enhanced the herbal aroma and green coloration, which was referred to as the "louche effect."<sup>120</sup> This ritual was commonly performed in the early evening, and thus the "green hour" was akin to a Parisian "happy hour."<sup>12</sup>

The earliest recorded use of wormwood is found in the Ebers papyrus, which covers writings from 3550 to 1550 B.C. in Egypt.<sup>12</sup> During the first century A.D., Pliny described the anthelmintic properties of wormwood in *Historia Naturalis*. Dioscorides' *De Materia Medica*, which was considered an authoritative medical text through the Middle Ages, described the ability of wormwood not only to treat intestinal worms but also to repel fleas and other pests with topical application.<sup>12</sup> For millennia, available wine was commonly fortified with wormwood, and the formulation is still known today, albeit in much more dilute concentrations, as vermouth (derived from the German word for wormwood, *Wermut*).<sup>139</sup>

Absinthe was first distilled in Switzerland but came to prominence during the early 19th century, with Pernod's distillery in France.<sup>120</sup> During the French-Algerian wars of the 19th century, absinthe was used medicinally by the French troops to ward off infection and prevent dysentery.<sup>119</sup> Subsequently, the returning troops introduced the drink to French society. As early as 1850, descriptions of toxicity were documented. By the 1910s, many countries had made it illegal. In the 20th century, thujone was discovered to be the toxic component of absinthe. Absinthe is still available as Pernod, a formulation that is free of thujone. However, thujone-containing absinthe, as well as recipes for making it at home, can be obtained on the Internet.

### Pharmacology

The bitter taste and anthelmintic properties come from the lactones absinthin and anabsinthin.<sup>164</sup> However, the toxicity of wormwood is due to its thujone content. Thujone is a monoterpene ketone that exists in  $\alpha$ - and  $\beta$ -diastereoisomeric forms. Oil of wormwood may contain up to 70% thujone ( $\alpha$ - and  $\beta$ -thujone).<sup>164</sup> The amount of the  $\beta$  isomer often exceeds that of  $\alpha$ -thujone but is less toxic.<sup>96</sup> After oral absorption, both isomers undergo species specific hydroxylation reactions by the cytochrome (CYP) P450 enzymes and are subsequently glucuronidated and renally eliminated.<sup>96</sup>  $\alpha$ -Thujone is metabolized primarily to 7-hydroxy  $\alpha$ -thujone by CYP3A4 in humans, but there are at least six other metabolites, some of which are more prominent in other animal models.<sup>95</sup> The 7-hydroxy metabolite achieves a higher concentration in the brain, but it is less potent in binding the  $\gamma$ -aminobutyric acid (GABA)<sub>A</sub> receptor and is less toxic compared with its parent compound.<sup>96</sup>

### Pathophysiology

$\alpha$ -Thujone is the more toxic of the two isomers and is a noncompetitive GABA<sub>A</sub> receptor antagonist, similar to picrotoxin.<sup>96</sup> This antagonism causes neuroexcitation, which results in hallucinations or seizures in a dose-dependent fashion. Ethanol enhances GABA activity and has a protective effect by reducing seizures in mice.<sup>96</sup> In the 1970s, it was speculated that thujone mediated the psychotropic effects of absinthe via cannabinoid receptors. However, further research demonstrated that despite low affinity for the CB1 and CB2 receptors, thujone failed to evoke any chemical signaling from binding.<sup>132</sup> Currently, research suggests that the psychotropic effects are mediated by the ability of  $\alpha$ -thujone to desensitize the 5-HT<sub>3</sub> receptor.<sup>53</sup>

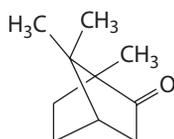

Thujones induce the synthesis of 5-aminolevulinic acid synthetase, leading to increased porphyrin production.<sup>23</sup> Individuals with defects in heme synthesis develop a porphyrialike syndrome upon ingestion of thujones. Some have speculated that Vincent Van Gogh had porphyria secondary to ingestion of absinthe and other volatile oils.

### Clinical Features

Clinical features of acute toxicity are similar to those of ethanol intoxication, including euphoria and confusion, which can progress to restlessness, visual hallucinations, and delirium. Seizures have also occurred. Studies in 19th-century France revealed that the oil of wormwood component in absinthe, rather than the ethanol or other aromatic herbs, was responsible for auditory and visual hallucinations and seizures in humans and dogs.<sup>6</sup> Absinthism was recognized as a disease distinct from alcoholism as early as 1850s. It was characterized by delirium, hallucinations, tremors, and seizures. Although thujone is the purported xenobiotic in the development of these symptoms, the patients also drank excessive amounts of ethanol, so differentiating this syndrome from chronic sequelae of alcoholism is difficult.<sup>6</sup>

Rhabdomyolysis and acute kidney injury (AKI) are also reported after ingestion of oil of wormwood intended for preparation as absinthe.<sup>186</sup> The etiology of the rhabdomyolysis is unknown.

### Camphor

### History

Originally derived from the bark of the camphor tree (*Cinnamomum camphora*), camphor has been widely used for centuries. It was described in writings from Marco Polo's visits to China, and in the 16th century it was referred to as the "balsam of disease."<sup>13</sup> Camphor has been used as an abortifacient, a contraceptive, a cold remedy, an aphrodisiac, an antiaphrodisiac, a lactation suppressor, and an antiseptic.<sup>10,83</sup> In the late 19th and early 20th centuries, it was also regarded as a cardiac stimulant and used extensively to treat congestive heart failure and cardiovascular compromise during influenza outbreaks.<sup>60,78,81,127,129</sup> By the 1920s, studies demonstrated that camphor was not

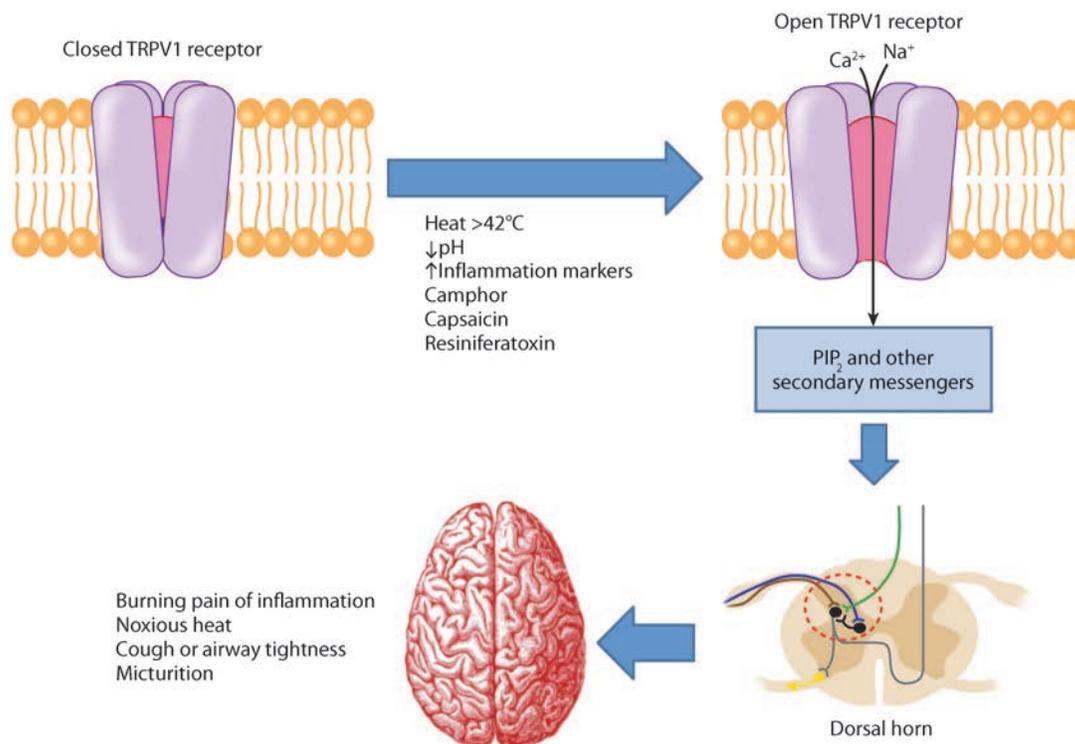

an effective cardiovascular stimulant, and its use began to fall out of favor.<sup>129</sup> In the 20th century, camphor was predominantly used as a topical rubefacient to provide local analgesia and antipruritic effects. It also became a key ingredient in paregoric (camphorated tincture of opium), a common household remedy for diarrhea and cough used until 1970. Throughout the 20th century, camphor was also available as a nonprescription remedy in the forms of camphorated oil, which was 20% camphor in cottonseed oil, and spirits of camphor, which was 10% camphor in alcohol. Toxicity occurred in cases in which camphorated oil was mistaken for castor oil and ingested in large amounts.<sup>13,40,179</sup> In 1982, the FDA limited any product from containing more than 11% camphor and banned camphorated oil after numerous reports of significant morbidity and mortality. It was also used extensively as a moth repellent. Today, camphor is found in topical products such as Vick's Vapo-Rub and Tiger Balm. Despite restrictions on its sale by the FDA, concentrated camphor products are still found in the United States. They are illegally sold in various communities for use as pesticides and medicinal remedies.<sup>111</sup>

### Pharmacology

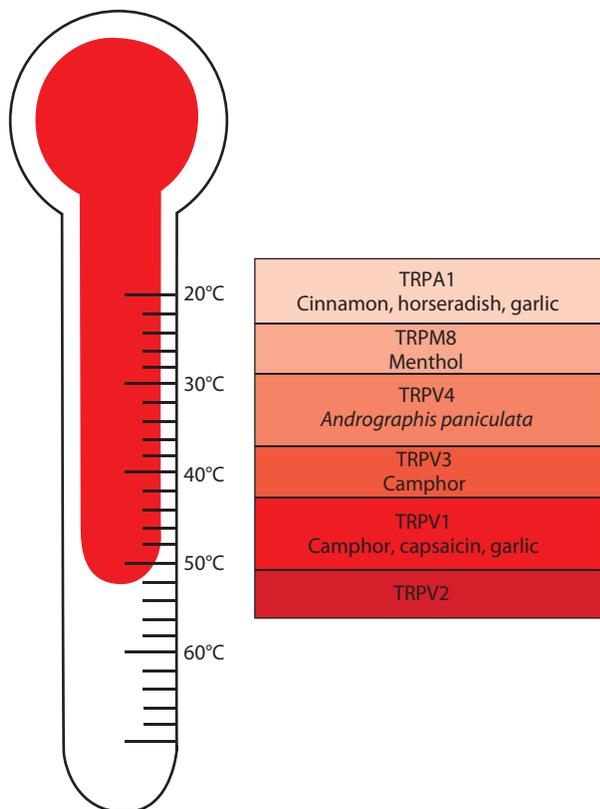

Camphor is a bicyclic monoterpene ketone that is rapidly absorbed from the gastrointestinal (GI) tract. Serum concentrations are detected within 15 minutes of ingestion.<sup>144,149</sup> It is also readily absorbed from the skin and mucous membranes.<sup>111</sup> It also crosses the placenta and blood-brain barrier.<sup>149</sup> A detectable concentration was found in amniotic fluid 20 hours after maternal ingestion.<sup>149</sup> Camphor is very lipophilic with a large volume of distribution. It is metabolized in the liver by CYP2A6 to 5-exo-hydroxycamphor, but other studies using animal models have cited 5-endo-hydroxycamphor and 3-hydroxycamphor as significant metabolites.<sup>85,152,179</sup> These metabolites then undergo glucuronidation and are excreted in the urine.<sup>152</sup>

### Pathophysiology

The mechanism for seizures is still unknown. Camphor desensitizes the transient receptor potential vanilloid subtype 1 (TRPV1) channel, a nonspecific cation channel that mediates thermosensation and nociception in the peripheral nervous system (Fig. 42-1).<sup>191</sup> Currently, there are seven known

**FIGURE 42-1.** The transient receptor potential vanilloid subtype 1 (TRPV1) receptor is a nonspecific cation channel that is located on the skin and bladder, in the peripheral nociceptors and the dorsal horn of the spinal cord, and in the airway. Stimulation by heat, acidemia, and inflammation increases its activity; camphor, capsaicin, and resiniferatoxin are direct agonists. When open, TRPV1 stimulates intracellular signaling via  $PIP_2$  to relay sensation of burning pain, noxious heat, airway tightness, and micturition.

**FIGURE 42-2.** Schematic of the seven known mammalian thermo-transient receptor potential (TRP) channels based on their temperature threshold for activation. Certain natural xenobiotics can activate these receptors, which may lead to burning or heat sensation. Transient receptor potential A1 cation channel subfamily M member 8 (TRPM8) mediates cold sensation in sensory neurons. Menthol and eucalyptus' cooling and analgesic effects are thought to be caused by TRPM8 activation. Camphor desensitizes TRP vanilloid subtype 1 (TRPV1), which could explain the initial hot and then cool sensation when applied to skin. Camphor antagonizes TRPA1, which may mediate its antitussive effects.

transient receptors (of 27 known receptors within the family) that perceive temperatures ranging from noxious heat to noxious cold, depending on the type or combination of receptors activated (Fig. 42-2).<sup>138,141,184</sup> These receptors are primarily expressed by small-diameter sensory neurons of the dorsal root ganglion and trigeminal nerves.<sup>18</sup> Similar to other topical analgesics with effects on these channels, it is postulated that desensitization mediates the analgesic and cooling effect of topical camphor products. Transient receptor potential A1, with TRPA1, is also implicated as an important part in the production of cough. Camphor's antitussive effects are presumed to be through the desensitization of TRPV1 and antagonism of TRPA1 (Fig. 42-2).<sup>76,131</sup> There are TRPV1 receptors found in the central nervous system (CNS), but it is unknown whether they are implicated in the CNS effect of camphor toxicity. Autopsies of human case reports and animal studies demonstrate neuronal necrosis and degeneration on pathology, but the mechanism of action remains elusive.<sup>166</sup>

Hepatotoxicity is also reported and can range from a mild elevation in aminotransferase concentrations to fulminant hepatic failure. Children are more susceptible to hepatotoxicity because they have relatively immature liver enzymes and glucuronidation systems. The hepatotoxicity presents similarly to Reye syndrome with vomiting, rapid neurologic deterioration to coma, and hepatomegaly, but it does not have the same characteristic findings on biopsy.<sup>103</sup>

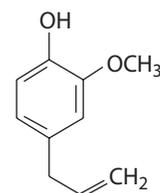

### Clinical Features

Camphor toxicity is reported after nasal, topical, inhalational, and oral administration.<sup>40,60,144,162,173,182</sup> Gastrointestinal signs and symptoms developed within 5 to 90 minutes after ingestion.<sup>14</sup> Case reports of delayed onset

of symptoms are complicated by unknown time of ingestion or concomitant illness.<sup>128</sup> In a retrospective review of 182 cases, no patient developed symptoms more than 6 hours after ingestion.<sup>83</sup> Two grams of camphor can cause significant toxicity in adults when ingested, and children have died from as little as 0.7 to 1 g of 20% camphorated oil (1 tsp).<sup>39,166</sup> Other reports describe children having seizures but surviving after ingesting 0.5 to 6 g of camphor.<sup>158</sup>

Generally, the first effects are related to GI irritation and include nausea and vomiting, although patients who were exposed via topical or inhalational administration rarely have GI symptoms. Patients complain of feeling warm, faint, and vertiginous and have headaches.<sup>104</sup> Severe effects and findings include confusion, agitation, delirium, and hallucinations.<sup>47,60,173</sup> Seizures are common and usually develop within minutes to a few hours of exposure.<sup>134</sup> Status epilepticus is reported.<sup>47,111</sup>

### Clove Oil

Eugenol

### History

Clove oil is extracted from the plant *Syzygium aromaticum*, also known as *Eugenia aromatica*. This evergreen plant is native to the Maluku islands of Indonesia (traditionally known as the Spice Islands). Its dried, unopened buds are known as cloves, a descriptive name derived from the Latin word *clavus*, meaning nail. During the Chinese Han dynasty, subjects were required to chew cloves to mask bad breath when appearing before the emperor. In medieval and Renaissance Europe, cloves were considered to be a valuable commodity. They were used for flavoring and fragrance, as well as for medicinal purposes, and that tradition remains intact today. The first recorded medicinal use of cloves in Western society is found in *The Practice of Physic*, which was written in French in the 1640s and translated into English in 1687.<sup>45</sup> Clove oil is commonly mixed with zinc oxide as a sealant in dentistry, a practice that dates as early as 1873.<sup>98</sup> Clove oil is still used to alleviate toothaches, and one study found it just as effective as topical benzocaine for analgesia.<sup>3</sup>

### Pharmacology

Typically, clove oil contains 60% to 90% eugenol, which is the primary active component. Eugenol undergoes sulfonation and glucuronidation in the liver, with a minor pathway involving the CYP enzymes to form a reactive intermediate that requires glutathione for proper elimination.<sup>177</sup>

### Pathophysiology

The anesthetic properties of eugenol are mediated by blockade of various ion currents in nerves. This was initially demonstrated by the ability to block conduction of action potentials in frog sciatic nerves.<sup>115</sup> Given the structural similarity to capsaicin, studies sought to determine if the effects were mediated by a common mechanism. Studies of rat dorsal root ganglion cells suggest that eugenol acts in both a capsaicin receptor mediated pathway and by an independent pathway.<sup>136</sup> Capsaicin requires the TRPV1 receptor to inhibit voltage-gated calcium channels to desensitize peripheral nociceptors, but eugenol does not (Fig. 42-1).<sup>122,135</sup> Eugenol also inhibits voltage-gated sodium channels independently of TRPV1, and this likely mediates its anesthetic effects.<sup>140</sup> Eugenol similarly blocks voltage-gated potassium channels in neurons, which suggests a possible mechanism for the irritating effects of eugenol because potassium efflux is required to terminate action potentials and neurotransmitter release.<sup>125</sup>

Studies with rat hepatocytes demonstrated that eugenol causes glutathione depletion and subsequent hepatotoxicity in a dose- and time-dependent

manner. The loss of glutathione occurred before the onset of cell death in these studies.<sup>177</sup> Furthermore, *N*-acetylcysteine (NAC) was able to prevent glutathione depletion and cell death. Eugenol inhibits prostaglandin synthetase, which would support the claims for its use as an antiinflammatory xenobiotic in dentistry.<sup>98</sup>

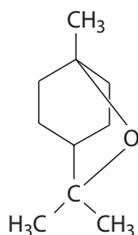

### Clinical Features

There are several reports of allergic reactions and local irritation when eugenol zinc oxide was used for dental procedures.<sup>17,116,156</sup> There are fewer case reports of systemic toxicity from other forms of exposure. However, infants and children ingesting clove oil are reported to develop depressed mental status, anion gap metabolic acidosis, and hepatotoxicity complicated by coagulopathy and hypoglycemia.<sup>27,68,89,102,121</sup>

A single case report described a 24-year-old woman who developed permanent infraorbital anesthesia and anhidrosis after spilling a small amount of clove oil on her face in an attempt to relieve a toothache.<sup>99</sup>

Acute respiratory distress syndrome (ARDS) is reported with intravenous (IV) administration of clove oil. Similar findings of perivascular, interstitial, and alveolar edema are found in animal studies. The proposed mechanism is oxidant mediated, but this has not been verified.<sup>112,189</sup>

### Eucalyptus Oil

Eucalyptol

### History

Oil of eucalyptus is derived primarily from *Eucalyptus globulus*, a tree native to Australia. Eighteenth-century British explorers noted that the aboriginal people traditionally used eucalyptus as a fever remedy, so they brought it to England for further examination. The introduction of eucalyptus oil to the West led to an increased demand because it was increasingly used to treat the symptoms of the common cold and influenza. The oil was believed to be so effective that there were public campaigns to grow the trees in areas of Europe stricken with malaria and other infectious diseases. Great effort was made to determine how best to cultivate these plants in the colder, damper European environment.<sup>8,150</sup> In the 19th and early 20th centuries, eucalyptus oil was a common household remedy for coughs and fevers, and it was also used as an antiseptic.<sup>44</sup> It was even reported as effective in treating hemorrhage, burns, and diabetes.<sup>9,165,178</sup>

### Pharmacology

Eucalyptus oil contains almost 70% eucalyptol, a monoterpene cyclic ether also known as 1,8-cineole. It is rapidly absorbed from the GI tract and metabolized by CYP3A4 and CYP3A5, to the 2-hydroxy and 3-hydroxy metabolites.<sup>61</sup>

### Pathophysiology

Eucalyptus inhibits potassium-induced contractions of airway smooth muscles causing a myorelaxant effect, thus alleviating some patient's upper respiratory irritation.<sup>126</sup> However, eucalyptus also potentiates acetylcholine-induced contractions of the trachea in vitro, possibly by inhibiting acetylcholinesterase.<sup>126</sup> This finding would explain the upper respiratory irritation that commonly plagues workers who process eucalyptus trees for papers and other materials. Eucalyptol inhibits monocytes from producing several cytokines, particularly tumor necrosis factor (TNF)- $\alpha$  and interleukin (IL)-1 $\beta$ , from being produced.<sup>106</sup> It also suppresses arachidonic acid metabolism. These findings underlie the ability of eucalyptol to control

mucous hypersecretion; making it a potential adjunct in controlling asthma and chronic obstructive pulmonary disease, for which it is frequently used as an alternative medicine.<sup>105,106,188</sup> The cooling effects of eucalyptus are likely mediated by TRPM8 (Fig. 42-2).<sup>30,174</sup>

The mechanism of toxicity has yet to be elucidated. Eucalyptol affects the autonomic nervous system, but animal studies are difficult to interpret because mice seem relatively insensitive to the oil, and other animals require extremely high amounts to achieve toxic effect.<sup>51,70</sup> Significant morbidity and mortality are rare.

### Clinical Features

Typical effects and findings of eucalyptus toxicity include drowsiness, slurred speech, ataxia, nausea, and vomiting.<sup>72,169</sup> Rarely, seizures and coma occur.<sup>84</sup> Cases of status epilepticus in children are reported.<sup>117</sup> Symptom onset is usually within minutes to hours and rarely exceeds 4 hours. In children, significant toxicity is reported after ingesting as little as a teaspoon. Fatalities are reported in adults who have ingested as little as 4 mL, but a patient survived a 120- to 200-mL ingestion after receiving mannitol infusions and dialysis.<sup>72,84</sup> Inhalational and dermal exposures have minimal toxicity as long as the patient is promptly removed or decontaminated from the exposure.<sup>169</sup>

### Lavender Oil

#### History

Lavender is one of the most commonly used essential oils for fragrance and aromatherapy.<sup>34</sup> It was used by the ancient Romans and Greeks for its believed antimicrobial, carminative, sedative, and antidepressive properties. The oil is produced by steam distillation of the flower heads and foliage of the *Lavandula* species. However, the chemical composition and fragrance of the oil are determined by the proportion of flowers distilled within a particular batch.

There are four commonly used lavenders: *Lavandula latifolia*, a Mediterranean variety; *Lavandula angustifolia*, commonly known as English lavender (or *L. officinalis*); *Lavandula stoechas*, commonly known as French lavender; and *Lavandula x intermedia*, which is a sterile cross fertilization between *L. latifolia* and *L. angustifolia*.<sup>34</sup> The lavenders generally have the same major chemical constituents in their oils and ethnobotanical history, but some species have specific therapeutic benefits ascribed to them. For example, *L. stoechas* was traditionally used as a headache remedy, *L. latifolia* as an abortifacient, and *L. angustifolia* as a diuretic.<sup>34</sup> However, many of these effects, regardless of species used, have never been substantiated in the medical and scientific literature. Lavender oil is most commonly used in aromatherapy to enhance mood, decrease anxiety, or control pain. Most studies demonstrating improved pain control, decreased anxiety, or improved mood were small studies or poorly controlled. Silexin is an oral preparation of *L. angustifolia* that is sold as an anxiolytic in Germany. It is made under a standardized manufacturing process to decrease contaminants and increase the linalyl acetate concentration. Studies show it to be noninferior to lorazepam or paroxetine in treatment of various anxiety disorders.<sup>107,108</sup>

### Pharmacology

The main components of lavender oil are linalool, linalyl acetate, 1,8-cineole,  $\beta$ -ocimene, terpinen-4-ol, and camphor.<sup>34</sup> The proportion of each within a given batch of oil depends on the plant used and type of distillation. Plants with smaller camphor components, such as *L. angustifolia*, are used more for fragrance and cosmetic purposes because their aroma is considered to be more pleasant. Plants with higher camphor content are traditionally used for insect repellent and antimicrobial uses.

Linalool and linalyl acetate are the components believed to be responsible for the neuropsychiatric effects of lavender oil, specifically sedative and narcotic effects. These compounds are rapidly absorbed through the skin and can reach peak serum concentrations as soon as 19 minutes postexposure.<sup>34,101</sup> Studies in mice show that lavender oil acts on serotonin receptors, rather than GABA receptors, and this underlies its anxiolytic effects.<sup>37,159</sup> A single study involving positron emission tomography scans of people taking Silexin show the 5HT<sub>1A</sub> receptor as a likely binding site.<sup>16</sup> Linalool inhibits both nicotinic receptor-mediated acetylcholine release and glutamate release.<sup>145,160</sup>

*Lavandula angustifolia* has activity against methicillin-resistant *Staphylococcus aureus* and vancomycin-resistant *Enterococcus faecalis* as well as other bacteria.<sup>190</sup> Its potential as an antimicrobial and preservative in cosmetics is demonstrated.<sup>118</sup> Further research suggests that the linalool in lavender oil is responsible for its antimicrobial properties. Linalool was found to have a synergistic effect when added to other essential oils with known antimicrobial properties such as tea tree oil and bergamot.<sup>93</sup>

### Pathophysiology

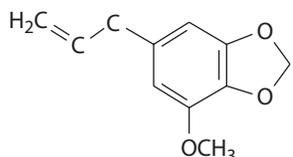

Lavender oil is very allergenic. Linalool is not electrophilic or chemically reactive, suggesting it would not be a contact allergen.<sup>86</sup> Linalyl acetate has an electrophilic center and is a weak allergen in studies.<sup>163</sup> However, both of these compounds immediately oxidize when exposed to air, generating hydroperoxides, which are strong allergens. This oxidation occurs regardless of whether pure linalool, linalyl acetate, or lavender oil is used.<sup>86,163</sup>

Several case series report the development of gynecomastia in prepubertal boys using lavender oil.<sup>22,56,92,109</sup> All the children in these reports had extensive endocrine evaluations, with no abnormalities detected, and in each case, the gynecomastia resolved when lavender oil was discontinued. Body washes and colognes containing lavender oil were frequently implicated as the source of exposure.<sup>56,92</sup> In vitro data showed that lavender oil elicits a dose-dependent increase in estrogen responsiveness and antiandrogenic activity in breast cancer cell cultures, similar to the effects of estradiol.<sup>92,109</sup>

### Clinical Features

The predominant clinical feature of exposure is contact dermatitis. Unexplained or “idiopathic” gynecomastia in prepubertal boys with negative endocrine evaluations should prompt questions regarding the use of these essential oils.

## Nutmeg Oil

Myristicin

### History

Nutmeg and mace originate from the evergreen tree *Myristica fragans*, which is native to the Maluku islands of Indonesia (Spice Islands) and was imported to Europe as early as the mid-12th century.<sup>73,161</sup> However, today, nutmeg is more commonly imported to the United States from Malaysia, Grenada, Trinidad, and other parts of the Caribbean.<sup>161</sup> The name *nutmeg* refers to the seed of the tree, which looks like a glossy brown nut. Mace is derived from the scarlet-colored aril that encloses the seed.

Although nutmeg is a common household spice and flavoring agent, it has been used for centuries for various ailments, including digestive disorders, cholera, rheumatic disease, psychiatric disorders, and pain.<sup>73</sup> Mace was used as an aphrodisiac, and nutmeg was commonly used in Europe and North America, albeit ineffectually, as an emmenagogue and abortifacient.<sup>146</sup> Indeed, most of the cases of nutmeg poisoning in the early 20th century were due to women attempting to terminate pregnancies or induce menses.<sup>82</sup> However, most cases of toxicity today are caused by people using nutmeg as a natural high.<sup>1,33,143,155</sup> The first reported case of nutmeg poisoning is attributed to Lobel, who described delirium in a pregnant woman who ingested 10 or 12 nutmeg seeds in 1576.<sup>33</sup> In 1832, the famous scientist Purkinje demonstrated the toxicity of nutmeg by ingesting seeds, causing delirium and then stupor.<sup>82</sup>

### Pharmacology

The nutmeg seed yields 7% to 16% volatile oil, 4% to 8% of which is myristicin.<sup>87</sup> Myristicin is believed to be the psychoactive component of the oil, but some

studies have brought that into question. It was initially hypothesized that myristicin was metabolized to the amphetamine derivative 3-methoxy-4,5-methylenedioxyamphetamine (MMDA) by the addition of ammonia to the allyl side chain. Elemicin, another main ingredient of the volatile oil, is metabolized to 3,4,5-trimethoxyamphetamine (TMA).<sup>157</sup> This was further supported by detection of MMDA by thin-layer chromatography of rat liver incubated with myristicin.<sup>25</sup> However, in vivo studies could neither replicate these results nor find evidence of the amphetamine derivatives. Gas chromatography of urine from rats and humans exposed to nutmeg, pure myristicin, or elemicin did not detect MMDA, TMA, or evidence of the original compounds.<sup>21</sup> However, other metabolites were found, suggesting extensive liver metabolism. It was later determined that CYP3A4 and CYP1A2 were primarily involved in the formation of the main metabolite of myristicin, 5-allyl-1-methoxy-2,3-dihydroxybenzene.<sup>193</sup>

### Pathophysiology

Studies in mice suggest that nutmeg and fresh myristicin are monoamine oxidase inhibitors (MAOIs) but that excessive doses could reverse that effect.<sup>181</sup> However, nutmeg was less potent than known MAOIs on the market at the time. In the 1960s, nutmeg was studied as a possible antidepressant in five patients with mixed results, but a formal trial of nutmeg as a psychiatric medication was never conducted.<sup>181</sup> Data from an in vitro study show that nutmeg stimulates the cannabinoid system by inhibiting enzymes that degrade the body's own endocannabinoids. This study also demonstrated that nutmeg did not bind directly to cannabinoid receptors, serotonergic receptors, dopamine receptors, GABA receptors, or adrenergic receptors. The authors proposed that enzyme inhibition mediates the cannabinoidlike effects that occur in exposed patients.<sup>69</sup>

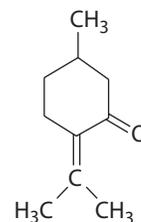

Animal data show that nutmeg can induce tachycardia and increase the speed of conduction through the atrioventricular node in the acute setting, but chronic exposure caused bradycardia.<sup>154</sup> The exact mechanism for this is unknown.

Cats appear to be exquisitely sensitive to nutmeg and develop not only acute mental status changes with nutmeg exposure but also liver damage, leading to hepatic encephalopathy.<sup>180</sup> This has not been reported in humans.

### Clinical Features

Tachycardia, nausea, and dry mouth are common in acute exposures. Some patients develop GI distress and vomiting. Central nervous system effects and findings range from giddiness to a sense of detachment or impending doom to hallucinations and delusions.<sup>1,11,46,82,142</sup> Nutmeg ingestion rarely causes significant morbidity or mortality. Only two deaths have been reported. In 1887, an 8-year-old boy became comatose after ingesting two nutmegs and died the next day; however, he also received a wide variety of analeptics that likely were more harmful than the initial exposure.<sup>33</sup> The other case involved a detectable serum myristicin concentration on autopsy of a 55-year-old woman who had a toxic serum concentration of flunitrazepam and whose stomach contents smelled strongly of nutmeg.<sup>170</sup> It is unclear if the nutmeg contributed to her death. Several retrospective studies from poison control center data did not show any deaths or life-threatening toxicity. Of those hospitalized, the majority of patients had taken other drugs in addition to the nutmeg, complicating the clinical picture.<sup>33,67</sup> A single report describes seizures and altered mental status requiring intubation in a patient who intentionally ingested 39 g of ground nutmeg as a suicide attempt.<sup>71</sup>

## Pennyroyal Oil

Pulegone

## History

Oil of pennyroyal is derived from the plant *Mentha pulegium* from the Labiatae family. It has a mintlike odor and is still used as a flavoring and fragrance agent in foods and cosmetics. Its initial use was as a flea repellent. Pulegium is derived from the word *pulex*, which is Latin for flea.<sup>80</sup> Pennyroyal has been used for centuries as an emmenagogue and abortifacient, and most reported toxicities were from women ingesting large quantities to induce these effects. Dioscorides listed pennyroyal as an abortifacient in his *Da Materia Medica*, and the Greek playwright Aristophanes made frequent reference to it in his plays.<sup>148</sup> Women still occasionally use pennyroyal for these purposes today.

## Pharmacology

The primary active ingredient in pennyroyal is pulegone, a monoterpene. In particular, *R*(+)-pulegone is the active isomer.<sup>79</sup> Pulegone is metabolized by the CYP450 enzymes into several metabolites, including menthofuran, which is thought to be the metabolite primarily responsible for hepatotoxicity, although other reactive intermediates are also implicated.<sup>80,175</sup>

## Pathophysiology

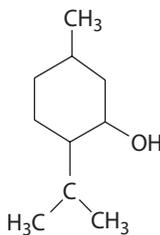

In animal studies, pennyroyal causes centrilobular hepatic necrosis.<sup>79</sup> In a rat model, pulegone depletes glutathione in hepatocytes and in the plasma. Furthermore, hepatotoxicity is significantly increased in glutathione-depleted animals. However, another unknown reactive metabolite is also implicated because blocking the CYP450 system prevents glutathione depletion. Menthofuran had a minimal effect on glutathione concentrations in the plasma and liver, and its ability to cause hepatotoxicity was not affected by glutathione depletion, suggesting a role on another reactive metabolite.<sup>176</sup>

*R*(+)-Pulegone also causes necrosis in lung epithelium, but the mechanism remains unknown.<sup>79</sup> In addition, *R*(+)-pulegone decreases inward current from L-type calcium channels and blocks the inward rectifying potassium channels on the rat myocardium.<sup>50</sup>

## Clinical Features

Common initial signs and symptoms are nausea, abdominal pain, and vomiting, often occurring within a few hours of exposure.<sup>7</sup> Central nervous system toxicity, including seizures and coma, develop in severe cases.<sup>24,62</sup> Ingestion of as little as 5 mL is implicated in severe CNS toxicity. However, in most cases, ingestion of 10 mL is primarily associated with GI symptoms and mild CNS symptoms such as dizziness and lethargy. Fatal cases involving liver failure, kidney failure, and disseminated intravascular coagulation occurred with ingestion of 15 mL, but these often involve large amounts or multiple doses over a short period of time.<sup>2,172,183</sup> In reported cases, patients either ingested a tea brewed from the leaves of *M. pulegium*, a tablet containing the herb, oil of pennyroyal, or essence of pennyroyal, which is an alcoholic preparation.<sup>24,38,62,77</sup> Most cases of severe toxicity involved women ingesting large amounts of the herb to induce an abortion; however, two cases involved confusing the leaves of *M. pulegium* for nontoxic mint leaves to make tea.<sup>15</sup>

## Peppermint Oil

Menthol

## History

Menthol or peppermint oil is one of the most commonly used flavoring agents in the world. It is derived from the distillation of leaves of the *Mentha piperita* herb, which is native to Europe and parts of Asia but easily grows in North

America as well.<sup>130</sup> Before World War II, menthol was primarily exported from China and Japan, but as those trade routes became disrupted during and after the war; Brazil became the predominant exporter.<sup>63</sup> Peppermint flavor is common in oral care products, candies, cosmetics, pharmaceuticals, and beverages. Pure crystalline menthol was extracted from plants and introduced as a medicine in the 19th century. In the late 19th century, its use in upper respiratory illness was described, but the author cautioned that more information was needed to “become familiar with its actions and know its limitations.”<sup>64</sup> However, menthol is still used today for many remedies with little supporting data. It is sold as an herbal remedy for pruritus, GI disorders such as irritable bowel syndrome, and cough and cold symptoms, as well as a topical analgesic.<sup>192</sup> Pure distilled peppermint oil is more expensive and primarily produced by the United States for toothpaste and other dental care products. Corn mint oil, also known for its minty scent and flavor, is derived from *Mentha arvensis* and contains 70% to 80% menthol. However, menthol derived from this plant has a more herbaceous flavor and is less commonly used commercially.<sup>63</sup>

## Pharmacology

There are eight pairs of stereoisomers that exist for menthol, given its three asymmetric carbons on the central ring of the structure. However, only the (–) menthol form is found in nature and is the most potent.<sup>63</sup> Peppermint oil typically contains 30% to 55% menthol.<sup>90</sup>

Menthol is very lipid soluble and easily absorbed through the skin. Menthol is rapidly metabolized by the CYP450 system to primarily to *p*-menthane-3,8 diol and then glucuronidated and eliminated in the urine.<sup>63</sup> Menthol is a moderate inhibitor of CYP3A4, but its effects on the metabolism of other drugs such as the dihydropyridine calcium channel blockers are not clear.<sup>59</sup> In human pharmacokinetic studies, only glucuronidated menthol is detected in urine in ranges of 45% to 46% of the menthol ingested.<sup>75</sup> The plasma half-life of menthol glucuronide was determined to be 56.2 minutes and 42.6 minutes, respectively, when mint teas and candies were used.<sup>75</sup>

## Pathophysiology

In the late 19th century, it was hypothesized that the cooling effects of menthol involved stimulation of a thermoreceptor. Many years later, two independent studies demonstrated the TRP cation channel subfamily M member 8 (TRPM8) is activated by both menthol and thermal stimuli in the cool to cold range of 46° to 82°F (8°–28°C) (Fig. 42–2).<sup>141</sup> This receptor TRPM8 is a member of the TRP family of excitatory ion channels (the same receptor family as TRPV1).<sup>18</sup> Menthol and cold stimuli increase intracellular calcium, which leads to depolarization and generation of an action potential. Some data suggest that the analgesic properties of menthol are mediated by its effects on sodium channels.<sup>74</sup>

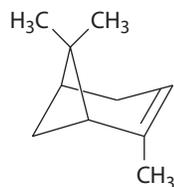

Menthol was investigated as an adjunct to irritable bowel syndrome therapy. In vitro data with isolated animal ileum and jejunum tissue show that menthol reduces contractions by reducing calcium influx, even when such tissue was exposed to acetylcholine, histamine, and serotonin.<sup>94</sup> The proposed mechanism of action is L-type calcium channel blockade.<sup>4</sup> However, another study shows that menthol is a nicotinic receptor antagonist in the gastric mucosa, also causing smooth muscle relaxation.<sup>5</sup> In some countries, menthol is sold in an acid-resistant preparation as a carminative for irritable bowel symptoms. Menthol and peppermint oil both inhibit 5-HT<sub>3</sub> receptors in vitro as well as reduce serotonin-induced contractions of rat ileum, which could mediate some of the antiemetic effects.<sup>90</sup>

Menthol is commonly used to relieve the symptoms of upper respiratory infections, in particular rhinitis. However, despite the sensation of improved airflow and decreased congestion, menthol actually causes increased nasal congestion.<sup>64,65</sup> Inhalation of menthol, camphor, or eucalyptus did not decrease nasal resistance to airflow even though all of the participants reported an increased sensation of airflow.<sup>29</sup> Similar results were found for nasal menthol lozenges.<sup>66</sup>

### Clinical Features

Application of menthol to skin or mucosa causes the sensation of coolness or warmth. Case reports regarding menthol toxicity are rare. One report pertains to Olbas oil, which contains 35% menthol. In addition to 35% eucalyptus oil, and other oils in smaller amounts. In this report, the child developed ataxia, nystagmus, and altered mental status.<sup>137</sup> A case report describes ARDS developing in a patient after an intentional IV injection of 5 mL of peppermint oil in a suicide attempt. Symptoms began within 2 hours of the exposure. Bronchoscopy and bronchoalveolar lavage did not show signs of aspiration or fat embolism as the etiology of the ARDS, suggesting direct cytotoxic injury from the peppermint oil.<sup>19</sup>

### Pine Oil

$\alpha$ -Pinene

### History

Pine oil is commonly used as a household cleaner, varnish, and polish. In the past, it had medicinal uses as an expectorant and topical liniment. Turpentine is an oleoresin solvent—a mixture of pine oils and resins distilled from the tree genus *Pinus*. Pine oil is also distilled from the same trees but does not include any resins. Turpentine is used as a degreaser and paint thinner. Pine oil is commonly found in Pine-Sol and similar household cleaners. These cleaners typically include 20% pine oil, 6% to 10% isopropyl alcohol, and other hydrocarbons.

### Pharmacology

The lethal dose is in the range of 60 to 120 g in adults.<sup>114</sup> The major terpene is  $\alpha$ -terpine. The major metabolite is bornyl acetate, which is produced by the enzymatic processes of hydration, hydroxylation, rearrangement, acetylation, and reduction in the liver.<sup>114</sup> The metabolites are excreted through the kidneys and lungs. Pine oil is readily absorbed, and clinical effects usually occur within 2 to 3 hours postingestion.<sup>110</sup>

### Pathophysiology

Pine oil and turpentine are volatile hydrocarbon compounds with low viscosity. Aspiration and inhalational injury are common when low-viscosity hydrocarbons are ingested or inhaled (Chap. 105). Animals injected with pine oil develop ARDS, but the mechanism is unknown.<sup>167,168</sup>

### Clinical Features

The most common reported symptoms are impaired mentation, psychomotor agitation, delirium, headache, nausea, ataxia, and GI distress. Gastrointestinal irritation and gastritis are reported, but actual perforation or high-grade lesions have not been found.<sup>41</sup> Acute kidney injury is also reported.<sup>114</sup> An isolated case report of hemorrhagic cystitis occurring after a patient ingested turpentine for several days to treat a cold has been described.<sup>113</sup> Fatalities are rare but are more likely to occur when the patient is an older adult.<sup>187</sup> The most severe outcomes involve an aspiration pneumonitis that can progress to ARDS or a secondary pneumonia.<sup>26,110</sup>

### Tea Tree Oil

#### History

Tea tree oil is derived from the distillation of leaves of *Melaleuca alternifolia*, a plant that is native to Australia. The *Melaleuca* genus belongs to the Myrtaceae family and contains more than 230 species. The international standard for tea tree oil does not specify which *Melaleuca* species must be used but rather dictates a certain chemical content.<sup>31</sup> Traditionally,

*M. alternifolia* has been the primary source for the oil. Nevertheless, synonyms and ambiguous naming of various oils and plants make it difficult to identify the primary plant product. Tea tree oil is also known as melaleuca oil or ti tree oil in many cases. Furthermore, ti tree is the Maori and Samoan common name for plants of the *Cordyline* genus, a completely different plant.<sup>31</sup> There are oils from other *Melaleuca* species on the market that possess different chemical properties from that of tea tree oil, further complicating matters. Tea trees can also be known as paperbark trees, but paperbark oil may refer to oil from another type *Melaleuca* tree or even a unrelated tree such as *Leptospermum* species.

The first reported use of *M. alternifolia* was in Australian Aborigines. Crushed leaves were inhaled to treat coughs and cold symptoms, and poultices of the leaves were applied to wounds. Oral histories describe swimming or bathing in healing lakes composed of decaying fallen tea tree leaves as a treatment for a variety of ailments.<sup>31</sup> The oil itself was not distilled until the 20th century, at which time it was touted as an antibacterial agent. Commercial production began after medicinal properties of the oil were first reported in the 1920s. Production slowed after World War II, presumably because of the increased use of antibiotics and decreased desire to use natural products. Renewed interest in the oil began in the 1970s, and production increased as well as became more standardized.

### Pharmacology

Data on safety and toxicity are scant. Pharmacokinetic and pharmacodynamic data are limited. Animal studies and case reports of human poisoning demonstrate toxicity with oral exposure. The median lethal dose for rats is 1.9 to 2.6 mL/kg, and rats dosed 1.5 mL/kg appeared lethargic and ataxic.<sup>31</sup>

Tea tree oil is composed of terpene hydrocarbons and contains more than 100 components.<sup>31</sup> There can be variability in the composition of oils sold on the market, but there is an international standard stipulating that tea tree oil should contain at least 30% terpinen-4-ol, which is believed to be the primary antimicrobial agent and less than 15% 1,8-cineole, which is believed to be primarily responsible for the irritating properties.<sup>31</sup> There are other hydrocarbons found in tea tree oil that help make up its specific chemotype for the standard but are less involved in the presumed medicinal properties.

### Pathophysiology

Tea tree oil is predominately used as a topical antiseptic, and its antimicrobial effects are the most studied use of the oil. It is bactericidal, but its mechanism of action is only partly elucidated. Tea tree oil, as a lipophilic hydrocarbon, disrupts the membranes of liposome model systems, supporting the hypothesis that it kills bacteria by disrupting their cell membranes.<sup>43</sup> Tea tree oil does not cause bacteria to lyse per se but makes them more susceptible to lysis when exposed to a hypertonic medium, or at least it causes an inability to recover from leakage of intracellular contents over time. This is demonstrated by leakage of potassium ions and 260-nm light-absorbing material (a marker of leakage of cytoplasm contents) in *S. aureus* and *Escherichia coli*.<sup>32,42</sup> Tea tree oil also inhibits respiration in *S. aureus*.<sup>32,43</sup> The hydrocarbons 1,8-cineole and terpinen-4-ol were primarily responsible for this phenomena.<sup>32</sup> Although 1,8-cineole was initially thought not to play a role in the antimicrobial activity of the oil, it seems to penetrate and disrupt the cellular membranes of bacteria. Terpinen-4-ol and  $\alpha$ -terpineol have the greatest antimicrobial activity.

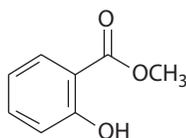

Tea tree oil also has antiinflammatory effects. Specifically, it inhibits lipopolysaccharide-induced production of the inflammatory mediators TNF- $\alpha$ , IL-1 $\alpha$ , IL-10, and prostaglandin E<sub>2</sub> by monocytes in vitro.<sup>88</sup>

### Clinical Manifestations

Skin irritation and allergic reactions are common effects with topical exposure. The allergic reactions are hypothesized to occur after the oil has undergone significant oxidation.<sup>153</sup> The hydrocarbon 1,8-cineole is implicated as the main irritating component, but there are few data to support this theory. In some of the cases of prepubertal gynecomastia reported in

boys exposed to lavender oil, the patients were also exposed to tea tree oil.<sup>92</sup> However, it has not been demonstrated that tea tree oil affects the endocrine system. When ingested, tea tree oil commonly causes drowsiness, ataxia, and slurred speech. Case reports of children unintentionally ingesting a 100% concentration of tea tree oil show symptoms developing within 30 minutes of exposure. One child had resolution of symptoms within 5 hours, and another had to be intubated but had improvement in neurologic symptoms within 10 hours.<sup>54,100,134</sup> A case report describes using surfactant to treat an 18-month-old boy who developed ARDS after an unintentional ingestion of 100% tea tree oil. The child did well and was able to extubated by hospital day 3.<sup>147</sup> Surfactant has been used in cases of aspiration pneumonia in children (Chap. 105). In all reported cases of pediatric and adult oral poisoning, patients responded well to supportive care alone; no deaths are reported.<sup>54,100,134</sup>

## Oil of Wintergreen

Methyl salicylate

### History

Oil of wintergreen was originally derived from *Gaultheria procumbens*, or the Eastern teaberry, which is a fragrant ground cover plant found in North America. The leaves were steamed and distilled to produce the oil that was used topically to relieve the symptoms of rheumatism. Oil of wintergreen is also obtained from the twigs of sweet birch, or *Betula lenta*. The active ingredient in oil of wintergreen is methyl salicylate, which has a pleasant, minty smell and taste, posing a significant hazard to children. Pure oil of wintergreen contains at least 98% methyl salicylate, but most commercial preparations of methyl salicylate contain far less.<sup>57</sup> The FDA regulations require that any drug containing more than 5% methyl salicylate have a warning against using it other than as a topical agent and keeping it out of the reach of children.<sup>48</sup> Oil of wintergreen has been used as a fragrance and flavoring agent in foods and household products.<sup>97</sup> It is also found in topical preparations worldwide, such as Tiger Balm and Ben-Gay, which are used to treat inflammation and myalgias. In many Asian countries, topical oils with benign, poetic names such as red flower oil and white flower oil contain high concentrations of methyl salicylate and are quite toxic when ingested.<sup>35,36</sup> Further confusing consumers and practitioners, there are many other names for this essential oil, including checkerberry oil, sweet birch oil, mountain tea, teaberry, groundberry oil, gaultheria oil, and spicewood oil.<sup>57</sup>

The first reported case of toxicity occurred in 1832, when six soldiers used the oil to flavor their tea.<sup>55</sup> The seminal case series was reported in the 1930s in which 43 exposures were tabulated, 20 involved children younger than the age of 4 years and had a 75% fatality rate.<sup>171</sup> The smallest lethal dose in this series was 4 mL of oil of wintergreen, and 6 mL was reported to be a lethal dose in a 21-year-old man.

### Pharmacology

Methyl salicylate is absorbed both from the GI tract and transdermally. Normally, only 12% to 20% of topical salicylate is absorbed from the skin after 10 hours of application.<sup>151</sup> Heat, inflamed or broken skin, and prolonged use of occlusive dressings increase absorption.<sup>28,91,133</sup> Children have died after topical application.<sup>28</sup> Children are presumed to be at greater risk for toxicity because of their higher surface area-to-weight ratio and more permeable skin. After it has been absorbed, methyl salicylate enters the circulation and is transported to the liver, where it undergoes hydrolysis to form salicylic acid.<sup>49</sup> Methyl salicylate is a carboxylic acid ester. Most of the studies of salicylate metabolism involve aspirin, which is a phenolic ester. It is assumed that all forms of salicylate have similar properties after they are converted to

salicylic acid. The salicylic acid undergoes conjugation with glycine and glucuronic acid, forming salicyluric acid, salicyl acyl, and phenolic glucuronide. Salicylates then undergo renal elimination in the forms of salicyluric acid (75%), free salicylic acid (10%), salicylic phenol (10%) acyl (5%) glucuronides, and gentisic acid (<1%).<sup>20,49,123,124</sup>

### Pathophysiology

Five milliliters (1 tsp) of oil of wintergreen is equivalent in salicylate content to 7 g of aspirin, which has been a fatal amount in some reported cases.<sup>57</sup> An extensive discussion of salicylate pathophysiology is given in Chap. 37.

### Clinical Features

An overdose of methyl salicylate presents similarly to that of other salicylates such as aspirin. Salicylate poisoning is characterized by diaphoresis, nausea, vomiting, tinnitus, hyperpnea, and tachypnea. Mental status changes represent severe toxicity. Symptom onset is typically within a few hours given rapid absorption of the oil. Severe toxicity is associated with seizures, cerebral edema, ARDS, coma, and death. Further details on evaluation and management can be found in Chap. 37.

## DIAGNOSTIC TESTING

Laboratory testing is of little utility in most essential oil toxicity, and the patient's clinical status will determine which tests are indicated. Some essential oil exposures do require specific studies, and they are listed below. Generally, blood or urine concentrations of the active ingredients are not available in a meaningful time frame and cannot and should not guide management. Patients who present with altered mental status or seizures warrant a complete evaluation that includes a rapid assessment of glucose, basic metabolic studies, a head computed tomography scan, and lumbar puncture for serious potential structural, infectious, or metabolic etiologies as guided by the history and examination. In patients who present with respiratory distress, chest radiographs, and continuous pulse oximetry are warranted.

- **Absinthe:** Laboratory studies should include a complete blood count (CBC), chemistry panel, creatine phosphokinase concentration, and glucose monitoring in patients who present with seizures. Urinalysis should be performed to evaluate for myoglobinuria.
- **Pennyroyal Oil:** A CBC and liver function studies, including the aminotransferases, bilirubin, prothrombin time, and partial thromboplastin time, and a  $\beta$ -human chorionic gonadotropin in women are indicated because many women ingest pennyroyal oil to terminate unwanted pregnancies.
- **Oil of wintergreen:** Serum salicylate concentrations, blood gas, serum potassium concentration, and urine pH initially should be sent every 1 to 2 hours to determine extent of toxicity and need for treatment (Chap. 37).

## TREATMENT

The mainstay of treatment of symptomatic essential oil toxicity is supportive care, including monitoring of vital signs, IV fluids, and supplemental oxygen as needed. A dose of activated charcoal is reasonable in alert patients with an intact airway, but if there is a concern for seizures, activated charcoal should be withheld or deferred until the airway is protected. Dermal exposures should be properly decontaminated to prevent further absorption. Benzodiazepines are the mainstay of treatment in patients who present with agitation and seizures. A case report of unintentional eucalyptus poisoning in an elderly woman demonstrated naloxone as a potential antidote for lethargy and respiratory depression. There is not enough evidence to recommend routine use of naloxone in essential oil intoxications.<sup>58</sup>

A few of the essential oils require specific treatment:

- **Absinthe:** Rhabdomyolysis should be treated with IV fluids.
- **Camphor:** Most patients need supportive care with a focus on airway and circulatory management as well as aggressive treatment of seizures. Barbiturates are frequently cited as a first-line treatment of seizures based on one animal study that demonstrated decreased

neuronal damage with administration of pentobarbital.<sup>166</sup> However, it is likely that appropriate use of benzodiazepines would be just as effective. Given the risk of seizures and altered mental status, inducing emesis is not recommended. There is no proof of any benefit with orogastric lavage, and the rapid absorption of camphor from the GI tract decreases its likelihood of utility. The molecular weight and lipophilic nature of camphor indicates that it would likely be absorbed by activated charcoal. One animal study that underdosed the amount of activated charcoal as well gave subtoxic doses of camphor indicated that activated charcoal was not effective.<sup>52</sup> There have been no further studies examining this issue; however, given the risk of aspiration from emesis and seizure, activated charcoal should only be administered in patients with massive life-threatening ingestions and protected airways (Chap. 102).

- **Clove oil:** In patients who exhibit signs of hepatotoxicity, it is reasonable to administer NAC. Although no definitive studies on NAC use in this patient population are available, the evidence that NAC is protective in the rat model, combined with the safety profile of NAC, warrant its use in the setting of eugenol-induced hepatotoxicity.<sup>177</sup>
- **Pennyroyal oil:** One case of ingestion of a potentially fatal amount of pennyroyal was successfully treated with NAC.<sup>7</sup> Given in vitro studies showing glutathione depletion, it is recommended to administer NAC in cases of pennyroyal-induced hepatotoxicity. Because there is no established dosing regimen, using the same regimen used for acetaminophen toxicity would be reasonable.<sup>176</sup>
- **Oil of wintergreen:** Alkalinization with sodium bicarbonate and hemodialysis are indicated in cases of severe toxicity. Exchange transfusion was used successfully in children with life-threatening toxicity after methyl salicylate overdose (Chap. 37).<sup>57</sup>

## SUMMARY

- Essential oils are used as an alternative form of medical therapy.
- These oils contain mixtures of complex hydrocarbons that are potentially toxic.
- Cutaneous use of these products in moderation is associated with minimal toxicity. However, ingestion, prolonged inhalation, or excessive topical use causes significant morbidity and mortality.
- Patients and health care providers should have open dialogues about the therapeutic use of these products and any concerning exposures should be referred to the regional poison control centers for guidance in management.

## PLANT- AND ANIMAL-DERIVED DIETARY SUPPLEMENTS

Lindsay M. Fox

### INTRODUCTION

Dietary supplements include vitamins, minerals, plant- and animal-derived preparations, amino acids, and a variety of other “natural” and “traditional” remedies with established history of use. Within the United States regulatory context, dietary supplements are distinct from *medications* because this term is reserved for drugs approved by the US Food and Drug Administration (FDA), which are regulated more rigorously in terms of safety and effectiveness. Although these products are distinct from medications, they contain xenobiotics that have many physiologic effects on the human body.

Many dietary supplements sold in the United States are based on diverse traditional healing practices from around the world, and they are often derived from plant and animal sources.

The study of plant- and animal-derived dietary supplements is complicated by the lack of standardized nomenclature. A variety of common, proprietary, and botanical names can cause confusion. A single plant preparation often has many common names, in addition to its botanical name. For example, *Datura stramonium* is also known as Jamestown weed, jimson weed, angel’s trumpet, devil’s apple, thornapple, apple of Peru, and tolgua-cha. Likewise, one common name for a plant refers to several plants. “Mandrake” refers not only to the belladonna-alkaloid-containing *Mandragora officinarum* but also the podophyllum-containing *Podophyllum peltatum*. Thus, accurate classification of plant- and animal-derived dietary supplements is difficult and often confusing. Using both common and botanical names, when possible, allows for more precise communication.

This chapter discusses the history, epidemiology, and regulation of plant- and animal-derived dietary supplements. Pharmacologic principles related to products derived from plants and animal sources are considered, as well as issues related to adulteration and contamination of supposedly natural products. The toxicities of select examples of plant- and animal-derived dietary supplements will be discussed. It is beyond the scope of this chapter to evaluate the effectiveness of dietary supplements for their purported uses. Reported traditional indications are mentioned in some cases to provide context without implying that the evidence for or against purported indications for these products was evaluated.

### HISTORY AND EPIDEMIOLOGY

Since ancient times, people of nearly all cultures have used plant- and animal-derived dietary supplements to treat disease and promote health. A 60,000-year-old Iraqi burial site contained eight different medicinal plants.<sup>104</sup> The Egyptian Ebers papyrus, written circa 1500 B.C., lists 160 medicinal plants and their intended uses, including the use of salicin-containing willow bark to treat pain.<sup>33</sup> The Hippocratic Corpus, compiled around 400 B.C., contains many descriptions of herbs, including a number of recipes for plant-based gynecologic remedies; it prescribes the use of a likely extinct silphium plant to “create a wind in the womb” to induce abortion or expel a dead fetus.<sup>108</sup> In the first century A.D., the Greek physician Dioscorides wrote *De Materia Medica*, which described the indications for use of more than 600 plant- and animal-derived preparations, many of which are still used by herbalists today.<sup>106</sup> China’s *Shennong Bencaojing*, or *Divine Farmer’s Materia Medica*, first inked around 200 A.D., discusses hundreds of herbs, such as cannabis, ma huang (ephedra), and ginger.

During the Scientific Revolution, scientists began to isolate purified extracts of plant products for use as medicinals, and many modern pharmaceuticals are still derived from plant products. In 1806, a French pharmacist isolated a substance from the *Papaver somniferum* plant that he named morphine, after Morpheus, the Greek god of dreams.<sup>117</sup> In 1828, the active

ingredient of the willow bark, salicin, was identified,<sup>33</sup> after which it began to be used to treat rheumatic fever. In 1897, acetylsalicylic acid was synthesized by scientists at Bayer, and it quickly became one of the most commonly used medications around the world.<sup>33</sup> The original name, aspirin (*a cetyl-spiric acid*), was derived from *Spiraea*, the plant genus from which salicylic acid once was prepared. *Artemisia annua* (sweet Annie, qing hao) was first described as a treatment for malaria (periodic fever) in China in 168 B.C.<sup>62</sup> In 1971, the active parent compound artemisinin was isolated by Chinese investigators. Artemisinin, an artemisinin, is now recommended by the World Health Organization as the first-line treatment for severe *Plasmodium falciparum* malaria.<sup>3</sup> Between 1981 and 2014, 25% of new drugs approved in the United States were derived from plant or animal products found in nature, and an additional 10% were synthetic mimics designed in the image of molecules found in nature.<sup>83</sup>

In the current era, naturopaths, traditional healers, shamans, and a multitude of sometimes dubious websites offer plant- and animal-derived dietary supplements for medicinal purposes, and the products they sell are unfortunately often highly unreliable and potentially injurious. An estimated 5% of children and 18% of adults in the United States use nonvitamin, non-mineral dietary supplements, many of which are plant- and animal-derived dietary supplements.<sup>58</sup> Dietary supplements are estimated to contribute to 23,000 emergency department visits in the United States per year.<sup>47</sup> Consumers buy dietary supplements from offices of complementary and alternative medicine practitioners, health food stores, grocery stores, pharmacies, drug stores, gasoline stations, mail order companies, and the Internet. United States dietary supplement sales were estimated at \$6.4 billion in 2014, representing direct sales of \$3.1 billion, natural and health food sales of \$2.2 billion, and \$1.1 billion from mass-market retailers.<sup>103</sup> For more than a decade, dietary supplement sales have increased every year, with a 6.8% increase in 2014.<sup>103</sup> Similarly, worldwide plant- and animal-derived dietary supplement usage continues to grow. The current global supplements and remedies market was valued at \$62 billion in 2012, and it is predicted to reach \$115 billion by 2020.<sup>49</sup>

### REGULATION OF DIETARY SUPPLEMENTS

In the United State, all dietary supplements are loosely regulated by the FDA. They are classified as a type of dietary supplement, meaning that they are considered nutrients with nondrug status.<sup>58</sup> Therefore, dietary supplements are not subject to the same rigorous standards as pharmaceutical products. There is little to no premarketing testing to assure quality and safety. Existing regulations are relatively weak, and those that exist are inadequately enforced. Enforcement relies heavily on a postmarketing surveillance approach to identify dangerous or contaminated products after consumers have suffered adverse consequences. As a result, American consumers are exposed to untested, unproven products that sometimes contain harmful ingredients, dangerous contaminants, or unlisted adulterants.

Current regulation of dietary supplements in the United States was defined in large part by the Dietary Supplement Health and Education Act of 1994 (DSHEA), which limited the authority of the FDA to regulate products categorized as dietary supplements.<sup>13,58</sup> Dietary supplements according to the DSHEA include vitamins, minerals, plant- and animal-derived products, amino acids, and any product that was sold as a “supplement” before October 15, 1994. After October 15, 1994, any new ingredient intended for use in dietary supplements requires notification and approval by the FDA at least 75 days in advance of marketing. The FDA must review and determine whether the proposed ingredient is expected to be safe under the intended

conditions for use. However, because most ingredients contained in dietary supplements were in use before 1994, the vast majority of dietary supplements are not subject to even this weakened premarket safety evaluation. Note that there is no requirement to show effectiveness, a typical expectation associated with approval of pharmaceuticals. The DSHEA allows dietary supplement vendors to make structure or function claims, suggesting that a particular compound or ingredient may promote health or well-being. However, the DHSEA does not allow claims that a supplement treats or cures disease, except in the specific case of a vitamin or nutrient treating the disease state associated with a particular nutritional deficiency. Substantiation of these claims is required only if challenged by regulators. In 1999, the FDA implemented new dietary supplement labeling rules. According to these rules, all dietary supplement labels must provide a statement of identity (eg, ginseng), net quantity of contents (eg, 60 capsules), structure–function claims with disclaimers that the product has not been evaluated by the FDA, directions for use, supplements fact panel (list of serving size, amount, and active ingredients), other ingredients list, and name and place of business of manufacturer, packer, or distributor. The Dietary Supplement & Nonprescription Drug Consumer Protection Act was passed in 2006 and requires companies producing dietary supplements to track serious adverse events and report them to the FDA within 15 days of knowledge that the serious adverse events occurred.<sup>13</sup> In 2007, the FDA updated the Current Good Manufacturing Practice regulations for dietary supplements, and these regulations require that dietary supplements are produced in a consistent manner and that producers ensure quality standards for identity, purity, strength, and composition.<sup>13</sup> The FDA Food Safety Modernization Act was passed in 2010 and enhances the ability of the FDA to recall both foods and dietary supplements.<sup>13</sup>

After marketing, if the FDA determines that a manufactured dietary supplement is unsafe or in violation of regulations, the agency can warn the public, suggest changes to make the supplement safer, recall the product, or ban the product. The FDA can exercise these powers if adverse effects occur during postmarketing surveillance, if there is evidence of adulteration or contamination, if products are mislabeled or make false claims, or if the company is not following good manufacturing practices.<sup>13</sup> The FDA banned or recalled dietary supplement products because of safety concerns identified in postmarketing surveillance on numerous occasions. In July 2001, the FDA warned dietary supplement manufacturers to stop marketing products containing aristolochic acid (AA) because of the potential for nephrotoxicity<sup>87</sup> and to remove comfrey-containing products from the market because of the potential for hepatotoxicity caused by pyrrolizidine alkaloids (PAs).<sup>71</sup> In November 2001, the FDA warned the manufacturer of LipoKinetix (containing phenylpropanolamine, caffeine, yohimbine, diiodothyronine, sodium usniate) to remove the supplement from the marketplace because of reports of associated hepatotoxicity.<sup>42</sup> In 2002, the FDA warned consumers and health care professionals of the risk of hepatotoxicity associated with the use of kava-containing products.<sup>40</sup> However, the FDA did not ban kava-containing products in the United States. In 2004, the FDA banned all sales of dietary supplements containing ephedra because of the risk of serious cardiovascular toxicity.<sup>38</sup> Other examples of dietary supplement products or ingredients that were recalled or banned by the FDA include 14 different Hydroxycut products in 2009, 1,3-dimethylamylamine in 2011, and OxyElite Pro and Aegeline in 2013.<sup>13</sup>

Although dietary supplements are not to be advertised for the treatment of disease without the approval of the FDA, research suggests that they often are. A study determined that 81% of websites marketing dietary supplements made one or more health claims without approval from the FDA, and of these sites, 55% made specific claim to treat, prevent, or cure a specific disease.<sup>81</sup>

In addition, two studies suggest that many dietary supplements do not even contain appreciable quantities of the listed herb. In one study of 54 ginseng products, 60% of those analyzed contained pharmacologically insignificant amounts of ginseng, and 25% contained no ginsenosides.<sup>73</sup> A study of echinacea preparations determined that 10% of preparations contained no measurable echinacea, the assayed species was consistent with labeled content in 52% of the sample, and only 43% met the quality standard described by

the label.<sup>48</sup> Perhaps more concerning than the insufficient quantities of herbs are the unlisted ingredients that contaminate and adulterate some dietary supplements. Metals and pharmaceutical compounds often taint these preparations, as is discussed in more detail later in the sections on contamination and adulteration of plant- and animal-derived dietary supplements.

The FDA has released data suggesting that its regulations alone are insufficient in ensuring the safety of dietary supplements sold in the United States. Between 2008 and 2012, the FDA found violations of manufacturing rules in nearly half of the 450 dietary supplement firms it inspected.<sup>109</sup> One in four inspected companies had violations serious enough to warrant release of an FDA warning letter that could result in a significant enforcement action such as halting production and distribution. The FDA also believes that adverse events associated with dietary supplements are significantly underreported by manufacturers even though it is required by law.<sup>76</sup> Even after a product is identified as unsafe, it can be a challenge for the FDA to take action to remove the product. It took more than a decade for the FDA to remove ephedra-containing products from the market even though they had caused hundreds of deaths and thousands of adverse reactions.<sup>76</sup>

Several studies have attempted to determine how US hospitals regulate dietary supplements use in their facilities.<sup>4,9,27,46</sup> Many hospitals do not have formal policies governing the use of dietary supplements in their facilities. Some hospitals ban dietary supplements, but most allow them as long as they were ordered by an authorized prescriber. Some concerns include difficulties in identifying products (particularly “home supply” products) and uncertainty about appropriate dosing, efficacy, safety, and consistency, as well as the potential for herb–xenobiotic interactions. Facilities struggle to balance patient-centered care with the legal, medical, and ethical concerns about the efficacy, safety, and cost of dietary supplements.<sup>12,46</sup>

In essence, regulation of dietary supplements has shifted from a poorly regulated food product into a unique category between a conventional food product and a drug. This has served to fuel the debate on both sides: those who view dietary supplements as more similar to food groups (eg, chamomile tea) and want less government regulation and others who argue that dietary supplements contain pharmacologically active drugs (eg, ephedra) that require greater regulation.<sup>77,82</sup>

## PHARMACOLOGIC PRINCIPLES

The pharmacologic activity of dietary supplements is classified by five active constituent classes: volatile oils, resins, alkaloids, glycosides, and fixed oils.<sup>105</sup>

**Volatile oils** are aromatic plant ingredients (Table 43–1). They are also called ethereal or essential oils because they evaporate at room temperatures and have an odor, which is generally pleasant. Many are mucous membrane irritants and have central nervous system (CNS) activity. Examples of herbs containing volatile oils include pennyroyal oil (*Mentha pulegium*), catnip (*Nepeta cataria*), chamomile (*Matricaria chamomilla*), and garlic (*Allium sativum*) (Chap. 42).

**Resins** are complex chemical mixtures of acrid resins, resin alcohols, resinol, tannols, esters, and resenes. These substances are often strong gastrointestinal (GI) irritants. Examples of resin-containing herbs include dandelion (*Taraxacum officinale*), elder (*Sambucus* spp), and black cohosh root (*Cimicifuga racemosa*).

**Alkaloids** are a heterogeneous group of alkaline and nitrogenous compounds. The alkaloid compound usually is found throughout the plant. This class consists of many pharmacologically active and toxic compounds. Examples of alkaloid-containing herbs include aconitum (*Aconitum napellus*), goldenseal (*Hydrastis canadensis*), and Jimson weed (*Datura stramonium*).

**Glycosides** are esters that contain a sugar component (glycol) and a nonsugar (aglycone), which yields one or more sugars during hydrolysis. They include the anthraquinones, saponins, cyanogenic glycosides, and lactone glycosides. The anthraquinones (senna {*Cassia acutifolia*} and aloe {*Aloe vera*}) are irritant cathartics. Saponins (licorice {*Glycyrrhiza lepidota*} and ginseng {*Panax ginseng* and *P. quinquefolius*}) are mucous membrane irritants, cause hemolysis, and have steroid activity. Cyanogenic glycosides found in apricot, cherry, and peach pits release cyanide. Lactone glycosides

TABLE 43–1 Selected Dietary Supplements, Popular Use, and Potential Toxicities

Herbal	Scientific Name	Other Common Names	Traditional and Popular Usage	Active or Toxic Ingredient(s)	Adverse Effects
Aconite	<i>Aconitum napellus</i> , <i>Aconitum kusnezoffii</i> , <i>Aconitum carmichaelii</i>	Monkshood, wolfsbane caowu, chuanwu, bushi	Topical analgesic, neuralgia, asthma, heart disease, arthritis	Aconite alkaloids (C19 diterpenoid esters), aconitine	GI upset, dysrhythmias
Alfalfa	<i>Medicago sativa</i>		Arthritis, diabetes	L-Canavanine	Lupus, pancytopenia
Aloe	<i>Aloe vera</i> and other species	Cape, Zanzibar, Socotrine, Curacao, Carrisyn	Heals wounds, emollient, laxative, abortifacient	Anthraquinones, barbaloin, isobarbaloin	GI upset, dermatitis, hepatitis
Apricot pits	<i>Prunus armeniaca</i>	—	(Laetrile) cancer remedy	Amygdalin	Cyanide poisoning
Aristolochia	<i>Aristolochia clematis</i> , <i>Aristolochia reticulata</i> , <i>Aristolochia fangchi</i>	Birthwort, heartwort, fangchi	Uterine stimulant, cancer treatment, antibacterial	Aristolochic acid	Nephrotoxicity, renal cancer, bladder cancer, retroperitoneal fibrosis
Astragalus	<i>Astragalus membranaceus</i>	Huang qi, milk vetch root	Immune booster, HIV, cancer, antioxidant, increase endurance	Astrogalosides, trigonoside, and flavonoid constituent	Alters effectiveness of immunosuppressives (eg, steroids, cyclosporine)
Atractylis	<i>Atractylis gummifera</i>	Piney thistle	Chewing gum, antipyretic, diuretic, gastrointestinal remedy	Potassium atractylate and gummiferin	Hepatotoxicity, altered mental status, seizures, vomiting, hypoglycemia
Autumn crocus	<i>Colchicum autumnale</i>	Crocus, fall crocus, meadow saffron, mysteria, vellorita	Gout, rheumatism, prostate, hepatic disease, cancer, gonorrhea	Colchicine	GI upset, kidney disease, agranulocytosis
Bee pollen, royal jelly	Derived from <i>Apis mellifera</i>	—	Increase stamina, athletic ability, longevity	Pollen mixture containing hyperallergenic plant pollen or fungi contamination	Allergic reactions
Bee venom	Derived from <i>Apis mellifera</i>	—	Immunomodulator	Phospholipase A2 and mellitin, hyaluronidases	Allergic reactions
Betel nut	<i>Areca catechu</i>	Areca nut, pinlang, pinang	Stimulant	Arecoline	Bronchospasm; chronic use associated with leukoplakia and oropharyngeal squamous cell carcinoma
Bitter orange	<i>Citrus aurantium</i>	Changcao, <i>Fructus aurantii</i> , green orange, kijitsu, Seville orange, sour orange, Zhi shi	Dyspepsia, increase appetite weight loss	Synephrine	Myocardial infarction, stroke, ephedrine-like effects
Black cohosh	<i>Cimicifuga racemosa</i>	Black snakeroot, squawroot, bugbane, baneberry	Abortifacient, menstrual irregularity, astringent, dyspepsia	Triterpene glycosides	Dizziness, nausea, vomiting, headache
Blue cohosh	<i>Caulophyllum thalictroides</i>	Squaw root, papoose root, blue ginseng	Abortifacient, dysmenorrhea, antispasmodic	N-methylcytisine (2.5% the potency of nicotine)	Nicotinic toxicity
Boneset	<i>Eupatorium perfoliatum</i>	Thoroughwort, vegetable antimony, feverwort	Antipyretic	Pyrrrolizidine alkaloids	Hepatotoxicity, dermatitis, milk sickness
Borage	<i>Borago officinalis</i>	Bee plant, bee bread	Diuretic, antidepressant, antiinflammatory	Pyrrrolizidine alkaloids, amabiline	Hepatotoxicity
Boron		Boron	Topical astringent, wound remedy	Boron	Dermatitis, GI upset, kidney toxicity and hepatotoxicity, seizures, coma
Broom	<i>Cytisus scoparius</i>	Scotch broom, Bannal, broom top	Cathartic, diuretic, induce labor, drug of abuse	L-Sparteine	Nicotinic toxicity
Buchu	<i>Agathosma betulina</i>	Bookoo, buku, diosma, bucku, bucco	Diuretic, stimulant, carminative, urine infections, insect repellent	Diosmin, hesperidin, pulegone	Hepatotoxicity
Buckthorn	<i>Rhamnus frangula</i>		Laxative	Anthraquinones	Diarrhea, weakness
Burdock root	<i>Arctium lappa</i> , <i>Arctium minus</i>	Great burdock, gobo, lappa, beggar's button, hareburr, niu bang zi	Diuretic, choleric, induce sweating, skin disorders, burn remedy, diabetes treatment	Atropine (contamination with belladonna alkaloids during harvesting)	Anticholinergic toxicity
Caapi	<i>Banisteriopsis caapi</i>	Ayahuasca, yage	Used to increase bioavailability of DMT in other plants as part of ayahuasca ritual	Harmine, harmaline, tetrahydroharmine	Serotonin toxicity, hallucinations
Cantharidin	<i>Cantharis vesicatoria</i> beetle	Spanish fly, blister beetles	Aphrodisiac, abortifacient, blood purifier	Terpenoid: cantharidin	GI upset, urinary tract and skin irritant, kidney toxicity
Carp bile (raw)	<i>Ctenopharyngodon idellus</i> , <i>Cyprinus carpio</i>	Grass carp, common carp	Improve visual acuity and health	Cyprinol, C27 bile alcohol	Hepatitis, kidney failure

(Continued)

TABLE 43–1 Selected Dietary Supplements, Popular Use, and Potential Toxicities (Continued)

Herbal	Scientific Name	Other Common Names	Traditional and Popular Usage	Active or Toxic Ingredient(s)	Adverse Effects
Cascara	<i>Rhamnus purshiana</i>	Cascara sagrada	Laxative	Anthraquinones	Diarrhea, weakness
Catnip	<i>Nepeta cataria</i>	Cataria, catnep, catmint	Indigestion, colic, sedative, euphoriant, headaches, emmenagogue	Nepetalactone	Sedation
Chacrana	<i>Psychotria viridis</i>	Chacrana	Ingested as part of ayahuasca ritual	DMT	Serotonin toxicity
Ch'an Su	<i>Bufo bufo gargarizans</i> , <i>Bufo bufo melanosticus</i>	Stone, lovestone, black stone, rock hard, chuan wu, kyushin	Topical anesthetic, aphrodisiac, cardiac disease	Bufodienolides, bufotenin	Dysrhythmias, hallucinations
Chamomile	<i>Matricaria chamomilla</i> , <i>Chamaemelum nobile</i>	Manzanilla	Digestive disorders, skin disorders, cramps	Allergens	Contact dermatitis, allergic reactions
Chaparral	<i>Larrea tridentata</i>	Creosote bush, greasewood, hediondilla	Bronchitis, analgesic, anti-aging, cancer	Nondihydroguaiaretic acid	Hepatotoxicity (chronic)
Chuen-Lin	<i>Coptis chinensis</i> , <i>Coptis japonicum</i>	Golden thread, Huang-Lien, Ma-Huang	Infant tonic	Berberine: displaces bilirubin from protein	Neonatal hyperbilirubinemia
Cinchona Bark	<i>Cinchona succirubra</i> , <i>Cinchona calisaya</i> , <i>Cinchona ledgeriana</i>	Red bark, Peruvian bark, Jesuit bark, China bark, Cinchona bark, quinaquina, fever tree	Malaria, fever, indigestion, cancer hemorrhoids, varicose veins, abortifacient	Quinine	Cinchonism: GI complaints, tinnitus, visual symptoms, cardiovascular toxicity, CNS toxicity
Clove	<i>Syzygium aromaticum</i>	Caryophyllum	Expectorant, antiemetic, counterirritant, antiseptic, carminative euphoriant	Eugenol (4-allyl-2-methoxyphenol)	Pulmonary toxicity (cigarettes)
Coltsfoot	<i>Tussilago farfara</i>	Coughwort, horsehoof, kuandong hua	Throat irritation, asthma, bronchitis, cough	Pyrrrolizidine alkaloids: tussilaglin, senkirkine	Allergy, hepatotoxicity
Comfrey	<i>Symphytum officinale</i> , <i>Symphytum</i> spp, <i>S. x uplandicum</i>	Knitbone, bruisewort, blackwort, slippery root, Russian comfrey	Ulcers, hemorrhoids, bronchitis, burns, sprains, swelling, bruises	Pyrrrolizidine alkaloids: symphytine, echimidine, lasiocarpine	Hepatotoxicity
Compound Q	<i>Trichosanthes kirilowii</i>	Gualougen, GLQ-223, Chinese cucumber root	Fevers, swelling, expectorant, abortifacient, diabetes, AIDS	Trichosanthin	Pulmonary injury (ARDS), cerebral edema, cerebral hemorrhage, seizures, fevers
Dong Quai	<i>Angelica polymorpha</i>	Tang kwei, dang gui	Blood purifier, dysmenorrhea, improve circulation	Coumarin, psoralens, safrole in essential oil	Anticoagulant effects, photodermatitis, possible carcinogen in oil
Echinacea	<i>Echinacea angustifolia</i> , <i>Echinacea purpurea</i>	American cone flower, purple cone flower, snakeroot	Infections, immunostimulant	Echinacoside	CYP1A2 inhibitor
Elder	<i>Sambucus</i> spp	Elderberry, sweet elder, sambucus	Diuretic, laxative, astringent, cancer	Isoquercitrin cyanogenic glycoside: sambunigrin in leaves	GI upset, weakness if uncooked leaves ingested
Ephedra	<i>Ephedra</i> spp	Ma-huang, Mormon tea, yellow horse, desert tea, squaw tea, sea grape	Stimulant, bronchospasm	Ephedrine, pseudoephedrine	Headache, insomnia, dizziness, palpitations, seizures, stroke, myocardial infarction
Evening primrose	<i>Oenothera biennis</i>	Oil of evening primrose	Coronary disease, multiple sclerosis, cancer, diabetes rheumatoid arthritis, premenstrual syndrome	Cis- $\gamma$ -linoleic acid	Seizures
Fennel	<i>Foeniculum vulgare</i>	Common, sweet, or bitter fennel	Gastroenteritis, expectorant, emmenagogue, stimulate lactation	Volatile oils: transanethole, fenchone; estrogens: diantethole, photoanethole	Ingestion of volatile oils: vomiting, seizures, pulmonary injury (ARDS), dermatitis, estrogen effects
Fenugreek	<i>Trigonella foenumgraecum</i>	Bird's foot, Greek hay seed	Expectorant, demulcent, anti-inflammatory, emmenagogue, galactagogue, diabetes	4-Hydroxyisoleucine	Hypoglycemia, hypokalemia
Feverfew	<i>Tanacetum parthenium</i>	Featherfew, altamisa, bachelor's button, featherfoil, febrifuge plant, midsummer daisy, nosebleed, wild quinine	Migraine headache, menstrual pain, asthma, dermatitis, arthritis, antipyretic, abortifacient	Parthenolide	Oral ulcerations, "post-feverfew syndrome," rebound of migraine symptoms, anxiety, insomnia following cessation of chronic use
Fo-Ti	<i>Polygonum multiflorum</i>	Climbing knotwood, he shou-wu	Scrofula, cancer, constipation therapy, promote longevity	Anthraquinones: chrysophanol, emodin, rhein	Cathartic

(Continued)

TABLE 43-1 Selected Dietary Supplements, Popular Use, and Potential Toxicities (Continued)

Herbal	Scientific Name	Other Common Names	Traditional and Popular Usage	Active or Toxic Ingredient(s)	Adverse Effects
Foxglove	<i>Digitalis purpurea</i> , <i>Digitalis lanata</i> , <i>Digitalis lutea</i> , <i>Digitalis spp</i>	Purple foxglove, throatwort, fairy finger, fairy cap, lady's thimble, scotch mercury, witch's bells, dead man's bells	Asthma, sedative, diuretic or cardiotonic, wounds and burns (India)	Cardioactive steroids (eg, digitoxin, gitoxin, digoxin, digitalin, gitaloxin)	Blurred vision, GI upset, dizziness, muscle weakness, tremors, dysrhythmias
Garcinia	<i>Garcinia cambogia</i>	Brindleberry, hydroxycitric acid	Weight loss	Hydroxycitric acid	Hypoglycemia in diabetics
Garlic	<i>Allium sativum</i>	Allium, stinking rose, rustic treacle, nectar of the gods, da suan	Infections, coronary artery disease, hypertension	Alliin, Ajoene	Contact dermatitis, gastroenteritis, antiplatelet effects
Germander	<i>Teucrium chamaedrys</i>	Wall germander	Antipyretic, abdominal disorders, wounds, diuretic, choleric	Furano neoclerodane diterpenes	Hepatotoxicity
Ginger	<i>Zingiber officinale</i>		Carminative, diuretic, antiemetic, stimulant, motion sickness	Volatile oil, phenol, zingerone	Anticoagulant and antiplatelet effects
Ginkgo	<i>Ginkgo biloba</i>	Maidenhair tree, kew tree, tebonin, tanakan, rokan, kaveri	Asthma, chilblain, digestive aid, cerebral dysfunction	Ginkgo flavone glycosides and terpene lactones (ginkgolides and bilobalide)	Extracts: GI upset, headache, skin reaction; leaf: antiplatelet: allergic reactions
Ginseng	<i>Panax ginseng</i> , <i>Panax quinquefolius</i> , <i>Panax pseudoginseng</i>	Ren shen	Respiratory illnesses, gastrointestinal disorders, impotence, fatigue, stress, adaptogenic, external demulcent	Ginsenosides: panaxin, ginsenin	Ginseng abuse syndrome: elevated blood pressure, insomnia, anxiety and diarrhea
Glucomanan	<i>Amorphophallus konjac</i>	Konjac, konjac mannan	Weight-reducing agent: "grapefruit diet," increase viscosity, decrease gastric emptying	Polysaccharides	Esophageal and lower GI obstruction
Glucosamine	2-Amino-2-deoxyglucose	Chitosamine	Wound-healing polymer, antiarthritic	Glucosamine	Hepatotoxicity
Goat's rue	<i>Galega officinalis</i>	French lilac, French honeysuckle	Antidiabetic	Galegine, paragalegine	Hypoglycemia
Goji	<i>Lycium barbarum</i> , <i>chinense</i>	Wolfberry, gou qi zi	Protect liver, improve eyesight, enhance immune system	Carotenoids, lutein, atropine	Interaction with warfarin likely due to CYP2C9 inhibition
Goldenseal	<i>Hydrastis canadensis</i>	Orange root, yellow root, turmeric root	Astringent, GI disorders, dysmenorrhea	Berberine, hydrastine	GI upset, paralysis and respiratory failure
Gordolobo yerba	<i>Senecio longiloba</i> , <i>Senecio aureu</i> , <i>Senecio vulgaris</i> , <i>Senecio spartoides</i>	Groundsel, liferoot	Gargle, cough, emmenagogue	Pyrrrolizidine alkaloids	Hepatotoxicity
Gotu Kola	<i>Centella asiatica</i>	Hydrocotyle, Indian pennywort, talepetrako	Wound healing, tonic, antibacterial	Asiaticoside, asiatic acid, madecassic acid	Contact dermatitis
Green tea	<i>Camillia sinensis</i>	Green tea	Antioxidant, weight loss, reduce cholesterol	Polyphenols (catechins and epigallocatechin gallate)	Hepatotoxicity from green tea extracts
Hawthorn	<i>Crataegus oxyacantha</i> , <i>Crataegus laevigata</i> , <i>Crataegus monogyna</i>	English hawthorn, haw, maybush, whitethorn	Hypertension, CHF, dysrhythmias, antispasmodic, sedative	Hyperoside, vitexin, procyanidin	Hypotension, sedation
Heliotrope	<i>Crotalaria specatabilis</i> , <i>Heliotropium europaeum</i>	Rattlebox, groundsel, viper's bugloss, bush tea	Cancer	Pyrrrolizidine alkaloids	Hepatotoxicity
Henbane	<i>Hyoscyamus niger</i>	Fetid nightshade, poison tobacco, insane root, stinky nightshade	Sedative, analgesic, antispasmodic, asthma	Hyoscyamine, hyoscine	Anticholinergic toxicity
Holly	<i>Ilex aquifolium</i> , <i>Ilex opaca</i> , <i>Ilex vomitoria</i>	English holly, American holly, and yaupon	Tea, emetic, CNS stimulant, coronary artery disease	Saponins	GI upset
Horse Chestnut	<i>Aesculus Hippocastanum</i>	Horse chestnut, California buckeye, Ohio buckeye, buckeye	Arthritis, rheumatism, varicose veins, hemorrhoids	Esculin, nicotine, quercetin, quercitrin, rutin, saponin, shikimic acid	Fasciculations, weakness, incoordination, GI upset, paralysis, stupor
Hydrangea	<i>Hydrangea arborescens</i> , <i>Hydrangea paniculata</i>	Seven bark, wild hydrangea	Diuretic, stimulant, carminative, cystitis, renal calculi, asthma	Hydrangin, saponin	Dizziness, chest pain, GI upset
Iboga	<i>Tabernanthe iboga</i>	Ibogaine	Aphrodisiac, stimulant, hallucinogen, addiction treatment	Ibogaine	Hallucinations, prolonged QT, torsade de pointes

(Continued)

TABLE 43–1 Selected Dietary Supplements, Popular Use, and Potential Toxicities (Continued)

Herbal	Scientific Name	Other Common Names	Traditional and Popular Usage	Active or Toxic Ingredient(s)	Adverse Effects
Impila	<i>Callilepis laureola</i>		Zulu traditional remedy	Potassium atractylatolike compound	Vomiting, hypoglycemia, centrilobular hepatic necrosis
Jalap	<i>Ipomoea purga</i>		Cathartic	Convolvulin	Profuse watery diarrhea
Jimsonweed	<i>Datura stramonium</i>	Datura, stramonium, apple of Peru, Jamestown weed, thornapple, tolgua	Asthma	Atropine, scopolamine, hyoscyamine, stramonium	Anticholinergic toxicity
Kava kava	<i>Piper methysticum</i>	Awa, kava-kava, kew, tonga	Relaxation beverage, uterine relaxation headaches, colds, wounds, aphrodisiac	Kava lactones, flavokwain A and B	Mild euphoria, muscle weakness, skin discoloration, liver failure
Khat	<i>Catha edulis</i>	Qut, kat, chaat, Kus es Salalin, Tchaad, Gat	CNS stimulant, depression, fatigue, obesity, ulcers	Cathine, cathinone	Euphoria, dysphoria, stimulation, sedation, psychological dependence, leukoplakia
Kola nut	<i>Cola acuminata</i>	Botu cola, cola nut	Digestive aid, tonic, aphrodisiac, headache, diuretic	Caffeine, theobromine, kolanin	CNS stimulant
Kombucha	Mixture of bacteria and yeast	Manchurian tea	Memory loss, premenstrual syndrome, cancer	Unknown bacteria	Hepatotoxicity, metabolic acidosis
Kratom	<i>Mitragyna speciosa</i>	Ketum	Pain, opioid replacement, psychoactive effects	Mitragynine	Intrahepatic cholestasis, seizure, arrhythmia, impaired memory, coma
Licorice	<i>Glycyrrhiza glabra</i>	Spanish licorice, Russian licorice, gancao	Gastric irritation	Glycyrrhizin	Flaccidity weakness, dysrhythmias, hypokalemia, lethargy
Lipoic acid		$\alpha$ -Lipoic acid, thioctic acid	Antioxidant, diabetes, neuropathy, AIDS	Lipoic acid	Hypoglycemia
Lobelia	<i>Lobelia inflata</i>	Indian tobacco	Antispasmodic, respiratory stimulant, relaxant	Lobeline	Nicotine toxicity
Mace	<i>Myristica fragrans</i>	Mace, muscade, seed cover of nutmeg	Diarrhea, mouth sores, insomnia, rheumatism	Myristicin (methoxysafrole)	Hallucinations, GI upset
Mandrake	<i>Mandragora officinarum</i>		Hallucinogen	Atropine, scopolamine, hyoscyamine	Anticholinergic toxicity
Mate	<i>Ilex paraguayensis</i>	Paraguay tea	Stimulant	Caffeine	Methylxanthine toxicity
Mayapple	<i>Podophyllum peltatum</i> <i>P. hexandrum</i>	Mayapple, podophyllum	Emetic, cathartic, warts	Podophyllotoxin	GI upset, delirium, hallucinations, coma, cranial nerve abnormalities, peripheral sensorimotor axonopathy, hematologic toxicity, microtubule toxin
Mistletoe	<i>Viscum album</i> , <i>Phoradendron leucarpum</i>	Isador	Antispasmodic, calmative, cancer, HIV	Viscotoxins, lectins	GI upset, bradycardia, delirium
Morning glory	<i>Ipomoea purpurea</i> , <i>Ipomoea violacea</i>	Heavenly blue, blue star, flying saucers	Hallucinogen	D-lysergic acid amide (ergine)	Hallucinations
Mugwort	<i>Artemisia vulgaris</i> , <i>Artemisia dracunculus</i> , <i>Artemisia lactiflora</i>	Felon herb, moxa, guizhou	Depression, dyspepsia, menstrual disorder, abortifacient	Lactones (sesquiterpenes)	Hallucinations allergic reaction (skin, pulmonary), vivid dreams
Nutmeg	<i>Myristica fragrans</i>	Mace, rou dou kou	Hallucinogen, abortifacient, aphrodisiac, GI disorders	Myristicin	Hallucinogen, GI upset
Oleander	<i>Nerium oleander</i>	Adelfa, laurier rose, rosa laurel, rose bay, rose francesca	Cardiac disorders, asthma, corns, cancer, epilepsy	Oleandrin, neriin, gentiobiosyl-oleandrin, odoroside A	GI upset, diarrhea, dysrhythmias
Ostrich fern	<i>Matteuccia struthiopteris</i>	Fiddlehead fern	Laxative	Flavonoids	GI upset if eaten undercooked
Parsley	<i>Petroselinum crispum</i>	Rock parsley, garden parsley	Diuretic, uterine stimulant, abortifacient	Myristicin, apiol, furocoumarin, psoralen	Uterine stimulant, photosensitization
Passion flower	<i>Passiflora incarnata</i>	Passiflora, maypop	Insomnia, analgesic stimulant	Harmala alkaloids	Sedation
Pau d'Arco	<i>Tabebuia</i> spp	Ipe roxo, lapacho, tahebo tea	Tonic, "blood builder," cancer, HIV	Napthoquinone derivative: lapachol	GI upset anemia, bleeding
Pennyroyal oil	<i>Hedeoma pulegioides</i> <i>Mentha pulegium</i>	American pennyroyal, Squawmint, mosquito plant	Abortifacient, regulate menstruation, digestive tonic	Cyclohexanone: pulegone	Hepatotoxicity

(Continued)

TABLE 43-1 Selected Dietary Supplements, Popular Use, and Potential Toxicities (Continued)

Herbal	Scientific Name	Other Common Names	Traditional and Popular Usage	Active or Toxic Ingredient(s)	Adverse Effects
Periwinkle	<i>Catharanthus roseus</i>	Red periwinkle, Madagascar or Cape periwinkle, old maid, church-flower, ram-goat rose, "myrtle," magdalena	Hallucinogen, ocular inflammation, diabetes, hemorrhage, insect stings, cancers	Vincristine, vinblastine, indole alkaloid	GI upset, altered mental status, peripheral neuropathy, microtubule toxin
Pokeweed	<i>Phytolacca americana</i> , <i>Phytolacca decandra</i>	American nightshade, Cancer jalap, inkberry, poke, scoke	Arthritis, emetic, purgative	Saponins: phytolaccigenin, jalignonic acid, phytolaccagenic acid, pokeweed mitogen	Gastroenteritis, blurry vision, weakness, respiratory distress, seizures, leukocytosis
Rue	<i>Ruta graveolens</i>	Herb of grace, herb grass	Emmenagogue, antispasmodic, abortifacient	Furocoumarins, bergapten, xanthoxanthin	Photosensitization
Sage	<i>Salvia officinalis</i>	Garden sage, true sage, scarlet sage, meadow sage	Antiseptic, astringent, hormonal stimulant, carminative, abortifacient	Camphor, thujone	Seizures
St. John's wort	<i>Hypericum perforatum</i>	Klamath weed, John's wort, goatweed, sho-rengyo	Anxiety, depression, gastritis, insomnia, promote healing, HIV	Hyperforin, hypericin	Occasional photosensitization; interacts with many different drugs via induction of CYP3A4, CYP2B6, P-glycoprotein activity, as well as inhibition of monoamine oxidase
Salvia	<i>Salvia divinorum</i> , <i>Salvia miltiorrhiza</i>	Sierra mazateca, diviner's sage, magic mint, Maria pastora	Hallucinogen, renal disease	Salvinorum A, lithospermate B	Hallucinations
Sassafras	<i>Sassafras albidum</i>	Lauraceae	Stimulant, antispasmodic, purifier	Sassafras oil (80% Safrole)	Hepatotoxicity, carcinogen
Saw palmetto	<i>Serenoa repens</i>	Sabal, American dwarf palm tree, cabbage palm	Genitourinary disorders, increase sperm production, sexual vigor	5 $\alpha$ -Reductase inhibitor	Diarrhea
Senna	<i>Cassia acutifolia</i> , <i>Cassia angustifolia</i>	Alexandrian senna	Stimulant, laxative, diet tea	Anthraquinone, glycosides (senosides)	Diarrhea, CNS effects
Slippery elm	<i>Ulmus rubra</i> , <i>Ulmus fulva</i>	Elm, elm bark, red elm	Acne, boils, indigestion, abortifacient	Polysaccharide mucilage Oleoresin	Contact dermatitis
Soapwort	<i>Saponaria officinalis</i>	Bruisewort, bouncing bet, dog cloves, fuller's herb, latherwort	Acne, psoriasis, eczema, boils, natural soaps	Saponins	Intravenous: highly toxic Oral: none
Soy isoflavone	<i>Glycine max</i>		Menopausal symptoms, heart disease	Phytoestrogens: genistein, daidzein, glycitein	Carcinogen
Squill	<i>Urginea maritima</i> , <i>Urginea indica</i>	Sea onion Red Squill	Diuretic, emetic, cardiotoxic, expectorant	Cardioactive steroid, scillaren A	Emesis, dysrhythmias
Syrian rue	<i>Peganum harmala</i>	Harmal, Espand, African rue, Mexican rue, Turkish rue	Antibiotic, anxiolytic, analgesic, emmenagogue, abortifacient, ayahuasca substitute, and as a protector against evil eye	Harmala alkaloids, quinazoline alkaloids	Serotonin toxicity, tremor, abortion
T'u-san-chi	<i>Gynura segetum</i>		Tea	Pyrolizidine alkaloids	Hepatotoxicity
Tonka bean	<i>Dipteryx odorata</i> , <i>Dipteryx oppositifolia</i>	Tonquin bean, cumaru	Food, cosmetics	Coumarin	Anticoagulant effect
Tung seed	<i>Aleurites moluccana</i> , <i>Aleurites fordii</i>	Tung, candlenut, candleberry, barnish tree, balucanat, otaheite	Wood preservative (oil), purgative (oil), asthma treatment (seed)	Saponins, phytotoxins	GI upset, hyporeflexia, latex: dermatitis
Valerian	<i>Valeriana officinalis</i>	Radix valerianae, Indian Valerian, red valerian	Anxiety, insomnia, antispasmodic	Valepotriates, valerenic acid	Sedation
White cohosh	<i>Actaea alba</i> , <i>Actaea rubra</i>	Baneberry, snakeberry, doll's eyes, coralberry	Emmenagogue	Protoanemonin	Headache, GI upset, delirium, circulatory failure
White willow bark	<i>Salix alba</i>	Common willow, European willow	Fever, pain astringent	Salicin	Salicylate toxicity: GI upset, tachypnea, anion gap metabolic acidosis, tinnitus, CNS toxicity, hyperthermia, cerebral edema, ARDS, coagulopathy

(Continued)

**TABLE 43–1** Selected Dietary Supplements, Popular Use, and Potential Toxicities (Continued)

Herbal	Scientific Name	Other Common Names	Traditional and Popular Usage	Active or Toxic Ingredient(s)	Adverse Effects
Wild lettuce	<i>Lactuca virosa</i> <i>Lactuca sativa</i>	Lettuce opium, prickly lettuce	Sedative, cough suppressant, analgesic	Unknown	Sedative, potentiates other sedatives
Woodruff	<i>Galium odoratum</i>	Sweet woodruff	Wound healing, tonic, varicose veins, antispasmodic	Coumarin	Hepatotoxicity, bleeding
Wormwood	<i>Artemisia absinthium</i>	Absinthes	Sedative, analgesic, antihelminthic	Thujone	Psychosis, hallucinations, seizures
Yarrow	<i>Achillea millefolium</i>	Bloodwort, carpenter's grass, dog daisy, nosebleed	Heal wounds, viral symptoms, digestive disorder, diuretic	Unknown	Contact dermatitis
Yew	<i>Taxus baccata</i>	Yew	Antispasmodic, cancer remedy	Taxine	Dizziness, dry mouth, bradycardia, cardiac arrest
Yohimbe	<i>Pausinystalia yohimbe</i>	Yohimbi, yohimbehe	Body building, aphrodisiac, stimulant	Yohimbine	Hypertension, abdominal pain, weakness

ADHD = attention-deficit/hyperactivity disorder; ARDS = acute respiratory distress syndrome; CHF = congestive heart failure; CNS = central nervous system; DMT = dimethyltryptamine; GI = gastrointestinal; HIV = human immunodeficiency virus; LSD = lysergic acid diethylamide.

(tonka beans [*Dipteryx odorata*]) have anticoagulant activities. Cardiac glycosides defined as cardioactive steroids (Chap. 62) are found in foxglove (*Digitalis* spp) and oleander (*Nerium oleander*).

**Fixed oils** are esters of long-chain fatty acids and alcohols. Herbs containing fixed oils are generally used as emollients, demulcents, and bases for other products. Generally, they are the least active and least dangerous of all plant- and animal-derived dietary supplements. Examples include olive (*Olea europaea*) and peanut (*Arachis hypogaea*) oils.

## PHARMACOKINETICS AND TOXICOKINETICS

For many dietary supplements, the details of absorption, distribution, metabolism, and excretion are poorly characterized. Many dietary supplements simply have not been studied rigorously. In addition, inadequately regulated manufacturing practices lead to a lack of consistency in dietary supplements. This lack of consistency poses challenges in attempts to research kinetics of plant- and animal-derived dietary supplements and limits the generalizability of results from the study of one product to other supposedly similar products. Contamination and adulteration further muddy efforts to document the therapeutic or toxic effects of a particular product. In addition, the inherent complexity and variation of the living organisms from which these preparations are derived creates unique considerations related to the pharmacokinetics and toxicokinetics of these products. This section describes considerations related to the pharmacokinetics and toxicokinetics of xenobiotics derived from complex, living organisms.

Dietary supplements are prepared using a variety of techniques, which introduces variation in the resulting product. The American Botanical Council describes a variety of methods for processing plants into dietary supplements, including decoction, infusion, tincture, liniment, poultice, essential oils, herbal infused oils, and percolation.<sup>2</sup> Herbalists extract xenobiotics from raw materials using water, oils, alcohols, or other solvents at different temperatures for varying lengths of time, leading to variation in content and concentration of xenobiotics that are available to be absorbed in the final product.

Some of the unique considerations relevant to understanding toxicokinetics and toxicodynamics of living organisms are illustrated through the example of the hepatotoxic PAs. The concentration of PA within a single species differs greatly depending on the environment in which a plant is grown.<sup>60</sup> The concentration of PA varies widely in different parts of the plant and is often higher in the roots and young shoots. The PA concentration of pepsin–comfrey capsules was found to vary from 270 mg/kg to 2,900 mg/kg, depending on whether leaves or roots were used as a source.<sup>56</sup> More than 600 different PA are recognized,<sup>94</sup> and an individual plant typically produces several different PAs, which vary greatly in toxicity. For example, in most *Senecio* species, the PA senecionine is

the backbone structure from which the seneciphylline, jacobine, and senkirkine PA are derived.<sup>75</sup> While a plant is alive, it bioconverts from one PA to another PA in response to environmental conditions, for example, in response to predation by herbivores.<sup>75</sup> Because certain PAs are much more toxic than others, the toxicity of an individual plant can change dynamically throughout the day. The production of PA also changes throughout the life cycle of a plant, often reaching peak shortly before flowering.<sup>60</sup> Even the death of a nearby PA-containing plant affects the PA content of the adjacent plants; for example, the PAs leached from rotting *Senecio jacobaea* plants are taken up by roots and translocated to leaves of nearby unrelated plant species.<sup>86</sup> There are many factors that create wide variation in the content and concentration of medicinally and toxicologically relevant xenobiotics contained in plants, reflecting the diversity of the natural world. This variation makes it difficult to predict the exact xenobiotics content without extensive testing of every individual dietary supplement product. After they have been absorbed, PAs are metabolized by cytochrome P450 monooxygenases in the liver to form highly reactive electrophilic metabolites that quickly adduct with nucleophilic groups in DNA and protein, explaining the predominance of hepatotoxicity.<sup>34</sup> However, a smaller amount of PAs are metabolized to less immediately reactive metabolites or bind to less nucleophilic groups and then are slowly released to act in other parts of the body. Therefore, some PAs are more likely to cause immediate liver damage and others more likely to persist over time and cause indolent damage to a variety of tissues.<sup>34</sup> Hydrolysis of ester bonds in PA leads to a nontoxic metabolite that is excreted by the kidney. Pyrrolizidine alkaloid toxicity is discussed in more detail later.

Because dietary supplements contain a multitude of biologically active compounds, one expects that these herb-derived compounds will have pharmacokinetic and pharmacodynamic interactions with one another, as well as with pharmaceutical products. These interactions are discussed in the next sections on pharmacologic interactions and pharmacologic synergy.

## PHARMACOLOGIC INTERACTIONS

A major concern related to the use of dietary supplements is the potential for interactions with pharmaceutical products (Table 43–2). Survey research suggests that 15% of patients taking pharmaceutical products use herbal preparations concurrently, and many of these products pose a risk for pharmacologic interactions.<sup>57</sup> The risk is highest in pharmaceutical products with a narrow therapeutic index, such as warfarin and digoxin. Additionally, pharmacologic interactions are particularly problematic in patients taking daily medications when decreased xenobiotic concentrations lead to severe health consequences, such as antiviral medications for patients infected with HIV or immunosuppressant medications to prevent organ rejection in transplant patients.

TABLE 43–2 Selected Dietary Supplement–Drug Interactions

Herbal Preparation	Scientific Name	Reported Drug Interactions	Proposed Mechanisms
Danshen	<i>Salvia miltiorrhiza</i>	Increased risk of bleeding in patients on warfarin	Pharmacokinetic and pharmacodynamic mechanisms
Garlic	<i>Allium sativum</i>	Increased clotting time and INR in patients taking warfarin Decreased concentration of saquinavir	Pharmacokinetic effects via inhibition of CYP2E1 and induction of P-glycoprotein
Ginkgo	<i>Ginkgo biloba</i>	Enhanced sedative effects of trazodone and benzodiazepines; increased risk of bleeding in patients taking aspirin, warfarin, and NSAIDs Increased concentration of digoxin Increases or decreases effects of antihypertensives, depending on dose, duration, and xenobiotic Lowers seizure threshold, decreasing effectiveness of antiepileptics or increasing risk of seizure in drugs with proconvulsant effects Enhances the efficiency and reduce the extrapyramidal side effects of the classic antipsychotic haloperidol in patients with schizophrenia	Pharmacokinetic effects via induction of CYP2C19 activity and inhibition of intestinal and hepatic CYP3A4 activity Pharmacodynamic effects
Ginseng	<i>Panax ginseng</i>	Decreased INR in patients on warfarin Case reports of headache, tremulousness, and manic episodes in patients taking phenelzine	Both pharmacokinetic and pharmacodynamic effects
Kava	<i>Piper methysticum</i>	Enhances sedative effects of alcohol and benzodiazepines Increased “off” periods in patient on levodopa for Parkinson’s disease	Pharmacodynamic effects via GABA agonism and dopamine antagonism Pharmacokinetic effects via inhibition of CYP2E1, CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP3A4, CYP4A9, and CYP4A11
Licorice	<i>Glycyrrhiza glabra</i>	Modulates metabolism of corticosteroids, leading to mineralocorticoid excess	Pharmacokinetic effects via both inhibition and/or induction of CYP3A activity depending on dose or duration; also inhibits 5 $\alpha$ -, 5 $\beta$ -reductase, and 11 $\beta$ dehydrogenase
Piperine	<i>Piper nigrum</i> Linn, <i>Piper longum</i> Linn	Increased concentrations of propranolol, rifampin, spartein, theophylline, phenytoin	Pharmacokinetic effects via inhibition of P-glycoprotein and CYP3A4 in enterocytes and hepatocytes
St. John’s wort	<i>Hypericum perforatum</i>	Decreases concentration of amitriptyline, nortriptyline, alprazolam, midazolam, ciclosporin, digoxin, imatinib, irinotecan, methadone, indinavir, nevirapine, quazepam, simvastatin, tacrolimus, irinotecan, finasteride Decreases effectiveness of oral contraceptives Decreases INR in patients taking warfarin Increases or decreases fexofenadine concentration depending on duration of treatment Increased risk of serotonin syndrome in patients taking SSRIs or other serotonergic agents Increased effect of clopidogrel on platelet aggregation in clopidogrel-resistant patients	Pharmacokinetic effects via induction of CYP3A4, CYP2E1, CYP2C19, and P-glycoprotein Pharmacodynamic effect via inhibition of monoamine reuptake, leading to interactions with antidepressants Also pharmacodynamics effects via inhibition of COX-1, leading to decreased platelet aggregation

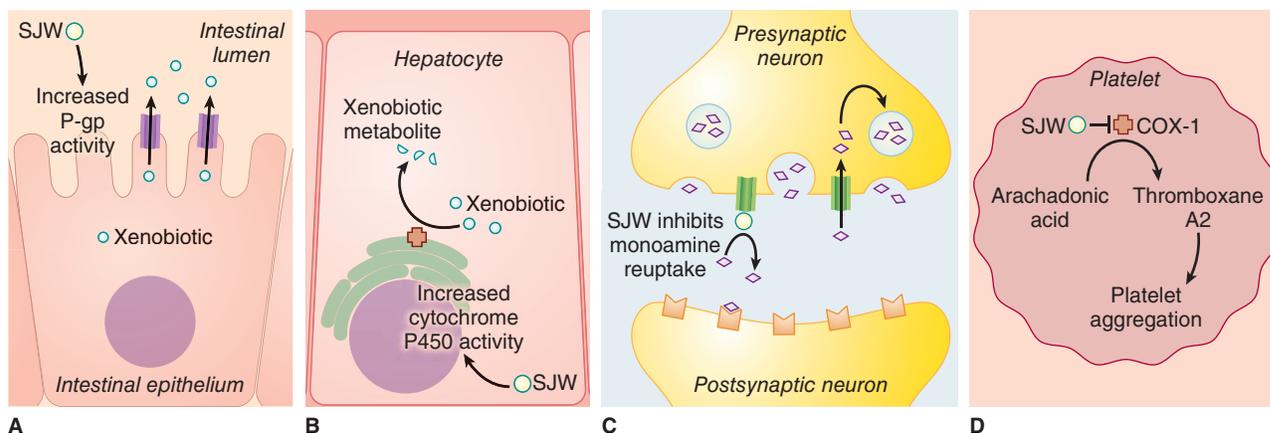

COX = cyclooxygenase; GABA =  $\gamma$ -aminobutyric acid; INR = international normalized ratio; NSAID = nonsteroidal antiinflammatory drug.

Data from references 25, 26, 55, 57, 70.

Pharmacologic interactions with dietary supplements occur via a variety of pharmacokinetic and pharmacodynamics mechanisms. Concurrent use of dietary supplements and pharmaceutical products causes pharmacokinetic interactions that affect absorption, distribution, metabolism, and excretion of various pharmaceuticals by competing for binding at drug transport sites and drug metabolism enzymes. Herbal preparations also cause pharmacodynamic interactions through action at end-organ receptors. Therefore, some dietary supplements acutely amplify or attenuate the effects of pharmaceutical products. Additionally, prolonged use of some dietary supplements affects the cellular expression of enzyme or transport systems within a body, leading to the development of subacute or chronic interactions that sometimes differ in character from the initial acute pharmacologic interactions.

St. John’s wort (*Hypericum perforatum*) is a common herbal preparation that exemplifies numerous pharmacokinetic and pharmacodynamics interactions (Fig. 43–1). St. John’s wort interacts with more than 20 different pharmaceutical products in humans and causes clinically significant consequences.<sup>25,55,57</sup> Chronic use of St. John’s wort induces P-glycoprotein (P-gp). P-glycoprotein is an efflux transporter located in the plasma

membranes of a variety of tissues. Increased P-gp activity in the intestines leads to decreased absorption and increased excretion of a variety of pharmaceutical products. Chronic use of St. John’s wort leads to decreased tissue concentrations of P-glycoprotein substrates.<sup>55,57</sup> St. John’s wort also induces CYP3A4, CYP2E1, and CYP2C19, leading to increased metabolism of pharmaceutical products that are substrates for these enzymes.<sup>57</sup> Through induction of P-gp and CYP enzymes, St. John’s wort use causes clinically significant pharmacokinetic interactions with a variety of pharmaceutical products. Concurrent use of St. John’s wort and the immunosuppressant medication cyclosporin leads to subtherapeutic concentrations of cyclosporin and rejection of transplanted organs in multiple cases.<sup>55</sup> St. John’s wort inhibits monoamine reuptake, increasing the levels of serotonin, norepinephrine, and dopamine in the synapse.<sup>119</sup> St. John’s wort has precipitated serotonin toxicity when combined with medications affecting serotonin utilization in numerous cases.<sup>55</sup> St. John’s wort increases the antiplatelet effects of clopidogrel via both pharmacokinetic and pharmacodynamics mechanisms. St. John’s wort induces CYP3A4, which increases the activation of clopidogrel, a prodrug, to its active metabolite.<sup>26,70</sup> Coadministration St. John’s wort was shown to increase

**FIGURE 43-1.** Mechanisms of pharmacokinetic and pharmacodynamic interactions involving St. John's wort (SJW). **(A)** Induction of P-glycoprotein (P-gp) in the intestinal mucosa. St. John's wort induces activity of the efflux transporter P-gp, leading to decreased absorption and increased excretion of a variety of xenobiotics along the intestinal mucosa. **(B)** Induction of CYP enzymes in hepatocytes. St. John's wort induces activity of CYP2E1 and CYP2C19. Increased activity of CYP enzymes leads to increased metabolism of many different xenobiotics. **(C)** Inhibition of monoamine reuptake in synapse. St. John's wort inhibits reuptake of monoamines serotonin, norepinephrine, and dopamine, increasing the amount of these neurotransmitters in the synapse and increasing risk of serotonin toxicity when combined with other xenobiotics that act on the serotonin system. **(D)** Inhibition of cyclooxygenase-1 (COX-1) in platelets. St. John's wort inhibits COX-1, decreasing conversion of arachidonic acid to thromboxane A2 and inhibiting platelet aggregation, especially in combination with other antiplatelet agents.

platelet inhibition in clopidogrel nonresponders after coronary stent placement.<sup>70</sup> Hyperforin, a constituent of St. John's wort, inhibits cyclooxygenase-1 (COX-1) in platelets,<sup>1</sup> suggesting that the enhanced platelet inhibition in clopidogrel nonresponders may have been due to a synergy of pharmacokinetics (CYP3A4 induction) and pharmacodynamics (COX-1 inhibition).

## PHARMACOLOGIC SYNERGY

Herbalists and traditional healers often suggest that the healing properties of plant- and animal-derived dietary supplements operate according to synergistic effects of multiple constituents that cannot be understood through a reductionist paradigm that focuses on the effects of a single active compound. Therefore, a whole plant is considered by some healers to be greater than the sum of its parts because the parts (ie, various xenobiotics) interact with one another to alter one another's pharmacologic effect. For example, the *Artemisia annua* plant contains artemisinin, from which the highly effective antimalarial drug artesunate was derived. Infusions of *A. annua* have been used for more than 1,000 years in China to treat symptoms related to malaria (periodic fever).<sup>65</sup> Traditionally prepared infusions of *A. annua* do not contain high enough concentrations of artemisinin to be effective against *P. falciparum*.<sup>65</sup> However, numerous in vitro and in vivo studies demonstrate that the dose of artemisinin necessary for effective activity against *P. falciparum* is much lower when administered in whole plant form than when artemisinin is used in isolation, possibly because of synergistic effects with flavonoids also contained in the plant.<sup>65</sup>

Herbalists often coadminister herbs, reasoning that different herbs work together in concert to have a greater effect or less toxicity than when administered alone. A well-described example of herbal synergy is the ayahuasca brew, which contains *Banisteriopsis caapi* and *Psychotria viridis*. The Quechua people administer ayahuasca in a traditional healing ceremony. According to the Quechua tradition, *B. caapi* is considered the spirit guide, and *P. viridis* is mixed to add light and color.<sup>100</sup> In fact, *B. caapi* contains harmala alkaloids that are monoamine oxidase inhibitors, increasing the oral bioavailability of the dimethyltryptamine (DMT) contained in *P. viridis* and collectively producing vivid hallucinations used in ceremonial rituals that neither plant could produce alone. Traditional Chinese medicine developed a detailed system based on synergy and describes four characteristics of medicinal preparations—the "principal" gives the primary therapeutic action, the "minister" amplifies the therapeutic action, the "assistant" decreases the toxicity of the preparation, and the "guide" helps bring the active xenobiotic to the proper location within the body.<sup>116</sup> The herbal preparation Xiao Chai Hu Tang, also

known as Sho-saiko-to, is a formula containing seven different herbs slows the progression of liver cirrhosis in clinical trials.<sup>32,88,116</sup> *Radix bupleuri* is considered the principal herb in the formula, with the other six herbs purported to serve various functions such as amplifying the therapeutic action of the principal herb or to reducing the toxicity of other herbs contained within the formula.<sup>59</sup> Preclinical research suggests that the effectiveness of the formula is greater when the herbs are used in combination than in isolation, suggesting the possibility of synergy.<sup>88,116</sup> More research is needed to elucidate whether traditional theories of synergy in plant- and animal-derived dietary supplements represent true pharmacokinetic or pharmacodynamics effects.

## ADULTERATION WITH PHARMACEUTICAL PRODUCTS

The FDA released reports of more than 80 sexual enhancement dietary supplements that were adulterated with unlisted ingredients such as pharmaceutical products.<sup>41</sup> The FDA has also found that many plant- and animal-derived dietary supplements contain unlisted and potentially harmful ingredients. Weight loss, sexual enhancement, and body building products are most commonly implicated in cases of unlisted pharmaceutical adulterants.<sup>39,41</sup>

Patent medications are ready-made preparations used by traditional Chinese herbalists. Patent medications sometimes contain combinations of herbs and pharmaceutical medications, such as acetaminophen, aspirin, antihistamines, or corticosteroids.<sup>22</sup> Many of these adulterant pharmaceuticals are not listed on the packaging and sometimes are not even approved for use in the United States.

For example, four cases of agranulocytosis followed consumption of *Chui Fong Tou Ku Wan*, a preparation that contains both aminopyrine (which is not approved for nonprescription sales in the United States) and phenylbutazone (which was withdrawn from the US market in the 1980s), neither of which is listed on the packaging.<sup>93</sup> Both aminopyrine and phenylbutazone are associated with agranulocytosis.

## CONTAMINATION WITH METALS AND MINERALS

Metal and mineral poisonings from lead, cadmium, mercury, copper, selenium, zinc, and arsenic are associated with plant- and animal-derived dietary supplement usage.<sup>19,21,30,92,98</sup> High concentrations of these salts in the product sometimes result from contamination during the growing or manufacturing process of some plant- and animal-derived dietary supplements. Pay-loo-ah, a red and orange powder used by the Hmong people as a fever and rash remedy, was contaminated with lead.<sup>17</sup> In one study, 20% of surveyed Ayurvedic products produced in South Asia and sold on a nonprescription

basis in stores in the Boston area contained potentially harmful concentrations of lead, mercury, or arsenic.<sup>96</sup> A follow-up study determined that a similar 21% of Ayurvedic products sold through the Internet also contained potentially harmful concentrations of these metals irrespective of whether manufacture occurred in the United States or India.<sup>97</sup> Herbal balls, hand-rolled mixtures of herbs and honey produced in China, are often associated with arsenic and mercury contamination.<sup>37</sup> Hai-ge-ten (clamshell powder) contamination with copper, chromium, arsenic, or lead has been described.<sup>54</sup> In some cases, as with cinnabar (mercuric sulfide) and calomel (mercurous chloride), these ingredients are intentionally included for purported medicinal benefit.<sup>61</sup> Ayurvedic remedies are either herbal only or *rasa shastra*, which, based on ancient traditional healing of India, deliberately combines metals such as gold, silver, copper, zinc, iron, lead, tin, and mercury and are used by the majority of the Indian population.<sup>19,91,96,97</sup> Azarcon (lead tetroxide) and greta (lead oxide) are used by an estimated Mexican families for treatment of *empacho*.<sup>611</sup> In Spanish, *empacho* means “blocked intestine,” but it refers to any type of chronic digestive problem, including such diverse symptoms as constipation, diarrhea, nausea, vomiting, anorexia, apathy, and lethargy. Azarcon and greta are fine powders with total lead contents varying from 70% to more than 90%.<sup>611</sup> Treatment of metal toxicity in this context consists of ceasing consumption of the offending product and use of an appropriate chelator when indicated. For more information on toxicity of various metals, please see Chaps. 86, 93, and 95.

## PATHOPHYSIOLOGY AND CLINICAL MANIFESTATIONS

### Amygdalin

Amygdalin is a cyanogenic glycoside that is contained in many different plants, and it is most abundant in the seeds of several fruits from the *Rosaceae* family. The highest concentrations of amygdalin have been found in the seeds of familiar fruits such as green plums (10 mg/g), apricots (14 mg/g), black plums (mg/g), peaches (7 mg/g), and red cherries (4 mg/g).<sup>10</sup> Amygdalin is also known as laetrile and “vitamin B<sub>17</sub>,” although it is not a vitamin. Amygdalin in the form of laetrile has been advertised as a cancer treatment despite lack of evidence of effectiveness.<sup>89</sup> Amygdalin is enzymatically metabolized to form glucose, benzaldehyde, and hydrogen cyanide. The degree to which cyanide production occurs is unpredictable and varies based on temperature, acidity, and contribution of  $\beta$ -glucosidase enzymes from ingested plant matter, intestinal bacteria flora, and the tissue of exposed individual. Cyanide toxicity is more likely to occur after oral ingestion than after intravenous (IV) administration.<sup>89</sup> Cyanide inhibits multiple enzymes, including cytochrome oxidase. Inhibition of cytochrome oxidase disrupts oxidative phosphorylation within the electron transport chain and prevents cells from being able to use oxygen to produce adenosine triphosphate even when oxygen is available. Cyanide poisoning leads to acidosis, elevated lactate, and cardiovascular collapse. A 4-year-old child presented with cyanide toxicity after he received IV and oral “vitamin B<sub>17</sub>.”<sup>99</sup> For more information about cyanide poisoning, see Chap. 123 and Antidotes in Depth: A41 and A42.

### Aconites

Aconites are derived from the roots of plants from the genus *Aconitum*. In China, aconite usually is derived from *Aconitum Carmichaelii* (chuan wu) or *A. kuznezoffii* (caowu). In Europe and the United States, aconite is derived from *A. napellus*, commonly known as *monkshood* or *wolfsbane*. Aconites are traditionally used to treat fever and pain and to induce diuresis and diaphoresis. Aconite toxicity is caused by C19 diterpenoid-ester alkaloids, including aconitine, mesaconitine, and hypaconitine.<sup>23</sup> Aconitine binds to the open state of voltage-sensitive sodium channels in heart, nervous system, and muscles, leading to increased and prolonged sodium influx through these channels.<sup>23</sup> Paresthesias of the oral mucosa and entire body may be followed by nausea, vomiting, diarrhea, and hypersalivation and then by progressive skeletal muscle weakness. In the heart, the sodium channel effects of aconite poisoning lead to increased inotropy, delayed afterdepolarization, and early afterdepolarization, all of which cause a variety of dysrhythmias, including torsade de pointes, ventricular ectopics, ventricular tachycardia, and

ventricular fibrillation.<sup>23,28</sup> Central nervous system toxicity leads to centrally mediated bradycardia and hypotension.<sup>23</sup> The onset of symptoms occurs from 5 minutes to 4 hours after ingestion. Aconite content varies depending on the plant species, the part of the plant used, the season of harvest, and the type of processing of the plant. Estimated fatal dose is 2 mg of pure aconitine, 5 mL of aconite tincture, or 1 g of the wild plant.<sup>23</sup> No specific antidote exists to treat aconite poisoning (Chaps. 57 and 118).

### Aristolochic Acids

The *Aristolochia* genus contains more than 500 species, many of which are used as herbal remedies by a variety of healing traditions. Traditional indications include treatment of infections and cancer and as a weight loss agent. *Aristolochia* plants contain toxic aristolochic acids, which cause aristolochic acid nephropathy (AAN) and urothelial cancer in dose-dependent fashion. The relationship between AA and kidney injury was first described in the early 1990s when an epidemic of kidney failure in more than 100 individuals in Belgium was linked to the use of *Aristolochia fangchi*, also known as birthwort, heart-wort, or fangchi, in a weight-loss regimen.<sup>110,111</sup> Since then, hundreds of cases of AAN were identified in more than 10 countries.<sup>50,118</sup> Aristolochic acids form covalent adducts with DNA, leading to dysfunction in DNA transcription and replication, ultimately causing cell cycle arrest.<sup>74</sup> Patients with AAN typically present with elevated serum creatinine, hypertension, anemia, glucosuria, proteinuria, white blood cell casts in the urine, and small kidneys with irregular cortical outlines on imaging.<sup>74</sup> A study of 300 patients with AAN in China described three different clinical presentations based on dose and duration of use.<sup>118</sup> Short-term, low-dose usage is associated with acute tubular dysfunction, which typically does not develop into end-stage renal disease (ESRD). Short-term, high-dose usage causes acute kidney injury, which generally progresses to ESRD over 1 to 7 years and sometimes leads to urothelial malignancy. Chronic use even at low levels frequently leads to ESRD within 2 years and poses an extremely high risk for urothelial cancer. A cumulative dose of more than 200 g of AA-containing compounds is suggested to pose a higher risk of urothelial carcinoma<sup>84</sup> (Chap. 27).

### Artemisia, Absinthe, and Artesunate

Wormwood (*Artemisia absinthium*) extract has a long history of use for a variety of traditional medical indications, most prominently as an antihelminthic, and it is also the main ingredient in absinthe liquor. This volatile oil is a mixture of  $\alpha$ - and  $\beta$ -thujone, which are monoterpene ketones.<sup>67,68</sup> Chronic absinthe use was formerly believed to cause “absinthism,” characterized by psychosis, hallucinations, intellectual deterioration, and seizures, although now it is believed that these symptoms more likely resulted from alcoholism than wormwood itself.<sup>67,68</sup> Thujone causes seizures in research animals in a dose-dependent fashion, possibly through effects on  $\gamma$ -aminobutyric acid (GABA) receptors.<sup>67,68</sup> Consumption of absinthe liquor does not expose individuals to enough thujone to be likely to have a significant pharmacologic effect.<sup>67,68</sup> A case of wormwood-induced seizures, rhabdomyolysis, and acute kidney failure was described involving a patient who purchased from the Internet and consumed approximately 10 mL essential oil of wormwood, believing it was absinthe liquor.<sup>114</sup> Treatment remains supportive.

Sweet wormwood (*Artemisia annua*) has a very long history of use as an antimalarial and is the source for the pharmaceutical artesunate, an important antimalarial drug. Artemisia is also thought to have antiviral and anticancer activity. *A. annua* has a long history of use, with essentially no reports of major toxicity, and is therefore likely safe<sup>65</sup> (Chap. 55).

### Betel Nut and Other Nicotinic

Betel (*Areca catechu*) is chewed by an estimated 200 million people worldwide for its euphoric effect. As an herb, it used as a digestive aid and as a treatment for cough and sore throat. Its active ingredient is arecoline, a direct-acting nicotinic agonist. The betel leaf also contains a phenolic volatile oil and an alkaloid capable of producing sympathomimetic reactions. Arecoline is a bronchoconstrictor, although weaker than methacholine, and sometimes exacerbate bronchospasm in patients with asthma chewing betel nut.<sup>107</sup> Treatment for betel nut toxicity is supportive. Long-term use of betel

nut is associated with leukoplakia and squamous cell carcinoma of the oral mucosa.<sup>85</sup> Many other herbal preparations have nicotinic effects. Examples of plants with nicotinic constituents include blue cohosh, broom, horse chestnut, lobelia, and tobacco.

### Bufadienolides and Other Cardioactive Steroids

Chàn Su, Kyushin, and “Love Stone” contain the secretions of the parotid and sebaceous glands of the toad *Bufo bufo gargarizans* or *Bufo melanostictus*.<sup>15,63</sup> Chàn Su and Kyushin are traditional Chinese medicines used for the treatment of tonsillitis, sore throat, furuncle, palpitations, and cardiovascular diseases.<sup>31</sup> “Love Stone,” also known as “Black Stone” and “Rock Hard,” is an “aphrodisiac” intended for topical use.<sup>18</sup> Bufo toad extracts contains two groups of toxic compounds: digoxinlike cardioactive steroids consisting of bufadienolides, and the tryptamine alkaloid bufotenin. Clinical findings after ingestion are similar to those after cardioactive steroid poisoning, including GI effects and dysrhythmias. Several fatalities have been related to oral ingestion of Bufo toad extracts intended for use as topical aphrodisiacs,<sup>18</sup> as well as a fatality related to chàn su that was mislabeled as a different preparation and unintentionally administered as a tea.<sup>63</sup> Severe toxic reactions and death are reported after mouthing toads, “licking,” or eating an entire toad, or ingesting toad soup or toad eggs.<sup>16</sup> Assays for serum digoxin unreliably cross-react with bufadienolides but sometimes qualitatively assist in making a presumptive diagnosis.<sup>18,63</sup> For more information on cardioactive steroid poisoning, see Chap. 62 and Antidotes in Depth: A22.

### Ephedra, Ephedrine, and Pseudoephedrine

Members of the genus *Ephedra* generally consist of erect evergreen plants resembling small shrubs. Common names include ma huang, sea grape, yellow horse, desert tea, squaw tea, and Mormon tea. *Ephedra* species have a long history of use as stimulants and for the management of bronchospasm. They contain the alkaloids ephedrine and pseudoephedrine among others.<sup>52</sup> In large doses, ephedrine causes nervousness, headache, insomnia, dizziness, hypertension, palpitations, skin flushing, tingling, vomiting, anxiety, restlessness, mania, and psychosis. Between 1995 and 1999, more than 1,000 cases of possible ephedra toxicity were reported to the FDA,<sup>53,95</sup> including many cases of serious cardiovascular events, such as stroke, myocardial infarction, and sudden death. In many cases when serious cardiovascular events occurred, the reported dose ingested appeared to be within the range recommended by the manufacturer’s guidelines.<sup>95</sup> Analysis of commercially available ephedra products has demonstrated substantial variation in ephedrine, pseudoephedrine, and other ephedra alkaloid content both between brands and between lots of the same brand, with some products containing only 1 mg of ephedrine per unit dose, and other containing nearly 20 mg per unit dose.<sup>52,95</sup> Additionally, analysis of the ratios of alkaloids within these purportedly herbal products suggested that some were likely adulterated with pharmaceutical ephedrine.<sup>52</sup> In 2004, the FDA banned the sale of ephedra-containing dietary supplements, and the number of reported poisonings dropped precipitously after the ban was enforced.<sup>120</sup> However, other herbal preparations, such as bitter orange (*Citrus aurantia*), contain ephedra-like alkaloids (synephrine), are still widely available, and may pose risk for cardiovascular events.<sup>8</sup> The treatment is similar to that for other CNS stimulants (Chap. 49).

### Glycyrrhizin and Other Endocrine Disruptors

Licorice root from the *Glycyrrhiza glabra* plant is widely used as an ingredient in candies, lozenges, teas, and herbal preparations. The root contains a saponin glycoside, glycyrrhizin, that inhibits 11- $\beta$ -hydroxysteroid dehydrogenase, decreasing conversion of cortisol to cortisone.<sup>112</sup> Chronic licorice consumption increases cortisol concentrations, which then act on renal mineralocorticoid receptors. Repeated consumption of licorice root causes a syndrome of mineralocorticoid excess with hypokalemia, sodium and water retention, peripheral edema, hypertension, and weakness.<sup>112</sup> Administration of 100 g of licorice by mouth over as little as 7 days resulted in decreased serum potassium concentrations below the normal range in previously healthy participants.<sup>35</sup> There are multiple reports of individuals experiencing cardiac dysrhythmias

or cardiac arrest in the context of chronic licorice consumption and profound hypokalemia.<sup>29,36</sup> *Serenoa repens*, commonly known as saw palmetto, interferes with estrogen and testosterone metabolism. It is sometimes used as a treatment for benign prostatic hypertrophy and alopecia. It has been associated with hot flashes followed by premature menarche in young girls.<sup>78,80</sup>

### Harmala Alkaloids

*Peganum harmala* and *Banisteriopsis caapi* contain various pharmacologically active alkaloids; the most toxicologically relevant are the  $\beta$ -carboline alkaloids (also known as harmala alkaloids), such as harmine and harmaline.<sup>79,90</sup> *Peganum harmala* is used in the Middle East and northern Africa for numerous traditional indications such as an antibiotic, anxiolytic, analgesic, emmenagogue, and abortifacient and as a protector against evil eye.<sup>72</sup> *Banisteriopsis caapi* is used in combination with plants containing DMT (eg, *Psychotria viridis*) to produce a hallucinogenic state as part of an ethnobotanical hallucinogenic ritual, or ayahuasca ceremonies. High doses of  $\beta$ -carboline alkaloids produce confusion, hallucinations, psychomotor agitation, diffuse tremors, ataxia, vomiting, diarrhea, slight elevation of body temperature, and mild changes in heart rate and blood pressure.<sup>44,79</sup> Harmaline is approximately twice as toxic as harmine based on animal research.<sup>72</sup> Although content varies dramatically, a typical dose of ayahuasca contain approximately 100 to 200 mg of harmine and 20 to 40 mg of harmaline.<sup>44,69</sup> A typical dose of *P. harmala* is 3 to 8 g of seeds, containing approximately 120 to 350 mg of harmine and 170 to 450 mg of harmaline.<sup>72,79</sup> When consumed alone or as traditionally recommended, the alkaloids from *P. harmala* and *B. caapi* have a high therapeutic index, and even individuals who consume much larger than recommended quantities and require medical attention generally recover within several hours without long-term sequelae.<sup>44,72,79</sup> But the globalization of ayahuasca has produced a proliferation of inexperienced “shamans,” some of whom are not trained in the traditional preparation of the ayahuasca brew, and sometimes add novel ingredients, leading to poor outcomes. Several fatalities related to ayahuasca are described in the medical literature. However, the cases in which details regarding the origin and content of the ayahuasca brew are available seem to suggest that severe intoxication and death have primarily resulted when inexperienced individuals prepare brews containing novel ingredients such as atropine, scopolamine, or nicotine or when nontraditional ingredients are substituted for traditional ingredients, for example when methoxy-*N,N*-dimethyltryptamine is used in place of DMT or when *P. harmala* is used in place of *B. caapi*.<sup>44,69</sup> In addition, the monoamine oxidase inhibition of  $\beta$ -carboline alkaloids poses risks for more severe serotonin toxicity when combined with other medications or drugs with serotonergic effects.<sup>44</sup> Management of  $\beta$ -carboline alkaloid toxicity is primarily supportive (Chaps. 69 and 71). For more information on psychoactive dietary supplement usage, see Table 43–3.

### Kratom

Kratom (*Mitragyna speciosa*) is used as an analgesic, antidepressant, anti-diarrheal, euphoriant, stimulant, and opioid replacement. Kratom contains the alkaloids mitragynine and 7-hydroxymitragynine, which are a  $\mu$ -opioid receptor agonists, and additionally have activity on adrenergic, serotonergic, and dopaminergic receptors.<sup>43</sup> Mitragynine also appears to interfere with rectifier potassium currents, presenting a risk for sudden cardiac death.<sup>106A</sup> A study of mitragynine kinetics in 10 chronic kratom users found that 30 mg of mitragynine was enough to produce desired kratom effects without undesired side effects.<sup>113</sup> However, mitragynine concentration varies greatly in kratom products, and kratom users have been documented to use as much as 275 mg of mitragynine to produce desired effects.<sup>113</sup> The toxic and lethal doses of mitragynine are not well-defined. Kratom has potential for abuse given its  $\mu$ -opioid activity and sometimes produces a withdrawal syndrome when discontinued after chronic use.<sup>43,66</sup> However, despite kratom’s opioid agonism, it has not been reported to cause respiratory depression.<sup>66,113</sup> Kratom use has been associated with hepatotoxicity, psychosis, seizure, coma, and death.<sup>5,43</sup> The United States Drug Enforcement Agency has considered classifying kratom as a controlled substance; however, at this time, it remains unscheduled and is regulated as a standard dietary supplement.

TABLE 43–3 Constituent Psychoactive Xenobiotics in Herbal Preparations

Labeled Ingredient	Scientific Name	Usage	Active Ingredients	Classification of Effect
Broom	<i>Cytisus scoparius</i>	Smoke for relaxation	l-Sparteine	Sedative
Caapi	<i>Banisteriopsis caapi</i>	Ingested in combination with other plants as part of ayahuasca ritual	Harmala alkaloids	Inhibits monoamine oxidase to increase bioavailability of DMT
California poppy	<i>Eschscholzia californica</i>	Smoke	Protopine, escholtzine, allocryptopine, californidine, chelirubine, sanguinarine, and macarpine	Euphoriant, sedative
Catnip	<i>Nepeta cataria</i>	Smoke or tea	Nepetalactone	Euphoriant
Ch'an Su	<i>Bufo bufo gargarizans</i> , <i>Bufo bufo melanostictus</i>	Smoke or lick	Bufotenin	Hallucinogen
Cinnamon	<i>Cinnamomum camphora</i>	Smoke, essential oil	Cinnamaldehyde	Stimulant
Chacruna	<i>Psychotria viridis</i>	Ingested as part of ayahuasca ritual	DMT	Hallucinogen
Clove	<i>Syzygium aromaticum</i>	Smoke in cigarette or "kreteks"	Eugenol	Euphoriant
Damiana	<i>Turnera diffusa</i>	Smoke	Unknown	Stimulant, hallucinogen
Hops	<i>Humulus lupulus</i>	Smoke or tea	Humulone, lupulone → methylbutenol	Sedative
Hydrangea	<i>Hydrangea paniculata</i>	Smoke	Hydrangin, saponin	Stimulant
Ibogaine	<i>Tabernanthe iboga</i>	Ingested	Ibogaine	Hallucinogen
Juniper	<i>Juniperus macrospoda</i>	Smoke as hallucinogen	Unknown	Hallucinogen
Jurema	<i>Mimosa hostilis</i>	Smoke, tea or used as source for extraction DMT	DMT	Hallucinogen
Kava kava	<i>Piper methysticum</i>	Smoke or tea	Kava lactones	Hallucinogen
Kola nut	<i>Cola acuminata</i>	Smoke, tea, or capsules	Caffeine, theobromine, kolanin	Stimulant
Kratom	<i>Mitragyna speciosa</i>	Smoke, tea, or capsules	Mitragynine	Euphoriant, stimulant, opioid
Lobelia	<i>Lobelia inflata</i>	Smoke or tea	Lobeline	Euphoriant
Mandrake	<i>Mandragora officinarum</i>	Tea	Atropine, scopolamine	Hallucinogen
Mate	<i>Ilex paraguayensis</i>	Tea	Caffeine	Stimulant
Mormon tea	<i>Ephedra nevadensis</i>	Tea	Ephedrine	Stimulant
Morning glory	<i>Ipomoea violacea</i>	Ingest seeds	D-lysergic acid amide (ergine)	Hallucinogen
Nutmeg	<i>Myristica fragrans</i>	Tea	Myristicin	Hallucinogen
Passion flower	<i>Passiflora incarnata</i>	Smoke, tea, or capsules	Harmala alkaloids	Sedative
Periwinkle	<i>Catharanthus roseus</i>	Smoke or tea	Indole alkaloids	Hallucinogen
Prickly poppy	<i>Argemone mexicana</i>	Smoke	Protopine, bergerine, isoquinolones	Analgesic
Salvia	<i>Salvia divinorum</i>	Smoke, chew	Salvinorum A	Hallucinogen
Snakeroot	<i>Rauwolfia serpentina</i>	Smoke or tea	Reserpine	Tranquilizer
Syrian rue	<i>Peganum harmala</i>	Smoke, ingested	Harmala alkaloids, quinazoline alkaloids	Serotonin toxicity, abortifacient
Thorn apple	<i>Datura stramonium</i>	Smoke or tea	Atropine, scopolamine	Hallucinogen
Tobacco	<i>Nicotiana</i> spp	Smoke	Nicotine	Stimulant
Valerian	<i>Valeriana officinalis</i>	Tea or capsules	Chatinine, velerine alkaloids	Sedative
Wild lettuce	<i>Lactuca sativa</i>	Smoke	Unknown	Analgesic, sedative
Wormwood	<i>Artemisia absinthium</i>	Smoke, tea, spirits	Thujone	Analgesic
Yohimbe	<i>Pausinystalia yohimbe</i>	Smoke or tea	Yohimbine	Hallucinogen

DMT = dimethyltryptamine.

### Pyrrolizidine Alkaloids and Other Hepatotoxins

The PAs are potent hepatotoxins that are estimated to be present in 3% of the world's flowering plants, among various diverse plant families.<sup>102</sup> Within the family Asteraceae, plants in the *Senecio* genus are responsible for numerous human poisonings when brewed in herbal teas or contaminating food products in diverse locations.<sup>115</sup> Within the family Fabaceae, plants in the *Crotalaria* genus have caused many cases of liver injury and death when brewed in bush tea in Jamaica and South Africa.<sup>115</sup> Within the family Boraginaceae, *Heliotropium* species caused thousands of poisonings when it contaminated wheat fields in Tajikistan and Afghanistan.<sup>112</sup> Also within the family Boraginaceae, plants within the *Symphytum* genus, commonly known as comfrey, cause poisonings when ingested as medicinal preparations or teas.<sup>115</sup> Numerous healing traditions throughout the world use plants that contain PAs. Many different PAs exist, which are classified into three categories based on structure: retronecine type, otonecine type, and platynecine type.<sup>94</sup> The retronecine types are the most toxic of the PAs.<sup>94</sup> Pyrrolizidine alkaloids contained in plants are protoxins that are activated by numerous hepatic cytochrome P450 isoenzymes to form highly reactive pyrrole esters, which then quickly form adducts with protein and DNA. Acute exposure to PAs causes a highly characteristic syndrome of hepatic sinusoidal hypertrophy and venous occlusion, resulting in hepatic sinusoidal obstruction syndrome, hepatomegaly, and cirrhosis<sup>34</sup> (Chap. 21). Chronic low-level exposure causes cirrhosis with a pathological profile that is difficult to distinguish from cirrhosis resulting from other causes, as well as pulmonary artery hypertension.<sup>34</sup> In addition, animal models and human cell cultures have demonstrated that PA metabolites bind to the gene encoding the tumor suppressor protein p53 and produce a wide variety of cancers in animal models, although definitive linkage to human cancers is not yet established.<sup>34</sup> It is recommended that daily intake of PA not exceed 7 ng/kg of dehydro-PAs per kilogram of body weight.<sup>34</sup>

Other herbs and extracts that have been associated with hepatotoxicity include black cohosh,<sup>14</sup> chaparral,<sup>51,101</sup> *Garcinia cambogia*,<sup>45</sup> germander,<sup>14</sup> green tea extract,<sup>14,45</sup> kava extract,<sup>14</sup> linoleic acid,<sup>45</sup> ma huang,<sup>45</sup> pennyroyal,<sup>3,7</sup> usnic acid,<sup>45</sup> and 1,3-dimethylamylamine.<sup>45</sup> In addition, products with the following names have been associated with liver toxicity: Herbalife,<sup>45</sup> Hydroxycut,<sup>45</sup> LipoKinetix,<sup>45</sup> and OxyELITE.<sup>45</sup>

### Strychnine

The Chinese herbal preparation maqianzi is derived from the dried seeds of *Strychnos nux vomica* plant and is traditionally used in China to treat rheumatism and other musculoskeletal complaints. Maqianzi contains the alkaloids strychnine and brucine that compete with glycine for binding to glycinergic chloride channels, resulting in a loss of inhibition from the ventral horn of the spinal cord. Strychnine poisoning is characterized by involuntary generalized muscle contractions, respiratory and metabolic acidosis, rhabdomyolysis, and hyperthermia. The traditional recommended dose for maqianzi ranges from 0.3 to 1.2 g by mouth, and the processed seeds generally contain 1% to 2% strychnine.<sup>24,64,121</sup> A randomized placebo-controlled trial<sup>64</sup> of maqianzi with verified strychnine and brucine content found that eight participants of 60 who were administered standard treatment doses of maqianzi developed a “nux vomica response” characterized by “slight sweating, tongue rigidity, girdle sensation, and slight muscular twitch.” An additional patient in this study had a more severe strychnine-like reaction that was not described in detail. This demonstrates there is overlap between the therapeutic dose and the toxic dose for this product. A woman who was reportedly administered 15 g of maqianzi developed muscle spasms and difficulty breathing, and her symptoms resolved within several hours.<sup>24</sup> For management of strychnine poisoning, see Chap. 114.

### Tropane Alkaloids, Anticholinergics

Many plants contain the tropane alkaloids atropine (D,L-hyoscyamine), hyoscyamine, and scopolamine (L-hyoscine). They are sometimes used therapeutically for treatment of asthma and occasionally are mistakenly

included in herbal teas.<sup>20</sup> Signs and symptoms of anticholinergic poisoning include mydriasis, diminished bowel sounds, urinary retention, dry mouth, flushed skin, tachycardia, and agitation. Mildly poisoned patients usually require only supportive care and sedation with IV benzodiazepines. More severe cases are treated with IV physostigmine (Antidotes in Depth: A11).

### SUMMARY

- Plant- and animal-derived supplements are diverse products, many of which have a long history of traditional and cultural use.
- Plant- and animal-derived dietary supplement are poorly regulated and sometimes contain dangerous contaminants and adulterants.
- Plant- and animal-derived dietary supplements contain xenobiotics that are pharmacologically active and have the potential to cause toxicity and pharmacologic interactions.
- The physiologic and toxicologic effects of plant- and animal-derived supplements are diverse and often difficult to predict because of immense variation in the content and composition of these products.

### Acknowledgment

## VITAMINS

Beth Y. Ginsburg

Vitamins are essential for normal human growth and development.<sup>5</sup> By definition, a vitamin is a substance present in small amounts in natural foods, is necessary for normal metabolism, and the lack of which in the diet causes a deficiency disease.<sup>46</sup>

A standard North American diet is sufficient to prevent overt vitamin deficiency diseases.<sup>71,82</sup> However, suboptimal vitamin status is common in Western populations and is a risk factor for chronic diseases such as cardiovascular disease, cancer, and osteoporosis.<sup>71,82</sup> Groups at risk include older adults, hospitalized patients, alcohol-dependent individuals, pregnant women those with gastrointestinal disorders, those following gastric bypass interventions and other patients with poor nutritional status. The American Dietetic Association posits that the best strategy for promoting optimal health and reducing chronic disease is to choose a wide variety of nutrient-rich foods, and the use of supplements can help some people meet their nutritional needs.<sup>167</sup> Health care professionals should identify patients with poor nutrition or other reasons for increased vitamin needs and offer guidance on vitamin supplementation. It is suggested without evidence that because most people do not consume an optimal amount of vitamins by diet alone, adults should take vitamin and mineral supplements because the potential benefits likely outweigh any risk in the general population and may be particularly beneficial in older adults. The choice of supplement should reflect the patient's age, gender, stage of life, health status, risk factors, and family history and should involve physician guidance.<sup>253</sup>

National Health and Nutrition Examination Survey (NHANES) data collected from 2003 to 2006 demonstrate that dietary supplement use was reported by 49% of the population age 1 year and older, an increase of approximately 10% from NHANES data from 1988 to 1994, with 79% of users taking them daily for the previous 30 days.<sup>22</sup> Among adults and children, multivitamins and multiminerals (MVMs) were the most commonly reported dietary supplement, with 33% of the population reporting use. The Council for Responsible Nutrition (CRN), a trade organization for the dietary supplement industry, has conducted yearly surveys since 2000 on the prevalence of dietary supplement use in the United States. Analysis of their data from 2007 to 2011 demonstrate an increased prevalence of dietary supplement use, 64% to 69% in adults, compared with previous NHANES surveys.<sup>1</sup> More recently, the CRN revealed in a 2015 report that the percentage of American adults taking dietary supplements has remained consistent at 68% from the years 2012 to 2015.<sup>188</sup> Ninety-eight percent of these dietary supplement users take vitamins and minerals, the most popular category of supplements, with the top five including a multivitamin (78%), vitamin D (32%), vitamin C (27%), calcium (24%), and vitamin B/B complex (18%). The CRN reported that the primary reasons given for supplement use are for overall health and wellness and to fill dietary nutrient gaps.<sup>1</sup> Current data suggest minimal, if any, risk associated with MVM use at recommended daily intake levels in healthy people.<sup>253</sup> Unfortunately, many individuals share the mistaken beliefs that vitamin preparations provide extra energy or promote muscle growth and regularly ingest quantities of vitamins in great excess of the recommended dietary allowances (RDAs) (Table 44–1). The most commonly used MVM preparations generally do not exceed 100% of the RDA, but excessive vitamin intake is more likely to occur in MVM users who also take single vitamin supplements.<sup>214</sup> Excess vitamin intake also occurs in individuals taking an MVM who eat a healthy diet that includes fortified foods and beverages.<sup>182</sup> Some vitamins are associated with consequential adverse effects when ingested in very large doses. Adverse effects also are associated with the use of some vitamins at the RDA or at amounts less than or approaching the established tolerable upper intake level (UL) in certain populations.

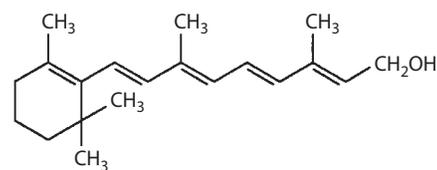

Individuals taking medications to reduce blood clotting, such as warfarin, should not take supplemental vitamin K because it is involved in blood clotting and reduces the effectiveness of warfarin and similar medications.

Vitamins was consistently among the 15 most common substance categories involved in human exposures reported to poison control centers in the United States and the sixth most common substance category in children 5 years old and younger, from 2011 to 2015 (Chap. 130). Vitamins were also among the top 25 substance categories with the greatest increase in serious exposures during this time period. However, vitamins were not among the substance categories associated with the largest number of fatalities.

Vitamins can be divided into two general classes. Most of the vitamins in the *water-soluble* class have minimal toxicity because they are stored to only a limited extent in the body. Thiamine, riboflavin, pantothenic acid, folic acid, and biotin are not reported to cause any toxicity after ingestion.<sup>5</sup> Vitamin B<sub>12</sub> also is in the water-soluble class of vitamins. It exists in several forms and contains the mineral cobalt. Compounds with vitamin B<sub>12</sub> activity are therefore given the group name of *cobalamins*. There is no toxicity associated with excess vitamin B<sub>12</sub> intake via ingestion of food and supplements in healthy individuals.<sup>124</sup> Ascorbic acid (vitamin C), nicotinic acid (vitamin B<sub>3</sub>), and pyridoxine (vitamin B<sub>6</sub>) are water-soluble vitamins with associated toxicity syndromes. The *fat-soluble* vitamins bioaccumulate and therefore have toxic potentials that greatly exceed those of the water-soluble group. Vitamins A, D, and E (but not K) are associated with toxic syndromes after very large overdose or chronic overuse. The adverse effect secondary to vitamin K is limited to severe and sometimes fatal anaphylactoid reactions with rapid administration of the intravenous (IV) preparation.<sup>80</sup>

### VITAMIN A

MW = 272.43 Da  
Therapeutic serum concentration = 65–275 IU/dL  
16.6–83.3 mcg/dL

### History and Epidemiology

Two independent groups discovered vitamin A in 1913.<sup>171,193</sup> They reported that animals fed an artificial diet with lard as the sole source of fat developed a nutritional deficiency characterized by xerophthalmia. They found that this deficiency could be corrected by adding to the diet a factor contained in butter, egg yolks, and cod liver oil. They named the substance “fat-soluble vitamin A.” The chemical structure of vitamin A was determined in 1930.<sup>135</sup> Vitamin A is also found naturally in liver, fish, cheese, and whole milk. In the United States and other parts of the world, including some developing countries, many cereal, grain, dairy, and other products, as well as infant formulas, are fortified with vitamin A.<sup>8,257</sup>

Vitamin A toxicity occurs in people who ingest large doses of preformed vitamin A in their daily diets. Inuits in the 16th century recognized that ingestion of large amounts of polar bear liver caused a severe illness characterized by headaches and prostration.<sup>81</sup> Arctic explorers in the 1800s knew of the poisonous qualities of polar bear liver and described an acute illness after its ingestion.<sup>90</sup> Explorers also described a condition among the Inuit population known as *pibloktoq*, or “Arctic hysteria,” characterized by depression,

<sup>a</sup>These values represent the adequate daily intakes. Values without an <sup>a</sup> represent the recommended dietary daily allowances. <sup>b</sup>, <sup>c</sup>.

NE = niacin equivalent; RAE = retinol activity equivalents;  $\alpha$ -TA =  $\alpha$ -tocopherol acetate.

Data from Dietary Reference Intakes for Calcium, Phosphorous, Magnesium, Vitamin D, and Fluoride (1997); Dietary Reference Intakes for Thiamin, Riboflavin, Niacin, Vitamin B<sub>6</sub>, Folate, Vitamin B<sub>12</sub>, Pantothenic Acid, Biotin, and Choline (1998); Dietary Reference Intakes for Vitamin C, Vitamin E, Selenium, and Carotenoids (2000); Dietary Reference Intakes for Vitamin A, Vitamin K, Arsenic, Boron, Chromium, Copper, Iodine, Iron, Manganese, Molybdenum, Nickel, Silicon, Vanadium, and Zinc (2001); Dietary Reference Intakes for Water, Potassium, Sodium, Chloride, and Sulfate (2005); and Dietary Reference Intakes for Calcium and Vitamin D (2011). These reports may be accessed via [www.nap.edu](http://www.nap.edu).

echolalia, insensitivity to extreme cold, and seizures, and believed it to be related to ingestion of polar bear liver and other organ meats.<sup>197</sup> Vitamin A toxicity was implicated in the etiology of pibloktoq because somatic and behavioral effects of vitamin A toxicity closely paralleled many of the symptoms reported in Inuit patients diagnosed with pibloktoq.<sup>145</sup> However, the toxic substance in polar bear liver was not identified as vitamin A until 1942.<sup>215</sup> The vitamin A content of polar bear liver is as high as 34,600 IU/g (10,400 RAE/g), supporting the view that vitamin A is the toxic factor in the liver.<sup>217</sup>

Vitamin A toxicity was reported in an adult who chronically ingested large amounts of beef liver,<sup>123</sup> as well as after ingestion of the liver of the grouper fish *Cephalopholis boenak*, which has a high content of vitamin A.<sup>47</sup> Ingestion of whale and seal liver, as well as the livers of large fish, such as shark, tuna, and sea bass, also is associated with development of vitamin A toxicity.

Vitamin A toxicity usually is not expected to occur after ingestion of large doses of provitamin A carotenoids. Vitamin A–induced hepatotoxicity and neurotoxicity were believed to have developed in an 18-year-old woman who maintained a diet nearly limited to foods rich in the carotenoid beta-carotene, including pumpkin, carrots, and laver (nori), for several years.<sup>184</sup> However, she also included an unspecified, although reportedly small, amount of fish, red meat, and liver in her diet.

Most reported cases of vitamin A toxicity result from inappropriate use of vitamin supplements.<sup>24,27</sup> In the United States, 28% of the population reported taking a dietary supplement containing vitamin A in 2003 to 2006.<sup>22</sup> Overall, vitamin A toxicity is not common with only 396 to 447 single exposures per year reported to United States poison control centers from 2011 to 2015. Of

these, most cases did not result in any outcome, and there were only nine or less moderate outcomes per year and one or no major outcomes per year.

Vitamin A is present in two forms. Preformed vitamin A as retinol is derived from retinyl esters, its storage form, in animal sources of food. Provitamin A carotenoids are vitamin A precursors and are found in plants. Among the carotenoids, beta-carotene is most efficiently made into retinol. The term *vitamin A* was classically only used to refer to the compound retinol. Currently, it is used to describe all retinoids, compounds chemically related to retinol that exhibit the biological activity of retinol. Retinol is converted in the body to the retinoids retinal and retinoic acid. Synthetic retinoids are developed via chemical modification of naturally occurring retinoids, often for a specific therapeutic purpose. Vitamin A activity is expressed in retinol activity equivalents (RAEs). One RAE corresponds to 1 mcg of retinol or 3.33 IU of vitamin A activity as retinol. One RAE also corresponds to 12 mcg of beta-carotene.

Vitamin A content varies widely among different food types. A 3-oz serving of cooked beef liver contains 30,325 IU (9,100 RAE) of vitamin A, and 1 cup of whole milk contains 305 IU (92 RAE) of vitamin A. Fish-liver oils, such as swordfish and black sea bass, have extremely large amounts of vitamin A, and some contain more than 180,000 IU (54,050 RAE) of vitamin A per gram of oil. Carotenoids are present in yellow and green fruits and vegetables. A raw carrot has a high beta-carotene content of approximately 20,250 IU (6,080 RAE). One half-cup serving of spinach contains approximately 7,400 IU (2,220 RAE) of beta-carotene, and an apricot or peach contains 500 to 600 IU (150–180 RAE). The average American diet provides about half of its daily vitamin A intake as carotenoids and about half as preformed vitamin A.<sup>9</sup>

The RDA of vitamin A is 900 mcg RAE/day (3,000 IU/day) for adult men and 700 mcg of RAE/day (2,300 IU/day) for women (Table 44-1).<sup>85</sup> The UL for adults is 3,000 mcg of RAE/day (9,900 IU/day).

As a group, retinoids have specific sites of action and varying degrees of biologic potency. Retinoic acid is primarily responsible for maintaining normal growth and differentiation of epithelial cells in mucus-secreting or keratinizing tissue.<sup>165</sup> Vitamin A deficiency results in the disappearance of goblet mucous cells and replacement of the normal epithelium with a stratified, keratinized epithelium. Dermal manifestations are the earliest to develop and include dry skin and hair and broken fingernails. In the cornea, hyperkeratization is called *xerophthalmia* and leads to permanent blindness. Alterations in the epithelial lining of other organ systems leads to increased susceptibility to respiratory infections, diarrhea, and urinary calculi. Vitamin A, in the form of 11-*cis*-retinal, plays a critical role in retinal function.<sup>250</sup> Deficiency results in *nyctalopia*, which is decreased vision in dim lighting, more commonly known as *night blindness*.

Vitamin A is prescribed for patients with specific dermatologic and ophthalmic conditions. Vitamin A toxicity often occurs in adults who continue to use the vitamin without medical supervision.<sup>91</sup>

Isotretinoin (Accutane), 13-*cis*-retinoic acid, is prescribed for treatment of severe cystic acne. Of concern is the teratogenicity associated with its use by pregnant women; therefore, it is contraindicated. There is no association between use of isotretinoin in men during the time of conception and birth defects. The iPLEDGE program is a mandatory United States Food and Drug Administration (FDA) Risk Evaluation and Mitigation Strategy for the distribution of isotretinoin that was initiated in 2006. Its goals are to inform prescribers, pharmacists, and patients about the serious risks of isotretinoin and safe-use conditions and to prevent fetal exposure to isotretinoin.<sup>126</sup> Components of the program include mandatory enrollment of male and female patients; documentation of a negative pregnancy test and birth control use; and prescriber, pharmacist, and patient education. The iPLEDGE program replaced the FDA's System to Manage Accutane-Related Teratogenicity (SMART) program that was initiated in 2002. Although both programs share many features, the SMART program was voluntary and did not include mandatory record keeping or reporting. A review after the implementation of the SMART program revealed an increase in the number of pregnant women prescribed isotretinoin compared with the previous year. It also revealed that prescribers were not providing adequate patient education regarding the risk of teratogenicity and that there was not compliance with essential portions of the pregnancy prevention program.<sup>213</sup>

All-trans-retinoic acid (ATRA), or tretinoin, is used as a differentiating chemotherapeutic in the treatment of acute promyelocytic leukemia (APL), a disease characterized by the accumulation of promyelocytic blasts in bone marrow caused by obstruction of differentiation of granulocytic cells.<sup>148</sup> All-trans-retinoic acid, in combination with anthracycline chemotherapy, improves the complete remission rate, often reported to be greater than 90%, and reduces the incidence of relapse to only 10% to 15% when used as maintenance therapy.<sup>75</sup> Acute promyelocytic leukemia differentiation syndrome (DS), previously known as ATRA syndrome or retinoic acid syndrome, is the main adverse effect and occurs in up 14% to 16% of patients who receive ATRA with an associated mortality rate of about 2%.<sup>199</sup> All-trans-retinoic acid also is used for the treatment of myelodysplastic syndrome and acute myelogenous leukemia.

### Pharmacology, Pharmacokinetics, and Toxicokinetics

Absorption of vitamin A in the small intestine is nearly complete. However, some vitamin A is eliminated in the feces when large doses are taken. The majority of vitamin A is ingested as retinyl esters, the storage form of retinol.<sup>165</sup> Retinyl esters undergo enzymatic hydrolysis to retinol by digestive enzymes in the intestinal lumen and brush border of the intestinal epithelial wall. A small portion of retinol is absorbed directly into the circulation, where it is bound to retinol-binding protein (RBP) and transported to the liver. Most of the retinol is taken into intestinal epithelial cells by RBP.<sup>190</sup> Subsequently, retinol is reesterified and incorporated into chylomicrons, which are released into the blood and taken up by the Ito cells of the liver. After large oral doses,

significant amounts of retinyl esters coupled to chylomicrons circulate in association with low-density lipoprotein (LDL) and are delivered to the liver. Approximately 50% to 80% of the total vitamin A content of the body is stored in the liver as retinyl esters.<sup>35</sup> The liver releases vitamin A into the bloodstream to maintain a constant plasma retinol concentration and is thus delivered to tissues as needed.

Carotenoid absorption requires bile and absorbable fat in the stomach or intestine. These components combine with carotenoids to form mixed lipid micelles that move into the duodenal mucosal cells via passive diffusion. Most beta-carotene that is metabolized undergoes central cleavage via oxidation to form retinal, which is then reduced to retinol. Retinol is then esterified with fatty acids and incorporated into chylomicrons, which are transported to the bloodstream via the lymphatics for delivery to the liver. Massive doses of beta-carotene are rarely associated with vitamin A toxicity because of decreased efficiency in absorption secondary to saturation of dissolution in bulk lipid, micellar incorporation, and diffusion caused by a reduction in the concentration gradient.<sup>196</sup> Unabsorbed beta-carotene is excreted in the feces. In addition, there is a decrease in the rate of conversion of carotenoids to vitamin A.<sup>63</sup> Excess absorbed beta-carotene is incorporated with lipoproteins and released into the bloodstream via the lymphatics for delivery to the adipose tissue and adrenals for storage.

The normal serum retinol concentration is approximately 30 to 70 mcg/dL.<sup>230</sup> These concentrations are maintained at the expense of hepatic reserves when insufficient amounts of vitamin A are ingested. A normal adult liver contains enough vitamin A to fulfill the body's requirements for approximately 2 years.<sup>177</sup> Excessive intake of vitamin A is not initially reflected by elevated serum concentrations because vitamin A is soluble in fat but not in water. Instead, hepatic accumulation is increased. This storage system allows for cumulative toxic effects. Although no quantitative relationship exists between the magnitude of liver stores and serum concentrations of vitamin A, in chronic vitamin A toxicity, serum concentrations are generally higher than 3.49  $\mu\text{mol/L}$  (95 mcg/dL).<sup>27</sup> Vitamin A has a half-life of 286 days.<sup>233,255</sup> Retinoids undergo a variety of metabolic and conjugation pathways and are subsequently eliminated in the feces, urine, or bile.

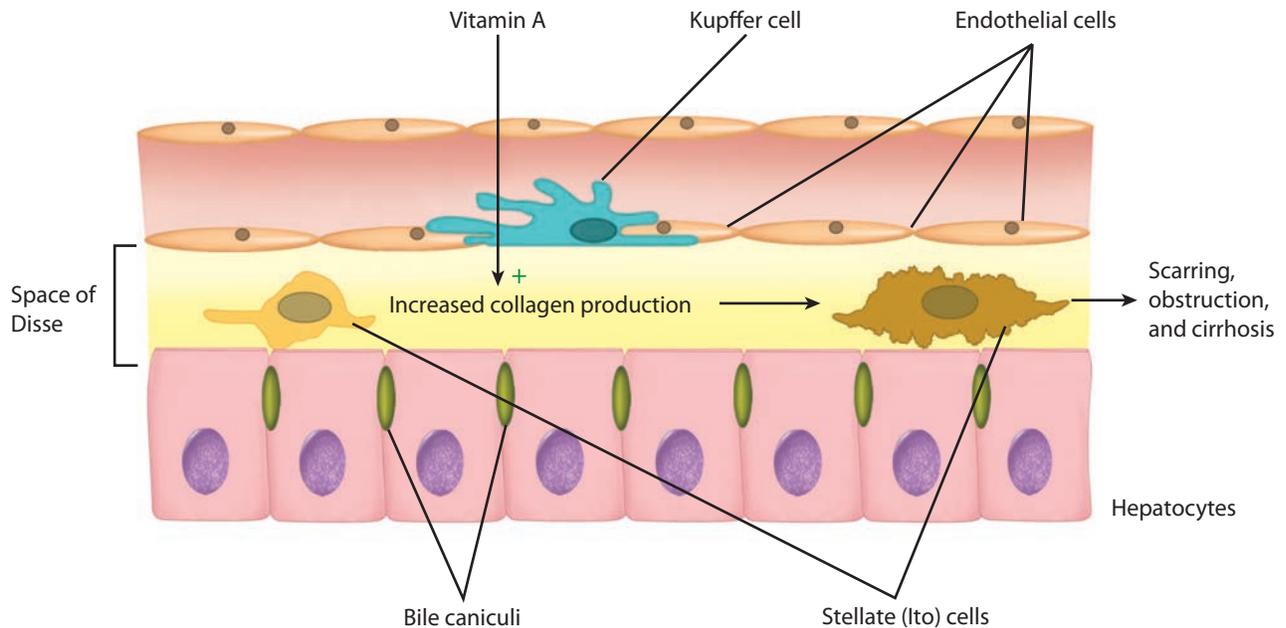

### Pathophysiology

The mechanism of action for many of the toxic effects of vitamin A is at the nuclear level. Retinoic acid influences gene expression by combining with nuclear receptors.<sup>165</sup> Retinoids also influence expression of receptors for certain hormones and growth factors. Thus, they can influence the growth, differentiation, and function of target cells.<sup>158</sup>

In epithelial cells and fibroblasts, retinoids affect changes in nuclear transcription, resulting in enhanced production of proteins such as fibronectin and decreased production of other proteins such as collagenase.<sup>163</sup> Excessive concentrations of retinoids where goblet cells are present lead to the production of a thick mucin layer and inhibition of keratinization. In addition, lipoprotein membranes have increased permeability and decreased stability, resulting in extreme thinning of the epithelial tissue.

In vitro studies in bone demonstrate that high doses of vitamin A are capable of directly stimulating bone resorption and inhibiting bone formation leading to osteoporosis. This effect is secondary to increased osteoclast formation and activity and inhibition of osteoblast growth.<sup>186</sup>

Hepatotoxicity develops secondary to a single large acute overdose or ingestion of smaller doses if taken over a prolonged time.<sup>91,142</sup> A total of 90% of hepatic vitamin A stores are in the Ito, or fat-storing, cells of the liver, which are in the perisinusoidal space of Disse, and are responsible for maintaining normal hepatic architecture.<sup>109,110</sup> Ito cells undergo hypertrophy and hyperplasia as vitamin A storage increases.<sup>142</sup> This results in transdifferentiation of the Ito cell into a myofibroblast-like cell that secretes a variety of extracellular matrix components, leading to narrowing of the perisinusoidal space of Disse, obstruction to sinusoidal blood flow, and noncirrhotic portal hypertension (Fig. 44-1).<sup>58,97,119,136,142,222</sup> Continued ingestion of vitamin A and hepatic storage leads to obliteration of the space of Disse, sinusoidal barrier damage, perisinusoidal hepatocyte death, fibrosis, and cirrhosis (Chap. 21).<sup>119,129,142,218</sup>

**FIGURE 44-1.** Schematic demonstration of hepatotoxicity resulting from excessive deposition of vitamin A in the Ito cells of the liver.

Vitamin A toxicity has long been thought to be the cause of the severe headaches and papilledema associated with idiopathic intracranial hypertension (IIH).<sup>209</sup> Increased concentrations of unbound retinol in the cerebral spinal fluid (CSF) of patients with IIH suggest that vitamin A is involved in the pathogenesis of IIH.<sup>240,254</sup> However, the mechanisms by which vitamin A leads to increased intracranial pressure (ICP) in IIH are not definitively known.<sup>209</sup> Unbound, circulating retinol and retinyl esters are proposed to interact with cell membranes and produce damage by membranolytic surface-active properties.<sup>127</sup> In the central nervous system (CNS), disruption of cell membrane integrity might lead to disruption of CSF outflow, thereby producing signs and symptoms consistent with IIH.<sup>93,127,139,162</sup> Vitamin A also can lead to intracranial hypertension via enhanced transcription of genes involved in CSF secretion or absorption.<sup>102</sup> Another explanation for the association of vitamin A with IIH involves the role of RBP as a signaling molecule altering CSF secretion or absorption.<sup>155</sup>

### Clinical Manifestations

Clinical toxicity correlates well with total body vitamin A content, which is a function of both dose and duration of administration. A randomized double-blind trial, in which 390 women received 400,000 IU (120,000 RAE) of vitamin A as a single dose were compared with 380 women who received placebo, suggested that dosing at this level is well tolerated.<sup>122</sup> Doses of 100,000 IU (30,000 RAE) of vitamin A in infants aged 6 to 11 months and 200,000 IU (60,000 RAE) of vitamin A every 3 to 6 months for infants and children aged 12 to 60 months result in few adverse events.<sup>26</sup> The minimal dose required to produce toxicity in humans is not established. However, an animal study demonstrated a median lethal acute dose in monkeys of 560,000 IU (168,000 RAE) per kilogram of body weight.<sup>161</sup> In this study, all monkeys receiving more than 300,000 RAE/kg (999,000 IU/kg) died, but none died at a dose of 100,000 RAE/kg (333,000 IU/kg).

Vitamin A toxicity occurs more frequently secondary to chronic ingestions of vitamin A. Hepatotoxicity typically requires vitamin A ingestions of at least 50,000 to 100,000 IU/day (15,000 to 30,000 RAE/day) for months or years.<sup>8,142</sup> One study found that in patients with vitamin A-induced hepatotoxicity, the average daily vitamin A intake was higher in patients who developed cirrhosis (135,000 IU/day, 40,500 RAE/day) compared with patients who developed noncirrhotic liver disease (66,000 IU/day, 20,000 RAE/day).<sup>89</sup> However, case reports have documented hepatotoxicity resulting from vitamin A dosages as low as 25,000 IU/day (7,500 RAE/day),<sup>91,142</sup> a dosage widely available in nonprescription vitamin A preparations.

Symptoms of an acute massive overdose of vitamin A often develop within hours to 2 days after ingestion.<sup>177</sup> Initial signs and symptoms include headache, papilledema, scotoma, photophobia, seizures, anorexia, drowsiness, irritability, nausea, vomiting, abdominal pain, liver damage, and desquamation.<sup>177</sup> Nonspecific symptoms and manifestations include fatigue, fever, weight loss, edema, polydipsia, dysuria, hyperlipidemia, anemia, and menstrual abnormalities.

Chronic toxicity of vitamin A affects the skin, hair, bones, liver, and brain. The most common skin manifestations include xerosis, which is associated with pruritus and erythema, skin hyperfragility, and desquamation.<sup>64,65,260</sup> Retinoid toxicity causes hair thinning and even diffuse hair loss in 10% to 75% of patients.<sup>84,95,138</sup> In addition, the characteristics of the hair change after regrowth. Hair sometimes becomes permanently curly or kinky.<sup>15</sup> Nail changes include a shiny appearance, brittleness, softening, and loosening.<sup>76</sup> Dryness of mucous membranes develops with chapped lips and xerosis of nasal mucosa, which sometimes is associated with nasal bleeding.<sup>55</sup>

Hypercarotenemia develops when massive doses of beta-carotenes are ingested over several weeks. It manifests as a yellow-orange skin discoloration that can be differentiated from jaundice by the absence of scleral icterus and usually is not associated with morbidity.

Findings from epidemiologic studies are consistent with bone loss and a resulting increase in fracture risk. In northern Europe, the region with the highest incidence of osteoporotic fractures, dietary intake of vitamin A is high. A study of this population demonstrated that reduced bone density and increased risk of hip fracture correlate with vitamin A intake.<sup>173</sup> This finding is supported by other studies demonstrating an increased risk of hip fracture among women with elevated serum vitamin A concentrations and in women ingesting large daily amounts of vitamin A as supplements or in their diets.<sup>78,191</sup>

Other musculoskeletal findings include skeletal hyperostoses, most commonly affecting the vertebral bodies of thoracic vertebrae, extraspinal tendon and ligament calcifications, soft tissue ossification, cortical thickening of bone shafts, periosteal thickening, and bone demineralization.<sup>55,177,179</sup> Many of these findings are apparent on radiographs. Patients often complain of bone and joint pain and muscle stiffness or tenderness. Hypercalcemia, with low or normal parathyroid hormone (PTH) concentrations, likely results from increased osteoclast activity and bone resorption.<sup>37</sup> Patients with chronic kidney disease are at increased risk for developing hypercalcemia at vitamin A doses lower than usual toxic doses secondary to decreased renal metabolism of retinol. This complication occurred in an 8-year-old boy with chronic kidney disease after a dosage of 12,000 IU/day

Vitamin A

(3,600 RAE/day) for at least 2 years.<sup>62</sup> Premature epiphyseal closure in children is reported.<sup>205</sup> Teratogenic effects include interference with skeletal differentiation and growth.<sup>37</sup>

The degree of hepatotoxicity appears to correlate with the dose of vitamin A and chronicity of use. Hepatotoxicity occurs in humans after an acute ingestion of a massive dose of vitamin A (>600,000 IU or 180,000 RAE).<sup>142</sup> With large doses, cirrhosis develops and leads to portal hypertension, esophageal varices, jaundice, and ascites.<sup>59,91,142</sup> Hepatotoxicity is associated with elevations in bilirubin, aminotransferases, and alkaline phosphatase concentrations.

Idiopathic intracranial hypertension is characterized by elevated ICP in the absence of a structural anomaly. It occurs in patients with altered endocrine function, systemic diseases, or impaired cerebral venous drainage or ingestion of various xenobiotics, including excessive vitamin A (Table 44–2).<sup>7</sup> The syndrome is most common in young obese women, but the etiology remains unknown in most cases. The first case of IIH associated with vitamin A toxicity was described in 1954.<sup>90</sup> However, the symptoms were first described in 1856 by an Arctic explorer who noted vertigo and headache after eating polar bear liver.<sup>229</sup> Patients typically present with headache and visual disturbances, including sixth nerve palsies, visual field deficits, and blurred vision, and have a normal mental status. Despite severe papilledema, visual loss often is minimal. However, permanent blindness sometimes results from optic atrophy.<sup>160</sup> Other manifestations of neurotoxicity include ataxia, fatigue, depression, irritability, and psychosis.<sup>33</sup>

Isotretinoin is effective in the management of acne. However, its use is associated with teratogenicity. It is thought to interfere with cranial neural crest cells, which contribute to the development of both the ear and the conotruncal area of the heart, and may cause malformed or absent external ears or auditory canals and conotruncal heart defects.<sup>144</sup> Although studies do not show a teratogenic risk with topical preparations, case reports describe fetal malformations associated with topical preparation use during pregnancy.<sup>19,42,131,156,228</sup> In addition, mucocutaneous abnormalities, IIH, corneal opacities, hypercalcemia, hyperuricemia, musculoskeletal symptoms, liver function abnormalities, elevated triglyceride concentrations, and spontaneous abortion are reported.<sup>12,83,89,106,107</sup>

Acute promyelocytic leukemia differentiation syndrome (DS), previously known as ATRA syndrome, is the main adverse effect of treatment with ATRA. The pathophysiology of DS is not well understood but involves an inflammatory response. Proposed mechanisms include tissue infiltration of APL cells,

particularly in the lungs but also in the liver, spleen, and heart, and leukocyte extravasation.<sup>146</sup> The onset of symptoms and manifestations is typically 2 to 21 days after initiation of ATRA.<sup>199</sup> The hallmarks of DS are fever and respiratory distress.<sup>199,216</sup> Other common signs and symptoms include an elevated white blood count, dyspnea, pulmonary edema, pulmonary infiltrates, and pleural and pericardial effusions.<sup>199,216</sup> Weight gain, bone pain, headache, hypotension, congestive heart failure, acute kidney injury, and hepatotoxicity occur less commonly.<sup>199,216</sup> There are no established criteria for diagnosis, but some suggest that three signs and symptoms are needed.<sup>216</sup> Elevated leukocyte counts at diagnosis or rapidly increasing counts during ATRA treatment predict the development of DS. Addition of dexamethasone to the ATRA treatment regimen decreases the incidence of DS from 25% of APL patients to approximately 15% and its mortality rate to 1%.<sup>74</sup> However, other data demonstrated a 17% occurrence of DS despite concurrent use of steroids, and not all authors support its use.<sup>199,259</sup>

### Diagnostic Testing

The diagnosis of vitamin A–associated hepatotoxicity is supported by histologic evidence of Ito cell hyperplasia with fluorescent vacuoles on liver biopsy.<sup>91</sup> Laboratory testing should include serum electrolytes, including calcium, hepatic enzymes, a complete blood cell count, and a vitamin A concentration. Because the liver has a large storage capacity for excess vitamin A, hepatotoxicity occurs before an elevation in the serum concentration of vitamin A, which may be normal or even low, in the setting of an acute overdose. As the hepatic storage capacity is overwhelmed, the serum concentration rapidly rises in a nonlinear fashion. Further evaluation should be guided by the clinical presentation and the need to evaluate for other causes. It may include bone radiographs, computed tomography, magnetic resonance angiography and venography, and lumbar puncture.

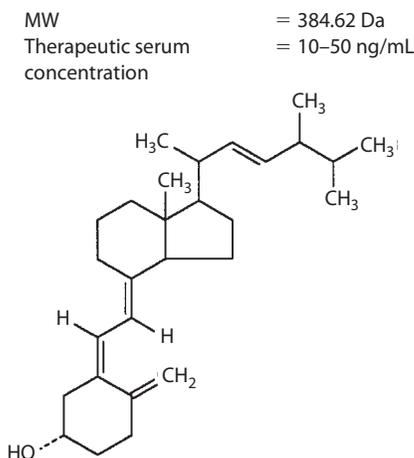

### Treatment

Management of a patient with a recent acute, large overdose of vitamin A should begin with gastrointestinal (GI) decontamination. This can be accomplished with a 50-g dose of activated charcoal. In extremely large overdoses that are expected to produce significant toxicity, it would be reasonable to perform gastric lavage if airway compromise is not a concern. Discontinuation of vitamin A and supportive care are the mainstays of treatment. Hypercalcemia should be treated in the usual manner with IV fluids, loop diuretics, calcitonin, bisphosphonates, and steroids, as needed depending on the severity.<sup>32</sup> Although most signs and symptoms of vitamin A toxicity resolve within 1 week after vitamin A discontinuation and treatment, papilledema, desquamation, and skeletal abnormalities sometimes persist for several months.

Idiopathic intracranial hypertension requires more aggressive therapy. Indications for treatment include visual field loss and symptoms of elevated ICP.<sup>209</sup> Acetazolamide, a carbonic anhydrase inhibitor, is the most commonly used treatment for IIH.<sup>209</sup> It is usually started at a dosage of 0.5 to 1 g/day and gradually increased until clinical improvement is seen to 3 to 4 g/day.<sup>209</sup> Acetazolamide has teratogenic effects in animals and is designated FDA Pregnancy Category C. Topiramate, a partial carbonic anhydrase inhibitor that is used in the treatment of migraine headaches and epilepsy, has demonstrated efficacy comparable to acetazolamide in the treatment of patients with IIH.<sup>43</sup> Furosemide is considered second-line treatment but is recommended in patients who cannot tolerate or receive acetazolamide.<sup>36,209</sup> The role of corticosteroids in the treatment of IIH is controversial, and they should not be used chronically for the treatment of papilledema.<sup>36</sup> However, a short course of high-dose corticosteroids is recommended in patients with acute visual loss from fulminant papilledema.<sup>157</sup> Lumbar puncture with CSF drainage is reasonable in patients with extremely high ICP but should be done in conjunction with a neurology consultation.

Treatment of APL DS involves prompt administration of corticosteroids, commonly dexamethasone 10 mg IV twice daily until symptoms resolve followed by a 2-week taper.<sup>216</sup> In patients with severe DS, an oncology consultation should be obtained to determine if ATRA should be discontinued or another chemotherapeutic, typically cytarabine, should be added to ATRA in patients with high white blood cell counts.<sup>199</sup> All-trans-retinoic acid can be reintroduced upon resolution of DS.

## VITAMIN D

### History and Epidemiology

Rickets, a disease of urban children living in temperate zones, was thought to result from the lack of a dietary factor or adequate sunshine. In 1919, two independent groups demonstrated that rickets could be prevented or cured by either the addition of cod liver oil to the diet or exposure to sunlight.<sup>121,174</sup> Vitamin D is found in cod liver oil and other foods, including butter, cheese, and cream, which contain 12 to 40 IU/100 g (0.3–1 mcg/100 g), eggs, which contain 25 IU/100 g (0.6 mcg/100 g), and fatty fish, such as salmon and mackerel, which contain 150 to 550 IU/100 g (4–14 mcg/100 g) and 1,100 IU/100 g (28 mcg/100 g), respectively. Some foods typically are fortified with vitamin D, including cereals, bread, and milk.<sup>116</sup> Many dietary supplements, such as multivitamins, contain vitamin D.

Rickets has been eliminated as a major public health concern in children in Europe and North America since the fortification of milk with vitamin D. Outbreaks of vitamin D poisoning subsequently occurred in Europe in the 1950s because of excessive fortification of milk and cereals to compensate for wartime nutritional deprivation of children.<sup>60</sup> This vitamin D poisoning led to a period of prohibition of vitamin D fortification of foods.<sup>116</sup> Subsequently, vitamin D supplementation resumed, and a study showed that milk and infant formulas rarely contain the amount of vitamin D stated on the label and may be either significantly underfortified or overfortified, leading to vitamin D deficiency or toxicity.<sup>116</sup> Vitamin D toxicity secondary to excessively fortified food and supplements continues to be a problem. In 2016, the Danish health authority recalled a vitamin D supplement that contained 75 times the recommended concentration of vitamin D.<sup>18</sup> At least 20 children had toxic serum concentrations of vitamin D, and more than half of these children had hypercalcemia.<sup>219</sup> Many cases of vitamin D toxicity result from continued supplementation of vitamin D and calcium initially prescribed for treatment of hypoparathyroidism, osteoporosis, or osteomalacia but inappropriately continued due among other reasons to inadequate patient physician communication.<sup>57,150,200</sup> Vitamin D toxicity is reported in dogs secondary to vitamin D<sub>3</sub> exposure in the form of rodenticides.<sup>86</sup>

Vitamin D deficiency should not occur in individuals who eat a well-balanced diet and are exposed to adequate sunlight. Casual exposure of cutaneous tissues to ultraviolet light during the summer months should produce adequate vitamin D storage for winter months.<sup>103</sup> Total body sun exposure provides the vitamin D equivalent of 10,000 IU/day (250 mcg/day); the body requires only a total vitamin D supply of 4,000 IU/day (100 mcg/day).<sup>248</sup> Breast-fed infants require supplemental vitamin D if they have limited exposure to sunlight because the vitamin D content of human milk is extremely low.<sup>5</sup> Other groups susceptible to vitamin D deficiency include older adults, vegans, persons with darkly pigmented skin, persons without adequate sunlight exposure such as those living in institutions and those who fastidiously employ sunblock.

The National Academy of Sciences issues dietary recommendations at the request of the governments of the United States and Canada. The IOM

found that although average total vitamin D intake was below the median requirement in North Americans, average serum concentrations of vitamin D as 25-hydroxyvitamin D (25(OH)D) were above the 20 ng/mL (50 nmol/L) concentration that the IOM determined to be needed for good bone health. It suggested that sun exposure contributes meaningful amounts of vitamin D and that most of the population is meeting its needs for vitamin D.<sup>50</sup> Despite this finding, in 2010, the IOM revised its dietary reference intakes with an increase in the RDA for vitamin D across all age groups (Table 44–1). The new RDA assumes minimal sunlight exposure and is 600 IU/day (15 mcg/day) for nonelderly adults. The new RDA may lead to an increased number of persons taking vitamin D either by prescription or in the form of a dietary supplement. In addition, the IOM found that testing for vitamin D deficiency has become widespread.<sup>50</sup> However, the measurements or cutpoints of sufficiency or deficiency used by laboratories are not based on scientific studies, and there is no central regulatory authority determining which cutpoint should be used. The IOM found that many laboratories use an inappropriately high cutpoint for deficiency, thereby leading to an increased number of diagnoses of vitamin D deficiency and possibly persons taking unnecessary vitamin D supplements.

In 2014, a Canadian report questioned the accuracy of the IOM's calculations in determining the RDA for vitamin D.<sup>246</sup> Their statistical analysis of the same data used by the IOM estimated an RDA approximately 10-fold higher than that of the IOM, which they acknowledge is well above the established UL. The authors cited two studies conducted in northern Canada in areas with limited sun exposure, in which 10% to 15% of participants who were taking vitamin D supplements to ensure compliance with the RDA had 25(OH)D serum concentrations less than 50 nmol/L.<sup>98,130</sup> They suggest that if the IOM's calculations were accurate, this percentage should not exceed 2.5%. At this time, the IOM has not made any changes to its 2010 recommendations.

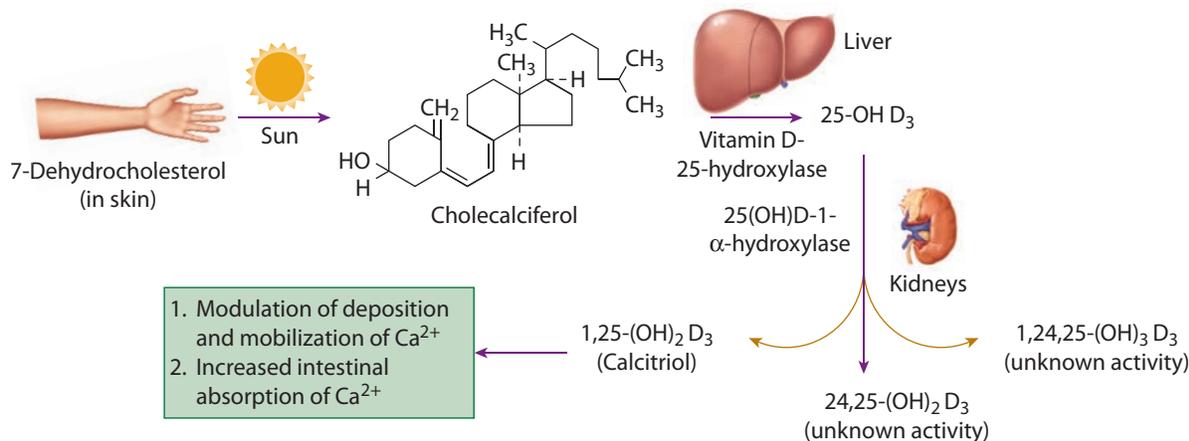

The use of vitamin D supplements to prevent and treat a variety of illnesses has increased substantially over the past decade.<sup>105</sup> Vitamin D deficiency is linked to autoimmune disease, cancer, cardiovascular disease, depression, dementia, infectious disease, musculoskeletal decline, and more.<sup>105</sup> However, the IOM concluded that vitamin D supplementation for indications other than musculoskeletal health is not supported by adequate scientific evidence.<sup>50</sup> Vitamin D is used for the prophylaxis and treatment of rickets, osteomalacia, and osteoporosis. It is also used for the treatment of hypoparathyroidism and skin conditions, including psoriasis.

Vitamin D is the name given to both ergocalciferol (vitamin D<sub>2</sub>) and cholecalciferol (vitamin D<sub>3</sub>). In humans, both forms of vitamin D have the same biologic potency although vitamin D<sub>3</sub> is typically recommended. One microgram of vitamin D is equivalent to 40 IU of vitamin D.

### Pharmacology, Pharmacokinetics, and Toxicokinetics

Vitamin D itself is not biologically active and must go through extensive metabolism to an active form, whether it is ingested from a food source in the form of vitamin D<sub>2</sub> and D<sub>3</sub> or synthesized in the body. Vitamin D<sub>3</sub> is synthesized in the skin from 7-dehydrocholesterol (provitamin D<sub>3</sub>) in a reaction catalyzed by ultraviolet B irradiation (Fig. 44–2).<sup>150</sup> Vitamin D<sub>3</sub> then is bound to vitamin D-binding protein, a protein that also binds vitamin D from the diet, and afterward enters the circulation. In the endoplasmic reticulum of the liver, vitamin D is metabolized to 25(OH)D by vitamin D-25-hydroxylase.<sup>87</sup> After forming, 25(OH)D is again bound to vitamin D-binding protein and transported to the proximal convoluted tubule in the kidney for hydroxylation to 1,25-dihydroxyvitamin D {1,25(OH)<sub>2</sub>D}, or calcitriol, by 25(OH)D-1- $\alpha$ -hydroxylase.<sup>87</sup> This enzyme is subject to inhibition by increases in serum calcium. After forming, 1,25(OH)<sub>2</sub>D is secreted back into circulation, bound to vitamin D-binding protein, and delivered to target cells where it binds to receptors.

Vitamin D might be more appropriately called a hormone rather than a vitamin because it is synthesized in the body, circulates in the blood, and then binds to receptors to evoke its biologic action. The primary role of vitamin D is regulation of calcium homeostasis via interactions with the intestines and bones. Protein-bound calcitriol is taken up by cells and then

**FIGURE 44-2.** Schematic representation of the synthesis and physiologic response to vitamin D.

binds to a specific nuclear vitamin D receptor protein that, in turn, binds to regulatory sequences on chromosomal DNA.<sup>150</sup> The result is induction of gene transcription and translation of proteins that carry out the cellular functions of vitamin D. In the intestines, calcitriol increases the production of calcium binding proteins and plasma membrane calcium pump proteins, thereby increasing calcium absorption through the duodenum.<sup>132</sup> In the bone, calcitriol stimulates osteoclastic precursors to differentiate into mature osteoclasts.<sup>115</sup> Mature osteoclasts, together with PTH, lead to mobilization of calcium stores from bone, thereby raising serum concentrations of calcium. Given sufficient serum concentrations of calcium, calcitriol promotes bone mineralization by osteoblasts, resulting in increased deposition of calcium hydroxyapatite into the bone matrix.<sup>115</sup> Calcitriol also binds to a vitamin D receptor in the parathyroid glands, which leads to decreased synthesis and secretion of PTH.<sup>185</sup> The vitamin D receptor is present in most cells of the body, including lymphocytes, epidermal skin cells, and tumor cells.<sup>221</sup> The binding of calcitriol can inhibit proliferation and induce terminal differentiation.<sup>203</sup> Although the role of vitamin D is not elucidated in all cells, abnormalities present during vitamin D deficiency may help identify the function of vitamin D in various tissues.

Vitamin D deficiency results in hypocalcemia, leading to increased secretion of PTH, which acts to restore plasma calcium concentrations at the expense of bone. In children, this situation leads to rickets in which newly formed bone is not adequately mineralized and results in bone deformities and growth defects. Adults develop osteomalacia, a disease characterized by undermineralized bone matrix. Patients typically present with bone pain and tenderness and proximal muscle weakness. Bone deformities are limited to the advanced stages of disease.

The literature varies regarding the toxic dose of vitamin D, with little scientific data available for corroboration. The current upper level intake is set at 4,000 IU/day (100 mcg/day) for persons aged 9 years and older, with lower levels set for children younger than 9 years of age.<sup>50</sup> This is an increase compared to the previous UL of 2,000 IU/day (50 mcg/day).<sup>248</sup> There also are studies showing that dosages as high as 4,400 IU/day (110 mcg/day) and 100,000 IU (2,500 mcg) for 4 days did not result in adverse effects.<sup>236,243,248</sup> Case reports describe toxicity in the setting of vitamin D intake of 50,000 to 600,000 IU or, simply, doses in the milligram range, daily for prolonged periods.<sup>57,96,159,200</sup>

### Pathophysiology

The hallmark of vitamin D toxicity is hypercalcemia. Vitamin D in the form of 1,25(OH)<sub>2</sub>D promotes calcium absorption from the gut and mobilization of calcium from bone. Vitamin D toxicity is associated with a serum concentration of 25(OH)D 20 times higher than normal, whereas the concentration of 1,25(OH)<sub>2</sub>D remains exceedingly variable.<sup>87,201</sup> 25-Hydroxyvitamin D mimics the action of 1,25(OH)<sub>2</sub>D when it is present in excess and binds to receptors usually specific for 1,25(OH)<sub>2</sub>D.<sup>87,150</sup> Alternatively, 25(OH)D, which has a higher affinity for vitamin D-binding protein compared with 1,25(OH)<sub>2</sub>D,

preferentially binds to vitamin D-binding protein when it is present in elevated concentrations, displacing 1,25(OH)<sub>2</sub>D and allowing it to circulate in an unbound form or loosely bound to albumin.<sup>247</sup> A study of patients with vitamin D toxicity who had normal or near normal total 1,25(OH)<sub>2</sub>D concentrations had elevated free 1,25(OH)<sub>2</sub>D concentrations.<sup>201</sup> The availability of 1,25(OH)<sub>2</sub>D to its receptors likely is increased, resulting in vitamin D toxicity. These mechanisms explain how hypercalcemia occurs in cases of vitamin D toxicity despite inhibition of the conversion of 25(OH)D to 1,25(OH)<sub>2</sub>D in the presence of increasing serum calcium concentrations.

Although hypercalcemia occurs with vitamin D supplementation, hypercalciuria and resultant nephrolithiasis do not necessarily occur. The degree of hypercalciuria that develops with vitamin D supplement use may not be sufficient to cause stone formation. Also, as serum calcium concentrations increase, inhibition of 25(OH)D-1-α-hydroxylase prevents the conversion of 25(OH)D to 1,25(OH)<sub>2</sub>D, thereby limiting hypercalciuria and stone development.<sup>94</sup> However, this is not necessarily true when 25(OH)D concentrations are very high as occur in overdose. Nephrolithiasis is noted to occur with vitamin D supplementation in association with genetic mutations. When the gene for 1,25 dihydroxyvitamin D-24-hydroxylase cytochrome P450, *CYP24A1*, is mutated, the enzyme it codes for is inactivated, thereby preventing the conversion of 1,25(OH)<sub>2</sub>D to the inactive calcitroic acid.<sup>241</sup> Individuals with one or two mutations of the gene develop hypercalcemia and hypercalciuria with stone formation, sometimes not presenting until adulthood. Compared with those with idiopathic stone formation, they have suppressed PTH concentrations, and high 1,25(OH)<sub>2</sub>D concentrations. This mutation could account for the tendency of vitamin D to cause hypercalciuria and calcium stones in certain individuals.<sup>94</sup>

### Clinical Manifestations

Patients with vitamin D toxicity present with signs and symptoms characteristic of hypercalcemia.<sup>150</sup> Early manifestations include weakness, fatigue, somnolence, irritability, headache, dizziness, muscle and bone pain, nausea, vomiting, abdominal cramps, and diarrhea or constipation (Chap. 12). As the calcium concentration increases, hypercalcemia induces polyuria and polydipsia. Diuresis results in salt and water depletion, further impairing calcium excretion. Although in some individuals, vitamin D supplementation can cause hypercalciuria, a known risk factor for nephrolithiasis,<sup>53</sup> a prospective analysis of three large cohort studies with multivariate adjustment for use of calcium supplements did not show any statistically significant association between vitamin D intake and risk of stone formation.<sup>77</sup> This finding is limited to chronic use and by a maximum mean total vitamin D intake of 1,317 IU/day, with a maximum mean dietary vitamin D intake of 410 IU/day and a maximum mean supplemental vitamin D dosage of 839 IU/day, across the three cohorts. A higher risk of nephrolithiasis with higher doses of vitamin D cannot be excluded. Severe hypercalcemia presents with ataxia, confusion, psychosis, seizures, coma, and acute kidney injury. In addition, cardiac

dysrhythmias result from a shortened refractory period and slowed conduction. Findings on electrocardiography include increased PR intervals, widening of QRS complexes, QT interval shortening, and flattened T waves (Chap. 15).<sup>187</sup> Patients can develop metastatic calcification of the kidneys, blood vessels, myocardium, lung, and skin. Several patients with vitamin D toxicity have presented with anemia.<sup>207,223</sup> Proposed mechanisms for anemia include a direct effect of vitamin D on hematopoietic cells and inhibition of erythropoietin production.<sup>207</sup>

### Diagnostic Testing

Vitamin D toxicity should be considered in patients presenting with signs and symptoms of hypercalcemia. In addition to an elevated serum calcium concentration, laboratory results reveal hyperphosphatemia given that vitamin D facilitates phosphate absorption in the small intestine, enhances its mobilization from bone, and decreases its excretion by the kidney.<sup>164</sup> The diagnosis should be suspected in children with nephrocalcinosis and hypercalciuria even if serum calcium and phosphorus concentrations are normal.<sup>180</sup> Serum 25(OH)D is measurable, but it is unlikely that results will be available quickly. According to the IOM, the desired 25(OH)D concentration range is 20 to 50 ng/mL.<sup>50</sup> The IOM also found that concentrations higher than 30 ng/mL were not consistently associated with increased benefit, and concentrations higher than 50 ng/mL may be cause for concern.

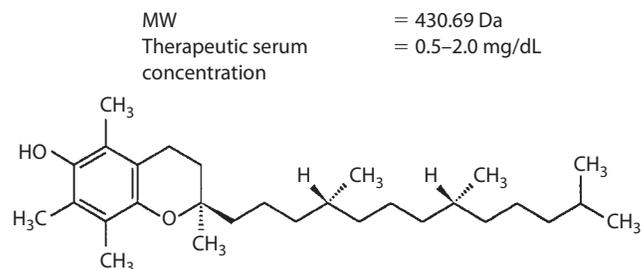

### Management

Treatment of hypercalcemia in patients with vitamin D toxicity should include discontinuation of both vitamin D and calcium supplementation, maintenance of a low calcium diet, and administration of adequate volumes of oral or IV fluid to overcome dehydration and increase renal calcium clearance.<sup>150</sup> Many cases of hypercalcemia will respond to such supportive care. When patients are euolemic, it is reasonable to add a loop diuretic in moderate cases of hypercalcemia requiring ongoing IV fluid administration. This helps prevent fluid overload and increases renal calcium clearance. However, electrolyte monitoring and replacement are necessary. Moderate to severe cases of hypercalcemia require additional treatment and should be managed like cases of moderate to severe hypercalcemia from other causes. Calcitonin is a hypocalcemic hormone secreted by the thyroid gland that decreases bone resorption by directly inhibiting osteoclast activity. It also reduces the serum calcium concentration by increasing renal calcium excretion. Salmon calcitonin is recommended at a dosage of 4 units/kg intramuscularly every 12 hours for up to 48 hours.<sup>175,261</sup> Calcitonin is more efficacious when administered with bisphosphonates, which also inhibit bone resorption via an effect on osteoclasts.<sup>73</sup> Pamidronate 90 mg IV over 2 hours or zoledronic acid 4 mg IV over 15 minutes is recommended.<sup>149</sup> Glucocorticoids decrease calcitriol production, thereby reducing serum calcium concentrations via a decrease in intestinal calcium absorption or inhibition of bone resorption.<sup>137,238</sup> It is reasonable to administer hydrocortisone 100 mg/day or prednisone 40 mg/day over 5 days to treat severe cases of hypercalcemia. Hemodialysis is reasonable in refractory cases of hypercalcemia.

### ANTIOXIDANTS (VITAMINS E AND C)

The antioxidants include vitamins E and C and beta-carotene. During the 1990s, the concept that antioxidants had a protective effect against atherosclerosis and carcinogenesis was widely promoted. This notion was based on the “oxidative-modification hypothesis” of atherosclerosis, which proposes that atherogenesis is initiated by lipid peroxidation of LDL.<sup>61</sup> Unregulated or prolonged production of cellular oxidants leading to oxidant-induced DNA damage is thought to be responsible for carcinogenesis.<sup>140</sup> Epidemiologic evidence seems to support the use of antioxidants for these indications.<sup>143,210,235</sup> However, several prospective, randomized, placebo-controlled clinical trials, designed to test for the effect of antioxidant vitamins on cardiovascular disease and cancer, demonstrated that commonly used antioxidant regimens do not significantly reduce or prevent overall cardiovascular events or cancer.<sup>40,100,101,112,189,263</sup>

### VITAMIN E

### History and Epidemiology

The existence of vitamin E was first demonstrated in 1922 by researchers noting that female rats deficient in a dietary principle were unable to sustain a pregnancy.<sup>69</sup> Testicular lesions in male rats were described in deficiency states, and vitamin E was referred to as the “anti-sterility vitamin.”<sup>165</sup> Vitamin E was first isolated from wheat-germ oil in 1936.<sup>68</sup> The richest sources of vitamin E include nuts, wheat germ, whole grains, and vegetable and seed oils, including soybean, corn, cottonseed, and safflower, and the products made from these oils. In general, animal products are poor sources of vitamin E. Human milk, in contrast to cow’s milk, has sufficient vitamin E in the form of alpha-tocopherol to meet the needs of breastfed infants.<sup>165</sup>

Vitamin E is an essential nutrient. It is believed to be necessary for normal functioning of the nervous, reproductive, muscular, cardiovascular, and hematopoietic systems. Vitamin E includes eight naturally occurring compounds in two classes—tocopherols and tocotrienols—that have differing biologic activities. The most biologically active form is RRR-alpha-tocopherol, previously known as D-alpha-tocopherol, which is the most widely available form of vitamin E in food. A synthetic form of alpha-tocopherol, often used in vitamin supplements, contains a mixture of *d* and *l* isomers and is designated *all-rac*-alpha-tocopherol (previously *d,l*-alpha-tocopherol). One IU is equivalent to 1 mg of alpha-tocopherol acetate (alpha-TA).

Vitamin E supplementation should not be necessary in persons who consume a well-balanced diet. Vitamin E deficiency is found in patients with malabsorption syndromes, which occur in the presence of pancreatic insufficiency or hepatobiliary disease, such as biliary atresia.<sup>34</sup> Patients with abetalipoproteinemia are at risk for vitamin E deficiency.<sup>20</sup> In this rare disease, absorption and transport of vitamin E are impaired secondary to a lack of chylomicron and beta-lipoprotein formation. Manifestations of deficiency are variable but seem to have the most effect in organ systems that rely on vitamin E for normal functioning.<sup>165</sup> The clinical syndrome is primarily manifested by a peripheral neuropathy and spinocerebellar syndrome that improves with supplemental vitamin E.<sup>176</sup> Clinical findings include ophthalmoplegia, hyporeflexia, gait disturbances, and decreased sensitivity to vibration and proprioception.<sup>34</sup>

Use of vitamin E is proposed for a wide range of conditions. In most cases, scientific rationale for its use is lacking or is based on in vitro or animal data that are not validated in humans or are associated with equivocal results.<sup>34</sup> As examples, vitamin E is used for treatment of recurrent abortion, hemolytic anemias, claudication, wound healing, tardive dyskinesia, epilepsy, and acute respiratory distress syndrome. In addition, much research over the past decade has focused on the use of vitamin E for the prevention and treatment of cardiovascular disease and cancer, with disappointing results.<sup>125</sup>

### Pharmacology, Pharmacokinetics, and Toxicokinetics

Vitamin E absorption is dependent on the ingestion and absorption of fat. The presence of bile also is essential. Vitamin E is passively absorbed in the intestinal tract into the lymphatic circulation by a nonsaturable process. Approximately 45% of a dose is absorbed in this manner and subsequently enters the bloodstream in chylomicrons, which are taken up by the liver. Vitamin E then is secreted back into the circulation, where it is primarily associated with LDL. Vitamin E is distributed to all tissues, with the greatest accumulation in adipose tissue, liver, and muscle.

The primary biologic function of vitamin E is as an antioxidant. It prevents damage to biologic membranes by protecting polyunsaturated fats within membrane phospholipids from oxidation.<sup>41</sup> It accomplishes this task by preferentially binding to peroxy radicals and forming the corresponding organic hydroperoxide and tocopheroxyl radical, which, in turn interacts with other antioxidant compounds, such as ascorbic acid, thereby regenerating tocopherol. Vitamin E is responsible for cell growth and proliferation by combating the inhibitory effects of lipid peroxidation.<sup>176</sup> Vitamin E has a negative role in the regulation of cellular proliferation through its nonoxidant properties, such as inhibition of protein kinase C activity.<sup>176</sup>

Large amounts of vitamin E, ranging from 400 to 800 IU/day (400–800 mg/day) for months to years, were previously thought to be without apparent harm.<sup>5</sup> Vitamin E supplementation results in few obvious adverse effects, even at dosages as high as 3,200 mg/day (3,200 IU/day).<sup>27</sup> In several species, the oral median lethal dose was 2,000 mg/kg (2,000 IU/kg) or more, and significant adverse effects were observed only when daily doses were greater than 1,000 mg/kg (1,000 IU/kg), equivalent to 200 to 500 mg/kg (200–500 IU/kg) in humans.<sup>177</sup> However, a meta-analysis reveals that all-cause mortality increases at doses equal to or greater than 400 IU/day (400 mg/day).<sup>178</sup>

### Pathophysiology

In vitro studies demonstrate that in high doses vitamin E may have a paradoxical prooxidant effect.<sup>3,39,178</sup> The prooxidant effect of vitamin E on LDLs is related to the production of alpha-tocopheroxyl radicals, which normally are inhibited by other antioxidants such as vitamin C. High doses of vitamin E displace other antioxidants, thereby disrupting the natural balance of the antioxidant system and increasing vulnerability to oxidative damage.<sup>120</sup> High doses of vitamin E inhibit human cytosolic glutathione S-transferases, enzymes that are active in the detoxification of xenobiotics and endogenous toxins.<sup>245</sup>

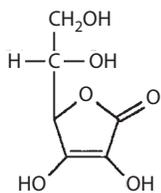

### Clinical Manifestations

Gastrointestinal symptoms, including nausea and gastric distress, were reported in patients who had received vitamin E 2,000 to 2,500 IU/day (2,000–2,500 mg/day).<sup>113,256</sup> Diarrhea and abdominal cramps were reported in patients who received a dosage of 3,200 IU/day (3,200 mg/day).<sup>11</sup> Reports of other adverse effects, including fatigue, weakness, emotional changes, thrombophlebitis, increased serum creatinine concentration, and decreased thyroid hormone concentrations, are not reproduced in other case series or clinical trials.<sup>177</sup>

The most significant toxic effect of vitamin E, at dosages exceeding 1,000 IU/day (1,000 mg/day), is its ability to antagonize the effects of vitamin K.<sup>5</sup> Vitamin E increases the epoxidation of vitamin K to its inactive form, thereby increasing the vitamin K requirement several-fold.<sup>13,28</sup> Although high oral doses of vitamin E typically do not produce a coagulopathy in normal humans with adequate vitamin K stores, coagulopathy develops in vitamin K-deficient patients and patients taking warfarin.<sup>13,28,51,72</sup> Animal studies demonstrate that absorption of both vitamins A and K is impaired by large doses of vitamin E.<sup>34,212</sup>

## VITAMIN C

MW	= 176.12 Da
Therapeutic serum concentration	= 0.4–2.0 mg/dL

### History and Epidemiology

Vitamin C, also known as ascorbic acid, is employed as a preventive for the common cold. Interestingly, an extensive review of 14 studies of the role of

vitamin C in the treatment of the common cold suggested that only eight were valid investigations, and none of the studies demonstrated any therapeutic benefit.<sup>45</sup> Its function as an antioxidant led to its use for the prevention and treatment of cardiovascular disease and cancer. Human data from clinical trials do not demonstrate that vitamin C significantly reduces or prevents overall cardiovascular events or cancer. Vitamin C may have a role as a reducing agent in the treatment of idiopathic methemoglobinemia (Chap. 124). However, it is less effective than standard treatment with methylene blue; therefore, it is not routinely indicated.<sup>166</sup> Vitamin C is popularly used to promote wound healing, treat cataracts, combat chronic degenerative diseases, counteract the effects of aging, increase mental attentiveness, and decrease stress.<sup>51,177</sup> However, little, if any, objective data demonstrate a benefit of treatment for any of these indications.<sup>5</sup> Vitamin C dietary supplements are commonly taken in dosages of 500 mg/day.

Vitamin C is used to prevent scurvy.<sup>166</sup> In 1747, James Lind, a physician in the British Royal Navy, analyzed the relationship between diet and scurvy and confirmed the protective and curative effects of citrus fruits. Vitamin C was isolated from cabbage in 1928 and subsequently shown in 1932 to be the active antiscorbutic factor in lemon juice. It was given the name *ascorbic acid* to indicate its role in preventing scurvy. Other dietary sources of vitamin C include tomatoes, strawberries, and potatoes. Today, those at risk for developing scurvy include older adults, alcoholics, chronic drug users, and others with inadequate diets, including infants fed formula diets with insufficient concentrations of vitamin C.<sup>166</sup> Symptoms include gingivitis, poor wound healing, bleeding, and petechiae and ecchymoses. Musculoskeletal signs and symptoms consisting of arthralgias, myalgias, hemarthroses, and muscular hematomas develop in 80% of cases.<sup>70</sup> Children experience severe pain in their lower limbs secondary to subperiosteal bleeding.<sup>70</sup>

### Pharmacology, Pharmacokinetics, and Toxicokinetics

After ingestion, intestinal absorption of vitamin C occurs via an active transport system that is saturable.<sup>211</sup> Saturation occurs with ingestion of approximately 3 g/day. When given as a single oral dose, absorption decreases from 75% at 1 g to 20% at 5 g. Vitamin C is distributed from the plasma to all cells in the body. Tissue uptake is also a saturable process.<sup>177</sup> Metabolic degradation of vitamin C to oxalate accounts for 30% to 40% of oxalate excreted daily.<sup>104</sup> Because absorption and metabolic conversion are saturable, large ingestions of vitamin C should not significantly increase oxalate production.<sup>227</sup> Only a small amount of vitamin C is filtered through the glomeruli, and tubular resorption, a saturable process that competes with uric acid, usually is almost complete.<sup>31</sup> Plasma concentrations of vitamin C typically are maintained at approximately 1 mg/dL. The kidney efficiently eliminates excess vitamin C as unchanged ascorbic acid.

Vitamin C is a cofactor in several hydroxylation and amidation reactions by functioning as a reducing agent.<sup>152,153</sup> As a result, vitamin C plays an important role in the synthesis of collagen, carnitine, folic acid, and norepinephrine. It also influences the processing of hormones such as oxytocin, antidiuretic hormone, and cholecystokinin. Vitamin C reduces iron from the ferric to the ferrous state in the stomach, thereby increasing intestinal absorption of iron. Vitamin C is involved in steroidogenesis in the adrenals. Vitamin C also has a prooxidant effect *in vivo*.<sup>202</sup> This effect is not believed to occur at dosages less than 500 mg/day but may occur in the setting of overdose.

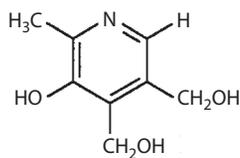

### Clinical Manifestations

The possibility of oxalate nephrolithiasis should not be a significant clinical concern.<sup>89</sup> Nevertheless, conflicting studies and reports exist regarding the association between vitamin C overdose and the development of oxalosis. A prospective study on the risk of kidney stones in men did not support an association between high daily vitamin C intake and stone formation.<sup>54</sup> This was also demonstrated in a study involving daily ingestion of 4 g of ascorbic

acid for 5 days in healthy men in whom there was no increase in urinary oxalate excretion.<sup>17</sup> Another study demonstrated increased rates of oxalate absorption and endogenous synthesis contributing to hyperoxaluria, but this effect was found in individuals with a prior history of renal calcium oxalate stones and not in individuals without a prior history of calcium oxalate stones.<sup>44</sup> Some reports of high urine oxalate concentrations likely were erroneous because of conversion of ascorbate to oxalate in alkaline urine samples left standing after collection.<sup>17,252</sup> By contrast, other reports show an increase in urinary oxalate and calcium oxalate crystallization after ingestion of high doses of vitamin C in both stone formers and non-stone formers.<sup>25,168</sup> A recent report of a large prospective study over 11 years of men aged 45 to 79 years at baseline without prior history of renal stones demonstrated that high-dose vitamin C supplementation was associated with a dose-dependent twofold increase risk in development of first incident cases of kidney stones.<sup>242</sup> Individual case reports documenting the presence of oxalate stones in the setting of vitamin C overdose often have involved IV administration.<sup>52,88,147,170,239,262</sup> Oxalosis also is more likely to develop in patients with chronic kidney disease.<sup>23,177</sup> Gastrointestinal effects of high doses of vitamin C include localized esophagitis, given prolonged mucosal contact with ascorbic acid, and an osmotic diarrhea.<sup>118,251</sup>

## VITAMIN B<sub>6</sub>

MW = 169 Da  
Therapeutic serum concentration = 3.6–18 ng/mL

### History

Pyridoxine, pyridoxal, and pyridoxamine are related compounds that have the same physiologic properties. Although all three compounds are included in the term *vitamin B<sub>6</sub>*, the vitamin is assigned the name *pyridoxine*. This vitamin was discovered in 1936 as the water-soluble factor whose deficiency was responsible for the development of dermatitis in rats.<sup>166</sup> In humans, deficiency is characterized by cheilosis, stomatitis, glossitis, blepharitis, and a seborrheic dermatitis around the eyes, nose, and mouth.<sup>231</sup> More important, pyridoxine deficiency is associated with seizures.

Pyridoxine is found in several foods, including meat, liver, whole-grain breads and cereals, soybeans, and vegetables.<sup>166</sup> Deficiency should not occur in humans who eat a well-balanced diet.<sup>231</sup>

In 2015, the American College of Obstetrics and Gynecology (ACOG) updated its recommendations on the treatment of nausea and vomiting of pregnancy (NVP) to include pyridoxine. According to ACOG, there is good and consistent scientific evidence (Level A) for the treatment of NVP with pyridoxine or pyridoxine plus doxylamine, and it is safe and effective and should be considered first-line pharmacotherapy.<sup>4</sup> Randomized controlled trials of pyridoxine compared with placebo show that pyridoxine is effective, compared with placebo, at reducing nausea and vomiting and that pyridoxine is effective at reducing severe vomiting but not mild vomiting.<sup>220,249</sup> However, a recent Cochrane review of randomized controlled trials found that pyridoxine improved nausea but did not decrease emesis.<sup>169</sup> In 2013, the FDA approved a delayed-release formulation of doxylamine and pyridoxine for the use in pregnant women with nausea and vomiting who do not respond to dietary and lifestyle changes.<sup>232</sup> A randomized controlled trial found that a delayed-release formulation of doxylamine and pyridoxine significantly improved NVP compared with placebo.<sup>141</sup> A retrospective analysis comparing pyridoxine to pyridoxine and doxylamine revealed that pyridoxine and doxylamine were more effective than pyridoxine alone in reducing NVP.<sup>204</sup>

This study did not compare pyridoxine and doxylamine to doxylamine alone. Doxylamine and pyridoxine are often recommended to be taken together individually in their nonprescription formulations because the combination formulation is expensive. The cause of NVP and the mechanism for how pyridoxine affects nausea are unknown.

Other historical uses of pyridoxine have included treatment of premenstrual syndrome and carpal tunnel syndrome.<sup>2,66</sup> High doses were suggested for treatment of schizophrenia and autism with variable results.<sup>79,151</sup>

### Pharmacology

All forms of vitamin B<sub>6</sub> are well absorbed from the intestinal tract. Pyridoxine is rapidly metabolized to pyridoxal, pyridoxal phosphate (PLP), and 4-pyridoxic acid.<sup>264</sup> Pyridoxal phosphate accounts for approximately 60% of circulating vitamin B<sub>6</sub> and is the primary form that crosses cell membranes.<sup>166</sup> Most vitamin B<sub>6</sub> is renally excreted as 4-pyridoxic acid, with only 7% excreted unchanged in the urine.<sup>166,264</sup> Experiments in anephric rats demonstrate an up to 10-fold increase in susceptibility to pyridoxine-induced neurotoxicity, suggesting a need for caution when prescribing pyridoxine to patients with chronic kidney disease.<sup>154</sup>

Pyridoxal phosphate is the active form of vitamin B<sub>6</sub>. It is a coenzyme required for the synthesis of  $\gamma$ -aminobutyric acid (GABA), an inhibitory neurotransmitter. Decreased GABA formation in the setting of pyridoxine deficiency contributes to seizures.<sup>166</sup> Isoniazid and other hydrazines inhibit the enzyme responsible for conversion of pyridoxine to PLP (Chap. 56 and Figs. 56–2 and 56–3).<sup>117</sup> In addition, isoniazid enhances the elimination of pyridoxine leading to neuropathy. Therefore, pyridoxine should be administered concomitantly with isoniazid to limit the development of peripheral neuropathy. Seizures resulting from isoniazid overdose often are successfully treated with pyridoxine (Antidotes in Depth: A15).

### Pathophysiology

Ironically, both pyridoxine deficiency and pyridoxine toxicity are characterized by neurologic effects. Studies indicate that the mammalian peripheral sensory nervous system is vulnerable to large doses of pyridoxine.<sup>224</sup> Peripheral sensory nerves are vulnerable to circulating xenobiotics because of the permeability of their associated blood vessels.<sup>224</sup> Compared with the CNS, these nerves lack the blood–brain barrier. In addition, the nerves of the CNS are relatively shielded from pyridoxine toxicity because pyridoxine is transported into the CNS by a saturable mechanism.<sup>224</sup> In 1942, pyridoxine was recognized to cause severe weakness and pathological changes in peripheral nerves and dorsal root ganglia in dogs and rats.<sup>14,234</sup> Administration of IV pyridoxine 2 g/kg in two patients for the treatment of mushroom poisoning resulted in permanent dorsal root and sensory ganglia deficits.<sup>6</sup>

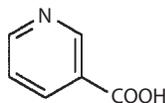

### Clinical Manifestations

Chronic overdoses are associated with progressive sensory ataxia and severe distal impairment of proprioception and vibratory sensation. Reflexes are diminished or absent. Touch, pain, and temperature sensation are minimally impaired. These findings were first described in 1983 in a case series of seven patients who were taking pyridoxine 2 to 6 g/day for 2 to 40 months for premenstrual syndrome.<sup>224</sup> Nerve conduction and somatosensory studies in these patients showed dysfunction in the distal sensory peripheral nerves. Nerve biopsy showed widespread, nonspecific axonal degeneration. This syndrome was reported with pyridoxine doses as low as 200 mg/day.<sup>198</sup> Among 26 patients with elevated serum pyridoxine concentrations, the most common findings reported were numbness (96%), burning pain (49.9%), tingling (57.7%), balance difficulties (30.7%), and weakness (7.8%).<sup>226</sup> In most cases, symptoms gradually improved over several months with abstinence from pyridoxine. However, clinical manifestations sometimes progress for 2 to 3 weeks after pyridoxine discontinuation.<sup>30</sup>

Acute neurotoxicity occurs when a massive amount of pyridoxine is administered as a single dose or given over a few days.<sup>6</sup> Large overdoses of pyridoxine are associated with incoordination, ataxia, seizures, and death.<sup>244</sup>

## NICOTINIC ACID

MW = 123 Da  
 Therapeutic concentration = Not determined

### History

Nicotinic acid, or niacin, was discovered as an essential dietary component in the early 1900s.<sup>92</sup> A deficiency of this vitamin, also known as vitamin B<sub>3</sub>, causes pellagra, which is characterized by dermatitis, diarrhea, and dementia. This disease was prevalent for centuries in countries that heavily relied on maize as a dietary staple until it was determined that pellagra could be prevented by increasing dietary intake of fresh eggs; milk; and fresh meat, including liver.<sup>166</sup> Other food sources of nicotinic acid include fish, poultry, nuts, legumes, and whole-grain and enriched breads and cereals. Supplementation of flour with nicotinic acid in 1939 probably is responsible for the near eradication of this disease in the United States. Chronic alcohol users still develop pellagra, likely secondary to malnutrition.<sup>21,108</sup>

Niacin was introduced as a treatment for hyperlipidemia in 1955.<sup>10</sup> Nicotinic acid reduces triglyceride synthesis, with a resultant drop in very-low-density lipoprotein cholesterol and LDL cholesterol and a rise in high-density-lipoprotein cholesterol.<sup>92</sup> Therapy usually is started with a single dose of 250 mg of the immediate-release formulation. The frequency of dose and total daily dose are gradually increased until a dose of 1.5 to 2.0 g/day, divided every 6 to 8 hours, is reached. If the LDL cholesterol concentration is not sufficiently decreased with this dosing regimen, then the dose is further increased up to a maximum dose of 6.0 g/day. Alternatively, an extended-release formulation is used with a starting dose of 500 mg. The dose is increased every 4 weeks based on effect and tolerance up to 1 to 2 g once daily. These doses of niacin are 100-fold higher than the amount necessary to meet adult nutritional needs.<sup>208</sup>

More recently, the nonmedicinal ingestion of niacin for altering or masking the results of urine testing for illicit drugs was noted.<sup>16,181,206</sup> However, there is no evidence that ingestion of niacin is capable of this effect.

### Pharmacology, Pharmacokinetics, and Toxicokinetics

Nicotinic acid is well absorbed from the intestinal tract and is distributed to all tissues. With therapeutic dosing, little unchanged vitamin is excreted in the urine. When extremely high doses are ingested, the unchanged vitamin is the major urinary component. Nicotinic acid ultimately is converted to nicotinamide adenine dinucleotide (NAD<sup>+</sup>) and nicotinamide adenine dinucleotide phosphate (NADP<sup>+</sup>), which are the physiologically active forms of this vitamin. The reduced forms of NAD<sup>+</sup> and NADP<sup>+</sup>, NADH and NADPH, respectively, act as coenzymes for proteins that catalyze oxidation-reduction reactions that are essential for tissue respiration.<sup>166</sup>

### Clinical Manifestations

The most common adverse effect associated with niacin use is a vasodilatory cutaneous flushing described as a sense of warmth in the face, ears, neck, trunk, and less frequently in the extremities, lasting less than 1 to 2.5 hours.<sup>128</sup> Other symptoms include erythema, itching, and tingling. These effects occur at dosages of 0.5 to 1 g/day.<sup>172</sup> Symptoms commence within 15 to 30 minutes after ingestion of immediate-release niacin, 30 to 120 minutes after ingestion of extended-release niacin and at more variable times after ingestion of sustained-release niacin.<sup>128</sup> Symptoms are caused by the production of prostaglandin (PG) D<sub>2</sub> and E<sub>2</sub> via the G protein-coupled receptor, GPR109A.<sup>29</sup> Flushing occurs because of the predilection of the skin as a site of PG production after niacin ingestion.<sup>237</sup> PGD<sub>2</sub> and PGE<sub>2</sub> act on receptors DP<sub>1</sub> and EP<sub>2/4</sub> in dermal capillaries, causing vasodilation.<sup>134</sup> Vasodilatory adverse events occur in almost all of patients, particularly when given an immediate-release

form of niacin.<sup>172</sup> Many patients discontinue niacin use because of flushing. Long-term tolerance to flushing does develop with continued dosing of niacin, secondary to decreased PGD<sub>2</sub> output.<sup>128</sup>

Because rapid absorption of niacin is related to development of flushing, modified-release preparations of niacin were developed. A meta-analysis of 4,000 patients who used various time-release preparations of niacin showed that among the 70% of patients who experienced flushing, 85% used immediate-release niacin, 66% used extended-release niacin, and 26% used sustained-release niacin.<sup>38</sup> The modified-release preparations are more likely to produce GI adverse effects, such as epigastric distress, nausea, and diarrhea.<sup>172</sup> In addition, niacin-induced hepatotoxicity occurs more frequently and is more severe in patients treated with modified-release niacin rather than immediate-release niacin.<sup>48,208</sup> Elevated hepatic aminotransferases occur with dosages as low as 1 g/day, but signs of hepatic dysfunction occur at dosages of 2 to 3 g/day.<sup>172</sup> These patients have elevated serum bilirubin and ammonia concentrations and a prolonged prothrombin time. They develop fatigue, anorexia, nausea, vomiting, and jaundice. In most cases, liver function improves after niacin withdrawal.<sup>67,172</sup> Severe cases progress to fulminant hepatic failure and hepatic encephalopathy.<sup>49,114,183</sup> Niacin also causes amblyopia, hyperglycemia, hyperuricemia, coagulopathy, myopathy, and hyperpigmentation.<sup>111</sup> A 16-year-old boy who ingested 13 g of niacin over 48 hours developed metabolic acidosis, hypoglycemia, and coagulopathy and had elevated hepatic aminotransferases.<sup>16</sup> The patient also complained of severe myalgias and chest and abdominal pain. His signs and symptoms resolved after 5 days with IV fluid resuscitation and bicarbonate infusion.

### Management

A dose of 325 mg of aspirin taken 30 minutes before ingestion of niacin diminishes flushing.<sup>258</sup> This is because aspirin inhibits cyclooxygenase, thereby decreasing production of PGs.

Other strategies for reducing flushing include dosing with meals and avoidance of alcohol, hot beverages, spicy foods, and hot baths or showers close to or after dosing.<sup>56</sup> Flushing is also decreased by starting at a low dose and gradually increasing to the full dose. Tolerance to flushing develops after several weeks, but flushing will recur if doses are missed.

Laropiprant, a PGD<sub>2</sub> antagonist at receptor DP<sub>1</sub>, has demonstrated efficacy in numerous studies (phase 1, 2, and 3 trials) for reducing niacin-associated flushing.<sup>128</sup> In Europe, laropiprant was approved for use in 2008 in the form of a combined tablet, 1,000 mg of extended-release niacin with 20 mg laropiprant, and sold under the trade name Tredaptive. In 2008, the FDA did not give approval for a similar product with the trade name Cordaptive made by the same pharmaceutical company. In 2013, the HPS2-THRIVE (Heart Protection Study 2-Treatment of HDL to Reduce the Incidence of Vascular Events) collaborative group reported an increased incidence of myopathy among patients taking simvastatin plus extended-release niacin/laropiprant (ERN/LRPT) compared with those taking simvastatin plus placebo.<sup>99</sup> Also, ERN/LRPT in addition to statin therapy did not significantly reduce the risk of major vascular events in patients with well-controlled LDL-cholesterol concentrations. As a result, the study was halted, and production of Tredaptive ceased. Other findings included that 25.4% of participants taking ERN/LRPT stopped their randomized treatment compared with 16.6% taking placebo, mostly because of adverse dermatologic and GI effects.

In vitro studies demonstrate that methylnicotinate induces serotonin release from human platelets in addition to PGD<sub>2</sub> release from human mast cells.<sup>194</sup> Animal studies demonstrate the ability of various serotonin antagonists including cyproheptadine to inhibit the niacin-induced temperature increase, associated with flush, by 90%.<sup>194</sup> Flavonoids also were studied as a potential treatment for niacin flush because of their ability to inhibit both niacin-induced plasma PGD<sub>2</sub> and serotonin increase in a rat model.<sup>195</sup> In a small human study, a dietary supplement containing 150 mg of the flavonoid quercetin decreased the severity and longevity of erythema and burning sensation scores on a visual scale.<sup>133</sup>

## SUMMARY

- Healthy adults consuming a well-balanced diet do not require vitamin supplementation.
- Vitamins are popularly believed to be a panacea and are commonly taken in supraphysiologic doses which produce serious adverse effects.
- Because the therapeutic index is large, toxicity generally does not develop unless very large doses are taken for sustained periods.
- Health care professionals should consider hypervitaminosis in the differential diagnosis when patients present with symptoms consistent with a vitamin toxicity syndrome.
- A thorough history, with emphasis on diet and underlying disease is essential before prescribing supplemental vitamins.

## IRON

Jeanmarie Perrone

### Iron

Molecular weight	= 55.85 Da
Serum normal concentration	= 80–180 mcg/dL
	= 14–32 $\mu$ mol/L

### INTRODUCTION

Iron poisoning has become uncommon. This success may underscore the importance of interventions gleaned from poison control center data and poison prevention advocacy. Blister packaging and smaller iron dosages, as well as education of parents and health care professionals have led to a great decline in iron-related morbidity. However, when significant iron poisonings do occur, clinicians must be aware of the nuances of presentation and diagnosis and be prepared to intervene if gastrointestinal (GI) toxic effects, acid–base disturbances, altered mental status, or hemodynamic compromise arise.

### HISTORY AND EPIDEMIOLOGY

Iron salts such as ferrous sulfate have been used therapeutically for thousands of years and continue to be available, both with and without a prescription, for the prevention and treatment of iron deficiency anemia in patients of all ages. Despite this long history of use, the first reports of iron toxicity only occurred in the mid-20th century. Since then, numerous cases of iron poisoning and fatalities have been reported, mostly in children. In 1950, the manufacturer of “fersolate,” an iron supplement, included a package warning: “Excessive doses of iron can be dangerous. Do not leave these tablets within reach of young children, who may eat them as sweets with harmful results.”<sup>78</sup>

The incidence of iron exposures continued to increase in the 1980s, becoming the leading cause of poisoning deaths reported to poison control centers among young children in the 1990s (Chap. 130). This problem was highlighted in a case series of five toddlers with unintentional fatal exposure to prenatal vitamins containing iron.<sup>11</sup> The association between iron poisoning and prenatal vitamins highlights the availability of these potentially lethal medications in the homes of families with young children as an unintended consequence of more rigorous use of prenatal iron in pregnant women. A case-control study in Canada identified a fourfold increase in the risk of iron poisoning to the older sibling of a newborn during the first postpartum month.<sup>38</sup> The authors concluded that almost half of all hospital admissions of young children for iron poisoning could be prevented by safer storage of iron supplements in the year before and the year after the birth of a sibling.

In 1997, the Food and Drug Administration (FDA) mandated that all iron salt–containing preparations display warning labels regarding the dangers of pediatric iron poisoning. In addition to the warning labels, the FDA launched an educational campaign to alert caregivers and prescribers of the potential toxicity of iron supplements. The FDA also required unit dosing (blister packs) of prescriptions for preparations containing more than 30 mg of elemental iron and limitations on the number of pills dispensed. These efforts to prevent unintentional exposures dramatically decreased the incidence of poisoning and were pivotal in decreasing morbidity and mortality associated with iron poisoning.<sup>73</sup> However, in 2003, the FDA rescinded the blister packaging requirement in response to a lawsuit by the Nutritional Health Alliance charging that the FDA did not have jurisdiction over the packaging of dietary supplements.<sup>20</sup> Although isolated fatalities continue to occur, analysis of the Annual Reports from the National Poison Data System suggests the initial

reduction in serious exposures from iron poisonings have been sustained (Chap. 130). Iron poisoning also occurs after ingestion of other iron salts used in industry, such as ferric chloride.<sup>89</sup>

### PHARMACOLOGY, PHARMACOKINETICS, AND TOXICOKINETICS

Iron is an element critical to organ function. As a transition metal, iron readily accepts and donates electrons, shifting between the ferric ( $\text{Fe}^{3+}$ ) and ferrous ( $\text{Fe}^{2+}$ ) oxidation states (Chap. 10). This redox capacity illuminates the role of iron in multiple protein and enzyme complexes, including cytochromes and myoglobin, although it is principally incorporated into hemoglobin in erythrocytes. Whereas insufficient iron availability results in anemia, excess total-body iron results in hemochromatosis.

The body cannot directly excrete iron, so iron stores are regulated by controlling iron absorption from the GI tract. The absorption of iron salts (iron ions as  $\text{Fe}^{2+}$  or  $\text{Fe}^{3+}$ ) occurs predominantly in the duodenum and is determined by the iron requirements of the body. In iron deficiency, iron absorption and uptake into intestinal mucosal cells increase from a normal 10% to 35% to as much as 80% to 95%. After uptake into the intestinal mucosal cells, iron is either stored as ferritin and lost when the cell is sloughed or released to transferrin, a serum iron binding protein. In therapeutic doses, some of these processes become saturated, and absorption into the intestinal cell is limited. However, in overdose, the oxidative effects of iron on GI mucosal cells lead to dysfunction of this regulatory balance, and passive absorption of iron increases down its concentration gradient (see Pathophysiology).<sup>72</sup> Iron ions are rapidly bound to circulating binding proteins, particularly transferrin. After transferrin is saturated with iron, “free” iron or non–transferrin-bound iron is widely distributed to the various organ systems, where it promotes damaging oxidative processes.

Iron supplements are available as the iron salts ferrous gluconate, ferrous sulfate, and ferrous fumarate and as the nonionic preparations carbonyl iron and polysaccharide iron. Additional sources of significant quantities of iron are vitamin preparations, especially prenatal vitamins (Table 45–1). Toxic effects of iron poisoning occur at doses of 10 to 20 mg/kg of elemental iron, which is defined as the amount of iron ion present in an iron salt (Table 45–1). Significant GI toxic effects occurred in human adult volunteers who ingested 10 to 20 mg/kg elemental iron.<sup>9,47</sup> In one volunteer study, six participants who ingested 20 mg/kg of elemental iron developed nausea and voluminous diarrhea within 2 hours, and five of the six participants had serum iron concentrations above 300 mcg/dL.<sup>9</sup>

In another study of human volunteers who ingested 5 to 10 mg/kg of elemental iron in the form of chewable iron-containing vitamins, peak serum iron concentrations occurred between 4.2 and 4.5 hours in all participants.<sup>47</sup> In overdose, peak concentrations of iron occur 2 to 6 hours after ingestion, depending on the iron preparation.<sup>9,47</sup> Chewable vitamins continue to entice children with their sweet taste and characteristic shapes, increasing the risk of significant exposure. Children’s chewable multivitamins contain less iron per tablet (10–18 mg of elemental iron) than typical prenatal vitamins (65 mg of elemental iron). Iron toxicity still results when large quantities of chewable children’s vitamins are ingested, but the therapeutic-to-toxic ratio is improved.<sup>2</sup> One animal study paradoxically demonstrates higher iron concentrations after ingestion of equivalent elemental iron doses of chewable versus solid iron tablets.<sup>57</sup> This finding was attributed, in part, to the limited gastric irritation associated with the chewable iron preparations, resulting in less vomiting.

The nonionic forms, carbonyl iron and iron polysaccharide appear to be less toxic after overdose than iron salts<sup>69</sup> despite their high elemental iron content.<sup>42</sup> Carbonyl iron is a form of elemental iron that is highly bioavailable

TABLE 45–1 Common Iron Formulations and Their Elemental Iron Content

Iron Formulation: Oral	Elemental Iron (%)
<b>Ionic</b>	
Ferrous chloride	28
Ferrous fumarate	33
Ferrous gluconate	12
Ferrous lactate	19
Ferrous sulfate	20
<b>Nonionic<sup>a</sup></b>	
Carbonyl iron	98
Polysaccharide iron	46
<b>Iron Formulation: Parenteral</b>	
Ferric carboxymaltose	5
Ferric gluconate	1.25
Ferumoxylol	3
Iron dextran (low molecular weight)	5
Iron sucrose	2

<sup>a</sup>Although the nonionic iron formulations contain higher elemental iron content than ionic formulations, carbonyl iron and iron polysaccharide have better therapeutic-to-toxic ratios because of their limited gastrointestinal absorption rates.

in therapeutic doses compared with other forms of iron because of its very fine, spherical particle size (5  $\mu\text{m}$ ).<sup>28</sup> In a rat model of iron toxicity, carbonyl iron had a median lethal dose ( $\text{LD}_{50}$ ) of 50 g/kg compared with an  $\text{LD}_{50}$  of 1.1 g/kg for ferrous sulfate.<sup>84</sup> No significant toxicity in humans exposed to carbonyl iron has been reported.<sup>69</sup> Iron polysaccharide contains approximately 46% elemental iron by weight. It is synthesized by neutralization of a ferric chloride carbohydrate solution. This form of iron also appears to have much lower toxicity than iron salts. The estimated  $\text{LD}_{50}$  in rats is more than 5 g/kg body weight. Retrospective poison control center data have failed to demonstrate significant toxicity from either of these products.<sup>42</sup>

Oral iron replacement is the primary treatment strategy for iron deficiency anemia; however, this may not be well tolerated or may be limited by absorption or ongoing bleeding. In contrast to oral iron, parenteral iron does significantly increase concentrations of hemoglobin, serum ferritin, and transferrin saturation. However, infusion of these iron formulations was historically associated with high rates of adverse events attributed to anaphylactoid reactions. It is postulated that early iron infusion events were related to the rapid release of large amounts of unbound iron causing severe toxicity. Subsequently, parenteral iron was complexed to high-molecular-weight dextran to stabilize and slow the release of iron and was widely administered to patients with kidney failure and chronic anemia, but measurable rates of adverse events persisted. More recently, iron combined with low-molecular-weight dextran was formulated and is a safer alternative. Newer parenteral formulations, including iron sucrose and sodium ferric gluconate, produce fewer adverse events.<sup>19</sup> A comparative analysis of nondialysis patients receiving intravenous (IV) iron for iron deficiency anemia further documented the highest risk of reactions in first exposures to iron dextran (including high- and low-molecular-weight formulations) and lowest with iron sucrose.<sup>82</sup> One case of self-poisoning by a nurse with IV iron infusion resulted in delayed hepatotoxicity but no acute toxicity.<sup>90</sup>

## PATHOPHYSIOLOGY

Iron participates in many oxidation reduction (redox) reactions. Iron catalyzes the generation of hydroxyl radicals intracellularly through the Fenton reaction and Haber-Weiss cycle and mediates its toxicologic effects as an

inducer of oxidative stress and inhibitor of several key metabolic enzymes (Chap. 10). Reactive oxygen species oxidize membrane-bound lipids and cause loss of cellular integrity and tissue injury.<sup>63,65</sup>

The initial oxidative damage to the GI epithelium produced by iron-induced reactive oxygen species permits iron ions to enter the systemic circulation. A postmortem series of 11 patients who died from iron ingestion substantiated these findings with measurements of elevated iron concentrations in most major organs examined, including the stomach, liver, brain, heart, lung, small bowel, and kidney.<sup>60</sup> Congestion, edema, necrosis, and iron deposition in the gastric and intestinal mucosa, as well as hemorrhage and congestion in the lungs, are noted on postmortem examination.<sup>32,49</sup>

Iron ions disrupt critical cellular processes such as mitochondrial oxidative phosphorylation. Subsequent buildup of unused hydrogen ions usually incorporated into the synthesis of adenosine triphosphate leads to liberation of  $\text{H}^+$  and development of a metabolic acidosis (Chap. 11). In addition, absorption of iron from the GI tract leads to conversion of ferrous iron ( $\text{Fe}^{2+}$ ) to ferric iron ( $\text{Fe}^{3+}$ ). Ferric iron ions exceed the binding capacity of plasma, leading to formation of ferric hydroxide and release of three protons ( $\text{Fe}^{3+} + 3\text{H}_2\text{O} \rightarrow \text{Fe}(\text{OH})_3 + 3\text{H}^+$ ) further contributing to the acidosis.<sup>63,72</sup>

Decreased cardiac output contributes to shock in animals.<sup>80,86</sup> Although this finding is often attributed to decreased preload and relative bradycardia,<sup>80</sup> a direct negative inotropic effect of iron on the myocardium is also demonstrated in animal models.<sup>3</sup> Reports of early coagulopathy unrelated to hepatotoxicity<sup>75</sup> led to the identification of non-transferrin-bound iron as an inhibitor of thrombin formation and the reduction of the effect of thrombin on fibrinogen.<sup>66</sup>

## CLINICAL MANIFESTATIONS

Classic teaching postulates five clinical stages of iron toxicity based on the pathophysiology of iron poisoning.<sup>5,37,62</sup> Although conceptually important, they are of limited benefit to clinicians managing poisoned patients. Although these stages are typically described in approximate postingestion time frames, a clinical stage should never be assigned based solely on the number of hours postingestion because patients do not necessarily follow the same temporal course through these stages.

The first stage of iron toxicity is characterized by nausea, vomiting, abdominal pain, and diarrhea. These “local” toxic effects of iron predominate, and subsequent salt and water depletion contribute to the ill appearance of the iron-poisoned patient. Intestinal ulceration, edema, transmural inflammation, and, in some extreme cases, small-bowel infarction and necrosis occur.<sup>21,64</sup> Hematemesis, melena, or hematochezia contribute to hemodynamic instability. Gastrointestinal symptoms and findings are prominent after significant overdose. Conversely, the absence of signs and symptoms, specifically vomiting, in the first 6 hours after ingestion, almost always excludes serious iron toxicity.

The second, or “latent,” stage of iron poisoning commonly refers to the period 6 to 24 hours after ingestion when resolution of GI symptoms and findings occurs but overt systemic toxicity has not yet developed. Delineation of this stage likely evolved from early case reports of patients whose GI symptoms and findings had resolved before subsequent deterioration.<sup>78</sup> This second stage is not truly quiescent because cellular toxicity continues.<sup>5</sup> Although clinicians should be wary of patients who no longer have active GI complaints after iron overdose, most such patients have, in fact, recovered and are not in the latent phase. Patients in the latent phase generally have lethargy, tachycardia, or metabolic acidosis. They should be readily identifiable as clinically ill despite resolution of their GI symptoms. Patients who have remained well since ingestion and who have stable vital signs, a normal mental status, and a normal acid–base balance will have a benign clinical course.

Patients who progress to the third, or “shock,” stage of iron poisoning have profound toxicity. This stage typically occurs in the first few hours after a massive (>60 mg/kg elemental iron) ingestion or as long as 12 to 24 hours after a more moderate (>40 mg/kg) ingestion. The cause of shock is likely multifactorial, resulting from one or more of these pathologic processes: hypovolemia, vasodilation, and poor cardiac output,<sup>80,86</sup> resulting in

decreased tissue perfusion and a metabolic acidosis. Iron-induced coagulopathy worsens bleeding and hypovolemia.<sup>75</sup> Systemic toxicity produces central nervous system effects such as lethargy, hyperventilation, seizures, or coma. The fourth stage of iron poisoning is characterized by hepatic failure, which typically occurs 2 to 3 days after ingestion.<sup>26</sup> The hepatotoxicity is directly attributed to iron uptake by the reticuloendothelial system in the liver, where it causes oxidative damage.<sup>24,88</sup> The fifth stage of iron toxicity is rarely manifest. Gastric outlet obstruction, secondary to strictures and scarring from the initial GI injury, develops 2 to 8 weeks after ingestion.<sup>23,31</sup>

Patients treated for chronic iron overload are at increased risk for *Yersinia enterocolitica* infection. Iron is a required growth factor for *Y. enterocolitica*; however, the bacterium lacks the siderophore to solubilize and transport iron intracellularly. Because deferoxamine (DFO) is a siderophore, it fosters the growth of *Y. enterocolitica*. Deferoxamine may similarly facilitate growth and infection by ferrophilic organisms such as *Klebsiella* spp, *Vibrio* spp, *Aeromonas hydrophila*, *Mucorales* spp, and other pathogens.<sup>22,46,55,71</sup> Thus, patients with chronic iron overload<sup>12</sup> or acute poisoning develop *Yersinia* infection or sepsis as a complication of iron poisoning or ironically DFO therapy.<sup>52</sup> *Yersinia* infection should be suspected in patients who experience abdominal pain, fever, and bloody diarrhea after resolution of iron toxicity. In this setting, cultures should be obtained, fluid and electrolyte repletion accomplished, and an appropriate antibiotic regimen initiated.

## DIAGNOSTIC TESTING

### Radiography

Iron is available in many forms, and the different preparations vary with respect to radiopacity on abdominal radiography.<sup>70</sup> Factors such as the time since ingestion and elemental iron content of the tablets are also important.<sup>56,70</sup> Liquid iron formulations and chewable iron tablets typically are not radiopaque.<sup>16</sup> A retrospective review of presumed iron ingestions in children revealed that abdominal radiographs were positive in only one of 30 patients who ingested chewable iron containing vitamin tablets.<sup>16</sup> Because adult tablet preparations have a higher elemental iron content and do not readily disperse, they tend to be more consistently radiopaque.<sup>56</sup> Finding radiopaque pills on an abdominal radiograph is helpful in guiding and evaluating the success of GI decontamination.<sup>33</sup> However, the absence of radiographic evidence of tablets is not a reliable indicator to exclude potential toxicity (Fig. 8–3).<sup>56,59</sup> Most patients with minimal symptoms should be managed without abdominal radiographs, given their lack of sensitivity. We recommend abdominal radiographs in patients with signs of severe poisoning to assess the quantity of retained tablets.

### Laboratory Studies

Various laboratory studies are used as surrogate markers to assess the severity of iron poisoning. An anion gap metabolic acidosis and an elevated lactate concentration will develop in patients with serious iron ingestions. Serial blood counts and electrolyte measurements should be used to assess progression and response to volume replacement. Anemia will result from GI blood loss but may not be evident initially because of hemoconcentration secondary to plasma volume loss.

Although one small retrospective study of iron-poisoned children found that a white blood cell (WBC) count above 15,000/mm<sup>3</sup> or a blood glucose concentration above 150 mg/dL was 100% predictive of iron concentration above 300 mcg/dL (a marker for clinical risk),<sup>45</sup> three subsequent similar studies were unable to validate this association.<sup>13,44,59</sup> In practice, an elevated WBC count or glucose concentration in the setting of a known or suspected iron ingestion should raise concern about an elevated serum iron concentration; however, assessment of the signs and symptoms of the patient is more reliable. Most important, a normal WBC count and glucose concentrations do not reliably exclude toxicity.

Although iron poisoning remains a clinical diagnosis, serum iron concentrations can be used effectively to gauge toxicity and the success of treatment.<sup>5</sup> In the previously mentioned human volunteer study of six adults who ingested 20 mg/kg of elemental iron, all six adults demonstrated

significant GI toxicity, and the four who required IV fluid resuscitation had peak serum iron concentrations in the range of 300 mcg/dL between 2 and 4 hours after ingestion.<sup>9</sup> Serum iron concentrations between 300 and 500 mcg/dL usually correlate with significant GI toxicity and modest systemic toxicity. Concentrations between 500 and 1,000 mcg/dL are associated with pronounced systemic toxicity and shock.<sup>83</sup> Concentrations above 1,000 mcg/dL are associated with significant morbidity and mortality.<sup>83</sup> Although elevated serum iron concentrations suggest the potential for significant toxicity, lower concentrations cannot be used to exclude the possibility of toxicity. A single serum iron concentration may not represent a peak concentration or may be falsely lowered by the presence of DFO interference in the colorimetric tests used routinely to measure iron. This inaccuracy in measurement can be avoided if the rarely available atomic absorption spectrometry technique is used.<sup>25,30</sup>

Total iron-binding capacity (TIBC) is a measurement of the total amount of iron that can be bound by transferrin in a given volume of serum.<sup>18</sup> Previously, clinical iron toxicity was thought not to occur if the serum iron concentration was less than the TIBC because insufficient circulating non-transferrin-bound iron was present to cause tissue damage. Although this is true, the error in interpretation results from the limitations of measuring TIBC values. Most important, the in vitro value of TIBC factitiously increases as a result of iron poisoning and thus has a tendency to apparently increase above a concurrently measured serum iron concentration.<sup>9,77</sup> Because of many confounding issues, the TIBC as currently determined has limited value in the assessment of iron-poisoned patients.

## MANAGEMENT

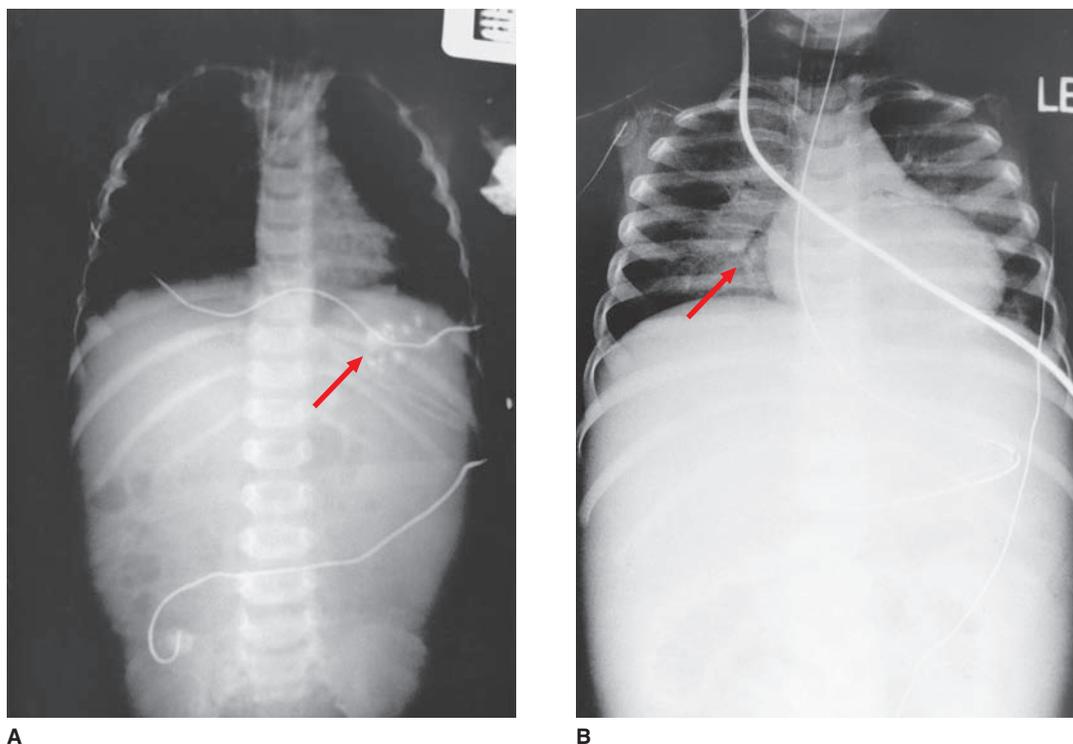

### Initial Approach

Following a significant ingestion, initial stabilization must include airway assessment and establishment of IV access. In the absence of coingestants, evidence of hematemesis or lethargy after an iron exposure is a manifestation of significant toxicity. Intravenous volume repletion should begin in any patient with a history of massive exposure (>60 mg/kg) or tachycardia, lethargy, or metabolic acidosis. In any lethargic patient at risk for further deterioration, early endotracheal intubation facilitates controlled GI decontamination. Abdominal radiography is recommended to estimate the iron burden in the GI tract given the caveats discussed earlier. Laboratory values, including chemistries, hemoglobin, iron concentration, coagulation, and hepatic profiles, should be obtained. An arterial or venous blood gas and a lactate concentration rapidly identify a metabolic acidosis. Patients who appear well and have had only one or two brief episodes of vomiting can be observed for 6 hours and then safely dispositioned. A serum iron concentration and most other laboratory testing are not indicated in patients who have minimal symptoms and normal vital signs.

### Limiting Absorption

Gastrointestinal decontamination procedures should be initiated after stabilization. Adequate gastric emptying is critical after ingestion of xenobiotics, such as iron, that are not well adsorbed to activated charcoal. Because vomiting is a prominent early finding in patients with significant toxicity, induced emesis is not recommended. Orogastric lavage is more effective but often is of limited value because of the large size and poor solubility of most iron tablets; their ability to form adherent masses, bezoars, or concretions;<sup>21,79</sup> and their movement into the bowel several hours after ingestion.<sup>39</sup> The presence and location of radiopaque tablets on abdominal radiography can help guide early orogastric lavage in patients with suspected significant poisoning. Orogastric lavage (Antidotes in Depth: A2) will not be successful after iron tablets move past the pylorus, when WBI will be more appropriate and effective (Fig. 45–1).

Many strategies were used in the past in attempts to improve the efficacy of orogastric lavage. At the present time, no data support the use of oral DFO,<sup>29,93,95</sup> bicarbonate, phosphosoda, or magnesium.<sup>72,88</sup> Although some of these techniques demonstrate efficacy, avoidance of the associated risks mandates using only 0.9% sodium chloride solution or tap water for orogastric lavage.

**FIGURE 45-1.** (A) A 17-month-old boy presented to the hospital with lethargy and hematemesis after a large ingestion of iron supplement tablets. Despite orogastric lavage and whole-bowel irrigation, iron tablets and fragments can be visualized in the stomach (→) 4 hours after ingestion. (B) The same 17-month-old child 10 hours after ingestion. Persistent iron pills were removed from the stomach by gastrotomy. No further radiopaque fragments can be visualized; however, acute respiratory distress syndrome (→) is now visible.

The value of WBI in patients with iron poisoning is supported primarily by case reports and one uncontrolled case series.<sup>39,74</sup> However, the rationale for WBI use is logical, especially considering the limitations of other gastric decontamination modalities. The usual dose of WBI with polyethylene glycol electrolyte lavage solution (PEG-ELS) is 500 mL/h in children and 2 L/h in adults. This rate is best achieved by starting slowly and increasing as tolerated, often using a nasogastric tube and an enteral feeding pump to administer large volumes. Antiemetics are recommended to treat nausea and vomiting. A large volume (44 L) of WBI was administered safely over a 5-day period to a child who had persistent iron tablets on serial abdominal radiographs<sup>39</sup> (Antidotes in Depth: A2 and Chap. 6).

For patients with life-threatening toxicity who demonstrate persistent iron in the GI tract despite orogastric lavage and WBI, it is reasonable to pursue upper endoscopy or gastrotomy and surgical removal of iron tablets adherent to the gastric mucosa.<sup>21</sup>

### Deferoxamine

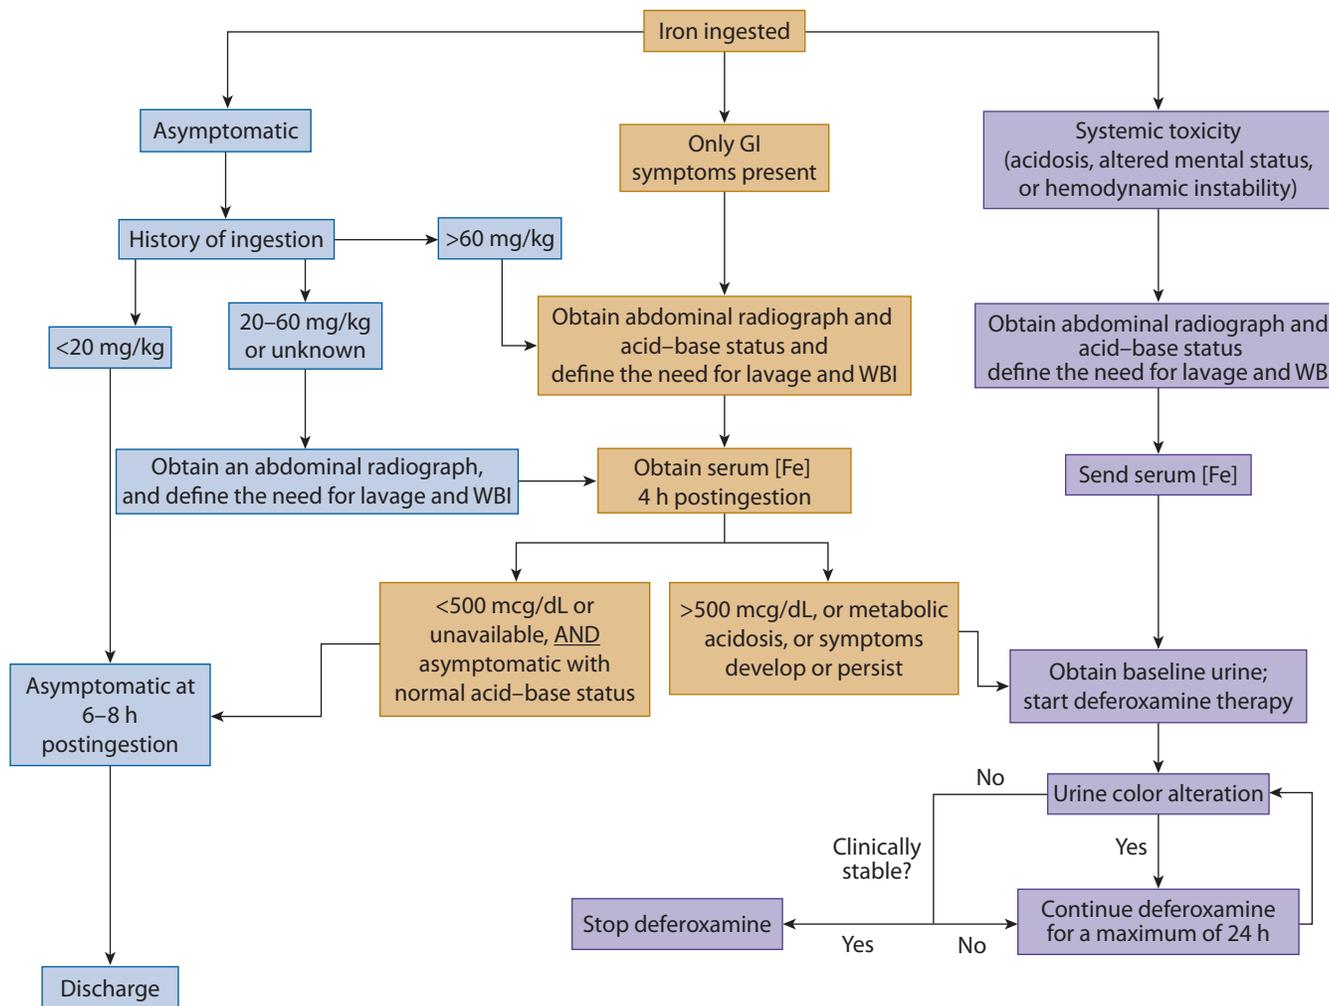

Deferoxamine has been available since the 1960s as a specific chelator for patients with acute iron overdose or chronic iron overload (eg, transfusion-dependent anemias). Deferoxamine, which is derived from culture of *Streptomyces pilosus*, has high affinity and specificity for iron. In the presence of ferric iron ( $\text{Fe}^{3+}$ ), DFO forms the complex ferrioxamine, which is excreted by the kidneys,<sup>40</sup> usually imparting a reddish-brown color to the urine (Fig. 45-2). Deferoxamine chelates non-transferrin-bound iron and the iron transported between transferrin and ferritin<sup>48,61</sup> but not the iron present in transferrin, hemoglobin, or cytochromes.<sup>40</sup> Deferoxamine works by other mechanisms in addition to binding excess systemic iron. Because 100 mg of DFO chelates approximately 8.5 mg of ferric iron, recommended or typical therapeutic dosing of DFO does not produce significant excretion of chelated iron in the urine, yet it does often result in dramatic clinical benefits (Antidotes in Depth: A7). Sufficient evidence suggests that DFO can reach intracytoplasmic and mitochondrial non-transferrin-bound iron, thereby limiting intracellular iron toxicity.<sup>48</sup>

Deferoxamine is recommended for iron-poisoned patients with any of the following findings: repetitive vomiting, toxic appearance, lethargy,

hypotension accompanied by metabolic acidosis or signs of shock, and any patients with serum iron concentrations above 500 mcg/dL. Deferoxamine is initiated as an IV infusion, starting at 5 mg/kg/h and gradually increasing to a rate of 15 mg/kg/h. Hypotension is the rate-limiting factor as more rapid infusions are used.<sup>34</sup> After several hours of infusion at 15 mg/kg/h, the patient should be reassessed and the dose decreased to keep the maximum dose less than 6 to 8 g/24 hours. Patients who have concentrations below 500 mcg/dL

**FIGURE 45-2.** Sequential urine samples in a 22-year-old woman who may have ingested 180 tablets of ferrous sulfate (300 mg). She received 8 hours of deferoxamine at 15 mg/kg/h, 30 mg/kg/h for 2 hours, and then 15 mg/kg/h for 4 hours. The first serum iron concentration was 4,573 mcg/dL at 3 hours postingestion. The patient's first urine sample is on the left and then follow in sequence over a number of hours. (Used with permission from Poison and Drug Information Service (PADIS), Alberta Health Services.)

**FIGURE 45-3.** Algorithm for decision analysis after iron salt ingestion. GI = gastrointestinal; WBI = whole-bowel irrigation.

and who do not appear toxic should be treated supportively without administration of parenteral DFO (Fig. 45-3).

Clinicians have attempted to define the earliest clear endpoints for DFO therapy because of possible DFO toxicity. In one report, a urine iron-to-creatinine ratio (U<sub>i</sub>/Cr) was used to determine if non-transferrin-bound iron excretion into the urine continued during DFO. This ratio is a more objective measure of the presence of ferrioxamine in the urine than the less reliable and more subjective use of urinary color change.<sup>43,51</sup> This method must be further studied clinically before its use can be advocated. Most authors agree that DFO therapy should be discontinued when the patient appears clinically well, the anion-gap acidosis has resolved, and urine color undergoes no further change.<sup>53</sup> The duration of DFO therapy should be limited to 24 hours to minimize risk of pulmonary toxicity. In patients with persistent signs and symptoms of serious toxicity after 24 hours of IV DFO, there is little evidence to define the risk or benefit for continuing DFO (Antidotes in Depth: A7).

#### Adverse Effects of Deferoxamine

Most adverse effects of DFO are reported in the setting of chronic administration for the treatment of hemochromatosis.<sup>35,67</sup> The same effects, such as acute respiratory distress syndrome (ARDS), are also described after treatment for acute iron overdose.<sup>76</sup> Four patients with serum iron concentrations ranging from 430 to 620 mcg/dL developed ARDS after IV administration of DFO for 32 to 72 hours.<sup>76</sup> An animal study revealed significantly increased pulmonary toxicity when high-dose DFO therapy was administered in the presence of high concentrations of oxygen (75%–80% FiO<sub>2</sub>).<sup>1</sup> The authors suggested that this effect was mediated via an oxygen free radical mechanism (Antidotes in Depth: A7).

#### Experimental Therapies

Deferasirox is an oral iron chelator approved for the treatment of chronic iron overload and has been studied as a potential iron antidote in human volunteers. In a randomized, double-blind, placebo-controlled study, 5 mg/kg of iron was followed by deferasirox or placebo.<sup>29</sup> Deferasirox resulted in lower iron concentrations in the treated group. However, concerns included the possibility that deferasirox may increase the absorption of iron complex and that the deferasirox dosing may need to be too high in patients with large exposures to affect these results. Further study is warranted before this therapy can be recommended. Deferiprone is another oral iron chelator now approved for the treatment of refractory chronic iron overload secondary to thalassemia. Deferiprone combines with iron in a 3:1 ratio to form a stable complex that is excreted in the urine. Although deferiprone decreased the mortality rate in animal models of acute iron toxicity,<sup>7,17</sup> it has not yet been studied in acute iron poisoning.

#### Patient Disposition

Many patients who ingest iron do not develop significant toxic effects. Recommendations for hospital referral of toddlers who ingest iron range from those with potential exposures of 20 mg/kg up to 60 mg/kg.<sup>5,43</sup> These wide ranges probably result from the interpretation of retrospective studies in possibly “exposed” toddlers for whom the actual doses were estimated and serum values were not determined. Many authors suggest that doses were overestimated in patients who subsequently did not develop toxicity (Chap. 130). If a toddler remains asymptomatic or develops minimal or no GI manifestations after a 6-hour observation period in the emergency department, then discharge to an appropriate home situation is reasonable. Patients

who develop GI symptoms and signs of mild poisoning including vomiting and diarrhea can be observed with supportive care in an observation unit. Patients who manifest signs and symptoms of significant iron poisoning, such as metabolic acidosis, hemodynamic instability, or lethargy, should be monitored and treated in an intensive care unit. Hospital evaluation is recommended for any child with an estimated unintentional (unsupervised) ingestion of more than 20 mg/kg of elemental iron, except in the case of carbonyl iron. Children who appear well with unintentional ingestions between 10 and 20 mg/kg of elemental iron and only an isolated episode of vomiting should be closely followed at home in consultation with the poison control center.

### Pregnant Patients

The use of iron to treat iron deficiency anemia during pregnancy has led to serious and even fatal iron ingestions in pregnant women.<sup>8,41,58</sup> In all cases of toxic exposures during pregnancy, maternal resuscitation should always be the primary objective, even if an antidote poses a real or theoretical risk to the fetus. Unproven concerns regarding possible DFO toxicity to the fetus have inappropriately, and at times, disastrously delayed therapy.<sup>58</sup> These fears about fetal DFO toxicity are not supported in either human or animal studies,<sup>15,50</sup> which have demonstrated that neither iron nor DFO is transferred to the fetus in appreciable quantities. An animal study demonstrated that fetal serum iron concentrations were not elevated and fetal DFO concentrations could not be detected in pregnant near-term ewes poisoned with iron and treated with DFO.<sup>15</sup> Fetal demise under these circumstances presumably results from maternal iron toxicity and not from direct iron toxicity to the fetus. Thus, DFO should be used to treat serious maternal iron poisoning and should never be withheld because of unfounded concern for fetal exposure to DFO.

### Adjunctive Therapies

Another modality explored experimentally for treatment of iron intoxication is continuous arteriovenous hemofiltration (Chap. 6). In a study of five iron-poisoned dogs, increased elimination of ferrioxamine in the ultrafiltrate was demonstrated when increasing doses of DFO were infused into the arterial side of the system.<sup>6</sup> A variant of this approach was used successfully in an iron-poisoned toddler, who was treated with DFO and venovenous hemofiltration.<sup>54</sup> The authors demonstrated a decreasing serum iron concentration, and although a minimal concentration of iron was measured in the ultrafiltrate, the large volumes of dialysate used would remove significant amounts of iron. Theoretically, ferrioxamine in the blood could be dialyzable with current hemodialysis techniques (Chap. 6).

In toddlers with severe poisoning, exchange transfusion should be considered early to help physically remove all iron from the blood while replacing it with normal blood. Exchange transfusion in children is effective for poisonings such as aspirin or theophylline when the volume of xenobiotic distribution is small and removal from the blood compartment can be expected. Treatment with exchange transfusion has been suggested in iron poisoning based on early reports and in the successful treatment of an 18-month-old toddler with iron poisoning.<sup>10</sup> However, removal of blood volume must be performed cautiously because it can worsen hypotension in iron-poisoned patients with hemodynamic instability.

### SUMMARY

- Iron is available in multiple formulations; prenatal vitamins, ferrous gluconate, ferrous fumarate, and ferrous sulfate are most toxic.
- Iron toxicity is determined by the amount of elemental iron ingested; signs and symptoms occur after ingestions of 20 mg/kg of elemental iron.
- Gastrointestinal decontamination, including orogastric lavage and WBI using PEG-ELS, are recommended when indicated because activated charcoal is ineffective in adsorbing iron.
- Abdominal radiography is recommended in determining the iron burden in the GI tract in those with large ingestions and those with symptoms. However, not all preparations are radiopaque.

- Gastrointestinal signs and symptoms of nausea, vomiting, diarrhea, hematemesis, and abdominal pain are prominent in iron poisoning.
- Systemic iron toxicity leads to metabolic acidosis, hypotension, coagulopathy, and multiorgan system failure.
- Diagnosis and treatment of shock and metabolic acidosis, as well as chelation with DFO, are critical.

## DEFEROXAMINE

Mary Ann Howland

## INTRODUCTION

Deferoxamine (DFO) is the parenteral chelator of choice for treatment of acute iron poisoning. Even though DFO has been used to treat patients with acute iron overdose for more than 60 years,<sup>35</sup> there is still much that is unknown. No controlled studies have evaluated the efficacy or dosing of DFO. Animal studies and case series from the 1960s and 1970s form the basis for current use of DFO. This information has been supplemented by case reports and clinical experience. Deferoxamine is also used for chelation of aluminum in patients with chronic kidney failure. The merits of DFO as a treatment strategy for acute iron overdose are discussed in Chap. 45 and for aluminum toxicity in Chap. 84.

## HISTORY

The development of DFO (or desferrioxamine B) resulted from an analysis of the iron-containing metabolites of a species of *Actinomycetes*. Ferrioxamine is a brownish-red compound containing trivalent iron (ferric,  $\text{Fe}^{3+}$ ) and three molecules of trihydroxamic acid isolated from the organism *Streptomyces pilosus*.<sup>40</sup> Deferoxamine is the colorless compound that results when the trivalent iron is chemically removed from ferrioxamine B (Fig. A7-1).<sup>40</sup>

## PHARMACOLOGY

## Chemistry

Deferoxamine is a water-soluble hexadentate chelator with a molecular weight of 561 Da. The commercial formulation is the mesylate salt with a

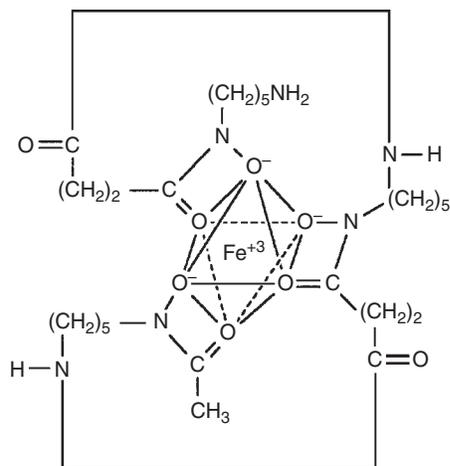

FIGURE A7-1. Ferrioxamine.

molecular weight of 657 Da. One mole of DFO binds 1 mole of  $\text{Fe}^{3+}$ ; therefore, 100 mg DFO as the mesylate salt theoretically can bind 8.5 mg  $\text{Fe}^{3+}$ .

Deferoxamine has a much greater affinity constant for iron ( $10^{22}$ ) and aluminum ( $10^{22}$ ) than for zinc, copper, nickel, magnesium, or calcium ( $10^2$ – $10^{14}$ ).<sup>40</sup> Thus, at physiologic pH, DFO complexes almost exclusively with ferric iron.<sup>30,91</sup>

## Related Chelators

Deferiprone, a bidentate oral iron chelator with a molecular weight of 139 Da, was approved by the US Food and Drug Administration (FDA) in 2011 for the treatment of iron overload in patients with thalassemia major in whom current treatment is inadequate.<sup>26</sup> Three moles of deferiprone are required to bind 1 mole of ferric ion to form a stable complex, which is excreted in the urine.<sup>34</sup> Inappropriate ratios of drug to iron are ineffective or even harmful because of the formation of potentially toxic intermediates.<sup>34</sup> Preliminary animal studies of the use of deferiprone in acute iron toxicity are contradictory.<sup>10,25,38,41</sup> A dose of 75 mg/kg deferiprone produces 60% of the total iron excretion that can be achieved with 50 mg/kg of DFO. All of the iron eliminated with deferiprone occurs in the urine, but DFO eliminates iron in the urine and feces.<sup>45</sup> In contrast to DFO, deferiprone is able to remove iron from transferrin and is often able to maintain normal iron stores in patients with chronic iron overload syndromes. Toxicity appears minimal, although some patients were required to stop deferiprone therapy to avoid iron deficiency. Adverse events include elevation of hepatic enzymes, gastrointestinal (GI) effects, arthralgia, and chromaturia. Because of embryofetal toxicity in animal studies, deferiprone is given an FDA pregnancy category D; DFO carries a boxed warning for neutropenia and agranulocytosis.<sup>26</sup> Deferiprone is now being combined with DFO because studies demonstrate additive or synergistic effects in chronic iron overload syndromes. It is hypothesized that deferiprone, because of its smaller size, can enter and chelate cardiac iron and then transfer it to DFO for elimination.<sup>23,44,45,87</sup>

Deferasirox, an oral iron chelator that was FDA approved in 2005, is indicated to treat chronic iron overload caused by blood transfusions or in patients with thalassemia major and elevated liver iron concentrations. Deferasirox, a tridentate ligand with a molecular weight of 373 Da, binds ferric iron in a 2:1 ratio. Deferasirox is lipid soluble with high protein binding (~99%). When bound to iron, the complex is predominantly eliminated in the feces. The serum half-life ( $19 \pm 6.5$  hours) is considerably longer than those of DFO and deferiprone (47–137 minutes). Preliminary studies demonstrate a comparable efficacy to DFO in patients with chronic iron overload.<sup>86</sup> One study using deferasirox in a human model of a modest supraphysiologic iron ingestion (only 5 mg/kg) demonstrated a reduction in serum iron concentrations when compared with placebo.<sup>31</sup> Concerns about achieving the effective dose ratio of deferasirox to iron of 2:1 and the effects of acidemia on the binding of deferasirox to iron in a large overdose limit its use.<sup>60</sup> In addition, similar to other oral chelators, concerns exist about increasing oral absorption of the deferasirox iron complex and the toxicity of this complex in an acute iron overdose.<sup>24,69,78</sup> Adverse events include boxed warnings for GI hemorrhage, kidney failure, and hepatic failure. Advanced age increases these risks.<sup>24</sup>

## Mechanism of Action

Deferoxamine binds  $\text{Fe}^{3+}$  at the 3 N–OH sites, forming an octahedral iron complex (Fig. A7-1). When bound, the resultant ferrioxamine is very stable.

Deferoxamine benefits iron-poisoned patients by chelating non-transferrin-bound iron (previously referred to as "free iron"), iron in transit between transferrin and ferritin (labile chelatable iron pool),<sup>4,34,49,71</sup> and hemosiderin and ferritin while not directly affecting the iron of transferrin, hemoglobin, and cytochromes.<sup>21,40</sup> Although the binding affinity of DFO for iron is greater than the binding affinity of transferrin for iron, the slow pharmacokinetics of DFO prevent appreciable iron removal from transferrin. Deferoxamine binds non-transferrin-bound iron found in the plasma after transferrin saturation, which occurs acutely after an overdose or chronically in iron overload syndromes.<sup>34</sup> In vitro studies demonstrate that DFO chelates and inactivates cytoplasmic, lysosomal, and probably mitochondrial iron, preventing disruption of mitochondrial function and injury.<sup>29,49</sup> An in vitro study suggests that DFO gains access to cytosol and endosomes through endocytosis rather than passive diffusion.<sup>29</sup> In chronic iron overload, DFO slows the amount of iron that accumulates in the liver that would result in hepatic fibrosis.<sup>21</sup>

### Pharmacokinetics and Pharmacodynamics

The volume of distribution of DFO ranges from 0.6 to 1.33 L/kg.<sup>40,46,63</sup> Because DFO is water soluble, entry into most cells is limited except for hepatocytes, in which facilitated uptake occurs.<sup>67-69</sup> The initial distribution half-life of DFO is 5 to 10 minutes.<sup>43,77</sup> The terminal elimination half-life of DFO is approximately 6 hours in healthy patients<sup>2</sup> but is approximately 3 hours in patients with thalassemia major. Deferoxamine is metabolized in the plasma to several metabolites (A-F), of which metabolite B is believed to be toxic.<sup>40,46,63,65</sup> Unchanged DFO undergoes glomerular filtration and tubular secretion.<sup>53</sup>

By comparison, ferrioxamine has a smaller volume of distribution than DFO. In nephrectomized dogs, the volume of distribution of ferrioxamine was calculated to be 19% of body weight compared with 50% of body weight for DFO.<sup>40</sup> This finding implies that DFO has a more extensive tissue distribution. The different pharmacokinetic characteristics are related to the potential for facilitated penetrance of the straight-chain molecule DFO compared with that of the octahedral ferrioxamine.<sup>65</sup> Experiments in dogs with normal kidney function demonstrate that intravenous (IV) ferrioxamine is entirely eliminated by the kidney within 5 hours via glomerular filtration and partial reabsorption.<sup>38,53</sup>

The pharmacokinetics of DFO and ferrioxamine differ in healthy compared with iron-overloaded patients. Whereas serum DFO concentrations in healthy patients are approximately twice the concentrations noted in patients with thalassemia major, ferrioxamine concentrations are five times greater in patients with thalassemia major compared with healthy patients.<sup>40,79</sup> The elimination of DFO occurs mostly by poorly identified plasma enzymes and to a lesser extent by biliary excretion into the feces.<sup>21</sup>

Deferoxamine is hemodialyzable. Deferoxamine can be administered during hemodialysis to remove ferrioxamine.<sup>92</sup> Hemodialysis,<sup>15,77</sup> particularly high-flux hemodialysis<sup>84</sup> and hemoperfusion,<sup>15</sup> are effective in ferrioxamine removal and are indicated in the treatment of patients with kidney failure. In one reported case, a child with a serum iron concentration of 3,906 mcg/dL received IV DFO at 15 mg/kg/h and underwent continuous venovenous hemofiltration; an iron concentration of 19 mcg/dL was eliminated in the dialysate fluid and 3,246 mcg/dL in the urine.<sup>54</sup>

### ROLE IN IRON TOXICITY

Because of the limited amount of iron that can be chelated by DFO, aggressive GI decontamination and supportive measures should accompany its use in iron overdose, as discussed in Chap. 45.

### Animal Studies

Guinea pigs given oral lethal doses of ferrous sulfate and oral DFO in a dose calculated to bind most of the iron showed dramatically improved survival rates.<sup>55</sup> Mortality rates in this study and in a swine study<sup>20</sup> were directly correlated with the delay to DFO administration.<sup>55</sup>

In two canine studies, dogs that received the iron-DFO complex orally had a 40% to 100% mortality rate.<sup>91,92</sup> When both oral and IV DFO were administered, the mortality rate was 67%.<sup>90</sup> A similar follow-up study demonstrated a 50% mortality rate in dogs given a lethal dose (225 mg/kg) of iron followed

by oral DFO (2.6 g) and IV DFO (0.75-1.5 mg/kg/min for 8-12 hours).<sup>92</sup> These studies discouraged further investigation in the use of oral DFO despite the more favorable results in other animal models.<sup>5,36,55,83</sup>

### Early Human Use and History of Dosing Recommendations

In one of the earliest case series, 172 hemodynamically stable children who were not severely poisoned were treated with 5 to 10 g oral DFO and either 1 or 2 g intramuscular (IM) DFO every 3 to 12 hours.<sup>90</sup> Patients who were in shock or severely ill received 1 g of DFO IV at a maximum of 15 mg/kg/h every 4 to 12 hours for 2 to 3 days as necessary. Of the 28 patients who developed coma, shock, or both, three died. One of the three patients who died received late treatment with DFO.

This case series was expanded to 472 patients, and guidelines for DFO dosing were formulated as a result of this clinical experience.<sup>89</sup> The recommended initial dose of DFO was suggested as 1 g IM followed by 0.5 g at 4 and 8 hours later and then every 4 to 12 hours as necessary, not to exceed 6 g in 24 hours. For patients in shock, DFO was recommended at an initial dose not to exceed 1 g IV and a rate not to exceed 15 mg/kg/h followed 4 and 8 hours later by two 0.5-g doses for a total dosage not to exceed 6 g in 24 hours. These recommendations for total dosages were not scientifically developed and appear to be based on arbitrary assumptions. However, the manufacturer continues to recommend these doses.<sup>21</sup>

### Intramuscular versus Intravenous Administration

Before 1976, IM DFO was the preferred route of administration, and IV DFO was reserved for patients in shock. However, when transfusion-induced iron overload was studied and IM and IV DFO administration were compared, IV DFO significantly enhanced urinary iron elimination.<sup>72</sup> This study provided compelling arguments against IM dosing, as did data showing higher peak and more stable DFO concentrations with IV infusions. A single patient was given 425 mg/kg IV over 24 hours without incident, although the increase in urinary iron excretion that occurred when the DFO dosage increased from 4 to 16 g/day appeared to be of limited benefit.

### Duration of Dosing

The optimum duration of DFO administration is unknown. In canine models, serum iron concentrations peak within 3 to 5 hours and then decrease quickly as iron is transported out of the blood into the tissues.<sup>85,93</sup> In one human study, initial iron concentrations of approximately 500 mcg/dL decreased to approximately 100 mcg/dL within 12 hours.<sup>47</sup> Other case reports also suggest that most of the easily accessible iron is distributed out of the blood compartment within 24 hours.<sup>22</sup> Although severely poisoned patients have received DFO for more than 24 hours, pulmonary toxicity is associated with prolonged DFO infusions.<sup>33,61,81</sup> Intuitively, in patients with acute iron overdose, DFO should be administered early and for a shorter duration while the iron is easily accessible in the blood. In patients with chronic iron overload, prolonged infusions of smaller DFO doses will act as a sink and slowly remove iron from the limited labile pool and tissue stores.<sup>37</sup>

### ROLE IN ALUMINUM TOXICITY

Patients with severe chronic kidney disease are at high risk for aluminum toxicity.<sup>95</sup> Acute aluminum toxicity resulting from bladder irrigations with alum for hemorrhagic cystitis is also reported.<sup>64</sup> Chronic aluminum toxicity is reported from the administration of aluminum salts as phosphate binders or from hemodialysis with a water source containing aluminum. Deferoxamine binds aluminum to form aluminioxamine, analogous to iron and ferrioxamine. The chelate is a 1:1 octahedral complex with aluminum.<sup>95</sup> Aluminioxamine is renally excreted. In patients with kidney insufficiency, hemodialysis (especially with a high-flux membrane) is effective in removing the aluminioxamine and should be used to prevent aluminum redistribution to the central nervous system (CNS) and other tissues.<sup>57</sup> The dosing of DFO is unclear but should be tailored to the patient's serum aluminum concentrations, symptoms, hemodialysis schedule, and response.<sup>57</sup> Periodic electroencephalographic monitoring is recommended. Deferoxamine dosages of 5 to 15 mg/kg/day, infused over several hours and 6 to 8 hours

before a 3- to 4-hour run of high-flux hemodialysis, have been successful and maximize aluminexamine removal without exacerbating adverse events.<sup>57,74</sup> The appropriate duration of this DFO dosing with hemodialysis is unknown and should be based on CNS symptoms, serum aluminum concentrations, and kidney function. The correlation of serum aluminum concentrations with toxicity is poorly defined and depends on the chronicity of aluminum exposure. Patients are treated with variable degrees of toxicity for several sessions infrequently (Chap. 84). The package insert states that dialysis patients with aluminum-associated encephalopathy who are treated with DFO may develop worsening neurologic function, dialysis dementia, or hypocalcemia with worsening hyperparathyroidism, but the standard treatment remains DFO with hemodialysis.<sup>21,57</sup>

## ADVERSE EFFECTS

Deferoxamine administration to patients with acute iron overdose causes rate-related hypotension and systemic hypersensitivity reactions, pulmonary toxicity, and infection, as well as injection site reactions. Deferoxamine administration to patients with chronic iron overload causes auditory, ophthalmic, kidney and pulmonary toxicity, and infections.<sup>9,13,37</sup>

Significant hypotension was first noted in 1965 in two children who were administered approximately 80 to 150 mg/kg DFO IV over 15 minutes.<sup>91</sup> The mechanism for rate-related hypotension is not fully understood, although histamine release is at least partially implicated. Although elevated histamine concentrations were documented in a canine experiment, pretreatment with diphenhydramine was not protective.<sup>92</sup> Intravascular volume depletion caused by iron toxicity also contributes to hypotension. No experiment has determined the maximum safe rate of DFO administration. Adverse events of DFO, including tachycardia, hypotension, and shock, were reported with rapid infusion.<sup>90</sup> These complications resulted in the current recommendations for less rapid IV infusions of DFO not to exceed 15 mg/kg/h.<sup>90-92</sup> Currently suggested IV infusion rates are somewhat empirical because of the lack of robust evidence. Higher rates were administered successfully in critically ill patients when time was of the essence.<sup>11,16,22</sup>

Acute respiratory distress syndrome (ARDS) occurs in patients with acute iron overdoses who have received IV administration of DFO (15 mg/kg/h) therapy for more than 24 hours.<sup>3,39,81</sup> Usually, iron concentrations are normal in these patients within 24 hours, and the rationale for continued administration of DFO in these cases was not reported. Examination of the nontoxicologic literature reveals other instances of ARDS occurring in patients receiving continuous IV DFO for hemosiderosis and malignancies.<sup>14,27,88</sup> Administration of continuous IV doses of DFO for prolonged periods (>24 hours) was common to all of these patients. The mechanism for development of pulmonary toxicity after DFO is unknown. Pulmonary toxicity is theorized to result from excessive DFO chelation of intracellular iron and depletion of catalase, resulting in oxidant damage,<sup>32</sup> or generation of free radicals.<sup>1</sup>

Deferoxamine therapy rarely leads to infection with a number of organisms, including *Yersinia enterocolitica*, *Zygomycetes* spp, and *Aeromonas hydrophilia*. The virulence of these organisms is facilitated when the DFO-iron complex acts as a siderophore for their growth.<sup>48,52,56</sup> Most cases of septicemia occurred when DFO was used for treatment of aluminum toxicity in patients receiving chronic hemodialysis.<sup>53</sup> Several cases of *Yersinia* sepsis were reported after acute iron overdose and treatment with DFO.<sup>52,56</sup>

Ophthalmic toxicity characterized by decreased visual acuity and peripheral visual field deficits, night blindness, color blindness, and retinal pigmentary abnormalities has occurred in patients who received continuous IV DFO for thalassemia major and other nonacute iron and aluminum excess conditions.<sup>8,12,19,59,62</sup> Ototoxicity documented by audiograms indicated partial or total deafness.<sup>65,66</sup> However, neither ophthalmic toxicity nor ototoxicity is reported in the treatment of acute iron overdose treatment. When DFO is used in the absence of iron overload, zinc deficiency and decreases in serum ferritin, mean corpuscular volume, and hemoglobin develop.<sup>42</sup>

Infusion pump malfunctions have occasionally led to acute kidney injury (AKI) caused by IV DFO overdose. This overdose was successfully treated

with hemodialysis after failure of medical management.<sup>17</sup> One inadvertent overdose of IV DFO in a patient with severe iron overload associated with sickle cell  $\beta$ -thalassemia resulted in AKI within 12 to 18 hours. The patient received a planned 45 g (700 mg/kg) 96-hour infusion over 8 hours because of incorrect programming of the infusion pump. High-efficiency hemodialysis instituted after an 8-hour trial of IV hydration and mannitol was unsuccessful in restoring kidney function.<sup>70</sup>

## PREGNANCY AND LACTATION

One literature review identified 61 cases of intentional iron overdose in pregnant women.<sup>82</sup> Serious iron toxicity with organ involvement was associated with spontaneous abortion, preterm delivery, and maternal death. There is no evidence to indicate that DFO is teratogenic.<sup>82</sup> Neither iron nor DFO appears to cross the ovine placenta.<sup>18</sup> A case report of a pregnant woman with thalassemia major and a review of 40 other pregnant patients with thalassemia treated extensively with DFO found no evidence of teratogenicity.<sup>75</sup> Thus, DFO should be administered to pregnant women with acute iron toxicity for the same indications as for nonpregnant women and is listed as FDA pregnancy category C. Excretion in breast milk is unknown.

## DOSING AND ADMINISTRATION

The indications and dosage schedules for DFO administration are largely empirical.<sup>6,73</sup> Systemic toxicity associated with acute iron poisoning manifested by coma, shock, or metabolic acidosis warrants IV infusion of DFO. The duration of therapy should be limited to 24 hours to maximize effectiveness while minimizing the risk of pulmonary toxicity. Some investigators have suggested that more than the recommended dose of 15 mg/kg/h be infused during the first 24 hours for life-threatening iron toxicity, but this recommendation remains to be validated.<sup>37</sup> We recommend starting with 5 mg/kg/h and increasing after 15 minutes, if tolerated, to 15 mg/kg/h to minimize the risk of hypotension. In adults, after the first 1,000 mg is infused, the subsequent doses can be adjusted to infuse the remainder of the 6 to 8 g during the next 23 hours. How exactly this should be done is uncertain. Theoretically, an adult patient with significantly elevated serum iron concentrations (>1,000 mcg/dL) who is severely symptomatic might do better with continuing at a rate of 15 mg/kg/h if tolerated for the first several hours and then reducing the dose to limit the total 24-hour dose to 6 to 8 g. If after the first 1,000 mg the patient improves clinically, then it is reasonable to administer the remainder of the 5 g over the next 23 hours. In a 70-kg patient, this would be about 3 to 4 mg/kg/h for the next 23 hours. Dosing in obese patients is unknown; however, because DFO is water soluble, limiting the hourly dose in obese adults to 1,000 mg is reasonable. Although patients with mild toxicity can be treated with IM injections of 90 mg/kg of DFO (maximum of 1 g in children or 2 g in adults), this volume of antidote cannot be given IM with ease or painlessly in children.<sup>21</sup> Therefore, few clinicians administer IM DFO, with most preferring the IV route (Chap. 45). The total daily parenteral dose is limited by the infusion rate in children (if the manufacturer's recommendations are followed). Conservative recommendations in adults limit the dosage to 6 to 8 g/day. Although dosages as high as 16 g/day with diverse dosing regimens have been administered without incident, there are no data at this time to support this recommendation.<sup>16,22,50,61,72,80</sup>

## URINARY COLOR CHANGE

To further define the role of DFO and the quantitative excretion of urinary iron, investigators studied urinary samples.<sup>55</sup> Several reviews of patients with acute iron poisoning who had received DFO<sup>51,94</sup> investigated the correlation between urinary iron concentrations and systemic toxicity. Most data suggest that the absence of a urine color change, often referred to as a *vin rose* color, after DFO administration indicates very little renal excretion of ferrioxamine.<sup>28</sup> However, unless a baseline urine color is obtained before DFO administration, post-DFO administration comparisons of urine color are unreliable. After DFO administration the *vin rose* color might not be appreciated despite severe iron toxicity or high serum iron concentrations

(Fig. 45–2).<sup>76</sup> No relationship between urinary iron excretion, clinical iron toxicity, and the effectiveness of DFO is established.

## FORMULATION AND ACQUISITION

Deferoxamine mesylate is available in vials containing 500 mg or 2 g of sterile, lyophilized powder.<sup>21</sup> Adding 5 or 20 mL of sterile water for injection to either the 500-mg or the 2-g vial, respectively, results in an approximately 100-mg/mL solution. The drug must be completely dissolved before using. The resulting solution is isotonic, clear, and colorless to slightly yellow<sup>21</sup> and can be diluted further with 0.9% NaCl solution, dextrose in water, or Ringer lactate solution for IV administration. For IM administration, a smaller volume of solution is preferred. Adding 2 or 8 mL of sterile water for injection to the 500-mg or 2-g vial, respectively, results in a stronger yellow-colored solution containing approximately 200 mg/mL.

## SUMMARY

- Deferoxamine is the parenteral chelator of choice for treatment of acute iron poisoning.
- No controlled studies have evaluated its efficacy or dosing.
- Deferoxamine should be administered intravenously.
- Early administration captures non–transferrin-bound iron still in the blood compartment.
- Administration for more than 24 hours after ingestion predisposes to ARDS.
- Deferoxamine is also used for chelation of aluminum in patients with chronic kidney failure.

## C. Pharmaceuticals

# PHARMACEUTICAL ADDITIVES

Sean P. Nordt and Lisa E. Vivero

### HISTORY AND EPIDEMIOLOGY

During the last century there were several outbreaks of toxicity in the United States associated with pharmaceutical additives (Chap. 2). The 1937 Massengill sulfanilamide disaster is the most notorious of these epidemics. Diethylene glycol, an excellent solvent and potent nephrotoxin, was substituted for the additives propylene glycol and glycerin in the liquid formulation of a new sulfanilamide antibiotic because of lower cost.<sup>27,64,73</sup> As a result, more than 100 people died from acute kidney failure.<sup>27</sup> Outbreaks of acute kidney failure occurred when diethylene glycol was used to solubilize acetaminophen in South Africa, Bangladesh, Nigeria, and Haiti, cough syrup in Panama, and teething powder in Nigeria.<sup>22,30,75,87,133,143</sup>

In December 1983, a new parenteral vitamin E formulation (E-Ferol) was introduced. It contained 25 units/mL of  $\alpha$ -tocopherol acetate, 9% polysorbate 80, 1% polysorbate 20, and water for injection. At the time, no premarketing testing was required for new formulations of an already approved drug. Several months after its release, a fatal syndrome in low-birth-weight infants, characterized by thrombocytopenia, acute kidney injury, cholestasis, hepatomegaly, and ascites, was described.<sup>1119</sup> Thirty-eight deaths and 43 cases of severe symptoms were attributed to E-Ferol. Vitamin E was thought to be the cause and E-Ferol was recalled from the market 4 months after its release. It is now believed that the polysorbate emulsifiers were responsible.<sup>1</sup>

Although these additive-related occurrences are rare, relative to the frequency of pharmaceutical additive use, they illustrate the potential of pharmaceutical additive toxicity.

Pharmaceuticals are labeled specifically to focus attention on the active ingredient(s) of a product, thus giving the misimpression that additive ingredients are inert and unimportant. Additives, or excipients as they are more properly termed, are necessary to act as vehicles, add color, improve taste, provide consistency, enhance stability and solubility, and impart antimicrobial properties to medicinal formulations. Although it is true that most cases of excipient toxicity involve exposure to large quantities, or to prolonged or improper use, these adverse events are nonetheless related to the toxicologic properties of the excipient.

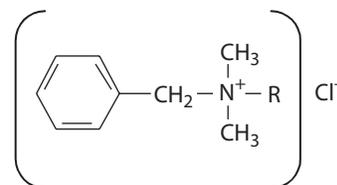

Prior to selecting the specific additives and quantity necessary for a drug formulation, the drug manufacturer must consider several factors, including the active ingredient's physical form, its solubility and stability, the desired final dosage form and route of administration, and compatibility with the dispensing container materials. Often, the same active ingredient requires different excipients to impart appropriate pharmacokinetic characteristics to different dosage forms, such as in long-acting and immediate-release formulations. Similarly, multiple-dose injection vials containing the same active ingredients as single-dose vials specifically require the addition of a bacteriostatic xenobiotic not necessary for single-dose vials.

Unlike requirements for active ingredients, there is no specific US Food and Drug Administration (FDA) approval system for pharmaceutical excipients. As such, the FDA determines the amount and type of data necessary to support the use of a specific excipient on a case-by-case basis. Under current practice, only excipients that were previously permitted for use in foods or pharmaceuticals are defined as *generally recognized as safe* (GRAS), or "GRAS listed." All components of a pharmaceutical product, including excipients, must be produced in accordance with current good manufacturing practice standards to ensure purity. The Safety Committee of the International Pharmaceutical Excipients Council developed guidelines for the toxicologic testing of new excipients.<sup>172</sup> Because of patent protection laws, it was

not until 1985 that manufacturers were required to provide a list of inactive ingredients contained in all pharmaceutical products. Although it is becoming easier to identify pharmaceutical additives in products, information on their effects and the mechanisms by which they cause adverse responses are often unknown or difficult to obtain.

This chapter summarizes the available literature on commonly used additives associated with direct toxicities (Table 46-1). Data on pharmacokinetics and mechanism of toxicity are presented when data are available. Although many additives are associated with hypersensitivity reactions, including anaphylaxis, these are not discussed because of their nonpharmacologic basis. However, excipients should always be considered as possibly causative in patients who develop hypersensitivity reactions.

### BENZALKONIUM CHLORIDE

Benzalkonium chloride (BAC, BAK), or alkyldimethyl (phenylmethyl) ammonium chloride, is a quaternary ammonium cationic surfactant composed of a mixture of alkyl benzyl dimethyl ammonium chlorides. Although it is the most widely used ophthalmic preservative in the United States, it is also considered the most cytotoxic (Table 46-2).<sup>96,104</sup> Benzalkonium chloride is also used in otic and nasal formulations, and in some small-volume parenteral preparations. The antimicrobial activity of BAC includes gram-positive and gram-negative bacteria, and some viruses, fungi, and protozoa. Because of its rapid onset of action, good tissue penetration, and long duration of action, BAC is preferred over other preservatives. The concentration of BAC in ophthalmic medications usually ranges from 0.004% to 0.01%.<sup>104</sup> Strong BAC solutions (>0.1%) can be caustic (Chap. 103).

TABLE 46-1 Potential Systemic Toxicity of Various Pharmaceutical Excipients

Cardiovascular	Ophthalmic
Chlorobutanol	Benzalkonium chloride
Propylene glycol	Chlorobutanol
Fluid and electrolyte	Renal
Polyethylene glycol	Polyethylene glycol
Propylene glycol	Propylene glycol
Sorbitol	
Gastrointestinal	
Sorbitol	
Neurologic	
Benzyl alcohol	
Chlorobutanol

Propylene glycol	

**TABLE 46–2** Benzalkonium Chloride Concentrations of Common Ophthalmic Medications

Medication	Percent
Apraclonidine	0.01
Artificial tears	0.005–0.01
Betaxolol	0.01
Brimonidine/timolol	0.005
Carteolol	0.005
Ciprofloxacin	0.006
Cyclopentolate	0.01
Dexamethasone	0.01
Dorzolamide/timolol	0.0075
Gentamicin	0.01
Ketorolac	0.01
Levobunolol	0.004
Naphazoline	0.01
Ofloxacin	0.005
Phenylephrine	0.01
Pilocarpine	0.01
Polymyxin B sulfate/trimethoprim	0.004
Tetrahydrozoline	0.01
Timolol	0.01
Tobramycin	0.01
Tropicamide	0.01

### Ophthalmic Toxicity

Corneal epithelial cells harvested from human cadavers within 12 hours of death were exposed to a medium containing 0.01% BAC.<sup>168</sup> The surfactant properties of BAC resulted in intracellular matrix dissolution and loss of epithelial superficial layers. Following exposure to the medium, mitotic activity ceased and degenerative changes to corneal epithelium were noted. During a 24-hour observation period, epithelial cell cytokinetic or mitotic activity did not occur. Patients with compromised corneal epithelia are at increased risk for the adverse effects of BAC.<sup>168</sup>

Two case reports demonstrate the potential toxicity of BAC and highlight the difficulty of diagnosing BAC toxicity. A 36-year-old woman complained of decreased vision when she inadvertently switched from Lensrins, a contact lens cleaning solution, to Dacriose, an isotonic boric acid solution preserved with BAC. After 3 days, she had inflammation, pain, and decreased visual acuity. Examination of the cornea revealed many superficial punctate erosions of the epithelium. An *in vitro* experiment identified significant binding of BAC to soft contact lenses.<sup>59</sup> In the second case, a 56-year-old man diagnosed with keratoconjunctivitis sicca was treated with topical antibiotics and artificial tears containing BAC. Following one year of continual use, the patient developed intractable pain, photophobia, and extensive breakdown of the corneal epithelium. Not suspecting the BAC-containing products, the patient continued to use the artificial tears solution for another 9 years despite continued pain and decreasing visual acuity. Replacement with a preservative-free saline solution resulted in resolution of pain, photophobia, and corneal changes.<sup>104</sup> Furthermore, there are newer ophthalmic medication preservatives available (eg, polyquaternium-1,

stabilized oxochloride complex, sodium perborate, Sof Zia), which in studies are less toxic than BAC.<sup>4</sup>

A case series of corneal endothelial injury following the inadvertent intraocular use of balanced salt solution (BSS) preserved with BAC instead of preservative-free BSS in 12 patients undergoing phacoemulsification, a surgical technique to remove cataract lenses. The BSS was instilled in the anterior chamber. The operating room had run out of preservative-free BSS and, unbeknownst to the surgeon, it was replaced with the BAC-containing BSS, which contained 0.013% BAC. This is in excess of recommended concentration for intraocular use and is associated with corneal endothelial injury and edema. Within 48 hours of instillation of the BSS, the visual acuity in all 12 patients was limited to only being able to count fingers at 2 feet. This persisted in 11 of the patients at a 6-month follow-up evaluation after the instillation of the BSS. One patient had improvement at 6 months of visual acuity to 20/120 and 20/30 without and with pinholes, respectively.<sup>106</sup>

### Nasopharyngeal and Oropharyngeal Toxicity

Human adenoidal tissue was exposed to oxymetazoline nasal spray preserved with BAC at concentrations ranging from 0.005 to 0.15 mg/mL for 1 to 30 minutes.<sup>16</sup> Irregular and fractured epithelial cells occurred at all concentrations; however, these findings developed earlier and more frequently with the higher concentrations. The number of beating ciliary bodies also decreased as the duration and the concentrations increased. Benzalkonium chloride decreases the viscosity of the normal protective mucous lining of the naso- and oropharynx, resulting in cytotoxicity.

Administration of one of 3 nasal corticosteroid sprays (beclomethasone dipropionate, flunisolide, budesonide) preserved with either 0.031% or 0.022% BAC in the right nostril of rats twice daily for 21 days caused squamous cell metaplasia and a decrease in the number of goblet cells, cilia, and mucus.<sup>17</sup> No histologic changes occurred in rats receiving any of the preservative-free steroids or in tissue exposed to 0.9% sodium chloride solution administered into the left nostril as the control. Similarly, in another study, epithelial desquamation, inflammation, and edema occurred when 0.05% and 0.10% BAC was applied hourly to the nostrils of rats for 8 hours.<sup>99</sup> No lesions developed in the nostrils of rats receiving 0.01% BAC.

In an *in vitro* study, cultured human nasal epithelial cells were exposed to varying concentrations of BAC compared with another preservative, potassium sorbate (PS), with phosphate-buffered saline (PBS) as a control. Cell viability was greatly reduced at the higher concentrations of BAC compared with no decrease in cell viability in the PS or PBS groups. Additionally, at concentrations used clinically, loss of microvilli, destruction of cell membranes, and poor cytoskeletal alignment demonstrated by electron microscopy occurred.<sup>84</sup>

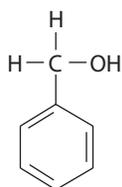

An *in vitro* study of human nasal mucosa exposed mucosa to either fluticasone or mometasone preserved with either BAC or PS at various concentrations with subsequent measure of ciliary beat frequency. Although PS did not affect ciliary beat frequency at any concentration, BAC adversely affected ciliary beat frequency. At lower concentrations, BAC slowed ciliary beat frequency and brought it to standstill at higher concentrations.<sup>85</sup> Another *in vitro* study in human nasal epithelial comparing budesonide, fluticasone propionate, azelastine hydrochloride, or levocabastine hydrochloride preserved with either BAC or PS at various concentrations showed similar results.<sup>92</sup>

Polyquaternium-1 (PQ), an alternative detergent preservative to BAC, is reported to be less toxic to various cell types. In an *in vitro* study of cultured human corneal and conjunctival cells exposed to various topical glaucoma medications preserved with either BAC with concentrations ranging from 0.001% to 0.005% or PQ 0.04% with other arms using BSS as “live” control and 70% methanol and 0.2% saponin as “dead” controls, PQ had less cytotoxicity to both cell types compared to BAC.<sup>5</sup> In an *in vivo* murine model comparing BAC concentrations 0.1% and 0.5% and PQ 0.1% and 0.5% to control BSS showed decreased tear production, increased corneal punctate lesions, increased in conjunctival injection, corneal neovascularization, and stromal inflammation in BAC compared to PQ and BSS.<sup>100</sup> It is important to note that both of these studies<sup>5,100</sup> involving PQ were funded by the manufacturer.

**TABLE 46-3** Benzyl Alcohol Concentration of Common Medications

Medication (concentration)	Percent	Benzyl Alcohol Dose (mg/dose volume)
Amiodarone (50 mg/mL)	2.0	60.6 mg/3 mL
Atracurium (10 mg/mL)	0.9	45 mg/5 mL
Bacteriostatic saline for injection	0.9	9 mg/mL
Bacteriostatic water for injection	0.9	9 mg/mL
Bumetanide (0.25 mg/mL)	1.0	40 mg/4 mL
Diazepam (5 mg/mL)	1.5	30 mg/2 mL
Enalaprilat (1.25 mg/mL)	0.9	9 mg/mL
Etoposide (20 mg/mL)	3.0	150 mg/5 mL
Glycopyrrolate (0.2 mg/mL)	0.9	9 mg/mL
Lorazepam (2 mg/mL, 4 mg/mL)	2.0	20 mg/mL
Methotrexate (25 mg/mL)	0.9	9 mg/mL
Midazolam (1 mg/mL, 5 mg/mL)	1.0	10 mg/mL
Prochlorperazine (5 mg/mL)	0.75	7.5 mg/mL

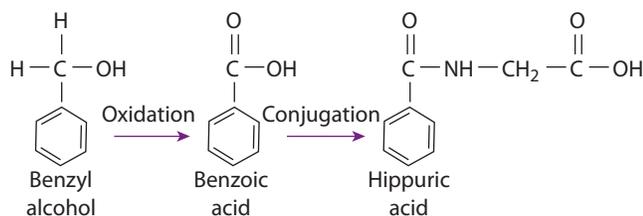

## BENZYL ALCOHOL

Benzyl alcohol (benzene methanol) is a colorless, oily liquid with a faint aromatic odor that is most commonly added to pharmaceuticals as a bacteriostatic (Table 46-3). In 1982, a “gasping” syndrome, which included hypotension, bradycardia, gasping respirations, hypotonia, progressive metabolic acidosis, seizures, cardiovascular collapse, and death, was first described in low-birth-weight neonates in intensive care units.<sup>23,66</sup> All the infants had received either bacteriostatic water or sodium chloride solution containing 0.9% benzyl alcohol to flush intravenous catheters or in parenteral medications reconstituted with bacteriostatic water or saline.<sup>23,66</sup> The syndrome occurred in infants who had received more than 99 mg/kg of benzyl alcohol (range, 99–234 mg/kg).<sup>66</sup> The World Health Organization (WHO) currently estimates the acceptable daily intake of benzyl alcohol to be not more than 5 mg/kg body weight.<sup>25</sup>

### Pharmacokinetics

In adults, benzyl alcohol is oxidized to benzoic acid, conjugated in the liver with glycine, and excreted in the urine as hippuric acid. Preterm babies have a greater ability to metabolize benzyl alcohol to benzoic acid than do term babies, but are unable to convert benzoic acid to hippuric acid, probably because of glycine deficiency. This results in the accumulation of benzoic acid (Fig. 46-1).<sup>66</sup> A fatal case of metabolic acidosis was reported in a

**FIGURE 46-1.** Oxidative metabolism of benzyl alcohol.

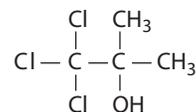

5-year-old girl who received 2.4 mg/kg/h diazepam preserved with benzyl alcohol for 36 hours to control status epilepticus. Elevated benzoic acid concentrations were identified in serum and urine samples. The estimated daily dosage of benzyl alcohol was 180 mg/kg.<sup>66,107</sup>

### Neurologic Toxicity

Benzyl alcohol is believed to have a role in the increased frequency of cerebral intraventricular hemorrhages and mortality reported in very-low-birth-weight (VLBW) infants (weight <1,000 g) who received flush solutions preserved with benzyl alcohol.<sup>83</sup> An increased incidence of developmental delay and cerebral palsy was also noted in the same VLBW patients, suggesting a secondary damaging effect of benzyl alcohol.<sup>14</sup>

There are several case reports of transient paraplegia following the intrathecal or epidural administration of chemotherapeutics or analgesics containing benzyl alcohol as a preservative.<sup>10,41,74,149</sup> The local anesthetic effects are most likely responsible for the immediate paraparesis and limited duration of effects, rather than actual demyelination of nerve roots. In a rat study, lumbosacral dorsal root action potential amplitudes were measured after exposure to 0.9% or 1.5% benzyl alcohol solutions in either 0.9% sodium chloride solution or distilled water.<sup>74</sup> Rats exposed to all benzyl alcohol solutions for less than one minute had inhibited dorsal root action potentials. This was attributed to the local anesthetic effects of benzyl alcohol as function was 50% to 90% restored after rinsing the nerves with 0.9% sodium chloride solution. Chronic intrathecal exposure to benzyl alcohol 0.9% over 7 days resulted in scattered areas of demyelination and early remyelination. The 1.5% benzyl alcohol solution–exposed dorsal nerve roots showed greater changes, with widespread areas of demyelination and fatty degeneration of nerve fibers.

## CHLOROBUTANOL

Chlorobutanol, or chlorbutol (1,1,1-trichloro-2-methyl-2-propanol), is available as volatile, white crystals with an odor of camphor. Chlorobutanol has antibacterial and antifungal properties and is widely used as a preservative in injectable, ophthalmic, otic, and cosmetic preparations at concentrations up to 0.5% (Table 46-4). Chlorobutanol also has mild sedative and local anesthetic properties and was formerly used therapeutically as a sedative–hypnotic.<sup>20</sup> The lethal human chlorobutanol dose is estimated to be 50 to 500 mg/kg.<sup>128</sup>

### Central Nervous System Toxicity

Chlorobutanol has a chemical structure similar to trichloroethanol (Fig. 72-1), the active metabolite of chloral hydrate, and is believed to exhibit similar

**TABLE 46-4** Chlorobutanol Concentrations of Common Medications

Medication (concentration)	Percent	Chlorobutanol Dose (mg/dose volume)
Epinephrine injection (1 mg/mL)	0.5	1.5 mg/0.3 mL
Isoniazid injection (100 mg/mL)	0.25	7.5 mg/3 mL
Methadone injection (10 mg/mL)	0.5	5 mg/mL
Thiamine injection (100 mg/mL)	0.5	5 mg/mL
Pyridoxine (100 mg/mL)	0.5	5 mg/mL
Tobramycin ophthalmic ointment	0.5	—
Vasopressin (20 U/mL) injectable	0.5	2.5 mg/0.5 mL
Vitamin A injection (50,000 IU/mL)	0.5	5 mg/mL

pharmacologic properties. Central nervous system depression was reported in a 40-year-old alcoholic man who chronically abused Seducaps (formerly available in Australia and several other countries), a nonprescription hypnotic containing chlorobutanol as the active ingredient.<sup>20</sup> On admission to the emergency department, he had drowsiness, dysarthria, slurred speech, and occasional episodes of myoclonic movements. His peak serum chlorobutanol concentration was 100 mcg/mL, decreasing to 48 mcg/mL over 2 weeks, with a half-life of 3 days based on serial declining concentrations. This is similar to human volunteer pharmacokinetic data following oral administration of chlorobutanol demonstrating an elimination half-life of  $10.3 \pm 1.3$  days.<sup>170</sup> His speech abnormality resolved after 4 weeks. Only chlorobutanol was detected in the patient's urine or serum. In a second case, a possible central nervous system depressant effect from chlorobutanol was suggested in a 19-year-old woman treated with high doses of intravenous morphine preserved with chlorobutanol.<sup>47</sup> She received approximately 90 mg/h of chlorobutanol for several days. Her peak serum chlorobutanol concentration was 83 mcg/mL, a concentration similar to that in the previous case report;<sup>20</sup> however, the coadministration of morphine precludes the effects being attributed to chlorobutanol alone.

Ketamine is neurotoxic when administered intrathecally to animals.<sup>116,117</sup> The potential neurotoxic effects of chlorobutanol as a preservative in ketamine compared with preservative-free ketamine was studied in rabbits.<sup>117</sup> Forty rabbits were given 0.3 mL intrathecally of either 1% preservative-free ketamine, 1% ketamine, 0.05% chlorobutanol, or 1% lidocaine as control. The rabbits were observed and hemodynamically monitored for 8 days and then euthanized. Histologic evaluation of the spinal cord as well as for blood-brain barrier lesions was performed. Seven of the 10 rabbits given intrathecal chlorobutanol showed both white and gray matter histologic changes as well as diffuse blood-brain barrier injury. No histologic changes were seen in either ketamine groups or the lidocaine group, and only one rabbit in each ketamine group had blood-brain barrier injury. These results suggest that chlorobutanol should not be administered intrathecally.<sup>117</sup>

A case series of 5 patients were given intra-arterial papaverine preserved with 0.5% chlorobutanol,<sup>155</sup> which is used to prevent cerebral vasospasm in patients with subarachnoid hemorrhage. Immediately after administration of papaverine in either the left, right, or bilateral anterior cerebral arteries, patients had an acute deterioration in neurologic status. Subsequent brain magnetic resonance imaging identified selective gray matter toxicity in the territories treated with papaverine. Postmortem brain histology in one patient also identified gray matter changes. The authors state the absence of white matter changes is not consistent with ischemic infarction but suggest direct toxic effect of either the papaverine or chlorobutanol. The manufacturer of the papaverine stated that no other reports had been made and the papaverine used came from 2 different lots; therefore, it is unclear if an unidentified independent variable caused these effects, but the authors caution using intra-arterial papaverine in patients with subarachnoid hemorrhage.<sup>155</sup>

### Ophthalmic Toxicity

Chlorobutanol is a commonly used preservative in ophthalmic preparations and is less toxic to the eye than benzalkonium chloride.<sup>132</sup> Chlorobutanol increases the permeability of cells by impairing cell membrane structure.<sup>168</sup> An *in vitro* experiment using corneal epithelial cells harvested from human cadavers demonstrated arrested mitotic activity following chlorobutanol exposure.<sup>168</sup> At the commonly formulated concentration of 0.5%, chlorobutanol can cause eye irritation, most likely due to cellular contraction of epithelial microfilaments, cessation of normal cytokinesis, cell movement, and mitotic activity.<sup>50</sup> Degeneration of human corneal epithelial cells specifically manifested as membranous blebs, cytoplasmic swelling, and occasional breaks in the external cell membrane has also occurred at this concentration.<sup>50</sup>

### LIPIDS

In general, there are 3 types of commercial intravenous lipid drug-delivery systems available: lipid emulsion, liposomal, and lipid complex (Table 46-5). Lipid emulsions are immiscible lipid droplets dispersed in an aqueous

TABLE 46-5 Lipid Carrier Formulations of Common Medications

Medication	Lipid Carrier
Amphotericin B	Lipid complex
Amphotericin B	Liposome
Bupivacaine	Liposome
Cytarabine	Liposome
Doxorubicin	Liposome (stealth)
Morphine sulfate	Liposome
Propofol	Emulsion

phase stabilized by an emulsifier (eg, egg, soy lecithin). Liposomes differ from emulsion lipid droplets in that they are vesicles composed of one or more concentric phospholipid bilayers surrounding an aqueous core. Lipophilic drugs are formulated for intravenous administration by partitioning them into the lipid phase of either an emulsion or liposome. Liposomes are capable of encapsulating hydrophilic xenobiotics within their aqueous core to exploit lipid pharmacokinetic properties.<sup>162</sup> Attaching a therapeutic drug to a lipid to form a lipid complex is another way to take advantage of lipid pharmacokinetics.

Lipid drug-delivery systems are biocompatible because of their similarity to endogenous cell membranes. They are created with stable lipid membranes resistant to hydrolysis or oxidation, to decrease toxicity, and to enhance therapeutic efficacy by altering drug pharmacokinetic and pharmacodynamic parameters. The biodistribution, and the rate of release and metabolism of a drug incorporated in a lipid drug-delivery system, is regulated by the type and concentration of oil and emulsifier used, pH, drug concentration dispersed in the medium, the size of the lipid particle, and the manufacturing process.<sup>134,162</sup> Intravenous formulations are usually isotonic and have a pH of 7 to 8.<sup>162</sup>

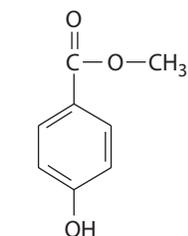

The rate of clearance of a lipid drug-delivery system from the blood depends on its physicochemical properties and the molecular weight of the emulsifier. Electrically charged lipid carriers are removed more rapidly than neutral particles.<sup>26,134</sup> Smaller lipid particle size and high-molecular-weight emulsifiers decrease clearance. "Stealth" liposome formulations incorporate a polyethylene glycol coating that prevents rapid detection and clearance of liposomes by the reticuloendothelial system, prolonging circulation time.<sup>134</sup> Active drug targeting is achieved by conjugating antibodies or vectors to side chains on the emulsifier.<sup>26,134</sup> For a therapeutic drug available in more than one lipid drug-delivery systems (eg, amphotericin B), it is important to note that any change in the lipid formulation can alter the pharmacokinetic, pharmacodynamic, and safety parameters of the drug; consequently, they are not equivalent dosage formulations (Chap. 54).

The physicochemical properties of lipid emulsions not only affect the therapeutic drugs carried by them, but the lipids themselves also have direct pharmacologic effects on the central nervous<sup>182</sup> and immune systems.<sup>103</sup> Lipid fatty acid mediators affect the membrane receptor channels of *N*-methyl-D-aspartate (NMDA) receptors, potentiating synaptic transmission.<sup>120,122,136,165</sup> Dogs given a medium-chain triglyceride emulsion intravenous infusion developed dose-related central nervous system metabolic and neurologic effects, accompanied by electroencephalographic changes consistent with encephalopathy observed when serum octanoate concentration reached 0.5 to 0.9 mM.<sup>120</sup> In an *in vitro* model, 3 of 9 lipid emulsions tested (Abbolipid, 20% soya and safflower oil; Intra-lipid, 20% soya oil; and Structolipid, 20% structured triglycerides) demonstrated a dose-related activation of cortical neuronal NMDA receptor channels.<sup>182</sup> The lipid source for all but one (Omegaven, 10% fish oil) of the emulsions tested was made up solely or partially by soya oil. The authors could not explain why the other 6 lipid emulsions did not induce membrane currents. Adequate control for the nonlipid constituent contribution of

these emulsions is lacking. In another in vitro study, the same authors found that NMDA-induced neuronal currents are reduced by an unknown factor in the aqueous portion of Abbolipid.<sup>183</sup> This suggests that lipid emulsions pharmacologically enhance the anesthetic effect of hypnotics such as propofol. The clinical relevance of these studies remains to be determined.

Triglycerides in parenteral nutrition emulsions are implicated in altering the immune system, leading to an increased susceptibility to infection,<sup>58,180</sup> and altering lung function and hemodynamics in patients with acute respiratory distress syndrome.<sup>103</sup> Phospholipid activation of phospholipase A<sub>2</sub> may be an initiating cause.<sup>58,103,180</sup> However, it is not clear if these immunologic effects are a consequence of factors other than the lipid in the emulsion.

## PARABENS

Methylparaben

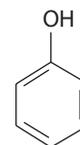

The parabens, or parahydroxybenzoic acids, are a group of compounds widely employed as preservatives in cosmetics, food, and pharmaceuticals because of their bacteriostatic, fungistatic, and antioxidant properties (Table 46-6).<sup>150</sup> A survey conducted by the FDA identified the parabens as the second most common ingredients in cosmetic formulations, with water being the most common.<sup>108</sup> Parabens are often used in combination, because the presence of 2 or more parabens are synergistic.<sup>107</sup> Methylparabens and propylparabens are most commonly used.<sup>150</sup> Pharmaceutical paraben concentrations usually range from 0.1% to 0.3%.<sup>144</sup>

Widespread usage of parabens since the 1920s demonstrates a relatively low order of toxicity.<sup>108</sup> However, because of their allergenic potential they are currently considered less suitable for injectable and ophthalmic preparations.<sup>144</sup> Based on long-term animal studies, the WHO has set the total acceptable daily intake of ethylparabens, methylparabens, and propylparabens to be 10 mg/kg body weight.<sup>144</sup> In addition to allergic reactions, parabens have the potential to cause other adverse effects. Bilirubin displacement from albumin-binding sites occurred with administration of methylparaben- and propylparaben-preserved gentamicin when serum paraben concentrations were 3 to 15 mcg/mL.<sup>43</sup> Gentamicin alone has no

effect on bilirubin displacement.<sup>109</sup> Spermicidal activity was demonstrated in an in vitro study of human semen specimens exposed to local paraben concentrations of 1 to 8 mg/mL.<sup>160</sup> Possible interference with conception and potential adverse effects on fertility were not investigated in this paper. However, other investigators show a direct toxic effect of parabens on sperm mitochondrial function.<sup>166</sup> Sperm require an enormous amount of ATP to adequately fertilize ova.

Concerns have arisen regarding the potential estrogenic and anti-androgenic effects of the parabens and their common metabolite, *p*-hydroxybenzoic acid. Xenobiotics with these effects are commonly referred to as *endocrine disrupting substances*. It has been suggested that methylparaben is less toxic than butyl and benzyl-parabens with regard to oxidative stress and resultant cytotoxicity.<sup>44,153</sup> The clinical significance of these effects is not elucidated.<sup>34,45,141,142,175</sup> There is a focus on the role of parabens and the development of breast cancer due to the estrogenic effects of parabens. In a study of breast tissue following mastectomies of women with primary breast cancer, concentrations of parabens were highest in the axillary region compared to other more medial regions. These authors suggest there may be a role of using cosmetics and deodorants under the arm increasing local estrogenic effects on breast tissue.<sup>12,77</sup>

## PHENOL

Phenol (carbolic acid, hydroxybenzene, phenylic acid, phenylic alcohol) is a commonly used preservative in injectable medications (Table 46-7). Phenol is a colorless to light pink, caustic liquid with a characteristic odor. When exposed to air and light, phenol turns a red or brown color.<sup>40</sup> Phenol exerts antimicrobial activity against a wide variety of microorganisms, bacteria, mycobacteria, and some fungi and viruses.<sup>40</sup> Phenol is well absorbed from the gastrointestinal tract, skin, and mucous membranes and is excreted in the urine as phenyl glucuronide and phenyl sulfate metabolites.<sup>40</sup> Although there are numerous reports of phenol toxicity following intentional ingestions or unintentional dermal exposures (Chap. 103), adverse reactions to its use as a pharmaceutical excipient are uncommon, most likely because of the small quantities used.<sup>40</sup>

### Cutaneous Absorption

Systemic toxicity from cutaneous absorption of phenol is reported. Ventricular tachycardia was observed in an 11-year-old boy following application of a chemical peel solution containing 88% phenol in water and liquid soap. The solution was applied to 15% of his body surface area for the treatment of xeroderma pigmentosum. Immediately following the onset of the ventricular

TABLE 46-6 Paraben Concentrations of Common Medications and Doses

Medication (concentration)	Percent	Paraben Dose (mg/dose volume)
Bupivacaine HCl injection <sup>a</sup>	0.1	1 mg/mL
Flumazenil injection (0.1 mg/mL)	0.2	4 mg/2 mL
Labetalol injection (5 mg/mL)	0.09	3.6 mg/4 mL
Lidocaine injection <sup>a</sup>	0.1	1 mg/mL
Methyl dopa injection (50 mg/mL)	0.17	8.5 mg/5 mL
Naloxone injection (0.4 mg/mL)	0.2	2 mg/mL
Ondansetron injection (2 mg/mL)	0.14	2.7 mg/2 mL
Pentazocine injection (30 mg/mL)	0.1	1 mg/mL
Sulfacetamide ophthalmic solution (100 mg/mL)	0.06	0.03 mg/drop

<sup>a</sup>Multidose vials of all strengths contain 0.1% paraben.

TABLE 46-7 Phenol Concentration of Common Medications

Medication	Percent	Phenol Dose (mg/dose volume)
Antivenom (Crotaline)	0.25	25 (per vial)
Antivenom ( <i>Micrurus fulvius</i> )	0.25	25 (per vial)
Pneumococcal 23 vaccine	0.25	1.25 mg/0.5 mL
Neostigmine methylsulfate injection <sup>a</sup>	0.45	4.5 mg/mL
Quinidine gluconate injection 80 mg/mL	0.25	25 mg/10 mL
Typhoid Vi vaccine	0.25	1.25 mg/0.5 mL

<sup>a</sup>Multidose vials of all strengths contain 0.45% phenol.

tachycardia, the phenol-treated areas were irrigated, an infusion of 0.9% sodium chloride solution was begun, and 2 intravenous lidocaine boluses were given followed by a lidocaine infusion. The dysrhythmia persisted for 3 hours. The urinary phenol concentration the following day was 58.9 mg/dL.<sup>173</sup> In a similar case, multifocal premature ventricular contractions were observed in a 10-year-old boy after application of a chemical peeling solution of 40% phenol, 0.8% croton oil in hexachlorophene soap, and water for the treatment of a giant hairy nevus.<sup>181</sup> The premature ventricular contractions were refractory to intravenous lidocaine but resolved with intravenous bretylium. No phenol concentrations were obtained to confirm systemic absorption. In a case series of 181 patients undergoing chemical face peeling with phenol-based solutions, 12 demonstrated cardiac dysrhythmias. This occurred more commonly in patients with comorbid diabetes mellitus, hypertension, or treatment with antidepressants.<sup>101</sup> Both lidocaine and propranolol treatment and pretreatment are reported to abate these dysrhythmias.<sup>101</sup> However, these are anecdotal reports and have not been formally studied sufficiently to support recommending their use.<sup>21,70,169</sup> Despite the risk of toxicity, phenol chemical peels are still used in some cases because phenol penetrates deep into tissues, providing both long-lasting and good cosmetic results. Most commonly, phenol chemical peels are used for deep acne scars and other severe skin disorders.

A 9-year-old girl sustained partial-thickness burns over 17% of her body following the topical administration of Creolin, which contains phenolic compounds. The Creolin was applied by her mother to delouse the patient. Creolin is not intended for human use and is generally used as deodorant cleanser for bathrooms, kennels, and barns. The child had 8 ounces poured onto her hair, which then flowed onto her neck, chest, back, left shoulder, and upper arm. Within minutes she became obtunded, requiring endotracheal intubation by paramedics. In the emergency department, she had sinus tachycardia with brief runs of ventricular tachycardia. She was decontaminated with soap and water, low-molecular-weight polyethylene glycol and ethanol. The patient experienced a mild elevation of hepatic aminotransferases and had dark-green–black urine while in the intensive care unit. This resolved and the patient was extubated and discharged to home on hospital day 4.<sup>177</sup>

Drowsiness, respiratory depression, and blue-colored urine were noted in a 6-month-old infant 12 hours after topical application of magenta paint over most of the body for seborrheic eczema.<sup>146</sup> Magenta paint (also known as Castellani paint) was widely used for seborrheic eczema and contained 4% phenol, magenta, boric acid, resorcinol, acetone, and ethanol. Further investigation found that phenol was detected in urine samples of 4 of 16 other infants with seborrheic eczema who had approximately 11% to 15% of their body surface area painted with magenta paint for 2 days.

## POLYETHYLENE GLYCOL

Polyethylene glycols (PEGs; Carbowax, Macrogol) include several compounds with varying molecular weights (200–40,000 Da).<sup>140</sup> They are typically available as mixtures designated by a number denoting their average molecular weight. Polyethylene glycols are stable, hydrophilic substances, making them useful excipients for cosmetics and pharmaceuticals of all routes of administration (Table 46–8). Pegylation, a process that modifies the pharmacokinetics of therapeutic liposomes and proteins (eg, peginterferon- $\alpha$ ), is the most recent application of PEG. At room temperature, PEGs with molecular weights less than 600 Da are clear, viscous liquids with a slight characteristic odor and bitter taste. Polyethylene glycols with molecular weights higher than 1,000 Da are soluble solids and range in consistency from pastes and waxy flakes to powders.<sup>140</sup> Commercially available products used for bowel-cleansing preparations and whole-bowel irrigation are solutions of PEG 3350 sometimes combined with electrolytes and known as PEG electrolyte lavage solution (Antidotes in Depth: A2).

The solid, high-molecular-weight PEGs are essentially nontoxic. Conversely, low-molecular-weight PEG exposures cause adverse effects similar to the chemically related toxic alcohols ethylene and diethylene glycol (Special Considerations: SC9).<sup>30</sup>

TABLE 46–8 Common Medications Containing PEG

Medication	PEG Molecular Weight (Da)
Etoposide injection	300
Lorazepam injection	400
Medroxyprogesterone depot	3,350
Mupirocin ointment	400, 3,350
PEG electrolyte lavage solution	3,350
Peginterferon $\alpha$ -2a	40,000

PEG = polyethylene glycol.

## Pharmacokinetics

High-molecular-weight PEGs (>1,000 Da) are not significantly absorbed from the gastrointestinal tract, but low-molecular-weight PEGs are absorbed when taken orally.<sup>49,156,157</sup> Topical absorption also occurs when PEGs are applied to damaged skin.<sup>24,163</sup> Once in the systemic circulation, PEGs are mainly excreted unchanged in the urine;<sup>49</sup> however, low-molecular-weight PEGs (eg, PEG 300, PEG 400) are partially metabolized by alcohol dehydrogenase to hydroxyacid and diacid metabolites. The pharmacokinetics of intravenously administered PEG 3350 Da has not been studied; however, it did not appear to have any systemic effects when unintentionally given by this route.<sup>145</sup>

## Nephrotoxicity

In rats fed various PEGs (200, 300, and 400) in their drinking water for 90 days, a solution of 8% PEG 200 produced renal tubular necrosis in all of the animals, followed by death within 15 days; however, a 4% PEG 200 solution resulted in only 2 of 9 rats dying within 80 days. A 16% PEG 400 solution killed all animals within 13 days; however, both 8% and 4% PEG 400 solutions had no observable effect except for a decrease in kidney weight when compared to control animals.<sup>158</sup> A canine study administering daily high-dose PEG 400 intravenously, up to 8.45 g/kg/day, failed to show serious renal toxicity. However, edema of kidney cells and increased glomerular volume occurred at these dosages, but were reversible.<sup>105</sup> Acute tubular necrosis was reported with oliguria, azotemia, and an anion gap metabolic acidosis following oral and topical exposures to low-molecular-weight PEGs (200 and 300). Acute kidney failure occurred in a 65-year-old man with a history of alcohol abuse and a seizure disorder after ingestion of the contents of a lava lamp containing 13% PEG 200.<sup>51</sup> About 48 hours after admission (approximately 50–72 hours post ingestion), the patient became oliguric with an anion gap metabolic acidosis and acute kidney failure. Blood sampling confirmed traces of the lava lamp fluid; none was detected in the urine. After clinical complications from ethanol withdrawal and aspiration pneumonitis, the patient was discharged 3 months later with residual kidney dysfunction attributed to the PEG component of the lamp contents. Acute tubular necrosis was noted at autopsy of 6 burn patients treated with a topical antibiotic cream in a PEG 300 base.<sup>24,163</sup> Mass spectrometry detected hydroxyacid and diacid metabolites in serum and urine samples. Oxalate crystals were seen in the urine of 2 cases. These effects were reproduced with the topical application of PEG for 7 days to rabbits with full-thickness skin defects.<sup>163</sup>

## Neurotoxicity

There are reports of neurologic complications, such as paraplegia and transient bladder paralysis, following intrathecal corticosteroid injections containing 3% PEG as a vehicle.<sup>15,19</sup> In an in vitro experiment, rabbit vagus nerves were exposed to concentrations of PEG 3350 ranging from 3% to 40% for one hour.<sup>15</sup> A total of 3% and 10% PEG had no effect on nerve action potential amplitude or conduction velocity. Doses of 20% and 30% PEG significantly slowed nerve conduction and had varying effects on the amplitudes of action potentials. Forty percent PEG completely abolished action potentials. These

changes were reversible and thought to be related to PEG-induced osmotic effects. The administration of PEG 1800 is a potential therapy for spinal cord injury by repairing damaged axons through cellular fusion of damaged cells following the short-term (2 minutes) application, in a guinea pig model. This increases compound action potential conduction.<sup>154</sup> Interestingly, administering a similar dose of PEG continuously for 25 minutes decreased compound action potentials approximately 64% in both damaged and nondamaged isolated mammalian spinal cords, suggesting dose-response toxicity.<sup>38</sup>

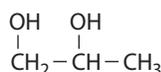

Another study in an ex vivo experiment of isolated injured spinal cords of Wistar rats showed combining hyperthermia (40°C) with various PEGs (400, 1000, and 2000) greatly improved compound action potential recovery compared to these PEGs at 25°C and 37°C. The lower-molecular-weight PEG 400 was the most effective. This occurs through PEG rapidly sealing damaged neuronal membranes.<sup>95</sup>

### Fluid, Electrolyte, and Acid–Base Disturbances

Hyperosmolality was reported in 3 patients with burn surface areas ranging from 20% to 56% following repeated applications of Furacin, a topical antibiotic dressing containing 63% PEG 300, 32% PEG 4000, and 5% PEG 1000.<sup>24</sup> Polyethylene glycol produces an osmotic effect that is greater than expected for its molecular weight.<sup>151</sup> It is theorized that PEG increases osmolality by sequestering water through hydrogen binding, which reduces the availability of water to interact with solutes, thus increasing the chemical and osmotic activity of the solute. Hyperosmolality following the administration of a PEG-containing substance supports systemic PEG absorption.

Two cases of metabolic acidosis were reported following administration of therapeutic dosages of an intravenous nitrofurantoin solution containing PEG 300.<sup>164</sup> Similarly, an otherwise unexplained increased anion gap was reported in 3 patients being treated with a topical PEG-based burn cream.<sup>24</sup> Metabolism of the lower-molecular-weight PEGs by alcohol dehydrogenase to hydroxyacid and diacid metabolites explained the metabolic acidosis.<sup>80</sup>

## PROPYLENE GLYCOL

Propylene glycol (PG), or 1,2-propanediol, is a clear, colorless, odorless, sweet, viscous liquid employed in numerous pharmaceuticals (Table 46–9), foods, and cosmetics. Propylene glycol is used as a solvent and preservative with

**TABLE 46–9 Propylene Glycol Concentration of Common Medications**

Medication (concentration)	Percent	Propylene Glycol Dose (g/dose volume)
Diazepam injection (5 mg/mL)	40	0.8 g/2 mL
Digoxin injection (250 mcg/mL)	40	0.8 g/2 mL
Etomidate (2mg/mL)	35	7 g/20 mL
Lorazepam injection (2 mg/mL, 4 mg/mL)	80	0.8 g/mL
Multivitamin injection	30	3 g/10 mL
Nitroglycerin injection (5 mg/mL)	30	3 g/10 mL
Pentobarbital sodium injection (50 mg/mL)	40	0.8 g/2 mL
Phenobarbital sodium injection (65 mg/mL, 130 mg/mL)	67.8	0.7 g/mL
Phenytoin injection (50 mg/mL)	40	0.8 g/2 mL
Trimethoprim-sulfamethoxazole injection (16–80 mg/mL)	40	2 g/5 mL

antiseptic properties similar to ethanol. The WHO has set the daily allowable intake of PG at a maximum of 25 mg/kg,<sup>184</sup> or 1.75 g/day for a 70-kg person.

### Pharmacokinetics

Propylene glycol is rapidly absorbed from the gastrointestinal tract following oral administration and has a volume of distribution of approximately 0.6 L/kg.<sup>118,160</sup> When applied to intact epidermis, the absorption of PG is minimal. Percutaneous absorption occurs following application to damaged skin (eg, extensive burn surface areas). Approximately 12% to 45% of PG is excreted unchanged in the urine,<sup>48</sup> the remainder is hepatically metabolized sequentially by alcohol dehydrogenase to lactaldehyde, which is metabolized further by aldehyde dehydrogenase to lactic acid. Lactic acid is also formed by another metabolite, methylglyoxal.<sup>131</sup> Lactic acid is reduced to pyruvate catalyzed by lactate dehydrogenase.<sup>131</sup> The terminal half-life of propylene glycol is reported to be between 1.4 and 5.6 hours in adults and as long as 16.9 hours in neonates.<sup>48,162</sup>

### Cardiovascular Toxicity

Intravenous preparations of phenytoin contain 40% PG to facilitate the dissolution of phenytoin. Nine years after intravenous phenytoin became available, several deaths were attributed to the rapid administration of phenytoin used for the treatment of cardiac dysrhythmias.<sup>65,171,195</sup>

Cardiovascular effects reported in these cases included hypotension, bradycardia, widening of the QRS complex, increased amplitude of T waves with occasional inversions, and transient ST segment elevations. Studies in cats<sup>110</sup> and calves<sup>71</sup> confirmed PG as the cardiotoxin. Bradycardia and depression of atrial conduction were not observed in cats pretreated with atropine, or in those with vagotomy following rapid intravenous infusion of PG, suggesting that these effects are vagally mediated.<sup>110</sup> Amplification of the QRS complex was noted in these same pretreated cats, also suggesting a direct cardiotoxic effect of PG. Similar results were reported in calves pretreated with atropine that received oxytetracycline in a PG vehicle.<sup>71</sup>

### Neurotoxicity

Infants appear to have a decreased ability to clear PG when compared with older children and adults.<sup>111</sup> An increased frequency of seizures was reported in low-birth-weight infants who received 3 grams of PG daily in a parenteral multivitamin preparation.<sup>111</sup> Seizures developed in an 11-year-old boy receiving long-term oral therapy with vitamin D dissolved in PG.<sup>8</sup> Serum, electrolytes, and blood glucose were normal. Seizures abated after the product was discontinued. Propylene glycol possesses inebriating properties similar to ethanol. Central nervous system depression was reported following an intentional oral ingestion of a PG-containing product.<sup>118</sup>

A formerly available oral solution protease inhibitor amprenavir (Agenerase) had a black-box warning added to the product information for its high PG (550 mg/mL) vehicle content.<sup>148</sup> The recommended daily dosage of amprenavir supplied 1,650 mg/kg/day of PG. A 61-year-old man experienced visual hallucinations, disorientation, tinnitus, and vertigo after receiving a 750-mg dose (474 mg/kg PG) of amprenavir solution.<sup>91</sup>

### Ototoxicity

Otic preparations contain up to 94% PG in solutions and 10% in suspensions as part of their vehicles.<sup>54</sup> In animal studies, application of high concentrations of PG (>10%) to the middle ear produced hearing impairment<sup>124,125,178</sup> and morphologic changes, including tympanic membrane perforation, middle ear adhesions, and cholesteatoma.<sup>124,125,190</sup> Although the effects of PG in the human middle ear have not been studied, all medications applied to the external ear canal are contraindicated in patients with perforated tympanic membranes.

### Fluid, Electrolyte, and Acid–Base Disturbances

Patients receiving continuous or large intermittent quantities of medications containing PG develop high PG concentrations, particularly those with renal or hepatic insufficiency.<sup>29,48</sup> Propylene glycol–induced electrolyte and metabolic disturbances are evidenced by hyperosmolality, and an elevated

osmolar gap attributed to the osmotically active properties of PG. In most cases, both an elevated anion gap and elevated lactate concentration are present. Metabolic acidosis and hyperlactatemia result from PG metabolism.<sup>28</sup> These adverse effects are typically reported with intravenous preparations such as lorazepam,<sup>7,76,86,192</sup> diazepam,<sup>186</sup> etomidate,<sup>174</sup> nitroglycerin,<sup>48</sup> pentobarbital,<sup>121</sup> pediatric multivitamins,<sup>67</sup> and topical silver sulfadiazine.<sup>13,55,98,185</sup>

Systemic absorption of PG from topical application of silver sulfadiazine cream<sup>55</sup> resulted in hyperosmolality in patients with burn surface areas greater than 35% of their body.<sup>13,55,98,185</sup> In one study, 9 of 15 burn patients had osmolar gaps (>12) after application of the cream.<sup>98</sup> Similarly, a 3-year-old boy with extensive second- and third-degree burns over 60% body surface area developed a persistent elevated osmolar gap and metabolic acidosis with elevated lactate for approximately 20 days following application of silver sulfadiazine cream. Other potential etiologies were excluded. The osmolar gap and metabolic acidosis both resolved within 24 hours of discontinuing silver sulfadiazine.<sup>185</sup>

Hyperosmolality occurred in 5 infants receiving a parenteral multivitamin that provided a daily PG dose of 3 g.<sup>67</sup> After 12 days, one premature infant had a PG concentration of 930 mg/dL and an osmolar gap of 136. Anion gap and lactic acid concentrations were normal. Eleven intubated children aged 1 to 15 months who were receiving continuous lorazepam infusions over 3 to 14 days accumulated serum PG concentrations of 17 to 226 mg/dL; however, increases in osmolar gap or serum lactate concentrations were not significantly different from baseline.<sup>35</sup> This was attributed to normal renal function and the low cumulative PG doses received (mean, 60 g).

A 72-year-old man died following the ingestion of the contents of a cold/hot therapy gel pack, which contained more than 99% of propylene glycol. Six hours after ingestion, he had an elevated osmolar gap accompanied by acute kidney injury. At 12 hours, he became comatose and an anion gap acidosis with a normal L-lactate concentration. He was found to have a very elevated D-lactate concentration, which was attributed to the PG ingestion. This patient had an extensive medical history and the course was complicated by multiorgan failure and death.<sup>94</sup>

Several small studies have found a strong correlation between elevated PG concentrations and increased osmolar gap measurements in critically ill patients receiving intravenous lorazepam and/or diazepam.<sup>7,187,191,192</sup> An osmolar gap greater than 10 is suggested as a marker for potential PG toxicity.<sup>191</sup> An osmolar gap of 20 corresponds to a serum PG concentration of approximately 48 mg/dL.<sup>7</sup> These authors provide a formula to estimate PG concentrations based on the osmolar gap:  $[PG] = (-82.1 + [\text{osmol gap} \times 6.5])$ . This equation should be used cautiously, as larger, more comprehensive studies are needed to validate it. In addition, elevated anion gap measurements and lactate concentrations occur. As PG toxicity mimics sepsis in these critically ill patients, sepsis should be excluded as the etiology of increased lactate, hypotension, and worsening renal function when considering PG toxicity. Hemodialysis is effective in removing PG and correcting acidemia. The administration of fomepizole should be considered with elevated PG concentrations to prevent further metabolism to lactic acid.<sup>135,194</sup>

### Nephrotoxicity

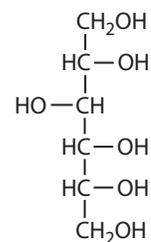

Human proximal tubular cells exposed in vitro to PG concentrations of 500 to 2,000 mg/dL exhibited significant cellular injury and membrane damage within 15 minutes of exposure.<sup>127</sup> Repeated exposure for up to 6 days produced dose-dependent toxic effects at lower concentrations (76, 190, and 380 mg/dL).<sup>126</sup>

The chronic administration of PG contributes to proximal tubular cell damage and subsequent decreased kidney function. In a retrospective study of 8 patients who developed elevations in serum creatinine concentration while receiving continuous lorazepam infusions, serum creatinine rose within 3 to 60 days (median, 9 days).<sup>192</sup> The magnitude of serum creatinine rise was found to correlate with the serum PG concentration and duration of infusion. Serum creatinine decreased within 3 days of discontinuing the infusion. Patients with chronic kidney disease are at greater risk for accumulating PG because 45% of PG is eliminated unchanged by the kidneys;<sup>48</sup> the

remainder is metabolized by the liver. Caution should be used when prolonged administration of a PG-containing medication is necessary in the presence of renal or hepatic dysfunction.<sup>127</sup>

There are reports of propylene glycol-induced renal tubular necrosis. Daily PG vehicle dosages of 11 to 90 g/day over 14 days was associated with rising serum creatinine concentrations (0.7–2.1 mg/dL), elevated serum lactate concentrations, osmolar and anion gaps, and a serum PG concentration of 21 mg/dL.<sup>193</sup> Urine sediment analysis revealed numerous granular, muddy-brown-colored casts and no eosinophils, suggesting an acute renal tubular necrosis. Kidney biopsy and electron microscopy showed extensive dilation of the proximal renal tubules, with swollen epithelial cells and mitochondria. Numerous vacuoles containing debris were also noted. A kidney biopsy of another case with a serum PG concentration of 30 mg/dL showed disrupted brush borders of the proximal renal tubules after a sudden rise in serum creatinine concentration (3.1 mg/dL), nonoliguric kidney failure, and metabolic acidosis. This was attributed to an average daily PG dose of 70 g for 17 days.<sup>76</sup>

### SORBITOL

Sorbitol (D-glucitol) is widely used in the pharmaceutical industry as a sweetener, moistening agent, and as a diluent (Table 46–10). Sorbitol occurs naturally in the ripe berries of many fruits, trees, and plants, and was first isolated in 1872 from the berries of the European mountain ash (*Sorbus aucuparia*).<sup>129</sup> It is particularly useful in chewable tablets because of its pleasant taste. In addition, it is widely used by the food industry in chewing gums, dietetic candies, foods, and enteral nutrition formulations. Sorbitol is approximately 50% to 60% as sweet as sucrose.<sup>129</sup>

### Pharmacokinetics

Unlike sucrose, sorbitol is not readily fermented by oral microorganisms and is poorly absorbed from the gastrointestinal tract. Any absorbed sorbitol is metabolized in the liver to fructose and glucose.<sup>129</sup> Sorbitol has a caloric value of 4 kcal/g and is better tolerated by diabetics than sucrose; however, because some of it is metabolized to glucose, it is not unconditionally safe for people with diabetes and is obviously not “dietetic.”<sup>79,129</sup>

TABLE 46–10 Common Medications Containing Sorbitol

Medication (concentration)	Percent	Sorbitol Dose (g/dose volume)
Amantadine syrup (10 mg/mL)	64	6.4 g/10 mL
Calcium carbonate suspension (250 mg/mL)	28	1.4 g/5 mL
Carbamazepine syrup (20 mg/mL)	17	0.85 g/5 mL
Cimetidine syrup (60 mg/mL)	46	2.3 g/5 mL
Digoxin elixir (50 mcg/mL)	21	1 g/5 mL
Ferrous sulfate infant drops (15 mg/mL)	31	0.3 g/mL
Furosemide solution (8 mg/mL)	35	1.75 g/5 mL
Methadone HCl solution (1 mg/mL, 2 mg/mL)	14	0.7 g/5 mL
Potassium chloride solution (1.33 mEq/mL)	17.5	2.6 g/15 mL
Pseudoephedrine liquid (3 mg/mL, 6mg/mL)	35	1.75 g/5 mL

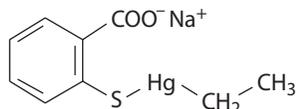

There is a concern of potentially fatal toxicity for individuals with hereditary fructose intolerance (HFI) receiving sorbitol-containing xenobiotics.<sup>56</sup> Hereditary fructose intolerance is an autosomal recessive disorder caused by a deficiency of fructose-1,6-bisphosphonate aldolase in the liver, kidney, cortex, and small intestine.<sup>93</sup> This results in the accumulation of fructose-1-phosphate, which prevents glycogen breakdown and glucose synthesis causing hypoglycemia. The prevalence of HFI is most commonly reported to be one in 20,000 persons, but can range between one in 11,000 and one in 100,000.<sup>2,90,93</sup>

There are reports of death following the prolonged administration of sorbitol, fructose, or sucrose in individuals with HFI.<sup>99,152</sup> Dietary exclusion of fructose, sucrose, and sorbitol prevents the adverse effects. This condition should not be confused with the more common disorder of dietary fructose intolerance, which is caused by a defect in the glucose-transport protein 5 system. This defect leads to the breakdown of fructose to carbon dioxide, hydrogen, and short-chain fatty acids by colonic bacteria, resulting in abdominal pain and bloating.<sup>102</sup> This latter syndrome is a potential cause of chronic abdominal pain in childhood.<sup>69</sup> Dietary fructose intolerance symptoms are minimized by limiting sorbitol, fructose, and sucrose in the diet.

### Gastrointestinal Toxicity

In large dosages, sorbitol causes abdominal cramping, bloating, flatulence, vomiting, and diarrhea. Sorbitol exerts its cathartic effects by its osmotic properties, resulting in fluid shifts within the gastrointestinal tract. Iatrogenic osmotic diarrhea is reported following administration of many different liquid medication formulations containing sorbitol.<sup>82,112</sup> In a human volunteer study, 42 healthy adults ingested 10 g of a sorbitol solution. Sorbitol intolerance was detected in up to 55% of participants.<sup>89</sup> One theoretical explanation for why all participants did not experience the gastrointestinal adverse effects is unrecognized dietary fructose intolerance. Diarrhea resulting from sorbitol-containing medications is common and often overlooked as a possible etiology.<sup>56,82</sup> Ingestion of large quantities of sorbitol (>20 g/day in adults) is not recommended (Antidotes in Depth: A2).<sup>129</sup>

## THIMEROSAL

Thimerosal (Merthiolate, Mercurothiolate), or sodium ethylmercurithiosalicylate, is an organic mercury compound that is approximately 49% elemental mercury (Hg<sup>0</sup>) by weight.<sup>147,179</sup> It is metabolized to ethylmercury and thiosalicylate. Thimerosal has a wide spectrum of antibacterial activity at concentrations ranging from 0.01% to 0.1%; however, higher concentrations are sometimes also used topically as an antiseptic.<sup>123,147</sup> Thimerosal has been widely used as a preservative since the 1930s in contact lens solutions, biologics, and vaccines, particularly those in multidose containers (Table 46-11). The use of thimerosal, which is necessary for the production process of some vaccines (eg, pertussis, influenza), leaves trace amounts in the final product.<sup>11</sup> High-dose thimerosal exposure resulted in neurotoxicity and nephrotoxicity. Although concerns exist regarding infant exposure to low-dose thimerosal through vaccinations and its effects on neurodevelopment, including possible links to causes of autism,<sup>18</sup> these concerns are unfounded (Chap. 95).<sup>46</sup>

Because specific guidelines for ethylmercury exposure have not been developed, regulatory guidelines for dietary methylmercury exposure were applied to monitor ethylmercury exposure from injected thimerosal-containing vaccines. Methylmercury is a similar, but more toxic, organic mercury compound (Chap. 95). Maximum daily recommended methylmercury exposures range from 0.1 mcg Hg/kg (US Environmental Protection Agency {EPA}) to 0.47 mcg Hg/kg (WHO).<sup>3,32,37</sup>

An FDA review of thimerosal-containing vaccines revealed that some infants, depending on the immunization schedule, vaccine formulations,

TABLE 46-11 Thimerosal Concentration of Common Medications

Medication	Percent	Dose (mg)
<b>Injectable</b>		
Antivenom (crotaline polyvalent immune) Fab	0.005	0.03 (per vial)

<sup>a</sup>Trace defined by the US Food and Drug Administration as <1 mcg mercury each dose. <sup>b</sup>Multidose vials only.

and infant's weight, might be exceeding the EPA exposure limit of 0.1 mcg Hg/kg/day for methylmercury. Over the first 6 months of life, a total cumulative dose of up to 187.5 mcg Hg total from thimerosal-containing vaccines was possible. The US Public Health Service and the American Academy of Pediatrics jointly responded by recommending the preemptive reduction or removal of thimerosal from vaccines wherever possible.<sup>3,31</sup> The WHO and European regulatory bodies have similar recommendations.<sup>57</sup> To date, thimerosal has been removed from most US-licensed immunoglobulin products. All vaccines routinely recommended for children younger than 7 years are either thimerosal-free or contain only trace amounts (<0.5 mcg Hg/dose), with the exception of some inactivated influenza vaccines. Multidose vials requiring thimerosal preservative remain important for immunization programs in developing countries because of a lack of ability to consistently refrigerate vaccines. Although efforts continue to eliminate all sources of mercury exposure, complete elimination of thimerosal from all vaccines is unlikely in the near future.<sup>11</sup> When a thimerosal-containing vaccine is the only alternative, the benefits of vaccination far exceed any theoretical risk of mercury toxicity.<sup>130</sup>

Prior to thimerosal use in pharmaceuticals, evidence for its safety and effectiveness was provided in several animal species and in 22 humans.<sup>139</sup> Only limited data exist on infant mercury exposure from thimerosal-containing vaccines. Clinical studies that assess the effects of thimerosal exposure on neurodevelopment and renal and immunologic function are lacking. Based on a comprehensive review of epidemiologic data from the United States,<sup>36,60,63,167,179</sup> Denmark,<sup>114,115</sup> Sweden,<sup>161</sup> and the United Kingdom,<sup>6,81</sup> the Institute of Medicine's Immunization Safety Review Committee,<sup>130</sup> the Global Advisory Committee on Vaccine Safety,<sup>189</sup> and the European Agency for the Evaluation of Medicinal Products<sup>52</sup> have all concluded that no causal relationship exists between thimerosal-containing vaccines and autism. Continued surveillance of autistic spectrum disorders as thimerosal use declines will be conducted to evaluate any associated trends.

### Pharmacokinetics

Limited pharmacokinetic data exist for thimerosal and ethylmercury. Once absorbed, thimerosal breaks down to form ethylmercury and thiosalicylate. Some ethylmercury further decomposes into inorganic mercury in the blood, and the remainder distributes into kidney and, to a lesser extent, brain tissue.<sup>114,115</sup> Because of its longer organic chain, ethylmercury is less stable and decomposes more rapidly than methylmercury, leaving less ethylmercury available to enter kidney and brain tissue.<sup>114</sup> Ethylmercury crosses the blood-brain barrier by passive diffusion.<sup>115</sup> Intracellular ethylmercury decomposes to inorganic mercury, which accumulates in kidney and brain tissues.<sup>115</sup> The half-life of thimerosal is estimated to be about 18 days.<sup>115</sup> Thimerosal is eliminated in the feces as inorganic mercury (Chap. 95).<sup>138</sup>

## Mercury or Thimerosal Toxicity

### Oral Administration

A case report described a 44-year-old man who ingested 5 g (83 mg/kg) of thimerosal in a suicide attempt; within 15 minutes, he began vomiting spontaneously. Gastric lavage was performed and chelation therapy begun with dimercaptopropane sulfonate. Gastroscopy revealed a hemorrhagic gastritis. Acute kidney injury was noted on the day of admission and persisted for 40 days. Four days after admission, the patient developed fever and a maculopapular exanthem attributed to thimerosal. The patient also developed an autonomic and ascending peripheral polyneuropathy that persisted for 13 days. Chelation therapy was continued for a total of 50 days with dimercaptopropane sulfonate followed by succimer. Elevated blood and urine mercury concentrations persisted for more than 140 days. The patient was discharged 148 days following the ingestion with only sensory defects in his toes. No other neurologic sequelae were noted.<sup>137</sup>

Oral absorption of thimerosal resulted in the fatal poisoning of an 18-month-old girl from the intra-otic instillation of a solution containing 0.1% thimerosal and 0.14% sodium borate. Tympanostomy tubes placed one year earlier allowed the irrigation solution to flow through the auditory tube into the nasopharynx, and subsequently to be swallowed and absorbed through the oral mucosa and gastrointestinal tract. A total of 1.2 L of solution (500 mg Hg) was instilled over a 4-week period, resulting in severe mercury poisoning. Four days after admission, the serum mercury concentration was 163 mcg/dL. The patient also received 1.7 g of boric acid. It is unclear what contribution, if any, the boric acid made to the serum mercury concentration. Chelation therapy with *N*-acetyl-D-penicillamine was initiated on day 51. Despite increased urinary mercury concentrations following administration of the *N*-acetyl-D-penicillamine, her neurologic function and blood mercury concentrations remained unchanged. The child died 3 months after admission. An autopsy was not performed.<sup>147</sup>

### Intramuscular Administration

Urine mercury concentrations of 26 patients with hypogammaglobulinemia, who received weekly intramuscular immunoglobulin G (IgG) replacement therapy preserved with 0.01% thimerosal, were studied. The dosages of IgG ranged from 25 to 50 mg/kg, containing 0.6 to 1.2 mg of mercury per dose.<sup>72</sup> The total estimated dose of mercury administered ranged from 4 to 734 mg over a period of 6 months to 17 years. Urine mercury concentrations were elevated in 19 patients, ranging from 31 to 75 mcg/L; however, no patients had clinical evidence of chronic mercury toxicity.<sup>72</sup>

Six cases of severe mercury poisoning resulting in 4 deaths were reported following the intramuscular administration of chloramphenicol preserved with thimerosal. A manufacturing error produced vials containing 510 mg of thimerosal (250 mg Hg) instead of 0.51 mg per vial. Two adults received 4 and 5.5 g of mercury each and 4 children received 0.2 to 1.8 g each. All 6 patients had extensive tissue necrosis at the site of injection. Fever, altered mental status, slurred speech, and ataxia were noted. Autopsy identified widespread degeneration and necrosis of the renal tubules; however, creatine kinase concentrations were not reported, so pigment-induced nephrotoxicity cannot be excluded. Elevated mercury concentrations were found in the injection site tissues, and in the kidneys, livers, and brains.<sup>9</sup>

### Topical Administration

Thirteen infants were exposed to 9 to 48 topical applications of a 0.1% thimerosal tincture for the treatment of exomphalos. Analysis for elevated mercury concentrations was performed in 10 of 13 infants who unexpectedly died. Mercury concentrations were determined in various tissues from 6 of the infants. Mean tissue concentrations in fresh samples of liver, kidney, spleen, and heart ranged from 5,152 to 11,330 ppb, suggesting percutaneous absorption from these repeated topical applications.<sup>53</sup>

### Ophthalmic Administration

Nine patients undergoing keratoplasty were exposed to a contact lens stored in a solution containing 0.002% thimerosal.<sup>188</sup> After 4 hours, the lens was removed and mercury concentrations of the aqueous humor and excised

corneal tissues were determined. Mercury concentrations were elevated in both aqueous humor (range, 20–46 ng/mL higher) and corneal tissues (range, 0.6–14 ng/mL higher) as compared with eyes that had not been fitted with contact lenses. Only residual amounts of mercury remained on the contact lenses after 4 hours of wear. The authors noted that although the aqueous humor concentrations were in the same range as those measured in 10 patients with vision loss from systemic mercury poisoning (11–104 ng/mL), adverse effects did not occur.

A possible drug interaction between orally administered tetracyclines and thimerosal was reported to result in acute, varying degrees of eye irritation in contact lens wearers using thimerosal-containing contact lens solutions who started treatment with tetracycline.<sup>42</sup>

## SUMMARY

- The benefits of pharmaceutical excipients include improved xenobiotic solubility, stability, and palatability, antimicrobial activity, the availability of various dosage forms, the provision of products with long-term storage, and the availability of multiple-dose packaging. Although excipients are essential and effective, they are suggested to possess no pharmacologic or toxicologic properties but are actually responsible for severe—and sometimes fatal—adverse effects.
- The toxicity of pharmaceutical excipients should be evaluated in patients requiring high doses or prolonged administration of any medication containing excipients, particularly those additives known to have toxicities.
- Under circumstances in which there is no option but to continue treating a patient with a particular xenobiotic, switching to a preservative-free product, or to another brand without the offending excipient, should obviate the need for discontinuation of an effective xenobiotic. In addition to inherent toxicities, many excipients are also responsible for allergic reactions.
- In the majority of cases, pharmaceutical excipients are safe and effective, and their benefits far exceed their potential for adverse effects when properly administered.

# ANTIDIABETICS AND HYPOGLYCEMICS/ ANTIGLYCEMICS

George M. Bosse

## Glucose

MW	= 180 Da
Normal fasting range (plasma)	= 60–99 mg/dL = 3.3–5.6 mmol/L

## HISTORY AND EPIDEMIOLOGY

Insulin first became available for use in 1922 after Banting and Best successfully treated diabetic patients using pancreatic extracts.<sup>13</sup> In an attempt to more closely simulate physiologic conditions, additional “designer” insulins with unique kinetic properties have been developed, including a rapid-acting insulin that mimics baseline (before meals) insulin secretion, known as lispro.<sup>81,157</sup> The hypoglycemic activity of a sulfonamide derivative used for typhoid fever was noted during World War II, and verified later in animals.<sup>90</sup> The sulfonylureas in use today are chemical modifications of that original sulfonamide compound. In the mid-1960s, the first-generation sulfonylureas were widely used. Newer second-generation drugs differ primarily in their potency.

Although insulin is widely used for treating diabetes mellitus, oral hypoglycemic exposures are more commonly reported to poison control centers than are insulin exposures, based on 15 years of data from 2001 to 2015 (Chap. 130). In an older review of 1,418 medication-related cases of hypoglycemia, sulfonylureas (especially the long-acting chlorpropamide and glyburide) alone or with a second hypoglycemic accounted for the largest percentage of cases (63%).<sup>147</sup> Only 18 of the sulfonylurea cases in this series involved intentional overdose. However, hypoglycemia is reported in as many as 20% of patients using sulfonylureas.<sup>73</sup> In a study of 99,628 emergency hospitalizations for adverse drug events in adults older than 65 years, 14% were due to insulin and 11% were due to oral hypoglycemics. The majority (95%) of the hospitalizations related to insulin and oral hypoglycemics were due to hypoglycemia.<sup>24</sup> Other causes of hypoglycemia are listed in [Table 47–1](#).

The biguanides metformin and phenformin were developed as derivatives of *Galega officinalis*, the French lilac, recognized in medieval Europe as

a treatment for diabetes mellitus.<sup>11</sup> Phenformin was removed from the US market in 1977 because of its association with life-threatening metabolic acidosis with an elevated lactate concentration.

Development of the  $\alpha$ -glucosidase inhibitors began in the 1960s when an  $\alpha$ -amylase inhibitor was isolated from wheat flour.<sup>143</sup> Acarbose was discovered more than 10 years later and approved for use in the United States in 1995. Troglitazone and repaglinide were approved for use in the United States in 1997. The US Food and Drug Administration subsequently directed the manufacturer of troglitazone to withdraw the product from the US market in 2000 because of associated liver toxicity. Exenatide, a synthetic form of a compound found in the saliva of the Gila monster, is an incretin mimetic. Incretin is a hormone that stimulates insulin secretion in response to meals. Liraglutide, dulaglutide, and albiglutide are synthetic analogs of human incretin. Other newer xenobiotics include the gliptins, the amylin analog pramlintide, and the sodium glucose co-transporter 2 (SGLT2) inhibitors.

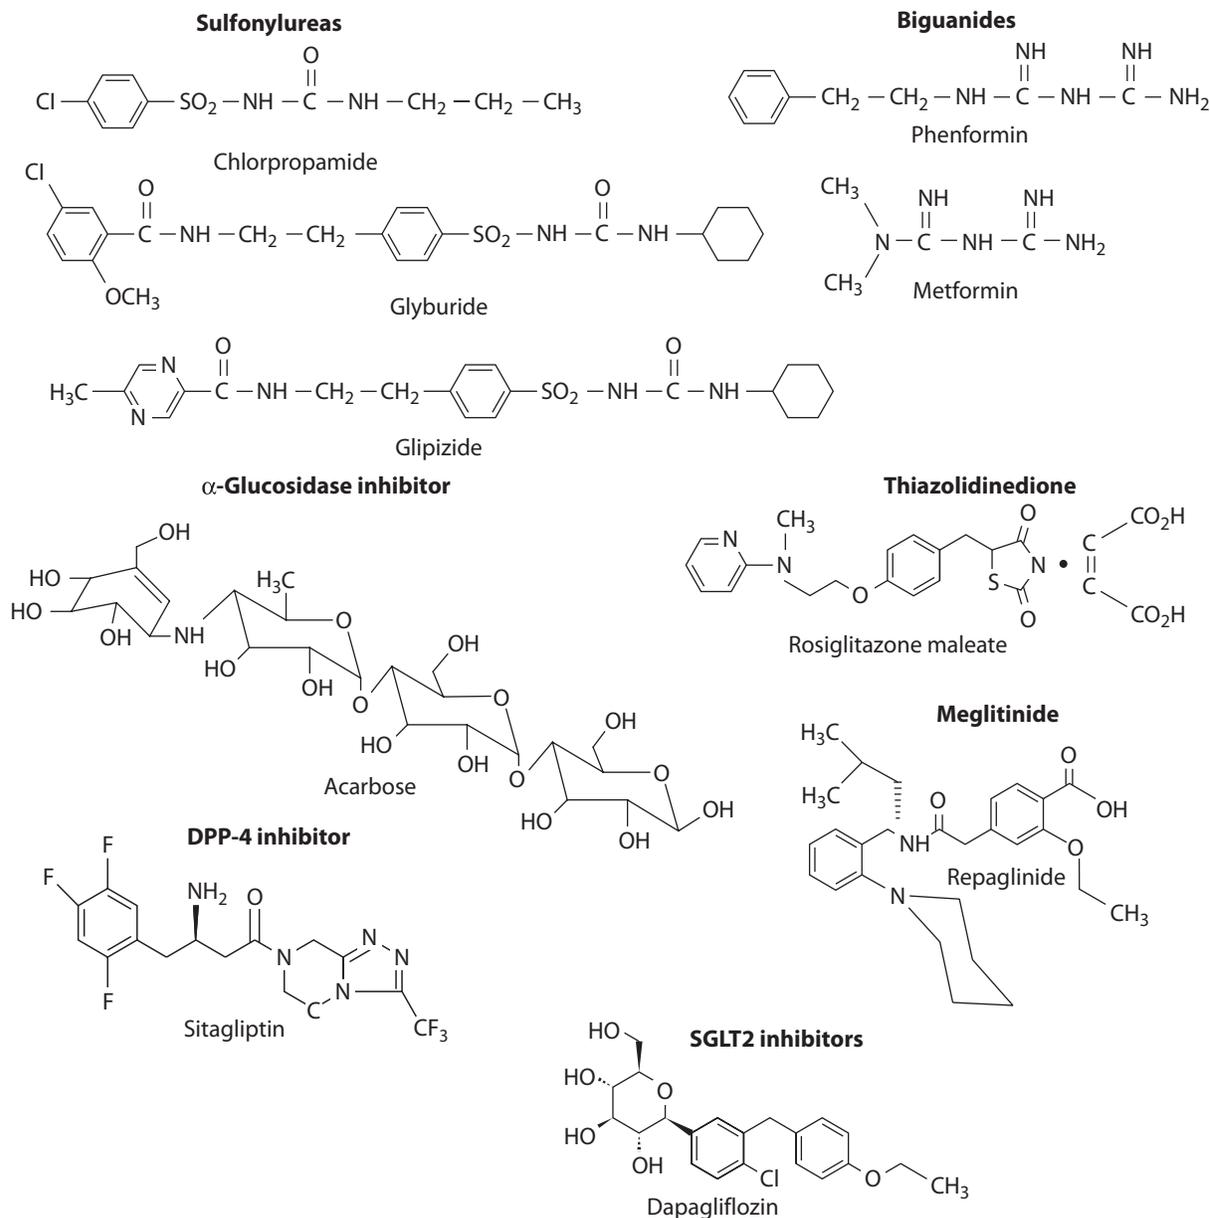

## PHARMACOLOGY

Insulin is synthesized as a precursor polypeptide in the  $\beta$  islet cells of the pancreas. Proteolytic processing results in the formation of proinsulin, which is cleaved, giving rise to C-peptide and insulin itself, a double-chain molecule containing 51 amino acid residues. Glucose concentration plays a major role in the regulation of insulin release.<sup>132</sup> Glucose is phosphorylated after transport into the  $\beta$  islet cell of the pancreas. Further metabolism of glucose-6-phosphate results in the formation of ATP. Adenosine triphosphate inhibition of the  $K^+$  channel results in cell depolarization, inward calcium flux, and insulin release. After release, insulin binds to specific receptors on cell surfaces in insulin-sensitive tissues, particularly the hepatic, muscle, and adipose cells. The action of insulin on these cells involves various phosphorylation and dephosphorylation reactions.

[Figure 47–1](#) depicts the chemical structures of noninsulin antidiabetics. The sulfonylureas stimulate the  $\beta$  cells of the pancreas to release insulin and are often referred to as insulin secretagogues. They are ineffective in type 1 diabetes mellitus that results from islet cell destruction ([Fig. 47–2](#)). This

**TABLE 47–1** Xenobiotic and Non Toxicologic Causes of Hypoglycemia

Artifactual	Medical Conditions	Neoplasms	Hypoglycin (Ackee)
Chronic myelogenous leukemia	Acquired immunodeficiency syndrome (AIDS)	Carcinomas (diverse extrapancreatic)	Indomethacin
Polycythemia vera	Alcoholism	Hematologic	Methylenecyclopropylglycine (Litchi)
<b>Endocrine Disorders</b>	Anorexia nervosa	Insulinoma	Pentamidine
Addison's disease	Autoimmune disorders	Mesenchymal	Propoxyphene
Glucagon deficiency	Burns	Multiple endocrine adenopathy type 1	Quinidine
Graves disease	Diarrhea (childhood)	Sarcomas (retroperitoneal)	Quinine
Panhypopituitarism (Sheehan syndrome)	Leucine sensitivity	<b>Reactive Hypoglycemia</b>	Quinine
<b>Hepatic Disease</b>	Muscular activity (excessive)	<b>Xenobiotics</b>	Ritodrine
Acute hepatic atrophy	Postgastric surgery (including gastric bypass)	$\beta$ -Adrenergic antagonists	Salicylates
Carcinoma	Pregnancy	Alloxan	Streptozocin
Cirrhosis	Protein calorie malnutrition	Antidiabetics	Sulfonamides
Galactose or fructose intolerance	Rheumatoid arthritis	Cibenzoline	Vacor
Glycogen storage disease	Septicemia	Disopyramide	Valproic acid
Neoplasia	Shock	Ethanol	Venlafaxine
<b>Kidney Disease</b>	Systemic lupus erythematosus	Gatifloxacin	
Chronic hemodialysis			
Chronic kidney disease			

**FIGURE 47-1.** Chemical structures of representative oral antidiabetics. The glucagonlike peptide (GLP-1) analogs and amylin analogs are large polypeptides. Their structures are not shown here. SGLT2=sodium-glucose cotransporter; DPP-4 inhibitor=dipeptidylpeptidase-4 inhibitor.

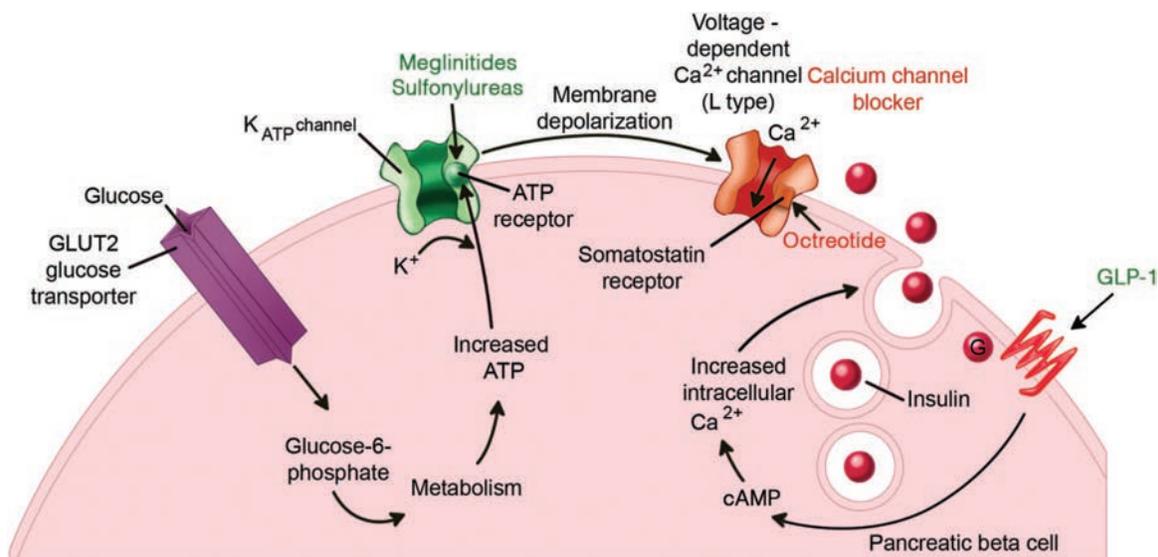

stimulatory effect diminishes with chronic therapy. All the sulfonylureas bind to high-affinity receptors on the pancreatic  $\beta$  cell membrane, resulting in closure of  $K^+$  channels.<sup>49,60,61</sup> Inhibition of potassium efflux mimics the effect of naturally elevated intracellular ATP and results in insulin release. High-affinity sulfonylurea receptors are also present within pancreatic  $\beta$  cells and are postulated to be either located on granular membranes or part of a regulatory exocytosis kinase. Binding to these receptors promotes exocytosis by direct interaction with secretory machinery not involving closure of the plasma membrane  $K^+$  channels.<sup>49,60,61</sup>

The linkage of 2 guanidine molecules forms the biguanides. Metformin is an oral biguanide approved for treatment of type 2 diabetes mellitus. It acts by several mechanisms, the most important of which involves the inhibition of mitochondrial complex I, which subsequently leads to activation of adenosine monophosphate activated protein kinase (AMPK). Adenosine monophosphate activated protein kinase activation is postulated to mediate antihyperglycemic effects, although alternative signaling pathways may be involved.<sup>22</sup>

Metformin has other actions that are independent of AMPK activation and result in beneficial as well as undesirable side effects.<sup>71</sup> These include

induction of mitochondrial stress, suppression of glucagon signaling, and activation of autophagy. Metformin inhibits glycerophosphate dehydrogenase, which is important in the glycerophosphate shuttle and results in inhibition of gluconeogenesis. Alteration of intestinal microbiota by metformin occurs and plays a role in the uptake and utilization of glucose by the intestines. Metformin also increases levels of glucagonlike peptide-1 (GLP-1) and induces GLP-1 receptors. Glucagonlike peptide-1 is an incretin that is released in response to an oral glucose load; it enhances the release of insulin, delays gastric emptying, and reduces food intake. Glucose lowering by metformin can be summarized to occur by a combination of effects, which include inhibition of gluconeogenesis, decreased hepatic glucose output, enhanced peripheral glucose uptake, decreased fatty acid oxidation, and increased intestinal use of glucose.

Acarbose and miglitol are oligosaccharides that inhibit  $\alpha$ -glucosidase enzymes such as glucoamylase, sucrase, and maltase in the brush border of the small intestine. As a result, postprandial elevations in blood glucose concentrations are blunted.<sup>171</sup> Delayed gastric emptying is another proposed mechanism for the antihyperglycemic effect of these oligosaccharides.<sup>136</sup>

**FIGURE 47-2.** Under normal conditions, cells release insulin in response to elevation of intracellular ATP concentrations. Sulfonylureas potentiate the effects of ATP at its “sensor” on the ligand gated  $K^+$  channels and prevent efflux of  $K^+$ . The subsequent rise in intracellular potential opens voltage-gated  $Ca^{2+}$  channels, which increases intracellular calcium concentration through a series of phosphorylation reactions. The increase in intracellular calcium results in the release of insulin. Release of insulin is also caused by binding of sulfonylureas to postulated receptor sites on regulatory exocytosis kinase and insulin granular membranes. Octreotide inhibits calcium entry through the  $Ca^{2+}$  channel, thereby inhibiting insulin release. GLP-1 acts on a G-protein coupled receptor, which results in accumulation of cAMP, and subsequent increased intracellular calcium stimulated insulin release. GLUT = membrane bound glucose transporter. GLP-1 = glucagonlike peptide-1; cAMP = cyclic adenosine monophosphate.

Insulin resistance in patients with type 2 diabetes mellitus occurs because of secretion of biologically defective insulin molecules, circulating insulin antibodies, or target tissue defects in insulin action.<sup>120</sup> The thiazolidinedione derivatives decrease insulin resistance by potentiating insulin sensitivity in the liver, adipose tissue, and skeletal muscle. Uptake of glucose into adipose tissue and skeletal muscle is enhanced, whereas hepatic glucose production is reduced.<sup>21,72</sup>

Repaglinide and nateglinide are representatives of the meglitinide class that also bind to  $K^+$  channels on pancreatic cells, resulting in increased insulin secretion.<sup>139</sup> Compared to the sulfonylureas, the hypoglycemic effects of the meglitinides are shorter in duration.

Exenatide, liraglutide, dulaglutide, and albiglutide are structurally similar to glucagonlike peptide-1 (GLP-1), an incretin that is released in response to an oral glucose load. Glucagonlike peptide-1 enhances the release of insulin, delays gastric emptying, and reduces food intake. Glucagonlike peptide-1 is metabolized very rapidly, rendering it therapeutically ineffective. The GLP-1 analogs have much longer half-lives, rendering them useful in the treatment of type 2 diabetes mellitus.<sup>165</sup> Sitagliptin, saxagliptin, linagliptin, and alogliptin inhibit dipeptidyl peptidase-4 (DPP-4), the enzyme responsible for the inactivation of GLP-1.<sup>3</sup> Pramlintide is an amylin analog. Amylin is produced in the pancreatic  $\beta$  cell and acts in conjunction with insulin to inhibit gastric emptying, decrease postprandial glucagon secretion, and promote satiety.<sup>91</sup>

The kidneys contribute significantly to glucose homeostasis. The SGLT2 inhibitors are located mainly in the proximal tubule, and account for up to 90% of glucose absorption. The SGLT2 inhibitors, such as canagliflozin, block the reabsorption of glucose, with subsequent excretion into the urine.<sup>50</sup>

## PHARMACOKINETICS AND TOXICOKINETICS

Pharmacokinetic parameters of the hypoglycemics are given in Tables 47-2 and 47-3. The onset and duration of action in therapeutic doses vary considerably among preparations. Insulin overdose usually occurs after administration by the subcutaneous or intramuscular route. As might be predicted based on slow onset and prolonged duration of action of some of the preparations, insulin overdose may result in delayed and prolonged hypoglycemia. However, hypoglycemia occurs with short-acting forms as well because of some unusual toxicokinetic features. Some of these unpredicted responses

are caused by a depot effect following intramuscular or subcutaneous administration, and poor absorption is further potentiated by the poor perfusion that occurs during periods of hypoglycemia.<sup>112,156</sup> Because there are a finite number of insulin receptors, insulin overdoses of varying amounts probably are equivalent in terms of the degree of resultant hypoglycemia once receptor saturation occurs, but not in terms of its duration. A comparison can be made with the current treatment of diabetic ketoacidosis, in which lower doses of insulin are as effective as the higher doses used in the past.<sup>80</sup>

Many of the sulfonylureas have long durations of action, which explains the unusually long period of hypoglycemia that occurs in both therapeutic use and overdose. Second-generation sulfonylureas (glimepiride, glipizide, glyburide) have half-lives that approach 24 hours and are characterized by substantial fecal excretion of the parent molecule. The sulfonylureas frequently cause hypoglycemia (Table 47-2). As with insulin, the sulfonylureas cause delayed onset of hypoglycemia following overdose.<sup>121,134</sup> The reason for the potential delayed onset of effects with sulfonylureas cannot be simply explained by known kinetic principles but could be related to counterregulatory mechanisms that fail over time.

Metformin metabolism is negligible, and the majority of an absorbed dose is actively secreted in the urine unchanged. With renal dysfunction, the clearance of metformin declines in proportion to the decline of creatinine clearance.<sup>64</sup> Plasma protein binding is negligible.<sup>12</sup> Repaglinide and nateglinide are prandial glucose regulators characterized by rapid onset and short duration of action. Overdose experience and toxicokinetic data for repaglinide are lacking. It is not clear whether hypoglycemia would be prolonged or delayed in onset following overdose. In one case of nateglinide overdose, hypoglycemia occurred early and was short lived.<sup>114</sup> Exenatide is available in an extended-release form, and dulaglutide and albiglutide are formulated such that these drugs are administered once weekly. The gliptins have long half-lives and cause pronounced inhibition of DPP-4, resulting in a long duration of action (approximately 24 hours) after therapeutic doses.<sup>88</sup> Pramlintide has a half-life of approximately 40 minutes when used in therapeutic doses.<sup>32</sup> The SGLT2 inhibitors have durations of action that allow for once-daily dosing.<sup>43</sup> The GLP-1 analogs and amylin analogs are large polypeptides; they represent the 2 classes of noninsulin antidiabetics that are only administered parenterally (subcutaneously).

TABLE 47-2 Characteristics of Noninsulin Antidiabetics

Xenobiotic	Duration of Action	Active Hepatic Metabolite	Active Urinary Excretory Product	Likelihood of Hypoglycemia in Overdose
<b>I. Sulfonylureas</b>

(++) = Substantial; (+) = Limited; (-) = None/Negligible; H = High Likelihood; L = Low Likelihood.

GLP-1 analogs = glucagonlike peptide analogs; SGLT2 = sodium-glucose cotransporter; DPP-4 inhibitor = dipeptidyl peptidase-4 inhibitor.

## PATHOPHYSIOLOGY OF HYPOGLYCEMIA

To varying degrees, the antidiabetics all produce a nearly identical clinical condition of hypoglycemia. The etiologies of hypoglycemia are divided into 3 general categories:<sup>54</sup> physiologic or pathophysiologic conditions (Table 47-1), direct effects of various hypoglycemics (Tables 47-2 and 47-3), and potentiation of hypoglycemics by interactions with other xenobiotics (Table 47-4).

Hypoglycemia usually results in decreased insulin secretion, with production of alternate fuels, particularly ketones. Ketone production occurs as a result of fatty acid metabolism.<sup>85</sup> Nonketotic hypoglycemia can occur with hyperinsulinemia such as from an insulinoma.<sup>123</sup>

Central nervous system (CNS) symptoms predominate in hypoglycemia because the brain relies almost entirely on glucose as an energy source. However, during prolonged starvation, the brain can utilize ketones derived from free fatty acids. In contrast to the brain, other major organs such as the heart, liver, and skeletal muscle often function during hypoglycemia because they can use various fuel sources, particularly free fatty acids.<sup>149</sup>

Emphasis on tighter glucose control as a means of preventing microvascular effects carries with it an increased risk for hypoglycemia.<sup>39,40</sup> Regulation of glucose control to near-normal glucose concentrations, the characteristics of each individual's awareness of hypoglycemia, and the individual counterregulatory mechanisms define the frequency and intensity of

**TABLE 47-3** Characteristics of Various Forms of Insulin

Insulin	Onset of Action (hours)	Duration of Action (hours)	Peak Glycemic Response (hours)
<b>Rapid Acting</b>			
Aspart	0.25	3–5	0.75–1.5
Glulisine	0.5	<5	1.5–2
Lispro	0.25–0.5	<5	0.5–2.5
<b>Short Acting</b>

Detemir	1.5	24	No true peak
Glargine	1.1	24	No true peak
Ultralente	4–6	20–36	8–20

hypoglycemia.<sup>148</sup> The Diabetic Control and Complications Trial research group reported 62 episodes of blood glucose concentration less than 50 mg/dL with CNS manifestations requiring assistance for every 100 patient-years in patients undergoing an intensive insulin therapy regimen. This was in comparison to a conventional therapy group, which had 19 such episodes per 100 patient-years.<sup>39,40</sup> The intensive therapy group received 3 or more insulin injections per day or used a pump in an effort to achieve a glucose concentration as close to normal as possible, whereas the conventional therapy group received one or 2 daily insulin injections.

There has also been an emphasis in tighter control of glucose in critically ill patients, even in the absence of known diabetes mellitus. Hyperglycemia occurs in critically ill patients due to several mechanisms and is associated with increased mortality in patients with a variety of medical and surgical diagnoses.<sup>82</sup> In a study of critically ill surgical patients, tight control of glucose was associated with decreased morbidity and mortality.<sup>169</sup> However,

such benefits in other studies are not always clearly replicated, and significant hypoglycemia is reported.<sup>52,168</sup>

The issue of tight glycemic control has to be analyzed with respect to various factors, such as old versus young age, outpatient versus critically ill (including surgical vs nonsurgical patients), microvascular versus macrovascular complications, and diabetic versus nondiabetic patients. Although benefits of tight glycemic control are demonstrable, these are often outweighed by the deleterious effects of hypoglycemia.<sup>1,56,95,96,103</sup>

The autonomic nervous system regulates glucagon and insulin secretion, glycogenolysis, lipolysis, and gluconeogenesis.  $\beta$ -Adrenergic antagonists affect all of these mechanisms and can result in hypoglycemia.  $\beta$ -Adrenergic antagonist-induced hypoglycemia is a particular risk<sup>65</sup> secondary to increased insulin half-life and reduced renal gluconeogenesis in the presence of renal dysfunction.<sup>124</sup> In addition, the clinical presentation of hypoglycemia may be muted when  $\beta$ -adrenergic antagonists are present because the expected autonomic responses of tachycardia, diaphoresis, and anxiety may not occur. Although this is assumed to be true, an adverse effect on hypoglycemic awareness could not be demonstrated in healthy volunteers given metoprolol, atenolol, and propranolol.<sup>78</sup>

The concept of hypoglycemia-associated autonomic failure in diabetes mellitus is well described.<sup>37</sup> Recurrent episodes of hypoglycemia result in autonomic failure by causing defective compensatory glucose counterregulation and subsequent hypoglycemic unawareness. As glucose concentrations fall, normal sensing mechanisms result in decreased insulin secretion and increased glucagon and epinephrine secretion. These counterregulatory defenses against hypoglycemia are defective in most people with type 1 diabetes mellitus and in many with type 2 diabetes mellitus. A comparison study was conducted in diabetes patients with hypoglycemia awareness and hypoglycemia unawareness, using positron emission tomography with radiolabeled fluorodeoxyglucose to measure changes in brain glucose kinetics.<sup>47</sup> Alterations in cortical responses to hypoglycemia were found in those with unawareness of hypoglycemia. This group also had significantly less epinephrine output in response to hypoglycemia.

Although various nonantidiabetic xenobiotics can cause hypoglycemia (Table 47-1), salicylates and ethanol are particularly notable for their unintended hypoglycemic effects. The mechanism of ethanol-induced hypoglycemia is discussed in Chap. 76. Salicylate inhibition of prostaglandin synthesis in the  $\beta$  cell of the pancreas is postulated to result in enhanced insulin secretion.<sup>14</sup> Salicylates may also cause hypoglycemia by mechanisms that do not involve enhanced insulin secretion. Hypoglycorrhachia in the presence of peripheral euglycemia was demonstrated in a mouse study,<sup>164</sup> and it correlates with reports in humans of reversal of euglycemic delirium after administration of dextrose.<sup>84</sup>

## CLINICAL MANIFESTATIONS

Hypoglycemia and its secondary effects on the CNS (neuroglycopenia) are the most common adverse effects related to insulin and the sulfonylureas. It is essential to remember that hypoglycemia is primarily a clinical, not a numerical, disorder. Clinical hypoglycemia is the failure to maintain a CSF glucose concentration that prevents signs or symptoms of glucose deficiency. The clinical presentations of patients with hypoglycemia are extremely variable and it must be excluded as an etiology of any neuropsychiatric abnormality, whether persistent or transient, focal or generalized. The cerebral cortex usually is most severely affected. These findings are categorized below:<sup>131</sup>

- Delirium with subdued, confused, or agitated behavior.
- Coma with multifocal brain stem abnormalities, including decerebrate spasms and respiratory abnormalities, with preservation of the oculocephalic (doll's eyes), oculovestibular (cold-caloric), and pupillary responses.
- Focal neurologic deficits simulating a cerebrovascular accident (CVA) with or without the presence of coma. There are numerous reports<sup>7,153</sup> and series<sup>145,170</sup> of patients with focal neurologic deficits.
- Seizure activity (single, multiple, or status epilepticus).

**TABLE 47-4** Xenobiotics Known to React with Hypoglycemics Resulting in Hypoglycemia

$\beta$ -Adrenergic antagonists
Angiotensin-converting enzyme (ACE) inhibitors
Allopurinol
Anabolic steroids
Chloramphenicol
Clofibrate
Disopyramide
Ethanol
Fluoroquinolones
Haloperidol
Methotrexate
Monoamine oxidase inhibitors
Pentamidine
Phenylbutazone
Probenecid
Quinine
Salicylates
Sulfonamide
Trimethoprim-sulfamethoxazole
Warfarin

These neuropsychiatric symptoms are usually reversible if the hypoglycemia is corrected promptly. The morbidity resulting from undiagnosed hypoglycemia is related partly to the etiology and partly to the duration and severity of the hypoglycemia. The etiologies of hypoglycemia encompass both severe diseases such as fulminant hepatic failure and benign problems such as a missed meal by an insulin-requiring diabetes patient or a patient on an oral antidiabetic. The literature with regard to outcome is difficult to interpret. Although a study of 125 emergency department (ED) cases of symptomatic hypoglycemia reported an 11% mortality rate,<sup>99</sup> only one death (0.8%) was attributed directly to hypoglycemia. In that same study, 9 patients (7.2%) presented with seizures (focal in one case), 3 patients (2.4%) presented with hemiparesis, and 4 survivors (3.2%) suffered residual neurologic deficits. In one tertiary care medical center, 1.2% of all admitted patients had numerical hypoglycemia (defined as a glucose concentration <50 mg/dL). The overall mortality was 27% for this group of 94 patients.<sup>54</sup> The longer and more profound the hypoglycemic episode, the more likely permanent CNS damage will occur.<sup>10</sup>

No absolute criteria available from the physical examination or history distinguish one form of metabolic coma from another. Moreover, all of the findings classically associated with hypoglycemia, such as tremor, sweating, tachycardia, confusion, coma, and seizures, are frequently absent.<sup>69</sup> The glycemic threshold is the glucose concentration below which clinical manifestations develop, a threshold that is host variable. In one study, the mean glycemic threshold for hypoglycemic symptoms was 78 mg/dL in patients with poorly controlled type 1 diabetes compared to 53 mg/dL in those without the disease.<sup>17</sup>

Many patients with well-controlled type 1 diabetes are unaware of hypoglycemia. It appears that even in the presence of numerical hypoglycemia, diabetes patients with near-normal glycosylated hemoglobin concentrations maintain near-normal glucose uptake by the brain, thereby preserving cerebral metabolism and limiting the response of counterregulatory hormones. The result of this limited response is unawareness of hypoglycemia.<sup>17,19</sup> A threshold is likely achieved below which the glucose concentration is inadequate, but this may be a concentration so close to that causing serious neuroglycopenia that patients have limited opportunity for corrective action.<sup>19</sup> Hypoglycemia unawareness is most likely in diabetes patients with chronic use of hypoglycemics because of hypoglycemia-associated autonomic failure.<sup>37</sup> Acute ingestion of hypoglycemics in nondiabetic patients typically would cause more classic signs and symptoms.

Sinus tachycardia, atrial fibrillation, and ventricular premature contractions are the most common dysrhythmias associated with hypoglycemia.<sup>89,119</sup> An outpouring of catecholamines in a response to hypoglycemia, transient electrolyte abnormalities, and underlying heart disease appear to be the most likely etiologies. Based on their mechanisms of action, both insulin and the sulfonylureas are expected to promote the shift of potassium into cells, and hypokalemia after insulin overdose is well documented.<sup>9,156</sup> Other cardiovascular manifestations including acute coronary syndromes rarely are the sole manifestations of hypoglycemia.<sup>16,46,128</sup> Increased release of catecholamines during hypoglycemia increases myocardial oxygen demand and decreases supply by causing coronary vasoconstriction, especially in patients with diabetes who are at increased risk of atherosclerosis. Hypoglycemia leads to catecholamine release which also causes cardiac repolarization abnormalities that contribute to atrial and ventricular dysrhythmias.<sup>167</sup>

Hypothermia often occurs in hypoglycemic patients.<sup>55,77,158</sup> If present, hypothermia usually is mild (90°F–95°F {32°C–35°C}), unless coexisting conditions such as environmental exposure, infection, head injury, or hypothyroidism are present. In a study comparing 2 groups of patients with depressed mental status, hypothermia was almost exclusively limited to the hypoglycemic patients; of these patients, 53% with demonstrated hypoglycemia showed hypothermia.<sup>158</sup> The central hypothalamic response to hypoglycemia stimulated by the sympathetic nervous system infrequently “overshoots” normal temperatures, resulting in hyperthermia following recovery.<sup>33</sup>

Besides decreasing glucose concentrations, the hypoglycemics can produce a number of adverse effects, both in overdose and in therapeutic doses.

Older sulfonylureas, predominantly chlorpropamide, cause a syndrome of inappropriate antidiuretic hormone secretion<sup>75</sup> and disulfiram-ethanol reactions.<sup>129</sup> These adverse effects are exceedingly uncommon with the newer second-generation sulfonylureas.

Hypoglycemia is at times delayed until 18 hours after lente insulin overdose,<sup>112</sup> persist for up to 53 hours after subcutaneous insulin glargine overdose,<sup>23</sup> and is reported to persist up to 6 days after ultralente insulin overdose.<sup>100</sup> Death after insulin overdose cannot be correlated directly with either the dose or preparation. Some patients have died with doses estimated in the hundreds of units, whereas others have survived doses in the thousands of units.<sup>144</sup> Mortality and morbidity likely correlate better with delay in recognition of the problem, duration of symptoms, onset of therapy, and type of complications, as opposed to the absolute degree of hypoglycemia or persistence of elevated insulin concentrations. In a retrospective study of insulin overdose, 7 of 17 cases (41%) developed recurrent hypoglycemia between 5 and 39 hours after overdose despite oral feeding and intravenous dextrose infusion ranging from 5 to 17 g of dextrose per hour.<sup>156</sup> A significant correlation was noted between the amount of insulin injected and the total amount of dextrose used for treatment. This is surprising because one would expect that the amount of dextrose infused would be independent of the dose of insulin following saturation of insulin receptors. Another study of intentional insulin overdose in 25 patients found no correlation between the insulin dose and the amount of administered dextrose.<sup>109</sup>

Insulin is a large polypeptide structure. Although one would expect significant degradation by gut enzymes if ingested, there is a report of hypoglycemia to as low as 25 mg/dL after ingestion of 3,000 units of a combination of aspart, lispro, and glargine.<sup>159</sup>

In a retrospective review of 40 patients with sulfonylurea overdoses, the time from ingestion to the onset of hypoglycemia, when known, was variable.<sup>121</sup> The longest delay was 21 hours after ingestion of glyburide and 48 hours after ingestion of chlorpropamide. In a retrospective poison control center review of 93 cases of sulfonylurea exposures in children, 25 patients (27%) developed hypoglycemia, with a time of onset ranging from 0.5 to 16 hours and a mean of 4.3 hours.<sup>134</sup> In a prospective poison control center study of sulfonylurea exposures in children, 56 of 185 (30%) patients developed hypoglycemia, with a time of onset ranging from 1 to 21 hours and a mean of 5.3 hours.<sup>152</sup> Single-tablet ingestions of chlorpropamide 250 mg, glipizide 5 mg, and glyburide 2.5 mg result in hypoglycemia in young children,<sup>134</sup> and the hypoglycemia is often delayed.<sup>160</sup> Hypoglycemia did not occur until 45 hours after ingestion of a 10-mg extended-release glipizide tablet in a 6-year-old child.<sup>125</sup>

Hypoglycemia is reported in a few cases of metformin overdose. In a 2-case series, metabolic acidosis with an elevated lactate concentration was evident on initial presentation.<sup>162</sup> Hypoglycemia was present initially in one of the cases but did not develop until 7 hours later in the second case. There is no mention of co-ingestants in these cases. Hypoglycemia is reported in a 15-year-old who presented 2 hours after ingestion of metformin and quetiapine.<sup>4</sup> Extensive laboratory investigation excluded insulin and sulfonylureas as causal. Hypoglycemia and metabolic acidosis with an elevated lactate concentration are reported in a case of overdose with metformin, atenolol, and diclofenac.<sup>66</sup> In a series of 36 metformin overdose cases, 2 patients developed hypoglycemia, and co-ingestants were not felt to be contributory.<sup>107</sup> Insufficient evidence supports the concept that metformin-associated hypoglycemia can develop in a patient who does not have metabolic acidosis. Because many patients receiving metformin also take sulfonylureas, hypoglycemia should be anticipated after overdose.

Despite limited overdose data, acarbose and miglitol are not likely to cause hypoglycemia based on their mechanism of action of inhibiting  $\alpha$ -glucosidase. The most common adverse effects associated with therapeutic use of these xenobiotics are gastrointestinal, including nausea, bloating, abdominal pain, flatulence, and diarrhea. Elevated aminotransferase concentrations were noted after use of acarbose in clinical trials.<sup>70</sup> Most patients were asymptomatic, and the aminotransferase concentrations returned to

normal after the drug was discontinued. The therapeutic use of acarbose in some cases reportedly led to hepatotoxicity that resolved after the drug was discontinued.<sup>8,30</sup>

Hypoglycemia would not be expected after thiazolidinedione overdose, despite limited overdose data. The most serious adverse effect of troglitazone is the development of liver toxicity with therapeutic doses, which in some cases was severe enough to require liver transplantation.<sup>62,117</sup> Liver toxicity related to therapeutic use of rosiglitazone<sup>6,57</sup> and pioglitazone is also reported.<sup>98,101</sup> Therapeutic use of pioglitazone and rosiglitazone may precipitate fluid retention in patients with congestive heart failure.<sup>116</sup> A meta-analysis concluded that rosiglitazone therapy is associated with an increased risk of myocardial infarction and death from cardiovascular causes.<sup>118</sup>

Hypoglycemia should be anticipated after repaglinide and nateglinide ingestion. Hypoglycemia is reported after nateglinide overdose,<sup>114</sup> and a case of intentionally self-induced hypoglycemia secondary to repaglinide is reported.<sup>68</sup> Hypoglycemia developed 14 hours postingestion in a case of repaglinide overdose.<sup>51</sup>

The GLP-1 analogs and gliptins are reported to have pharmacologic effects that are glucose-dependent.<sup>58</sup> This does not necessarily apply to the overdose situation, and hypoglycemia is uncommonly reported in such settings. "Severe hypoglycemia" was reported in a phase III clinical trial after inadvertent administration of 10 times the normal dose of exenatide. The specific glucose concentration is not noted in the report.<sup>27</sup> Injection of 90 mcg of exenatide in a 40-year-old and 1,800 mcg in a 46-year-old resulted in gastrointestinal symptoms but no hypoglycemia.<sup>35,83</sup> As a result of a transcription error, a 67-year-old received 18 mg liraglutide daily over a 7-month period. He had several hospitalizations for evaluation of nausea, vomiting, and diarrhea but never developed hypoglycemia.<sup>15</sup> A 33-year-old injected 72 mg of liraglutide and developed nausea and vomiting, but no hypoglycemia.<sup>113</sup>

An 86-year-old ingested 1,700 mg of sitagliptin in a suicide attempt and did not develop hypoglycemia during an overnight hospitalization.<sup>59</sup> A multicenter poison control center study reviewed 650 cases of gliptin exposure, with exclusion of co-ingestant cases.<sup>141</sup> Three of these reportedly developed hypoglycemia, although the description of these cases is not clear with respect to associated neuroglycopenia. The glucose concentrations were based on bedside testing, not on specimens sent to the laboratory.

There are limited overdose data with regard to amylin analogs. Pramlintide is used therapeutically in conjunction with insulin, and hypoglycemia in this setting is more likely than with insulin use alone.<sup>91</sup>

Therapeutic use of SGLT2 inhibitors results in euglycemic ketoacidosis.<sup>161</sup> This is one of the newest classes of drugs used for diabetes, with limited overdose data. Based on their pharmacology, inhibition of renal glucose reabsorption would not be expected to occur to a degree that would result in hypoglycemia.<sup>38</sup>

## DIAGNOSTIC TESTING

Suspicion of hypoglycemia, particularly neuroglycopenia, is important in any patient with an abnormal neurologic examination. The most frequent reasons for failure to diagnose hypoglycemia and mismanaging patients are the erroneous conclusions that the patient is not hypoglycemic but rather is psychotic, epileptic, experiencing a CVA, or intoxicated because of an "odor of alcohol" on the breath (Chap. 76). Compounding the problem of misdiagnosis is the erroneous assumption that a single bolus of 0.5 to 1 g/kg of hypertonic dextrose will always be sufficient.

Plasma glucose concentrations, although generally accurate, are time consuming, so treatment should not be delayed pending the results of laboratory testing. Glucose reagent strip testing can be performed at the bedside. The sensitivity of these tests for detecting hypoglycemia is excellent, but these tests are not perfect. Several interfering substances may cause false elevations of bedside glucose reagent strip concentrations, including maltodextrin, acetaminophen, bilirubin, triglyceride, and uric acid.<sup>48,79</sup> Bedside glucose testing is discussed in more detail in Antidotes in Depth: A8.

Diagnostic studies other than determinations of glucose concentrations are often indicated, depending on the clinical situation. In some instances, determination of serum ethanol concentration is helpful in confirming alcohol as a contributing or sole etiologic factor. Analysis of BUN, creatinine, and eGFR (estimated glomerular filtration rate) indicates the presence of renal dysfunction as a causative factor of hypoglycemia. This commonly occurs in patients with diabetes taking insulin, who often develop renal dysfunction after they have had the disease for several years, with insulin half-life increasing as eGFR decreases. Measures of hepatic function will be a clue to liver disease as a cause of hypoglycemia, although liver disease will also be evident on physical examination. Seizures are commonly associated with hypoglycemia, but other studies, such as electrolytes, and imaging of the brain, are indicated if doubt about the etiology exists.

In the majority of overdose cases, laboratory testing for specific anti-diabetics is not helpful. Exceptions might include malicious, surreptitious, or unintentional overdoses (discussed in the next section). Metformin concentrations vary and do not necessarily correlate with the clinical condition.<sup>5,86,87</sup>

For known diabetic patients in whom intentional, unintentional or malicious overdose is not suspected, the clinician must search diligently for the cause of hypoglycemia. Sometimes it is as simple as a missed meal in an insulin or oral antidiabetic user or an unusually strenuous exercise routine, but in many cases the cause cannot be clearly defined. Numerous medical conditions, as well as a variety of xenobiotics, are commonly involved (Table 47-1), and diagnostic testing must be individualized for each episode depending on the clinical suspicion. Diagnosing the etiology as "idiopathic" is never acceptable.

## EVALUATION OF MALICIOUS, SURREPTITIOUS, OR UNINTENTIONAL INSULIN OVERDOSE

The physical examination will often provide helpful clues to the evaluation of a suspected malicious, surreptitious, or unintentional insulin overdose. A meticulous search will reveal a site that is erythematous, hemorrhagic, atypically boggy in nature, or even painful if the subcutaneous or intramuscular injection of insulin was particularly large. A simple unexplained needle puncture mark in the appropriate clinical setting suggests insulin injection.

An understanding of how the  $\beta$  cells of the pancreas secrete insulin in response to glucose concentrations in the blood is essential to understanding the investigation of fasting hypoglycemia.<sup>36</sup> When the plasma glucose concentration is less than 45 mg/dL, insulin secretion should be almost completely suppressed, so plasma insulin concentrations should be minimal or absent.<sup>130</sup> Moreover, insulin is secreted as proinsulin, which is cleaved in vivo to form insulin (a double-stranded peptide), and C-peptide, which are released into the blood in equimolar quantities. Insulin is biologically active, whereas proinsulin has limited activity, and C-peptide has no activity. Although insulin is normally cleared during hepatic transit, C-peptide is not. For this reason, C-peptide can be utilized as a quantitative marker of endogenous insulin secretion. In contrast, commercially available exogenous human insulin does not contain C-peptide fragments (Table 47-5). When plasma glucose concentration falls to hypoglycemic concentrations (usually <60 mg/dL), insulin concentration should fall to less than 6  $\mu$ U/mL. If hypoglycemia is caused by exogenous insulin administration, plasma C-peptide concentrations should be less than 0.2 nmol/L in the presence of insulin concentrations that are substantially higher than insulin concentrations resulting from an insulinoma. With insulinoma, insulin concentrations generally are greater than 6  $\mu$ U/mL in the presence of hypoglycemia. Insulinoma results in elevations of both C-peptide and insulin concentrations. Sulfonylurea overdose is expected to have similar effects, but concentrations in reported cases of sulfonylurea-induced hypoglycemia vary considerably.<sup>44</sup> In the face of uncertainty, sulfonylurea concentrations are available from reference laboratories. Animal insulin can be distinguished from human insulin by high-performance liquid chromatography.<sup>63</sup> However, this technique has limited use because of the virtually exclusive use of recombinant insulin at present.

**TABLE 47–5** Laboratory Assessment of Fasting Hypoglycemia

Clinical State	Insulin <sup>a</sup> (Serum) (μU/mL)	C-Peptide (Serum) (nmol/L)	Proinsulin Serum (pmol/L)	Antiinsulin Antibodies <sup>b</sup>
Normal	<6	<0.2	<5	–
Exogenous insulin	Very high	Low (suppressed)	Absent	Present <sup>c</sup>
Insulinoma	High	High	Present	Absent
Sulfonylurea ingestion <sup>d</sup>	High	High	Present	Absent
Autoimmune	Very high (artifact)	Low (or) high (artifact)	Present	Present
Decreased glucose production	Low	Low	Present	Absent
Neoplasia (non-β-cell)	Low	Low	Present	Absent

<sup>a</sup>Insulin concentrations are determined during fasting induced hypoglycemia at low concentrations, preferably <60 mg/dL of plasma glucose. <sup>b</sup>The antiinsulin antibodies produced spontaneously differ from those of treated (exposed to exogenous insulin) and those of untreated insulin-dependent diabetic patients. The presence of antiinsulin antibodies occurs less frequently in those exposed only to human insulin. <sup>c</sup>Sulfonylurea ingestion is diagnosed by detection of the parent compound metabolites in serum or urine.

In summary, patients with exogenous insulin-induced hypoglycemia will have high insulin concentrations, the presence of insulin-binding antibodies (if chronic insulin users),<sup>53</sup> and low C-peptide concentrations. Those who have taken sulfonylureas will have high insulin concentrations, absent insulin-binding antibodies, high C-peptide concentrations, and the presence of urinary sulfonylurea metabolites (Table 47–5). The issues of evidence collection that are appropriate to document malicious or surreptitious use of insulin successfully are described (Chap. 138).<sup>94</sup>

## MANAGEMENT

Treatment centers on the correction of hypoglycemia and the anticipation that hypoglycemia may recur. Symptomatic patients with hypoglycemia require immediate treatment with 0.5 to 1 g/kg hypertonic intravenous dextrose in the form of D<sub>50</sub>W in adults, D<sub>25</sub>W in children, and D<sub>10</sub>W in neonates. Occasionally, patients require a larger dose to achieve an initial response. If hypoglycemia is suspected but not confirmed, as in the absence of rapid reagent strip availability or when such readings are “borderline,” dextrose should be administered. Theoretical risks are associated with use of hypertonic dextrose in the setting of acute cerebral ischemia, but failure to rapidly correct hypoglycemia will lead to deleterious neurologic effects. Appropriate emergency and toxicologic uses of hypertonic dextrose are covered in detail in Antidotes in Depth: A8.

We recommend not to use glucagon as an antihypoglycemic except in the uncommon situation where intravenous access cannot be obtained. Glucagon has a delay to onset of action and is ineffective in patients with depleted glycogen stores, as in the malnourished elderly, cancer patients, or alcoholics. Glucagon also stimulates insulin release from the pancreas, which is reported to lead to prolonged hypoglycemia in settings such as sulfonylurea ingestion and insulinoma.<sup>163</sup>

Numerous studies have evaluated approaches for treating insulin reactions with carbohydrates in tablet, solution, or gel forms in a well-defined diabetic population.<sup>150</sup> None of these forms is appropriate for the undifferentiated, possibly hypoglycemic patient if intravenous access is available, but should be carried by all diabetic patients.

A common occurrence involves symptomatic hypoglycemic patients who receive intravenous dextrose in the prehospital setting and subsequently refuse transport to the hospital. The authors of a retrospective review of 571 paramedic runs involving hypoglycemic patients concluded that out-of-hospital treatment of hypoglycemic diabetic patients is safe and effective even when transport is refused.<sup>151</sup> However, of the 159 patients who agreed to hospital transport, 40% were admitted. The admitted group was older than those released from the ED. The admission rate for transported patients on oral hypoglycemics was higher than those on insulin. The reasons for admission are not otherwise detailed. The authors of a prospective study involving 132 hypoglycemic diabetic patients who refused transport after therapy

concluded that most such patients have good short-term outcome, but they still encouraged transport because of the risk of recurrent hypoglycemia.<sup>108</sup> One patient died in each of these 2 studies. A prospective study in 35 patients with 38 hypoglycemic events related to insulin use concluded that most patients were successfully treated in the prehospital setting without transport.<sup>92</sup> However, 2 patients developed recurrent hypoglycemia that they treated themselves, and one of these patients required placement in a long-term care facility for posthypoglycemic encephalopathy. We therefore recommend that all hypoglycemic patients should be transported to the ED.

Emesis, lavage, and catharsis are of limited benefit in the management of patients who overdose on hypoglycemics. The extensive affinity between chlorpropamide, tolazamide, tolbutamide, glyburide, glipizide, and activated charcoal is demonstrated in vitro.<sup>76</sup> The affinities ranged from 0.45 to 0.52 g/g activated charcoal at pH 7.5 and were higher at pH 4.9. Single-dose activated charcoal should be beneficial in the management of these overdoses. Although affinity studies are lacking for the other oral hypoglycemics, their chemical characteristics are such that single-dose activated charcoal is expected to be beneficial for these overdoses as well.

In patients who overdose on insulin, case reports describe the use of surgical excision of the injection site.<sup>29,93,104</sup> However, this technique has not been studied in a systematic fashion and we recommend against excision. Needle aspiration of a depot site is less invasive and can be performed, but intravenous dextrose should be sufficient in most cases.

## MAINTAINING EUGLYCEMIA AFTER INITIAL CONTROL

After the patient is awake and alert, further therapy depends on the pharmacokinetics of the xenobiotic involved and pancreatic islet cell function. Some patients, particularly those with prolonged hypoglycemia, have persistent altered mental status despite euglycemia. Whether the event was unintentional or intentional with suicidal or homicidal intent must be determined. One problem associated with dextrose administration occurs in individuals who can produce insulin via glucose-stimulated insulin release (non-diabetic patients and those with type 2 diabetes mellitus), placing them at substantial risk for recurrent hypoglycemia. This complication occurs with insulin overdose but is particularly problematic with overdoses of sulfonylurea or meglitinide because these hypoglycemics stimulate insulin release. Treatment with hypertonic dextrose solutions can be expected to result in dramatic yet only transient increases in glucose concentrations, with a subsequent fall in plasma glucose concentration, possibly back to hypoglycemic concentrations.

For patients with diabetes who unintentionally inject an excessive amount of insulin and are not neuroglycopenic, feeding (carbohydrates and proteins) should be initiated and intravenous access maintained while avoiding routine dextrose infusion. In the event of recurrent symptomatic hypoglycemia, a hypertonic intravenous dextrose bolus followed by

an infusion of  $D_5W$  is recommended. Overdose in the setting of suicidal or homicidal intent likely involves significant quantities of insulin. Nondiabetic patients are particularly prone to significant hypoglycemia because they lack insulin resistance. Feeding is recommended with a target of maintaining glucose concentrations in the 100- to 150-mg/dL range using a hypertonic dextrose infusion ( $D_{10}W$  or greater) as needed based on serial measurements of plasma glucose concentrations.

Central venous lines should be used when a  $D_{20}W$  or greater infusion is instituted, because hypertonic dextrose solutions are venous irritants and sclerosing to the vasculature. The presence of glycosuria is not an adequate indicator of euglycemia; frequent serial blood or reagent strip glucose concentrations should be obtained. The appropriate timing of glucose monitoring varies depending on the clinical situation. Mental status must be observed. As a rough guide, glucose monitoring every 1 to 2 hours after initial control is reasonable, with subsequent spacing of the intervals to once every 4 to 6 hours. Phosphate concentrations should be monitored because dextrose loading may lead to hypophosphatemia.<sup>110</sup> Potassium concentrations should be monitored because dextrose administration leads to hypokalemia in nondiabetic patients and rarely hyperkalemia in patients with impaired insulin secretion.<sup>34</sup> The duration of serial sampling depends on the stability of the patient, the underlying metabolic disorders, the extent of overdose, and the rate of improvement. When the patient begins to eat an adequate diet and the initial hypoglycemia is controlled, the plasma glucose concentration will rise, and the concentration and rate of dextrose infusion can be tapered. Many patients may actually develop significant hyperglycemia.

The therapeutic approach differs for patients who overdose on sulfonylureas or meglitinides. After initial control of hypoglycemia with hypertonic dextrose, feeding is again recommended. Intravenous access is necessary, but routine continuous dextrose infusion should be avoided. As with insulin overdose, frequent monitoring of glucose concentrations and mental status is critical. We recommend use of octreotide for recurrent hypoglycemia in this setting because of the significant risk of glucose-stimulated insulin release.

Octreotide, a semisynthetic long-acting analog of somatostatin with an intravenous half-life of 72 minutes, inhibits glucose-stimulated  $\beta$  cell insulin release via receptors coupled to G proteins on  $\beta$  islet cells.<sup>18</sup> Somatostatin is present in diverse tissues such as the hypothalamus, pancreas, and gastrointestinal tract. It alters the secretion of growth hormone and thyroid-stimulating hormone, gastrointestinal secretions, and the endocrine pancreas (glucagon and insulin).<sup>137,138</sup> Octreotide was compared to intravenous hypertonic dextrose and to diazoxide and concomitant dextrose in normal subjects brought to hypoglycemia using glipizide.<sup>18</sup> Fewer episodes of recurrent hypoglycemia occurred after octreotide therapy, and overall dextrose requirements were lower than in the dextrose-alone and dextrose-plus-diazoxide groups. Several successful clinical experiences with octreotide are reported with quinine-induced hypoglycemia resulting from malaria therapy,<sup>127</sup> insulinoma,<sup>67</sup> nesidioblastosis of infancy,<sup>41</sup> hypoglycemia related to therapeutic use of gliclazide,<sup>20</sup> and tolbutamide overdose.<sup>18</sup> In a retrospective study of 9 patients with hypoglycemia resulting from either glyburide or glipizide, octreotide effectively reduced the risk of recurrent hypoglycemia.<sup>105</sup> Despite limited evidence, octreotide would be expected to be effective in the treatment of recurrent hypoglycemia following overdose of all classes of non-insulin antidiabetics.

Octreotide appears to be relatively free of serious side effects. The most likely adverse effects are injection-site discomfort if it is administered subcutaneously and gastrointestinal symptoms such as nausea, bloating, diarrhea, and constipation.<sup>97</sup> Our suggested adult octreotide dose is 50 mcg subcutaneously every 6 hours (Antidotes in Depth: A9). The patient should be monitored for 12 to 24 hours after the last dose of octreotide. This observation will ensure that recurrence of hypoglycemia does not occur. Like octreotide, diazoxide is reportedly effective in patients with refractory sulfonylurea-induced hypoglycemia.<sup>74,121</sup> However, octreotide is the preferred therapy because diazoxide has the potential to cause hypotension, cerebrovascular compromise and myocardial infarction.<sup>105</sup>

## ADMITTING PATIENTS TO THE HOSPITAL

The decision to admit a patient is complex, but several guidelines can be followed. Admission is usually required for hypoglycemia related to sulfonylureas, ethanol, starvation, hepatic failure, and renal dysfunction, and for hypoglycemia of unknown etiology. The decision to admit a patient often depends on finding an etiology for hypoglycemia, particularly in the setting of insulin use. In most cases, if a diabetic patient on therapeutic doses of insulin develops hypoglycemia after a missed meal, the patient can be discharged after a 4- to 6-hour observation period during which the individual eats a meal and remains asymptomatic with no evidence of hypoglycemia. Patients receiving therapeutic doses of insulin usually require inpatient evaluation of recurrent and unexplained hypoglycemic episodes. Patients with hypoglycemia after unintentional overdose with long-acting insulin should generally be admitted. Hospitalization is usually recommended after unintentional overdose with ultrashort-acting, short-acting, or intermediate-acting insulin if hypoglycemia is persistent or recurrent during a 4- to 6-hour observation period in the ED. Many factors are responsible for unintentional insulin overdose, such as patient error because of impaired vision, syringe structure, and prescription error when undiagnosed hospital admission is recommended. Admission is usually indicated for any patient, regardless of serum glucose concentration or presence or absence of symptoms, who intentionally overdoses on a sulfonylurea or any form of injected insulin, because delayed, profound, and protracted hypoglycemia is expected. Although intravenous insulin overdose is expected to result in more immediate symptoms, experience with this scenario is limited. Admission in this setting is generally advised unless short-acting insulin is involved. Glargine is expected to act like regular insulin when administered intravenously. It is long-acting when administered subcutaneously because of the formation of microprecipitates that are absorbed slowly. Hypoglycemia related to sulfonylurea use in any setting including a missed meal or a viral illness typically necessitates hospitalization.<sup>25</sup>

Patients with possible intentionally self-induced hypoglycemia should generally be admitted. Intentionally self-induced hypoglycemia is most commonly recognized by members of the medical profession. Administration of insulin to a nondiabetic child is a form of child abuse or an attempt at homicide<sup>45</sup> (Chap. 31). Children who have been given an inappropriate dose of insulin, as well as any patient who may be a victim of attempted homicide, should generally be admitted.

A 4- to 6-hour observation period is recommended after metformin overdose. Further observation or hospital admission is usually not required for patients who remain asymptomatic during this period with no evidence of metabolic acidosis, elevated lactate concentration, renal dysfunction, emesis, or hypoglycemia. Patients who overdose on  $\alpha$ -glucosidase inhibitors are not expected to have delayed or serious systemic toxicity, and routine medical admission is unnecessary. There are limited data regarding the risk of hypoglycemia and other adverse events after thiazolidinedione ingestion. Based on the mechanism of action and existing clinical experience, hypoglycemia is possible but uncommon after unintentional thiazolidinedione overdose. Delayed onset of hypoglycemia or other serious clinical manifestations is unlikely. A 4- to 6-hour observation period after thiazolidinedione overdose is recommended. Meglitinides are expected to behave pharmacologically like sulfonylureas. For this reason alone, hospital admission after meglitinide overdose is generally advisable, even when the patient is asymptomatic. A 4- to 6-hour observation period is recommended after overdose of GLP-1 analogs, gliptins, amylin analogs, and SGLT2 inhibitors. Delayed onset of clinical manifestations is unlikely.

Children who unintentionally ingest one or more sulfonylurea tablets should generally be hospitalized for 24 hours. Although this recommendation may be controversial and some authors suggest shorter observation periods<sup>26</sup> or even home monitoring in some cases,<sup>140</sup> we believe that delayed hypoglycemic effects of sulfonylurea ingestion in children are well documented<sup>134,152,160</sup> and convincing enough to support admission in most cases. Asymptomatic children with single-tablet exposures to sulfonylureas

are best managed without prophylactic intravenous dextrose, which could contribute to delayed onset of hypoglycemia.<sup>26</sup> Elevations in glucose concentrations stimulate insulin release by the pancreas. Such patients instead are best managed by early feeding, frequent checks of glucose concentrations, and observation of mental status.

### METABOLIC ACIDOSIS WITH AN ELEVATED LACTATE CONCENTRATION

Throughout this chapter, the term *metabolic acidosis with an elevated lactate concentration* (MALA) is used rather than *metformin-associated lactic acidosis* or *metformin-induced metabolic acidosis*. The biochemical and pathophysiologic processes involving lactate are complex, but a few points are worth summarizing. An elevated lactate concentration occurs in various diseases and can be present in the absence of acidosis. The production of lactic acid does not result in a net increase in hydrogen ion concentration unless there is associated impairment of oxidative metabolism. Impaired oxidative metabolism leads to an increase in hydrogen ion production through the hydrolysis of ATP.<sup>111</sup> In a pig overdose model, metformin caused metabolic acidosis with an elevated lactate concentration, mitochondrial dysfunction, and inhibition of oxygen consumption. Infusion of lactic acid alone did not cause inhibition of oxygen consumption (Fig. 47-3).<sup>133</sup>

The biguanides are uniquely associated with the occurrence of MALA. Phenformin causes lactic acid production by several mechanisms, including interference with cellular aerobic metabolism and subsequent enhanced anaerobic metabolism. Phenformin suppresses hepatic gluconeogenesis

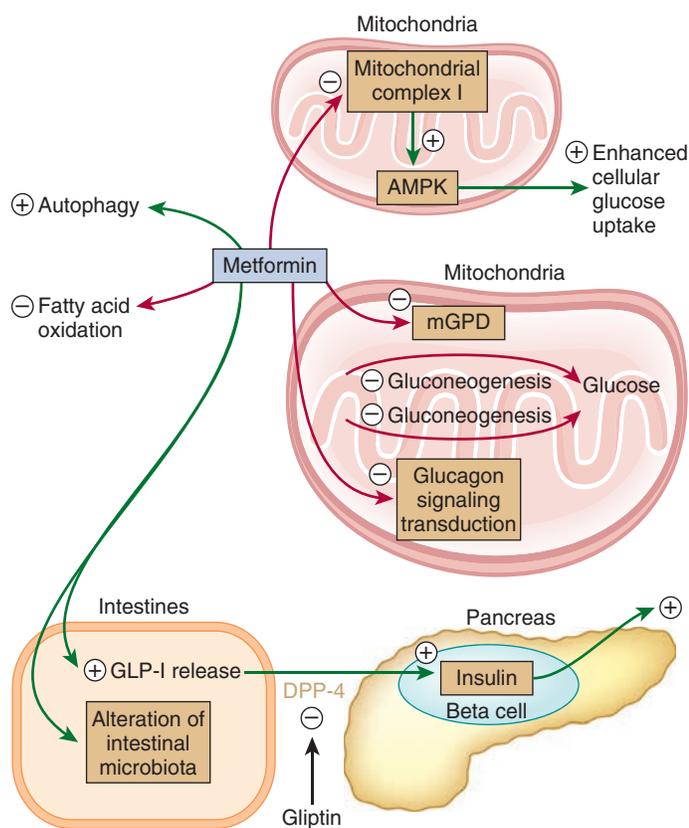

from pyruvate and causes a decrease in hepatocellular pH, resulting in decreased lactate consumption and decreased hepatic lactate uptake. Metformin-associated metabolic acidosis with an elevated lactate concentration occurs 20 times less commonly than that occurring with phenformin. In isolated perfused rat liver, metformin inhibits both hepatic lactate uptake and conversion of lactate to glucose.<sup>135</sup> Metabolic acidosis with an elevated lactate concentration related to metformin usually occurs in the presence of an underlying condition, particularly renal dysfunction.<sup>31</sup> In this setting, increased tissue burden of metformin, which is renally eliminated, probably occurs. Other risk factors include cardiorespiratory insufficiency, septicemia, liver disease, a history of MALA, advanced age, alcohol abuse, and use of radiologic contrast media.<sup>12,31</sup> Iodinated contrast material induces acute renal dysfunction, leading to accumulation of metformin and subsequent risk of development of MALA. However, the risk of developing MALA after contrast administration is low in patients taking metformin who have normal renal function and no other risk factors.<sup>102,115</sup> The American College of Radiology recommends and we concur on the temporary discontinuation of metformin for 48 hours after administration of intravenous contrast media if the eGFR is less than 30 mL/min/1.73 m<sup>2</sup>.

Metabolic acidosis with an elevated lactate concentration occurs after acute metformin overdose<sup>87,106,122,162</sup> but is uncommon. In one case,<sup>106</sup> metabolic acidosis was not diagnosed until 14 hours after metformin overdose. The patient had early symptoms of repeated vomiting at 1 hour postingestion. The presence of early gastrointestinal symptoms prompted prolonged observation, allowing for the diagnosis of delayed-onset metabolic acidosis. Metabolic acidosis with an elevated lactate concentration occurred in 2 of 65 adult metformin exposures reported to a poison control center<sup>154</sup> and was not reported in a poison control center series of 55 pediatric metformin exposures.<sup>155</sup> In a retrospective review of 398 cases of acute metformin exposures from 2 poison control centers, MALA in 9.1% of single product overdose and in 0.7% of polypharmacy overdoses.<sup>172</sup> In a retrospective review, MALA was reported in 11 of 36 metformin overdose cases.<sup>107</sup> Acid-base data are detailed in only a few of these cases described as having severe toxicity; the lowest blood pH was 7.16.

A systematic review from the Cochrane Library concluded that therapeutic use of metformin is not associated with an increased risk of MALA compared with other antidiabetic treatments if no contraindications are present.<sup>142</sup> This erroneous conclusion was based on a review of prospective comparative trials and observational cohort studies. However, the risk of MALA in the setting of overdose or renal dysfunction was not assessed. Although MALA after overdose is not common, it does occur with sufficient frequency to require vigilance on the part of the treating physician. In this setting, metformin is clearly responsible for causing metabolic.<sup>28</sup> Case reports were not used in the Cochrane review, and a few cases of MALA in the setting of therapeutic use with no underlying risk factors are reported.<sup>31,126,166</sup>

It is difficult to predict outcome after metformin overdose. A retrospective literature review found no deaths in cases with a nadir serum pH greater than 6.9, a peak serum lactate concentration less than 25 mmol/L, or a peak serum metformin concentration less than 50 mcg/mL.<sup>42</sup> However, a retrospective review of intensive care unit patients with MALA found no association between metformin concentrations in survivors and nonsurvivors.<sup>146</sup> There was an association between mortality and lactate concentrations and pH.

Metformin-associated MALA is a potentially lethal condition. Recognition and awareness of this disorder are important. Symptoms are nonspecific and include abdominal pain, nausea, vomiting, malaise, myalgia, and dizziness. However, gastrointestinal symptoms are common adverse effects associated with therapeutic use of metformin and do not necessarily require discontinuation of the drug. More severe clinical manifestations of metformin-associated MALA include confusion, blindness, mental status depression, hypothermia, respiratory insufficiency, and hypotension. Serum metformin concentrations can be obtained as a diagnostic aid, but these not necessarily correlate with the clinical condition in both the acute overdose setting and in the setting of therapeutic metformin use.<sup>86,87</sup>

**FIGURE 47-3.** Metformin inhibits mitochondrial complex I, which activates adenosine monophosphate activated protein kinase (AMPK), resulting in enhanced cellular glucose uptake. Metformin also causes inhibition of mitochondrial glycerophosphate dehydrogenase (mGPD), leading to inhibition of gluconeogenesis. Inhibition of glucagon signaling transduction also leads to inhibition of gluconeogenesis. Metformin enhances glucagonlike peptide-1 (GLP-1) release from the intestines, and stimulates GLP-1 receptors on pancreatic beta islet cells, leading to enhanced insulin release. Gliptins enhance the effect of GLP-1 by inhibition of its inactivation by dipeptidyl peptidase-4. Other mechanisms of metformin include induction of autophagy, inhibition of fatty acid oxidation, and favorable alteration of intestinal microbiota.

Aggressive airway management and vasopressor therapy should be given as clinically indicated. Indications for use of intravenous sodium bicarbonate in critically ill patients with metabolic acidosis with an elevated lactate concentration of various etiologies are poorly defined and controversial. Rather than using an arterial pH cutoff, we recommend using sodium bicarbonate given evidence of impaired buffering capacity based on a serum bicarbonate threshold concentration of less than 5 mEq/L.

Metformin would be expected to be dialyzable based on its small size and limited protein binding. However, it has a large volume of distribution. A literature review concluded that metformin is moderately dialyzable, and extracorporeal treatment is recommended if either the blood lactate concentration is greater than 20 mmol/L, or the pH is less than or equal to 7.00, or standard therapies, including sodium bicarbonate, are not effective.<sup>28</sup> Even if metformin removal is inadequate, clinical improvement may occur due to correction of acid–base status.

## SUMMARY

- Numerous xenobiotics and medical conditions may cause hypoglycemia.
- Hypoglycemia is the predominant adverse effect related to therapeutic use and overdose of many of the drugs used for treatment of diabetes mellitus.
- Various clinical manifestations, particularly neuropsychiatric, may occur and can be confused with conditions such as ethanol intoxication, psychosis, epilepsy, and cerebrovascular accidents.
- The potential for delayed and prolonged hypoglycemia must be recognized in overdose situations.
- Although several treatment options exist, rapid intravenous administration of dextrose is the most important measure.
- Octreotide is useful for patients with recurrent hypoglycemia following sulfonylurea or meglitinide overdose, and would be expected to be useful for the treatment of recurrent hypoglycemia following overdose with all other noninsulin antidiabetics.

# DEXTROSE (D-GLUCOSE)

Vincent Nguyen and Larissa I. Velez

Dextrose (D-glucose)

## INTRODUCTION

Hypoglycemia is a common cause of altered mental status. Although classically associated with tachycardia, tremor, and diaphoresis, the predictive value of these manifestations is too low to be relied on.<sup>25</sup> As a result, all patients with altered consciousness require either rapid point-of-care testing of their glucose concentrations or empiric treatment for presumed hypoglycemia. When rapidly diagnosed and treated, hypoglycemic patients typically recover without sequelae. Delayed or incomplete therapy may lead to permanent neurologic dysfunction.

## HISTORY

In 1891, Fisher performed the unbelievable feat of identifying the 16 possible different spatial configurations of aldohexose (C<sub>6</sub>H<sub>12</sub>O<sub>6</sub>), the most prominent member being dextrose or D-glucose.<sup>44</sup> This discovery won him the 1902 Nobel Prize in chemistry. This chapter will use *dextrose* as the term for the antidote and *glucose* as the general term for aldohexose.<sup>10</sup> The diverse manifestations of hypoglycemia, and the treatment of severe cases with intravenous dextrose, have been appreciated for decades.<sup>80</sup>

## Chemistry and Physiology

*Sugar* is the general term used for sweet carbohydrates that are used as food. Simple sugars are called monosaccharides and include glucose (also known as dextrose, as the L-isomer is hardly found in nature), fructose (also known as fruit sugar, the sweetest of them all) and galactose. The disaccharides include maltose, lactose, and sucrose (also known as table or granulated sugar).

Sugars (sucrose) are found in the tissues of most plants but are only present in sufficient concentrations for efficient extraction in sugarcane and sugar beet. Commercially, glucose is produced from the hydrolysis of starch. Several crops are the source of starch, with corn being the most common in the United States.

In humans, carbohydrates are absorbed and transported via 2 main systems. Sodium-dependent glucose transporters (SGLT1 through SGLT6) are responsible for the intestinal and renal glucose absorption.<sup>20</sup> Their discovery was the first description of the mechanism of “flux coupling” or co-transporting, in which transporting one substrate down its concentration gradient (sodium in this case) creates energy that is used to transport a second substrate against a concentration gradient (glucose). The SGLT2 inhibitors (commonly termed “gliflozins”) are a family of drugs used to manage type 2 diabetes mellitus that inhibit SGLT2 in the proximal tubule of the nephron, resulting in glycosuria.<sup>41,99,105,147</sup> Glucose uptake transporters include GLUT1-GLUT14 and HMIT (H<sup>+</sup>/myo-inositol transporter). Facilitative transporters move molecules down their concentration gradient. This facilitative diffusion process does not require energy. Binding of glucose to one of the GLUT receptors causes a conformational change that results in its translocation across the membrane.<sup>64</sup> GLUT4 is expressed in insulin-sensitive tissues and

regulates whole-body glucose homeostasis.<sup>96</sup> Even in low substrate conditions such as in neurons and the placenta, the high affinity for glucose by GLUT3 facilitates transport.<sup>12</sup> The absorption of fructose in the small intestine is dependent on GLUT5.<sup>16</sup> The GLUT5 transporter has wide variability and is dependent on the amount of glucose ingested relative to the fructose. Decreased fructose absorption leads to abdominal bloating and osmotic diarrhea in susceptible individuals.<sup>65</sup>

Glucose delivered hematogenously to the liver, adipose tissue, and muscle cells is absorbed and stored as glycogen—under the influence of insulin—or used by all cells to produce adenosine triphosphate (ATP) and pyruvate via glycolysis. Hepatic glycogen can later be converted to glucose and returned to the blood when insulin is low or absent. In contrast, glycogen found in muscle and adipose cells is used internally and not released into the systemic circulation. Some glucose is converted to lactate by astrocytes, and then utilized as an energy source.<sup>115,128,138</sup> Finally, glucose is also directly used by intestinal cells and red blood cells.

## Pharmacokinetics

Accurate prediction of the amount of dextrose required to effectively treat patients with hypoglycemia is complex. At equilibrium, 25 g of dextrose distributed in total body water in a 70-kg adult is calculated to increase the serum glucose concentration by about 60 mg/dL.<sup>63</sup> In the few clinical studies performed, the magnitude of glucose elevation after oral or IV dextrose loading was unpredictable. In one study, 25 g (50 mL) of D<sub>50</sub>W administered to both diabetic and nondiabetic adults resulted in a mean blood glucose elevation of 166 mg/dL when measured in the opposite extremity 3 to 5 minutes after the bolus; however, the range of this elevation was between 37 and 370 mg/dL above baseline.<sup>2</sup> In a human model of insulin-induced hypoglycemia, oral administration of 10 or 20 g of dextrose increased the serum glucose concentration from 60 to 120 mg/dL over one hour.<sup>148</sup> Another study used 25 nondiabetic volunteers and administered 25 g of IV dextrose as D<sub>50</sub>W. Glucose concentrations were then measured at 5, 15, 30, and 60 minutes. Volume of distribution formulas could not accurately predict postinfusion glucose concentrations. The serum glucose elevation was statistically significant from baseline at 5 and 15 minutes, with glucose concentrations returning to baseline at 30 minutes postinfusion.<sup>9</sup>

Two prehospital studies also evaluated the magnitude of glucose elevation in hypoglycemic patients after a 10-g dextrose bolus (100 mL of D<sub>10</sub>W). Pretreatment mean serum glucose concentrations were 37 and 38 mg/dL, respectively. After the bolus, the median glucose concentrations were 91 and 98 mg/dL, respectively. Therefore, the median rise in serum glucose concentration was between 54 and 60 mg/dL.<sup>60,71</sup> In these studies, the time to measurement of serum glucose concentration after the bolus was not uniform, but the median time to testing was 8 minutes.

## Pharmacodynamics

Adenosine triphosphate provides the metabolic energy that fuels all critical cellular processes in all organs. In the adult brain, the anaerobic and aerobic metabolism of glucose occurring through glycolysis and the citric acid cycle, respectively, are the primary sources of ATP (Chap. 11). Although the adult brain can use fatty acids, amino acids, lactate, and ketones as alternate substrates for ATP synthesis, these are not adequate to sustain normal cerebral

function in the setting of glucose deprivation. In contrast, in fetal and neonatal brains, glucose is the only substrate for ATP production.<sup>109,139</sup>

Although a blood or serum glucose less than 60 mg/dL defines hypoglycemia, clinical hypoglycemia cannot be entirely predicted by strict numerical values. Rather, it is best defined by organ dysfunction in the setting of inadequate glucose concentrations. The onset of numerical hypoglycemia in both adults and children is often followed rapidly by global cerebral dysfunction, owing to neuroglycopenia. In individuals with diabetes, the density and sensitivity of neuronal insulin receptors vary as a function of glycemic control, such that diabetic patients with poor glycemic control have fewer and less sensitive neuronal insulin receptors and experience hypoglycemic symptoms at much higher blood concentrations of glucose than those who are normally euglycemic. An important study of diabetic patients demonstrated that the mean blood glucose concentration for symptomatic hypoglycemia in poorly controlled diabetic patients was  $78 \pm 5$  mg/dL compared with  $53 \pm 5$  mg/dL in well-controlled patients.<sup>13</sup> This differential response to hypoglycemia is also described at higher glucose concentrations in poorly controlled versus intensely controlled diabetic patients.<sup>67</sup> Thus, in a subset of diabetics neuroglycopenia occurs despite “normal” peripheral blood glucose concentrations.<sup>143</sup> Additionally, a report described 2 patients with salicylate toxicity who presented with altered mentation that resolved after treatment with D<sub>50</sub>W, despite normal serum glucose concentrations. The etiology was attributed to salicylate-induced neuroglycopenia.<sup>76</sup> The occurrence of low brain glucose concentrations despite normal serum glucose concentration is described in a rat model of salicylate toxicity.<sup>132</sup> In rare cases, glucose-consuming cancer cells can produce large amounts of lactate (Warburg effect), which is available as an alternate source of energy for the brain. Even in the presence of profound hypoglycemia, these patients remain asymptomatic.<sup>38</sup>

On the other hand, while *chronic hyperglycemia* causes the glycemic threshold at which counterregulatory response occurs to be reset to a higher glucose concentration, *repeated hypoglycemia* causes the glycemic threshold at which counterregulatory response occurs to be reset to a lower glucose concentration. Diabetic patients with repeated episodes of hypoglycemia—usually those subjected to tight control—will have neuroglycopenia *before* the appearance of autonomic warning signs such as sweating, palpitations, and anxiety. This condition, known as hypoglycemia-associated autonomic failure, often termed “hypoglycemia unawareness,” results in prolonged exposure to low serum glucose concentrations.<sup>24,69,102,111,129</sup> The etiology of hypoglycemia unawareness is not completely understood. There is strong evidence from animal studies that the activity of neurons in the ventromedial hypothalamus (VMH) plays a critical role in initiating compensatory responses to hypoglycemia. The VMH is a key component of a complex glucose-sensing network.<sup>89</sup> Recurrent hypoglycemia lowers the glucose concentration at which these neurons are activated, giving the patients less time to react to hypoglycemia.<sup>90</sup> Risk factors include chronic exposure to low glucose concentrations, antecedent hypoglycemia, recurrent severe hypoglycemia, duration of diabetes, and the failure of counterregulatory hormones.<sup>22,23,29</sup>

Hypoglycemia causes a myriad of neuropsychiatric sequelae that are clinically indistinguishable from those of other toxic-metabolic, infectious, and structural brain injuries.<sup>33,87,94,118,142,150</sup> In a case series, presenting signs and symptoms of hypoglycemia included dizziness and tremulousness (8%); focal stroke syndromes (2%); movement disorders or seizures (7%); irritability, confusion, or bizarre behavior (30%); delirium, stupor, or coma (52%); and irreversible encephalopathy.<sup>87</sup> These incidences are similar to those in a case series of patients with insulinomas.<sup>28</sup> In cases of undifferentiated coma, both the absence of pupillary light reflex (sensitivity 83% and specificity 77%, positive predictive value {PPV} 70% and negative predictive value {NPV} 87%, likelihood ratio {LR} 3.56) and the presence of anisocoria (sensitivity 39% and specificity 96%, PPV 86 and NPV 70, LR 9) are helpful in diagnosing structural (intracerebral hemorrhage, subarachnoid hemorrhage, subdural hematoma, cerebral infarction, epidural hematoma) instead of metabolic causes (drug overdose, hypoglycemia, sepsis).<sup>133</sup> Hypoglycemic hemiplegia is a well-recognized, although rare, entity, and therein

lies the relevance of a serum glucose concentrations in patients with focal neurologic symptoms.<sup>87</sup>

The heart is partially dependent on glucose as an energy substrate. Hypoglycemia causes myocardial stress that manifests as angina and/or dysrhythmias. There are 2 mechanisms postulated for hypoglycemia-induced dysrhythmias. First, it causes potassium current inhibition, which results in QT interval prolongation.<sup>98</sup> This is aggravated by the systemic catecholamine response to hypoglycemia, which results in increased intracellular calcium, another dysrhythmogenic stimulus.<sup>35,79,93,97,98,101</sup> Nocturnal hypoglycemia is associated with the “dead in bed” syndrome. The postulated mechanisms are hypotonia of the respiratory muscles with an impaired awakening, mediated by orexin-A neurons, and QT interval prolongation and other dysrhythmogenic effects of hypoglycemia.<sup>48,103</sup> Orexins (hypocretins) are novel neuropeptides that play a role in the regulation of energy balances. They are highly excitatory neuropeptides that affect an organism’s wakefulness. Repeated episodes of hypoglycemia result in adaptations in orexin-A, causing defective awakening and hypotonia of the upper airway muscles during sleep.<sup>103</sup> Finally, counterregulatory hormone responses to hypoglycemia are also impaired by sleep.<sup>31,68</sup>

## ROLE IN HYPOGLYCEMIA

### Empiric Treatment Considerations

The history and physical examination, although always important to ascertain, do not reliably detect hypoglycemic patients.<sup>62</sup> Tachycardia, diaphoresis, pallor, hypertension, tremors, hunger, and restlessness tend to predominate when the decline in blood glucose concentration is rapid. However, neuroglycopenia, even when severe, will not always trigger autonomic responses.<sup>28</sup> Signs and symptoms are further blunted or absent in the setting of concurrent use of  $\beta$ -adrenergic antagonists. Similarly, GABA agonists blunt autonomic nervous system, neuroendocrine, and metabolic counterregulatory responses to hypoglycemia, an effect that reportedly persists for days.<sup>59</sup> Central nervous system signs of neuroglycopenia are also nonspecific. They include visual disturbances, psychiatric disturbances, confusion, stupor, coma, seizures, and focal neurologic findings.<sup>87,119</sup> In children, sometimes the only sign of neuroglycopenia is lethargy or irritability.<sup>153</sup>

The bedside diagnosis of hypoglycemia is limited by the sensitivity and specificity of reagent strips, which do not have the reliability and accuracy of laboratory analysis.<sup>104</sup> Sensitivities of commonly available reagent strips for detection of hypoglycemia range between 92% and 97%.<sup>18,19,66,78,86,117</sup> The accuracy of these point-of-care testing methods is affected by the source of blood, whether arterial, venous, or capillary, and by the poor perfusion associated with shock and cardiac arrest.<sup>8,21,34,47,70,75,77,85,130</sup> A critical care unit study that evaluated patients in shock showed that 32% were incorrectly diagnosed as hypoglycemic when capillary blood was used. All these patients were either normoglycemic or hyperglycemic. Results of reagent strip tests of venous blood correlated well with laboratory results, correctly classifying all patients. No cases of hypoglycemia were missed.<sup>8</sup> Therefore, capillary determinations of glucose should be used with caution in the critically ill population, recognizing that false-positive detection of hypoglycemia might occur.<sup>85</sup> When feasible, laboratory measurements are preferred in these patient populations. A second best alternative is reagent strip testing using venous blood rather than capillary blood samples.

Several studies compared the accuracy of reagent strips for the detection of hypoglycemia from capillary and venous blood compared with the gold standard of the laboratory. Two studies, one with 97 subjects<sup>47</sup> and one with 270 subjects,<sup>75</sup> evaluated the agreement between reagent strip determinations of capillary and venous blood glucose concentrations in healthy euglycemic volunteers. In the larger study, 18% of subjects had a >15 mg/dL difference between capillary and venous reagent strip tests. In this study, capillary measurements were better correlated with the laboratory values. Whether these results have any clinical significance is not clear because none of the subjects were outside the euglycemic range. However, the results suggest that the capillary blood glucose test has greater accuracy in the euglycemic range and in healthy individuals.

The “safe” number at which no cases of symptomatic hypoglycemia are missed by reagent strip testing is a subject of debate because of the inherent risk of error from lack of sensitivity. In one study in which hypoglycemia was defined as a blood glucose concentration below 60 mg/dL, 2 of 33 hypoglycemic patients were not detected at the bedside. A cutoff of 90 mg/dL would have detected 100% of numerically hypoglycemic patients.<sup>78</sup> Based on these studies, it can be argued that a bedside reagent measurement of 90 mg/dL is a conservative cutoff for assurance of euglycemia in all patients.

With reagent strip testing, variations in hematocrit and the presence of isopropyl alcohol in the sample also alter the accuracy of the test.<sup>11,52</sup> In some specific tests, such as one using glucose dehydrogenase pyrroloquinolinequinone (GDH-PQQ), accuracy is affected by a number of interfering substances and xenobiotics, such as serum acetaminophen concentrations above 8 mg/dL, a serum bilirubin concentration above 20 mg/dL, a serum galactose concentration above 10 mg/dL, a maltose concentration above 16 mg/dL, a serum uric acid above 10 to 16 mg/dL, serum triglycerides above 5,000 mg/dL, and the presence of D-xylose in the sample. All of these result in falsely elevated glucose measurements.<sup>37</sup> There are also *in vitro* reports of interference with the use of intravenous lipid emulsion therapy as an antidote.<sup>53</sup> Notably, icodextrin, an ingredient in peritoneal dialysis, results in overestimation of glucose measurements because it is metabolized to maltose. In several case reports and at least 18 cases reported in a review, this resulted in excess insulin administration and subsequent hypoglycemia.<sup>37,45,74,112</sup> Glucose-monitoring systems that use the GDH-PQQ method should not be used in patients using icodextrin in the PD fluid.<sup>134</sup> Maltose is also contained in some immunoglobulin solutions, and the same interference is expected.<sup>39,126</sup> Glucose measurements by the GDH-PQQ and the amperometric methods are also affected by the hematocrit.<sup>125,144</sup> Whereas hematocrits lower than 20% result in a falsely elevated glucose measurements, hematocrits above 55% result in falsely low measured glucose concentrations.<sup>37</sup> In a retrospective review of patients admitted to a hospital over a 12-month period, 1.2% were identified as having interfering substances. Of these, 36% patients had active orders for insulin products. The most common interferences identified were a low hematocrit (44% of patients) and a high serum uric acid (29% of patients).<sup>37</sup>

One final consideration is in patients with salicylate toxicity (Chap. 37), in which serum glucose is not an accurate reflection of brain glucose concentrations.<sup>131,132</sup> Salicylate poisoning is a relatively uncommon cause for drug-induced hypoglycemia.<sup>107,123</sup> Salicylates uncouple oxidative phosphorylation, which results in increased intracellular glucose demands. Rarely, patients demonstrate symptoms of neuroglycopenia despite normal serum glucose concentrations. Dextrose administration reverses the signs and symptoms and likely improves survival.<sup>76,131</sup>

Recent advances in monitoring technology include continuous glucose monitoring, which uses a sensor placed under the skin that measures interstitial fluid glucose.<sup>110</sup> These sensors are generally accurate at normal glucose concentrations. However, in situations where the glucose is fluctuating, the interstitial glucose concentration lags for up to 15 minutes. Patients are encouraged to measure a capillary blood glucose before making treatment decisions.<sup>149</sup> Currently, there are no FDA-approved noninvasive glucose-measuring devices in the United States.<sup>124</sup> **Table 47–1** summarizes xenobiotics and nontoxicologic conditions that are associated with hypoglycemia.

## ROLE IN ETHANOL DISORDERS

Alcoholic ketoacidosis (AKA) is a metabolic emergency (Chap. 76). It occurs when malnourished chronic alcoholic patients cease or significantly decrease their food intake. This is often accompanied by vomiting. The result is salt and water depletion with an anion gap metabolic acidosis that is typically accompanied by a normal to low serum glucose (unlike diabetic ketoacidosis).<sup>5</sup> In children, hypoglycemia occasionally ensues after exposure to ethanol and other ethanol-containing products.<sup>40,108</sup> Newborns and young infants, present with irritability, feeding problems, lethargy, cyanosis, tachypnea, and/or hypothermia.<sup>58</sup>

The management of AKA consists of rehydration using isotonic, dextrose-containing solutions; parenteral thiamine administration; potassium replacement; and addressing the underlying medical problem that led to AKA (Chap. 76).<sup>46</sup>

## ROLE IN SALICYLATE POISONING

Patients with salicylate toxicity demonstrate symptoms of neuroglycopenia despite normal serum glucose concentrations. Dextrose administration reverses these signs and symptoms of neuroglycopenia.<sup>76</sup> Chapter 37 provides an in-depth discussion of salicylate toxicity and its management.

## ROLE IN CARDIOVASCULAR TOXICITY

High-dose insulin (HDI) is one of the cornerstones of management of patients with drug-induced cardiovascular toxicity. Insulin improves carbohydrate utilization by the cells and restores calcium fluxes. This improves cardiac contractility and allows for improved vascular tone.<sup>92</sup> The available data are strongest for calcium channel blocker toxicity, and there are also reports that describe benefits in cases of  $\beta$ -adrenergic antagonist toxicity.<sup>81,154</sup> The initial bolus of 1 unit/kg and subsequent infusion of 1 unit/kg/h of regular insulin must be supplemented with sufficient dextrose to maintain euglycemia. The use of continuous dextrose infusions with HDI is reviewed in Antidotes in Depth: A21.

Aluminum phosphide is a fumigant for grains that releases phosphine gas, which causes injury due to free radical formation. Deaths occur from both pulmonary (acute respiratory distress syndrome) and cardiac toxicity.<sup>56</sup> The management remains supportive, but in one report the use of HDI improved mortality (72.7% in conventional treatment vs 50% in the HIE group,  $P = .03$ ).<sup>57</sup>

## ROLE IN HYPERKALEMIA

Hyperkalemia occurs most commonly as a result of end-stage kidney disease. It also represents an adverse medication reaction. Intravenous insulin is used to redistribute potassium inside the cell. A dose of 0.1 Units/kg of regular insulin is usually followed by 25 g of IV 50% dextrose.<sup>82,146</sup> The onset of action for this intervention is less than 15 minutes and peaks at 30 to 60 minutes. This regimen results in an average serum potassium decrease of about 0.6 mEq/L.<sup>146</sup>

## ADVERSE EFFECTS AND SAFETY ISSUES

The most serious complication associated with hypoglycemia is directly attributable to the failure to diagnose and treat it. Most complications due to the administration of concentrated IV dextrose are either clinically insignificant or exceedingly rare. Phlebitis and sclerosis of veins occurs. Tissue necrosis is reported after soft tissue extravasation of D<sub>50</sub>W and after inadvertent intraarterial injection.<sup>7,30</sup> Inappropriately large boluses of D<sub>50</sub>W in children are associated with seizures, brain hemorrhage, and hyperosmolar coma.<sup>120</sup> Anaphylactoid reactions are rarely reported after the administration of D<sub>50</sub>W.<sup>27</sup> Iatrogenic exacerbation of Wernicke's encephalopathy with acute glucose or carbohydrate loading in the absence of adequate thiamine replacement was a once popular myth stemming from a single article reporting a handful of patients have had unrecognized Wernicke's encephalopathy before prolonged periods of glucose administration.<sup>140,145</sup> A single acute administration of dextrose does not appear to cause this effect.<sup>54</sup> Therefore, correction of hypoglycemia should never be delayed in order to administer thiamine (Antidotes in Depth: A27).<sup>114</sup>

Dilute dextrose solution should not be simultaneously infused through the same intravenous line as blood as it causes pseudoagglutination of erythrocytes. These solutions can also result in electrolyte dilution and excess intravascular volume.

An important consideration is the development of rebound hypoglycemia when dextrose is used typically to treat sulfonyleurea-induced hypoglycemia, although this also occurs in other patients who received concentrated dextrose solutions as a bolus (Chap. 47). As mentioned above, serial measurements of glucose and close patient monitoring should follow any dextrose

boluses.<sup>91</sup> Patients should also receive oral carbohydrates as soon as clinically safe and feasible.

Patients with prolonged or severe hypoglycemia frequently remain in a persistent state of altered consciousness despite normalization of blood glucose concentrations—a condition loosely defined as posthypoglycemic encephalopathy or hypoglycemic encephalopathy. The pathophysiology of hypoglycemic encephalopathy is poorly understood.<sup>127</sup> In large part because there is no generally accepted clinical definition, the clinical course, magnetic resonance imaging (MRI) findings, and overall outcomes are highly variable. Magnetic resonance imaging studies reported a broad spectrum of possible lesion patterns involving both gray and white brain matter.<sup>6,72,83,88,95</sup> Mortality rates of patients with posthypoglycemic encephalopathy reportedly range from 23.7% to 46%; however, survivors frequently recover with little or no disability.<sup>151</sup>

### Concerns Regarding Elevated Blood Glucose Concentrations in Patients With Critical Illness

Hyperglycemia (and insulin resistance) is a common phenomenon after acute critical illness.<sup>135</sup> The evidence suggesting an association between high glucose concentrations on admission, persistent hyperglycemia, and high glucose variability and worse clinical outcomes is substantial.<sup>4,32,61,73,84,100,106,121,152</sup>

Although it is evident that hyperglycemia in critically ill patients is undesirable, the optimal blood glucose range is controversial. Initial trials suggested that intensive glucose control could reduce morbidity and mortality.<sup>136,137</sup> Subsequent trials did not confirm these findings, showing instead that targeting a blood glucose of 80 to 110 mg/dL increases the incidence of hypoglycemia,<sup>42,43</sup> which is independently associated with increased mortality.<sup>113</sup> The current literature supports moderate, early glucose control in most critical illnesses (goal glucose of 180 mg/dL) while avoiding hypoglycemia.<sup>1,3,14,122,141</sup>

### PREGNANCY AND LACTATION

Dextrose is a pregnancy category C (IV) and A (oral), as studies do not exist regarding its safety to the fetus. Hypoglycemia is a serious concern for fetal and neonatal well-being, and the best evidence suggests that hypoglycemia in a pregnant woman should be approached in the same manner as in a non-pregnant patient.<sup>55</sup> Although there are no data regarding the use of hypertonic dextrose in lactation, it is unlikely to be a concern, because even if the concentration of glucose in subsequent breast milk is significantly increased, the effect will be transient.

### Dosing and Administration

Patients with asymptomatic or minimally symptomatic hypoglycemia should be treated with oral carbohydrates (juice, milk, candy, or glucose tablets). For adults, we recommend a dose of 20 g which should result in symptomatic improvement in 15 to 20 minutes.<sup>26</sup> Because this improvement is transient and can result in reactive hypoglycemia, we also recommend that the initial glucose intake be followed by a more substantial meal whenever feasible. For the patient unable (coma, seizures) or unwilling (from neuroglycopenia) to receive oral glucose, the IV route must be used. In an adult, a bolus dose of 0.5 to 1.0 g/kg of IV dextrose is recommended. Similarly, the improvement in serum glucose concentration is transient, and the patient should be monitored closely for recurrence of hypoglycemia.<sup>26</sup> In common practice, a dextrose infusion follows the initial dextrose bolus, with the recognition that this supplies very little caloric content and is insufficient in most cases where glucose is being rapidly redistributed and utilized.<sup>26</sup>

Rapid increases in serum glucose are sufficient to stimulate insulin release from the pancreas and result in reactive (or rebound) hypoglycemia. Therefore, glucose concentrations must be closely followed after a bolus of concentrated dextrose solutions. This effect is exaggerated in patients, particularly those with normally functioning pancreatic islet cells, who have ingested sulfonylureas, which increase the glucose-responsive release of insulin by the islet cells.<sup>49,50</sup>

**TABLE A8-1** Dosing of Dextrose for Symptomatic Hypoglycemia

Age	Concentration	Bolus	Dose in mL/kg
Adult	D <sub>50</sub> W (50% = 0.5 g/mL)	0.5–1.0 g/kg	1–2
Child	D <sub>25</sub> W (25% = 0.25 g/mL)	0.5–1.0 g/kg	2–4
Infant	D <sub>10</sub> W (10% = 0.1 g/mL)	0.5–1.0 g/kg	5–10

In most cases, the rapid correction of hypoglycemia by the administration of 0.5 to 1.0 g/kg of concentrated IV dextrose (Table A8-1) immediately reverses the neurologic and cardiac effects caused by hypoglycemia. However, prolonged or severe hypoglycemia can result in permanent brain injury, myocardial infarction, and death.<sup>17,36,95</sup> Because of the myriad presentations of hypoglycemia, the difficulties inherent in making the clinical diagnosis, and the serious consequences of failure to treat the condition, the empirical administration of hypertonic dextrose to all patients with altered mental status was once a standard prehospital and emergency department practice.<sup>15,62,63</sup>

### Formulation and Acquisition

Dextrose is available in multiple formulations between 2.5% and 70% for intravenous use. Concentrations greater than 10% should be infused via a central venous catheter, except in emergencies. Table A8-1 summarizes the most commonly available preparations.

### SUMMARY

- Dextrose is an effective antidote for patients with hypoglycemia, an essential substrate for those with alcoholic ketoacidosis and an adjunct to maintain euglycemia during high-dose insulin therapy for cardiovascular drug toxicity.
- Hypoglycemia mimics many syndromes, producing diverse alterations in consciousness, including focal neurologic syndromes.
- The currently available reagent strips reliably demonstrate the absence of significant hypoglycemia at reading concentrations greater than 90 mg/dL. Profound neurologic impairment likely is not the result of hypoglycemia with such concentrations, even in diabetic patients.
- In patients with shock or cardiac arrest, testing venous blood is preferred over capillary blood.
- Dextrose should be administered to all patients with altered levels of consciousness and a serum glucose concentration <90 mg/dL by rapid testing methodology.
- Dextrose should be empirically administered to patients with altered levels of consciousness in the rare cases where bedside reagent strips are not readily available.

## OCTREOTIDE

Silas W. Smith and Mary Ann Howland

## INTRODUCTION

Octreotide is a long-acting, synthetic octapeptide analog of somatostatin, a hormone that inhibits the release of numerous anterior pituitary and gastrointestinal hormones, including pancreatic insulin. It is the essential complement to dextrose (Antidotes in Depth: A8) for the treatment of refractory hypoglycemia induced by overdoses of inhibitors of insulin secretagogues such as sulfonylureas (and rarely the meglitinides) and quinine (and rarely other quinolones).

## HISTORY

Somatostatin is a collective term for shorter fragments (SRIF-28, SRIF-25, and SRIF-14) cleaved from preprosomatostatin (116 amino acids) and prosomatostatin (92 amino acids).<sup>17</sup> In 1973 during the search for growth hormone-releasing factor, somatostatin was identified as a growth hormone inhibitor.<sup>15</sup> Somatostatin has far-reaching effects as a central nervous system (CNS) neurotransmitter and as a modulator of hormonal release.<sup>64,75</sup> The importance of somatostatin on insulin secretion led to the need to create an analog as a therapeutic tool, as somatostatin use is limited by its short duration of action. Octreotide was synthesized in 1982 in an effort to develop a longer-acting somatostatin analog.<sup>7</sup> Octreotide is currently approved by the FDA for the treatment of acromegaly, carcinoid tumors, and vasoactive intestinal peptide tumors. It is also used therapeutically for the treatment of pituitary adenomas, pancreatic islet cell tumors, portal hypertension, esophageal varices, and secretory diarrhea.<sup>64</sup>

## PHARMACOLOGY

## Mechanism of Action on Insulin Secretion

The effects of somatostatin are mediated by high-affinity binding to membrane receptors on target tissues. The six different known somatostatin receptor subtypes belong to a superfamily of G-protein coupled receptors and are identified and assigned numbers (SSTR1–SSTR5) according to their order of discovery, with SSTR2 having 2 splice variants (SSTR2A and SSTR2B).<sup>17,23,76,88</sup> By sequence homology, SSTR2, SSTR3, and SSTR5 belong to one group, which bind the classic somatostatin receptor ligands (SRLs), whereas SSTR1 and SSTR4 do not.<sup>76</sup> Somatostatin receptor type 2 (SSTR2) is

found in the brain, pituitary, stomach, liver, kidney, lung, intestine, spleen, thymus, uterus, prostate, and adrenal gland; SSTR5 is found in brain, pituitary, stomach, intestine, thyroid, and adrenal gland.<sup>64,72,84,108</sup> These varied SSTR targets underlie the use of SRLs in acromegaly; carcinoid, vasoactive intestinal peptide, and neuroendocrine tumors; portal hypertension; esophageal varices; and secretory diarrhea.<sup>64</sup> The pancreas contains all 5 subtypes, but SSTR5 is more prevalent in the  $\beta$ -cells and SSTR2 is more prevalent in the  $\alpha$ -cells in mice.<sup>108</sup> In humans, SSTR2 is the functionally dominant somatostatin receptor in pancreatic  $\beta$ - and  $\alpha$ -cells.<sup>55,72</sup>

Experiments in both healthy human volunteers and an isolated perfused canine pancreas model demonstrate the ability of somatostatin to inhibit glucose-stimulated insulin release.<sup>2,36</sup> In pancreatic  $\beta$ -cells that hypersecrete insulin through targeted mutagenesis of the sulfonylurea receptor, octreotide suppresses C-peptide, and insulin release.<sup>46</sup> Somatostatin inhibits insulin secretion by a G-protein-mediated decrease in calcium entry through voltage-dependent  $\text{Ca}^{2+}$  channels.<sup>51</sup> This is distinct from the site of action of sulfonylureas and diazoxide, which respectively open and close the ATP-sensitive  $\text{K}^+$  ( $\text{K}_{\text{ATP}}$ ) channel (Fig. 47-2).<sup>31,66,79,97</sup> Somatostatin, like epinephrine, stimulates a pertussis toxin-sensitive,  $\text{G}_i$ -coupled receptor that inhibits adenylyl cyclase and production of cyclic adenosine monophosphate (cAMP) to decrease intracellular calcium and thereby reduce insulin secretion.<sup>47</sup> Simultaneous distal reduction in phosphorylation of specific proteins also reduces insulin secretion.<sup>31,47,62</sup> This latter mechanism is independent of  $\text{Ca}^{2+}$ .<sup>31,47</sup> In human pancreatic  $\beta$ - and  $\alpha$ -cells, somatostatin agonism via SSTR2 hyperpolarizes human  $\beta$ -cells and decreases depolarization-evoked exocytosis in both  $\alpha$ - and  $\beta$ -cells via several mechanisms.<sup>55</sup> There is an increased activation of  $\text{K}^+$  channels such as the G-protein gated inward rectifying potassium (GIRK, Kir3.x) channel and others.<sup>14,55</sup> This effect is independent of the  $\text{K}_{\text{ATP}}$  channel, and thus it remains effective when the  $\text{K}_{\text{ATP}}$  channel is antagonized by a sulfonylurea. Somatostatin also appears to inhibit a depolarization leak current (mediated by an as yet unidentified channel). Furthermore, somatostatin reduces voltage-gated P/Q-type  $\text{Ca}^{2+}$  currents<sup>55</sup> and directly inhibits  $\text{Ca}^{2+}$  dependent insulin (and glucagon) exocytosis.<sup>44,55</sup> Thus, in  $\alpha$ -cells, somatostatin SSTR2 stimulation leads to inhibition of glucagon secretion.<sup>77</sup> One additional mechanism involves  $\beta$ -cell activation of SSTR to decrease insulin gene promoter and/or transcription factor activity and thus reduce insulin biosynthesis.<sup>31,113</sup> The relative importance of all somatostatin mechanisms under various physiological conditions, somatostatin concentrations, and xenobiotics remains to be fully elucidated.

Octreotide, lanreotide, and vapreotide are somatostatin receptor ligands (SRLs) with high binding affinity for subtype SSTR2, a lower affinity for SSTR5 and SSTR3, and almost no affinity for SSTR1 and SSTR4.<sup>64</sup> Pasireotide is second-generation SRL characterized by significantly higher binding to SSTR5 (40 times), SSTR1 (30 times), and SSTR3 (5 times) and lower binding to SSTR2 (2.5 times less) compared to octreotide.<sup>24</sup> Octreotide and SRLs thus inhibit growth hormone, glucagon, and insulin release. Octreotide also suppresses the response of luteinizing hormone to gonadotropin-releasing hormone; decreases splanchnic blood flow; and inhibits the release of thyroid-stimulating hormone and the gastrointestinal signal transmitters serotonin, gastrin, vasoactive intestinal peptide, secretin, motilin, and pancreatic polypeptide.<sup>66,75</sup> The antiproliferative effects of octreotide in neuroendocrine tumors are mediated by SSTR regulation of the PI3K/Akt (MAP kinase) pathway and indirectly by inhibition of mitogenic growth factors

and tumor angiogenesis.<sup>101,104</sup> Studies comparing octreotide to somatostatin in rats and monkeys demonstrate that octreotide is 1.3 times as potent as somatostatin in inhibiting insulin secretion. Likewise, compared with somatostatin, octreotide was 45 times more potent in inhibiting growth hormone secretion and 11 times more potent in inhibiting glucagon release.<sup>7</sup> Pasireotide was more efficacious than octreotide in preventing hypoglycemia in glyburide-treated rats.<sup>93</sup> Octreotide had no effect on the responses of adrenocorticotropic, cortisol, prolactin, luteinizing hormone, and follicle-stimulating hormone to insulin-induced hypoglycemia.<sup>66</sup> In contrast, growth hormone and thyroid hormone are significantly inhibited.<sup>27,66,105</sup>

Clinically, the ability of somatostatin to inhibit glucose- and glucagon-mediated insulin response was confirmed in a study of human volunteers.<sup>36</sup> Intravenous (IV) infusion of 1 g of tolbutamide over 2 minutes caused insulin concentrations to rise and serum glucose concentration to drop sharply. In the presence of somatostatin and tolbutamide, administration of IV glucagon caused a rise in glucose concentration without the expected subsequent glucose-stimulated rise in insulin. The effects of somatostatin were short-lived. Within 5 minutes of stopping the somatostatin, the insulin-releasing effects of tolbutamide continued, and within 15 minutes the serum glucose concentration fell. Peak insulin concentrations were achieved within 25 minutes. In another human volunteer study, somatostatin provided as a continuous infusion suppressed insulin secretion induced by glucagonlike peptide-1 (GLP-1) infusion.<sup>94</sup> Indeed, the efficacy of somatostatin (and later octreotide) in suppressing insulin secretion led to its utilization in the clinical insulin suppression test (IST) and in multiple pancreatic glycemic clamping technique experiments (with various glucose, insulin, and glucagon concentrations) in order to probe human physiology.<sup>29,53,60,109</sup> When measured in patients with sulfonylurea intentional overdose, octreotide also suppressed insulin concentrations.<sup>41</sup>

### Related Xenobiotics

Lanreotide, vapreotide, and pasireotide are long-acting, FDA-approved SRLs.<sup>24</sup> Use of these pharmaceuticals in insulin secretagogue-induced hypoglycemia is unstudied in humans at this time and therefore cannot be recommended.

### Pharmacokinetics

The pharmacokinetics of IV and subcutaneous (SC) octreotide were studied in 8 healthy adult volunteers.<sup>61</sup> Subjects received 25, 50, 100, and 200 mcg IV octreotide over 3 minutes and 50, 100, 200, and 400 mcg SC octreotide in random order. Following IV administration, the distribution half-life averaged 12 minutes, and the elimination half-life ranged from 72 ± 22 minutes to 98 ± 37 minutes. The apparent volume of distribution ( $V_d$ ) of the central compartment was dose dependent and increased from approximately 5.7 L at 25, 50, and 100 mcg IV to 10 L at 200 mcg IV doses.<sup>61</sup> The  $V_d$  determined by area under the curve (AUC) ranged from 18 ± 6 L to 30 ± 30 L and showed no dose dependency.<sup>61</sup> Approximately 30% of elimination was renal, and this was reduced in the elderly and in those with chronic kidney disease.<sup>75</sup> After SC administration, bioavailability was 100%, and peak concentrations were achieved within 30 minutes with an absorption half-life of 5 to 12 minutes. The elimination half-life was 88 to 102 minutes. Peak serum concentrations after SC administration ranged from 2.4 ng/mL at doses of 50 mcg to 23.5 ng/mL at doses of 400 mcg. After IV administration, peak serum concentrations ranged from 9.6 ng/mL at doses of 50 mcg to 27.8 ng/mL at doses of 200 mcg.<sup>61</sup> To place these values in perspective, octreotide acetate binds SSTR2 with an affinity of approximately 1 ng/mL, but requires concentrations of 10 ng/mL to completely saturate the receptor.<sup>112</sup>

The pharmacokinetics in patients with pathologic conditions differ from the pharmacokinetics in healthy volunteers; patients with acromegaly achieve lower peak concentrations and a higher steady-state  $V_d$ .<sup>75</sup> In volunteer studies, octreotide pharmacokinetics differ in patients with kidney and liver disease, with increases in the area under the curve and decreased clearance.<sup>54,78</sup> The half-life prolongs to 2.5 hours (creatinine clearance, 40–60 mL/min), 3.0 hours (creatinine clearance, 10–39 mL/min), 3.1 hours (creatinine

clearance <10 mL/min), 3.4 hours (steatosis and nonalcoholic liver disease), and 3.7 hours (cirrhosis). The half-life in the elderly is prolonged by 46%.<sup>75</sup> In one case of maternal to fetal transfer of octreotide, the neonatal octreotide half-life was 350 minutes.<sup>20</sup> Out of concern that the site of injection could lead to variable efficacy due to absorptive differences, octreotide pharmacokinetics were studied in 16 volunteers. Each received 500-mcg SC octreotide in the extremity (arm) and abdomen; there were no statistically significant differences in octreotide plasma peak, AUC, or half-life.<sup>83</sup> It is important to note that octreotide kinetics are markedly different in the long-acting release (LAR) depot formulation, which is provided at 4-week intervals.

### Pharmacodynamics

The duration of action of octreotide is variable and dependent on the outcome or organ system of interest. When used for tumor suppression, the duration lasts up to 12 hours.<sup>75</sup> The duration of action for inhibition of insulin secretion is unknown but presumed to be somewhere between 6 and 12 hours. When used for persistent hyperinsulinemic hypoglycemia of infancy (PHHI; also known as congenital hyperinsulinism), octreotide required continuous infusion.<sup>81</sup>

### ROLE OF OCTREOTIDE FOR INSULIN SUPPRESSION

Octreotide inhibits glucose-stimulated insulin release.<sup>2,36</sup> Octreotide was studied in humans in several clinical conditions, including insulinomas and hypoglycemia of infancy, and is utilized as part of the insulin suppression test.<sup>3,28,37,50,53,56,81,100</sup> In most instances, octreotide suppressed insulin concentrations and glucose concentrations rose. Occasionally, worsening or refractory hypoglycemia was observed when suppression of  $\alpha$  cell glucagon release outlasts suppression of  $\beta$  cell insulin release, despite appropriate catecholamine and cortisol counterregulatory response.<sup>8,16,35,71,74,100</sup> Another reason for variable effects in these conditions includes the absence of octreotide-susceptible SSTR receptor subtypes.<sup>26</sup>

Octreotide currently is used in toxicology for treatment of patients with hypoglycemia from insulin secretagogues. Controlled studies in rabbits given oral gliclazide demonstrate that a single dose of octreotide 50 or 100 mcg SC resulted in fewer hypoglycemic events and dextrose boluses, although single dosing did not eliminate hypoglycemia entirely.<sup>45</sup>

Octreotide efficacy for sulfonylurea-induced hypoglycemia was demonstrated in an early experimental study. Eight healthy volunteers were given 1.43 mg/kg glipizide orally and randomized to receive either a variable dextrose infusion to remain euglycemic, diazoxide 300 mg IV over 30 minutes and repeated every 4 hours with dextrose, or octreotide 30 ng/kg/min IV continuously.<sup>11</sup> Following glipizide administration, hypoglycemia of 50 mg/dL was achieved within 30 to 165 minutes.<sup>11</sup> Insulin concentrations in the diazoxide group were comparable with those in the glipizide group and were 4 to 5 times higher than in the octreotide group. Four of the 8 patients in the octreotide group did not require supplemental dextrose. At the fifth hour of the protocol, an IV bolus of 50 mL of 50% dextrose was given to the octreotide group to study the response to hyperglycemia. Approximately 6.5 hours was necessary for the serum glucose concentration to drop to 85 mg/dL, whereas only 3 hours was necessary in the dextrose and diazoxide groups.<sup>11</sup> This demonstrates that octreotide suppresses ability of hyperglycemia to result in the endogenous release of insulin. Diazoxide infusion was associated with higher norepinephrine concentrations, whereas epinephrine concentrations were similar in all groups.<sup>11</sup> All xenobiotics were stopped at 13 hours, and serum glucose concentrations fell to less than 65 mg/dL within 1.5 hours in subjects who received the dextrose and diazoxide, whereas the serum glucose concentrations remained greater than 65 mg/dL in 6 of the 8 octreotide subjects for the 4-hour observation period. Without additional octreotide, hypoglycemia recurred for as long as 30 hours after the initial glipizide administration. In 3 patients with sulfonylurea-induced hypoglycemia, insulin and C-peptide concentrations were appropriately suppressed following octreotide administration.<sup>34</sup> One prospective, randomized controlled trial of 40 hypoglycemic, poisoned patients who received a single octreotide 75-mcg dose SC demonstrated

consistently higher glucose values for the duration for which octreotide would be expected to be effective (6–8 hours).<sup>32</sup> The failure to control for carbohydrate intake and combined exposure to insulin complicates interpretation of these results.

Multiple case studies, case series, and evidence-based reviews support the efficacy of octreotide following overdoses of chlorpropamide, glibenclamide, gliclazide, glimepiride, glipizide, glyburide, nateglinide, and tolbutamide.<sup>1,12,13,19,21,25,30,34,38,39,41,42,59,67,69,73,85,92,107</sup> These cases encompass both intentional and unintentional overdoses in children and adults with and without diabetes and with and without kidney dysfunction. In these case reports, therapeutic doses have ranged considerably, and the most frequent doses were 50 to 100 mcg SC repeated every 6 to 12 hours in the adult patients and 1 to 2 mcg/kg SC or IV as a starting dose in children and repeated every 6 hours as needed.<sup>13,19,38</sup>

The meglitinides (repaglinide, nateglinide, and mitiglinide) typically have a short duration of action and carry a low risk for hypoglycemia.<sup>31,98</sup> Nevertheless, hypoglycemia is reported in both overdose and with therapeutic meglitinide doses.<sup>49,68,82</sup> Octreotide, at doses of 75 to 100 mcg subcutaneously successfully treated meglitinide-induced hypoglycemia.<sup>33,96</sup>

Quinine is a quinoline antimalarial similar to chloroquine, halofantrine, hydroxychloroquine, and mefloquine.<sup>31</sup> Life-threatening hypoglycemia is a well-recognized complication of quinine treatment of *Plasmodium falciparum* malaria, and occasionally complicates therapy with other quinolines.<sup>4,106</sup> Intravenous chloroquine (800 mg infused over 3 hours) decreased blood glucose by 25% in healthy volunteers.<sup>40</sup> In a randomized, double-blinded study, hydroxychloroquine significantly increased insulin concentrations and lowered serum glucose in response to an oral glucose challenge.<sup>95</sup> Quinine (and its analogues) block the  $K_{ATP}$  channel in a dose-dependent fashion in an analogous manner to sulfonylureas.<sup>9,43,79</sup> In this setting, hypertonic dextrose and diazoxide therapy are frequently inadequate, with ensuing refractory hypoglycemia. In controlled studies of healthy volunteers, octreotide suppressed the release of insulin associated with quinine.<sup>87</sup> In an investigation of the potential hypoglycemia-sparing effect of octreotide given for treatment of quinine-induced hypoglycemia, healthy adults were given 50 mcg/h octreotide or placebo as a continuous IV infusion for 4 hours, followed at the first hour by infusion of a 490-mg quinine base.<sup>86</sup> In the control subjects, serum insulin concentrations rose and serum glucose concentrations fell significantly, whereas in the octreotide group, insulin concentrations fell and glucose concentrations remained constant. This effect of octreotide began within 30 minutes and persisted for 2 hours after octreotide was stopped. Octreotide was used successfully to treat refractory hypoglycemia in a woman receiving 600 mg quinine IV for malaria.<sup>86</sup> A subsequent treatment study<sup>87</sup> confirmed these findings and noted that a single octreotide (100 mcg) dose suppressed quinine-induced hypoglycemia within 15 minutes. Because quinolone antibiotics such as ciprofloxacin, levofloxacin, gatifloxacin, and nalidixic acid share a 4-quinolone nucleus with quinine, they are also infrequently associated with hypoglycemia due to  $K_{ATP}$  channel inhibition.<sup>65</sup> There are case reports of octreotide reversal of quinolone-associated hypoglycemia.<sup>57</sup>

The imidazolines such as clonidine, phentolamine, and yohimbine also inhibit the  $K_{ATP}$  channel.<sup>31,89,90</sup> This provides a mechanistic explanation for the rare hypoglycemia that occurs clinically with the imidazole antagonists.<sup>52</sup> Although not reported clinically, octreotide is a reasonable therapeutic approach for repeated episodes of imidazoline-associated hypoglycemia.

## ADVERSE EFFECTS AND SAFETY ISSUES

Octreotide is generally well tolerated, but toxicologic experience is limited. Adverse reactions occurring with short-term administration usually are local or gastrointestinal such as nausea, abdominal cramps, diarrhea, fat malabsorption, and flatulence.<sup>64</sup> Stinging at the injection site occurs in approximately 7% of patients but rarely lasts more than 15 minutes.<sup>110</sup> Healthy adult volunteers receiving octreotide noted no side effects when given IV doses of 25 or 50 mcg or SC doses of 50 or 100 mcg. At higher doses, early transient nausea and later-appearing but longer-lasting diarrhea and

abdominal pain frequently occur.<sup>60,61</sup> Healthy adult volunteers were given IV bolus doses of octreotide as high as 1,000 mcg and infusion doses of 30,000 mcg over 20 minutes and 120,000 mcg over 8 hours without serious adverse effects. Single doses in healthy adult volunteers resulted in decreased biliary contractility and bile secretion.<sup>75</sup> Diarrhea (76%), abdominal pain/distention (29%), and dizziness (12%) were common features when healthy adult volunteers were given octreotide 0.5 mcg/min with a 25-mcg bolus.<sup>53</sup> Long-term octreotide therapy lasting weeks to months results in biliary tract abnormalities.<sup>75,111</sup> Octreotide use to reverse sulfonylurea-induced and episodic hypoglycemia rarely results in bradycardia, hypokalemia, hyperkalemia, anaphylactoid reactions, hypertension, and apnea.<sup>1,6,18,25,102</sup> Product information and clinical trials suggests the potential for acute cholecystitis, biliary abnormalities including sludge, stones, infections, and obstruction, cholestatic hepatitis, and pancreatitis.<sup>10,50,75</sup>

No side effects were noted in 7 small-for-gestational-age neonates given octreotide 8 to 18 mcg/kg/day for 9 to 45 days to treat PPHI.<sup>81</sup> In a combined single-arm, open-label clinical trial (5 patients) and observational registry study (19 patients) of octreotide administered for diazoxide-resistant PPHI, no severe adverse events related to octreotide were observed during an observation period of 695 patient-months.<sup>50</sup> Gallstones/sludge, vomiting, hyperglycemia, diarrhea/whitish stool, and elevation of alkaline phosphatase were the most common nonsevere side effects.<sup>50</sup> In a review of 428 infants prescribed 490 courses of octreotide primarily for chylothorax, pleural effusion, hypoglycemia, and gastrointestinal hemorrhage that did not control for indication, octreotide administration was associated with hypoglycemia (<40 mg/dL) in 2% of octreotide courses, hyperglycemia (>250 mg/dL) in 1% of octreotide courses, and necrotizing enterocolitis (NEC) in 2% of octreotide courses.<sup>103</sup>

Octreotide alters the balance among insulin, glucagon, and growth hormone. Serum glucose concentrations must be serially monitored. Hyperglycemia often occurs, but as noted above cases of hypoglycemia are also reported.<sup>10</sup> The package labeling states that symptomatic hypoglycemia occurs in patients with type I diabetes and their insulin requirements will likely be reduced.<sup>75</sup> The most likely explanation is suppression of counter-regulatory hormones, in particular when glucagon suppression is more persistent than insulin suppression.<sup>35,71,75</sup> Long-term administration of octreotide or octreotide use in circumstances other than sulfonylurea-induced hypoglycemia is also associated with hypothyroidism, bradycardia and cardiac conduction abnormalities, worsening congestive heart failure and QT interval prolongation, pancreatitis, hypoxemia and pulmonary hypertension in premature neonates, NEC, altered fat absorption, hyperkalemia, and decreased vitamin B<sub>12</sub> concentrations.<sup>1,6,35,48,50,63,75,103</sup>

Drug interactions are expected with xenobiotics that affect glucose regulation. Octreotide significantly decreases oral absorption of cyclosporine and increases the bioavailability of bromocriptine.<sup>10</sup> Because octreotide suppresses the activity of the cytochrome P450 enzymes, in particular CYP3A4, drugs with narrow therapeutic indices metabolized by these enzymes should be monitored more closely.<sup>75</sup> Total parenteral nutrition solutions are incompatible with octreotide because of the formation of a glycosyl octreotide conjugate.<sup>10</sup>

## PREGNANCY AND LACTATION

Octreotide is considered a category B drug.<sup>75</sup> Maternal to fetal transfer of exogenous octreotide is documented.<sup>20</sup> Studies of octreotide excretion in breast milk are not reported. However, intravenous <sup>111</sup>In-labeled octreotide is taken up by breast tissue, and <sup>111</sup>In decreases in breast milk followed a biexponential pattern with a half-life of 0.45 to 4.9 days.<sup>22</sup>

## DOSING AND ADMINISTRATION

No controlled trials have evaluated the optimal dose of octreotide for the management of sulfonylurea overdose. In adults, a dose of 50 mcg octreotide SC given every 6 hours is recommended for a total duration of 24 hours. In children, a dose of 4 to 5 mcg/kg/d SC divided every 6 hours, up to the adult dose, is recommended for initial therapy. This pediatric dose is derived

from the literature on treatment of PHHI.<sup>37</sup> In situations where compromised peripheral blood flow is expected, octreotide is recommended to be administered IV in the same dose but every 4 hours instead of every 6 hours. An increase in the dose is occasionally required, and continuous octreotide infusions are utilized in refractory cases.<sup>39,67</sup>

While the optimal duration of octreotide therapy awaits definitive study, several principles and patient factors help guide management. The duration of action of every sulfonylurea except tolbutamide exceeds 12 hours, and this will be altered with extended-release formulations, sulfonylureas with enterohepatic recirculation, in overdose, and with coingestions or coadministrations.<sup>32,85,91</sup> The onset of hypoglycemia can be significantly delayed following ingestion (as late as 21 to 48 hours, depending upon the sulfonylurea), and hypoglycemic recurrence as late as 30 to 70 hours is reported in the literature.<sup>58,80,85,99</sup> In one cohort of type 2 diabetic patients with sulfonylurea-induced hypoglycemia, in-hospital recurrent hypoglycemia occurred in 36%.<sup>13</sup> Acute or chronic kidney dysfunction (whether intrinsic or secondary to insufficient perfusion as in cases of congestive heart failure), which can predispose to sulfonylurea-induced hypoglycemia in the first place, alters the elimination of both oral sulfonylureas and antidotal octreotide. A controlled animal study demonstrated the failure of single-dose octreotide to completely eliminate recurrent late (9–24 hour) hypoglycemic episodes.<sup>45</sup> Human experimental and pragmatic data demonstrate the inadequacy of a single or a few octreotide doses. In humans administered glipizide in a controlled fashion, after 13 hours, of continuously provided octreotide therapy, 2 of 8 subjects (25%) had glucose concentrations decrease more than 3 hours after stopping octreotide. Without ongoing octreotide, hypoglycemia persisted for as long as 30 hours and hyperinsulinemia persisted for greater than 16 hours after the initial glipizide administration.<sup>11</sup> Treatment failures (episodes of glucose <60 mg/dL) occurred in 10 of 22 patients (45%) in a prospective, randomized controlled trial employing only a single-dose octreotide strategy; 2 events occurred at 12 and 13 hours after octreotide administration.<sup>32</sup> In one case series, treatment failure (hypoglycemia) occurred 14 hours after the last dose of octreotide (more than 30 hours after glyburide ingestion), and an additional failure occurred 36 hours after a single dose of octreotide (40 hours after ingestion of extended-release glipizide).<sup>69</sup> In another case series of pediatric patients ingesting glipizide or glyburide, 4 of 5 experienced recurrence of hypoglycemia after octreotide dosing, at 6, 7, 10, and 17 hours.<sup>18</sup> Repeat octreotide was required in one of 5 adult type 2 diabetic patients treated for sulfonylurea-induced hypoglycemia.<sup>13</sup> In a separate case series, recurrent hypoglycemia was seen in 3 of 6 adult patients with sulfonylurea-induced hypoglycemia, despite octreotide administration.<sup>34</sup>

The available pharmacokinetic, animal, and human data suggest that one or 2 octreotide doses is likely to be insufficient, and that 24 hours to several days of therapy and/or observation will be required, depending on the particular xenobiotic, quantity of ingestion, coingestants, caloric intake, and individual patient factors. Regardless of the dosing strategy utilized, it is recommended that during octreotide therapy and for 12 to 24 hours following termination of octreotide therapy before discharge, all patients be carefully monitored for recurrent hypoglycemia with careful attention to mental status and frequent checks of glucose concentrations, particularly during sleep.<sup>11</sup> The potential for unrecognizable recurrent hypoglycemia during sleep necessitates that patients must not be discharged during a high-risk circadian phase (eg, evening or night), unless the patients are monitored for an adequate amount of time after completing octreotide therapy and after a dextrose challenge (which can increase the release of insulin). The ability to consume sufficient calories should be ensured. Other patients at risk for hypoglycemia unawareness (ie, defective glucose counterregulation and hypoglycemia without warning symptoms)<sup>5</sup> should also be carefully monitored for 12 to 24 hours following octreotide termination.

Both SC and IV administration are acceptable, although the usual route is SC, which is preferred because of the pharmacokinetic limitations of the IV route delineated above. The SC administration sites should be rotated. For IV infusion, octreotide can be diluted in sterile 0.9% sodium chloride solution or D<sub>5</sub>W and infused over 15 to 30 minutes or by IV bolus over 3 minutes.<sup>75</sup>

Refrigeration of octreotide is recommended for prolonged storage, although octreotide is stable at room temperature for 14 days when protected from light. Active warming of refrigerated octreotide is not recommended, although passive warming to room temperature prior to administration is suggested to reduce the pain of SC administration.<sup>70</sup> Using the smallest volume possible also reduces the pain with SC administration. A depot formula designed to last for 4 weeks is available (Sandostatin LAR Depot). Although the depot formula is useful for patients with insulinomas, its duration of action far exceeds that of any insulin secretagogue, making it an unnecessary choice and therefore not recommended for the management of xenobiotic-induced hypoglycemia. Vapreotide, lanreotide, and pasireotide are somatostatin analogs that are available in the United States but are inappropriate for use in the setting of xenobiotic-induced insulin secretion.

## FORMULATION AND ACQUISITION

Octreotide acetate injection is available in ampules and multidose vials ranging in concentration from 50 to 1,000 mcg/mL. The multidose vials contain phenol. It should not be confused with the long-acting LAR formulations.

## SUMMARY

- The available evidence indicates that octreotide is useful for preventing the reoccurrence of hypoglycemia induced by the insulin secretagogues such as sulfonylureas (and rarely the meglitinides) and quinine (and rarely other quinolones).
- Octreotide is more effective and is better tolerated than diazoxide in suppressing insulin release.
- Octreotide is not a substitute for IV dextrose for the immediate treatment of hypoglycemia and does not decrease the need for frequent glucose assessments and assurance of sufficient caloric intake.
- Before discharge, the following should be ensured: the effects of octreotide have dissipated, the patient remains euglycemic following an adequate oral dextrose challenge, and there is a sufficiently prolonged observation time since ingestion to ensure that hypoglycemia will not occur in a fasting or sleeping patient.

## ANTIEPILEPTICS

Suzanne Doyon

### HISTORY AND EPIDEMIOLOGY

Epilepsy affects 6 per 1,000 population in the United States.<sup>54</sup> More than 50 distinct epileptic syndromes are identified; they are categorized into partial (60%) and generalized (40%) epilepsies.<sup>31</sup> Partial epileptic seizures arise from localized cortical sites, and generalized epileptic seizures involve both cerebral hemispheres.<sup>31</sup>

Historically, seizures were treated by a variety of methods, including ketogenic diets, fluid restriction, and surgical excision of scars or irritable cortical foci.<sup>118</sup> The first truly effective antiepileptic therapy was introduced in 1857, when the administration of bromides was noted to sedate patients and significantly reduce their seizures.<sup>118</sup> Phenobarbital, a sedative–hypnotic, was first used to treat seizures in 1912. Most of the subsequently introduced antiepileptics, such as primidone (2-desoxyphenobarbital), had chemical structures similar to that of phenobarbital, and sedation was erroneously believed to be an essential component of antiepileptic therapy.

The search for nonsedating antiepileptics led to the introduction of phenytoin in 1938 and benzodiazepines, carbamazepine, and valproic acid (VPA) in the 1960s. These antiepileptics were the only medications available until the 1990s, when second-generation antiepileptics were introduced: gabapentin, lamotrigine, levetiracetam, oxcarbazepine, tiagabine, topiramate, felbamate, vigabatrin, lacosamide, and zonisamide.

Broad-spectrum antiepileptics are effective in the management of all seizure types. Narrow-spectrum antiepileptics are restricted to patients who have partial (localized) epilepsy with partial or secondarily generalized seizures.<sup>54</sup> Antiepileptics are also currently used for a host of disorders, including psychiatric illnesses, refractory pain, drug withdrawal syndromes, migraines, cluster headaches, spasms, and chronic cough. Based on reports, in 2009, the Food and Drug Administration issued a warning about increased risk of suicidal thoughts or actions following treatment with carbamazepine, lamotrigine, levetiracetam, oxcarbazepine, phenytoin, tiagabine, topiramate, valproic acid, and zonisamide.<sup>25,50,88</sup>

Carbamazepine, lamotrigine, oxcarbazepine, and valproic acid are associated with pregnancy complications such as preeclampsia, premature births, spontaneous abortions, and stillbirths.<sup>8,12</sup>

This chapter reviews the toxicity and management of overdoses with antiepileptics other than the benzodiazepines and barbiturates, which are discussed in Chap. 72.

### PHARMACOLOGY

The mechanisms of action of antiepileptics include (1) sodium channel blockade; (2) calcium channel blockade; (3) blockade of excitatory amines; (4) GABA (gamma-aminobutyric acid) potentiation; and (5) binding to synaptic vesicle glycoprotein 2A (SV2A). Some antiepileptics have multiple mechanisms of action. Table 48–1 and Figs. 48–1 and 48–2 summarize these effects.

Voltage-gated Na<sup>+</sup> channels are fundamental units that evoke action potentials in neurons. These fast channels are large integral membrane proteins with an important alpha subunit and 2 smaller auxiliary beta subunits which act as modulators. Nine different Na<sup>+</sup> channels exist (Na<sup>+</sup> 1.1–1.9), each with a slightly different alpha subunit. Alpha subunits have multiple (up to 7) distinct binding sites. Carbamazepine, eslicarbazepine, lamotrigine, oxcarbazepine, phenytoin, rufinamide, topiramate, VPA, and zonisamide all bind to the batrachotoxin-binding site (or adjacent area) on alpha subunits of Na<sup>+</sup> channels. They close the internal gates, thereby preventing action potential propagation and decreasing repetitive firing.<sup>58,125,198</sup> At therapeutic concentrations, binding of antiepileptics to a Na<sup>+</sup> channel is largely selective. At toxic

concentrations, selectivity is lost, and both high-frequency and spontaneous sodium channels are blocked, including those found in cardiac tissue.<sup>22,98,141,176</sup> Lacosamide enhances slow inactivation of Na<sup>+</sup> channel (Fig. 48–1).<sup>43</sup>

Voltage-gated Ca<sup>2+</sup> channels are multisubunit complexes that are broadly classified into high- and low-voltage groups. High-voltage Ca<sup>2+</sup> channels include the L, N, P/Q, and R-type channels located primarily on presynaptic neurons; low-voltage Ca<sup>2+</sup> include the T-type channels located on dendrites of thalamic neurons.<sup>9</sup> Gabapentin and pregabalin bind to the  $\alpha_2\delta_1$  subunit of the high-voltage N-type Ca<sup>2+</sup> channels, reducing the frequency of calcium fusion of synaptic vesicles to membranes and thereby reducing glutamate exocytosis.<sup>60</sup> Levetiracetam also inhibits N-type Ca<sup>2+</sup> channels, but this is not its major mechanism of action.<sup>114</sup> Lamotrigine inhibits N- and P/Q-type Ca<sup>2+</sup> channels.<sup>190</sup> Topiramate inhibits L-type Ca<sup>2+</sup> channels; these channels are found on smooth and striated muscle cells, endocrine cells, and, importantly, cardiomyocytes. Finally, zonisamide inhibits T-type Ca<sup>2+</sup> channels, thus reducing the neuronal pacemaker current (Fig. 48–1).<sup>179</sup>

Several excitatory amine receptors have been identified. They are located on the postsynaptic membrane and are glutamate-activated ligand-gated ion channels. *N*-methyl-D-aspartate (NMDA), kainate, and alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) are the predominant excitatory amine receptors. When activated, these receptors allow for the influx of Na<sup>+</sup>, K<sup>+</sup>, and Ca<sup>2+</sup> into cells. VPA competitively inhibits the NMDA receptor.<sup>59</sup> Topiramate inhibits the kainate receptor.<sup>65</sup> Perampanel, a third-generation antiepileptic, inhibits the AMPA receptor (Fig. 48–1).<sup>23</sup>

Synaptic vesicle glycoprotein 2A (SV2A) is a member of the superfamily of proteins called membrane transporters that are an integral part of secretory vesicles in neuronal tissue. Synaptic vesicular glycoprotein 2A plays an important role in seizure pathophysiology.<sup>85</sup> Levetiracetam binds to SV2A, inducing a conformational change in the protein that leads to inhibition of vesicular exocytosis of glutamate from the presynaptic neuron (Fig. 48–1).<sup>110,116</sup>

$\gamma$ -Aminobutyric acid is an inhibitory neurotransmitter that is the target of antiepileptics, which often aim to increase concentrations of GABA in the synapse. Vigabatrin irreversibly inhibits GABA transaminase, the enzyme primarily responsible for GABA metabolism.<sup>34</sup> Valproic acid is reported to have similar effects.<sup>139</sup> Tiagabine inhibits the GABA transporter GAT-1 (also known as SLC6A1) and thereby prevents reuptake of GABA into presynaptic neurons.<sup>11</sup> Neither gabapentin nor pregabalin, despite their structural similarity to GABA, mimics GABA when iontophoretically applied to GABA neurons (Fig. 48–2).<sup>129</sup>

Lastly, ezogabine (retigabine in Europe) is a unique antiepileptic that opens voltage-gated K<sup>+</sup> channels and increases the M current, thereby hyperpolarizing the membrane.<sup>117</sup>

### CARBAMAZEPINE

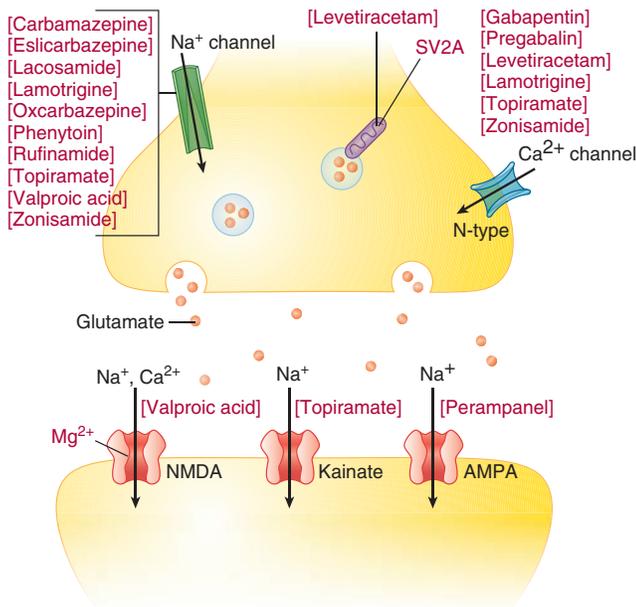

Carbamazepine is structurally related to the cyclic antidepressants. It is approved for the management of seizures and trigeminal neuralgia and is a pregnancy category D medication associated with kinked ribs and cleft palate.<sup>14</sup>

#### Pharmacokinetics and Toxicokinetics

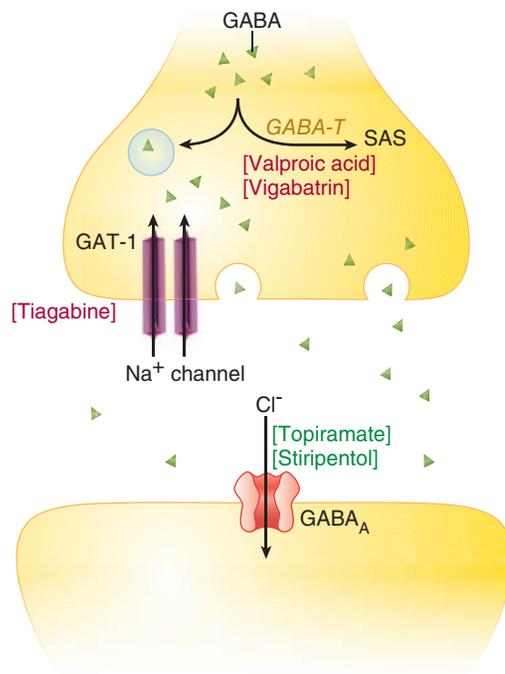

Carbamazepine is lipophilic, with slow and unpredictable absorption after oral administration and rapid distribution to all tissues. Peak concentrations can be delayed postingestion up to 100 hours.<sup>19,145</sup> It is metabolized primarily by CYP3A4 to carbamazepine 10,11-epoxide, which is pharmacologically active. This quantifiable metabolite is further degraded by epoxide hydrolase to carbamazepine-diol, a largely inactive compound.<sup>92</sup> Carbamazepine is unique because it induces its own metabolism after 2 to 4 weeks. The

TABLE 48-1 Comparison of Mechanisms of Action of Antiepileptics	Na <sup>+</sup> Channel	Ca <sup>2+</sup> Channel	GABA	GABA Transaminase	GABA Reuptake	NMDA AMPA kainate	Synaptic Vesicle Glycoprotein 2A	K <sup>+</sup> Channel	Carbonic Anhydrase
Carbamazepine	Blocks							Potentiates?	
Eslicarbazepine acetate	Blocks	Blocks (T-type)							
Ezogabine								Potentiates	
Gabapentin		Blocks (N-type)							
Lacosamide	Blocks								
Lamotrigine	Blocks	Blocks (N-, P/Q-type)							
Levetiracetam		Blocks (N-type)					Binding		
Oxcarbazepine	Blocks

Vigabatrin				Blocks					
Zonisamide	Blocks	Blocks (T-type)							Blocks

GABA =  $\gamma$ -aminobutyric acid; NMDA = *N*-methyl-D-aspartate; AMPA = alpha-amino-3-hydroxyl-5-methyl-4-isoxazolepropionate.

**FIGURE 48-1.** Excitatory neurons. In presynaptic neurons, carbamazepine, eslicarbazepine, lamotrigine, oxcarbazepine, phenytoin, rufinamide, topiramate, valproic acid and zonisamide all inhibit the Na<sup>+</sup> channel, preventing the release of the excitatory neurotransmitter glutamate. Lacosamide binds differently and enhances slow inactivation, i.e. inhibitory effect. Gabapentin, lamotrigine, levetiracetam, pregabalin, topiramate, and zonisamide all inhibit the Ca<sup>2+</sup> channel, preventing the release of glutamate. In post synaptic neurons, perampnel, topiramate, and valproic acid each inhibit a different excitatory receptor. AMPA=alpha-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; NMDA = *N*-methyl-D-aspartate. SV2<sub>a</sub> = Synaptic vesicle protein 2<sub>a</sub>.

**FIGURE 48-2.** Inhibitory neurons. In presynaptic neurons, valproic acid and vigabatrin inhibit GABA metabolism; tiagabine inhibits its transporter; the end result is increased GABA in the synaptic cleft. In post synaptic neurons, stiripentol and topiramate modulate GABA<sub>A</sub> receptors. GABA =  $\gamma$ -aminobutyric acid; GABA-T = GABA transaminase; GAT1= GABA transporter; SAS = succinic acid semialdehyde.

IR = immediate release; ER = extended release; CBZ = carbamazepine; <sup>a</sup>Not yet established; <sup>b</sup> = saturable.

elimination half-life is 25 to 65 hours at initiation of therapy and decreases to 12 to 17 hours with continued dosing.<sup>42</sup> Zero-order elimination kinetics are observed following large overdoses (Tables 48-2 and 48-3).<sup>194</sup>

### Clinical Manifestations

Acute carbamazepine toxicity is characterized by neurologic and cardiovascular effects. The neurologic disturbances include nystagmus, ataxia, seizures, and coma.<sup>19,75,115</sup> Status epilepticus is reported.<sup>168</sup> Cardiovascular effects include sinus tachycardia, hypotension, myocardial depression, and, rarely, cardiac conduction abnormalities such as QRS complex and QT interval prolongation.<sup>28,48,64</sup> The toxicity of carbamazepine in children differs slightly from that in adults. Children experience a higher incidence of dystonic reactions, choreoathetosis, and seizures and have a lower incidence of ECG abnormalities.<sup>166,175</sup> Chronic carbamazepine overdose can result in headaches, diplopia, ataxia, and leukopenia.<sup>155</sup>

The incidence of carbamazepine-induced hyponatremia ranges from 1.8% to 40%. Increased antidiuretic hormone secretion (SIADH) or increased sensitivity of peripheral osmoreceptors to antidiuretic hormone are suggested mechanisms (Chap. 12).<sup>99,186</sup>

### Diagnostic Testing

Therapeutic serum concentrations of carbamazepine are 4 to 12 mg/L. Carbamazepine-10,11-epoxide concentrations are 1 to 10 mg/L and can exceed 10 mg/L with therapeutic use of lamotrigine or VPA, secondary to epoxide hydrolase inhibition (Table 48-4). Electrolytes should be checked in patients with altered mental status because of the risk of hyponatremia.<sup>99,186</sup> Carbamazepine cross-reacts with some toxicology screening for tricyclic antidepressants (Chap. 68).<sup>52</sup>

### Management

Rigorous supportive care underlies management. Multiple-dose activated charcoal is associated with improved outcomes in several studies and is recommended for patients presenting with large overdoses, if there are no contraindications.<sup>13,70,115</sup> Seizures should be treated with benzodiazepines. Vasopressors should be used for hypotension that is refractory to fluids. Sodium bicarbonate is recommended if the QRS complex duration exceeds 100 milliseconds (ms).<sup>48</sup> Serial serum concentrations should be obtained owing to delays in peak concentrations. Extracorporeal drug removal is reasonable in cases of severe poisonings associated with intractable seizures or life-threatening dysrhythmias.<sup>62</sup> Intermittent hemodialysis (HD) is preferred.<sup>62</sup>

### ESLICARBAZEPINE ACETATE

Eslicarbazepine acetate is a third-generation antiepileptic that belongs to the dibenzazepine family, which includes carbamazepine (first-generation) and oxcarbazepine (second-generation). It is a prodrug that is presystemically metabolized in the liver to *S*(+)-licarbazepine (95%) and *R*(-)-licarbazepine (5%).<sup>162</sup> *S*(+)-Licarbazepine is also the pharmacologically active metabolite of oxcarbazepine (Tables 48-2 and 48-3).<sup>162</sup> Eslicarbazepine is expected to be more effective than oxcarbazepine and is further discussed in the oxcarbazepine section.<sup>162</sup>

### EZOGBABINE

Ezogabine (Retigabine in Europe) is a recently approved antiepileptic. Hepatic hydrolysis/*N*-acetylation followed by glucuronidation are responsible for 50% to 65% of its metabolism. Uridine-diphosphate-glucuronosyltransferase

**TABLE 48–3 Metabolism of Antiepileptics and Effects on CYP Enzymes**

	<i>Metabolized by</i>	<i>Induction</i>	<i>Inhibition</i>

Vigabatrin	None	None	None
Zonisamide	3A4; acetylation	None	None

UGT = uridine-diphosphate-glucuronosyltransferase.

(UGT1A4) is the principal isoenzyme involved.<sup>200</sup> It is associated with bluish skin discoloration (6%), maculopathy, urinary disorders, and QT prolongation (Tables 48–2 and 48–3).<sup>127</sup>

## GABAPENTIN

Gabapentin is a narrow-spectrum antiepileptic approved for the management of seizures, postherpetic neuralgia, chronic neuropathic pain, migraine headaches, and restless leg syndrome.<sup>54</sup> Gabapentin can be misused and abused.<sup>45</sup> It is a category C medication with limited human data in pregnancy.<sup>14</sup>

### Pharmacokinetics and Toxicokinetics

The bioavailability of gabapentin is approximately 60% in the therapeutic dose range. Absorption kinetics are dose-dependent, with decreasing bioavailability at increased dosage because of saturation of the L-amino acid transport system.<sup>15,185</sup> It has high water solubility but poor lipid solubility.<sup>15</sup> Dosage adjustments are necessary in patients with creatinine clearance or estimated glomerular filtration rate (eGFR) of 60 mL/min or less.<sup>140</sup> It is not metabolized by and does not affect the CYP450 system and has no significant interactions with other antiepileptics (Tables 48–2 and 48–3).<sup>200</sup>

### Clinical Manifestations

Sedation, ataxia, movement disorders, slurred speech, and gastrointestinal (GI) symptoms are reported after acute gabapentin overdose.<sup>78,95,193</sup> Gabapentin withdrawal is characterized by agitation, confusion, tachycardia, and possibly seizures.<sup>128</sup>

### Diagnostic Testing

Therapeutic serum concentrations of gabapentin are 2 to 20 mg/L. Because of its large therapeutic index, monitoring of serum gabapentin concentrations is not routinely necessary.<sup>97</sup>

## Management

Treatment is largely supportive. Saturation of the transporter system limits GI absorption and movement across the blood–brain barrier.<sup>15,185</sup> Hemodialysis and hemoperfusion are not generally necessary, but up to 35% is removed by HD in anuric patients.<sup>39,78</sup> Gabapentin withdrawal does not respond well to administration of benzodiazepines and should be treated with tapering doses of gabapentin.<sup>128</sup>

## LACOSAMIDE

Lacosamide is a functionalized amino acid with high water solubility.<sup>97</sup> It is a category C medication with limited data in human pregnancy.<sup>14</sup>

### Pharmacokinetics and Toxicokinetics

Lacosamide is almost 100% bioavailable orally. It is predominantly excreted unchanged in the urine and 30% metabolized in liver (2C19).<sup>82</sup> Enzyme inducers such as carbamazepine and phenytoin can significantly reduce serum lacosamide concentrations (Tables 48–2 and 48–3).<sup>82</sup>

### Diagnostic Testing

Lacosamide's therapeutic serum concentration is 5 to 10 mg/L.<sup>82</sup> Monitoring of concentration is not routinely recommended in overdose.

### Clinical Manifestations

Gastrointestinal effects, QRS complex prolongation, dysrhythmias, intractable hypotension, and death are reported following acute overdose.<sup>26,119</sup> Prolongation of the QRS complex is reported following overdose of a mix of lacosamide and other Na<sup>+</sup> channel blockers.<sup>37,142</sup>

## Management

Electrocardiographic monitoring and supportive care are recommended. QRS complex prolongation responds to administration of sodium bicarbonate, and hypotension responds to administration of vasopressors making these reasonable therapeutics.<sup>26,119</sup>

## LAMOTRIGINE

Lamotrigine is a phenyltriazine antiepileptic also approved for maintenance treatment of bipolar mood disorder.<sup>82</sup> It is a category C medication with limited human data in pregnancy.<sup>14</sup>

### Pharmacokinetics and Toxicokinetics

The bioavailability of lamotrigine approaches 100%.<sup>82</sup> It is predominantly glucuronidated to lamotrigine-2-*N*-glucuronide.<sup>82</sup> The elimination half-life is approximately 25 hours but can be significantly reduced (12 hours) in the presence of phenytoin and carbamazepine.<sup>199</sup> The half-life is doubled by VPA, an enzyme inhibitor. Significantly reduced clearance of lamotrigine occurs in patients with Gilbert syndrome (syndrome of defective glucuronidation) (Tables 48–2 and 48–3).<sup>198</sup>

### Clinical Manifestations

Neurologic and cardiovascular manifestations predominate following lamotrigine overdose. In large case series, seizures, central nervous system depression, agitation, myoclonus, and hyperreflexia were present.<sup>134</sup> Status epilepticus is reported.<sup>109,141</sup> Tachycardia, hypertension, and tachypnea are also frequently present along with QRS complex prolongation, Brugada-like ECG abnormalities, and third-degree heart block.<sup>22,134,141,176</sup> Chronic supratherapeutic dosing resulted in oculo-lyric crises in 4 patients.<sup>188</sup>

### Diagnostic Testing

Therapeutic serum concentrations of lamotrigine are 2 to 15 mg/L.<sup>82</sup> Monitoring of concentration is not routinely recommended in overdose.

## Management

Supportive care and cardiac monitoring should be provided. Lamotrigine-induced seizures respond to benzodiazepines.<sup>134,191</sup> Data on HD and hemoperfusion are not available. Intravenous lipid emulsion is not recommended owing to toxicity based on limited data (Antidotes in Depth: A23).<sup>22,134</sup>

TABLE 48–4 Antiepileptic Drug Interactions

	Toxicity Increased by	Anticonvulsant Effect Decreased by	Increases Concentrations of	Decreases Concentrations of

Vigabatrin	None	None	None	Phenytoin
Zonisamide	None	CBZ, phenobarbital, phenytoin	?CBZ	-CBZ

CBZ = carbamazepine; INH = isoniazid; OCP = oral contraceptive pill; VPA = valproic acid.

## LEVETIRACETAM

Levetiracetam is an enantioselective isomer (*S*) piracetam analogue antiepileptic that may also be effective in the treatment of traumatic brain injury.<sup>71,82</sup> It is a category C medication with limited human data in pregnancy.<sup>14</sup>

### Pharmacokinetics and Toxicokinetics

The bioavailability of levetiracetam approaches 100%. The major metabolic pathway involves enzymatic hydrolysis of the acetamide group. This reaction occurs in the blood and is not dependent on hepatic CYP450 activity.<sup>82</sup> There are no active metabolites.<sup>82</sup> Dosage adjustments are necessary in patients with creatinine clearances or eGFR of 80 mL/min or less (Tables 48–2 and 48–3).<sup>91,173</sup>

### Clinical Manifestations

Mild central nervous system (CNS) depression and ataxia were reported in one large case series.<sup>104</sup> Respiratory depression requiring intubation was occurred in one case report.<sup>7</sup> Chronic therapy is not associated with behavioral problems in adults but is associated with aggression and agitation in up to 20% of children.<sup>73,123</sup>

### Diagnostic Testing

Therapeutic serum concentrations of levetiracetam are 12 to 46 mg/L. Because of its large therapeutic index, routine monitoring of serum levetiracetam concentrations is not necessary.<sup>82</sup>

### Management

Supportive care should be provided. Extracorporeal removal treatment is not recommended.

## OXCARBAZEPINE

Oxcarbazepine is an analog of carbamazepine that functions as a prodrug of licarbazepine, also known as monohydroxycarbazepine.<sup>162</sup> It is a category C medication with limited data in human pregnancy.<sup>14</sup>

### Pharmacokinetics, Toxicokinetics

Oxcarbazepine has 100% bioavailability. Rate-limited presystemic ketoreduction rapidly metabolizes oxcarbazepine to licarbazepine, also known as monohydroxycarbazepine. Metabolism is skewed toward formation

of *S*(+)-licarbazepine (80%), which is pharmacologically active.<sup>162</sup> Plasma elimination half-life of oxcarbazepine is 2 hours, and licarbazepine, 8 to 15 hours.<sup>146</sup> Oxcarbazepine minimally inhibits CYP3A4 but increases glucuronidation.<sup>146,199</sup> Licarbazepine concentrations are reduced by 25% in the presence of enzyme inducers such as carbamazepine and phenytoin (Tables 48–2 and 48–3).<sup>146,200</sup>

### Clinical Manifestations

Central nervous system effects (lethargy, nystagmus, dizziness) and cardiovascular effects (tachycardia, hyper/hypotension) are reported after overdose.<sup>148,170</sup> In severe cases, coma, respiratory depression and seizures are noted.<sup>170</sup> The rate-limited enzymatic conversion to the active metabolite may limit toxicity; in some cases, serum concentrations of oxcarbazepine were very high (10-fold), while concentrations of *S*(+)- and *R*(-)-licarbazepine were low (2-fold).<sup>56,148,187</sup> In one large case series of acute overdoses, electrolyte abnormalities were rarely reported.<sup>170</sup> Oxcarbazepine is associated with drug-induced liver injury.<sup>77</sup>

### Diagnostic Testing

Therapeutic serum concentrations of oxcarbazepine are 10 to 35 mg/L. Licarbazepine (monohydroxycarbazepine) serum concentrations are 3 to 35 mg/L.<sup>112</sup> Monitoring of concentrations is not routinely recommended in overdose. Electrolytes should be checked in patients with altered mental status because of the risk of hyponatremia (<135 mmol/L).<sup>112</sup>

### Management

Rigorous supportive care underlies management. Hemodialysis (HD) does not increase the clearance of oxcarbazepine/10-hydroxycarbazepine, so HD is not recommended.<sup>56</sup>

## PERAMPANEL

Perampanel is a recently approved antiepileptic with a unique mechanism of action. It is a noncompetitive (allosteric) AMPA receptor antagonist.<sup>10</sup> It has a favorable pharmacokinetic profile and an extremely long elimination half-life of 70 hours.<sup>10</sup> Perampanel's metabolism is induced by carbamazepine and phenytoin.<sup>10</sup> Therapeutic serum concentrations have not yet been established.<sup>82</sup> Lethargy and slurred speech were observed for 48 hours following one case report of a large overdose.<sup>76</sup> Supportive care and monitoring of mental status are recommended in overdose (Tables 48–2 and 48–3).

## PHENYTOIN AND FOSPHENYTOIN

Phenytoin was first synthesized in 1908 but its antiepileptic properties were not discovered until 1938. It is a pregnancy category D medication, associated with the fetal hydantoin syndrome and cerebral hemorrhage in neonates.<sup>14</sup>

Fosphenytoin is a water-soluble phosphate ester prodrug of phenytoin. Advantages include more rapid administration, availability for intramuscular (IM) administration, and low potential for tissue injury at injection sites.<sup>57</sup>

### Pharmacokinetics and Toxicokinetics

Phenytoin is rapidly distributed to all tissues following a 2-compartment model. Oral loading doses of 20 mg/kg yield therapeutic (>10 mg/L) serum concentrations at 5.6 ± 0.2 hours.<sup>180</sup> In cases of very large oral overdoses, GI absorption is altered and peak serum concentrations can be delayed for days.<sup>24,29,61</sup> Additionally, phenytoin occasionally forms concretions in the GI tract.<sup>24,29</sup>

Phenytoin is extensively bound to serum proteins, mainly albumin. Only the unbound free fraction is pharmacologically active. A significant fraction of phenytoin remains unbound in neonates, uremic patients, and other patients with hypoalbuminemia, such as patients in ICUs.<sup>36</sup>

Phenytoin is predominantly metabolized by CYP enzymes (2C9 and 2C19) to inactive metabolites, less than 1% is excreted unchanged in the urine. Its rate of elimination varies as a function of its concentration (ie, rate is non-linear; Michaelis–Menten kinetics).<sup>152</sup> At phenytoin concentrations below 10 mg/L, elimination usually is first-order, and half-life is 6 and 24 hours. At higher concentrations, zero-order elimination occurs because of saturation

of the hydroxylation reaction, and the apparent half-life increases to 20 to 105 hours (Chap. 9) (Tables 48–2 and 48–3).<sup>46</sup>

Fosphenytoin is metabolized by tissue and blood phosphatases to phenytoin, phosphate, and formaldehyde. The half-life of conversion of fosphenytoin to phenytoin is 7 to 15 minutes.<sup>51</sup> Although molar conversion is equivalent, differences in molecular mass necessitate a 1.5:1 conversion factor from fosphenytoin–phenytoin; for example, 1.5 g fosphenytoin sodium = 1 g phenytoin sodium.<sup>113</sup>

### Clinical Manifestations

Acute phenytoin toxicity produces predominantly neurologic dysfunction, affecting the cerebellar and vestibular systems. Phenytoin concentrations greater than 15 mg/L are associated with nystagmus; concentrations greater than 30 mg/L are associated with ataxia and poor coordination; and concentrations exceeding 50 mg/L are associated with lethargy, slurred speech, and pyramidal and extrapyramidal manifestations.<sup>29,131</sup> Ophthalmoplegia, opsoclonus, and other focal neurologic deficits are also reported.<sup>174</sup> Cardiovascular instability, de novo seizures, and death following oral overdoses are rare.<sup>174,197</sup>

Intravenous overdose produces the same symptoms as oral overdose, with the addition of cardiotoxicity, hypotension, and dysrhythmias. These manifestations are usually attributed to the diluents propylene glycol (40%) and ethanol (10%).<sup>41,46,67,132</sup>

Metabolism of fosphenytoin releases phosphate and formaldehyde. Iatrogenic overdoses of fosphenytoin are associated with hyperphosphatemia, hypocalcemia, bradycardia, hypotension, and asystole.<sup>90,102,124,154</sup>

The purple glove syndrome is a serious complication of IV phenytoin or fosphenytoin administration whose incidence ranges from 1% to 6%.<sup>57</sup> Pathophysiology is unclear but appears to be related either to micro-extravasation or an unidentified procoagulant mechanism. Symptoms begin 2 to 12 hours after administration and include discoloration and edema distal to the site of administration.<sup>18</sup> Mild symptoms typically resolve over days, but when severe, lead to necrosis, possibly necessitating amputation.<sup>57</sup> The risk of purple glove syndrome associated with fosphenytoin is lower because of its water solubility.<sup>57</sup>

Chronic therapy results in gingival overgrowth in up to 20% of patients.<sup>133</sup> It is also associated with decreased ADH, osteomalacia, hepatotoxicity, and megaloblastic anemia.<sup>161</sup>

### Diagnostic Testing

Serum phenytoin concentrations are 10 to 20 mg/L. Because of zero-order elimination, very high serum phenytoin concentrations often take days to return to the therapeutic range.<sup>29,47,111</sup>

Measurement of free phenytoin concentration is helpful in neonates, elderly, hypoalbuminemic, and uremic patients because it compares more reliably with the cerebrospinal fluid concentration.<sup>36,69</sup> Therapeutic free phenytoin concentrations are 1.0 to 2.1 mg/L.

### Management

The treatment of patients with oral phenytoin overdoses is largely supportive. Oral multidose activated charcoal (MDAC) is recommended in severe overdoses presenting with profound coma.<sup>5,165</sup> Hemodialysis, charcoal hemoperfusion, plasmapheresis, and other extracorporeal techniques such as molecular adsorbents recirculating systems (MARS) is reasonable in severe cases with life-threatening cardiovascular instability or profound neurologic impairment.<sup>5</sup> All patients admitted to the hospital for oral phenytoin overdose require frequent neurologic assessments; routine cardiac monitoring is not necessary because of the low risk of cardiac toxicity following oral overdose.<sup>44,197</sup> Phenytoin-induced agranulocytosis can be treated successfully with administration of granulocyte colony–stimulating factor.<sup>178</sup>

Intravenous phenytoin is associated with hypotension, cardiac dysrhythmias, and dyskinesias. These are usually transient and resolve in 60 minutes. Stopping the phenytoin infusion for a few minutes and administering a bolus of 250 to 500 mL of 0.9% sodium chloride solution generally is sufficient to treat the hypotension. Restarting the infusion at half the initial rate is recommended.

Fosphenytoin IV overdose is associated with QT interval prolongation due to hyperphosphatemia and hypocalcemia. Electrolytes should be corrected immediately; HD may be required.<sup>124</sup> Dysrhythmias are reported and require prolonged periods of cardiopulmonary resuscitation.<sup>102,154</sup>

The management of extravasation is discussed in Special Considerations: SC8.

## PREGABALIN

Pregabalin is an antiepileptic developed as a more potent analog of gabapentin. It is indicated in the management of seizures and neuropathic pain.<sup>157</sup> Pregabalin is abused and misused.<sup>45,72,177</sup> It is a category C medication with limited human data in pregnancy.<sup>14</sup>

### Pharmacokinetics and Toxicokinetics

Pregabalin, unlike gabapentin, does not have a saturable GI transporter protein and is highly bioavailable, with rapid absorption. It is not protein-bound, and more than 90% is excreted unchanged in the urine.<sup>151,199</sup> Dose adjustments are necessary in patients with GFR less than 60 mL/min.<sup>195</sup> Pregabalin has no significant interactions with other antiepileptics except perhaps increasing the steady-state concentrations of tiagabine (Tables 48–2 and 48–3).<sup>15</sup>

### Clinical Manifestations

Cerebellar dysfunction (including dizziness, ataxia, and nystagmus), tremors, twitching, and seizures are described after overdose.<sup>83,130,143,164,195</sup> Third-degree atrioventricular block, QT interval prolongation, encephalopathy, and respiratory failure are observed.<sup>2,101,195</sup> Peripheral edema, weight gain, and decompensated congestive heart failure occur with chronic therapy.<sup>135</sup>

### Diagnostic Testing

Therapeutic concentrations of pregabalin are 2.8 to 8.3 mg/L.<sup>82</sup> Monitoring of concentration is not routinely recommended in overdose.

### Management

Rigorous supportive care underlies management.<sup>2,101,195</sup> Cardiac monitoring is recommended. It is reasonable to utilize HD in patients with severe CKD.

## RUFINAMIDE

Rufinamide is a recently approved antiepileptic. Therapeutic serum concentrations are 10 to 35 mg/L and metabolism is induced by carbamazepine and phenytoin (Tables 48–2 and 48–3). In clinical trials, the most frequently reported adverse events at high doses included lethargy, aggravated seizures, vomiting, and rashes.<sup>192</sup> There are no data on overdose.

## TIAGABINE

Tiagabine inhibits GABA reuptake and is a category C medication with limited data in human pregnancy.<sup>14</sup>

### Pharmacokinetics and Toxicokinetics

Tiagabine is quickly absorbed and has 90% bioavailability.<sup>146</sup> It is predominantly (98%) metabolized in the liver, via CYP3A4.<sup>146</sup> The elimination half-life is 8 hours and can be shortened to 2 to 3 hours in the presence of carbamazepine, phenytoin, or phenobarbital (Tables 48–2 and 48–3).<sup>82</sup>

### Clinical Manifestations

In a large case series, lethargy, confusion, and tachycardia were observed following acute overdose.<sup>171</sup> Facial myoclonus (grimacing) and seizures are also reported.<sup>21,169,171</sup>

### Diagnostic Testing

Therapeutic tiagabine concentrations are 0.02 to 0.2 mg/L.<sup>82</sup> Monitoring of concentration is not routinely recommended in overdose.

### Management

Supportive care should be provided. Seizures respond to administration of benzodiazepines.<sup>55,84,89,144</sup> Status epilepticus resistant to benzodiazepines should be treated with barbiturates or propofol. Posturing and grimacing

are treated with benzodiazepines.<sup>21</sup> Hemodialysis will likely not be effective because of very high protein binding.

## TOPIRAMATE

Topiramate is an antiepileptic approved for mood stabilizing and migraine prophylaxis.<sup>54</sup> Its sulfamate moiety weakly inhibits carbonic anhydrase, specifically the II and IV isoforms, present in the kidneys and CNS.<sup>38</sup> Topiramate is a pregnancy category D medication because of the risk of oral clefts.<sup>14</sup>

### Pharmacokinetics and Toxicokinetics

Topiramate is 80% bioavailable.<sup>146</sup> Approximately 50% is excreted unchanged by the kidneys and the rest is metabolized in the liver, using yet-to-be identified CYP enzymes.<sup>146</sup> Elimination half-life is 20 to 30 hours (Tables 48–2 and 48–3).<sup>120,146</sup>

### Clinical Manifestations

Lethargy, ataxia, nystagmus, myoclonus, hallucinations, coma, seizures, and status epilepticus are all reported following topiramate overdose.<sup>100,193</sup> Abnormal speech patterns and disturbances in verbal fluency appear at high concentrations.<sup>121</sup> In some overdoses, effects last for days.<sup>107</sup> Hyperchloremic non-anion gap metabolic acidosis results from inhibition of renal cortical carbonic anhydrase (lowest reported bicarbonate concentration, 12 mEq/L) along with hypocitraturia and high urine pH leading to formation of calcium phosphate stones.<sup>66,86</sup> The hyperchloremic metabolic acidosis typically appears within hours of ingestion and can persist for days.<sup>27,49,149,184</sup>

Chronic topiramate therapy is associated with acute bilateral secondary acute angle-closure glaucoma, acute bilateral myopia, and other visual problems in the first 2 weeks of therapy.<sup>53</sup> Additionally, chronic topiramate is associated with a risk of kidney stone in up to 1.5% of patients.<sup>86</sup>

### Diagnostic Testing

Therapeutic concentrations of topiramate are 5 to 20 mg/L. Electrolytes should be evaluated for the presence of a hyperchloremia and metabolic acidosis.<sup>86</sup> Monitoring of concentration is not routinely recommended in overdose.

### Management

Meticulous supportive care should be provided. Severe hyperchloremic metabolic acidosis (pH <7.2) should be treated with sodium bicarbonate 1 to 2 mEq/kg bolus intravenously and an infusion. Sodium bicarbonate impairs the antiepileptic effect of topiramate.<sup>27,49</sup> Intermittent HD can increase topiramate clearance 12-fold.<sup>16,120</sup> It is reasonable to consider intermittent HD in patients with life-threatening topiramate toxicity presenting with significant neurologic impairment, intractable electrolyte abnormalities, or anuria. Calcium phosphate stones should be treated with fluids, restriction of sodium intake, and possible supplementation with potassium citrate.<sup>86</sup>

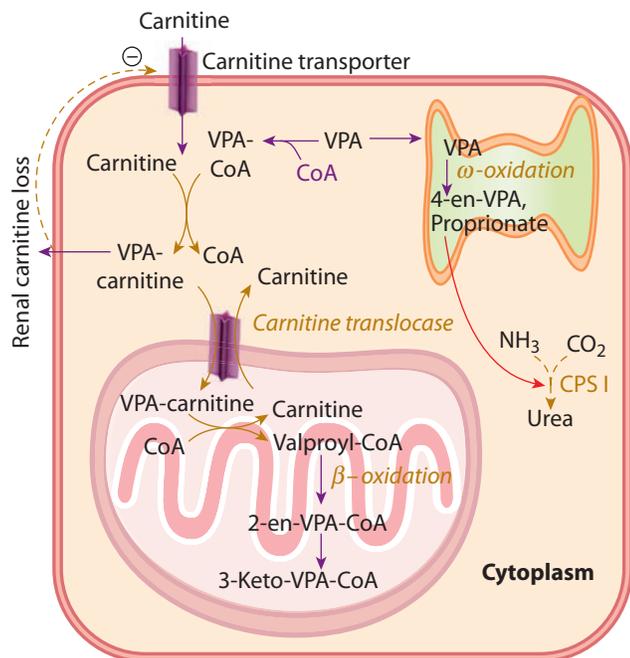

## VALPROIC ACID

Valproic acid (di-*n*-propylacetic acid {VPA}) is a simple branched-chain carboxylic acid antiepileptic that is also approved for treatment of mania associated with bipolar disorder and in migraine prophylaxis.<sup>54</sup> It is a category D drug in pregnancy and is associated with neural tube and facial defects.<sup>14</sup>

### Pharmacokinetics, Toxicokinetics, and Pathophysiology

Valproic acid is well absorbed from the GI tract with a bioavailability of 90%. Peak concentrations usually are reached in 6 hours, except for enteric-coated and extended-release preparations, where peak concentrations can be delayed up to 24 hours.<sup>46,93</sup> Valproic acid is 90% protein bound at therapeutic concentrations. Protein binding can decrease to 15% when VPA concentrations increase as a result of saturation of binding sites (Tables 48–2 and 48–3).<sup>63</sup>

Valproic acid is predominantly metabolized in the liver, with less than 3% excreted unchanged in the urine.<sup>183</sup> Glucuronidation (50%),  $\beta$ -oxidation (40%), and  $\omega$ -oxidation (10%) account for most of the hepatic metabolism of VPA.<sup>160</sup>  $\beta$ -Oxidation occurs in the mitochondrial matrix and starts with passive diffusion of VPA across the mitochondrial membrane and ends with

**FIGURE 48-3.** Valproic acid (VPA) metabolism by the hepatocyte. Valproic acid is linked to coenzyme A (CoA) by acyltransferase I and subsequently transferred to carnitine. Valproylcarnitine (VPA-carnitine) is shuttled into the mitochondrion, where, after transfer back to CoA by acyltransferase II, it undergoes  $\beta$ -oxidation, yielding several metabolites. These metabolites sequester CoA, preventing its use in the  $\beta$ -oxidation of other fatty acids. This process may lead to a Reye-like syndrome of hepatic steatosis. Alternatively, valproylcarnitine may diffuse from the cell and be renally eliminated, or it may inhibit cellular uptake of carnitine. In either case, the cellular depletion of carnitine shifts valproate metabolism toward microsomal  $\omega$ -oxidation, which occurs in the endoplasmic reticulum. This pathway forms 4-en-valproate, a putative hepatotoxin.  $\omega$ -Oxidation products and reduced *N*-acetylglutamate also interfere with carbamoylphosphate synthase I (CPS I), the initial step in the urea cycle, resulting in hyperammonemia.

the transport of metabolites in the opposite direction using acetyl-CoA and carnitine as transporters (Fig. 48-3 and Table 48-5).<sup>106,181</sup>

Mitochondrial  $\beta$ -oxidation of VPA depletes carnitine stores through various mechanisms. First, VPA increases carnitine excretion via formation of valproylcarnitine, which is renally excreted. Second, valproylcarnitine inhibits the adenosine triphosphate (ATP)-dependent carnitine transporter located on the plasma membrane. Third, VPA metabolites trap mitochondrial CoA. Mitochondrial CoA trapping decreases ATP production, which in turn negatively affects the carnitine transporter.<sup>106,160,181</sup> Reduced mitochondrial CoA activity decreases the formation of *N*-acetylglutamate, an obligatory cofactor for carbamoylphosphate synthetase I (CPS I). CPS I is the primary enzyme responsible for incorporation of ammonia into the urea cycle. The result is failure to metabolize ammonia and hyperammonemia. Hyperammonemia can injure muscle and brain tissue.<sup>6,188</sup>

Mitochondrial dysfunction, inhibition of  $\beta$ -oxidation, depletion of carnitine, depletion of acetyl-CoA, and possibly depletion of glutathione stores impair lipid metabolism and lead to fatty acid accumulation, steatosis, lysosomal leakage, formation of reactive oxygen species, and cytotoxicity histologically similar to Reye syndrome.<sup>150,160</sup>

### Clinical Manifestations

Valproic acid toxicity is associated with neurologic symptoms and metabolic disturbances. Ataxia and lethargy are common.<sup>63</sup> In one large case series, patients with serum VPA concentrations greater than 850 mg/L manifested coma, respiratory depression, and hypotension.<sup>167</sup> Hypernatremia, hypocalcemia, and hyperammonemia are reported.<sup>46,163,167</sup> Anion gap metabolic acidosis is a poor prognostic sign. It results from accumulation of ketoacids, carboxylic, and propionic acid.<sup>3,32,70</sup> Bone marrow suppression occurs 3 to 5 days

after acute massive overdoses and is characterized by pancytopenia.<sup>3,167</sup> Pancreatitis, hepatotoxicity, and acute kidney injury are rare manifestations of acute toxicity.<sup>3,32,94</sup>

Chronic VPA therapy may lead to hepatotoxicity and microvesicular steatosis secondary to the aforementioned metabolic aberration in fatty acid metabolism.<sup>17,40</sup> Clinical findings vary from asymptomatic elevation of aminotransferase concentrations to fatal hepatitis.

Valproate-induced hyperammonemic encephalopathy is characterized by impaired consciousness with lethargy, focal or bilateral neurologic signs, and aggravated seizures. It is not always accompanied by elevated VPA concentrations or hepatotoxicity. The etiology is uncertain, but elevated ammonia concentrations coupled with elevated concentrations of some of the more neurotoxic VPA metabolites are likely responsible.<sup>20,47,189</sup>

### Diagnostic Testing

Therapeutic serum concentrations of VPA are 50 to 100 mg/L.<sup>82</sup> Electrolytes should be monitored because of the risk of hypernatremia, hypocalcemia, elevated serum lactate, and hyperammonemia.<sup>160</sup>

### Management

Rigorous supportive care should be provided. Activated charcoal is recommended in the initial management. Repetitive doses are reasonable in massive overdoses.

L-Carnitine is recommended to treat hyperammonemia or hepatotoxicity.<sup>87,105,181</sup> L-Carnitine depletion results in an accumulation of toxic metabolites and hyperammonemia. L-Carnitine loading dose is 100 mg/kg IV over 30 minutes (maximum, 6 g) followed by 15 mg/kg IV over 10 to 30 minutes every 4 hours until clinical improvement occurs. Whereas IV L-carnitine is preferred in symptomatic patients, oral carnitine is sufficient in asymptomatic patients (Antidotes in Depth: A10). Extracorporeal drug removal is recommended in cases of severe intoxication associated with VPA serum concentrations greater than 900 mg/L, coma, respiratory depression requiring intubation, or pH <7.1.<sup>63</sup> Intermittent HD is preferred.<sup>63,163</sup>

### VIGABATRIN

Vigabatrin, or vinyl GABA, is a stereospecific irreversible inhibitor of GABA-transaminase.<sup>54</sup> It is a category C medication in pregnancy.<sup>14</sup>

### Pharmacokinetics, Toxicokinetics

Vigabatrin is rapidly absorbed and has a 60% to 80% bioavailability.<sup>14</sup> Duration of action is 24 hours.<sup>146</sup> It is completely excreted unchanged in the urine.<sup>146</sup> Dosage adjustments are necessary in patients with creatinine clearance or eGFR less than 80 mL/min.<sup>156</sup> Drug interactions are not common (Tables 48-2 and 48-3).<sup>146</sup>

### Clinical Manifestations

Agitation, coma, and psychosis are reported following acute ingestion.<sup>33,103</sup> Chronic toxicity may result in dizziness, tremor, depression, and psychosis.<sup>103</sup> The use of vigabatrin is associated with a risk of retinopathy and irreversible peripheral field defects, and permanent visual loss in up to 44% of patients.<sup>82,158</sup>

### Diagnostic Testing

Therapeutic serum concentrations of vigabatrin are 0.8 to 36 mg/L.<sup>82</sup> Monitoring of concentration is not routinely recommended in overdose.

### Management

Supportive care should be provided. Benzodiazepines are recommended for severe agitation. Visual defects may be irreversible.<sup>82</sup> Cases of mild vigabatrin-induced psychosis resolve on withdrawal of the medication.<sup>103</sup>

### ZONISAMIDE

Zonisamide is a sulfonamide derivative. Similarly to topiramate, zonisamide inhibits carbonic anhydrase enzymes.<sup>82</sup> It is a category C medication in pregnancy.<sup>14</sup>

TABLE 48–5 Adverse Events Associated With Therapy

	Common	Serious	DRESS Syndrome
Carbamazepine	Dizziness, sedation, blurred vision, ataxia, weight gain, nausea, leukopenia	Agranulocytosis (1/200,000), aplastic anemia (1/500,000), rash (10%), SJS (rare), hyponatremia (1.8%–40%)	Yes
Eslicarbazepine	Dizziness, sedation, nausea, ataxia, diplopia	Rash	Yes
Ezogabine	Skin and nail discoloration, dizziness, sedation, ataxia	Maculopathy, urinary disorders, QT interval prolongation	No
Gabapentin	Sedation, dizziness, mild weight gain, ataxia, behavioral effect (children)	None	No
Lamotrigine	Dizziness, blurred vision, insomnia, headache	Rash, SJS (1–3/1,000), hypersensitivity (rare), hepatotoxicity (rare)	Yes
Lacosamide	Dizziness, sedation, ataxia, nausea	Rash	No
Levetiracetam	Fatigue, irritability, anxiety, asthenia	Psychosis (rare)	Yes
Oxcarbazepine	Fatigue, dizziness, ataxia, diplopia, nausea, headache	Rash, SJS or TEN (0.5–6/million), hyponatremia (2.5%), anaphylaxis (rare)	Yes
Perampanel	Dizziness, sedation, ataxia	Psychiatric and behavioral problems	No
Phenytoin	Fatigue, dizziness, ataxia, nausea, headache, gingival hypertrophy, hirsutism, osteopenia	Rash, SJS or TEN (2–4/10,000), megaloblastic anemia (rare), hepatotoxicity (rare), lupuslike syndrome	Yes
Pregabalin	Sedation, weight gain, peripheral edema	Peripheral edema	No
Rufinamide	Sedation, dizziness, nausea, headache, diplopia	Rash	Possible
Tiagabine	Fatigue, dizziness, ataxia, somnolence, anxiety	Seizures	No
Topiramate	Sedation, ataxia, word-finding difficulty, slowed speech, difficulty concentrating, anorexia, weight loss, paresthesias, oligohidrosis (children)	Metabolic acidosis (3%), nephrolithiasis (1.5%), acute glaucoma (rare), heat stroke	No
Valproic acid	Sedation, ataxia, weight gain, nausea, tremor, hair loss	Hepatotoxicity (1/20,000), pancreatitis (1/3,000), thrombocytopenia, hyperammonemia, aplastic anemia (rare)	No
Vigabatrin	Fatigue, headache, dizziness, weight gain	Peripheral vision loss, psychosis	No
Zonisamide	Sedation, ataxia, difficulty concentrating, irritability, nausea, headache	Aplastic anemia, nephrolithiasis (0.2%–4%), rash (1%–2%), SJS or TEN (rare), heat stroke (rare)	No

DRESS = Drug Reaction with Eosinophilia and Systemic Symptoms; SJS = Stevens–Johnson syndrome; TEN = toxic epidermal necrolysis.

### Pharmacokinetics, Toxicokinetics

Zonisamide is 65% bioavailable.<sup>82</sup> It is primarily metabolized by the liver via CYP3A4.<sup>82</sup> The elimination half-life is 60 hours.<sup>82</sup> Metabolism is increased by enzyme inducers such as carbamazepine and phenytoin (Tables 48–2 and 48–3).<sup>200</sup>

### Clinical Manifestations

Symptoms include lethargy, coma, seizures, and hyperchloremic metabolic acidosis.<sup>126</sup> QT prolongation, hypotension, and cardiac arrest are reported.<sup>74,126,182</sup>

### Diagnostic Testing

Therapeutic serum concentrations of zonisamide are 10 to 40 mg/L.<sup>82</sup> Low serum bicarbonate is occasionally present.<sup>30,126</sup> Monitoring of concentration is not routinely recommended in overdose.

### Management

Supportive care is the mainstay of management.<sup>126</sup> Zonisamide is cleared via HD in chronically hemodialyzed patients.<sup>81</sup> There are no data in overdose and HD is not recommended.

## DRUG-INDUCED HYPERSENSITIVITY SYNDROME (DIHS)

Drug-induced hypersensitivity syndrome (DIHS) is a severe adverse drug event first described in 1950.<sup>79</sup> Previously known as the anticonvulsant hypersensitivity syndrome or Drug Reaction with Eosinophilia and Systemic Symptoms (DRESS), there exists no current consensus on nomenclature. Drug-induced hypersensitivity syndrome is characterized by fever, morbilliform cutaneous

eruption, and multiorgan manifestations.<sup>79</sup> The syndrome occurs in approximately one of every 1,000 to 10,000 uses of antiepileptics. The most commonly implicated antiepileptics are carbamazepine, phenytoin, phenobarbital, and lamotrigine but oxcarbazepine, levetiracetam, and rufinamide are also involved (Fig. 17–9).<sup>68,136,153</sup> The etiology of DIHS remains unknown but data suggest a genetic defect in drug metabolism (*HLA-A\*3101* in Northern Europeans and Japanese individuals) or epigenetic disruption leading to reactivation of T cells that harbor latent herpesviruses (particularly HHV-6).<sup>35,147</sup>

Drug-induced hypersensitivity syndrome occurs most frequently within the first 2 months of therapy and is not related to dose or serum concentration. The pathophysiology is related to the accumulation of reactive arene oxide metabolites resulting from decreased epoxide hydrolase enzyme activity. These metabolites bind to macromolecules and cause cellular apoptosis and necrosis. They also form neoantigens that trigger T cell–mediated delayed (type IV) hypersensitivity reactions. Interestingly, the same metabolite is believed to cause other serious dermatologic reactions, such as Stevens–Johnson syndrome and toxic epidermal necrolysis (Chap. 17 and Fig. 17–6).<sup>172</sup>

Initial symptoms include fever (38°C–40°C) for 1 to 2 weeks followed by a diffuse, pruritic macular exanthem that spreads from face to trunk to extremities. Facial edema is common.<sup>1</sup> Mucositis is present in 30%, and tender lymphadenopathy in 75% of cases.<sup>4,80</sup> Multiorgan involvement usually occurs 1 to 2 weeks into the syndrome. The liver is the most frequently affected organ (>80% of cases), although involvement of the CNS (encephalitis), heart (myocarditis), lungs (pneumonitis), kidney (nephritis), and thyroid are possible. Liver disturbances range from mildly elevated aminotransferase

concentrations to fulminant hepatic failure.<sup>80</sup> Eosinophilia ( $>2.0 \times 10^9$  eosinophils per L) and mononucleosis-type atypical lymphocytosis are common.<sup>79,147</sup> This syndrome is commonly mistaken for sepsis.<sup>79</sup> Fatality rates are reportedly as high as 5% to 10%.<sup>80,136</sup>

Skin biopsies reveal dense perivascular lymphocytic infiltration, with extravasated erythrocytes, eosinophils, and dermal edema.<sup>79</sup> Lymph node histology reveals benign hyperplasia or pseudolymphoma.<sup>79</sup> Other laboratory abnormalities include positive rheumatoid factor, antinuclear antibodies, anti-double-stranded DNA smooth muscle antibodies, cold agglutinins, and hypo- or hypergammaglobulinemia.<sup>80</sup> There is no reliable standard for the diagnosis of this syndrome, and separate diagnostic criteria have been developed by the European Registry for Severe Cutaneous Adverse Reaction and the Japanese Research Committee on Severe Cutaneous Adverse Reaction.<sup>79</sup> Prompt discontinuation of the offending antiepileptic is essential and benzodiazepines should be used temporarily to control seizures. Patients should be admitted to the intensive care or burn unit for fluid replacement, correction of electrolytes, warming environment, high caloric intake diet, prevention of bacterial or viral superinfection, and appropriate skin care. Topical steroids should be applied for symptomatic relief.<sup>137</sup> Methylprednisolone 30 mg/kg is recommended. Intravenous immunoglobulin 2 g/kg over 5 days is recommended if patient fails to respond quickly to methylprednisolone.<sup>80,122</sup> Corticosteroids should be gradually tapered over 3 to 6 months.<sup>35</sup> Extracorporeal membrane oxygenation (ECMO), intraaortic balloon pump, and left ventricular-assist devices can be used to treat myocarditis, and organ transplantation is recommended in cases of intractable liver or heart failure.<sup>35,108</sup> The major cause of death is hepatic necrosis.<sup>80</sup>

In one case series, 90% of patients with this syndrome showed in vitro cross-reactivity to other aromatic antiepileptics.<sup>96</sup> Based on this evidence, avoidance of phenytoin, carbamazepine, phenobarbital, primidone, lamotrigine, levetiracetam, oxcarbazepine, and rufinamide is recommended; benzodiazepines, VPA, gabapentin, topiramate, and tiagabine are safe alternatives. Clinicians should report all cases of DIHS to the US Food and Drug Administration Adverse Event Reporting System (FAERS) (<http://www.fda.gov/Drugs/GuidanceComplianceRegulatoryInformation/Surveillance/AdverseDrugEffects/ucm115894.htm>).

## SUMMARY

- All antiepileptics produce CNS symptoms in overdose; therefore, differentiation based on clinical findings is difficult. Lethargy, sedation, ataxia, and nystagmus occur after overdoses of almost all the antiepileptics.
- Coma occurs after substantial overdose of all antiepileptics with perhaps the exception of gabapentin. Seizures are possible following carbamazepine, lamotrigine, pregabalin, and zonisamide overdoses.
- Hemodynamic instability and abnormal ECGs are rare findings. Carbamazepine, lamotrigine, and possibly topiramate can cause QRS complex prolongation.
- Except for VPA overdoses, there are no specific antidotes or overdoses of antiepileptics. Supportive care alone usually yields beneficial outcomes.
- Patients with severe VPA overdoses or VPA-induced hyperammonemia should be treated with L-carnitine. Extracorporeal drug removal is rarely necessary.

reduced serum L-carnitine concentrations.<sup>8,19,32,34</sup> In the absence of hepatic dysfunction, the postulated mechanisms for hyperammonemia are unclear but are likely to result from interference with hepatic synthesis of urea or a small increase in ammonia production by the kidney.<sup>33,55</sup> Valproic acid, essentially a short-chain fatty acid, induces both carnitine and acetyl-CoA deficiencies by combining with L-carnitine as valproylcarnitine and with acetyl-CoA as valproyl-CoA. Ultimately,  $\beta$ -oxidation of all fatty acids is reduced, resulting in decreased energy production and accumulation of hepatic fatty acid stores. Valproylcarnitine inhibits the renal reabsorption of L-carnitine in experimental models.<sup>38</sup>

Valproic acid stimulates glutaminase, favoring glutamate uptake and ammonia release from the kidney. Glutamate dehydrogenase, acting on this glutamate, produces further ammonia in the conversion of this glutamate to  $\alpha$ -ketoglutaric acid. In addition, the formation of valproyl-CoA in the mitochondria inhibits the synthesis of *N*-acetylglutamate synthase leading to reduced concentrations of hepatic *N*-acetylglutamate (NAGA). Without sufficient NAGA, a cofactor for carbamoyl phosphate synthetase I (CPS I), the synthesis of urea from ammonia in the liver is impaired and ammonia concentrations rise (Figs. 11–10 and 48–3).<sup>1</sup>

In humans taking valproic acid, L-carnitine supplementation reduces ammonia concentrations.<sup>2,4,6,8,28,42,46,48,56</sup> An early report suggests that supplementation of L-carnitine improved ammonia elimination (3–15 hours) compared with published controls (11–90 hours), although the difference was not statistically significant.<sup>52,53</sup> Subsequently, in one case report administration of L-carnitine along with discontinuation of the valproic acid resulted in rapid neurologic improvement and normalization of the EEG within 24 hours whereas the ammonia concentration decreased from 204 to 47  $\mu\text{mol/L}$  within 6 hours.<sup>46</sup> And in another reported case, the ammonia concentration dropped from 256 to 124  $\mu\text{mol/L}$  in 4 hours following L-carnitine administration.<sup>40</sup>

## ROLE IN VALPROIC ACID–ASSOCIATED HEPATOTOXICITY

Valproic acid therapy is commonly associated with a transient dose-related asymptomatic increase in liver enzyme concentrations and a rare symptomatic, life-threatening, idiosyncratic hepatotoxicity similar to Reye syndrome.<sup>50,51</sup> Liver histology demonstrates microvesicular steatosis, similar to that described in both hypoglycin-induced Jamaican vomiting sickness (Chap. 118) and Reye syndrome. This occurrence presumably results from either L-carnitine or acetyl-CoA deficiency, which inhibit mitochondrial  $\beta$ -oxidation of valproic acid and other fatty acids, causing hepatocellular accumulation. One study compared valproic acid administration in mice bred to have decreased carnitine stores with normal mice and found that those with decreased carnitine stores developed microvesicular steatosis of the liver and demonstrated decreased mitochondrial oxidative capacity.<sup>26</sup>

Rat studies demonstrate that toxic doses of valproic acid over 7 days cause microvesicular steatosis, mitochondrial swelling, hyperammonemia, and hypocarnitinemia.<sup>50</sup> When coadministered with L-carnitine, the mitochondrial swelling, hyperammonemia, and carnitine concentrations were similar to control rats, and the microvesicular steatosis was reduced.<sup>50</sup> In one study in which rats were rendered carnitine deficient, the administration of carnitine decreased the concentration in plasma and urine of valproic acid metabolites associated with  $\beta$ -oxidation and increased the urinary concentration of the valproic acid glucuronide metabolite.<sup>24</sup>

The strongest evidence for the benefit of L-carnitine treatment in improving survival from valproic acid–induced hepatotoxicity comes from the retrospective analysis of patients identified by the International Registry for Adverse Reactions to valproic acid.<sup>7</sup> When 50 patients with acute, symptomatic hepatic dysfunction who were not treated with L-carnitine were compared with 42 similar patients treated with L-carnitine, only 10% of the untreated patients survived, but 48% of the L-carnitine–treated patients survived.<sup>7</sup> Early diagnosis, prompt discontinuance of valproic acid, and administration of intravenous (IV) rather than PO L-carnitine was associated with the greatest survival rate.<sup>7</sup> Most patients received 50 to 100 mg/kg/day of L-carnitine regardless of the route of administration.<sup>7</sup>

Acute valproic acid overdose rarely causes hepatotoxicity.<sup>52</sup> However, if a patient were to develop hepatotoxicity after a valproic acid overdose, we recommend the administration of L-carnitine.<sup>25,27,28,37,41,47</sup> The development of hepatotoxicity after a valproic acid overdose cannot be predicted, leading many authors to recommend administering prophylactic doses of L-carnitine to patients with severe overdoses, often defined by encephalopathy or a valproic acid concentration greater than 450 mg/L, with or without evidence of hepatotoxicity.<sup>28,41,47,52</sup> It is reasonable to administer L-carnitine to patients with encephalopathy, with or without hepatotoxicity, and in the setting of an acute overdose if the patient develops a metabolic acidosis. There is not enough evidence to recommend carnitine based solely on a valproic acid concentration.

## L-CARNITINE CONCENTRATIONS

In the serum, 80% of L-carnitine is free, and approximately 20% is acylated.<sup>15</sup> In adults who eat all food groups and children older than 1 year of age, the normal serum concentration of free L-carnitine is 22 to 66  $\mu\text{mol/L}$  and the total L-carnitine concentration is 28 to 84  $\mu\text{mol/L}$ . Vegetarians have L-carnitine concentrations 12% to 30% lower than omnivores.<sup>43</sup>

Studies in patients taking valproic acid demonstrate decreases in both free and total serum L-carnitine concentrations<sup>42</sup> and decreases in both total and free muscle L-carnitine concentrations.<sup>3</sup>

Case studies demonstrate reduced serum free L-carnitine concentrations and abnormal valproic acid metabolite profiles that normalize with L-carnitine supplementation.<sup>23,35,36</sup> All of these data support the therapeutic use of L-carnitine and provide a potential mechanism for its beneficial effects in valproic acid–induced hepatotoxicity.

## ADVERSE EFFECTS AND SAFETY ISSUES

L-Carnitine administration is well tolerated.<sup>30,34</sup> Transient nausea and vomiting are the most common side effects reported, with diarrhea and a fishy body odor noted at higher doses.<sup>10</sup> Following long-term high doses of L-carnitine in patients with severely compromised kidney function, the potentially toxic L-carnitine metabolites trimethylamine and methylamine *N*-oxide accumulate. The importance of trimethylamine and its metabolite dimethylamine accumulation may contribute to cognitive abnormalities and the fishy odor.<sup>14</sup> In a pharmacokinetic study after IV administration of 6 g of L-carnitine over 10 minutes, 2 of 6 subjects complained of transient visual blurring; one subject also complained of headache and lightheadedness. The manufacturer of L-carnitine has received case reports of convulsive episodes after L-carnitine use by patients with and without preexisting seizure disorders. No reports of seizures related to L-carnitine use can be found in the human literature.<sup>57</sup> The only data suggesting carnitine-related seizures are found in a rat model.<sup>17</sup>

There are no known contraindications to the use of L-carnitine. However, only the L isomer and not the racemic mixture should be used. The D-isomer is considered harmful and leads to depletion of L-carnitine in serum and in cardiac and skeletal muscles.<sup>49</sup> The D, L mixture interferes with mitochondrial utilization of L-carnitine and is associated with myasthenialike symptoms and cardiac dysrhythmias.<sup>49</sup>

## OVERDOSE OF L-CARNITINE

No cases of toxicity from overdose are reported, although large oral doses infrequently cause diarrhea.<sup>10</sup> The LD<sub>50</sub> in rats is 5.4 g/kg IV and 19.2 g/kg PO.<sup>10</sup>

## PREGNANCY AND LACTATION

L-Carnitine is considered FDA pregnancy category B. There is no information on excretion into breast milk.

## DOSING AND ADMINISTRATION

The optimal dosing of L-carnitine for valproic acid–induced hyperammonemia or hepatotoxicity has not been established. Recommendations for IV L-carnitine administration to patients with acute metabolic disorders resulting from L-carnitine deficiency range from 50 to 500 mg/kg/day.<sup>10,13</sup>

In the setting of severe metabolic crisis, a loading dose equal to the daily dose is recommended to be given initially followed by the daily dose divided and administered every 4 hours, and never more than every 6 hours.<sup>10</sup> The 500 mg/kg/day dose was intended for children<sup>9</sup> and offers no maximum dose. After the IV loading dose, a maximal daily dose of 6 g is reasonable. The oral dosing of L-carnitine is 50 to 100 mg/kg/day up to 3 g/day and should be reserved for patients who are not acutely ill. In adults, this is achieved by providing 990 mg (3 × 330-mg tabs) 3 times a day.

For patients with an acute overdose of valproic acid and without hepatic enzyme abnormalities or symptomatic hyperammonemia, L-carnitine administration is reasonable to prevent hepatotoxicity, and enteral doses of 100 mg/kg/day divided every 8 hours up to 3 g/day are appropriate. For patients with valproic acid–induced symptomatic hepatotoxicity, symptomatic hyperammonemia, metabolic acidosis, or encephalopathy, IV L-carnitine is recommended at a dose of 100 mg/kg IV up to 6 g administered over 30 minutes as a loading dose followed by 15 mg/kg every 6 hours administered over 10 to 30 minutes.

## FORMULATION AND ACQUISITION

L-Carnitine is available as a sterile injection for IV use in 1 g/5 mL single-dose vials.<sup>10</sup> L-Carnitine is supplied without a preservative. After the vial is opened, the unused portion should be discarded. L-Carnitine injection is compatible with and stable when mixed with 0.9% sodium chloride solution or lactated ringer solution in concentrations as high as 8 mg/mL for as long as 24 hours.<sup>10</sup> L-Carnitine is also available as 250- and 330-mg tablets; as an oral solution with artificial cherry flavoring, malic acid, sucrose syrup, and methylparaben and propylparaben as preservatives; and as sugar-free oral solutions at a concentration of 100 mg/mL that contain parabens and some also contain propylene glycol.<sup>9</sup> The PO solution does not require dilution but dilution in other drinks improves palatability by masking the taste. Slow consumption reduces gastrointestinal side effects.<sup>10</sup>

## SUMMARY

- L-Carnitine is recommended for patients with valproic acid–induced hyperammonemia, hepatotoxicity, metabolic acidosis, and encephalopathy.
  - Symptomatic patients should receive intravenous L-carnitine, not the oral preparation.
  - Asymptomatic patients should receive oral L-carnitine.

## CASE STUDY 7

**History** A 27-year-old man was found acting abnormally in a train station. When approached by police, he seemed to be hallucinating and answering questions inappropriately, for which emergency medical services was activated. When the paramedics arrived, they recorded: a blood pressure of 148/92 mm Hg, a pulse of 142 beats/min, and a respiratory rate of 16 breaths/min. They noted dilated pupils and disorientation, but did not comment on other abnormalities. An intravenous line was inserted, and the patient was given oxygen via nasal cannula at 4 L/min during transport to the hospital. No further history could be obtained.

**Physical Examination** On arrival to the hospital, the patient appeared to be a well-nourished, appropriately dressed man in significant distress. Vital signs were blood pressure, 152/92 mm Hg; pulse, 155 beats/min; respiratory rate, 22 breaths/min; rectal temperature, 99.4°F; oxygen saturation, 100% on nasal cannula at 4 L/min; and glucose, 117 mg/dL. Physical examination revealed a normal head without signs of trauma, the pupils were 7 to 8 mm and not reactive (Fig. CS7-1), and the extraocular muscles appeared normal. His neck was supple. His chest was clear to auscultation, and other than tachycardia, his heart sounds were normal. His abdomen was slightly distended and tender in the suprapubic area with absent bowel sounds. His skin was warm and dry. The neurologic examination was notable for good strength in all four extremities with intermittent myoclonic jerking, slight symmetrical hyperreflexia, and plantar flexion. He was mumbling incoherently, looking about the

room as if he were responding to external stimuli and could not answer questions.

Because the patient could not provide any history, his belongings were searched for possible information. Despite being well dressed, he had no wallet, cell phone, pills, or other useful information in his pockets, suggesting that perhaps the patient was surreptitiously drugged and then robbed.

**Initial Management** The patient was immediately attached to a cardiac monitor, and an electrocardiogram (ECG) was obtained. An intravenous line (IV) was inserted and the patient was rapidly given 1 L of 0.9% sodium chloride solution.

**What Is the Differential Diagnosis?** The patient's presentation is notable for hypertension, tachycardia, and tachypnea with dilated, nonreactive pupils, and hallucinations. The toxicologic differential diagnosis includes anticholinergics and antihistamines (Chap. 49), certain antipsychotics and antidepressants (Chaps. 67 and 68), ethanol and sedative-hypnotic withdrawal (Chap. 77), sympathomimetics such as amphetamines and cocaine (Chaps. 73 and 75), and hallucinogens (Chap. 79). However, a more detailed evaluation of the physical examination was suggestive of an anticholinergic toxic syndrome (Chap. 3 and Table 3-2) in that the skin was dry, the pupils were widely dilated and poorly responsive, the bowel sounds were diminished, and the bladder was distended. All of these findings were inconsistent with sympathomimetics, hallucinogens, and ethanol or sedative-hypnotic withdrawal. Although cyclic antidepressants and some antipsychotics

are potent anticholinergics, their toxicity is usually associated with hypotension and somnolence.

**What Clinical and Laboratory Analyses Help Exclude Life-Threatening Causes of this Patient's Presentation?** In patients with suspected anticholinergic toxicity, the single most consequential test is to obtain an ECG. The ECG is used primarily to identify signs of sodium channel blockade that are characteristic of cyclic antidepressant overdose (Chaps. 15 and 68) but also occur with some phenothiazine antipsychotics (Chap. 67), diphenhydramine (Chap. 49), type IA and IC antidysrhythmics (Chap. 57), cocaine (Chap. 75), and some other xenobiotics. A prolonged QRS complex duration would not only help provide a diagnosis in patients with TCA poisoning but would also indicate the need to intervene with hypertonic sodium bicarbonate (Antidotes in Depth: A5). The patient's ECG is shown in Fig. CS7-2.

Additional life-threatening conditions that might be anticipated in patients with anticholinergic toxicity include hyperthermia, seizures, and rhabdomyolysis. Blood samples were sent to the laboratory for a complete blood count, electrolytes, creatine phosphokinase, and concentrations of acetaminophen and ethanol.

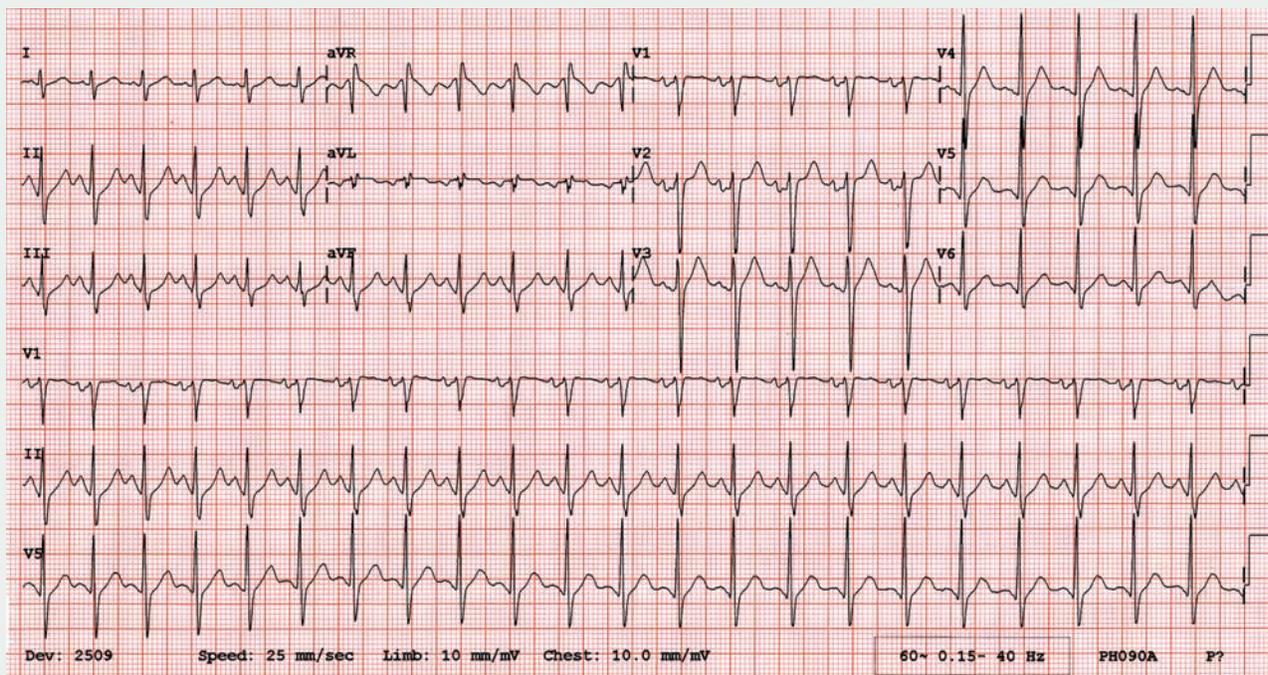

**Further Diagnosis and Treatment** The combination of a clinical anticholinergic syndrome with subtle markers of sodium channel blockade and a normal blood pressure was most suggestive of diphenhydramine toxicity. Given that the patient was uncomfortable and unable to provide a history, a decision was made to administer physostigmine (Antidotes in Depth: A11). Atropine was brought to the bedside. One milligram of physostigmine was infused over 5 minutes. Over the next few minutes, the patient's pupils became smaller, and his heart rate dropped to 110 beats/min. He became calm, but his speech was still garbled and incoherent and his bowel sounds were quiet. A second dose of 1 mg of physostigmine was given over 5 minutes. Shortly thereafter, the patient's speech became clear, and he asked to drink water and use a urinal. He spontaneously voided 800 mL of clear urine. His blood pressure was 132/84 mm Hg, and his pulse was 98 beats/min.

He related that he had no medical history, no surgical history, and no allergies to medications and was not taking any prescription, nonprescription, or illicit drugs. The last thing he remembered was that he was early for his

**FIGURE CS7-1.** The patient's right eye demonstrating a large and fixed pupil.

## CASE STUDY 7 (CONTINUED)

**FIGURE CS7-2.** Electrocardiogram showing sinus tachycardia with a QRS complex duration of 90 milliseconds (ms), a QT interval of 320 ms (QTc 506 ms), and findings consistent with early sodium channel blockade (an S wave in I and an R wave in aVR despite a relatively normal QRS complex duration).

train and went to the station bar for a drink with someone he met while waiting.

All of the patient's laboratory tests were within normal limits except for his blood ethanol concentration, which was 32 mg/dL.

The health care team was concerned about drug-facilitated robbery and had the department social worker meet with the patient. He was offered the opportunity for comprehensive testing as well as filing a report with the

police, which he declined. He was observed for 8 hours and remained well, so he was discharged at his own request.

Sophie Gosselin

Antihistamines and decongestants rank among the highest prescription and nonprescription xenobiotics used in the United States. In 2015, antihistamines and cough and cold preparations ranked respectively 6th and 12th in substance categories most frequently involved in human exposure-related calls to US Poison Control Centers. Antihistamines ranked 14th in categories associated with the largest number of fatalities in 2015 (Chap. 130).<sup>113</sup>

Popular beliefs suggests that expectorants or decongestants depress cough and relieve congestion, and antihistamines also promote sleep. In an effort to retain selected drugs on the nonprescription market, the US Food and Drug Administration (FDA) developed a nonprescription monograph rule allowing some medications in use before 1972 to remain on the market without new clinical trials. As such, many nonprescription decongestants, antihistamines, and expectorants remained available for children without adequate safety or efficacy data in younger age groups. Between the years 1998 and 2007, 8.7% of US parents surveyed reported to have used an antihistamine- or decongestant-containing remedy for their children younger than 12 years in the past week. The majority of these children were younger than 5 years. Pseudoephedrine, brompheniramine, and chlorpheniramine were the 3 most common ingredients used.<sup>180</sup>

Unwanted effects associated with their use posed significant public health problems, particularly in children. Fatality studies associated with nonprescription cough and cold medicines reported that although uncommon, most deaths involved nontherapeutic dosages, administration for sedation purposes, and use in children primarily younger than 2 years of age.<sup>34</sup> However, the causality of death by cough and cold medicine is often debated. The data needed to prove this relationship are often incomplete because of such factors as the lack of postmortem drug quantification.<sup>134</sup> In 2007, a group of pediatricians and pharmacists petitioned the FDA requesting a change in labeling for children younger than 6 years on the basis that safety was never demonstrated in this age group. This petition alerted the general public of the underestimated adverse effects of these xenobiotics.<sup>144,168</sup> In early 2008, the FDA Public Health Advisory announced that cough and cold products were not recommended for children younger than 2 years, and later that same year the Consumer Healthcare Products Association (CHPA), a trade group of generic drug manufacturers, announced that its members were voluntarily modifying product labels for cough and cold medicines to exclude children younger than 4 years.<sup>173</sup>

Despite their widespread use, many reviews of nonprescription medications for cough in adults and children found no evidence for the effectiveness.<sup>155</sup> Conclusions are similar regarding the use of antihistamines or decongestants in otitis media.<sup>28</sup> Moreover, many well-conducted studies of antihistamines in monotherapy or in combination with a decongestant for patients with upper respiratory illness reported a significant absence of overall symptom improvement.<sup>155,178</sup> It is also suggested that the majority of any perceived benefit of cough suppressants are due to the sensory impact of sweetness and the placebo effect as well as the concerning intent of using the known adverse effect of sedation as a therapeutic goal.<sup>45</sup>

A systematic review on the toxicity of common cough and cold remedies in children younger than 12 years concluded there is sufficient evidence of an unfavorable risk-to-benefit ratio to support measures aimed at restricting use of cough and cold medications in younger age groups.<sup>74</sup> As individuals seek to ameliorate the symptoms of an unpleasant illness, official restrictions in younger age groups have yielded concerns of increased off-label use of medicines intended for older age groups or substitution with other xenobiotics. Two analyses of both poison control center data and emergency department (ED) visits reported significant decreases in annual rates of

both therapeutic medication errors and overall ED visits related to cough and cold medicines. However, the rate of unintentional ingestions did not change after the marketing revisions in 2007, implying that further efforts to increase packaging safety and parental education are needed.<sup>88,101,148</sup>

Despite many consumer-directed newsletter and media campaigns, the overall use in the general population seems constant. This is indicated by the rising sales in the category “cough- and cold-related” nonprescription medications between 2008 and 2011, reaching \$4.2 billion in 2011, higher than analgesics (\$2.7 billion).<sup>29</sup> A survey done in 2010 for CHPA found that 93% of US adults prefer to treat their minor ailments with nonprescription products before seeking professional care, and 85% would do the same for their children.<sup>161</sup>

Recreational use of antihistamines and decongestants was reported as early as the 1970s.<sup>125</sup> The popular “T’s and blues,” referring to the combination of pentazocine (Talwin) and the blue-colored antihistamine tripelemamine were used intravenously as a substitute for heroin. In 1983, when naloxone was included in pentazocine (Talwin NX), abuse patterns decreased.<sup>10</sup> Nonprescription sympathomimetics, such as pseudoephedrine, are also used as precursors in the illicit synthesis of methamphetamine. Although the rates of potential adverse events are perceived as low, the issue takes on added significance when the magnitude of the exposure rates for these xenobiotics is considered. In a survey of 2528 participants distributed across the United States, 4.5% of adult participants in 2006 reported taking pseudoephedrine within the past week compared with 8.1% in 2002, and 3.8% reported the use of diphenhydramine compared with 4.4% in 2002.<sup>82,154</sup> Both poison control center and clinical experience suggests that recreational use of antihistamines are increasing. Dextromethorphan-containing products are widely used for recreational purposes (Chap. 36).

Regardless of intent, exposures to these xenobiotics are relatively frequent, as illustrated by the number of calls received to the American Association of Poison Control Centers (AAPCC). Compilation of the National Poison Data System (NPDS) reports for the years 2000 to 2015 shows that the total number of exposure calls related to antihistamines has increased in the last 10 years, reaching 3.8% of calls and ranked eighth in the substance category with the greatest rate of exposure increase.<sup>113</sup> In contrast, both pediatric and adult cough and cold preparation-related calls have decreased since 2007 (Chap. 130).

In combination with each other, analgesics or antipyretics, antihistamines, and decongestants are easily accessible to the public. This availability perpetuates the widespread public impression that nonprescription xenobiotics are “safe” and contributes to their frequent use, misuse, and abuse.

## ANTIHISTAMINES

### History and Epidemiology

#### History

After the discovery of histamine, Bovet and other researchers at the Pasteur Institute attempted to synthesize antagonists to better understand its physiological role. In 1939, pyrilamine was found to be extremely effective in guinea pigs but not safe enough for humans. In 1941, phenbenzamine was the first antihistamine deemed suitable for clinical use.<sup>157</sup> Diphenhydramine was synthesized in 1943, and shortly after, in 1947, orphenadrine was derived. The more pronounced anticholinergic effects of the hydrochloride salt of orphenadrine explain its use in the treatment of Parkinson disease, and the citrate salt is used as a muscle relaxant. In the same years, Searle and Company, in Chicago, modified diphenhydramine to reduce drowsiness. Dimenhydrinate,

the resulting 8-chlorotheophylline salt, serendipitously cured a patient of her long-standing motion sickness. This benefit was proven in a clinical trial in 1949, in which 25% of the troops crossing the Atlantic from New York who received a placebo experienced seasickness compared with only 4% of those receiving dimenhydrinate.<sup>157</sup>

Reports of adverse effects and toxicity were soon published. The first report of a death associated with diphenhydramine occurred in 1948.<sup>14</sup> However, in this patient, several other factors could have contributed to her demise. Deaths were also reported with methapyrilene, but given its frequent coingestion with propoxyphene or scopolamine and the variable postmortem serum concentrations reported, attribution of causality was difficult.<sup>135</sup> In the 1950s, more pediatric overdose cases were reported, and the resemblance to atropine poisoning was noted. At the time, treatment consisted of phenobarbital, “pressure respirations,” and cooling with tepid water sponges.<sup>132</sup>

In the following decade, more than 5,000 compounds were synthesized by more than 500 chemists and tried for human use. Bovet was awarded the Nobel Prize in Physiology or Medicine in 1957 for his work related to the synthesis of compounds blocking the effects of bodily substances such as histamine.<sup>16</sup>

Cyclizine, a piperazine rather than a dimethylamine, was developed in the 1960s. It proved to be long acting and was used during the first manned flight to the moon by the National Aeronautic and Space Administration to control space sickness. It is no longer approved for use in the United States, although its derivative, hydroxyzine, remains in use.<sup>157</sup> In the 1970s, terfenadine was synthesized as a tranquilizer, but it lacked central nervous system (CNS) penetration. However, its peripheral antihistaminic effects proved useful. In 1989, more than 773 reactions to terfenadine were reported ranging from prolonged QT intervals to convulsions in supratherapeutic ingestions.<sup>35</sup> In 1992, the FDA issued a warning for the risk of torsade de pointes with terfenadine when administered with CYP3A4 inhibitors. Fexofenadine, its active metabolite, was marketed instead.<sup>157</sup>

None of the initial xenobiotics could antagonize histamine-induced gastric acid secretion, leading to the determination of the existence of more than one type of histamine receptors. The histamine receptor subtypes were identified as H<sub>1</sub> and H<sub>2</sub>. The H<sub>2</sub> receptors were noted to be located in the stomach. Attempts to identify H<sub>2</sub> receptor antagonists identified guanylhistamine, a partial agonist, and initiated the understanding of the physiology of histamine receptors.<sup>156</sup>

Cimetidine was synthesized in 1972, but its binding to the heme moiety of the cytochrome P450 with resultant inhibition caused medication interactions as well as altered mental status.<sup>175</sup> Ranitidine, a less polar molecule, did not enter the CNS and did not interfere with the P450 cytochromes. It rapidly became one of the best-selling drugs and has remained so for many years.

Seeking to better understand the action of histamine in the CNS, animal studies in the early 1980s postulated the existence of another histamine receptor located presynaptically. The existence of a distinct H<sub>3</sub> receptor inhibiting the neuronal synthesis of histamine (autoreceptor) when stimulated was validated with the development of the selective agonist R- $\alpha$ -methylhistamine and antagonist thioperamide.<sup>6</sup> A fourth histamine receptor is now recognized. Its primary function seems to modulate inflammatory and immune responses as well as nociception.<sup>71</sup> The numerous functions of histamine and its receptors in the nervous system, immune system, and other organs are continually being appreciated. Trials are under way for the use of H<sub>3</sub> and H<sub>4</sub> histamine receptor antagonists in CNS cognitive disorder, Parkinson disease, rheumatoid arthritis, obesity, and allergic rhinitis treatments.<sup>167,194</sup>

### Epidemiology

Antihistamines are available worldwide, and many do not require a prescription. These medications find widespread application in the treatment of conditions such as anaphylaxis, benign positional vertigo, dystonic reactions, hyperemesis gravidarum, gastroesophageal reflux disease, stress gastritis, and other histamine-mediated disorders. They are also used for their ability

to act on other receptors in the treatment of serotonin toxicity. Additionally, they are used for symptomatic relief of allergy symptoms as in allergic rhinitis, conjunctivitis, or urticaria and are included in many combination cough and cold preparations as discussed previously. First-generation antihistamines are widely available without prescription and are also marketed as sleep aids. These 2 factors contribute to their common ingestion in suicide attempts.<sup>127</sup> Second- and third-generation H<sub>1</sub> antihistamines are less frequently implicated in suicide attempts. Although reporting is not comprehensive, about one in 5 antihistamine-related exposures called to poison control centers are intentional. More than 42% of antihistamine exposures are related to confirmed diphenhydramine and 62% of those are from non-prescription sources (Chap. 130).

The H<sub>2</sub> antihistamines have a better safety profile in therapeutic and overdose situations.<sup>111</sup> Even though many references cite the possibility of bradydysrhythmias, hypotension, and cardiac arrest with massive ingestions or intravenous (IV) administration of H<sub>2</sub> antihistamines, these reports are rare. The incidence of adverse cardiovascular events with H<sub>2</sub> antihistamines is largely unknown. In the largest published review assessing 881 cases of solely cimetidine exposures, most were in children from 12 to 36 months of age, and 76% were unintentional in nature. No fatalities were observed.<sup>91</sup> A review of NPDS reports from 2001 to 2015 did not identify any fatalities from single-product ingestion of cimetidine or other H<sub>2</sub> antihistamines.<sup>113</sup> Only a few case reports of fatalities associated with acute exposures to H<sub>2</sub> antihistamines in adults can be found, mainly in forensic literature with little clinical information.<sup>78</sup>

Children seem to be at increased risk for antihistamine toxicity and most of the reported deaths in this age group involve diphenhydramine. Perhaps this is due to the ease of obtaining a toxic dose in milligrams per kilogram of body weight with very few tablets or liquid concentration in the commercial products available.<sup>104,115</sup>

Fatalities are also reported with other antihistamines, albeit often in combination with dextromethorphan and pseudoephedrine, making it difficult to attribute the cause of death to the antihistamine alone.<sup>15</sup> Liquid formulations and topical preparations are available and attractive to children, resulting in unintentional ingestions when accessible. First-generation antihistamines are also administered for their sedative properties by parents and prescribed by pediatricians for various purposes, including promoting recovery of sick children or as a relief for working parents.<sup>2,120</sup> However, the result of a randomized trial of diphenhydramine for this indication showed it was no more effective than placebo for nighttime awakenings or parental happiness.<sup>109</sup>

## Pharmacology

### Histamine Receptor Physiology

The H<sub>1</sub> receptors are located in the CNS, heart, vasculature, airways, sensory neurons, gastrointestinal (GI) smooth muscle, immune system, and adrenal medulla. Through H<sub>1</sub> receptors, histamine interacts with G proteins in the plasma membranes. Stimulation of H<sub>1</sub> receptors results in increased synthesis by phospholipases A<sub>2</sub> and C, inositol-1,4,5-triphosphate, and several diacylglycerols (DAGs) from phospholipids located in cell membranes. Inositol-1,4,5-triphosphate causes release of calcium, which then activates calcium-calmodulin-dependent myosin light-chain kinase, resulting in enhanced cross-bridging and smooth muscle contraction. The active and inactive forms of this receptor subtype are in equilibrium at baseline, and histamine shifts the equilibrium to the active conformation.<sup>150</sup>

The H<sub>1</sub> receptors are most commonly associated with mediation of inflammation. The other functions of histamine and the H<sub>1</sub> receptor include control of the sleep-wake cycle, cognition, memory, and endocrine homeostasis. The H<sub>1</sub> receptor stimulation also causes vasodilation, increases vascular permeability, and increases bronchoconstriction. Cardiac histamine H<sub>1</sub> receptor stimulation increases atrioventricular nodal conduction time.<sup>36</sup>

The H<sub>2</sub> receptors are located in cells of the gastric mucosa, heart, lung, CNS, uterus, and immune cells. The H<sub>2</sub> receptor stimulation is mediated by adenylate cyclase activation of cyclic adenosine monophosphate

(cAMP)-dependent protein kinase in smooth muscle and in parietal cells of the stomach and results in increased gastric acidity through stimulation of the  $H^+$ , $K^+$ -ATPase pump, causing release of  $H^+$  into the gastric lumen. The action of histamine on the  $H_2$  receptor increases sinus node automaticity, ventricular contraction force, and coronary flow as well as vascular permeability and mucus production in the airways.<sup>71,150</sup>

The  $H_3$  receptors are found in neurons of the central and peripheral nervous systems, airways, and GI tract. The action of histamine on  $H_3$  receptors of the CNS decreases further release of histamine, acetylcholine, dopamine, and serotonin. These receptors partly act to prevent excessive bronchoconstriction and are implicated in control of neurogenic inflammation and pro-inflammatory activity.<sup>98</sup>

The  $H_4$  receptors are located in leukocytes, bone marrow, spleen, lung, liver, colon, and hippocampus. The  $H_4$  receptor plays a role in the differentiation of myeloblasts and promyelocytes and in eosinophil chemotaxis.<sup>98</sup>

All 4 types of histamine receptors are heptahelical transmembrane molecules that transduce extracellular signals via G proteins to intracellular second-messenger systems.<sup>150</sup> Xenobiotics acting at each of the 4 histamine-modulated receptor sites are identified. To date, no  $H_3$  or  $H_4$  antihistamines are available for commercial clinical use (Fig. 49-1).

### HISTAMINE RECEPTORS: INVERSE AGONISTS VERSUS ANTAGONISTS

All known  $H_1$  histamine antagonists function as inverse agonists and are not simply reversible competitive antagonists. Rather than preventing the binding of histamine to its receptor as in a classical competitive antagonist model, these xenobiotics stabilize the inactive form of the histamine receptor and shift the equilibrium to this inactive conformation (Fig. 49-2).<sup>150</sup>

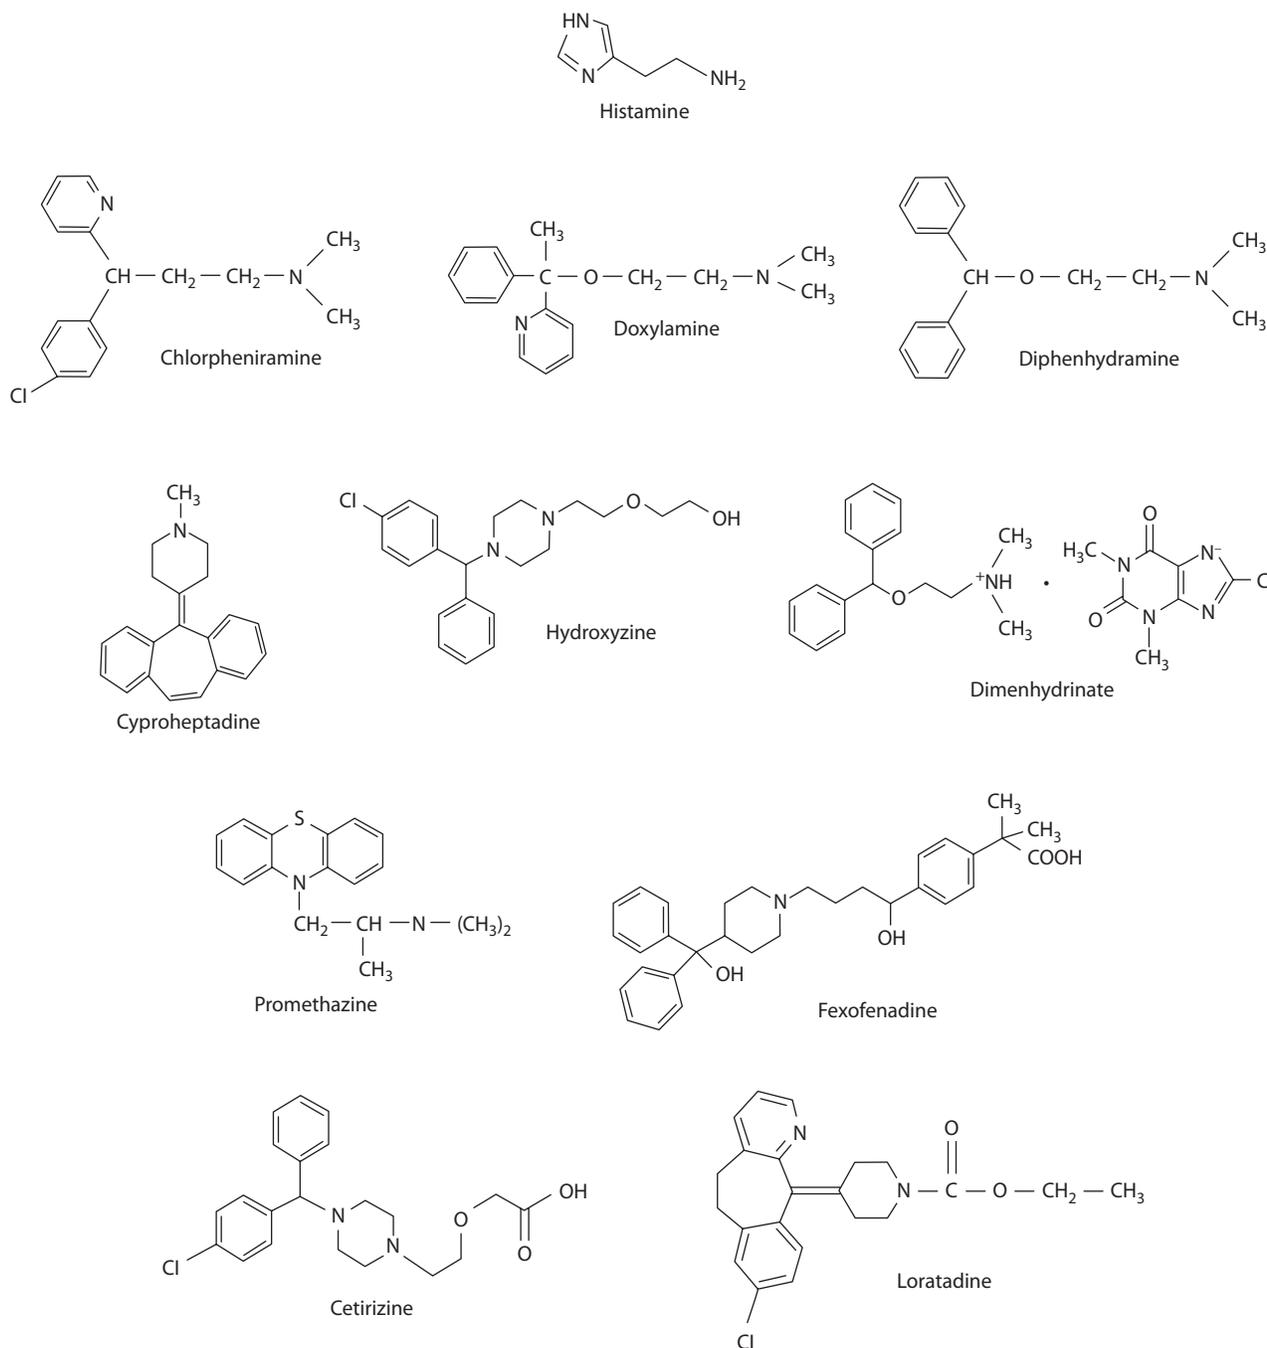

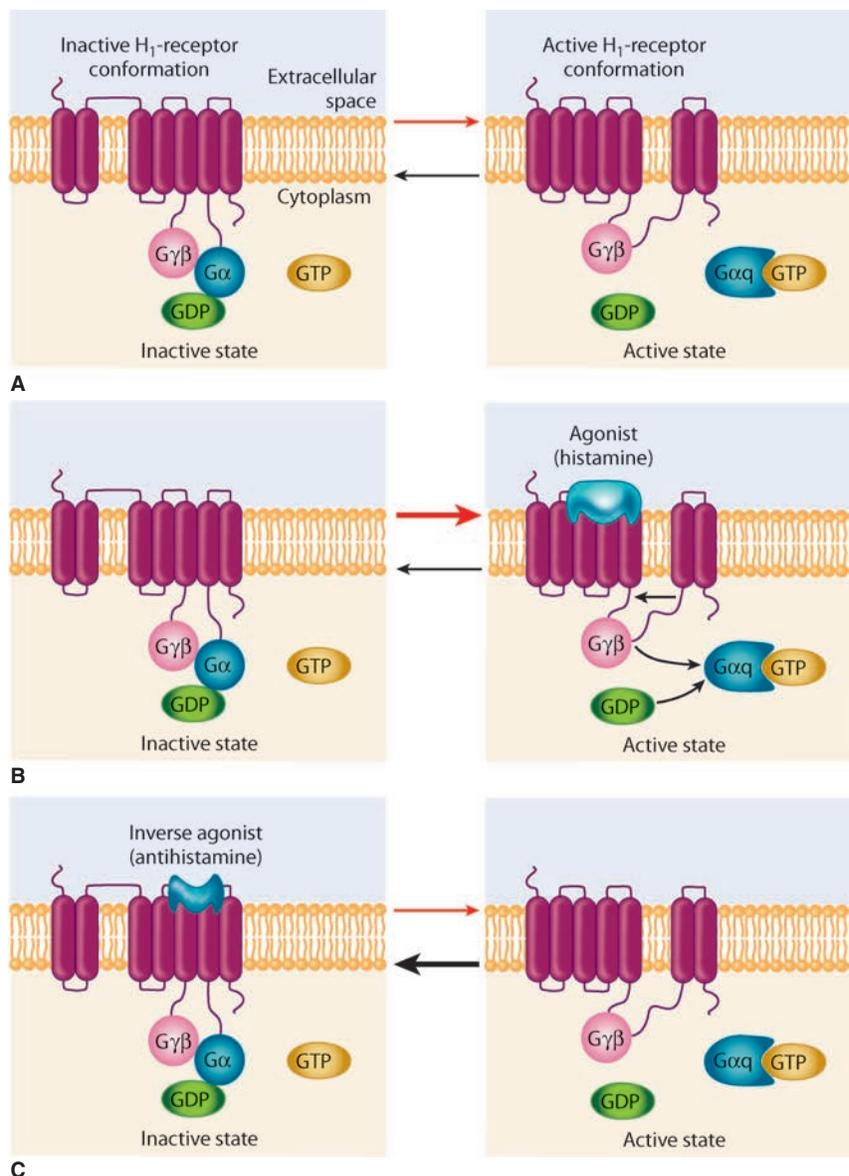

FIGURE 49-1. Structure of histamine and selected  $H_1$  receptor antihistamines.

**FIGURE 49-2.** Action of histamine and antihistamines on the  $H_1$  receptor. *Molecular basis of action of histamine and antihistamines.* (A) The inactive state of the histamine  $H_1$  receptor is in equilibrium with the active state. (B) The agonist, histamine, has preferential affinity for the active state, stabilizes the receptor in this conformation, and shifts the equilibrium toward the active state. (C) An  $H_1$  antihistamine (inverse agonist) has preferential affinity for the inactive state, stabilizes the receptor in this conformation, and shifts the equilibrium toward the inactive state. GDP = guanosine diphosphate; GTP = guanosine triphosphate. (Reproduced with permission from Simons FE, Simons KJ. Histamine and  $H_1$ -antihistamines: celebrating a century of progress. *J Allergy Clin Immunol.* 2011 Dec;128(6):1139-1150.)

However, for consistency with the medical literature and the current terminology for these xenobiotics, the terms *antihistamine* or *histamine antagonist* rather than *inverse agonist* are used.

### $H_1$ Antihistamines

Antiallergic and antiinflammatory activities of the  $H_1$  antihistamines involve multiple mechanisms. Inhibition of the release of mediators from mast cells or basophils involves a direct inhibitory effect on calcium ion channels, thereby reducing the inward calcium current activated when intracellular stores of calcium are depleted. Inhibition of the expression of cell adhesion molecules and eosinophil chemotaxis involves downregulation of the  $H_1$  receptor-activated nuclear factor ( $\kappa B$ ), which binds to promoter or enhancer regions of genes that regulate the synthesis of proinflammatory cytokines and adhesion proteins.<sup>150</sup>

Another classification system of  $H_1$  antihistamines stratifies them by sedating properties and ability to cross the blood-brain barrier and refers to them in terms of generations as they appeared into clinical use. Positron

emission tomography (PET) is now the standard method used to assess  $H_1$  receptor occupancy of antihistamines in the CNS.<sup>192</sup>

**First-generation  $H_1$  antihistamines** readily penetrate the blood-brain barrier and produce CNS effects, including sedation and performance impairment. Central effects of the first-generation  $H_1$  antihistamines likely result from their high lipophilicity or lack of recognition by the P-glycoprotein efflux pump on the luminal surfaces of vascular endothelial cells in the CNS. First-generation  $H_1$  antihistamines also bind to muscarinic, serotonin and to  $\alpha$ -adrenergic receptors as well as cardiac ion channels. Their binding to the voltage-gated  $Na^+$  channels produces use-dependent block because of their much higher affinity to the inactivated  $Na^+$  channels, and their binding to the  $K^+$  channels alters repolarization (Chap. 15).<sup>25,150</sup>

Six major classes of  $H_1$  antihistamines are traditionally recognized based on molecular structure. The classes were initially populated by first-generation derivatives of ethylenediamine (mepyramine, tripelemamine), ethanolamine (diphenhydramine, doxylamine, orphenadrine, dimenhydrat),

alkylamines (pheniramine, chlorpheniramine, brompheniramine), phenothiazines (promethazine), piperazines (hydroxyzine), and piperidines (azatadine). Many of the classic antihistamines are substituted ethylamine structures with a tertiary amino group linked by a 2- or 3-carbon chain with 2 aromatic groups. This structure differs from histamine by the absence of a primary amino group and the presence of a single aromatic moiety.

Some  $H_1$  antihistamines have relatively unique properties that have led to special uses or marketing. Although dimenhydrinate, chlorpheniramine, cyproheptadine, promethazine, and pyrillamine were studied for their local anesthetic properties mediated by  $Na^+$  channel binding, diphenhydramine is the most used antihistamine for this purpose in dentistry since the 1960s.<sup>92</sup> Concerns arose with tissue irritation and skin necrosis when diphenhydramine hydrochloride 5% was used. Even though the 1% solution produces erythema without necrosis, its use should be reserved for patients truly allergic to conventional local anesthetics.<sup>153</sup> Diphenhydramine and doxylamine find frequent application in nonprescription sleeping medications because of their sedative effects. Diphenhydramine and dimenhydrinate have relatively strong antimuscarinic activity and are used for the management of motion sickness. Oxatomide, a sedating  $H_1$  antihistamine, possesses mast cell-stabilizing properties possibly mediated via  $Ca^{2+}$ -channel blockade and is associated with dyskinesia especially in children. Cyproheptadine which has 5-HT<sub>2</sub> antagonist properties is used in the treatment of serotonin toxicity and as prophylaxis for children with migraine headaches (Chap. 69).

**Second-generation  $H_1$  antihistamines** are peripherally selective and have a higher therapeutic index. Second-generation  $H_1$  antihistamines do not penetrate the CNS well because of their hydrophilicity, their relatively high molecular weight, and recognition by the P-glycoprotein efflux pump on the luminal surfaces of vascular endothelial cells in the CNS.<sup>25</sup> Second-generation  $H_1$  antihistamines include astemizole, azelastine, cetirizine, ebastine, ketotifen, levocabastine, loratadine, mizolastine, olopatadine, and terfenadine. They have lower binding affinities for the cholinergic,  $\alpha$ -adrenergic, and  $\beta$ -adrenergic receptor sites than do the first-generation antihistamines. Many are prodrugs that need to be converted in the liver to water-soluble metabolites.

Although not officially accepted terminology, metabolites or active enantiomers of second-generation  $H_1$  antihistamines such as desloratadine, levocetirizine, and fexofenadine are sometimes referred to as *third-generation antihistamines*. They have fewer adverse drug reactions, but no study has confirmed their therapeutic advantages over the parent compounds. Fexofenadine, however, does not have the cardiac toxicity of its parent drug terfenadine. In a test of wheal suppression, which correlates better to receptor occupancy than plasma concentrations, fexofenadine had the earliest onset of action, and levocetirizine showed maximal inhibition at 3 and 6 hours.<sup>57</sup>

Cautious prescribing practices lead to a preference for second-generation  $H_1$  antihistamines in patients whose activities are "safety critical" and would be affected by any psychomotor impairment (eg, those who operate motor vehicles).<sup>64,103</sup> In a randomized placebo-controlled driving simulator trial, 60 mg of fexofenadine did not interfere with driving performance. However, 50 mg of diphenhydramine produced poorer driving performance than ethanol (100 mg/dL). Of note, subjective feelings of drowsiness were not predictors of impairment.<sup>185</sup> Despite these findings, care must be exercised in the selection and use of second-generation  $H_1$  antihistamines because some subjective or objective sedation still results from their use, especially if higher-than-recommended dosages are taken, and particularly with cetirizine.<sup>38,138</sup> Furthermore, a meta-analysis suggested that the differentiation between sedating and nonsedating  $H_1$  antihistamines is subtle, with some studies lacking the methodology to correctly distinguish between medication adverse effects and the signs and symptoms of the condition being treated.<sup>12,164</sup> Overall, the relative incidence of anticholinergic and CNS adverse effects caused by second-generation  $H_1$  antihistamines are similar to that produced by placebo.<sup>38</sup> Using recommended doses of antihistamines, PET scanning shows that first-generation antihistamines occupy more than 70% of the  $H_1$  receptors in the frontal cortex, temporal cortex, hippocampus,

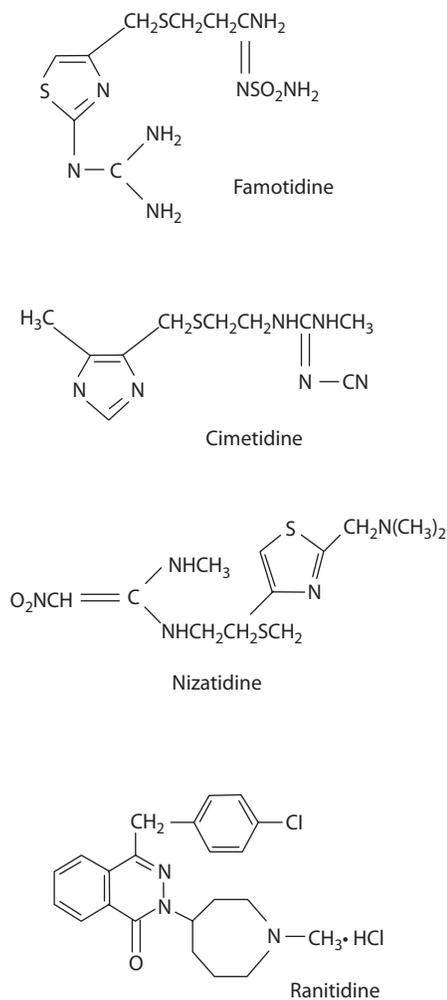

FIGURE 49-3. Structures of  $H_2$  receptor antagonists.

and pons. In contrast, the second-generation antihistamines occupy less than 20% to 30% of the available CNS  $H_1$  receptors.<sup>163,164</sup>

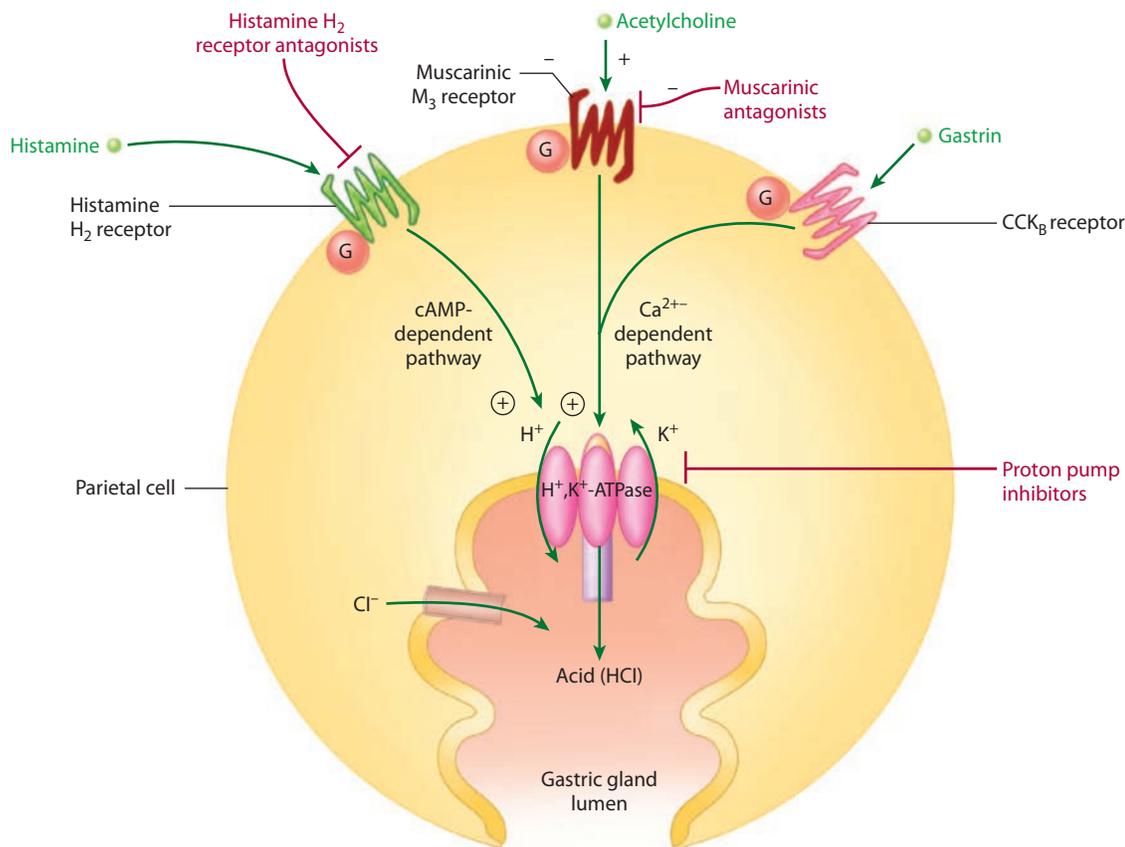

## $H_2$ Antihistamines

These structural analogs of histamine are highly selective inhibitors of the  $H_2$  receptor site. Cimetidine is the original antihistamine in this class; it includes the imidazole ring of histamine (Fig. 49-3). Although ranitidine and famotidine have a furan (ranitidine) or thiazole (famotidine) group instead, they retain significant structural similarity to histamine.

The effectiveness of  $H_2$  antihistamines in the treatment of diseases caused by excessive gastric acid secretion is improved further by their concomitant alteration in the response of parietal cells to acetylcholine and gastrin, 2 other stimulants for gastric acid secretion (Fig. 49-4). Of note,  $H_2$  antihistamines have little pharmacologic effect elsewhere in the body, and they have weak CNS penetration secondary to their hydrophilic properties.

## $H_3$ Antihistamines

These xenobiotics are the focus of much research; however, none is currently commercially available.<sup>194</sup> Some prototypical drugs include ciproxifan, clobenpropit, pitolisant, and thioperamide. This category is further divided into the imidazole-based and non-imidazole-based series.<sup>174</sup> Because of nootropic (cognitive enhancement) and stimulant effects, it is suggested that  $H_3$  antihistamines might play a future role in the treatment of attention deficit and hyperactivity disorder, narcolepsy, depression, or dementia. Pitolisant was granted orphan drug status in the European Union and United States. Its benefit in the treatment of narcolepsy is contested, and it is currently in clinical trials for Parkinson disease and schizophrenia.<sup>143</sup> Conessine, a herbal used in Ayurvedic medicine for dysentery, is also a selective  $H_3$  antihistamine.<sup>55,139</sup>

**FIGURE 49–4.** Schematic representation of a gastric parietal cell demonstrating the mechanism of hydrogen ion secretion into the lumen. Gastric acid is modulated by both the calcium-dependent and cyclic adenosine monophosphate (cAMP)–dependent pathway. Histamine binding to the  $H_2$  receptor increases gastric acidity by increasing cAMP. Both acetylcholine and gastrin increase gastric acidity by increasing the influx of calcium. Whereas acetylcholine binds at the muscarinic 3 ( $M_3$ ) receptor, gastrin binds the cholecystokinin B ( $CCK_B$ ) receptor.

#### $H_4$ Antihistamines

No xenobiotics of this class are currently commercially available. Because of their association with mast cells and eosinophils, clinical trials of  $H_4$  antagonists are studying their potential therapeutic benefit in the treatment of allergic rhinitis, asthma, and autoimmune disorders. The compounds with the most published information are JNJ 397588979 and JNJ 38518168, with efficacy in preclinical models of pruritus, dermatitis, asthma, and arthritis. Toreforant (JNJ 38518168) a histamine  $H_4$  receptor antagonists showed promised in phase II studies in patients with rheumatoid arthritis treated with methotrexate.<sup>167</sup>

#### Atypical Antihistamines

Other xenobiotics are named atypical antihistamines because of their inhibitory effect on the enzyme histidine decarboxylase, which catalyzes the transformation of histidine to histamine as opposed to action on the  $H_1$  receptor. Triloqualine has been commercially available in Europe since the 1960s and is used for persistent allergic rhinitis.<sup>126</sup> To date, no case report of overdose with atypical antihistamines are published.

#### Pharmacokinetics and Toxicokinetics

##### $H_1$ Antihistamines

**Absorption.** The  $H_1$  antihistamines are generally well absorbed after oral administration, and most achieve peak plasma concentrations within 2 to 3 hours. Although less well studied, dermal absorption appears to be consequential, especially with extensive or prolonged application to abnormal skin.<sup>169</sup> The maximum antihistaminic effect occurs several hours after peak serum concentrations. In supratherapeutic or overdose circumstances, absorption is often prolonged by the antimuscarinic effect on the GI tract.

Although ingestion is the usual route of exposure, rare cases of topical preparations containing diphenhydramine and promethazine cause agitation attributed to anticholinergic toxicity in children. Blood concentrations in these patients are often above the peak therapeutic concentration of 0.06 mg/L.<sup>50,73,142,147,190</sup> Many cases were associated with concomitant varicella infection, blurring the causality of the clinical findings attributed to topical diphenhydramine alone. Lumbar punctures were not done to exclude encephalitis, but symptoms improved with cessation of diphenhydramine. Several cases occurred after a bath, calling into question the role of peripheral vasodilation in increasing dermal absorption. Some patients had concomitant oral diphenhydramine therapy but none exceeding the recommended dose of 5 mg/kg/day. One death solely after exposure to topical diphenhydramine is reported in a child with eczema.<sup>169</sup> All cases of topical antihistamine-induced toxicity involved administration covering a significant body surface area of abnormal skin.

**Distribution.** Antihistamines are typically lipid soluble with variable octanol/water partition coefficients. They are also highly bound to plasma protein in therapeutic concentrations. The saturability of protein binding in toxic concentrations is largely unknown. The average volume of distribution is between 0.5 and 12 L/kg but extends to 30 L/kg with desloratadine.

**Metabolism.** Hepatic metabolism is the primary route of metabolism for antihistamines.<sup>122</sup> Cetirizine, fexofenadine, and levocetirizine are exceptions. A poor metabolizer phenotype of desloratadine is identified in both children and adults. In these individuals, the apparent half-life of desloratadine is 50 hours or more compared with the average population whose half-life is around 26 hours.<sup>129</sup> This variability does not appear to impact the safety profile of desloratadine. Many Asian patients acetylate therapeutic concentrations of diphenhydramine to a nontoxic metabolite twice as rapidly as Caucasian patients, making Asians much less sensitive to both the

psychomotor and sedative effects.<sup>159</sup> Results of a study of 100 patients in a sample of 2074 antihistamine users reporting excessive daytime sleepiness after use of H<sub>1</sub> antihistamines (predominantly chlorpheniramine) suggest that the presence of the CYP2D6\*10 allele is a risk factor for development of H<sub>1</sub> antihistamine-induced adverse drug reactions.<sup>140</sup>

**Excretion.** All antihistamines and their metabolites are renally excreted. Moreover, chlorpheniramine elimination is increased in acidic urine. Elderly adults (mean age, 69 years) had similar time to peak concentrations but longer elimination half-lives of diphenhydramine compared with young adults.<sup>152</sup>

Elimination half-life is quite varied for all H<sub>1</sub> antihistamines, with chlorpheniramine, hydroxyzine, azelastine, and levocabastine exhibiting the longest termination half-lives up to 24 hours.<sup>150</sup>

The duration of action ranges from 3 to 24 hours, which is much longer than predicted from the serum elimination half-lives of the antihistamines. One study addressing the pharmacokinetics of diphenhydramine found that children (mean age, 8.9 years) reached peak plasma concentrations faster and had a shorter mean elimination half-life than young adults for the same dosage per kilogram.<sup>150</sup> Similar findings were observed with hydroxyzine.<sup>151</sup> In another volunteer study, desloratadine doses of 1 and 1.25 mg in children between the ages of 6 months and 2 years were found to provide a single-dose target exposure (area under the plasma concentration-time curve) comparable with that experienced by adults receiving the recommended 5-mg dose.<sup>58</sup>

Modifications in therapeutic doses are reasonable for patients with liver or kidney dysfunction, young people, and the elderly. Such modifications often must be made empirically because formal studies and recommendations for many xenobiotics are lacking. Patients with kidney dysfunction are likely more susceptible to developing toxicity from acute ingestion of a second-generation antihistamine, and dose adjustment is recommended for cetirizine, desloratadine, fexofenadine, levocetirizine, and loratadine.<sup>33</sup>

**Drug interactions.** Recognized pharmacokinetic drug interactions involving the H<sub>1</sub> antihistamines are generally caused by modulation of CYP450 metabolism (most often CYP2D6 or CYP3A4) or via interference with active transport mechanisms such as P-glycoprotein or organic anion transporter polypeptide (OATP). The currently available second-generation H<sub>1</sub> antihistamines undergo fewer clinically relevant pharmacokinetic interactions than the first-generation H<sub>1</sub> antihistamines.<sup>9,40</sup>

## H<sub>2</sub> Antihistamines

**Absorption.** Cimetidine is rapidly and completely absorbed after oral administration, but only 40% to 50% of ranitidine and famotidine are bioavailable with a peak concentration within 3 hours. All have reduced absorption when administered concomitantly with food.

**Distribution.** Cimetidine has a volume of distribution of approximately 2 L/kg. Famotidine and ranitidine have a variable volume of distribution in different age groups ranging from 1 to 4 L/kg. All have protein binding in the range of 15% to 25%.

**Metabolism.** Cimetidine has some hepatic metabolism (15%), but ranitidine and famotidine do not (<5%).

**Excretion.** Up to 70% of ranitidine is eliminated unchanged in the urine, and 10% is eliminated unchanged in the stool. Famotidine and cimetidine are also primarily renally excreted. Kidney excretion is lower for oral than for IV administration.

**Elimination half-life.** The elimination half-life in patients with normal kidney function is approximately 2 hours, but the half-life is substantially prolonged with impaired renal function (up to 10 hours) and in elderly adults (4 hours).

**Interactions.** Cimetidine is responsible for numerous drug-drug interactions because it inhibits cytochrome P450 activity, thereby impairing hepatic drug metabolism. It also reduces hepatic blood flow, resulting in decreased clearance of drugs that are highly extracted by the liver. None of the other currently available H<sub>2</sub> antihistamines inhibit the cytochrome P450 oxidase system.<sup>105</sup> Additionally, by altering gastric pH, cimetidine and all of the other

H<sub>2</sub> antagonists potentially alter the absorption of acid-labile xenobiotics. Finally, cimetidine and ranitidine are associated with myelosuppression, particularly when administered with xenobiotics capable of causing bone marrow suppression.<sup>7</sup>

Cimetidine is an inhibitor of ethanol-oxidizing activity of gastric alcohol dehydrogenase (ADH) in human enzymes, but inhibition by nizatidine and famotidine is negligible. It is likely a result of the thiazole group of these H<sub>2</sub> antihistamines preventing binding to the enzymatic substrate site.<sup>160</sup> In vitro data regarding ranitidine inhibition of gastric ADH yielded conflicting results. However, a human study comparing oral versus IV ethanol kinetics with ranitidine showed a significant reduction in first-pass metabolism.<sup>19,65</sup> The first-pass metabolism of ethanol is influenced by the gastric mucosa, but it is unclear by which mechanisms ranitidine might influence increases in blood ethanol concentrations.<sup>118</sup> The literature on the clinical relevance of these effects is conflicting.<sup>18</sup> A meta-analysis of the effect of H<sub>2</sub> antihistamines on serum ethanol concentrations reported small elevations with cimetidine and ranitidine when administered concurrently, but the overall effect seemed unlikely to be clinically significant related to the accepted legal definitions of intoxication.<sup>186</sup> However, a subsequent study when ranitidine was taken regularly for 7 days before drinking demonstrated elevated ethanol concentrations in the range known to impair driving skills.<sup>5</sup> Many Asians have increased gastric ADH as well as decreased ALDH-2.<sup>119</sup> Combined therapy with H<sub>1</sub> and H<sub>2</sub> antihistamines were investigated as a treatment for the "Asian flush" reaction with encouraging results. However, only H<sub>2</sub> antihistamines blocked the flushing reaction<sup>110</sup> (Table 49-1).

## Pathophysiology

The pathophysiology of acute H<sub>1</sub> antihistamine overdose is largely an extension of the expected therapeutic and adverse effects. These effects are best classified in broad categories according to the type of receptors involved. Acute H<sub>2</sub> antihistamine toxicity is explained by a loss of selectivity for the gastric H<sub>2</sub> receptor and inhibition of the cardiac H<sub>2</sub> receptors responsible for positive chronotropy and inotropy.<sup>84,189</sup>

The pathophysiology of H<sub>1</sub> antihistamine abuse is thought to be multifactorial. Humans are reported to abuse dimenhydrinate and diphenhydramine for their euphoric and hallucinogenic effects as well as for their reported anxiolytic and anticholinergic properties.<sup>51</sup> Recreational ingestion up to 5 g is reported, although most common recreational doses used to experience euphoria and hallucinations average 1 g.<sup>60</sup> Promethazine often combined with codeine is widely abused in certain demographic groups.

However, animal studies of self-administration and conditioned place preferences suggest that antihistamines also have a rewarding potential independent of its euphoric effects, which increases with use. Dimenhydrinate abuse is linked to the stimulant effect of the 8-chlorotheophylline component but alone does not produce rewarding effects. However, diphenhydramine antagonizes muscarinic receptors, modulates serotonin function, enhances dopamine concentrations, and potentiates opioid receptors. It is now thought that the combination of diphenhydramine and the methylxanthine (8-chlorotheophylline) as in dimenhydrinate has a synergistic effect on the rewarding potential.<sup>60</sup> The dose-response for this to occur in humans remains to be studied. Older antihistamines such as chlorpheniramine are also selective serotonin receptor inhibitors, which might explain their non-medical use (Table 49-2).<sup>63</sup>

## Clinical Manifestations

### H<sub>1</sub> Antihistamines

The toxic doses for each antihistamine are not well defined. The commonly cited threshold of toxicity of 3 to 5 times the therapeutic dose for first-generation antihistamines as well as cetirizine, loratadine, and fexofenadine originating from algorithms in various articles is not validated.<sup>165</sup> Extrapolating plasma concentrations to an ingested dose is not accurate in predicting clinical effects for diphenhydramine and doxylamine.<sup>89,90</sup> A dose-dependent relationship for diphenhydramine toxicity was published, indicating a high risk of seizures with ingestions above 1.5 g in adults.<sup>130</sup>

TABLE 49-1 Pharmacokinetics Properties of Commonly Used Antihistamines in the United States

Antihistamine		Half-Life (h) <sup>b</sup>	Duration of Action (h) <sup>a</sup>	Hepatic Metabolism	Log D <sup>c</sup>	V <sub>d</sub> (L/kg) <sup>b</sup>	Urinary Elimination (%)	
H <sub>1</sub> antihistamines	First-generation	Chlorpheniramine	12–43 (urine pH dependent)	24	Yes	1.13	5–7	30
		Cyproheptadine	N/A	4–6	Yes	4.93	N/A	72
		Diphenhydramine	3–14	12	Yes	1.92	3–4	4
		Doxylamine	10–11	N/A	Yes	1.15	2.7	N/A
		Hydroxyzine	13–27	24	Yes	2.21	13–31	15
		Promethazine	9–16	4–6	Yes	2.73	9–19	<1

**Neurologic.** Acute overdose of first-generation H<sub>1</sub> antihistamine usually results in the onset of toxicity within 2 hours. Dose–response effects account for the wide spectrum of altered mental status observed. Drowsiness that occurs in milder poisoning rapidly progresses to obtundation and seizures with larger ingestions. Compared with adults, children more commonly

present with excitation, irritability, or ataxia as well as being more prone to having hallucinations or seizures.<sup>8</sup> Patients typically exhibit an anticholinergic syndrome, including mydriasis, tachycardia, hyperthermia, dry mucous membranes, urinary retention, diminished bowel sounds, and altered mental status such as disorientation and hallucinations. The skin appears flushed,

TABLE 49-2 Effects of H<sub>1</sub> Antihistamines

Effects	Clinical Result	First Generation	Second Generation
Mast cell histamine inhibition	Decreased itching Decreased vascular permeability Vasodilation	Therapeutic	Therapeutic
Calcium channel blockade	Decreased mediator release	Therapeutic	Therapeutic
CNS antihistamine receptor occupancy	Sedation Impaired psychomotor performance	Marked effect in therapeutic and overdose	Minimal or no effect reported with cetirizine in overdose
CNS serotonin receptor antagonism	Increased appetite Weight gain	Occurs in therapeutic doses; no significance in overdose	No effect
Peripheral muscarinic receptor antagonism	Dry mucosa Decreased peristalsis Urinary retention Sinus tachycardia Mydriasis	Marked effect in overdose; minimal effect can occur at therapeutic doses	Minimal or no effect
Central muscarinic receptor antagonism	Agitation Delirium Hallucinations	Marked effect in overdose	No effect
α-Adrenergic receptors	Dizziness Hypotension	Marked effect in overdose; minimal effect can occur at therapeutic doses	No effect
Cardiac sodium and potassium channel blockers	Prolonged QRS complex Prolonged QT interval	Marked effect in overdose on Na <sup>+</sup> channel	Minimal or no effect at therapeutic doses except terfenadine, astemizole on K <sup>+</sup> channel

CNS = central nervous system.

warm, and dry. Hyperthermia occurs in severe cases and correlates with the extent of agitation, ambient temperature and humidity, and length of time during which the patient cannot dissipate heat because of anticholinergic-mediated reduction in sweating (Chap. 29).

Some patients with high therapeutic dosing or after overdose develop a central anticholinergic syndrome in which CNS anticholinergic effects, such as hallucinations, outlast peripheral anticholinergic effects. At a later stage of ingestion the lack of tachycardia, skin changes, or other peripheral anticholinergic manifestations complicates establishment of the correct diagnosis for antihistamine poisoned patients unless there is a clear exposure history.<sup>56,184</sup> Ingestion of second-generation H<sub>1</sub> or H<sub>2</sub> antihistamines usually does not result in significant CNS depression or anticholinergic effects except perhaps in pediatric patients or in adults with altered pharmacokinetic parameters. Although dry mouth and mydriasis are common adverse therapeutic effects, sedation is of the greatest concern.

Seizures occur at any point in time in the course of the poisoning but typically begin in the first few hours and represent severe toxicity. Chlorpheniramine is both a serotonin reuptake inhibitor and a postsynaptic 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptor agonist.<sup>79</sup> Agonism of 5-HT receptors is associated with seizures. All first-generation H<sub>1</sub> antihistamines produce seizures, although pheniramine seems to be more proconvulsant than others.<sup>21</sup> Up to 22% of drug-induced seizures in children are related to an antihistamine exposure, and diphenhydramine is a common cause of recreational drug-induced seizures.<sup>1,52,166</sup>

Mydriasis develops at both therapeutic and toxic doses, with most patients describing blurred vision or diplopia. Both vertical and horizontal nystagmus occur in patients with diphenhydramine overdose.<sup>48</sup>

In a review of 136 patients with diphenhydramine overdose, somnolence, lethargy, or coma occurred in approximately 55% of patients, and 15% experienced a catatonic stupor.<sup>89</sup> Several reports suggest that young children experience more respiratory complications, CNS stimulation, anticholinergic effects, and seizures than do adults.<sup>115</sup> In a placebo-controlled study comparing the CNS effects of the first- and second-generation H<sub>1</sub> antihistamines, the second-generation antihistamines caused less cognitive dysfunction and somnolence.<sup>38,70</sup> This finding was corroborated in the simulated driving model in which loratadine produced significantly less impairment than diphenhydramine.<sup>64</sup> Use of diphenhydramine compared with loratadine in a work setting results in significantly higher injury rates.<sup>51</sup> Observational post-marketing cohort studies conducted in England on large numbers of patients reported rates of sedation or drowsiness of fewer than 1% for desloratadine and levocetirizine.<sup>95,96</sup>

**Cardiovascular.** Sinus tachycardia is a consistent finding after overdose with an H<sub>1</sub> antihistamine with anticholinergic effects and can persist after other toxic manifestations and delirium have resolved. Both hypotension and hypertension occur.<sup>100</sup> These findings probably relate more to the patient's age, volume status, and vascular tone than to a specific class of antihistamines. Binding to cardiac ion channels results in prolongation of both the QRS complexes and QT intervals and are reported with most first-generation H<sub>1</sub> antihistamines at doses that are supratherapeutic.<sup>27,92</sup> Brugada-pattern electrocardiographic (ECG) changes are also reported.<sup>99,193</sup>

Cardiotoxicity observed with terfenadine and astemizole resulted from accumulation of the parent drug in cardiac tissue after inhibition of drug elimination (eg, terfenadine–ketoconazole interaction) and was potentially exacerbated by electrolyte (eg, Ca<sup>2+</sup>) imbalances or concomitant use of another ion channel blocker.<sup>13,69</sup> Terfenadine and astemizole are no longer approved for use in the United States and many other countries. Second-generation H<sub>1</sub> antihistamines currently available are less dysrhythmogenic.<sup>56,128</sup> Rare cases of QT interval prolongation are reported in therapeutic situations but the incidence of dysrhythmias with second-generation H<sub>1</sub> antihistamines in overdose is unknown.<sup>3</sup> One study reported 6 cases of patients taking amiodarone with loratadine who presented with episodes of torsade de pointes and syncope. Amiodarone accumulation is reported with co-treatment with loratadine, and all patients made a full recovery after loratadine was stopped. Loratadine accumulation via CYP3A4 inhibition by amiodarone is

the mechanism suspected to explain this occurrence.<sup>4</sup> Prolongation of the QT interval is reported with cetirizine (mainly with kidney failure or large ingestions), but no cases are published with desloratadine or levocetirizine.<sup>3</sup>

**Other.** Rhabdomyolysis occurs in patients with extreme agitation or seizures after an H<sub>1</sub> antihistamine overdose.<sup>53</sup> Rhabdomyolysis is commonly noted in patients who overdose with doxylamine even in the absence of trauma or other common etiologies such as seizures, shock, or crush injuries. The mechanism remains undefined. A prospective study found that 87% of patients who ingested more than 20 mg/kg of doxylamine developed rhabdomyolysis, and this dose was the best predictor of this complication.<sup>76</sup> Another retrospective review found a dose of more than 13 mg/kg to be the only predictive factor of doxylamine-induced rhabdomyolysis.<sup>86</sup> Rhabdomyolysis is reported as a rare adverse event after diphenhydramine overdose.<sup>47</sup> One case of compartment syndrome following ingestion of diphenhydramine alone is published.<sup>179</sup> This complication more commonly occurs in association with other factors such as ethanol intoxication or immobilization. Creatine phosphokinase concentrations are reported as high as 262,000 IU/L without seizure activity.<sup>42,47,85</sup>

Unless complications such as aspiration or kidney failure develop, most patients are symptomatic for 24 to 48 hours with resolution of cardiac symptoms occurring before neurologic recovery. Anticholinergic delirium and residual sinus tachycardia can last a few days, but generally neither requires cardiac monitoring in intensive care settings. Other adverse effects that mostly occur in therapeutic use include pancytopenia and cholestatic jaundice (cetirizine), fixed-drug rash, urticaria, photosensitivity, hyperthermia, elevated aminotransferases, or agranulocytosis. Hypersensitivity reactions to antihistamines are exceptionally rare but are reported.<sup>39</sup> Postmortem findings are generally limited to pulmonary and visceral congestion, suggesting cardiogenic causes of death.<sup>80</sup>

**Special populations.** Elderly patients are more susceptible to adverse events because kidney and liver dysfunction delay antihistamine metabolism.<sup>70</sup> All H<sub>1</sub> antihistamines cross the placenta, and some are teratogenic in animals. First- and second-generation antihistamines fall into FDA categories B and C and should be individually addressed, avoiding or minimizing exposure when possible (Chap. 30). Because of their antimuscarinic effects, the first-generation antihistamines are generally contraindicated in patients with glaucoma or benign prostatic hypertrophy.

## H<sub>2</sub> Antihistamines

These xenobiotics are well tolerated in overdose even after large ingestions. Patients uncommonly develop tachycardia, dilated and sluggishly reactive pupils, slurred speech, and confusion.<sup>158,175</sup> In a retrospective study of acute cimetidine overdoses, 8.9% of patients had symptoms related to the ingestion, and those with reported moderate medical outcomes had ingested cimetidine with suicidal intent. Severe dysrhythmias, including ventricular fibrillation and bradycardia leading to fatal cardiac arrest are reported following rapid IV infusion of cimetidine.<sup>146</sup> Deaths are reported in rare instances of large ingestion of cimetidine.<sup>87</sup>

Famotidine and ranitidine produce even fewer dose-related toxicities in overdose. In addition, they are less likely than cimetidine to induce or inhibit the CYP enzyme system, thereby producing fewer drug–drug interactions.<sup>72</sup>

## Diagnostic Testing

The bedside diagnosis of antihistamine toxicity is a clinical one. Antihistamines cause false-positive results on several rapid urine drug screens by immunoassay for amphetamines (ranitidine), methadone (diphenhydramine, doxylamine), and phencyclidine (diphenhydramine, doxylamine). Cyproheptadine, diphenhydramine, and hydroxyzine also produce false-positive results to tricyclic antidepressants (TCAs) in serum immunoassays only.<sup>162</sup> Such results are of concern, particularly in children, and should always be confirmed if malicious intent is suspected.<sup>136</sup>

Comprehensive blood or urine analysis screening with liquid chromatography/mass spectroscopy (LC/MS) or gas chromatography/mass

spectroscopy (GC/MS) provides antihistamine concentrations, but these are more useful in medicolegal or forensic situations. The turn-around time usually needed is unlikely to provide results at the time of initial assessment. Moreover, treatment is based on alleviation or correction of toxic signs or symptoms and should not depend on a concentration result that does not correlate with toxicity.<sup>85,89,90</sup> Measurement of antihistamine concentrations in body fluids is not readily available and is generally unnecessary for clinical assessment and management.

Several publications estimate the toxic diphenhydramine concentration in children to be approximately 5 mg/L. Fatal antihistamine concentrations are reported with great variability. However, as occurs in adults, toxic effects and fatalities are reported with lower concentrations. Considering diphenhydramine is subject to postmortem redistribution, it would be prudent to obtain blood samples as soon as possible to aid in determining the cause of death in fatalities involving these xenobiotics.<sup>8</sup>

## Management

### General Management

The initial management of a given exposure should begin with a consultation with a poison control center. Guidelines are published and validated with regard to the evidence-based out-of-hospital management of diphenhydramine and dimenhydrinate exposure and allow for home observation for any ingestion under 7.5 mg/kg in children younger than 6 years or under 300 mg or 7.5 mg/kg for adults and older children.<sup>11,141</sup> Other criteria for medical evaluation for other antihistamines vary according to local practices, but in general, ingestions of less than 5 times the maximal therapeutic dose is rarely toxic.

Patients presenting to hospitals after exposure of any antihistamine must be triaged and medically assessed quickly, generally within 30 minutes of arrival, because those who will develop severe complications are initially indistinguishable from those who will have a benign course, and the window for GI decontamination may soon elapse.

The individual should be attached to a cardiac monitor and observed for signs of Na<sup>+</sup> channel blockade (increased QRS complex duration), potassium channel blockade (prolonged QT interval), and related dysrhythmias, as well as for seizures. Intravenous access should be established and airway protection ensured.

Gastrointestinal decontamination is recommended with care to avoid aspiration in patients with large ingestions of first-generation H<sub>1</sub> antihistamines or early presentations but is generally not needed for H<sub>2</sub> antihistamines. The use of oral activated charcoal (AC), although more effective if administered early with regard to time of ingestion, is reasonable even after a delay for ingestion of large amounts that might reduce absorption time. Multiple-dose AC or whole-bowel irrigation (WBI) is usually not indicated. Neostigmine administration was used with success in drug-induced ileus, thus facilitating gut decontamination, but there is not enough evidence to routinely recommend this at the current time.<sup>24</sup>

Enhanced elimination techniques do not benefit the toxicity of these xenobiotics because of their large volumes of distribution, extensive protein binding, and absence of enterobiliary circulation. However, exceptional case reports are published using hemoperfusion and hemodialysis with resolution of the dysrhythmias previously unresponsive to treatment. These patients had ingested 20 mg/kg (adult) and 50 mg/kg (child) of diphenhydramine. All cases reported diphenhydramine concentrations in the fatal range. The mechanism proposed to explain these recoveries is that removal of diphenhydramine from the toxic compartment during extracorporeal treatment might have been enough to improve the distributive shock suspected to be from  $\alpha$ -adrenergic blockade.<sup>106,114,181</sup> Unfortunately, no clearance data, only blood concentrations before and after dialysis, are reported, thus making conclusions on the efficacy of enhanced removal debatable and not recommended.

Assessment of the serum acetaminophen concentration is important because of its inclusion in many cough and cold products. Other laboratory studies should be obtained as indicated by history or physical signs and symptoms. Kidney function and creatine kinase should be obtained on

all patients, particularly in patients with seizures or doxylamine overdose. Serum pregnancy tests should be obtained in women of childbearing age. An ECG should be obtained on all patients during the initial assessment and repeated at regular intervals, particularly if physostigmine use is considered. Continuous ECG monitoring is preferable for high-risk patients such as those with altered mental status or large ingestions.

The patient's vital signs and mental status must be monitored. Serial assessments of the patient's vital signs, particularly temperature, and mental status should be made. The potential for clinical deterioration necessitates management of symptomatic patients in a monitored environment.

### Specific Treatments

**Sedation** can increase the risk for aspiration. Intubation to secure the airway is recommended when excessive sedation compromises ventilation.

**Seizures** should be treated with an IV benzodiazepine such as 2 to 4 mg (0.05–0.1 mg/kg in children) of lorazepam, 2 to 5 mg (0.02 mg/kg in children) of midazolam, or 10 mg (0.2–0.5 mg/kg in children) of diazepam with repeated dosing as necessary.<sup>49,75</sup> Hypertonic saline (3%) was shown to be effective in diphenhydramine-induced seizures in an animal model, but there is not enough evidence to routinely recommend this at the current time.<sup>68</sup> Recurrent seizures refractory to benzodiazepines or hypertonic sodium bicarbonate (see below) should be treated with propofol or general anesthesia. Phenytoin use is discouraged as in most toxicologic-induced seizures.

**Hypotension** generally responds to isotonic fluids (0.9% sodium chloride solution or lactated Ringer solution). If the desired increase in blood pressure is not attained, hypertonic sodium bicarbonate therapy or vasopressors should be titrated to achieve an acceptable blood pressure. In one instance, cardiogenic shock and myocardial depression resulting from a 10-g ingestion of pyrilamine could only be reversed with an intraaortic balloon counterpulsation device.<sup>54</sup> This approach should rarely be needed.

The Na<sup>+</sup> channel blockade (type IA antidysrhythmic) properties of diphenhydramine and other antihistamines leads to wide-complex dysrhythmias that resemble those that occur after cyclic antidepressant overdose (Chap. 68). Hypertonic sodium bicarbonate reverses diphenhydramine or other antihistamine-associated conduction abnormalities (Antidotes in Depth: A5).<sup>27,49,75,145</sup>

Type IA (quinidine, procainamide, disopyramide), IC (flecainide), and III (amiodarone, sotalol) antidysrhythmics are contraindicated because of their capacity to prolong the QRS complex and the QT interval. The successful use of IV lipid emulsion is reported in several case reports, but its efficacy is debated because of other reports with no change in the patient's clinical condition. Because of the current equipoise in its possible efficacy and known adverse effects, its use is reasonable in cases of cardiovascular compromise refractory to standard treatments. The use of lipid emulsion is explained in more detail in another chapter (Antidotes in Depth: A23).

**Rhabdomyolysis**-associated nephrotoxicity should be prevented by early use of IV fluid, NaCl 0.9%, to produce a urine output of 1 to 3 mL/kg/h. Once established, antihistamine-induced rhabdomyolysis is treated with IV fluids.<sup>121</sup> Although urinary alkalization is reportedly helpful to prevent myoglobin-induced nephrotoxicity, its usefulness is controversial and might be best reserved when urinary pH is lower than 6.5 (Antidotes in Depth: A5).<sup>26</sup> Serum potassium concentration and ECGs should be obtained to exclude significant hyperkalemia from muscle injury or acute kidney injury. Initial hypocalcemia caused by precipitation of phosphate from muscle breakdown should not be replaced unless dangerously low because calcium redistributes into the circulation in later phases.<sup>121</sup>

**Hyperthermic** patients should be monitored for the development of disseminated intravascular coagulation and other complications. Cooling via evaporative methods (tepid mist or cooling blanket or fan) is generally sufficient, but patients with severe hyperthermia should receive more rapid cooling using an ice bath (Chap. 29). The goal is to return the patient to a normothermic state as rapidly as possible. There is insufficient evidence to recommend therapeutic hypothermia in poisoned patients with antihistamines.

**Agitation** or psychosis generally responds readily to titration of a benzodiazepine. Although most commonly a direct central effect, other frequent causes of agitation such as urinary retention or bright lights shone into dilated eyes unable to react should not be forgotten. Physostigmine effectively reverses the peripheral or central anticholinergic syndrome and is recommended as a benzodiazepine-sparing strategy, but should only be administered after the initial cardiovascular toxicity, if present, has resolved or is no longer a possibility. It should be used with caution in an attempt to reverse coma or sedation caused by anticholinergic toxicity (Antidotes in Depth: A11).

In a retrospective comparison of physostigmine and benzodiazepines, physostigmine was safer and more effective for treating anticholinergic agitation and delirium.<sup>22</sup> Contraindications to physostigmine use include wide QRS complex or bradycardia noted by ECG, asthma, and pulmonary disease. The primary benefits of physostigmine use in patients with antihistamine overdose include restoration of GI motility, elimination of agitation, and possible obviation of the need for computed tomography (CT) scan or lumbar puncture if the patient regains a normal mental status and can provide a clear history. The anticipated benefits of physostigmine must outweigh the potential risks before its use.

Before physostigmine is administered, the patient should be attached to a cardiac monitor, and secure IV access should be established. Physostigmine (1–2 mg in adults; 0.5 mg in children) should be administered by IV bolus over 5 to 10 minutes with continuous monitoring of vital signs, ECG, breath sounds, and oxygen saturation by pulse oximetry. The initial dose of physostigmine can be repeated at 5- to 10-minute intervals if anticholinergic symptoms are not reversed and cholinergic symptoms such as salivation, diaphoresis, bradycardia, lacrimation, urination, or defecation do not develop. When improvement occurs as a result of physostigmine, repeated doses of physostigmine at 30- to 60-minute intervals are often necessary, taking into account the fact metabolism of the offending xenobiotic is occurring and that subsequent doses might need to be lowered to avoid cholinergic symptoms. Another alternative for confirmed central anticholinergic symptoms expected to last many hours could be the administration of oral anticholinesterases such as donepezil, tacrine, or rivastigmine.<sup>37,117</sup> They are noncompetitive reversible anticholinesterases, crossing the blood–brain barrier, with a longer duration of action than physostigmine. Continuous infusion of physostigmine is a reasonable option to reverse symptoms of anticholinergic toxicity but requires constant ICU level monitoring.<sup>124</sup> A dose of IV atropine should be available at the patient's bedside to treat cholinergic toxicity if it occurs. Although benzodiazepines can be used, excessive sedation with repetitive dosing presents undesirable effects.

## DECONGESTANTS

### History and Epidemiology

#### History

Decongestants are xenobiotics acting on  $\alpha$ -adrenergic receptors, producing vasoconstriction, decreasing edema of mucous membranes, and improving bronchiolar air movement. Ma Huang, the horsetail plant of the Red Emperor, was used in China for at least 2,000 years before it was introduced into Western medicine in the late 19th century by Japanese researchers, who isolated the active ingredient from Ephedra plants. Ephedrine, the first xenobiotic of the sympathomimetic amine class to be used pharmaceutically, was first approved in 1926 by the Council of Pharmacy and Chemistry of the American Medical Association and was very popular in the treatment of asthma. Amphetamines were later synthesized to palliate to a shortage of Ephedra plant availability. Pseudoephedrine is a natural stereoisomer of ephedrine, and phenylephrine was introduced into clinical medicine in the 1930s and in 1949 replaced amphetamines in several compounds. Amphetamine was marketed as nasal decongestant (Benzedrine Inhaler), which was eventually withdrawn in the 1960s because of widespread abuse.

Imidazoline decongestants, on the other hand, were derived from piperazine compounds while investigating their use as uric acid remedies to combat gout. As more imidazolines were synthesized for gout treatment,

one of the compound, tolazoline, was found to have weak adrenergic blocking activity but its naphthyl analogue produced the reverse effect. Naphazoline was introduced in the 1940s as a decongestant. In the decades that followed, many imidazoline decongestants have been developed and tried for clinical use.<sup>156</sup>

### Epidemiology

Despite many years of widespread decongestant use in the United States and sporadic case reports of adverse effects, the magnitude and public health significance of adverse effects of this class of medications was only relatively recently appreciated. From 1991 to 2000, the FDA received 22 spontaneous reports of hemorrhagic stroke associated with phenylpropanolamine (PPA) use, and more than 30 other cases were reported in the literature since 1979. Statistical analysis published in 2000 confirmed that PPA is an independent risk factor for hemorrhagic stroke in women.<sup>23,83</sup> The FDA recommended removal of PPA from the market in 2000 because of its association with intracranial hemorrhages. Many manufacturers took steps to remove or reformulate PPA-containing products well before the FDA rule-making process could be completed.

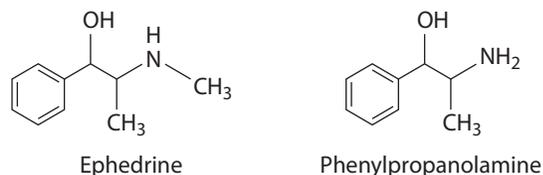

Fatality rates with decongestants suffer from the selection bias of case reporting as well as which xenobiotics are examined. One study addressing the cause of death in children did not include imidazoline derivatives in their search strategy but these xenobiotics might have been included in part of the cases assessed.<sup>34</sup> Despite these biases, studies report a positive association between fatalities in children younger than 2 years and pseudoephedrine-containing cough and cold medications resulting in high pseudoephedrine concentrations. Additional nonfatal adverse events also occurred in the children during that study period.<sup>30</sup>

The majority of reported exposures are unintentional. Data from the 2015 NDPS report shows that only one in 5 cough and cold preparation exposures are intentional.<sup>113</sup> In another study, postmortem analysis of unexpected infant fatalities yielded 10 deaths (ages 17 days–10 months) associated with the use of cough and cold medicines.<sup>134</sup> In response to new information and concerns, the FDA required labeling changes on medications aimed toward young children. In January 2012, the US Consumer Product Safety Commission proposed a new rule requiring child-resistant packaging for any nonprescription drug product containing the equivalent of 0.08 mg or more of an imidazoline in a single package.<sup>172</sup>

Recreational use of ephedrine-containing stimulants is common, and combinations of these xenobiotics with caffeine or other herbs may be marketed as “herbal ecstasy” (Chap. 43). The sale of dietary supplements containing Ephedra, Ma Huang, *Sida cordifolia*, and Pinellia (ephedrine alkaloids) was banned by the FDA in 2004 because of concerns over their cardiovascular effects, including hypertension, seizures, stroke, and dysrhythmias.<sup>39</sup> Companies challenged this rule in court, but it was finally upheld in 2006. Xenobiotics that contain chemically synthesized ephedrine, traditional Chinese herbal remedies, and herbal teas are not covered by the rule. Specific guidelines as to what constitutes a traditional remedy are still unclear and are currently under the FDA dietary supplement category.<sup>171</sup> Since then, many manufacturers have substituted ephedra by *Citrus aurantium*, whose principal ingredient is *p*-synephrine, and are marketing products as being “ephedra free.”<sup>133</sup> The FDA ban on sales of ephedra had a significant reduction on the number of calls to poison control centers and in the number of death.<sup>195</sup>

Imidazoline abuse is also associated with strokes, although population incidences are not reported.<sup>97</sup> Of all the decongestants, only ephedrine and pseudoephedrine are on the list of xenobiotics monitored in competitive sports.<sup>191</sup> Phenylephrine and synephrine concentrations in urine are no longer monitored.

The Combat Methamphetamine Epidemic Act signed into law in March 2006 limited methamphetamine precursor availability and additional precautions in pharmacies such as dispensing limits for nonprescription quantities, requesting personal identification, and storage of the medications behind pharmacy counters. This aimed to reduce potential harm associated with these xenobiotics by closing loopholes contained in the

**FIGURE 49-5.** Structure of ephedrine and phenylpropanolamine decongestants.

previous regulations.<sup>170</sup> The success of such stricter measures has yet to be quantified.<sup>107,116,136</sup> Travel and Internet purchases being more common, it can also be expected that individuals might present with toxicity from xenobiotics not otherwise available in their countries of residence.

## Pharmacology

Decongestants are divided into 2 categories, sympathomimetic amines and imidazolines.

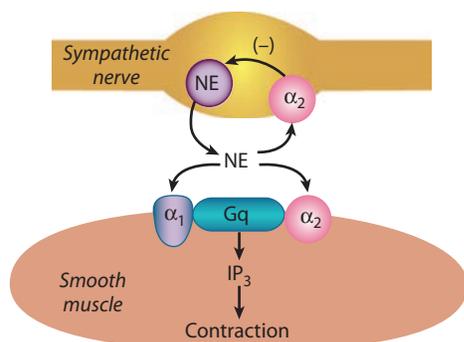

### Sympathomimetics

The decongestants phenylephrine, pseudoephedrine, ephedrine, and PPA (Fig. 49-5) reduce nasal congestion by stimulating the  $\alpha$ -adrenergic receptor sites on vascular smooth muscle.<sup>77</sup> Both  $\alpha_1$ - and  $\alpha_2$ -adrenergic receptor subtypes are linked to a Gq protein activating smooth muscle contraction via the IP<sub>3</sub> signal transduction pathway (Fig. 49-6). This process constricts dilated arterioles and reduces blood flow to engorged nasal vascular beds. The  $\alpha$ -adrenergic mediated decrease in volume ultimately lowers resistance to airflow. Prolonged topical administration produces rebound congestion upon discontinuation; possible mechanisms include desensitization of receptors and mucosal damage. This damage is caused by  $\alpha_2$ -adrenergic-mediated arteriolar constriction, resulting in decreased blood supply to the mucosa.

Phenylephrine is a direct  $\alpha_1$ -adrenergic receptor agonist with very little  $\beta$ -adrenergic agonist activity at therapeutic doses. Pseudoephedrine and ephedrine are mixed-acting direct and indirect nonspecific  $\alpha_{1,2}$ -adrenergic and  $\beta_{1,2}$ -adrenergic receptor agonists. Pseudoephedrine is the D-isomer of ephedrine and has only up to 25% of the adrenergic receptor activity of ephedrine.<sup>43</sup> Phenylpropanolamine is an  $\alpha_{1,2}$ -adrenergic receptor agonist devoid of  $\beta$ -adrenergic receptor activity. Phenylpropanolamine both directly stimulates  $\alpha_{1,2}$ -adrenergic receptors and indirectly stimulates these receptors by causing norepinephrine release.

### Imidazolines

The decongestant effects of the imidazoline class of xenobiotics results from their vasoconstrictive action as  $\alpha$ -adrenergic agonists, with binding to  $\alpha_2$ -adrenergic receptors on blood vessels. In addition, these medications

**FIGURE 49-6.** Mechanism of action of the  $\alpha$ -adrenergic decongestants. The  $\alpha$ -adrenergic decongestants stimulate postsynaptic  $\alpha_1$ - and  $\alpha_2$ -adrenergic receptors to increase the concentration of inositol triphosphate (IP<sub>3</sub>), which mediates vasoconstriction of blood vessels and reduces swollen mucosa. The imidazoline decongestants also bind to postsynaptic  $\alpha_2$ -adrenergic receptors on these blood vessels.

**TABLE 49-3** Effects of Decongestants

	Therapeutic	Duration Action (h)	Toxic
<b>Imidazolines</b>			
Naphazoline	Nasal decongestant	8	Acute: hypertension followed by hypotension, bradycardia, hypoventilation, hypotonia, CNS depression, hallucinations Chronic: mydriasis from ocular administration
Oxymetazoline	Otorrhea reduction	6-7	
Tetrahydrozoline	Nasal decongestant	4-8	
Xylometazoline	Nasal decongestant	5-6	
<b>Sympathomimetic</b>			
Ephedrine	Nasal decongestant	3-5	Hypertension, tachycardia, insomnia, psychosis
Phenylephrine	Nasal decongestant, vasopressor	1	Hypertension, reflex bradycardia
Pseudoephedrine	Nasal decongestant	3-4	Hypertension, tachycardia, insomnia, psychosis

have high affinity for imidazoline receptors, which are located in the ventrolateral medulla and some peripheral tissues. Three classes of imidazoline receptors are recognized. Imidazoline<sub>1</sub> (I<sub>1</sub>) receptors mediate the inhibitory actions of imidazoline xenobiotics to lower blood pressure. The imidazoline<sub>2</sub> (I<sub>2</sub>) receptor is an important binding site for monoamine oxidase, and the imidazoline<sub>3</sub> (I<sub>3</sub>) receptor regulates insulin secretion from pancreatic cells.<sup>62</sup> The imidazoline receptor field is in expansion as more physiological roles are found for these receptors, namely cell proliferation, regulation of body fat, inflammation, pain and opioid addiction, appetite, epilepsy, and neuroprotection. Table 49-3 summarizes the pharmacologic and toxic effect of available decongestants.

The imidazoline (I) category of direct sympathomimetic receptor agonists is generally reserved for topical application. The agonists in this class are used for their local effects in the nasal passages and the eyes. The more common medications include oxymetazoline, tetrahydrozoline, and naphazoline (Fig. 49-7). The  $\alpha_1$ -adrenergic-mediated vasoconstriction is complemented by an additive effect of preferential binding to  $\alpha_2$ -adrenergic receptors located on resistance vessels regulating blood flow. The imidazoline decongestants such as oxymetazoline and naphazoline are pure central and peripheral  $\alpha_2$ -adrenergic receptor agonists; tetrahydrozoline stimulates  $\alpha_2$ -adrenergic receptors and H<sub>2</sub> receptors. These medications are primarily used as nasal decongestants. Tetrahydrozoline is available without a prescription as an ophthalmic preparation to decrease conjunctival injection.

Selective  $\alpha_2$ -adrenergic receptor agonists acting on nasal veins for decongestant effect are being developed to minimize toxicity and adverse effects associated with current nonselective decongestants affecting nasal veins and arteries.<sup>31</sup>

## Pharmacokinetics and Toxicokinetics

### Sympathomimetics

Phenylephrine and other decongestants of this class are pharmacologically active after topical or oral administration. Absorption from the GI tract is rapid, with peak blood concentrations occurring within 2 to 4 hours of ingestion. They have variable hepatic metabolism via monoamine oxidase and mainly renal elimination. Children have shorter elimination half-lives of pseudoephedrine than adults at doses under 60 mg. Urinary elimination of pseudoephedrine is pH dependent.<sup>149</sup> Pseudoephedrine is excreted in breast milk, but use during lactation is considered acceptable.

Toxic effects occur at therapeutic dosage in patients with altered pharmacokinetics such as those with end-stage kidney disease. A meta-analysis found a dose-response relationship between blood pressure and

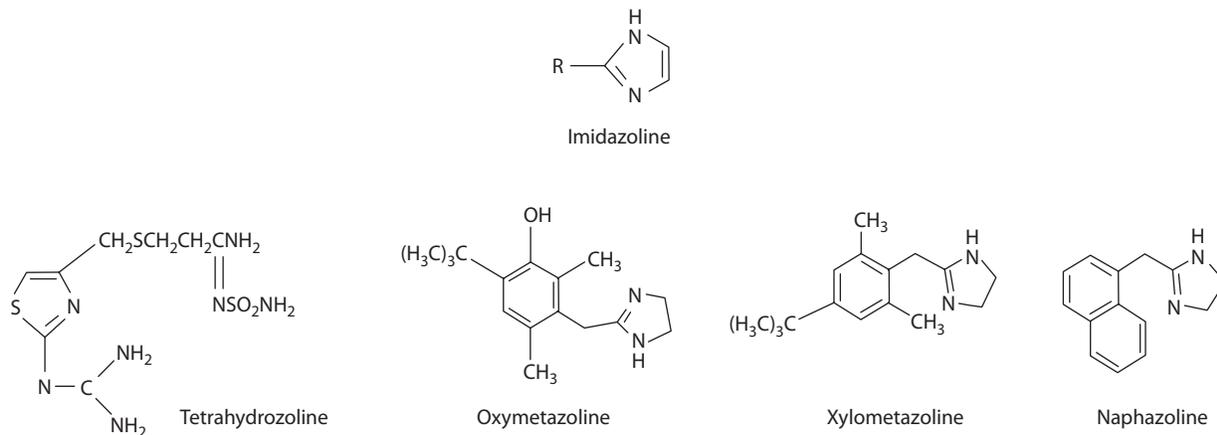

FIGURE 49-7. Structure of imidazoline and the imidazoline decongestants.

pseudoephedrine in therapeutic situations.<sup>137</sup> Toxic symptoms are an extension of the adverse effects and follow a similar dose–response curve.

### Imidazolines

The imidazolines are rapidly absorbed from the GI tract and mucous membranes. Despite their use for many decades, their metabolism is poorly studied.<sup>102</sup> Their elimination half-lives are from 2 to 4 hours. All imidazoline preparations have a relatively rapid onset of action, with 60% of maximum effectiveness occurring after only 20 minutes. Oxymetazoline is the only medication with a duration of action more than 8 hours. The other preparations have an average duration of action of approximately 4 hours.

The toxicity of these medications follows a dose–response curve and accentuates the action on receptors. There is no information regarding modification of pharmacokinetics parameters in suprathreshold conditions.

### Pathophysiology

#### Sympathomimetic

Sympathomimetic decongestants cause their toxic effects via excessive stimulation of the adrenergic system and in effect produce signs and symptoms associated with the sympathomimetic toxidrome. Excessive vasoconstriction can result in end-organ damage to the brain, retina, heart, and kidneys.

### Imidazolines

Imidazolines stimulate imidazoline receptors and produce a sympatholytic effect that in suprathreshold conditions results in marked bradycardia and hypotension.

### Clinical Manifestations

#### Sympathomimetics

Ingestions of less than 1 mg/kg of pseudoephedrine in children are reported to produce almost no toxicity and are generally managed conservatively without the need for hospital evaluation. A study of acute ingestions in children age 6 months to 5 years reported an absence of symptoms at doses lower than 120 mg and lethargy with doses above 360 mg.<sup>188</sup> Following a decongestant overdose of this class, most patients present with a sympathomimetic syndrome with CNS stimulation, hypertension, tachycardia, or reflex bradycardia in response to pure  $\alpha_1$ -adrenergic agonist induced hypertension (Chap. 73). Approximately 4 to 5 times the recommended dose of pseudoephedrine is required to cause hypertension.<sup>43,46</sup> An increase in sinus dysrhythmias is reported in adults with ingestion of 120 mg of pseudoephedrine and moderate exercise.<sup>17</sup> Headache was the most common initial symptom (39%) reported by patients who later developed severe toxicity from PPA. In 45 patients who developed hypertensive encephalopathy from PPA ingestion, 24 patients developed intracranial hemorrhages, 15 developed seizures, and 6 died.<sup>93</sup> Seizures, myocardial infarction, bradycardia, atrial and ventricular dysrhythmias, ischemic bowel infarction, and cerebral hemorrhages are reported, even with therapeutic dosing.<sup>23,182</sup> In a review of 500 reports of

adverse reactions from patients who had ingested ephedrine and associated stimulants as dietary supplements, 8 fatalities from myocardial infarction and cerebral hemorrhage were reported.<sup>123</sup> Psychosis, agitation, and manic behavior are reported with acute ingestion.

### Imidazolines

When ingested, the imidazoline decongestants naphazoline, oxymetazoline, tetrahydrozoline, and xylometazoline are potent central and peripheral  $\alpha_2$ -adrenergic and imidazoline receptor agonists. In overdose, they cause CNS depression, and initial brief hypertension followed by hypotension, bradycardia, and respiratory depression similar to clonidine (Chap. 61).<sup>67</sup> Children are particularly sensitive to the effects of the imidazoline decongestants. Cases of acute stroke are reported in adults with naphazoline abuse.<sup>32</sup>

Rare cases of cardiomyopathy with apical ballooning (Takotsubo) are reported after large ingestion or chronic use of pseudoephedrine or oxymetazoline.<sup>183,196</sup> Acute respiratory distress syndrome from vasoconstriction of pulmonary vessels can also occur with both classes of decongestants. Reversible encephalopathy with bilateral posterior hemispheric edema on neuroimaging was reported after nonprescription use of pseudoephedrine albeit in a patient with an autoimmune disorder that might have been a predisposing factor.<sup>44</sup> Toxic effects usually resolve within 8 to 16 hours. However, they may persist for more than 24 hours if a sustained-release product is ingested.

### Diagnostic Testing

The bedside diagnostic of decongestant toxicity is a clinical one. Sympathomimetic decongestants cause false-positive results for amphetamines on several rapid urine drug screens by immunoassay.<sup>112</sup> Comprehensive blood or urine analysis screening test by LC/MS or GC/MS can be obtained for research purposes, in child abuse, or in forensic studies to determine the cause of death. They have no role in the immediate clinical management of poisoned patients.

### Management

Patients presenting after an exposure to decongestants should be triaged promptly and brought to a monitored environment. A cardiac monitor should be attached to the patient and observed for dysrhythmias. Intravenous access should be established and airway protection ensured. Gastrointestinal decontamination with AC is recommended in patients with large ingestions of pseudoephedrine if no contraindications are present. A retrospective study of xylometazoline ingestion in children reported toxicity above nasal or oral exposure exceeding 0.4 mg/kg body weight. Ingestions of more than 0.1 mg/kg of naphazoline or tetrahydrozoline produced severe toxicity in children. The decision to give AC in these instances should be made individually because liquid formulations are rapidly absorbed and might not be amenable to AC adsorption by the time of presentation.<sup>176</sup> Activated charcoal administration is reasonable even several hours after ingestion of sustained-release decongestant preparations. More than one dose of AC is reasonable to complete GI

decontamination in massive ingestion of oral preparations, but multidose AC for enhanced elimination purposes has no role. Whole-bowel irrigation and renal-enhanced elimination techniques are not indicated.

### Specific Treatment

**Neurologic toxicity.** Patients with extreme agitation, seizures, and psychosis should initially be treated with administration of oxygen and IV benzodiazepines, titrated upward to effect. A patient with a persisting headache, focal neurologic deficits, or abnormal neuropsychiatric findings after decongestant ingestion should be evaluated for cerebral hemorrhage by noncontrast head CT. If the timing of the imaging is delayed, reducing the sensitivity of this modality, subsequent lumbar puncture to exclude subarachnoid hemorrhage is reasonable based on clinical suspicion.

**Respiratory toxicity.** Children presenting with respiratory depression from imidazoline decongestants have responded to naloxone. These case reports are too few to establish the efficacy of this therapy. Nevertheless, the use of naloxone in imidazoline toxicity is reasonable and low risk in non-opioid-dependent patients.<sup>20,81</sup>

**Cardiovascular toxicity.** Tachycardia, palpitations, and hypertension that occur in mild sympathomimetic poisonings usually respond to benzodiazepines. For a patient who remains hypertensive or is believed to have chest pain of ischemic origin treatment with phentolamine, an  $\alpha$ -adrenergic antagonist, or nicardipine is recommended. Labetalol has been proposed and used in some reported cases; however, because of its different affinity for  $\alpha$ - and  $\beta$ -adrenergic receptors depending on the route of administration, its use is not recommended when coronary vasospasm is suspected.<sup>177</sup> Labetalol is a more potent  $\beta$ - than  $\alpha$ -adrenergic receptor antagonist when given intravenously.<sup>94,108</sup> Beta-adrenergic antagonists should be avoided because of concern for unopposed  $\alpha$ -adrenergic effects. An ECG is required, and any elevation of the ST segment warrants immediate consultation with a cardiologist.

Patients with ventricular dysrhythmias from sympathomimetic decongestants should be treated with standard doses of lidocaine or sodium bicarbonate (if the QRS complex is prolonged). The evidence for efficacy of amiodarone in this setting is still lacking.<sup>41,131</sup> Phenylpropanolamine causes hypertension with a reflex bradycardia and atrioventricular block that is responsive to standard doses of atropine. Atropine must be used with caution because it can cause a dangerous increase in blood pressure as the reflex bradycardia reverses. Therefore, a vasodilator such as phentolamine is recommended because the stimulus for the bradycardia is corrected with reversal of the hypertension.

Imidazoline-induced hypertension rarely requires therapy, but in the setting of symptomatic hypertension, a short-acting  $\alpha$ -adrenergic antagonist such as phentolamine is reasonable.<sup>187</sup> However, the hypertension is generally transient and followed by hypotension. Initial antihypertensive therapy could exacerbate toxicity and should only be reserved for cases in which severe hypertension represents a true urgency for end-organ damage.

### SUMMARY

- Within a few hours of ingestion of H<sub>1</sub> antihistamines, anticholinergic toxicity is expected.
- Cardiotoxicity via sodium channel blockade can be fatal and is treated with sodium bicarbonate.
- Physostigmine or other anticholinesterases are recommended to reverse anticholinergic effects of H<sub>1</sub> antihistamines.
- H<sub>2</sub> antihistamines rarely result in symptoms or signs of toxicity.
- Decongestants used for recreational purposes can be ingested in doses that produce toxic sympathomimetic effects.
- Patients with abnormal mental status or seizures should be investigated to exclude intracranial hemorrhages.
- Topical imidazoline decongestants can produce toxicity, typically in the form of hypotension and bradycardia.
- The treatment of patients with toxicity from sympathomimetic decongestants follows the same treatment guidelines as amphetamines and other sympathomimetics.

## PHYSOSTIGMINE SALICYLATE

Mary Ann Howland

## INTRODUCTION

Physostigmine is a carbamate that reversibly inhibits cholinesterases in both the peripheral and central nervous system (CNS).<sup>60</sup> The tertiary amine structure of physostigmine permits CNS penetration and differentiates it from neostigmine and pyridostigmine, which are quaternary amines that have limited ability to enter the CNS. The inhibition of cholinesterases prevents the metabolism of acetylcholine, allowing acetylcholine to accumulate and antagonize the antimuscarinic effects of xenobiotics such as atropine, scopolamine, and diphenhydramine.<sup>23,43,72</sup> Although physostigmine previously was used as an antagonist to the antimuscarinic effects of cyclic antidepressants and phenothiazines, we currently recommend against this use because of a poor risk-to-benefit ratio, and the potential for exacerbation of life-threatening cardiotoxicity. Similarly, physostigmine has a poor risk-to-benefit ratio in the management of presumed  $\gamma$ -hydroxybutyric acid (GHB) and baclofen toxicity.<sup>5,49,63,73</sup> Atypical antipsychotics have complex pharmacologic effects. Although some atypical antipsychotics, such as quetiapine and olanzapine, have significant antimuscarinic side effects, the benefit of treating these anticholinergic effects with physostigmine must be weighed against the potential risks of exacerbating cardiotoxicity.<sup>10,25,61,70</sup>

## HISTORY

The history of physostigmine dates back to antiquity and the Efik people of Old Calabar in Nigeria.<sup>21,27,30,60</sup> The chiefs in this area used a poisonous concoction made from the beans of an aquatic leguminous perennial plant found in the area to create a judicial test, the *esere ordeal*. *Esere* was the word used to represent both the bean and the ritual used to test the innocence or guilt of an accused person. The chiefs also believed that the *esere* had the power to detect and kill persons practicing witchcraft. Supposedly, innocent persons quickly swallowed the poison, which resulted in immediate emesis.<sup>30</sup> Vomiting allowed the innocent to survive without therapy or to be given an antidote of excrement in water. The guilty, however, hesitated swallowing, leading to speculation that sublingual absorption led to severe systemic symptoms without the benefit of vomiting. These persons were noted to develop mouth fasciculations and died foaming at the mouth. Daniell, a British medical officer stationed in Calabar, brought samples of the bean and the plant back to England in 1840.<sup>30</sup> John Balfour, a professor of medicine and botany at the Edinburgh Medical School, characterized the plant, which became known as *Physostigma venenosum Balfour* (family Leguminosae), in 1857. The active alkaloid was isolated by Jobst and Hesse in 1864 and was named physostigmine. Independently, one year later Vee and Leven also isolated and named the active alkaloid eserine. This year also saw physostigmine's first antidotal use.<sup>41</sup>

Christison performed the first toxicologic studies, including self-experimentation with increasing doses of the seed. Fraser, Christison's student and successor, originated the concept of antagonism from his experiments with physostigmine and atropine. Fraser plotted the dose relationships between the effects of atropine versus physostigmine on various organs such as the eye and the heart, demonstrating the antidotal effects of atropine for the lethal effects of physostigmine.<sup>21</sup> Subsequent experiments with physostigmine led to the development of the theory of neurohumoral transmission.<sup>27</sup> By the 1930s, physostigmine was used as a miotic for patients with glaucoma, a treatment for myasthenia gravis, for reversal of the paralytic effects of curare, and an antidote for atropine and nicotinic insecticides.

## PHARMACOLOGY

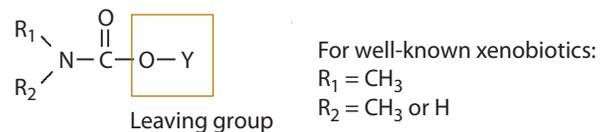

## Chemistry

Physostigmine salicylate is the salicylate salt of physostigmine, a carbamate with a molecular weight of 275 Da. **Figure A11-1** shows the general formula for carbamate cholinesterase inhibitors and the chemical structures of physostigmine ( $C_{15}H_{21}O_2N_3$ ), a tertiary amine, and neostigmine, a quaternary amine. Naturally occurring physostigmine consists of a racemic mixture with the (-) isomer greater than 100 times more potent in inhibiting acetylcholinesterase.<sup>56</sup>

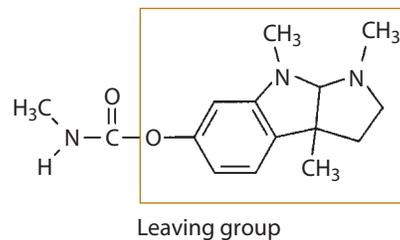

## Mechanism of Action

Physostigmine is a reversible inhibitor of acetylcholinesterase. Similar to acetylcholine, physostigmine is a substrate for the cholinesterases (choline ester hydrolases), erythrocyte acetylcholinesterase, and plasma cholinesterase. Both acetylcholine and physostigmine bind to cholinesterases to form a complex, from which part of the complex known as the *leaving group* (ie, choline for acetylcholine) is removed, and the remaining acetylated (for acetylcholine) or carbamylated (for physostigmine) enzyme is hydrolyzed, regenerating the enzyme and freeing the acetate or carbamate groups, respectively (**Figs. 110-2** and **110-3**). For acetylcholine, the

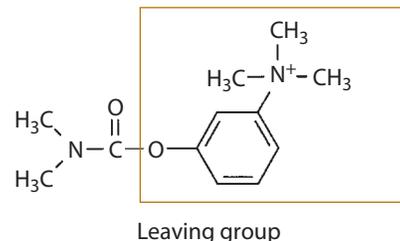

## A. General structure of carbamate inhibitors

## B. Physostigmine

## C. Neostigmine

**FIGURE A11-1.** (A) General formula for carbamate cholinesterase inhibitors. (B) Structure of physostigmine. (C) Structure of neostigmine.

process is extremely rapid, with a turnover time of 150 milliseconds. In contrast, the half-life for hydrolysis of the carbamylated enzyme is 15 to 30 minutes.<sup>60</sup> The  $I_{50}$  (molar concentration that inhibits 50% of the enzyme) of physostigmine is  $2.3 \times 10^{-7}$  mol/L (M) for acetylcholinesterase, which is much weaker than for other carbamates at  $1 \times 10^{-10}$  M and many organic phosphorus compounds at  $1 \times 10^{-11}$  M.<sup>28</sup> Only the *S*-isomer of physostigmine inhibits cholinesterases, with plasma cholinesterase slightly more sensitive than acetylcholinesterase.<sup>4</sup> Newer xenobiotics used in the treatment of Alzheimer disease<sup>13</sup> show selectivity for the CNS and for acetylcholinesterase. This group includes tacrine, donepezil, and galantamine, which are reversible cholinesterase inhibitors, and rivastigmine, considered a pseudo-irreversible or slowly reversible inhibitor. These pharmaceuticals and neostigmine<sup>29</sup> have undergone limited study for reversal of anticholinergic poisoning.<sup>13,29,33,53</sup>

### Pharmacokinetics and Pharmacodynamics

Physostigmine is poorly absorbed orally, with a bioavailability of less than 5% to 12%.<sup>1,46</sup> Cholinesterases rapidly cleave the ester linkage, resulting in very little unaltered physostigmine elimination in the urine. Pharmacokinetic parameters after intravenous (IV) administration of 1.5 mg over 60 minutes in 9 patients with Alzheimer disease demonstrated the following: volume of distribution,  $2.4 \pm 0.6$  L/kg; half-life,  $16.4 \pm 3.2$  minutes; peak serum concentration,  $3 \pm 0.5$  ng/mL; and clearance, 0.1 L/min/kg (7.7 L/min). There was a threefold interindividual variability in plasma physostigmine concentrations. Plasma cholinesterase concentrations demonstrated inhibition within 2 minutes of initiating the physostigmine infusion. The half-life of plasma cholinesterase inhibition was  $83.7 \pm 5.2$  minutes, with full recovery within 3 hours of termination of physostigmine infusion. The effects on plasma cholinesterase inhibition lasted approximately 5 times longer than the half-life of physostigmine.<sup>32</sup> All patients experienced varying degrees of diaphoresis, nausea, vomiting, headache, and generalized fatigue despite pretreatment with 2.5 mg of methscopolamine.<sup>3,32</sup>

### ROLE IN ANTIMUSCARINIC TOXICITY

Physostigmine was first used as an antidote in 1864 to counteract severe atropine poisoning.<sup>41</sup> Today its role is primarily in the treatment of antimuscarinic poisoning. More than 600 xenobiotics respond to physostigmine.<sup>14</sup> Anticholinergics fall into the categories of antimuscarinic (atropine, scopolamine, hyoscyamine, propantheline, benztropine, trihexyphenidyl), neuromuscular blockers (curare), and ganglionic blockers (trimethaphan). Other xenobiotics (antihistamines, antipsychotics, and antidepressants) have antimuscarinic properties that are not their primary therapeutic actions and are often considered adverse drug effects.

The clinical use of physostigmine has varied over time.<sup>2,15,51,55,67</sup> Owing to its ability to cause CNS arousal, physostigmine was used in the 1970s to reverse the CNS effects of a large number of antimuscarinics and used inappropriately to treat toxicity from nonantimuscarinics.<sup>22,37,39,42,47</sup> The success with regard to antimuscarinics is directly related to the inhibition of cholinesterase. The effects of physostigmine on nonantimuscarinic xenobiotics such as the benzodiazepines, opioids,<sup>34,48,68</sup> GHB,<sup>5,63</sup> and baclofen<sup>50</sup> result from either the direct action of acetylcholine on the reticular activating system or interdependence of central neurotransmitters.<sup>42</sup> Few serious adverse effects are reported.<sup>66</sup> However, asystole followed administration of physostigmine in 2 patients with tricyclic antidepressant (TCA) overdose, and others have also reported these findings.<sup>44,52,62</sup> In addition, animal experiments do not support the use of physostigmine for this overdose.<sup>19,64,71</sup> This occurrence led to the realization that toxicity from TCA is complex and consists of more than just antimuscarinic effects.<sup>44</sup> Cyclic antidepressant-induced sodium channel blockade causes myocardial depression, QRS complex prolongation, and ventricular dysrhythmias. Physostigmine augments vagal effects, thus contributing to decreased cardiac output and cardiac conduction defects. An extensive review of the literature concluded that the safety of physostigmine use for seizures or cardiotoxicity in the setting of cyclic antidepressant toxicity was difficult to predict and thus not recommended, and we agree.<sup>59</sup>

In most instances, risks of physostigmine use for xenobiotics that are not primarily antimuscarinic outweigh any benefit.

This analysis is certainly also true with regard to GHB (Chap. 80).<sup>63</sup>  $\gamma$ -Hydroxybutyric acid is often used concomitantly with other xenobiotics, and the clinical manifestations are highly variable.<sup>73</sup> Recovery from GHB typically occurs spontaneously within several hours (16 minutes to 6 hours).<sup>8,9,17,35,63,65</sup> Three patients in whom a presumptive diagnosis of GHB toxicity was made were treated with physostigmine.<sup>8</sup> The 3 patients had an improved mental status within 5 to 15 minutes. One of these patients relapsed and then fully awakened 40 minutes later. This patient was incontinent of feces, an adverse effect likely caused by the physostigmine.<sup>8</sup> All 3 of the patients were arousable before physostigmine use. Although anesthetic study of GHB in the 1970s is the rationale cited for the current use of physostigmine, it is illogical in the care of those who illicitly use GHB because of limited demonstrated benefit and significant undetermined risks.<sup>26</sup>

However, in cases of antimuscarinic overdose, physostigmine use clearly is beneficial.<sup>7,51</sup> A study of 52 patients showed that whereas benzodiazepines controlled agitation in 24% of patients and were ineffective in reversing delirium, physostigmine controlled agitation and reversed delirium in 96% and 87% of patients, respectively.<sup>7</sup> A shorter time to recovery after agitation was observed in those treated with physostigmine. No significant differences between these groups with regard to side effects or length of stay were noted.<sup>7</sup>

We recommend the use of physostigmine in the presence of peripheral or central antimuscarinic manifestations without evidence of significant QRS complex prolongation. Peripheral manifestations of an antimuscarinic include dry mucosa, dry skin, flushed face, mydriasis, hyperthermia, decreased bowel sounds, urinary retention, and tachycardia. Central manifestations include agitation, delirium, hallucinations, seizures, and coma.<sup>20,24,36</sup> The peripheral and central findings are usually present on clinical presentation.<sup>1,6,11,16,18,28,54,58</sup> Rarely, the central findings may persist longer than the peripheral findings, or be more prominent.

### ADVERSE EFFECTS AND SAFETY ISSUES

An excess of physostigmine results in accumulation of acetylcholine at peripheral muscarinic receptors, nicotinic receptors (skeletal muscle, autonomic ganglia, adrenal glands), and CNS sites.<sup>31</sup> Muscarinic effects produce stimulation of smooth muscle and glandular secretions in the respiratory, gastrointestinal, and genitourinary tracts, and inhibition of contraction of most vascular smooth musculature.<sup>2,40</sup> Nicotinic effects are stimulatory at low doses and depressant at high doses. For example, acetylcholine excess at the neuromuscular junction produces fasciculations followed by weakness and paralysis. Its effect on the CNS results in anxiety, dizziness, tremors, confusion, ataxia, coma, and seizures.<sup>31</sup> Electroencephalograms demonstrate asynchronous discharges followed by higher voltage discharges and a pattern similar to tonic-clonic seizures.<sup>31</sup> The cardiovascular effects are dose dependent and directly related to the presence of the diverse muscarinic and nicotinic effects.<sup>31</sup> In addition to its inhibition of cholinesterase, physostigmine has a direct action on the nicotinic acetylcholine receptor ionic channel.<sup>38,57</sup>

Physostigmine toxicity results when physostigmine is used in the absence of antimuscarinic toxicity or when excess doses are administered relative to the antimuscarinic xenobiotic exposure. Patients overdosed with physostigmine should be managed with intensive supportive care, including mechanical ventilation if needed; IV atropine<sup>69</sup> titrated to reverse bronchial secretions; and, rarely, pralidoxime to reverse skeletal muscle effects.<sup>12</sup>

We do not recommend administering physostigmine to patients with reactive airway disease, peripheral vascular disease, intestinal or bladder obstruction, intraventricular conduction defects, and atrioventricular block or in patients receiving therapeutic doses of choline esters and succinylcholine.<sup>45,46</sup> It is unclear why the package insert also lists diabetes as a contraindication and there is no reason to limit use for these patients if indicated clinically.<sup>45</sup> Drug interactions with cholinergic agonists (eg, ophthalmic pilocarpine); depolarizing neuromuscular blockers; or other anticholinesterases such as carbamates, organic phosphorus compounds, and pyridostigmine are

expected to be additive clinical effects when taken concomitantly with physostigmine. The actions of xenobiotics metabolized by plasma cholinesterases such as cocaine, succinylcholine, or mivacurium are expected to be prolonged.

Physostigmine salicylate injection contains sodium metabisulfite as a preservative.<sup>45</sup> Sulfites may cause life-threatening anaphylactoid reactions in susceptible individuals.

## PREGNANCY AND LACTATION

Physostigmine is US Food and Drug Administration pregnancy category C. Little information is available regarding the effects of physostigmine in pregnancy. Transient muscular weakness occurred in 10% to 20% of neonates whose mothers received anticholinesterase treatment for myasthenia gravis.<sup>46</sup> Physostigmine should only be given when the benefit clearly outweighs the risk. Safety in lactation is not established.

## DOSING AND ADMINISTRATION

Prior to administration of physostigmine, the patient should be attached to a cardiac monitor and atropine placed at the bedside. The recommended dose of physostigmine is 1 to 2 mg in adults and 0.02 mg/kg (maximum, 0.5 mg/dose) in children intravenously infused over at least 5 minutes. The onset of action usually is within minutes.<sup>28</sup> It is reasonable to repeat this dose after 10 to 15 minutes if an adequate response is not achieved and muscarinic effects are not noted. Rapid administration is likely to cause bradycardia, hypersalivation leading to respiratory difficulty, and seizures. Although the half-life of physostigmine is approximately 16 minutes, its duration of action usually is much longer (often >1 hour) and is directly related to the duration of cholinesterase inhibition.<sup>3</sup> After reversal of anticholinergic symptoms, additional doses are recommended if clinical relapse occurs. The effective dose depends on the ingested dose and duration of action of the antimuscarinic xenobiotic. Although a total of 4 mg in divided doses usually is sufficient in most clinical situations,<sup>20</sup> significant interindividual variability exists. Atropine should be available at the bedside and titrated to effect should excessive cholinergic toxicity develop. A dose of atropine administered at half the physostigmine dose is recommended.

## FORMULATION AND ACQUISITION

Physostigmine is available in 2-mL ampules containing 1 mg/mL of physostigmine salicylate. The vehicle contains sodium metabisulfite and benzyl alcohol.<sup>45</sup>

## SUMMARY

- Physostigmine is used for the management of patients with an antimuscarinic syndrome, particularly those who have an agitated delirium and a normal QRS complex duration.
- In these patients, physostigmine has an excellent risk-to-benefit profile.

# CHEMOTHERAPEUTICS

Richard Y. Wang

Chemotherapeutics or antineoplastics are a unique class of pharmaceuticals commonly used to kill cancer cells. The conventional chemotherapeutics are also toxic to noncancerous cells in the host, which makes an overdose of these pharmaceuticals a major concern to clinicians. Most overdoses from conventional chemotherapeutics are iatrogenic, and they involve misreading of the product label, and errors in dosing and transcription of orders (Chap. 134). A key element in these incidents is the lack of familiarity of the clinician with the use of these select pharmaceuticals. In the last several years, the use of chemotherapeutics has changed. For example, therapeutic indications now include other diseases, such as autoimmune diseases; the new chemotherapeutics target cancer cells and many of them are administered orally, and new delivery techniques are available. These new developments will increase the number and frequency of unintentional exposures and unintended dosing regimens, although the adoption of safety standards for the administration limits these errors (Chap. 134).<sup>24,31</sup>

Although overdoses of chemotherapeutics are infrequent, these events are of greater consequence than overdoses of many other xenobiotics because these drugs have a narrow therapeutic index. This is evident from surveillance data from poison control centers in the United States. From 1988 to 2015, the median annual number of people exposed to chemotherapeutics reported to US poison control centers was about 1200. In the last 10 years of data, the number of annual exposures to these chemotherapeutics went from 1649 in 2006 to 2039 in 2015 (Chap. 130). These exposures represent about 0.1–0.2% of pharmaceutical exposures, or 0.06–0.1% of all exposures annually reported to US poison control centers. Approximately two-thirds of the people exposed to chemotherapeutics in these reports were adults, one-fourth of the group were young children, and the remainder were adolescents. The annual trend for the proportion of exposures among adults and children remained at approximately 70% and 25%, respectively, from 2001 to 2015. Children and adolescents between the ages of 6 and 19 years accounted for approximately 6% of the population annually exposed, and this frequency did not change during these years. Although these differences among age groups might represent the incidence of cancer in these populations, further analysis is warranted to better define the reasons for these observations.

Among single exposures to chemotherapeutics reported to US poison control centers from 2007 to 2015, the annual percentage of unintentional exposures approached 90% and the annual percentage of exposures resulting in moderate or major severity in toxicity remained at approximately 6%. The mortality was about 0.2–0.3% of single exposures in this same period. These observations are attributed to the substantial toxicity of these chemotherapeutics. A prospective study on medication safety in the ambulatory chemotherapy setting demonstrated that potential adverse drug events from medical errors for chemotherapy orders were more likely to be serious than nonchemotherapy orders.<sup>21</sup> The prevalence of the exposure to chemotherapeutics is expected to continue increasing because of the increased availability of oral formulations<sup>71</sup> and their expanding therapeutic indications, but their severity is likely to fall as the immunotherapies become more widely utilized.

## PATIENT-SPECIFIC FACTORS CONTRIBUTING TO TOXICITY

Aside from unintentional exposures, additional factors leading to increased toxicity associated with chemotherapeutics include age, sex, comorbidities, compromised host state, and diminished kidney and liver functions. Diminished hepatic clearance caused by altered enzyme expression is accounted for by age, sex, smoking status, and the concurrent use of other xenobiotics. Differences in sex contributes to varying pharmacokinetic parameters, including bioavailability, distribution, metabolism, and elimination. Women

treated with 5-fluorouracil (5-FU) for colon cancer had a twofold higher frequency of drug-related toxicity than men.<sup>68</sup> The manifestations included leukopenia, diarrhea, and stomatitis. Although the basis for this difference in toxicity between sexes is not known, it can result from a decreased 5-FU clearance in women.<sup>74</sup>

At an individual level, genetic polymorphisms can contribute to differences in xenobiotic response with resultant toxicity by altering targets, transporters, and enzyme complexes. Such variations are characterized for several enzymes that are involved in the metabolism of chemotherapeutics. Two examples of this type of toxicity include irinotecan used for the treatment of metastatic colon cancer and 5-fluorouracil used for the treatment of certain types of gastrointestinal (GI) and breast cancers. Irinotecan is a topoisomerase I inhibitor that works through its active metabolite, SN-38, which causes diarrhea and neutropenia at elevated concentrations.<sup>70</sup> A genetic variant of uridine diphosphate glucuronosyltransferase (UGT1A1) containing the T7 allele glucuronidates SN-38 at a slower rate than other variants, which results in increased SN-38 concentrations and increased toxicity.<sup>3,29</sup> Another example is 5-fluorouracil (5-FU), which is an antagonist to uracil, and it is inactivated by dihydropyrimidine dehydrogenase (DPD) in the liver (Chap. 51). The enzyme DPD metabolizes more than 80% of 5-FU to 5,6-dihydro-5-fluorouracil and alpha-fluoro-beta-alanine, and low or absent activity of this enzyme results in hematologic and GI toxicities from treatment with 5-FU or its prodrug capecitabine. The genetic variant DPYD\*2A (rs3918290) of DPD is an inactive enzyme, and patients homozygous for this allele are at risk for severe toxicity and advised to seek an alternative therapeutic.<sup>8</sup> There are additional polymorphisms in metabolism associated with chemotherapeutics<sup>19</sup>; however, further work is necessary to define their clinical significance. Because of the narrow therapeutic index of the chemotherapeutics, the significance of such findings demonstrates the benefit of individual drug monitoring and genetic screening for use to maximize the therapeutic efficacy while limiting host toxicity.

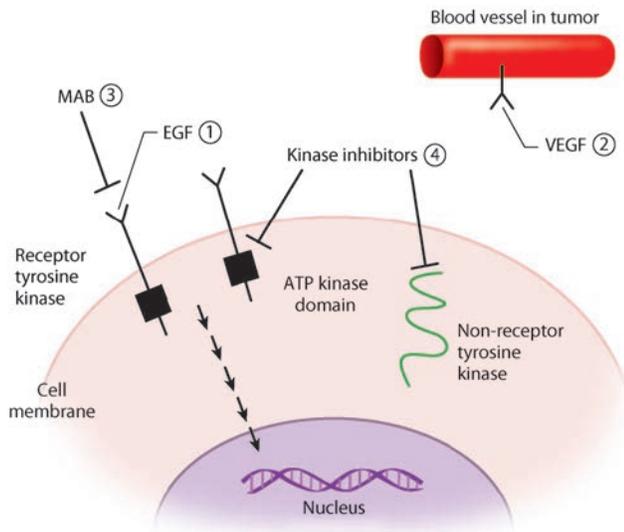

## CLASSES OF CHEMOTHERAPEUTICS

Most chemotherapeutics are grouped into one of 5 categories: alkylating agents, antibiotics, antimetabolites, antimetotics, and platinum-based complexes (Table 50–1). Some new chemotherapeutics target specific proteins located on the cell membrane, such as growth factor receptors, to inhibit the proliferation of tumor cells (Fig. 50–1).<sup>36,50</sup> These chemotherapeutics are categorized as monoclonal antibodies and protein kinase inhibitors based on their mechanisms of action. The antimetabolites are grouped by the substrates with which they interfere. Methotrexate is a folate antagonist; other nonchemotherapeutics with a similar mechanism, but lesser toxicity include trimethoprim and pyrimethamine. The antimetotics are plant alkaloids and they exert toxic effects by interrupting microtubule assembly. Others are naturally derived and include the antibiotics and the enzyme L-asparaginase, which is isolated from bacteria. The alkylating agents are more commonly used than other chemotherapeutics and cause covalent binding to nucleic acids, which inhibits DNA activity (Fig. 50–2). The more notable chemotherapeutics in this class, including those with similar activity, are the nitrogen mustards, nitrosoureas, and platinum-based complexes. The alkylating agents affect the cell at all phases in the cell cycle. Some xenobiotics are cell cycle phase-specific; that is, they affect the cell at only a specific phase in the cell cycle. For example, vincristine is M phase-specific and cytarabine is S phase-specific, in their sites of action. Other chemotherapeutics inhibit topoisomerase, which is necessary for DNA replication because it allows for reversible DNA strand breaks.

TABLE 50-1 Classification of Chemotherapeutics, Their Adverse Effects, and Antidotal Therapy

Class	Antineoplastic	Adverse Effects	Overdose	Antidotes
Alkylating agents	Busulphan	Hyperpigmentation, pulmonary fibrosis, hyperuricemia	Myelosuppression	
	Dacarbazine	Hypotension, hepatocellular toxicity, influenzalike illness		
	Nitrogen mustards Chlorambucil, cyclophosphamide, ifosfamide, mechlorethamine, melphalan	Hemorrhagic cystitis, encephalopathy, pulmonary fibrosis	Seizures, encephalopathy, myocardial necrosis, acute kidney injury, hyponatremia	MESNA; methylene blue
	Nitrosoureas Carmustine, lomustine, semustine, streptozocin	Pulmonary fibrosis, hepatocellular toxicity, acute kidney injury	Myelosuppression (delayed onset and prolonged duration)	
	Procarbazine	Inhibition of monoamine oxidase (MAOI)		
	Temozolomide		Myelosuppression	
Antibiotics	Anthracycline Daunorubicin, doxorubicin, epirubicin, idarubicin	Dilated congestive cardiomyopathy	Dysrhythmias, cardiomyopathy, CHF, myelosuppression	Dexrazoxane
	Bleomycin	Pulmonary fibrosis		
	Dactinomycin	Hepatocellular toxicity		
	Mitomycin C	Hemolytic uremic syndrome		
	Mitoxantrone	Dilated cardiomyopathy	Cardiomyopathy, CHF	None
Antimetabolites	Methotrexate	Mucositis, nausea, diarrhea, hepatocellular toxicity	Mucositis, myelosuppression, acute kidney injury	Folinic acid; Glucarpidase (carboxypeptidase-G <sub>2</sub> )
	Purine analogs Fludarabine	Encephalopathy, muscle weakness		
	Mercaptopurine	Hyperuricemia, pancreatitis, cholestasis	Myelosuppression, hepatocellular toxicity	
	Pentostatin	Hepatocellular toxicity		
	Thioguanine	Hyperuricemia		
	Pyrimidine analogs Cytarabine	Acute respiratory distress syndrome, neuropathy, cerebellar ataxia		
	Fluorouracil, capecitabine	Cardiogenic shock, cardiomyopathy, cerebellar ataxia, diarrhea, mucositis, myelosuppression, neuropathy	Mucositis, myelosuppression, myocardial ischemia, cardiac conduction disorders	Uridine triacetate
Antimitotics	Taxanes Docetaxel, paclitaxel	GI perforation, peripheral neuropathy, dysrhythmias		None
	Vinca alkaloids Vinblastine, vincristine, vindesine	Peripheral neuropathy, hyponatremia (SIADH)	Encephalopathy, seizures, autonomic instability, paralytic ileus, myelosuppression	
Enzyme	L-Asparaginase	Hypersensitivity, pancreatitis, and coagulopathy	No reports	None
Monoclonal antibodies	Many: Gemtuzumab, trastuzumab	Hypersensitivity, specific to the site of action, and infection	No reports	None
Platinum-based complexes	Cisplatin, carboplatin, oxaliplatin	Acute kidney injury, peripheral neuropathy, hypomagnesemia, hypocalcemia, hyponatremia, ototoxicity, myelosuppression	Seizures, encephalopathy, ototoxicity, retinal toxicity, myelosuppression, peripheral neuropathy	Amifostine; thiosulfate
Protein kinase inhibitors	Many: Gefitinib, sorafenib, erlotinib	GI (nausea, diarrhea), acneiform rash (folliculitis), nail fragility, and xerosis (EGFR inhibitor), interstitial lung disease (erlotinib, gefitinib), hypertension (inhibitors of VEGF and PDGFR), hypothyroidism (sunitinib), and infection	Nausea, vomiting, facial rash, and edema	None
Topoisomerase inhibitor	Camptothecins	Neutropenia, mucositis, diarrhea, early onset cholinergic syndrome (irinotecan)	Myelosuppression	None
	Irinotecan			
	Topotecan			
	Epipodophyllotoxins Etoposide, teniposide	CHF, hypotension		

CHF = congestive heart failure, EGFR = epidermal growth factor receptor; GI = gastrointestinal; MESNA = mercaptoethane sulfonate; MAOI = monoamine oxidase inhibitor; PDGFR = platelet-derived growth factor receptor; SIADH = syndrome of inappropriate antidiuretic hormone; VEGF = vascular endothelial growth factor.

**FIGURE 50-1.** Sites of action of selected targeted agents. Tyrosine kinases initiate signal transduction pathways and production of transcription factors that are responsible for cellular processes, including proliferation, survival, angiogenesis, and progression. Growth factors, such as endothelial growth factor (EGF) and vascular endothelial growth factor (VEGF), bind and activate transmembrane tyrosine kinases by causing receptor dimerization and phosphorylation ①. VEGF promotes endothelial cell mitogenesis and migration, which leads to vascular proliferation ②. Tyrosine kinases are inhibited by monoclonal antibody (MAB) binding at the cell surface receptor site ③ or by kinase inhibitors at the adenine triphosphate (ATP) binding site or substrate-binding site, or causing a change in the conformation of the enzyme (NIB) ④.

**MECHANISMS OF ACTION**

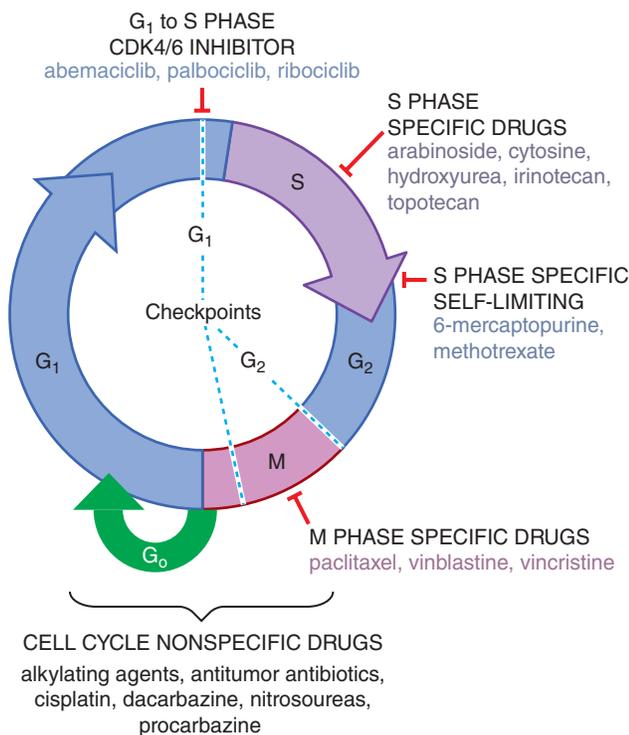

The mechanisms responsible for the cytotoxic effects of the chemotherapeutics are the disruption of cellular growth and proliferation (Chap. 23), which impairs DNA function by causing strand breaks, inhibiting strand relaxation, and serving as inhibitory analogs of essential cofactors and nitrogenous bases of nucleic acids (Fig. 50-3). For example, alkylating agents form reactive intermediates that covalently bind to nitrogenous bases on the DNA structure, which leads to the formation of strand breaks and mispairings. Cross-linkages between strands occurs with the nitrogen mustards because they contain 2 reactive chloroethyl side chains (Fig. 23-2). The planar anthracycline antibiotics intercalate with DNA, impair topoisomerase II activity, and cause DNA strand breaks through oxidative damage induced by a reactive semiquinone intermediate. The relaxation of DNA strands is impaired by topoisomerase I inhibitors, such as topotecan. Topotecan is derived from camptothecin, which is isolated from the tree *Camptotheca acuminata*. Single methyl transfer reactions and base pairings are essential activities during DNA synthesis that are affected by the antimetabolites, which include structural analogs to folate, pyrimidines, and purines.

Recent cancer therapy includes chemotherapeutics that limit cellular proliferation by inhibiting growth factor receptor activation and enhancing cell lysis by antibody-dependent cell-mediated cytotoxicity and complement-dependent cytotoxicity. Monoclonal antibodies to tumor cell surface antigens, such as CD20, CD22, and CD30, and the C1q complement are used to direct host defense mechanisms or deliver chemotherapeutics to these sites. For example, brentuximab vedotin is an antibody conjugated to the anti-mitotic agent, monomethyl auristatin E, and it is directed at CD30-positive tumor cells, which is common to lymphomas. Other antibody conjugates include radioactive isotopes (eg, Yttrium-90) and pseudomonas exotoxin A.<sup>61</sup> In addition to the above antigens, monoclonal antibodies against tumor growth factor receptors are available.

Tumor growth factors promote cell growth and proliferation (by angiogenesis). Their receptors located at the cell membrane are characterized for certain tumors, such as epidermal growth factor receptor (EGFR) found in lung, kidney, and gastrointestinal tumors, and human epidermal growth factor receptor 2 (HER2) in the breast. Vascular endothelial growth factor receptor (VEGFR) and platelet-derived growth factor receptor (PDGFR) are active in angiogenesis. Inactivation of these receptors is accomplished with therapeutic monoclonal antibodies (MAB) and protein kinase inhibitors. Monoclonal antibodies prevent the activation of these receptors by inhibiting substrate binding to the receptor located at the extracellular surface. Kinase inhibitors are considered to be small molecule therapeutics that impair the ATP activation of growth factor receptors, serine/tyrosine kinase inhibitors, mTOR kinase inhibitors, and certain signal transduction proteins responsible for tumor cell division and angiogenesis.

The disruption of the proliferation of keratinocytes, and intestinal epithelial cells at these tissue sites accounts for the anticipated toxic effects from the use of MABs and kinase inhibitors directed at EGFR. The therapeutic use of the protein kinase inhibitors of VEGFR and PDGFR, such as sunitinib and sorafenib, is associated with hypertension, which is attributed to endothelial dysfunction and diminished microvascular regrowth.

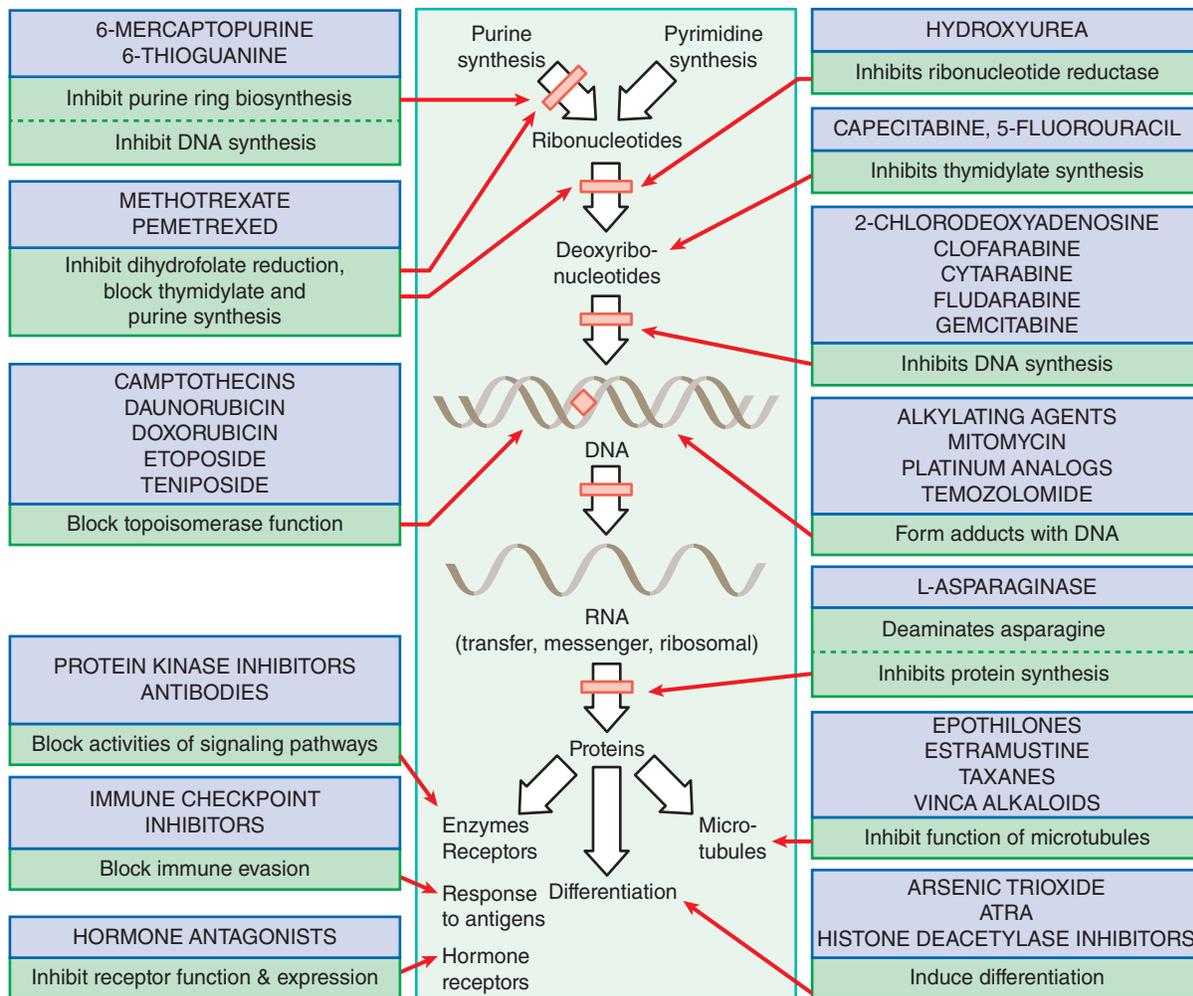

These monoclonal antibodies are derived from both human and chimeric (human and murine) sources, which contributes to the toxicity. The nomenclature scheme for this class of therapeutics is available elsewhere.<sup>75</sup> Immunologic responses to the presence of foreign proteins include rigors, nausea, vomiting, and rashes. Some organ-specific effects of varying antibodies include bone marrow, skin (via EGFR), kidney (hypomagnesemia via EGFR), gastrointestinal (via EFGR), and cardiac (via HER2, trastuzumab).

**FIGURE 50-2.** Cell cycle specificity of chemotherapeutics: selected class of cell style phase-specific chemotherapeutics and their sites of action in the cell cycle. Arrows represent the progression of the cell cycle by phases, G<sub>0</sub> (resting), G<sub>1</sub> (gap1), G<sub>2</sub> (gap2), M (mitosis), and S (DNA synthesis). (Reproduced with permission from Brunton LL, Hilal-Dandan R, Knollmann BC. Goodman & Gilman's: The Pharmacological Basis of Therapeutics, 13th ed. New York, NY: McGraw Hill Education; 2018.)

**MANIFESTATIONS OF TOXICITY**

The chemotherapeutics are primarily toxic to cells, with a high level of mitotic activity, such as hematopoietic and intestinal epithelial cells (Chap. 23). This characteristic feature accounts for their common clinical manifestations of toxicity, including mucositis, alopecia, and bone marrow suppression.

**FIGURE 50-3.** Summary of the mechanisms and sites of action of some chemotherapeutics useful in neoplastic disease. ATRA = all-trans retinoic acid. (Reproduced with permission from Brunton LL, Hilal-Dandan R, Knollmann BC. *Goodman & Gilman's: The Pharmacological Basis of Therapeutics*, 13th ed. New York, NY: McGraw Hill Education; 2018.)

They also cause protracted vomiting because they stimulate the chemoreceptor trigger zone in the medulla by vagal and sympathetic pathways either directly or indirectly through the GI tract. The likelihood for vomiting depends on the dose, the route of administration, and the type of chemotherapeutic. Although the onset of emesis typically occurs within 6 hours and lasts for 24 hours, delayed or persistent (>24 hours since administration) emesis occurs with cisplatin, cyclophosphamide, carboplatin, and doxorubicin. The factors attributed to acute or early onset of vomiting during therapy are serotonin (5HT<sub>3</sub> receptor) (primary) and dopamine (DA<sub>2</sub> receptor) mediated pathways. In contrast, persistent vomiting is attributed to various factors, including a tachykinin substance P (neurokinin [NK<sub>1</sub>] receptor), local GI effects, and inflammation from cellular breakdown.

The time of onset for the other manifestations is typically in the first week following treatment, with mucositis preceding leukopenia, which varies depending on the chemotherapeutic and the dose. For example, the nadir and full recovery for neutropenia is about 10 to 14 days and 21 days, respectively, but more prolonged delays occur for busulfan and carmustine, and when higher doses are used. Anthracyclines and platinum-based complexes are likely to cause severe neutropenia, and methotrexate, 5-fluorouracil, bleomycin, and doxorubicin are likely to cause mucositis and severe dehydration because of the amount of GI fluid loss from diarrhea and vomiting. Death usually results from overwhelming sepsis as enteric organisms traverse compromised intestinal epithelium, enter the bloodstream, and attack a host with neutropenia from bone marrow suppression. Some of the unique manifestations of certain chemotherapeutics involve the skin, heart, central and peripheral nervous systems, and kidneys.

Dermatologic manifestations caused by chemotherapeutics include hypersensitivity reactions, extravasations (Special Considerations: SC8), and cytotoxicity from the use of tyrosine kinase inhibitors for the EGFR (eg, gefitinib, erlotinib).<sup>77</sup> Patients commonly develop pruritus, xerosis, erythema, and folliculitis or an acneiform rash that can desquamate during therapy. These reactions develop within the first week of treatment and continue for several weeks. The folliculitis is a dose-dependent response and typically resolves within weeks after treatment. The dermal response is more intense with monoclonal antibodies than the kinase inhibitors for the EGFR. The other kinase inhibitors (ie, sunitinib, sorafenib) involved with growth factor receptors for angiogenesis (ie, VEGFR, PDGFR) are associated with a “hand-foot” skin reaction, which is a painful erythema and edema of the palm and sole that leads to desquamation.

The cardiovascular manifestations of toxicity depend on the chemotherapeutic, and the common adverse effects include congestive heart failure (CHF), dysrhythmias, and hypertension. The anthracyclines, cyclophosphamide, 5-fluorouracil, and arsenic trioxide are examples of chemotherapeutics that cause cardiac toxicity (Tables 50-2, 15-1, 16-4). Although the anthracyclines classically produce late-onset cardiomyopathy (nonischemic), they also cause acute cardiac manifestations. Those occurring within 24 hours of therapy include dysrhythmias, ST segment and T wave changes on the electrocardiogram (ECG), diminished left ventricular ejection fraction (LVEF) leading to congestive heart failure, pericarditis, myocarditis, and sudden death.<sup>7,57,58,65,76</sup> Arsenic trioxide (As<sub>2</sub>O<sub>3</sub>) used for the treatment of acute promyelocytic leukemia causes dose-dependent prolongation of the QT interval and ventricular tachydysrhythmias, including torsade de pointes, during

**TABLE 50-2 Cardiovascular Manifestations of Toxicity of Selected Chemotherapeutics**

Chemotherapeutic	Time of Onset Since Treatment	Manifestation
Anthracycline	<24 hours	Dysrhythmias, ST segment and T wave changes on ECG; diminished LVEF leading to CHF, pericarditis, myocarditis, and sudden death
	Months to years, typically at 1–4 months	Dilated congestive cardiomyopathy
Arsenic trioxide	Days	Prolongation of QT interval on ECG leading to ventricular tachydysrhythmias (torsade de pointes)
Cyclophosphamide	Days	CHF, hemorrhagic pericarditis, tamponade, and death
5-Fluorouracil	Hours to days	Myocardial ischemia, cardiac conduction disorders, and cardiogenic shock

CHF = congestive heart failure, ECG = electrocardiogram; LVEF = left ventricular ejection fraction.

the course of treatment.<sup>5</sup> Inorganic arsenic inhibits the slow ( $I_{Ks}$ ) and rapid ( $I_{Kr}$ ) delayed rectifier  $K^+$  channels of ventricular myocytes, which impairs the efflux of potassium ions during ventricular repolarization (Chap. 86). These ECG changes tend to develop after several days of drug therapy, reverse upon discontinuation of the drug, and occur more frequently during intravenous than oral therapy because of the increased blood concentration of arsenic from the intravenous route of administration.<sup>60</sup> Patients at increased risk for cardiac conduction disorders during arsenic trioxide therapy include those with hypokalemia and hypomagnesemia, on medications that prolong the QT interval, and with underlying cardiac conduction disorders. Myocardial ischemia leading to cardiogenic shock occurs from the high-dose infusion of 5-fluorouracil.<sup>69</sup> The metabolite fluoroacetate is purported to cause endothelial damage and result in vasospasm.<sup>425</sup> Normalization of ECG findings, including diminished QRS complex voltage and abnormal ventricular wall motion, is expected by 48 hours after the discontinuation of infusion therapy.<sup>13</sup> Within a few days of exposure at high doses from therapy during bone marrow transplant or the overdose setting, cyclophosphamide causes CHF, hemorrhagic pericarditis, tamponade, and death at high doses. The cardiomyopathy from anthracyclines involves biventricular failure and its onset is variable, from months to years. Although this period is usually 1 to 4 months, it tends to be longer for the less toxic anthracycline analogs.<sup>22,32,62</sup> Trastuzumab is associated with a slight increase in the incidence of CHF from diminished LVEF among patients previously treated with anthracyclines or with underlying heart disease.<sup>23</sup> A potential mechanism for the enhanced cardiac toxicity from the drug interaction is that trastuzumab disrupts the HER2-neuregulin compensatory response by the heart to the exposure to anthracyclines.<sup>14</sup> Lapatinib is another chemotherapeutic targeting HER2, but by inhibiting phosphorylation at the tyrosine kinase domain, and it slightly decreases LVEF.<sup>47</sup>

The neurologic toxicities of chemotherapeutics include central and peripheral manifestations. The acute manifestations of toxicity include alterations in mental status and seizures, which occur from the systemic administration of high doses of nitrogen mustards (cyclophosphamide, ifosfamide, and chlorambucil), nitrosoureas (lomustine), methotrexate, and vincristine. The inappropriate intrathecal administration of vincristine and methotrexate causes central nervous system toxicity (Special Considerations: SC7). Patients with prior seizure disorders, delayed drug clearance, and altered drug pharmacokinetics (eg, nephrotic syndrome)<sup>55</sup> are at increased risk for seizures. L-Asparaginase, 5-fluorouracil, and procarbazine are associated with alterations in mental status.<sup>72</sup> Cerebellar dysfunction is described in 5% of patients treated with 5-FU,<sup>48</sup> and high-frequency ototoxicity occurs

with cisplatin toxicity. The delayed-onset manifestations of neurotoxicity from chemotherapeutics include leukoencephalopathy and peripheral neuropathies. Leukoencephalopathy from methotrexate typically presents as a delayed onset of behavioral and progressive dementia and is irreversible. Peripheral neuropathy involving both sensory and motor findings is seen with the vinca alkaloids (vincristine) and bortezomib, whereas only sensory involvement is noted with cisplatin and paclitaxel.<sup>39</sup>

Kidney failure from tubulointerstitial pathology occurs from methotrexate, cisplatin, ifosfamide, or nitrosoureas in a dose-dependent manner. The nitrosoureas such as semustine can cause glomerular injury leading to sclerosis. Kidney damage is attributed to the formation of insoluble intratubular precipitates of drug metabolites (7-OH MTX metabolite for MTX) or reactive intermediates (cisplatin, nitrosoureas) that lead to cell death. The nitrosoureas also form isocyanates, which impair enzymes and contribute to irreversible kidney damage.<sup>38</sup> The onset, severity, and reversibility of kidney toxicity depend on the administered dose and the chemotherapeutic. For example, streptozocin is more nephrotoxic than the other nitrosoureas: semustine, lomustine, and carmustine. Patients at increased risk for worsening kidney function from these chemotherapeutics include those with prior kidney disease, increased age, salt and water depletion, hypotension, and concomitant use of nephrotoxic xenobiotics, such as aminoglycosides. Young children (<5 years old) are more vulnerable to ifosfamide-induced proximal tubular toxicity leading to urinary loss of phosphate and bicarbonate than older patients.<sup>41,66</sup> Also, patients with third space fluid, such as ascites and pleural effusions, and aciduria are at increased risk for MTX-induced kidney toxicity because of the prolonged half-life of the drug and the increased likelihood for the formation of insoluble precipitates in the renal tubules at a low urinary pH. The kidney failure from methotrexate, cisplatin, and streptozocin typically presents within 1 to 2 weeks. Patients treated with semustine present with kidney compromise months to years following exposure.<sup>73</sup> Patients develop fluid and electrolyte abnormalities from the above chemotherapeutics, causing renal tubular disorders, and from vincristine, causing centrally mediated syndrome of inappropriate antidiuretic hormone secretion (SIADH) (Chaps. 12 and 34).

## DIAGNOSTIC TESTING

The determination of a chemotherapeutic concentration in a clinical specimen is not routinely available, except for methotrexate. At certain research centers, the testing for specific xenobiotics such as busulfan,<sup>64</sup> cisplatin (platinum),<sup>17</sup> cyclophosphamide,<sup>49</sup> fluorouracil ( $\alpha$ -fluoro- $\beta$ -alanine),<sup>49</sup> ifosfamide,<sup>49</sup> and vincristine<sup>15</sup> are available. These concentrations are used to assist in confirming exposure and monitoring drug clearance, but should not be relied on to determine initial management because of the difficulty in obtaining these tests and ability to correlate the concentrations with clinical toxicity.

For certain chemotherapeutics, the presence of typical clinical manifestations strongly suggest their toxicity, for example, cisplatin (acute kidney injury and ototoxicity), vinca alkaloids (peripheral neuropathy, central autonomic instability) and SIADH, anthracyclines (CHF and dilated cardiomyopathy), ifosfamide (encephalopathy and seizures), and methotrexate (acute kidney injury, mucositis, and pancytopenia). The diagnosis of a patient with toxicity from these xenobiotics is based on a historical evidence for exposure, clinical manifestations, and laboratory findings that support toxicity or exposure. For patients presenting with delayed symptoms, the association between toxicity and exposure requires an increased level of awareness to establish the causation.<sup>22</sup> Additional studies should be performed to evaluate for specific disorders noted on the clinical examination, such as electromyography and nerve conduction studies for peripheral neuropathies, electroretinogram for retinopathies, and echocardiography for cardiac dysfunction.

## GENERAL MANAGEMENT

The initial management of these patients includes stabilization of the hemodynamic status, decontamination, institution of antidotal therapy, and enhanced elimination. Maximal benefits from antidotes and enhanced

elimination can be obtained through their timely institution. Hypotension typically results from salt and water depletion, cardiac dysfunction, or sepsis. It is reasonable to treat patients with myocardial ischemia from 5-FU with coronary vasodilators, such as nitrates and calcium channel blockers. Seizures are treated with benzodiazepines, and propofol. Encephalopathy from high-dose ifosfamide has been treated with methylene blue (adult: 50 mg intravenously {IV}) (Antidotes in Depth: A43).<sup>46</sup> Patients with blood dyscrasias, including neutropenia and thrombocytopenia, should be evaluated for gastrointestinal bleeding and infections. Those at risk for overwhelming sepsis should be started on broad-spectrum antibiotics and granulocyte colony stimulating factor as indicated. Oral activated charcoal is recommended for patients who present soon after an oral exposure to limit the gastrointestinal bioavailability of the agent. Repeat oral doses of activated charcoal are reasonable to enhance the clearance of methotrexate in patients with acute kidney injury.<sup>20</sup>

Patients with chemotherapeutic-related vomiting are typically difficult to manage. Combination therapy involving multiple antiemetics are needed to treat patients exposed to chemotherapeutics with high emetogenic potential (eg, cisplatin, doxorubicin, cyclophosphamide, lomustine) or excessive doses of chemotherapeutics with low emetogenic potential (eg, 5HT<sub>3</sub> Vinca alkaloids, fluorouracil). Recommended therapies include serotonin receptor antagonists, corticosteroids, dopamine receptor antagonist, NK<sub>1</sub> receptor antagonist, or a benzodiazepine.<sup>27</sup> Serotonin receptor antagonists are effective for vomiting starting within 6 hours of exposure and are used with dexamethasone and a NK<sub>1</sub> receptor antagonist in patients with protracted vomiting. Once the serotonin receptors are saturated, additional doses are no longer effective. Neurokinin receptor antagonists used in combination with a corticosteroid, such as dexamethasone, are effective for managing delayed-onset vomiting, which can last for 5 days. Atypical antipsychotics (ie, olanzapine) and phenothiazines are reasonable to treat breakthrough vomiting. Benzodiazepines are reasonable in this setting, but they are most effective for the prevention of vomiting. A basic chemistry panel, complete blood count, urinalysis, and ECG should be obtained for patients with a significant overdose to evaluate toxicity and to establish baseline values. Pregnant women exposed to chemotherapeutics require individualized care that include consultations with an obstetrician-gynecologist, neonatologist, or a medical oncologist.<sup>43,54</sup> Information regarding the gestational age at the time of the exposure, and the name and class of the chemotherapeutic are important for this discussion.

The patient's peripheral blood count should be followed for up to 2 weeks after a chemotherapeutic is administered because of the delayed onset of myelosuppression.

Gastrointestinal fluid losses from vomiting, diarrhea, and mucosal ulcerations can lead to salt and water depletion, which should be treated with intravenous fluids. Intravenous fluids are important for patients with cisplatin and methotrexate toxicity to promote the renal elimination of toxic metabolites. Patients with cisplatin toxicity should be treated with 0.9% sodium chloride and an osmotic diuretic to maintain an adequate chloride gradient to promote the renal elimination of cisplatin. Urinary alkalization is recommended for patients with MTX toxicity to limit the precipitation of drug metabolites in the renal tubules.

Antidotal therapy is available for only a few xenobiotics, including anthracyclines (dexrazoxane), methotrexate (leucovorin, glucarpidase), cisplatin (amifostine, thiosulfate), 5-FU or capecitabine (uridine triacetate), and ifosfamide (methylene blue, mercaptoethane sulfonate). These antidotes permit the use of higher doses of chemotherapeutics in cancer patients. However, patients with overdoses from chemotherapeutics also benefit from the use of these antidotes, which should be initiated soon after the decision to treat has been made. Additional information regarding them is found in Chap. 51 and Antidotes in Depth: A12, A13, A14, and A43.

Information on the use of enhanced elimination to remove these chemotherapeutics and their metabolites is limited to case reports in the literature. The effectiveness of these procedures is based on principles similar to other xenobiotics, including molecular size, extent of protein binding, and volume

of distribution. Patients with diminished endogenous clearance from kidney failure or third spacing of fluid can benefit from these procedures as well. For example, cisplatin is highly protein bound and favored for removal by plasmapheresis, but patients with kidney failure also benefit from hemodialysis. Hemoperfusion was used for doxorubicin and it is recommended for use when it is available.<sup>11,30,40,78</sup> For the nitrogen mustards and the alkyl sulfonates, hemodialysis has been used. The early institution of these procedures can maximize the potential benefits to the patient.

The decision to use myeloid growth factors in patients with agranulocytosis depends on the severity and nature of the neutropenia, the anticipated speed of recovery, and the tumor type. Granulocyte-macrophage colony-stimulating factor (GM-CSF) was used for several patients with overdoses such as cisplatin, melphalan, bleomycin, fluorouracil, and methotrexate.<sup>12,26,33-35,37,42,45,63</sup> Typically, if promyelocytes and myelocytes are present in the bone marrow, neutrophil recovery will occur spontaneously in 4 to 7 days, following the withdrawal of the offending chemotherapeutic.<sup>18</sup> However, when granulopoiesis is completely absent, neutrophil recovery cannot be expected for at least 14 days. The use of granulocyte colony-stimulating factor (G-CSF) or GM-CSF accelerates neutrophil recovery during cytotoxic chemotherapy. When myeloid precursors are present in the bone marrow, G-CSF accelerates neutrophil recovery in 1 to 4 days. If myeloid precursors are absent, neutrophil recovery with G-CSF takes longer, but is still enhanced. Granulocyte macrophage colony-stimulating factor is specifically indicated for use in older adult patients with neutropenia following induction chemotherapy for acute myelogenous leukemia, in mobilization of progenitor cells into the peripheral compartment for leukapheresis, and in myeloid recovery following transplantation of peripheral blood progenitor cells or bone marrow transplantation.

The serum concentration of the chemotherapeutic should be below detection before institution of G-CSF to gain maximal response; typically, G-CSF is initiated within one to 3 days of the completion of the treatment cycle. The treatment with G-CSF is continued beyond the expected white blood cell (WBC) nadir for an approximately 2-week course, although it can be prolonged for CCNU (lomustine) overdoses because of direct toxicity to progenitor cells in the bone marrow (Chap. 23).<sup>1,67</sup> The absolute neutrophil count (ANC) is monitored twice a week to assess the response to G-CSF. Bone pain should be anticipated from the use of colony-stimulating factors, presumably because of the increase in cellularity in the marrow space. Additional expected side effects from GM-CSF therapy include myalgia, fevers, and pericarditis.

Granulocyte macrophage colony-stimulating factor produces a transient beneficial response in the WBCs in patients with aplastic anemia.<sup>10</sup> However, when the anemia is severe, the GM-CSF therapy is not effective. Another hematopoietic growth factor, erythropoietin, is approved for use in patients with anemia associated with cancer chemotherapy.<sup>6,52</sup> Although the purpose of this therapy is to decrease the need for red blood cell transfusions, it does not replace the need for red blood cell transfusion when indicated.

## CHEMOTHERAPEUTICS IN THE WORKPLACE

Pharmacists, nurses, physicians, and others involved in the preparation and dispensing of chemotherapeutics, and those who may be exposed to the body fluids of patients treated with chemotherapeutics, are at increased risk for toxicity. Several studies demonstrate that chemotherapeutics are detected at the work environment and measured in workers,<sup>28,53,56</sup> and there is concern about the possible genotoxic effects from these exposures.<sup>16,59</sup> The worker adsorption of these xenobiotics occurs by either the dermal, inhalational, or gastrointestinal route. The factors determining the amount of worker exposure include the nature of the work, the amount of drug used, the frequency and duration of exposure, the physical and chemical nature of the drug, and the use of ventilated cabinets and personal protection equipment during the handling of these chemotherapeutics. The workplace guidelines for chemotherapeutics fall under the broader category of hazardous agents. National Institute for Occupational Safety and Health (NIOSH) defines a "drug" as a "hazardous agent" if it is carcinogenic, teratogenic, genotoxic, associated with developmental or reproductive toxicity, or toxic to organs at low dose. A sample list of drugs considered to be hazardous by NIOSH is available.<sup>9</sup>

Regulatory and workplace recommendations for exposure levels and the waste management of these xenobiotics are available from various agencies and organizations. These recommendations are limited in scope because only a small number of xenobiotics or adverse health effects have been adequately studied, and many xenobiotics do not meet the current definition for inclusion. US Environmental Protection Agency (Resource Conservation and Recovery Act, 40 CFR §§260–279)<sup>51</sup> regulates 9 chemotherapeutics (arsenic trioxide, chlorambucil, cyclophosphamide, daunorubicin, melphalan, mitomycin C, naphthylamine mustard, streptozocin, and uracil mustard) and the equipment and devices associated with their preparation or delivery, as well as their disposal, as hazardous waste.<sup>51</sup> The current recommendations for worker safety with these xenobiotics at the workplace include the proper management of the work environment (eg, storage, handling, preparation, administration, use of personal protection equipment, decontamination, and waste disposal) and the institution of a medical surveillance program with approved laboratory testing.<sup>2,44,59</sup>

## SUMMARY

- The chemotherapeutics are a unique therapeutic class because their cytotoxicity is a direct effect.
- Most conventional chemotherapeutic overdoses are iatrogenic, involving misreading of the product label, and errors in dosing and transcription of orders (Chap. 134). A key element is the lack of familiarity of the health care provider with the use of these select xenobiotics.
- Clinical manifestations of chemotherapeutic toxicity depend on the mechanism of action, route of administration, and duration of exposure. The gut epithelium and hematopoietic cells are extremely susceptible to toxicity because of their high mitotic activity. They are important because their failure will lead to overwhelming sepsis and death.
- Treatment remains primarily supportive in nature. The early institution of cytoprotectants, such as leucovorin, glucarpidase for methotrexate, amifostine for cisplatin, uridine triacetate for 5-FU and capecitabine, and dexrazoxane for anthracyclines, as antidotal therapy in overdosed patients can limit further toxicity. However, further work is needed to better define their use in these situations.
- The best treatment for chemotherapeutic overdoses is prevention, which can be accomplished by maintaining a heightened awareness when working with these xenobiotics, educating the patient and health care provider regarding their use, and providing increased skilled and standardized care.

# METHOTREXATE, 5-FLUOROURACIL, AND CAPECITABINE

Richard Y. Wang

Methotrexate and the fluoropyrimidines (5-fluorouracil and capecitabine) belong to the chemotherapeutic class of antimetabolites. Patients affected by these chemotherapeutics present with significant clinical toxicities that are potentially fatal. Clinicians must recognize these patients early and be prepared to provide immediate interventions that include specific antidotal therapies. The oral formulations of methotrexate and capecitabine present a risk for intentional or unintentional chemotherapeutics ingestion in the home.

## METHOTREXATE

Methotrexate (MTX) is commonly used for a many malignant conditions. Its immunosuppressive activity also allows it to be used for rheumatoid arthritis, organ transplantation, psoriasis, trophoblastic diseases, and termination of pregnancy.<sup>20,47</sup>

Risk factors for MTX toxicity include impaired kidney function (primary route of drug elimination); third compartment spacing; ascites and pleural effusions; concurrent use of nephrotoxins, such as nonsteroidal antiinflammatory drugs (NSAIDs) and aminoglycosides<sup>55</sup> and certain intravenous radiologic contrast agents;<sup>30,40</sup> age; folate deficiency; and concurrent infection.<sup>95</sup> Methotrexate toxicity depends on the dose, but even more on the duration of exposure.

## Pharmacology

The therapeutic and toxic effects of methotrexate are based on its ability to limit DNA and RNA syntheses by inhibiting dihydrofolate reductase (DHFR) and thymidylate synthetase (Fig. 51-1). Dihydrofolate reductase reduces folic acid first to dihydrofolate and then to tetrahydrofolate (FH<sub>4</sub>), which serves

as an essential cofactor in the synthesis of purine nucleotides that are used in the synthesis of DNA and RNA. Methotrexate, a structural analog of folate, competitively inhibits DHFR by binding to the enzymatic site of action. Methotrexate polyglutamates are formed intracellularly by folylpolyglutamate synthetase and they also inhibit DHFR. The inhibition of DHFR diminishes reduced folate production, which is necessary for the formation of purine nucleotides. Reduced folates are also required by thymidyl synthetase to serve as methyl donors in the formation of thymidyl. Thymidyl is then used for DNA synthesis. In addition, thymidyl production is impaired by the direct inhibition of thymidylate synthetase by polyglutamated derivatives of methotrexate.

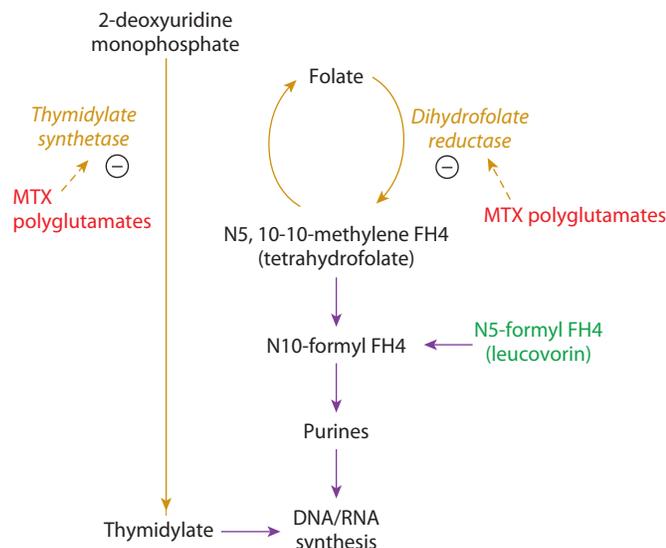

The antiinflammatory effect of MTX likely involves the following mechanisms: (1) inhibition of trans-methylation (by depletion of intracellular folate stores) which causes the death of T cells and inhibits the formation of polyamines (spermine and spermidine) that are involved in the inflammatory cascade, (2) reduction in intracellular concentration of glutathione, and (3) inhibition of intracellular 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) transformylase, which leads to increased extracellular concentration of adenosine through a series of steps (see below). Adenosine binds to the A<sub>2a</sub> receptor located on the surface of leukocytes, and it affects selected functions, where it inhibits the syntheses of cytokines (TNF  $\alpha$ ) and complements produced by macrophages, and inhibits lymphocyte proliferation and migration to targeted sites.<sup>23,69</sup>

The de novo synthesis of purine nucleotides involves the formylation of the intermediate AICAR to formyl-AICAR by AICAR transformylase in the latter steps of the pathway. Formyl-AICAR proceeds to form inosine and then adenosine. The latter step is facilitated by adenosine deaminase. Adenosine is phosphorylated to AMP, ADP, and ATP. These phosphorylated species of adenosine can translocate to the extracellular compartment, where they are converted to adenosine. Polyglutamates of MTX inhibit AICAR transformylase, which causes an increase in the concentration of AICAR and then the inhibition of AMP and adenosine (via AICA ribonucleoside) deaminases.<sup>74</sup> The inhibition of these deaminases increases the intracellular concentrations of adenosine and its phosphorylated derivatives, and contributes to the movement of these products to the extracellular compartment.

The bioavailability of methotrexate is limited by a saturable intestinal absorption mechanism. At oral doses less than 30 mg/m<sup>2</sup>, the absorption is 90% and the peak plasma MTX concentration is achieved at one to 2 hours. In children administered oral MTX, peak blood concentrations mean (SD) of MTX were 0.71 (0.17)  $\mu\text{mol/L}$  and 1.48 (0.46)  $\mu\text{mol/L}$  for doses at less than or equal to 10 and 30 mg/m<sup>2</sup>, respectively.<sup>92,98</sup> In adults, MTX administered as an oral dose of 7.5 mg, 15 mg, or 50 mg achieved peak blood concentrations (mean, SD) of 0.48 (0.09)  $\mu\text{mol/L}$ , 0.84 (0.3)  $\mu\text{mol/L}$ , and 1.84 (0.70)  $\mu\text{mol/L}$ , respectively.<sup>4,99</sup> At oral doses greater than 30 mg/m<sup>2</sup>, gut bioavailability significantly decreases. For example, at doses greater than 80 mg/m<sup>2</sup>, the absorption is less than 10% to 20%.<sup>14</sup>

Methotrexate dosing regimens for chemotherapy are variable, but high-dose therapy is equal to or is greater than 1,000 mg/m<sup>2</sup>. Conventional intravenous doses of up to 100 mg/m<sup>2</sup> are often administered without leucovorin rescue. Doses of 1,000 mg/m<sup>2</sup> are considered potentially lethal. Much higher doses (2,000–3,000 mg g/m<sup>2</sup>) can be given when MTX is followed by leucovorin “rescue” in order to prevent life-threatening toxicity. Mortality from high-dose MTX is approximately 6%, and occurs primarily when MTX concentrations are not monitored.<sup>95,101</sup>

Methotrexate has a triphasic plasma clearance. The initial plasma distribution half-life is short at 0.75 hours. The second half-life is 2 to 3.4 hours and represents renal clearance of the drug. The third phase has a half-life of

**FIGURE 51-1.** Mechanism of MTX toxicity. Methotrexate inhibits dihydrofolate reductase activity, which is necessary for DNA and RNA synthesis. Leucovorin bypasses blockade to allow for continued synthesis. MTX = methotrexate.

about 8 to 10.4 hours and represents tissue redistribution into the plasma. This third phase is prolonged in the setting of kidney failure and is associated with bone marrow and gastrointestinal (GI) toxicity. The volume of distribution is 0.6 to 0.9 L/kg and protein binding is 50%. Healthy kidneys eliminate 50% to 80% of MTX unchanged within 48 hours of administration. When the creatinine clearance is less than 60 mL/min, MTX clearance is delayed.<sup>83,105</sup> Ten percent to 30% of MTX is eliminated unchanged in the bile, which contributes to enterohepatic circulation of the chemotherapeutic. In the setting of kidney failure, the half-life of MTX is prolonged by the recirculation of MTX in the gut.

Hepatic aldehyde oxidase metabolizes a minor portion (<10%) of MTX to 7-hydroxy methotrexate (7-OH-MTX), which inhibits DHFR but to a lesser extent than MTX. Aldehyde oxidase is also found in renal tubules, but not in the glomerulus, and its contribution to the local production of 7-OH-MTX and kidney injury remains to be determined.<sup>70</sup> Another metabolite is 2,4-diamino-*N*(10)-methylpteroic acid (DAMPA), and it accounts for less than 5% of MTX. In the gut, bacterial carboxypeptidase acts on MTX to form DAMPA, which is reabsorbed into the blood compartment. Approximately 50% of -*N*(10) DAMPA is eliminated unchanged by the kidneys, and this metabolite is inactive at DHFR based on poor cellular uptake and inhibition of the enzyme when compared to MTX.<sup>112</sup>

### Pathophysiology

At high doses, methotrexate and the insoluble drug metabolites 7-OH-MTX and DAMPA accumulate and precipitate in the renal tubules, causing reversible acute tubular necrosis. Methotrexate is one-tenth as soluble at a pH of 5.5 as it is at a pH of 7.5.<sup>14,85</sup> Expressed another way, the plasma concentration threshold for nephrotoxicity is 2.2 mmol/L when the urine pH is 5.5, and 22 mmol/L when the urine pH is 6.9. Thus, patients who are either inadequately hydrated or not alkalinized are at risk for acute kidney failure from high-dose MTX treatment.<sup>3,48</sup> Methotrexate is excreted unchanged in the urine by both glomerular filtration and active tubular secretion. A small amount of MTX is metabolized intracellularly to polyglutamate derivatives, which inhibit DHFR and thymidyl synthetase and are believed to be responsible for the persistent cytotoxic effect of MTX because they do not easily diffuse outside of the cell. The threshold concentration for MTX in plasma that inhibits DNA synthesis is lower for intestinal epithelial cells (0.005 μM/L) than for hematopoietic cells (0.01 μmol/L) by one order of magnitude.<sup>20</sup> Thus, patients with a significant exposure to MTX will develop GI toxicity before bone marrow toxicity.

The decreased production of reduced folates and diminished folate content in the hepatocyte likely contribute to injury, which leads to hepatic fibrosis from the stimulation of hepatic stellate cells by adenosine.<sup>74,75</sup> Patients on long-term therapy with MTX and elevated aminotransferases can develop hepatic fibrosis from persistent injury to the liver.

### Clinical Manifestations

In the course of MTX therapy, a variety of disorders can occur, resulting from either increased patient susceptibility to toxicity or excessive administration. The clinical manifestations of MTX toxicity include stomatitis, esophagitis, kidney failure, myelosuppression, hepatitis, and central neurologic system dysfunction. In a group of 23 patients who received 45 courses of high-dose MTX therapy with leucovorin rescue, the most commonly observed signs included increased aspartate aminotransferase (AST) or alanine aminotransferase (ALT) (81%), nausea and vomiting (66%), mucositis (33%), dermatitis (18%), leukopenia (11%), thrombocytopenia (9%), and creatinine elevation (7%).<sup>77</sup>

Nausea and vomiting, considered rare from cancer therapy with MTX at 40 mg/m<sup>2</sup>, typically begin 2 to 4 hours after high-dose therapy (1,000 mg/m<sup>2</sup>) and last for about 6 to 12 hours. Mucositis, characterized by mouth soreness, stomatitis, or diarrhea, usually occurs in the first week of therapy, and can last for 4 to 7 days. Other gastrointestinal effects resulting from MTX therapy include pharyngitis, anorexia, gastrointestinal hemorrhage, and toxic megacolon.<sup>9</sup> Hepatocellular toxicity, as defined by increased hepatic enzymes (AST, ALT), and hyperbilirubinemia occur with both acute and chronic therapies.<sup>62,71,77</sup> It is usually associated with high dose regimens, and

elevations in AST/ALT will begin within one to 3 days following an exposure to a significant dose of MTX. Laboratory abnormalities improve within 1 to 2 weeks of discontinuation of MTX. The mechanism is incompletely understood, but toxicity is attributed to reduced liver folate stores resulting from intracellular competition with polyglutamates of MTX for glutamyl conjugation in chronic exposures,<sup>11</sup> and cellular damage from oxidative stress<sup>5,41</sup> or the precipitation of 7-OH-MTX in the bile duct<sup>17</sup> in acute exposures. Factors associated with hepatotoxicity are sustained high plasma concentrations, increased cumulative dosages, chronic therapy, and host factors such as increase in age, obesity, alcoholism, and prior liver disease.<sup>107</sup>

Pancytopenia usually occurs within the first 2 weeks after an acute exposure. There are several reports demonstrating the occurrence of pancytopenia in individuals receiving chronic MTX therapy for rheumatoid arthritis and psoriasis.<sup>27,54,62,80</sup>

When used at intravenous (IV) doses of 40 to 60 mg/m<sup>2</sup>, MTX is not associated with appreciable nephrotoxicity. However, at doses greater than 5,000 g/m<sup>2</sup> (approximately 130 mg/kg for an adult), several investigators report severe kidney injury, with oliguria, azotemia, and kidney failure.<sup>13</sup> The incidence of kidney injury (serum creatinine  $\geq 1.5$  to  $3.0 \times$  upper limit of normal) in patients with osteosarcoma and treated with high-dose MTX in conjunction with hydration, urinary alkalinization, and leucovorin is 1.8%.<sup>109</sup> Kidney function typically recovers over time. Patients at risk for nephrotoxicity include the elderly, those with underlying kidney disease defined as a glomerular filtration rate of less than 60 mL/min, and those who receive concurrent drug therapy that can delay MTX excretion, which includes agents that reduce renal blood flow such as NSAIDs, the nephrotoxins such as cisplatin, and the aminoglycosides, or weak organic acids such as salicylates and piperacillin which inhibit renal secretion.<sup>46,95</sup>

The neurologic complications associated with either high-dose systemic MTX therapy or intrathecal administration are the most consequential manifestations. The incidence of neurologic toxicity from high dose MTX therapy is approximately 5% to 15%.<sup>49</sup> The manifestations usually occur from hours to days after the initiation of therapy and include hemiparesis, paraparesis, quadriparesis, seizures, and dysreflexia.<sup>49,61,96,103</sup> These events are reversible to varying degrees.<sup>2</sup> Clinical findings occurring within several hours (usually within 12 hours) of therapy are attributed to chemical arachnoiditis, and they include acute onset of fever, meningismus, pleocytosis, and increased cerebrospinal fluid (CSF) protein concentration.<sup>42</sup> Leukoencephalopathy is associated with the onset of behavioral disorders and progressive dementia from months to years after treatment and is irreversible, although manifestations presenting soon after treatment can be reversible depending on the extent of involvement.<sup>6,113</sup> Patients with increased age and prior cranial radiation are at risk for this disorder.<sup>37</sup> Patients with leukoencephalopathy have findings consistent with edema, and demyelination or necrosis of the white matter on computed tomography (CT) and magnetic resonance imaging (MRI) of the brain.<sup>6</sup>

### Diagnostic Testing

Plasma MTX concentrations are monitored during therapy to limit clinical toxicity. For example, patients with a plasma concentration greater than 1.0 μmol/L at 48 hours posttreatment are considered at risk for bone marrow and gastrointestinal mucosal toxicities.<sup>95</sup> In the former example, the MTX concentration since the time of administration is used in cancer therapy to minimize bone marrow toxicity (suppression) and maximize the efficacy of the therapeutic.<sup>32</sup> The drug concentration and the duration of exposure are indirect indicators of the efficacy of the drug during therapy. In patients with an unintentional exposure to MTX and not receiving MTX therapy, their exposure to MTX (concentration and duration) should be minimized because they are vulnerable to GI toxicity (mucositis). The threshold concentration of MTX for the inhibition of DNA synthesis is one order of magnitude lower for intestinal epithelial cells than hematopoietic cells.

There are several analytical methods available to measure the concentration of MTX, which is routinely conducted in blood (serum or plasma) (Table 51-1). It is important to select the appropriate analytical method to measure MTX because the performance characteristics are variable among these methods.

**TABLE 51–1** Analytical Techniques Used to Measure Methotrexate and Selected Metabolites

Technique	Analyte	LOD ( $\mu\text{M/L}$ )	LOQ ( $\mu\text{mol/L}$ )	CV (MTX, $\mu\text{mol/L}$ )*	AMR ( $\mu\text{mol/L}$ )	Matrix	Comments
FPIA <sup>1,16</sup>	MTX	0.02	0.03	14% (0.07) 5.9% (0.8)	0.03–1.0	Serum, plasma	Assay cross-reacts with DAMPA

	7-OH-MTX	0.0004					
	DAMPA	0.0023					

\*CVs for inter- and intraday at selected MTX concentrations: +CV for interday; & for measurements made in plasma.

AMR = analytical measurement range; CSF = cerebrospinal fluid; CMIA = chemiluminescent microparticle immunoassay (Abbott); CV = coefficient of variation; DAMPA = 2,4-diamino-*N*(10)-methylpteroic acid; EMIT = enzyme multiplied immunoassay (ARK); FPIA = fluorescence polarization immunoassay (monoclonal antibody, Abbott); HPLC = high-performance liquid chromatography; LC = liquid chromatography; LOD = limit of detection; LOQ = limit of quantification; MS = mass spectrometry; MTX = methotrexate; 7-OH-MTX = 7-hydroxymethotrexate; UVD = ultraviolet detection.

The measurement of methotrexate concentrations in the clinical setting is routinely conducted using an immunoassay technique such as enzyme multiplied immunoassay (EMIT), chemiluminescent microparticle immunoassay (CMIA), or fluorescence polarization immunoassay (FPIA) (Table 51–1).<sup>1,7,10,16,36</sup> These measurements are performed on serum or plasma. The presence of the MTX metabolite DAMPA but not 7-OH-MTX diminishes the specificity of these analytical methods for MTX. The amount by which DAMPA affects the MTX concentration depends on the assay.

At low concentrations of MTX, analytical methods based on high-performance liquid chromatography with ultraviolet detection (HPLC-UVD) or mass spectrometry (LC-MS or LC-MS/MS) provide increased sensitivity and specificity compared to the immunoassays (Table 51–1). The primary advantage of the HPLC-UVD technique over the immunoassay is the ability to measure MTX independent of DAMPA.<sup>12</sup> The advantages of mass spectrometry are increased sensitivity and specificity compared to HPLC-UVD or immunoassays. For example, analytical methods based on mass spectrometry detect or quantify MTX at a concentration one to 2 orders of magnitude lower than methods using either one of the former 2 techniques, and they can quantify 7-OH-MTX and DAMPA in a single analytical run.<sup>15,79</sup> The limitations of methods using HPLC (with UVD or mass spectrometry) are their availability and turnaround time for the test result.

When patients are treated with glucarpidase (carboxypeptidase G<sub>2</sub>) (Antidotes in Depth: A13), it is preferable to use an HPLC method to measure MTX because of the presence of DAMPA during therapy. The FPIA method with monoclonal antibodies is recommended not to be used in patients who have developed antibodies to mouse monoclonal antibodies or elevated concentrations of DAMPA.

An elevated CSF methotrexate concentration (>100  $\mu\text{mol/L}$ ) is indicative of an excessive intrathecal dose or delayed cerebrospinal fluid outflow obstruction.<sup>72</sup> Radiologic imaging of the brain, such as computed tomography and magnetic resonance imaging, are useful to evaluate for meningeal inflammation, demyelination and necrosis of the white matter, or other pathologies such as a cerebrovascular accident.

## Management

The initial approach to the patient exposed to MTX is to determine whether the exposure is acute or chronic because the priorities are different for these

patients. For example, a patient with chronic MTX toxicity is more likely to die from overwhelming sepsis than the patient with an acute exposure because the former patient typically presents with bone marrow suppression and severe gastroenteritis. Fluid resuscitation, stabilization, and assessment for neutropenia and kidney and liver injuries are essential steps during the evaluation of the patient with chronic MTX toxicity.

The patient with an acute exposure to MTX typically presents early after an oral exposure. The essential steps during the evaluation of this patient are limiting further gut absorption of MTX, and administering leucovorin early. Leucovorin is most effective as a competitive antidote to MTX when the intracellular concentration of MTX is still low. The time to peak blood concentration of MTX from an oral therapeutic dose of MTX is about 2 hours (1–3 hours). Using the above perspective as a framework for the management of these patients, the following discussion will review the roles of activated charcoal, urinary alkalinization, colony-stimulating factor, and antidotal therapies.

Activated charcoal adsorbs methotrexate and administration is recommended as soon as possible to limit absorption in the setting of oral exposure.<sup>38</sup> The administration of multiple-dose activated charcoal and cholestyramine<sup>29,89</sup> can significantly decrease the elimination half-life of methotrexate by interrupting the enterohepatic circulation.<sup>34,38</sup> This approach can increase MTX clearance but is of most benefit to patients with diminished creatinine clearance. Multiple-dose activated charcoal is recommended for patients with evidence of delayed MTX clearance, such as kidney injury or prolonged half-life (based on blood MTX concentration). Activated charcoal should be withheld in patients with gastrointestinal hemorrhage.

Adequate hydration with 0.9% sodium chloride solution as well as urinary alkalinization with IV sodium bicarbonate (to urine pH 7 to 8) (Antidotes in Depth: A5) is recommended because these modalities prevent or limit kidney injury from the precipitation of MTX and its metabolites in patients who receive inadvertent high doses of glucarpidase.<sup>21</sup> Serial measurements of serum creatinine and blood MTX concentration will determine the duration of urinary alkalinization.

The complete blood count (CBC) should be monitored at least as frequently as days 7, 10, and 14 to assess the impact on the cells in the bone marrow.<sup>56</sup> Granulocyte-macrophage colony-stimulating factor (GM-CSF)

was used in patient with a chronic MTX overdose and pancytopenia.<sup>94</sup> The patient had a serum MTX concentration of 1.25  $\mu\text{mol/L}$  on admission and was in kidney failure. Bone marrow biopsy showed promyelocytes, but no mature white cells, and a marked reduction of megakaryocytes. Because of deteriorating conditions, GM-CSF (125 mcg/m<sup>2</sup>/d) was administered when the MTX concentration fell below the reference value for toxicity. Seven days after the initiation of GM-CSF, the white blood cell (WBC) count rose and reached expected values within 10 days. Colony-stimulating factor is recommended for patients with febrile neutropenia and who are at high risk for complications from an infection or are likely to have a poor outcome (eg, absolute neutrophil count <100 cells/ $\mu\text{L}$ , prolonged neutropenia {>10 days}, age 65 years or older, and hypotension with multiorgan dysfunction).<sup>91</sup>

Patients presenting with meningismus or altered mental status following MTX therapy should receive an initial MRI of the brain and then CSF analysis for infection.<sup>52</sup> Although not considered standard, it would be reasonable to measure the CSF concentration of MTX if excessive exposure to this compartment is suspected. The peak therapeutic concentration of methotrexate in CSF after the intrathecal administration of 12 mg MTX by lumbar puncture is 100  $\mu\text{mol/L}$ , and the terminal half-life of MTX in the cerebrospinal compartment is 7 to 16 hours.<sup>72</sup> Magnetic resonance imaging of the brain can demonstrate a high signal throughout the pachymeningeal (dura mater) region, which is consistent with a chemical meningitis,<sup>33</sup> or a high signal of the white matter with a decreased diffusion coefficient in a diffusion-weighted image to indicate the presence of edema, which is an early finding of leukoencephalopathy.

### Antidotes

The available antidotes or rescue agents (term used in cancer therapy for therapeutics that extend the use of chemotherapeutics) for methotrexate toxicity are leucovorin (folinic acid) (Antidotes in Depth: A12) and glucarpidase (carboxypeptidase G<sub>2</sub>) (Antidotes in Depth: A13). The effectiveness of these therapies depends on both the timing of administration and the dose, which warrants the monitoring of plasma MTX concentrations during the use of these antidotes. Leucovorin rescue therapy limits the bone marrow and gastrointestinal toxicity of MTX by allowing for the continuation of essential biochemical processes that are dependent on reduced folates. The purpose of the initial dose of leucovorin is to achieve a plasma concentration equal to the MTX and subsequent doses should be adjusted according to plasma MTX concentrations at 24 and 48 hours postexposure (Fig. 51–1).<sup>31,108</sup> Leucovorin treatment is continued until the MTX concentration is less than 0.01  $\mu\text{mol/L}$ .<sup>20</sup> In patients with marrow toxicity and no cancer, leucovorin therapy should be continued until marrow recovery occurs, even if plasma MTX is no longer detectable,<sup>60</sup> because MTX polyglutamates can still be present in the cytosol and adversely affect cellular activity. Among 36 patients undergoing MTX therapy (amount varied from 2 to 13 mg MTX per week) for rheumatoid arthritis, all of these patients had indirectly detected MTX polyglutamates in red blood cells and nondetected MTX in the plasma by FPIA and MAB.<sup>43,44</sup>

Glucarpidase (carboxypeptidase G<sub>2</sub>) is a recombinant bacterial enzyme that is used as a rescue therapy to inactivate MTX by hydrolyzing it to DAMPA and glutamate. Glucarpidase is used in patients with an elevated plasma MTX concentration (>1.0  $\mu\text{mol/L}$ ) and delayed renal clearance of MTX.<sup>102</sup> Glucarpidase is not indicated for patients with a plasma MTX concentration that is consistent with the expected clearance for MTX at the dose administered (ie, a concentration that is within 2 SD of the mean MTX elimination curve for the dose administered), or for patients with no more than mild kidney injury. Following glucarpidase therapy, plasma MTX concentrations need to be monitored because residual concentrations of MTX in the blood after initial enzymatic therapy can result from the fact that the action of glucarpidase occurs solely within the vascular compartment; inadequate dose of glucarpidase occurs in patients with large MTX exposures or following redistribution of MTX from tissue stores to the blood compartment.<sup>18,86,110</sup> Glucarpidase can also be successfully administered intrathecally to reduce

elevated MTX concentrations in the cerebrospinal space (Special Considerations: SC7).<sup>111</sup>

### Extracorporeal Elimination

The patient with delayed renal clearance of a toxic concentration of MTX and who is not a candidate for glucarpidase therapy can benefit the most from extracorporeal elimination of MTX when the procedure is instituted early during the patient's course. Once MTX distributes into the cell and peripheral tissue compartments, the procedure cannot remove intracellular polyglutamate derivatives of MTX, and multiple sessions can be required to clear additional MTX stored at peripheral sites.<sup>108</sup> In addition, the procedure can be performed safely in the patient before he or she develops pancytopenia and gastrointestinal hemorrhage from MTX toxicity.

There are several reports of the use of hemodialysis or hemoperfusion (or both) for patients with MTX toxicity.<sup>51,68,78,97,105</sup> Although the volume of distribution (0.6–0.9 L/kg) and protein binding (50% that is not concentration dependent) suggest that MTX is cleared by hemodialysis, older clinical evidence suggests otherwise.<sup>94</sup> In one report, less than 10% of an initial 700 mg dose of methotrexate was cleared in 12 sessions of hemodialysis.<sup>97</sup> The measured clearance was only 38 mL/min, which can be compared to 5 mL/min for peritoneal dialysis,<sup>39</sup> 0.28 to 24 mL/min for continuous venovenous hemodiafiltration,<sup>50,53</sup> and 180 mL/min for normal renal clearance.<sup>57</sup> The ability of hemofiltration to extract MTX from the blood is also limited by the magnitude of the concentration gradient for MTX, which decreases as the concentrations of MTX decreases in the blood.<sup>22</sup> Plasma exchange transfusion is not recommended to remove MTX because the drug has a low degree of protein binding, which limits the efficacy of this procedure.<sup>13,53,73,97</sup>

Acute intermittent hemodialysis with a (F-80B Fresenius Dialyzer) high-flux dialyzer membrane yielded an effective mean plasma MTX clearance of  $92 \pm 10.3$  mL/min in 6 patients with kidney failure that was a result of either chronic disease or high-dose MTX therapy.<sup>105</sup> These patients received high-dose MTX therapy and had predialysis serum MTX concentrations ranging from 1.45 to 1,813  $\mu\text{mol/L}$ . The time of dialysis initiation after MTX treatment was from 1 hour to 6 days in this patient population. A serum MTX concentration of 0.3  $\mu\text{mol/L}$  was used as an end point for dialysis. The reported plasma MTX clearance by this technique closely approximates normal renal MTX clearance and is indicated to enhance the clearance of MTX in patients with diminished renal clearance and a toxic plasma MTX concentration when it can be conducted safely.<sup>83</sup>

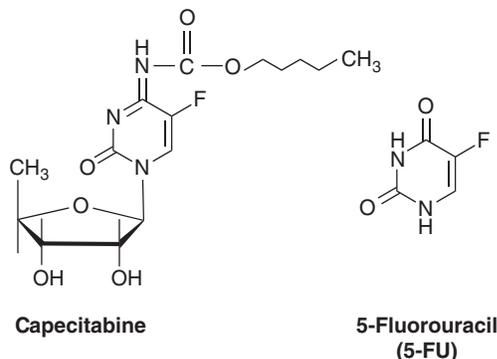

Charcoal hemoperfusion removed more than 50% of MTX in 4 patients with impaired renal clearance during high dose MTX therapy.<sup>26,78</sup> This was thought to have prevented severe skin and mucosal toxicity. Sequential hemodialysis and hemoperfusion were used for a patient with substantial MTX toxicity.<sup>38</sup> These procedures decreased the half-life of elimination from 45 hours to 7.6 hours. In experimental animals, hemoperfusion significantly reduced the terminal half-life of methotrexate. In surgically anephric dogs, hemoperfusion decreased the half-life from more than 20 hours to 1.3 hours.<sup>45</sup> Unfortunately, hemoperfusion is currently typically unavailable but modern standard hemodialysis is quite effective in MTX removal (Chap. 6).<sup>78</sup>

In vitro studies indicate that the toxic effects of 100  $\mu\text{mol/L}$  of MTX cannot be reversed by 1,000  $\mu\text{mol/L}$  of leucovorin.<sup>76</sup> This suggests the need for extracorporeal elimination, such as high-flux hemodialysis, or glucarpidase (or both) to lower persistent plasma MTX concentrations of greater than 100  $\mu\text{mol/L}$ .<sup>78</sup> It is important to perform high-flux hemodialysis early, prior to distribution into tissues. Rebound of MTX concentrations from tissues can be expected with intermittent hemodialysis, which typically begins at 2 hours postdialysis and plateau at 16 hours.<sup>35,39,105</sup>

Patients who are at the greatest risk for developing MTX toxicity despite leucovorin treatment should receive glucarpidase (Antidotes in Depth: A13). If the patient with diminished renal clearance and a toxic MTX concentration is not a candidate for glucarpidase therapy, it is reasonable to use hemodialysis early in the patient's course. Current standard hemodialysis can offer the additional benefit of correcting fluid and electrolyte disorders resulting from

kidney failure. Other treatment options to limit additional organ toxicity, including leucovorin and urinary alkalization, should be continued during extracorporeal MTX removal. Leucovorin needs to be replaced postdialysis because it is water-soluble and will be removed by hemodialysis.<sup>24,78,88,90</sup>

## 5-FLUOROURACIL AND CAPECITABINE

The fluoropyrimidines used in chemotherapy are 5-fluorouracil (5-FU), capecitabine, tegafur, and floxuridine. The fluoropyrimidines are competitive analogues to uridine and they disrupt the syntheses of DNA (during the S-phase of the cell cycle) and RNA (Chap. 50). Although floxuridine is metabolized to 5-FU, it has limited systemic toxicity because it is administered to the target organ by the arterial route. These chemotherapeutics are used to treat breast and selected GI cancers, such as colorectal. Common risk factors for toxicity from these chemotherapeutics are selected genetic polymorphisms (ie, dihydropyrimidine dehydrogenase {DPD} deficiency), and underlying liver, kidney, and coronary artery diseases.

### Pharmacology

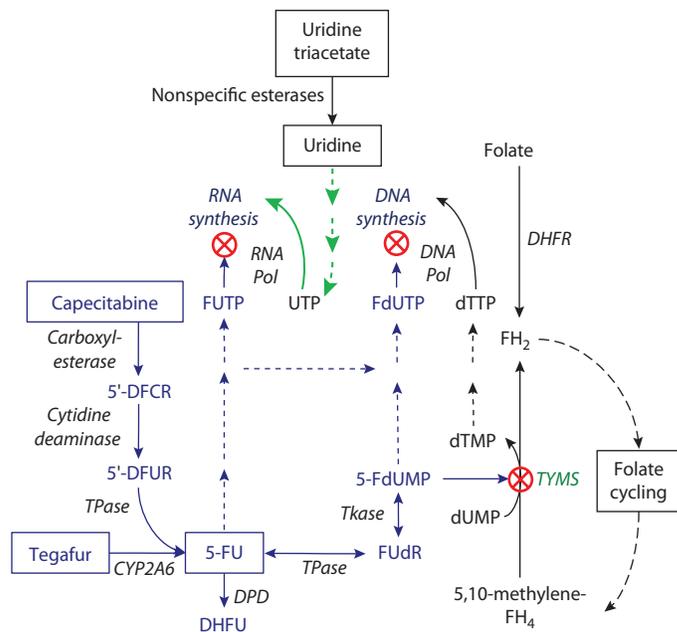

Capecitabine is an oral pro-drug of 5-FU; it is well absorbed by the gut, and then metabolized to 5-FU. In comparison, 5-FU has an erratic oral absorption in the gut and needs to be administered by the intravenous route as a bolus or a continuous infusion. Technical problems with the infusion pump or a pump programming error are reported causes of clinical toxicity from an overdose of 5-FU.<sup>59,84</sup>

The time to peak blood concentration for capecitabine is 1.5 to 2 hours (3.9 mg/L).<sup>104</sup> A median peak blood 5-FU concentration was 55.4 mg/L for a group of 18 patients receiving bolus therapy (400 mg/m<sup>2</sup> 5-FU) for colon cancer.<sup>19</sup> 5-Fluorouracil has an apparent volume of distribution of 8–11 L/m<sup>2</sup>, distributes to third spaces or compartments, such as peritoneal and pleural fluids, and is approximately 10% protein bound. The plasma protein binding for capecitabine is 60%. The terminal half-lives for 5-FU and capecitabine in the blood compartment are about 15 and 45 minutes, respectively.

Whether a patient experiences therapeutic effects or toxic effects from the use of these chemotherapeutics depends on the balance between the enzymatic reactions involved with the formation of active metabolites and the enzymatic reaction that degrades these metabolites and the parent compound. This is important because these chemotherapeutics require enzymes that can have variable levels of potential to activate and inactivate them.

Capecitabine undergoes 3 enzymatic reactions in the liver to form 5-FU. Capecitabine is initially metabolized by carboxylesterase to 5'-deoxy-5-fluorocytidine (5-DFCB) and then to 5'-deoxy-5-fluorouridine (5'-DFUR) by cytidine deaminase (Fig. 51-2). In the liver or at the tumor site, thymidine phosphorylase converts 5'-DFUR to 5-FU. Inside the cell, 5-FU is converted to active metabolites: FdUMP, FTP, and FdUTP. Floxuridine (5-FUDR) is metabolized to 5-FU and then to FdUTP and FdUMP. Tegafur is an additional prodrug that is bioactivated by CYP2A6 to 5-FU. CYP2C9 is also capable of metabolizing tegafur, but it did not appear to significantly contribute to overall activation of tegafur in a human liver microsome system.

Hepatic metabolism by DPD inactivates approximately 80% of 5-FU to 5,6-dihydro-5-fluorouracil and alpha-fluoro-beta-alanine (FBAL), and these

**FIGURE 51-2.** 5-Fluorouracil, capecitabine, and tegafur chemotherapeutic mechanisms of action and uridine triacetate antidotal rescue. 5'-DFCR = 5'-deoxy-5-fluorocytidine; 5'-DFUR = 5'-deoxy-5-fluorouridine; 5-FdUMP = fluorodeoxyuridine monophosphate; 5-FU = 5-fluorouracil; 5,10-methylene-FH<sub>4</sub> = 5,10-methylenetetrahydrofolate; CYP2A6 = cytochrome P450, family 2, subfamily A, polypeptide 6; DHFR = dihydrofolate reductase; DHFU = 5,6-dihydrofluorouracil; DNA Pol = DNA polymerase; DPD = dihydropyrimidine dehydrogenase; dTMP = deoxythymidine monophosphate; dTTP = deoxythymidine triphosphate; dUMP = deoxyuridine monophosphate; FdUTP = fluorodeoxyuridine triphosphate; FH<sub>2</sub> = dihydrofolate; FUDR = floxuridine; FUTP = fluorouridine triphosphate; RNA Pol = RNA polymerase; TKase = thymidine kinase; TPase = thymidine phosphorylase; TYMS = thymidylate synthase; UTP = uridine triphosphate. (Used with the permission from Silas W. Smith, MD.)

products are excreted in the urine. The enzyme DPD has nonlinear kinetics because of saturation, and its level of activity depends on the genetic variant. The frequencies of genetic variants with complete and partial DPD deficiencies in adults are 0.1% to 0.5% and 3% to 5%, respectively.<sup>63</sup> Patients with a significant DPD deficiency based on certain genetic variants will present with early-onset and severe manifestations of toxicity from 5-FU or capecitabine.<sup>58,64</sup>

Cytidine deaminase is another enzyme with a variable level of expression in the general population. Patients with a markedly elevated level of activity for this enzyme can develop capecitabine toxicity. Patients with certain genetic variants of cytidine deaminase are “ultra-metabolizers” of capecitabine, and they form higher than expected concentrations of 5-FU and present with early-onset toxicities, including severe gastroenteritis and bone marrow suppression.<sup>25,58,65,87</sup> Lastly, certain thymidylate synthase polymorphisms are associated with more severe toxicity.

The proportions of unchanged 5-FU that are eliminated in the urine and bile are less than 10% and approximately 2% to 3%, respectively. Capecitabine and its metabolites are eliminated primarily by the kidneys (84% in the first 24 hours).<sup>104</sup> Capecitabine is contraindicated when the creatinine clearance is less than 30 mL/min.

### Pathophysiology

The therapeutic and toxic effects of 5-FU (and capecitabine) are based on its ability to limit DNA and RNA activities by serving as an antagonist to the pyrimidine uracil in these macromolecules (Fig. 51-2). The specific sites of action and consequence are as follows: (1) 5-FU (as FdUMP) replaces dUMP and it irreversibly inhibits thymidylate synthetase with the cofactor 5,10-methylenetetrahydrofolate (affects DNA synthesis and repair), (2) FdUTP replaces dUTP and it inhibits DNA replication (because of depleted thymidine triphosphate), and (3) fluorouridine triphosphate

(FUTP) replaces UTP and inhibits RNA and protein syntheses. Although the primary mechanism of action in chemotherapy for 5-FU is inhibition of thymidylate synthetase, the impairment of RNA synthesis causes significant toxicity to the host.

### Clinical Manifestations

The clinical manifestations of toxicity from 5-FU or capecitabine are primarily gastroenteritis and bone marrow suppression.<sup>28,66</sup> In the setting of an overdose (5-FU), nausea and diarrhea present early (<3 days) after the completion of the administration of the chemotherapeutic.<sup>84</sup>

Patients with a significant genetic variant of a critical enzyme (eg, DPD, cytidine deaminase or thymidylate synthase) present with severe manifestations of toxicity that are similar to an overdose of 5-FU or capecitabine.<sup>81</sup> However, these clinical findings typically appear soon after the administration of the first course of treatment. For capecitabine, patients susceptible to toxicity will develop manifestations later than patients on 5-FU—usually on days 3 to 9 during a 14 day course of treatment.<sup>25,59,65</sup>

Hand-and-foot syndrome (palmar plantar erythrodysesthesia) presents with erythema, edema, and pain on the palms of the hand and soles of the feet. The skin desquamates and blisters, and the lesions can appear at other locations on the body. The dermatitis is more common with capecitabine than 5-FU therapy.<sup>28</sup> It has a variable time of onset (from 11 to 360 days), and is reversible upon discontinuation of the chemotherapeutic.<sup>104</sup>

Cardiac and central nervous system (CNS) manifestations of toxicity are uncommon in patients treated with these chemotherapeutics. The incidence of cardiotoxicity from 5-FU varies from 1.6% to 18%, and patients with an underlying coronary artery disease are at risk for toxicity.<sup>82,93</sup> Cardiac manifestations of toxicity include dysrhythmias, myocardial infarction, myocardial ischemia (from coronary artery vasospasm), heart failure, and cardiogenic shock.<sup>59,82</sup> In patients with documented cardiotoxicity from 5-FU, it is recommended not to resume therapy because the recurrence rate is high, varying from 82% to 100%.<sup>93</sup> The manifestations of CNS toxicity include confusion, encephalopathy, and coma. Although the causes of these cardiac and neurologic manifestations are unknown, toxicity from the metabolite fluorouracil and genetic polymorphisms, such as significant DPD deficiency, are under consideration.<sup>59,67,81</sup>

### Diagnostic Testing

Clinical laboratory tests for 5-FU or capecitabine and their metabolites (FBAL), and the type of genetic variant or level of activity for selected enzymes, such as DPD<sup>8,63</sup> or cytidine deaminase<sup>25,87</sup> are not routinely available.

### Management

It is reasonable to administer activated charcoal as soon as possible to a patient presenting early after an oral overdose of capecitabine because it can limit gut absorption of the chemotherapeutic. Initiate supportive management with IV fluid hydration for dehydration and an antiemetic for vomiting (as needed) and assess for electrolyte disorders, cardiac and kidney injuries, neutropenia, and sepsis. If the patient presents with an acute coronary syndrome, conservative antianginal therapy (eg, nitrates and calcium channel blockers) should be initiated. The patient will require a cardiac monitored setting, and serial ECGs and cardiac enzymes.<sup>82,93</sup> Patients with a new-onset altered mental status should receive a computed tomography scan of the brain and possibly a lumbar puncture to assess for CNS infection.

### Antidotes

Uridine triacetate is administered in a timely manner in an attempt to improve the survival of patients adversely affected by 5-FU or capecitabine. In an open-label, multicenter study of patients with 5-FU or capecitabine toxicity and treated with uridine triacetate, there were 117 overdoses and 18 early-onset severe symptoms. An overdose was defined as the administration of 5-FU at a dose or rate (via infusion pump) greater than the maximum tolerated dose for the patient's intended regimen of 5-FU or capecitabine. Patients with early onset of signs or symptoms were presumed susceptible

to toxicity from a genetic variant of a critical enzyme. In the study, there were 130 survivors at 30 days among the 135 patients treated with uridine triacetate.<sup>59</sup> By comparison, when uridine triacetate was not available in a historical reference group of patients with 5-FU or capecitabine toxicity, there were 38 deaths among 42 patients.<sup>59</sup> When uridine triacetate was administered within 96 hours of the last dose of the chemotherapeutic to patients with early onset of severe toxicity, all 18 patients survived. However, only 3 of 8 patients survived when uridine acetate was administered after 96 hours.<sup>59</sup>

Uridine triacetate is available for the emergency treatment of patients with (1) an overdose of 5-FU or capecitabine regardless of the presence of clinical toxicity, (2) an early onset (<96 hours) of severe or life-threatening manifestations of toxicity (cardiovascular, central nervous system), or (3) an early onset of an unusually severe adverse reaction, such as gastroenteritis or neutropenia, within 96 hours of the administration of 5-FU or capecitabine during the course of chemotherapy.<sup>100</sup> Uridine triacetate is not recommended for the treatment of patients with common or anticipated manifestations of these chemotherapeutics during therapy.<sup>100</sup>

Uridine triacetate is administered orally and it is deacetylated by non-specific esterases in the gut and blood to form uridine. Upon entry into the cell, uridine is activated by phosphorylation to uridine triphosphate (UTP) (Fig. 51-2). Uridine competes with FUTP as UTP during the synthesis of RNA and serves as a source of UTP for the synthesis of new RNA. A plasma uridine concentration of at least 70 µmol/L is desired for treatment of 5-FU toxicity.<sup>59</sup> A single oral dose of 6 to 10 g of uridine triacetate yields a peak plasma uridine concentration of approximately 150 µmol/L at about 2 hours.<sup>84,106</sup> The half-life for uridine is about 3 hours.<sup>106</sup>

The amount of uridine triacetate indicated for 5-FU or capecitabine toxicity in adults for each single dose is 10 g administered every 6 hours for 20 doses for a total of 5 days. For children, a single dose of uridine triacetate is 6.2 g/m<sup>2</sup> of body surface area up to a maximum of 10 g per dose. The dose and schedule for uridine triacetate are not adjusted by sex, amount of 5-FU or capecitabine, or hepatic or renal clearance.<sup>102</sup> A common side effect from this therapy is nausea, vomiting, and diarrhea.

### SUMMARY

- The number of patients with potential MTX toxicity is anticipated to increase because of the expanding therapeutic indications and available multiple formulations of this chemotherapeutic.
- Specific interventions for MTX include supportive care, monitoring plasma MTX concentration, urinary alkalinization to limit kidney toxicity, enhanced elimination, and antidotal therapy with leucovorin and enzymatic cleavage with glucarpidase.
- Patients with significant genetic variants of critical enzymes involved with 5-FU or capecitabine typically present with severe clinical toxicity soon after the administration of the first course of treatment.
- Specific interventions for 5-FU or capecitabine toxicity include supportive care and antidotal therapy with uridine triacetate.
- The early recognition of these patients and institution of these therapies can offer the patient the best outcome.

# FOLATES: LEUCOVORIN (FOLINIC ACID) AND FOLIC ACID

Silas W. Smith and Mary Ann Howland

Folic Acid

Folinic Acid

Folates refer to the metabolically active reduced forms of folic acid, including dihydrofolate and tetrahydrofolate. These folates are vital to cellular biochemistry, including the synthesis of purines and DNA. Folic acid must be reduced *in vivo* by dihydrofolate reductase to tetrahydrofolate. Dihydrofolate reductase inhibitors such as methotrexate (MTX), pyrimethamine and pemetrexed prevent this reduction. Leucovorin (folinic acid) and levoleucovorin, do not require dihydrofolate reductase for activation. Therefore, either leucovorin or levoleucovorin is the primary antidote for a patient who receives an overdose of MTX or another dihydrofolate reductase inhibitor.

Methanol is metabolized to the active and toxic formic acid. Folates, including folic acid and leucovorin, speed up the conversion of formic acid to nontoxic metabolites. Because methanol does not interfere with the synthesis of tetrahydrofolate, either folic acid or leucovorin is acceptable for a patient poisoned by methanol. Preliminary evidence also suggests a role for folic acid to enhance arsenic elimination.

## HISTORY

In 1930–1931, Lucy Wills, while studying pregnant textile workers with macrocytic anemia in Mumbai, India, discovered that a yeast extract provided to these nutritionally deficient individuals cured and prevented their anemia.<sup>105</sup> Mitchell isolated the active ingredient from spinach in 1941 and named it folic acid from the Latin *folium*, meaning leaf.<sup>33</sup> Subsequently, the synthesis and chemical structure of folate was described in 1945–1946.<sup>3</sup> In 1948, the first reported clinical success in inducing temporary remission of acute leukemia by the antifolate aminopterin was reported, soon followed by success with the

less toxic amethopterin (ie, MTX).<sup>24</sup> That same year, in studies exploring links to anemia, a factor in the gram-positive bacteria *Leuconostoc citrovorum* was identified as required in growth media for deficient species.<sup>79</sup> Two years later in 1950, this “citrovorum factor”—later named leucovorin (folinic acid)—successfully reversed aminopterin and MTX toxicity, which had resisted folate therapy.<sup>82</sup> In the 1960s, the concept emerged of providing higher doses of MTX for improved chemotherapeutic efficacy, which was then coupled with subsequent leucovorin “rescue” to mitigate toxicity.<sup>53</sup> Since then, the many roles of folate and natural or induced folate deficiency continue to be studied.

## PHARMACOLOGY

Folic acid (pteroylglutamic acid), an essential water-soluble vitamin, consists of a pteridine ring joined to PABA (*para*-aminobenzoic acid) and glutamic acid.<sup>3</sup> Folic acid is the most common of the many folate congeners that exist in nature and are essential for normal cellular metabolic functions. Folic acid is rarely called vitamin B<sub>9</sub>. After absorption, folic acid is reduced by dihydrofolate reductase (DHFR) to dihydrofolic acid and then tetrahydrofolic acid (THF), which accepts one-carbon groups. Tetrahydrofolic acid serves as the precursor for several biologically active forms of folic acid, including 5-formyltetrahydrofolic acid (5-formyl THF), which is best known as folinic acid, leucovorin, and citrovorum factor. The biologically active forms of folate are enzymatically interconvertible and function as cofactors, providing the one-carbon groups necessary for many intracellular metabolic reactions, including the synthesis of thymidylate and purine nucleotides, which are essential precursors of DNA.<sup>69,76,86,89,99</sup> The minimum daily requirement of folic acid is normally approximately 50 mcg, but nutritionally deprived, acutely ill patients may require 100 to 200 mcg, and women who are preconception or pregnant are advised to take 400 mcg to 1,000 mcg of folic acid daily.<sup>18,37</sup>

Leucovorin is a mixture of the active and inactive diastereoisomers of 5-formyl-THF, of which the levo-(6*S*)-form is active and available as levoleucovorin.<sup>88</sup> Both are available as the calcium salt, with the same chemical formula. The molecular weight (MW) is 511.5 Da; levoleucovorin for injection is supplied as the calcium pentahydrate form for a total MW of 601.6.<sup>88</sup> Absent metabolic inhibition, folate and leucovorin are rapidly metabolized to several active folates, including 5-methyltetrahydrofolate (5-methyl-THF). The dose of levoleucovorin is half of leucovorin. Leucovorin *increases* the toxicity of 5-fluorouracil (5-FU). Leucovorin is converted to (6*R*)-5,10-methylene-THF, which stabilizes the ternary complex with the 5-FU metabolite, fluoro-deoxyuridine monophosphate (5-FdUMP) and thymidylate synthase, leading to thymidylate depletion.<sup>20,80</sup>

After a DHFR inhibitor such as MTX inhibits the formation of tetrahydrofolic acid, the intracellular machinery for the synthesis of indispensable thymidylate and purine nucleotides comes to a halt, and DNA production ceases. Leucovorin and levoleucovorin are biologically active forms of folic acid and bypass this inhibition of DHFR caused by MTX.

Folate catalyzes the formation of carbon dioxide and water from formic acid, the final metabolic step in methanol elimination. Because there is no inhibition of the formation or recycling of active folate, either folic acid or leucovorin is beneficial (Chap. 106).

Investigations suggest that folic acid aids in the methylation and subsequent elimination of arsenic. Folate supplementation in folate-deficient subjects enhanced the elimination of arsenic and potentially decreased chronic arsenic toxicity (Chap. 86).<sup>27,70</sup>

## Related Xenobiotics

The predominant form of dietary folate, *levo*-(6*S*)-5-methyl-THF, which is required for methionine biosynthesis from homocysteine, is available commercially both as the natural form and as mefolinate, the diastereoisomeric, 1:1 mixture (6*R,S*)-5-methyl-THF.<sup>20</sup> It is also found in combination with pharmaceuticals (eg, oral contraceptive pills).<sup>26</sup> (6*R*)-5,10-methylene-THF also bypasses activation to produce higher (6*R*)-5,10-methylene-THF concentrations compared to leucovorin in order to enhance 5-FU efficacy.<sup>100</sup> It is also undergoing evaluations as an MTX rescue agent (ClinicalTrials.gov Identifier: NCT01987102).

## Leucovorin Pharmacokinetics

Whereas leucovorin is naturally formed in the body as the active *levo* (*l*)-(6*S*)-isomer, the initial commercial preparation was a racemic mixture consisting of equal amounts of the inactive *dextro* (*d*)-(6*R*) and active (*l*) isomers. The pharmacokinetics of the racemic mixture of leucovorin and its active metabolite were studied after a single intravenous (IV) infusion and as a constant infusion in healthy human volunteers.<sup>91,92</sup> During a constant infusion of 500 mg/m<sup>2</sup>/day, the steady-state concentration for the active (*l*) isomer was 2.33 μmol/L, the half-life was 35 minutes, and the volume of distribution ( $V_d$ ) was 13.6 L. The active isomer is metabolized to an active metabolite, *l*-(6*S*)-5-methyl-THF, which achieved a steady-state concentration of 4.85 μmol/L and a half-life of 227 minutes. Similar values were achieved for half-life and  $V_d$  after single IV doses ranging from 25 to 100 mg. The inactive *d*-isomer achieved higher concentrations and had a much longer half-life with oral administration, which is saturable and stereoselective, resulting in absorption of the active isomer that is 4 to 5 times greater than that of the inactive isomer. Studies of stereospecific oral absorption demonstrate that 100% of the *l*-leucovorin is absorbed, but only 20% of the *d*-leucovorin is absorbed at this dose.<sup>95</sup> One study detected no adverse effects of the inactive isomer on the intracellular uptake of the active isomer and concluded that giving the active isomer provided no pharmacokinetic advantage over the racemic mixture.<sup>81</sup> In 5 normal subjects given 1,000 mg of leucovorin as a 2-hour intravenous infusion, peak plasma concentrations of *l*-(6*S*) leucovorin, *d*-(6*R*) leucovorin, and 5-methyl-THF were 5.91 ± 22 μmol/L, 148 ± 32 μmol/L, and 17.8 ± 17 μmol/L, respectively.<sup>80</sup> Intravenous leucovorin results in an area under the curve (AUC) for inactive (6*R*) LV that was 4.16 ± 1.4 times greater than the combined AUCs for *l*-(6*S*) leucovorin and 5-methyl-THF.<sup>80</sup> Two hundred milligrams of levoleucovorin was compared to 400 mg of leucovorin, each administered as a 2-hour IV infusion as a crossover study in 40 healthy volunteers; the area under the curve and the maximum serum concentrations of *l*-5-CH<sub>3</sub>-THF were similar for both.<sup>88</sup>

The pharmacokinetics of IV leucovorin was compared with intramuscular (IM) and oral administration in male volunteers given 25 mg. At this dose, oral leucovorin was 92% bioavailable and the mean peak active *l*-5-methyl-THF concentration of 258 ng/mL ( $5.5 \times 10^{-1}$  μmol/L) at 1.3 hours after IV administration, 226 ng/mL at 2.8 hours for IM, and 367 ng/mL at 2.4 hours for oral administration, respectively.<sup>61</sup> The pharmacokinetics of orally administered leucovorin was studied in healthy, fasted male volunteers in single doses ranging from 20 to 100 mg and 200 mg IV over 5 minutes compared with 200 mg orally.<sup>61,74</sup> Bioavailability decreased from 100% for the 20-mg dose to 78% for the 40-mg dose and ultimately to 31% for the 200-mg dose. A microbiologic assay was used to measure total tetrahydrofolates (reduced and active folates). Normal serum folate concentrations are approximately 0.05 μmol/L.<sup>44</sup> The 200-mg oral dose produced a peak serum concentration of 1.82 μmol/L compared with 0.66 μmol/L for the 20-mg oral dose and 27.1 μmol/L for the 200-mg IV dose.<sup>61,74</sup>

After IV administration of both leucovorin and levoleucovorin, *l*-5-methyl-THF enters the CSF. The concentration of CSF *l*-5-methyl-THF achieved was 100 to 1,000-fold less than that obtained after direct MTX intra-Ommaya reservoir administration during a period of 2 days of observation.<sup>64</sup> Because *l*-5-methyl-THF is cleared slowly from CSF (half-life = 85 hours), progressive accumulation occurs from chemotherapy cycle to cycle.<sup>96</sup> Thus, the significant reductions in *l*-5-methyl-THF that occurs with IV and intrathecal MTX

can recover with ongoing leucovorin treatment.<sup>9,93</sup> The limitations of oral leucovorin therapy were demonstrated in one study in which oral leucovorin (10 mg every 6 hours for 11 doses) failed to provide adequate *l*-5-methyl-THF to exceed CSF MTX concentrations in 6 of 9 patients.<sup>2</sup> Intrathecal administration of leucovorin and levoleucovorin is contraindicated, as it can lower seizure threshold and is associated with fatal neurotoxicity.<sup>25,45,88,97</sup>

## ROLE IN METHOTREXATE TOXICITY

Methotrexate, an antimetabolite, is a structural analog of folic acid, differing only in the substitution of an amino group for a hydroxyl group at the number 4 position of the pteridine ring (Chap. 51). Methotrexate binds to the active site of DHFR, rendering it incapable of reducing folic acid to its biologically active forms and incapable of regenerating the necessary active forms required for the synthesis of purine nucleotides and thymidylate.<sup>87</sup> Under various conditions, the binding between MTX and DHFR is competitive and very tight, with an inhibition constant ranging from 0.0034 nmol/L to 0.093 ± 0.021 nmol/L.<sup>5,19</sup> 7-HydroxyMTX, a major MTX metabolite, more weakly inhibits DHFR ( $K_i = 8.9$  nM).<sup>5</sup> This compares to a  $K_m$  of 2.7 ± 0.5 μmol/L for dihydrofolic acid.<sup>19</sup> Leucovorin is a reduced, active form of folate. As such, it does not require DHFR for enzymatic interconversion to the form required for purine nucleotide and thymidylate formation. Folic acid is unable to counteract MTX toxicity because after MTX therapy, DHFR is unavailable to convert folic acid to an active reduced form. High-dose MTX therapy provides chemotherapeutic benefit, although it is associated with significant toxicity. *Leucovorin rescue* describe the standard practice of limiting the toxic effects associated with high-dose MTX, by providing leucovorin after the initial MTX infusion and in cases of diminished MTX elimination, which can be due to MTX toxicity itself or other factors.<sup>102</sup>

## ROLE IN METHANOL AND FORMATE TOXICITY

The formate produced from methanol is metabolized to 10-formyl tetrahydrofolate in the presence of tetrahydrofolate, which can be acted upon by 10-formyltetrahydrofolate dehydrogenase to produce carbon dioxide and to regenerate tetrahydrofolate.<sup>7</sup> Higher folate activity correlates with a faster formate elimination half-life across multiple species.<sup>90</sup> Monkeys experimentally rendered folate deficient develop methanol toxicity at lower methanol concentrations.<sup>62</sup> Folic acid supplementation (2.5 mg/kg IV) provided to dogs poisoned with 2 g/kg methanol lowered maximum formate accumulation in plasma from 3 to 1 mmol/L.<sup>90</sup> Similarly, administering folic acid to healthy monkeys accelerates formate metabolism.<sup>62</sup> Pretreatment with folic acid or leucovorin decreased both formate concentrations and the accompanying metabolic acidosis without affecting the rate of methanol elimination.<sup>62</sup> In monkeys given repeated injections of leucovorin, either before or concurrent with the administration of methanol, decreased formate concentrations and an absence of metabolic acidosis were observed.<sup>4</sup> Leucovorin remained effective in monkeys in hastening the metabolism of formate when given as late as 10 hours after methanol administration.<sup>67</sup>

In methanol-poisoned humans, the hepatic concentrations of total folate, leucovorin, and folate dehydrogenase (which increases leucovorin concentrations) are all diminished.<sup>46</sup> In a methanol-poisoned patient treated without folic acid, the formate half-life was 2.8 hours.<sup>42</sup> In 6 methanol-poisoned patients treated without folic acid, the mean serum formate half-life was 2.6 hours.<sup>38</sup> By comparison, in a single methanol-poisoned patient who was given folic acid, ethanol, and hemodialyzed, the half-life of formate was 1.1 hours during hemodialysis.<sup>68</sup> In another methanol-poisoned patient, the formate half-life was 3.9 hours, which decreased to 1.2 hours after leucovorin treatment.<sup>38</sup> In an intentional ingestion of 110 g of formic acid treated with folic acid (1 mg/kg every 4 hours for the first 24 hours), low plasma formic acid concentrations were present during leucovorin administration, which rose significantly after leucovorin cessation.<sup>66</sup> In human placental ex vivo experiments, folic acid reversed the toxic effects of formic acid on the placenta of decreased maternal hCG secretion.<sup>41</sup> These comparative data are inadequate to draw definitive conclusions. However, the evidence supports the continued recommendation for a therapeutic role of folate or leucovorin

in addition to definitive therapy with fomepizole (Antidotes in Depth: A33) and/or hemodialysis.<sup>7</sup>

## ROLE IN ARSENIC TOXICITY

Arsenic contamination of drinking water has plagued millions, causing increased manifestations of chronic arsenic toxicity, including cancer and cardiovascular, dermatologic, and neurologic disorders.<sup>17,60</sup> In a folate-dependent mechanism, arsenic undergoes methylation to monomethylarsonic acid (MMA) and then to dimethylarsinic acid (DMA) via one-carbon metabolism, and this methylation facilitates urinary arsenic excretion.<sup>28,33</sup> Patients with higher intakes of folate-related nutrients had lower percentages of inorganic arsenic and higher MMA to inorganic arsenic ratios.<sup>33</sup> Folate deficiency, hyperhomocysteinemia, and low urinary creatinine, each of which is associated with decreased arsenic methylation capacity, are risk factors for arsenic-induced skin lesions.<sup>71</sup> In a study of arsenic's epigenetic effects on histone modification, arsenic concentration in women were associated with lower total plasma histone concentrations only among women with folate deficiency.<sup>94</sup> The absolute methylation amount and product probably depends on the degree of upregulation, age, and available methyl groups (Chap. 86).<sup>31,40</sup> In animal models, folic acid supplementation decreased arsenic embryotoxicity, malformations, and abnormal cardiac and neural development.<sup>58</sup> This effect appeared to be mediated by decreasing subcellular reactive oxygen species when tested in human embryonic kidney cells.<sup>58</sup>

These findings encouraged the study of folate supplementation, along with other nutrients, with the aim to diminish the chronic health effects of arsenic toxicity. A randomized, double-blind, placebo-controlled trial of folic acid supplementation (400 mcg daily for 12 weeks) to participants with low plasma folate concentrations demonstrated enhanced arsenic methylation.<sup>27</sup> In a randomized, controlled trial of 622 patients, daily folic acid of 800 mcg for 12 and 24 weeks' treatment lowered blood arsenic to a greater extent than placebo, an effect that was sustained without rebound for 12 weeks after treatment cessation.<sup>70</sup>

## ROLE IN TOXICITY FROM DIHYDROFOLATE REDUCTASE INHIBITOR ANTIBIOTICS

Pyrimethamine is a dihydrofolate reductase competitive inhibitor used to treat infections from *Toxoplasma*, *Isospora*, and *Pneumocystis*. In a dose-dependent fashion, leucovorin significantly reduces cytogenetic aberrations associated with pyrimethamine in vitro.<sup>21</sup> Leucovorin is routinely added to pyrimethamine therapy for toxoplasmosis.<sup>73,98</sup> One large outbreak of pyrimethamine toxicity reported a 23% fatality rate in 664 cardiac patients who received isosorbide mononitrate contaminated with 50 mg of pyrimethamine.<sup>48</sup> Once the contaminant was determined, leucovorin was administered at a dose of 30 mg every 6 hours for 2 days and then every 12 hours until complete recovery.<sup>48</sup> Trimetrexate glucuronate, another dihydrofolate reductase inhibitor used in to treat *Pneumocystis*, has been discontinued in the United States. It required administration with concurrent IV leucovorin in order to preclude serious or life-threatening bone marrow suppression, oral and gastrointestinal mucosal ulceration, and renal and hepatic dysfunction (20 mg/m<sup>2</sup> over 5–10 minutes every 6 hours for a total daily dose of 80 mg/m<sup>2</sup>, or orally as 4 doses of 20 mg/m<sup>2</sup> spaced equally throughout the day for 24 days).<sup>63</sup>

## ADVERSE EFFECTS AND SAFETY ISSUES

Reports of adverse reactions to parenteral injections of folic acid, leucovorin, or levoleucovorin are uncommon. However, reported adverse reactions include allergic or anaphylactoid reactions.<sup>95</sup> Seizures are also rarely associated with leucovorin or levoleucovorin administration.<sup>65</sup> The calcium content of leucovorin and levoleucovorin warrants a slow IV infusion at a rate not faster than 160 mg/min in adults. There are 0.004 mEq of calcium per milligram of leucovorin calcium injection. Extremely large doses of leucovorin on the order of 1,000 mg every 3 hours might lead to hypercalcemia.<sup>106</sup> Neither leucovorin nor levoleucovorin should be administered intrathecally due to neurotoxic adverse effects.<sup>25,45,52,77,97</sup> As described in the pharmacology

section, leucovorin and levoleucovorin are not antidotes for 5-FU, and both enhance the chemotherapeutic and toxic effects of fluoropyrimidines including 5-FU and 5-FU prodrugs such as capecitabine and tegafur.<sup>20,57,88,95,100</sup>

Protocols recommend separating leucovorin and levoleucovorin from glucarpidase by 2 hours (Antidotes in Depth: A13). Otherwise, leucovorin acts as a substrate for glucarpidase, which cleaves the active *L*-(6*S*)-leucovorin approximately 50% faster than the inactive *d*-(6*R*)-form.<sup>1,23,34,84</sup>

There is a potential for dosing errors when interchanging leucovorin and levoleucovorin. The dose of levoleucovorin is one-half the dose of leucovorin.<sup>88</sup>

## PREGNANCY AND LACTATION

Folic acid is a Food and Drug Administration (FDA) category A drug and is safe and essential during pregnancy and compatible with breastfeeding. Leucovorin and levoleucovorin are FDA pregnancy category C drugs.<sup>88,95</sup> Although definitive reproductive studies do not exist, folinic acid has successfully treated megaloblastic anemia during gestation<sup>83</sup> and is considered compatible with pregnancy.<sup>13</sup> In addition, there are case reports of maternal administration of leucovorin, in combination with 5-FU and oxaliplatin chemotherapy during pregnancy, with subsequent healthy fetal delivery.<sup>49,59</sup> Breast milk excretion is unstudied, but leucovorin is considered compatible with breastfeeding.<sup>13</sup>

## DOSING AND ADMINISTRATION

After MTX overdose, a dose of leucovorin estimated to produce the same plasma concentration as the MTX dose should be given as soon as possible, preferably within one hour. One mole of MTX weighs 454.4 Da, and 1 mole of leucovorin calcium weighs 511.5 Da, with the MW of the leucovorin portion equal to 471.4 Da. Because of the safety of leucovorin and because of the toxicity of MTX, underdosing leucovorin should be avoided. Although serum MTX concentrations are often closely followed in patients on diverse oncologic regimens,<sup>11,12</sup> in the overdose setting, or in MTX toxicity related to treatment for tubal pregnancies, it is inappropriate to wait for a serum concentration before initiating treatment with leucovorin.<sup>6</sup> The toxic threshold for MTX is reported as  $1 \times 10^{-8}$  mol/L (0.01  $\mu$ mol/L or 10 nmol/L), based on mouse studies evaluating DNA synthesis.<sup>15</sup> Normal serum folic acid concentrations are in the range of 13 to 43 nmol/L. Oral MTX doses as low as 2 mg in adults resulted in mean maximal MTX serum drug concentration of 0.215  $\mu$ mol/L at one to 2 hours after ingestion.<sup>85</sup> The MTX half-life for the 2 mg dose rose from 2.4 hours to 3.2 hours when three 2-mg tablets were ingested 12 hours apart.<sup>85</sup> If the patient's MTX exposure is not for chemotherapeutic intent, there is no rationale to permit MTX to remain unantagonized by leucovorin. Cases and case series demonstrate that organ-level toxicity is rare, but still possible from single-adult and pediatric oral intentional and unintentional ingestions of MTX.<sup>8,30,32,75</sup> Even in light of the known MTX oral saturation limits, in one retrospective series of 19 cases of children and adults with MTX ingestions with subsequent MTX concentrations, all were above 0.01  $\mu$ mol/L, the concentrations known to impair DNA and RNA synthesis in GI epithelium and bone marrow when present for as little as 10 hours, and several MTX concentrations were above 1  $\mu$ mol/L.<sup>16</sup> A second poison control center review determined MTX concentrations in 15 of 103 oral ingestions, which ranged from 0.02 to 3.23  $\mu$ mol/L.<sup>32</sup> Even when not associated with acute organ toxicity or symptoms, these MTX concentrations present a gametogenetic and stochastic carcinogenic risk.<sup>15</sup>

Methotrexate bioavailability decreases from 100% with oral doses less than 30 mg/m<sup>2</sup> to approximately 10% to 20% with doses greater than 80 mg/m<sup>2</sup>.<sup>10,78</sup> A compilation of pharmacokinetic studies reported that the bioavailable dose appears to saturate at approximately  $14.4 \pm 1.64$  mg/m<sup>2</sup>, with several notable outliers.<sup>16</sup> As an example, if a child unintentionally ingests 100 (2.5 mg) MTX tablets for a total dose of 250 mg, only part of this dose is absorbed because MTX absorption is saturable.<sup>30</sup> In this case, it is reasonable to assume that a bioavailability of 50% or less would result in an absorbed dose of MTX of less than 125 mg. For this exposure, an IV dose of 125 mg of leucovorin would be reasonable to provide over 15 to 30 minutes. This dose of IV leucovorin

would be expected to produce serum concentrations in excess of that of the MTX, given that the  $V_d$  of leucovorin is about 25% less than MTX and the MWs are similar. It is reasonable to repeat this dose of IV leucovorin every 3 to 6 hours until the serum MTX concentration is less than 0.01  $\mu\text{mol/L}$ , preferably zero.<sup>55,95</sup> This differs from recommendations in patients receiving MTX therapeutically (see later discussion).

The MTX half-life varies from 5 to 45 hours, depending on the dose and the patient's kidney function. For this reason, it is reasonable to continue leucovorin therapy for 12 to 24 doses (3 days) or longer if MTX concentrations are unavailable. Patients can develop third-space storage in ascites or pleural effusions, and thus can require leucovorin dosing for an extended period of time. Patients with bone marrow toxicity require more prolonged dosing because plasma half-lives of MTX do not reflect persistent intracellular concentrations.

### Therapeutic Methotrexate Therapy

The dose of leucovorin for "leucovorin rescue" after "high-dose" MTX therapy (doses of 500  $\text{mg}/\text{m}^2$  or greater) ranges from 10 to 25  $\text{mg}/\text{m}^2$  IM or IV every 6 hours for 72 hours up to 1,000  $\text{mg}/\text{m}^2$  every 6 hours in patients with renal compromise and delayed elimination.<sup>14,39,95,101,104</sup> If a neonate must be treated, a benzyl alcohol-free preparation must be used because of the toxicity of benzyl alcohol in neonates (Chap. 46).<sup>29,51</sup> For MTX overdoses, equimolar serum leucovorin concentrations theoretically provide adequate protection, but because precise determinations are invariably delayed, leucovorin administration should be initiated without delay.

As a rough guide, a single dose of 25 mg of IV leucovorin in an adult produces a peak concentration of the active *l*-5- $\text{CH}_3$ -THF metabolite of approximately 258  $\text{ng}/\text{mL}$ , which is 0.55  $\mu\text{mol/L}$ .<sup>95</sup> A dosage of about 150 mg every 4 hours in an adult achieves a steady-state concentration of about 4.85  $\mu\text{mol/L}$ .<sup>91</sup> Although the dose of leucovorin can be as high as 1,000  $\text{mg}/\text{m}^2$  every 6 hours, this is rarely warranted and cannot adequately compete with serum concentrations of MTX above 100  $\mu\text{mol/L}$ .<sup>72</sup> Under these circumstances, it is recommended to administer glucarpidase (Antidotes in Depth: A13). An IV leucovorin dose of 150  $\text{mg}/\text{m}^2$  every 3 to 6 hours is anticipated to be effective in all but the most severe overdoses and should be administered IV as soon as possible over 15 to 30 minutes, but not faster than 160  $\text{mg}/\text{min}$  in adults because of the calcium content. We recommend that this dose be continued a minimum of several days or until the serum MTX concentration falls below 0.01  $\mu\text{mol/L}$ .<sup>55,95</sup> One case series of 11 patients receiving MTX over 4 hours at 10 to 12  $\text{g}/\text{m}^2$  for osteosarcoma or 3.5  $\text{g}/\text{m}^2$  for central nervous system lymphoma required high-dose leucovorin rescue for MTX concentrations at high risk for toxicity at 24, 48, or 72 hours, usually because of acute kidney injury. The dosage of leucovorin ranged from 0.24 to 10  $\text{g}/\text{day}$  and was titrated downward as the MTX concentration fell. It took an average of 11  $\pm$  3 days for the MTX concentration to drop below 0.1  $\mu\text{mol/L}$  (Table A12-1). Table A12-2 is offered in recognition of the importance and complexity associated with switching complex methotrexate concentrations precisely.

Leucovorin rescue strategies after high-dose MTX are aligned in the leucovorin, levoleucovorin, and methotrexate package inserts, with 15 mg leucovorin (7.5 mg of levoleucovorin) provided at baseline every 6 hours for 10 doses beginning 24 hours after MTX administration, so as not to compromise chemotherapeutic efficacy.<sup>36,88,95</sup> In the setting of early or delayed methotrexate elimination or acute kidney injury, leucovorin dosing must be increased to counteract the persistent adverse effects of MTX (Table A12-1).<sup>36,88,95</sup> Other protocols call for leucovorin rescue using a 4-level tiered pharmacokinetically guided rescue strategy depending upon the MTX concentration at different time points (Fig. A12-1).<sup>11,39,101</sup> Healthcare facilities have also implemented leucovorin rescue stratified by multiple checkpoint MTX concentrations at 24, 36, 42, 48, and 72 hours, with multiple leucovorin dosing adjustments depending upon the MTX concentrations at these time-points.<sup>14,39</sup> Administration of high-dose MTX by continuous infusion over 24 hours may also invoke different leucovorin rescue protocols. Regardless of the specific rescue dosing regimen chosen, systematic protocol implementation in treatment sites reduces variance in the time to MTX concentration

**TABLE A12-1** Leucovorin Dosage and Administration with Chemotherapeutic Methotrexate Use<sup>a,b</sup>

Clinical Situation	Laboratory Findings	Leucovorin Dosage
Normal methotrexate elimination	Serum [methotrexate] $\sim$ 10 $\mu\text{mol/L}$ at 24 hours after administration, 1 $\mu\text{mol/L}$ at 48 hours, and $<$ 0.2 $\mu\text{mol/L}$ at 72 hours	15 mg PO, IM, or IV every 6 hours for 60 hours (10 doses starting at 24 hours after the start of methotrexate infusion)
Delayed late methotrexate elimination	Serum [methotrexate] remaining $>$ 0.2 $\mu\text{mol/L}$ at 72 hours and $>$ 0.05 $\mu\text{mol/L}$ at 96 hours after administration	Continue 15 mg PO, IM, or IV every 6 hours until [methotrexate] is $<$ 0.05 $\mu\text{mol/L}$
Delayed early methotrexate elimination or evidence of acute kidney injury	Serum [methotrexate] of $\geq$ 50 $\mu\text{mol/L}$ at 24 hours or $\geq$ 5 $\mu\text{mol/L}$ at 48 hours after administration or a $\geq$ 100% increase in serum [creatinine] at 24 hours after methotrexate administration (eg, an increase from 0.5 to $\geq$ 1 $\text{mg}/\text{dL}$ )	150 mg IV every 3 hours until [methotrexate] is $<$ 1 $\mu\text{mol/L}$ ; then 15 mg IV every 3 hours until [methotrexate] is $<$ 0.05 $\mu\text{mol/L}$

<sup>a</sup>Leucovorin should not be administered intrathecally. <sup>b</sup>Data from references 36, 88, and 95. IM = intramuscular; IV = intravenous; PO = oral.

measurements and time to first leucovorin rescue dose and increases appropriate leucovorin dose escalation and appropriate leucovorin at discharge.<sup>14</sup> A constant IV infusion of 21  $\text{mg}/\text{m}^2/\text{h}$  has been safely administered for 5 days. A transition to oral administration of leucovorin depends on the serum concentration of MTX and whether adequate serum concentrations of leucovorin can be achieved orally. In adults, a 200-mg oral dose of leucovorin produces a peak serum concentration of 1.82  $\mu\text{mol/L}$  compared with 27.1  $\mu\text{mol/L}$  with a 200-mg IV dose.

Levoleucovorin, the active *l*-isomer of folinic acid, is available and should be dosed at half the dose of racemic leucovorin.<sup>88</sup> Because of the calcium content of the levoleucovorin solution, the rate of intravenous infusion should not exceed more than 16 mL (160 mg of levoleucovorin) per minute.<sup>88,95</sup>

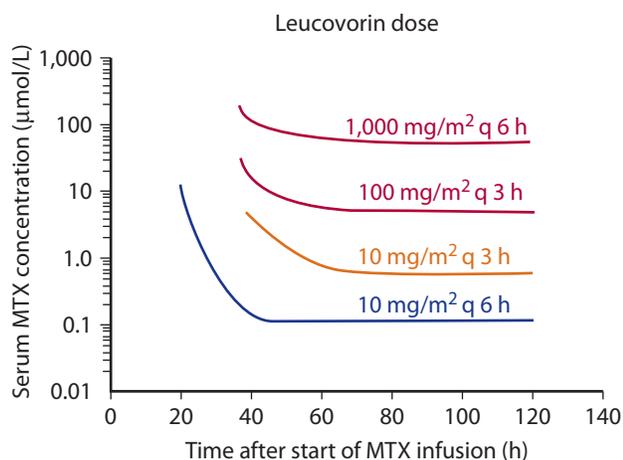

Administration of activated charcoal (AC) limits the benefit of subsequent administration of oral leucovorin. In addition to leucovorin, other modalities to treat patients with MTX overdoses include AC (Antidotes in Depth: A1), urinary alkalization (Antidotes in Depth: A5), glucarpidase (Antidotes in Depth: A13), and extracorporeal removal (Chap. 51).

### Intrathecal Methotrexate Overdose

Unintentional overdose with intrathecal MTX is potentially quite serious and is dose dependent.<sup>45,54</sup> In these cases, IV leucovorin and *not* intrathecal leucovorin should be administered. Intrathecal leucovorin was considered a major factor in the death of a child given a slightly higher dose of intrathecal MTX than was prescribed.<sup>52</sup> Although some cases have been managed with IV leucovorin with or without additional drainage procedures,

**TABLE A12-2** Rapid Calculations

1 mole = 1 g molecular weight
1 molar = 1 mole/L
$1 \times 10^{-3}$ moles = 1 millimole = 1 mmol
$1 \times 10^{-6}$ moles = 1 micromole = 1 $\mu\text{mol}$
$1 \times 10^{-9}$ moles = 1 nanomole = 1 nmol
1 mole of methotrexate weighs 455 Da; 1 mole methotrexate = 455 g
1 molar methotrexate = 455 g/L = 455 mg/mL
$0.01 \times 10^{-6}$ molar methotrexate = $455 \times 10^{-8}$ g/L = $455 \times 10^{-8}$ mg/mL = $455 \times 10^{-5}$ mcg/mL = $455 \times 10^{-2}$ ng/mL = 4.55 ng/mL
To convert methotrexate concentrations in mg/L (mcg/mL) to $\mu\text{mol/L}$ , multiply by 2.2
To convert methotrexate concentrations in mg/L (mcg/mL) to nmol/L, multiply by 2,200

**FIGURE A12-1.** Example of a nomogram developed by Bleyer<sup>10</sup> for pharmacokinetically guided leucovorin rescue after high-dose methotrexate (MTX) administration.

it is reasonable to administer intrathecal glucarpidase in cases of significant intrathecal MTX overdose or signs of neurotoxicity.<sup>22,43,77,103</sup> In intrathecal MTX overdoses, consultation with experienced hematologists/oncologists and medical toxicologists is warranted (Special Considerations: SC7).<sup>50</sup>

### Pemetrexed Toxicity

Pemetrexed toxicity is similar to that of methotrexate. Toxicity is attenuated initially with a low dose of vitamin B<sub>12</sub> and leucovorin as described below. In clinical trials, leucovorin was permitted for NCI Common Terminology Criteria (CTC) Grade 4 leukopenia lasting  $\geq 3$  days, CTC Grade 4 neutropenia lasting  $\geq 3$  days, and immediately for CTC Grade 4 thrombocytopenia, bleeding associated with Grade 3 thrombocytopenia, or Grade 3 or 4 mucositis.<sup>56</sup> Leucovorin was administered as 100 mg/m<sup>2</sup> IV once, followed by 50 mg/m<sup>2</sup> IV every 6 hours for 8 days.<sup>56</sup>

### Methanol Toxicity

Either folic acid or leucovorin (folinic acid) parenterally is recommended at the first suspicion of methanol poisoning. Folic acid is most commonly used. No complications were reported with the use of 50 to 70 mg of IV folic acid every 4 hours for the first 24 hours in the treatment of methanol-poisoned patients.<sup>68</sup> The precise dosage necessary is unknown, but 1 to 2 mg/kg every 4 to 6 hours is probably sufficient. Given that case reports demonstrate that plasma formic acid concentrations can rise after leucovorin cessation,<sup>66</sup> it is recommended to continue folic/folinic acid until the methanol and formate are eliminated. Because the first dose is usually administered before hemodialysis, a second dose is recommended at the completion of hemodialysis because this highly water-soluble vitamin will have been eliminated.

### FORMULATION AND ACQUISITION

Leucovorin (folinic acid) powder for injection is available in 50-, 100-, 200-, and 350-mg vials. Each milligram of leucovorin contains 0.004 mEq of calcium. Reconstitution with sterile water for injection—5 mL to the 50-mg vial, 10 mL to the 100-mg vial, or 20 mL to the 200-mg vial—results in a final concentration of 10 mg/mL. Adding 17.5 mL of sterile water for injection to the 350-mg vial results in a final concentration of 20 mg/mL, where each milliliter contains 0.002 mmol of leucovorin.<sup>95</sup> These lyophilized products contain no preservatives. The only inactive ingredient is sodium chloride added to adjust tonicity. Reconstitute with Sterile Water for Injection, USP; when doses greater than 10 mg/m<sup>2</sup> are used (to avoid excess benzyl alcohol contained in Bacteriostatic Water for Injection, USP) and use immediately.<sup>88</sup> Further dilute in 100 to 1,000 mL of 0.9% sodium chloride or D<sub>5</sub>W for infusion.<sup>55</sup> When protected from light, leucovorin both undiluted in glass containers and when diluted with 0.9% sodium chloride (250 mL) in polyethylene bags, has remained stable, with less than 10% degradation for at least

30 days at room and refrigerator temperatures.<sup>47</sup> Leucovorin is also available in a single-use vial as a solution for injection at a concentration of 10 mg/mL in a 50-mL vial. Because of the calcium content, the rate of IV administration should not be faster than 160 mg/min in adults.<sup>95</sup> Leucovorin is also available orally in a variety of strengths, including 5-, 10-, 15-, and 25-mg tablets.

Levoleucovorin lyophilized powder for injection is available in a single-use 50-mg vial containing the equivalent of 50 mg of levoleucovorin as the calcium pentahydrate salt and 50 mg of mannitol.<sup>88</sup> Reconstitution with 5.3 mL of 0.9% sodium chloride injection yields a concentration of 10 mg/mL.<sup>88</sup> Levoleucovorin is also available as a sterile solution in a single-use 175-mg vial that contains 17.5 mL of sterile solution in which each milliliter contains levoleucovorin calcium pentahydrate equivalent to 10 mg of levoleucovorin and 8.3 mg of sodium chloride. Because of the calcium content, the rate of IV administration should not be faster than 160 mg/min (16 mL of reconstituted solution/min).<sup>88</sup> Further dilution to concentrations of 0.5 mg/mL in 0.9% sodium chloride injection or 5% dextrose injection is acceptable, but should be used within 4 hours when stored at room temperature.<sup>88</sup>

Folic acid is available parenterally in 10-mL multidose vials with 1.5% benzyl alcohol in concentrations of 5 or 10 mg/mL from a variety of manufacturers. Once opened, the vial must be kept refrigerated.

If administration to neonates is necessary, a benzyl alcohol-free preparation must be used because of the toxicity of benzyl alcohol in neonates (Chap. 46).

### SUMMARY

- Leucovorin (folinic acid) is the primary antidote for a patient who receives an overdose of methotrexate.
- Leucovorin is the biologically active, reduced form of folic acid, the synthesis of which is prevented by methotrexate.
- Only leucovorin (folinic acid) is an acceptable antidote for a patient with methotrexate toxicity, but either folic acid or leucovorin is acceptable for a patient poisoned by methanol.
- After a methanol overdose, folic acid enhances the elimination of formate.
- Leucovorin increases the toxicity of 5-FU. Uridine triacetate (Antidotes in Depth: A14) is the appropriate antidote in the case of 5-FU overdose.

# GLUCARPIDASE (CARBOXYPEPTIDASE G<sub>2</sub>)

Silas W. Smith

## INTRODUCTION

Glucarpidase (carboxypeptidase G<sub>2</sub>, CPDG<sub>2</sub>) is indicated for the management of methotrexate (MTX) toxicity. When given intravenously or intrathecally, it rapidly enzymatically inactivates MTX, folates, and folate analogues. It does not substitute for, and must be used in conjunction with, leucovorin (Antidotes in Depth: A12). Leucovorin should not be administered within 2 hours before or after a dose of glucarpidase.

## HISTORY

Soon after the description of the structure and synthesis of folate,<sup>6</sup> a *Flavobacterium* species capable of removing the glutamate moiety of folate was discovered.<sup>47</sup> From 1955 to 1956, the inactivation of folate analogues (including chemotherapeutic aminopterin) was demonstrated in bacteria and yeasts.<sup>61,92</sup> Purification of “carboxypeptidase G,” a pseudomonad-derived zinc-dependent enzyme responsible for MTX cleavage, was reported in 1967.<sup>35,48</sup> Other bacterial carboxypeptidases that differed in their substrate specificity and kinetics were isolated and purified in 1971 (*Pseudomonas stutzeri* carboxypeptidase G<sub>1</sub>),<sup>52</sup> 1978 (*Flavobacterium* carboxypeptidase),<sup>5</sup> and 1992 (*Pseudomonas* sp. M-27 carboxypeptidase G<sub>3</sub>).<sup>104</sup> By 1976, carboxypeptidase G<sub>1</sub> was scaled to pilot manufacturing production.<sup>25</sup> Carboxypeptidase G<sub>1</sub> (CPDG<sub>1</sub>) was initially explored as a chemotherapeutic to deprive growing tumors of folate.<sup>9,10,20,42</sup> Human usage of CPDG<sub>1</sub> for this purpose was reported in 1974.<sup>10</sup> The antidotal potential of carboxypeptidase was first suggested in 1972 when it was noted that CPDG<sub>1</sub> rapidly decreased serum MTX concentrations and improved survival in mice injected with lethal MTX doses.<sup>21</sup> Carboxypeptidase G<sub>1</sub> was first used for rescue in a patient receiving MTX with kidney failure in 1978.<sup>40</sup> Carboxypeptidase G<sub>1</sub> was subsequently used to selectively eliminate systemic MTX in patients treated with high dosages targeting central nervous system (CNS) malignancies.<sup>1,2</sup> Unfortunately, the enzyme source of CPDG<sub>1</sub> was then lost.<sup>4,106</sup> The carboxypeptidase currently used in clinical practice (CPDG<sub>2</sub>) was cloned from *Pseudomonas* strain R-16 and sequenced, characterized, and expressed in *Escherichia coli* in the early 1980s.<sup>57-59,81</sup> The preliminary crystal structure was provided in 1991, with a characterization (at 2.5 Å) and description of the active site, and biochemical mechanism of action in 1997.<sup>49,74,89</sup> Following the renewed availability of the recombinant CPDG<sub>2</sub> product, it underwent nonhuman primate testing for both intravenous (IV) and intrathecal (IT) rescue of MTX overdose.<sup>34</sup> Reports of successful use in human IV and IT MTX overdose rapidly emerged.<sup>26,40,44,45,60,62,75,97,99,106</sup> The US FDA designated glucarpidase an Orphan Product in 2003 and granted marketing approval as Voraxaze in January 2012.<sup>16</sup>

## PHARMACOLOGY

### Chemistry/Preparation

Glucarpidase is produced by recombinant DNA technology. The enzyme cloned from *Pseudomonas* strain R16 is expressed in *Escherichia coli* strain RV308.<sup>31</sup> The final commercial drug product is freeze-dried, and packaged in the United States.<sup>31,39</sup>

### Mechanism of Action

Glucarpidase is a dimerized protein structure with 2 domains—a β-sheet interaction site and a zinc-dependent catalytic domain.<sup>74</sup> As a peptidase, the catalytic domain of glucarpidase hydrolyzes the C-terminal glutamate

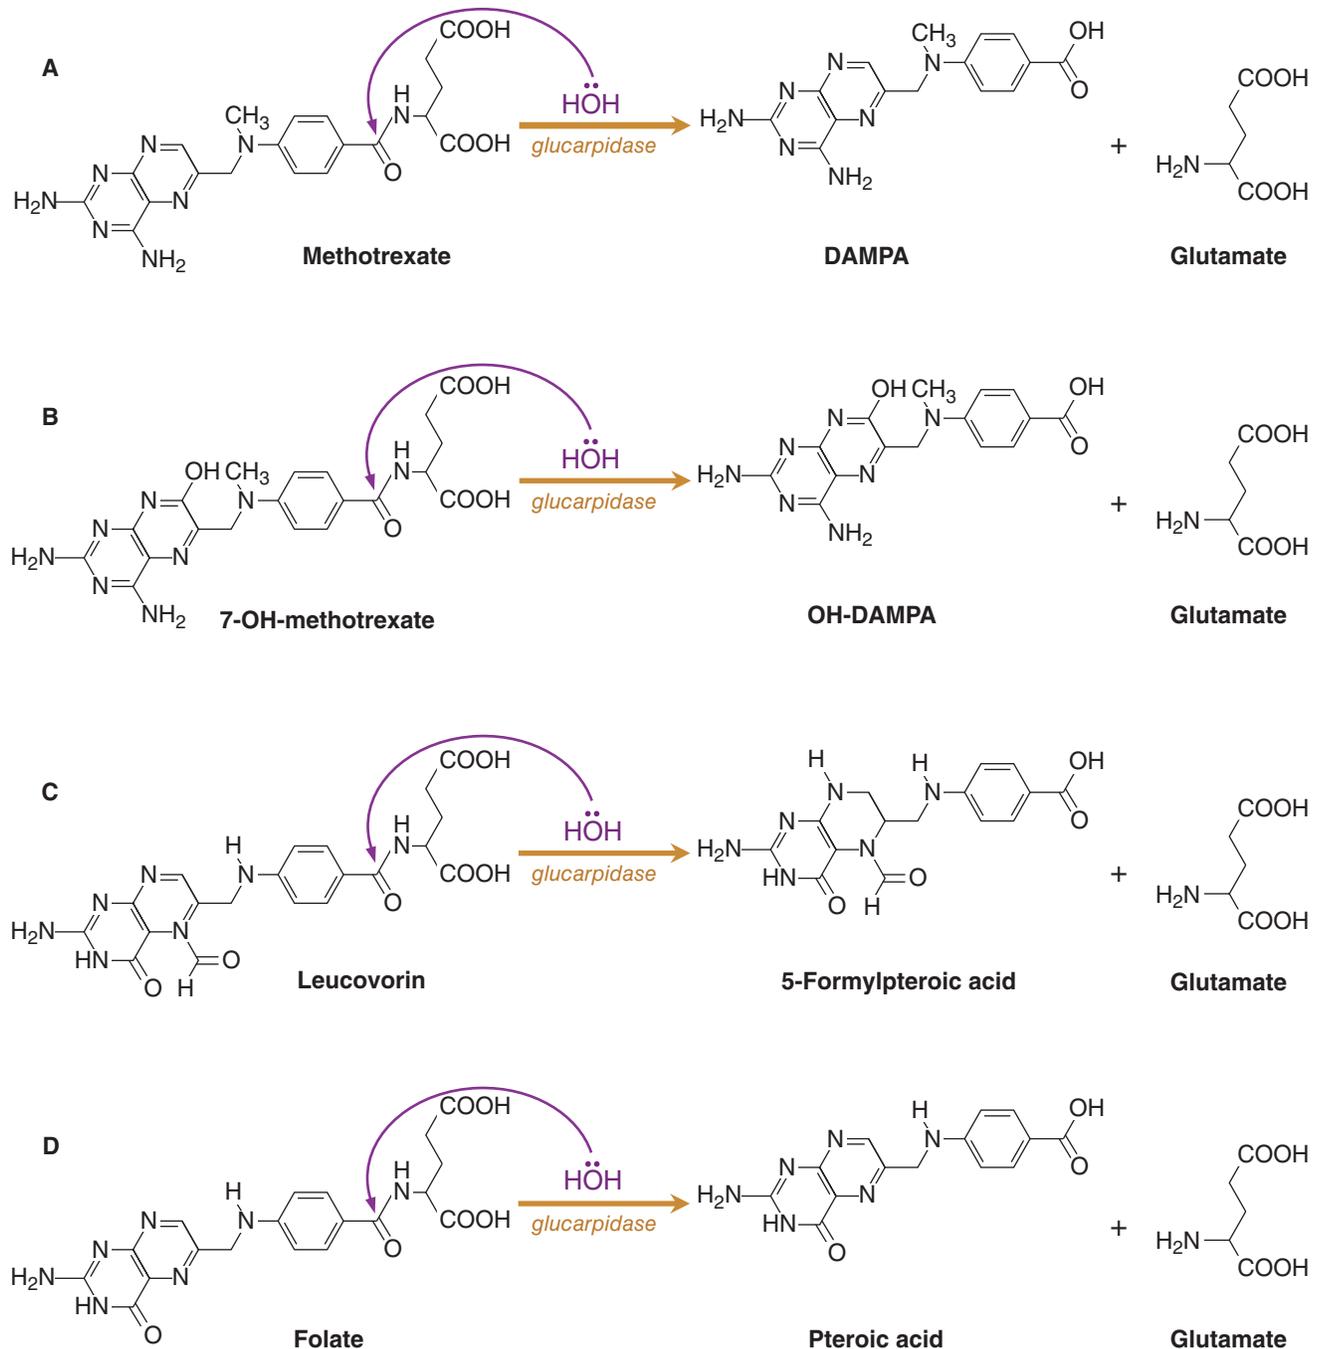

residues of folate and folate analogues such as MTX. Molecular modeling suggests that the 2 zinc (2<sup>+</sup>) ions bind a water molecule, promoting its polarization and nucleophilic attack on the carbonyl group of the substrate (Fig. A13-1).<sup>90</sup> Methotrexate and its metabolite 7-OH-MTX are thus split into inactive DAMPA (2,4-diamino-N(10)-methylpteroic acid) and OH-DAMPA plus glutamate.<sup>102</sup> DAMPA undergoes subsequent hepatic metabolism. Glucarpidase similarly inactivates leucovorin and folate by cleaving their terminal glutamate residues (Fig. A13-1).<sup>5</sup>

### Pharmacokinetics

In one study, 50 units/kg of glucarpidase was given IV to 8 volunteer subjects with normal kidney function and 4 volunteers with impaired function (calculated creatinine clearance <30 mL/min, range 9.8–27.4 mL/min).<sup>71</sup> Those with normal kidney function achieved a mean maximum serum concentration of glucarpidase of 3.1 mcg/mL, with a mean half-life of 9.0 hours. These values were essentially unaffected in the setting of an impaired glomerular filtration rate (GFR); therefore, renal dosing is not indicated.<sup>16</sup> Glucarpidase restriction to the plasma compartment was implied by a volume of distribution of 3.6 L.<sup>71</sup> The large protein size (83-kDa dimer) of glucarpidase precludes traversing the blood-brain barrier, crossing the cell membranes to act intracellularly, acting on MTX within the gut lumen or urinary collecting system, or treating MTX extravasation.<sup>1,21,26,56</sup>

### Pharmacodynamics

One unit of glucarpidase activity catalyzes the hydrolysis of 1 μmol of MTX per minute at 37°C.<sup>3</sup> The mean enzymatic activity half-life of glucarpidase was 5.6 hours in normal volunteers and 8.2 hours in volunteers with impaired GFR.<sup>71</sup> Its activity is optimal at a pH between 7.0 and 7.5, compatible with human physiology. After glucarpidase administration, serum MTX concentrations rapidly declined by 71% to 99% with the original Center for Applied Microbiology and Research (CAMR) product, with the concurrent appearance of inactive DAMPA in both serum and urine.<sup>17,45,77,82,94,95,97</sup> DAMPA undergoes subsequent hepatic metabolism and renal elimination (~50%).<sup>102</sup> Commercial glucarpidase rapidly decreases serum MTX concentrations by greater than 97% within 15 minutes (Table A13-1).<sup>16,23,32,66,82,85</sup> In the primary efficacy study of 22 patients used as the basis for approval, glucarpidase induced MTX reductions of greater than 95% for up to 8 days, although 5 patients also received hemodialysis and 12 of 22 patients (54.5%) did not meet the primary endpoint of an MTX concentration ≤1 μmol/L in all samples, either because of a high baseline MTX concentration and/or significant MTX redistribution and rebound.<sup>32</sup> The ongoing glucarpidase enzymatic activity, which persists after the initial rapid MTX concentration declines, has led authors to explore glucarpidase efficacy at doses lower than the FDA-approved dose (50 units/kg). In one reported case of a patient who received late administration of approximately 8 units/kg glucarpidase, the serum MTX as measured by immunoassay declined from 1.2 to 0.5 μmol/L.<sup>87</sup> In 11 patients who received lower glucarpidase doses (10–31 units/kg) because of a supply shortage, there was no difference in MTX pharmacokinetics, toxicity, or survival.<sup>77</sup> In a retrospective evaluation of 26 patients who received glucarpidase after high-dose MTX, a multivariable analysis could not find any statistically significant relationship between glucarpidase dose and the percentage decrease in plasma MTX concentration as measured by immunoassay or high-performance liquid chromatography (HPLC).<sup>80</sup> Higher dosages of glucarpidase did not lead to more rapid recovery of kidney

**FIGURE A13-1.** The catalytic domain of glucarpidase permits hydrolysis of the C-terminal glutamate residue of folate and folate analogues such as MTX via hypothesized nucleophilic attack of a zinc-bound water molecule.<sup>90</sup> (A, B) MTX and its metabolite 7-hydroxy-MTX are split into inactive DAMPA (2,4-diamino-*N*(10)-methylpteroic acid) and hydroxy-DAMPA plus glutamate. Glucarpidase similarly inactivates (C) leucovorin (folinic acid) and (D) folate by cleavage of terminal glutamate residues.

function, and lower doses (13–50 units/kg) were equally efficacious.<sup>80</sup> These findings were confirmed in another clinical trial in which almost half of the patients were treated with glucarpidase doses below 50 units/kg (as low as 20 units/kg), and the dose per kilogram did not correlate with the time for serum MTX concentration to decrease below 0.2  $\mu\text{mol/L}$  or with the overall reduction in MTX concentration.<sup>85</sup>

### ROLE IN METHOTREXATE TOXICITY

Patients receiving high-dose MTX therapy are routinely “rescued” with leucovorin (eg, 10–15 mg every 6 hours).<sup>105</sup> Treatment nomograms and institutional algorithms recommend higher leucovorin doses when MTX concentrations are excessive or the elevation of the concentration is prolonged (Antidotes in Depth: A12).<sup>11,19,94,105</sup> However, at MTX concentrations

above 100  $\mu\text{mol/L}$  ( $1 \times 10^{-4}$  mol/L), data suggest that adequate leucovorin concentrations cannot be achieved for competitive and complete reversal of toxicity.<sup>17,45,50,72</sup> Also, leucovorin administration provides 0.004 mEq calcium per milligram of leucovorin and is rarely associated with hypercalcemia in extremely high-dose therapy.<sup>106</sup> Necessary urine alkalization and diuresis can also be limited by serum pH, sodium, and fluid administration ceilings once patients develop toxicity.<sup>24,79</sup> Thus, despite adequate leucovorin rescue, alkalization, diuresis, and supportive care, additional antidotal strategies are required in the setting of persistently elevated MTX concentrations. High-dose MTX-induced kidney dysfunction developed in 1.8% of patients with osteosarcoma enrolled in clinical trials.<sup>95</sup> In a 10-year retrospective review of 1,982 patients who received high-dose MTX (HDMTX) for leukemia, lymphoma, and osteosarcoma, 21 patients (1.1%) required glucarpidase

rescue for delayed MTX elimination.<sup>22</sup> In a recent clinical trial with prespecified CPD<sub>2</sub> administration when the serum MTX concentration was greater than 250 μmol/L at 24 hours, greater than 30 μmol/L at 36 hours, or greater than 10 μmol/L at 42 hours in combination with reduced kidney function (at least 50% creatinine increase), glucarpidase was required in 47 of 1,286 children (3.7%).<sup>85</sup> This yielded a relative risk for delayed MTX elimination of approximately 0.5% per each HDMTX cycle.<sup>85</sup> Chemotherapeutic regimens that combine MTX with renal toxic medications such as cisplatin may also increase the risk. Thus, it is reasonable to anticipate the need for glucarpidase in approximately 1% to 4% of patients receiving HDMTX, depending on the specific indication, dose, and regimen.

Glucarpidase is labeled for patients with serum MTX concentrations greater than 1 μmol/L in the setting of impaired kidney function (as evidenced by an MTX concentration not falling within 2 standard deviations of the mean MTX excretion curve for the specific administered MTX protocol).<sup>16</sup> In the absence of an MTX concentration, significant mucositis, gastrointestinal distress, myelosuppression, hepatitis, or neurotoxicity should prompt administration of glucarpidase in addition to aggressive leucovorin therapy, while awaiting confirmation. The primary glucarpidase efficacy and safety studies in adults and children are summarized in Table A13-1. These trials provide data for glucarpidase use in the setting of elevated MTX concentrations and the failure of leucovorin rescue and standard care approach. The CAMR product, which was used in initial clinical trials,<sup>17,77,96</sup> was not

demonstrated to be bioequivalent to the current commercial product.<sup>32</sup> Although no fully reported trial has yet demonstrated the superiority of glucarpidase as adjuvant therapy to leucovorin and supportive care alone, the pharmacodynamic efficacy is clear: glucarpidase immediately decreases serum MTX concentrations by greater than 97%.<sup>16,23,32,66,82,85,96</sup>

The expansion of glucarpidase use to include routine provision at 24 hours in addition to leucovorin rescue after HDMTX was studied in a double-blind, randomized, crossover phase II clinical trial, in which HPLC plasma [MTX] were determined daily until less than 0.2 μmol/L.<sup>68</sup> In 16 patients, routine glucarpidase use reduced delays to subsequent chemotherapy cycles and the severity of mucositis, but it did not reduce MTX-associated nephrotoxicity or the overall total MTX area under the plasma drug concentration-time curve (AUC).<sup>66-68</sup> Upon further exploration, although glucarpidase decreased the MTX AUC<sub>24-72 hours</sub>,<sup>66-68</sup> the overall MTX AUC was not statistically significantly changed, primarily because of the contribution of MTX exposure in the first 24 hours (prior to glucarpidase).<sup>66-68</sup> Clinical trials have also highlighted pharmacokinetic limitations beyond glucarpidase's impressive immediate decrease in [MTX]. In studies, a rapid and sustained clinically important reduction in MTX concentration (RSCIR, [MTX] < 1 μmol/L), occurred in only 45%,<sup>32</sup> 59%,<sup>100</sup> and 67%<sup>23</sup> of patients. This failure of RSCIR reflects MTX redistribution, and underscores the need for continued leucovorin therapy.<sup>79</sup> Patients with [MTX] of greater than or equal to 50 μmol/L were less likely to achieve RSCIR than

those with of less than 50  $\mu\text{mol/L}$  (although glucarpidase did lead to a higher percentage reduction in those with higher [MTX]),<sup>100</sup> In exploratory analysis, patients with osteosarcoma—who received higher MTX doses (eg, 8–12  $\text{g/m}^2$ )—experienced less benefit with glucarpidase.<sup>32</sup> Another evaluation concluded that glucarpidase was unable to prevent fatal MTX toxicity in 3% of patients.<sup>16</sup> However, overall, the data support the use of glucarpidase to treat those at risk for toxicity from MTX because of either persistently elevated [MTX] or kidney dysfunction.<sup>17,36,77,95</sup> More recent trials have demonstrated more favorable outcomes. In one trial where glucarpidase intervention was required in 50 cycles of HDMTX in 47 of a total of 1286 HDMTX-treated children, mortality was 0%.<sup>85</sup> The use of glucarpidase to manage MTX toxicity has also permitted earlier resumption of MTX chemotherapy.<sup>7,23,28,68,84</sup>

Intracellular MTX is polyglutamated, which hinders transmembrane transport and increases intracellular half-life. This MTX pool is inaccessible to glucarpidase (and hemodialysis) and can persist, causing cytotoxicity and a rebound in serum [MTX] for up to 85 hours after glucarpidase administration.<sup>34,77,96,98</sup> In one trial, MTX rebound was seen in 6 of 28 patients (21%) at a median of 24 hours after glucarpidase administration.<sup>66</sup> Delaying glucarpidase more than 96 hours after MTX initiation, once intracellular MTX is established, is associated with failure to prevent significant MTX toxicity.<sup>77,96</sup> This emphasizes the need for close monitoring of [MTX] to ensure early administration of glucarpidase as soon as indicated. Persistent intracellular or otherwise inaccessible MTX requires ongoing leucovorin therapy for 48 hours at the same leucovorin dose as that prior to glucarpidase, which is continued until the [MTX] is below the leucovorin treatment threshold (50–100  $\text{nmol/L}$ , 0.05–0.1  $\mu\text{mol/L}$ ; 0.05–0.1  $\times 10^{-6}$  molar) for a minimum of 3 days.<sup>16,17,23,32,38,43,66,77,80,85,86,94,96,100,103</sup>

In the setting of oral MTX overdose, gastrointestinal decontamination should be performed (Chap. 51), because glucarpidase has no intraluminal activity. Leucovorin is contraindicated for IT administration, and it has rarely been associated with seizures.<sup>30,41,55,88</sup> Simian studies and human case reports demonstrate that IT glucarpidase provides an effective means to rapidly lower cerebrospinal fluid [MTX] in cases of overdose or prolonged CNS persistence.<sup>3,13,62,98</sup> Reductions in CSF [MTX] after glucarpidase administration range from 72% to 99.8%.<sup>13,98</sup> Intravenous leucovorin with or without steroid administration has also been employed to minimize toxicity.<sup>46,73</sup> Patent applications revealed experiments demonstrating glucarpidase cleavage of pemetrexed and raltitrexed.<sup>53,54</sup> In vitro, glucarpidase hydrolyses pemetrexed ( $K_m = 25 \mu\text{M}$ ,  $k_{\text{cat}} = 1,808 \text{ s}^{-1}$ ) with a similar reaction kinetic profile to MTX ( $K_m = 10 \mu\text{M}$ ,  $k_{\text{cat}} = 1,039 \text{ s}^{-1}$ ).<sup>8</sup> These promising kinetic data await animal and human investigations before a definitive recommendation can be made regarding glucarpidase treatment of toxicity because of other chemotherapeutic antifolates.<sup>14</sup>

## ADVERSE EFFECTS AND SAFETY ISSUES

### Antidotal Compromise

The affinity of CPDG<sub>2</sub> for MTX is 10- to 15-fold higher than for leucovorin; however, its affinity for the active metabolite of leucovorin, 5-methyltetrahydrofolate (5-mTHF) and folate are similar.<sup>5,29,81</sup> Although racemic leucovorin is commonly administered, the active enantiomer is also commercially available. Because glucarpidase cleaves active *levo*-(6S)-leucovorin approximately 50% faster than inactive *dextro*-(6R)-leucovorin,<sup>37</sup> glucarpidase will compromise leucovorin rescue if both antidotes are administered contemporaneously. Further, once the MTX has been rapidly cleaved, glucarpidase persistence (recalling its enzymatic activity half-life of 5.6 hours in volunteers and 8.2 hours in kidney failure) would risk compromising the endogenous folate pool and exogenously administered leucovorin. Healthy volunteers provided leucovorin 2 hours after glucarpidase had their leucovorin concentrations decreased by 50%, and activated *levo*-5-MeTHF became undetectable. When leucovorin therapy was delayed 26 hours after glucarpidase administration, enzymatic cleavage by glucarpidase still decreased leucovorin and 5-MeTHF concentrations to

80% and 75%, respectively.<sup>29</sup> In MTX trials within 15 minutes after administration of glucarpidase, the median leucovorin concentrations fell by 8% to 18%, with the remaining leucovorin likely being the inactive *d*-isomer.<sup>94,96</sup> This is of concern, as the *d*-isomer may accumulate and inhibit passive transport of the active “l”-isomer.<sup>12</sup> Active 5-methyltetrahydrofolate concentrations also declined precipitously by greater than 97%.<sup>94,96</sup> Given these concerns of antidotal leucovorin destruction, a later trial of 20 patients evaluated leucovorin and [(6S)-5-MeTHF] for a period of 3 hours after leucovorin administration in patients who had received HDMTX, glucarpidase, and leucovorin or HDMTX and leucovorin alone.<sup>78,91</sup> Leucovorin was not provided within 2 hours of glucarpidase (median, 2.2 hours later). The study’s interpretation is limited by unbalanced trial arms. In the glucarpidase group, pretreatment [MTX] were higher; body surface areas (BSAs) and leucovorin administration were greater; and serious and other adverse events were more common. When accounting for unequal BSAs, and despite the greater than 2+-hour delay in subsequent leucovorin administration, the patients given glucarpidase experienced a decrease in dose-normalized *levo*-(6S)-leucovorin  $\text{AUC}_{0-3 \text{ hours}}$ , *levo*-(6S)-leucovorin  $C_{\text{max}}$ , active (6S)-5MeTHF  $\text{AUC}_{0-3 \text{ hours}}$ , and 5MeTHF  $C_{\text{max}}$  by 33%, 52%, 92%, and 93%, respectively.<sup>18</sup> This trial and others confirmed the recommendation that leucovorin should not be administered for at least 2 hours before or after glucarpidase and that the ongoing leucovorin dose should be based on the pre-glucarpidase [MTX].<sup>16,18,29,32,38</sup>

### Immunogenicity

Initial studies reported adverse effects in 4 of 9 patients treated with CPDG<sub>1</sub>, including development of inactivating antibodies, “sensitization” to CPDG<sub>1</sub>, and anaphylactoid reactions.<sup>1,2,10,40</sup> The current recombinant glucarpidase (CPDG<sub>2</sub>) imparts a much lower incidence of adverse effects than the initial CPDG<sub>1</sub> enzyme, including paresthesias (2%), flushing (2%), nausea/vomiting (2%), hypotension (1%), headache (1%), and rash (0.3%).<sup>16,32</sup> However, in intentional repeated dosing of glucarpidase with HDMTX, 2 of 4 patients experienced allergic reactions.<sup>32</sup> In patients administered CPDG<sub>2</sub> fused to a murine single-chain Fv antibody, 36% (11 of 30) developed anti-CPDG<sub>2</sub> antibodies, but no antimurine antibodies were detected.<sup>51</sup> Studies using the noncommercial (CAMR) lot reported antiglucarpidase antibody (AGA) development in none of 28 patients<sup>96</sup> and in 3 of 7 patients,<sup>77</sup> respectively. In clinical trials using the commercial product, 19% (19 of 99) developed AGAs following a single glucarpidase dose and 28.5% (6 of 21) developed AGAs after 2 doses, consistent with increased antibody development with multiple exposures.<sup>16,32</sup> Neutralizing antibodies were found in 11 of the 25 patients who tested positive for AGA-binding antibodies, of whom 8 had received only a single dose.<sup>16</sup> Antiglucoarpidase antibodies were found in 43% (6 of 14) of assessed patients in another trial, all of whom became positive following the second glucarpidase dose.<sup>66</sup> In a broader evaluation of 205 patients treated with glucarpidase from 2007 to 2012, AGAs developed in 32 of 176 (18%) patients following a single glucarpidase dose and in 11 of 29 (37.9%) after 2 or more doses; 14 of 176 (8.0%) single-dose patients had neutralizing antibodies, which increased to 8 of 29 (27.6%) after 2 or more doses.<sup>101</sup> Although AGAs might decrease clinical efficacy or predispose to allergic reaction upon re-exposure,<sup>2,4,29,77</sup> many patients have been successfully treated with more than one dose of glucarpidase for persistently elevated MTX concentrations.<sup>17,26,45,64,70,77,83,85,99,106</sup>

### Other Considerations

Because “inactive” DAMPA has a pH-dependent urinary solubility 8 to 10 times less than MTX,<sup>37,95</sup> in the absence of a contraindication (eg, volume overload), alkalinization and saline diuresis should be continued to prevent DAMPA precipitation and further renal compromise.<sup>17,94</sup> Although the supplied product contains lactose and Tris-HCl with zinc buffer, lactose-intolerant patients can receive glucarpidase. Previous concerns of allergic reactions to lactose-containing xenobiotics and patients with rare hereditary problems of fructose intolerance, galactose intolerance, galactosemia, or glucose-galactose malabsorption, are unaddressed in prescribing guidelines.<sup>16</sup>

## PREGNANCY AND LACTATION

Glucarpidase carries a pregnancy category C designation, although formal human and animal data are lacking. The excretion of glucarpidase in breast milk is unknown.

## DOSING AND ADMINISTRATION

Glucarpidase is dosed in units per kilogram in both children and adults. After reconstituting each 1,000-unit vial with 1 mL of sterile sodium chloride (0.9%), a single dose of 50 units/kg is administered immediately by IV injection over 5 minutes. If not used immediately, reconstituted glucarpidase can be stored under refrigeration at 36° to 46°F (2°–8°C) for up to 4 hours.<sup>16</sup> Although clinical trials permitted additional glucarpidase doses 24 to 48 hours later in cases of persistent elevated MTX concentrations, repeat administration has not demonstrated significant efficacy and is not recommended.<sup>16,17,65,76</sup> The substantial cost of glucarpidase<sup>93</sup> and the apparent glucarpidase efficacy of lower doses<sup>77,80,85,87</sup> has led some authors to advocate rounding the glucarpidase doses down (eg, to the nearest vial size) or capping glucarpidase doses (eg, at 2,000 units), although this practice is not consistent with the FDA-approved dose (50 units/kg). Although this approach awaits further formal study, this approach would be reasonable in cases of glucarpidase shortage or the need to triage dosing. In cases of IT MTX overdose, a fixed dose of glucarpidase (2,000 units) reconstituted in sterile 0.9% sodium chloride has been administered intrathecally (off label) over 5 minutes and is recommended in this scenario.<sup>13,62,98</sup> A lack of compatibility studies precludes glucarpidase mixing with other xenobiotics.

## Monitoring and Analytical Considerations

False elevations of [MTX] are reported with all of the various immunoassay techniques after glucarpidase administration.<sup>28,37,45,70,99,106</sup> The DAMPA metabolite significantly cross-reacts with both the MTX radioimmunoassay and competitive dihydrofolate reductase-binding assays.<sup>27</sup> Both MTX metabolites (7-OH-MTX and DAMPA) appreciably interfere with fluorescence polarization immunoassay (FPIA) and enzyme-multiplied immunoassay technique (EMIT) assays. For DAMPA, the cross-reactivity rates are 100% (EMIT) and 36% to 44% (FPIA).<sup>69</sup> The cross-reactivity of 7-OH-MTX using EMIT is 4% to 31%, and 0.6% to 3% with FPIA.<sup>33,69</sup> This interference persists despite newer immunoassays.<sup>63</sup> Clinically, the concentrations of DAMPA detected are comparable to those of MTX after administration of CPD<sub>2</sub>.<sup>26</sup> Thus, HPLC should be used to determine actual [MTX] when glucarpidase is given.<sup>15,16</sup>

## FORMULATION AND ACQUISITION

Branded glucarpidase (Voraxaze) is available in single-use glass vials each containing lyophilized glucarpidase (1,000 units) with lactose monohydrate (10 mg), buffered to pH 6.5 to 8.0 with Tris-HCl (0.6 mg) and zinc acetate dihydrate (0.002 mg). It should be maintained at 36° to 46°F (2°–8°C), but not frozen. The manufacturer's website details acquisition information for inside and outside of the United States (<http://www.btgplc.com/products/specialty-pharmaceuticals/voraxaze> and <http://www.btgplc.com/contact-us/contacts>, respectively).

## SUMMARY

- Glucarpidase is a bacterially derived enzyme used in the treatment of MTX toxicity. It cleaves MTX in the serum compartment to rapidly reduce serum [MTX].
- Glucarpidase does not substitute for leucovorin, which should be continued to counteract persistent intracellular and CNS MTX.
- Leucovorin should not be administered within 2 hours before or after a dose of glucarpidase to avoid the enzymatic destruction of leucovorin and its active metabolites.
- The measurement of [MTX] after glucarpidase administration will be unreliable unless HPLC is used.

## URIDINE TRIACETATE

Silas W. Smith

**INTRODUCTION**

Uridine triacetate (2',3',5'-tri-*O*-acetyluridine) is used to treat cases of toxicity from fluoropyrimidines such as fluorouracil and fluorouracil prodrugs such as capecitabine and tegafur. Uridine triacetate is a prodrug that is taken orally to provide uridine as a source for uridine triphosphate for endogenous RNA incorporation.

**HISTORY**

In 1950, leucovorin (folinic acid) successfully mitigated chemotherapeutic toxicity from aminopterin and methotrexate, for which folate antidotal therapy was inefficacious.<sup>39</sup> Fluorouracil (5-FU) synthesis and its antitumor activity were reported in 1957.<sup>18</sup> A decade later, the concept of leucovorin “rescue” emerged to mitigate toxicity from higher methotrexate chemotherapy doses.<sup>27</sup> However, in 1982 leucovorin was reported to paradoxically both increase 5-FU chemotherapeutic efficacy as well as cytotoxicity in humans by increasing inhibition of thymidylate synthase.<sup>30</sup> Additional studies in 1982 reported successful use of uridine to “rescue” mice from lethal 5-FU doses, as well as the ability to deliver higher 5-FU chemotherapeutic doses with concomitant uridine.<sup>25,32</sup> Human phase I uridine rescue trials soon followed in 1984.<sup>28</sup> Intravenous uridine was associated with severe phlebitis when administered peripherally and with cellulitis and thrombosis when given centrally.<sup>41,42</sup> This necessitated a shift toward oral administration. However, oral uridine was limited by poor bioavailability.<sup>43</sup> To prevent uridine catabolism by uridine phosphorylase and increase lipophilicity, uridine was modified to uridine triacetate in the late 1980s<sup>45</sup> and introduced in mice in 1996.<sup>4</sup> Phase I human studies of oral uridine, then also known as PN401, were reported soon after in 1997.<sup>22</sup> Meanwhile, capecitabine, which was synthesized in the early 1990s and patented abroad in 1992, underwent pilot/phase I studies in 1996 and received US market approval in 1998.<sup>3,5,17</sup> The FDA designated uridine triacetate an orphan product in 2009, and ultimately granted marketing approval in January 2015 to treat 5-FU or capecitabine overdose and early-onset, severe or life-threatening toxicity.<sup>6</sup>

**PHARMACOLOGY****Chemistry/Preparation**

Uracil (demethylated thymine) is a naturally occurring pyrimidine and one of the 4 fundamental bases of ribonucleic acid (RNA). Uracil has a molecular weight of 112.1 Da. Uridine is uracil attached by a  $\beta$ -*N*<sub>1</sub>-glycosidic bond to a ribose ring. Uridine triacetate (or triacetyluridine) is uridine that has been triacetylated at the 2', 3', and 5' positions. Uridine triacetate has a molecular weight of 370.3 Da.

**Mechanism of Action**

Uridine as uridine triphosphate is an essential component of RNA, while uridine as uridine diphosphate glucose is an important precursor to

glycogen synthesis.<sup>48</sup> Mechanisms of toxicity by the fluoropyrimidines (5-FU, capecitabine, tegafur, and floxuridine) are reviewed in Chap. 51 and summarized in Fig. 51–2. The 5-FU metabolite fluorouridine triphosphate (FUTP) is incorporated in RNA. Uridine triacetate, once absorbed and metabolized, supplies uridine, which can serve as a source for uridine triphosphate to compete with FUTP for RNA incorporation.<sup>26</sup> The enzyme thymidylate synthase generates deoxythymidine monophosphate (dTMP), which is necessary for DNA synthesis, from deoxyuridine monophosphate (dUMP). Uridine triacetate does not reverse inhibition of thymidylate synthase by the 5-FU metabolite fluorodeoxyuridine monophosphate (5-FdUMP), nor does it reverse incorporation of fluorodeoxyuridine triphosphate into DNA, as uridine is not present in DNA.

**Related Agents**

Various uridine formulations that are marketed as dietary supplements are available but they are not recommended to treat fluoropyrimidine toxicity because of a lack of quality control. Uridine triacetate is also packaged as branded Xuriden for treatment of hereditary orotic aciduria (HOA), at a dose that is different than for fluoropyrimidine toxicity.<sup>47</sup>

**Pharmacokinetics and Pharmacodynamics**

The pool of physiologically available uridine arises both from pyrimidine salvage pathways and through the *de novo* synthesis of uridine monophosphate (UMP) by the enzyme uridine monophosphate synthetase (UMPS). Uridine monophosphate synthetase catalyzes UMP generation from orotate and phosphoribosylpyrophosphate (PRPP), which is itself a product of the pentose phosphate pathway.<sup>48</sup> Uridine phosphorylase metabolizes uridine to uracil, and uracil is further degraded to dihydrouracil, 3-ureidopropionate, and ultimately to  $\beta$ -alanine by dihydropyrimidine dehydrogenase, dihydropyrimidinase, and  $\beta$ -ureidopropionase, respectively.<sup>48</sup> Unlike uracil, uridine is not a substrate for dihydropyrimidine dehydrogenase (DPD), the enzyme responsible in humans for metabolizing approximately 80% of 5-FU.<sup>9,37</sup>

In one of the earliest studies in a small group of 7 healthy volunteers, baseline uridine concentrations were  $2.32 \pm 0.58 \mu\text{mol/L}$  in plasma, and  $10.44 \pm 5.06 \mu\text{mol/L}$  in bone marrow.<sup>14</sup> Other studies found human plasma physiological uridine concentrations more typically ranging from 3 to  $8 \mu\text{mol/L}$ .<sup>28,48</sup> When given in only trace amounts, radiolabeled uridine elimination was triphasic, with initial half-lives of  $0.57 \pm 0.28$  and  $1.79 \pm 0.62$  minutes, and a terminal half-life of  $17.5 \pm 7.3$  minutes.<sup>14</sup> This rapid elimination could be slightly altered with increasing dose. Intravenous uridine bolused at large doses of 1 to  $12 \text{ g/m}^2$  cleared from the plasma in a biphasic manner with an initial half-life of  $25 \pm 8$  minutes and a terminal half-life of 118 minutes.<sup>28</sup> Uridine concentrations increased linearly with increased IV doses.<sup>28</sup> The volume of distribution ( $V_d$ ) of uridine averaged  $0.481 \pm 0.07 \text{ L/kg}$  with trace amounts and  $0.634 \text{ L/kg}$ , with large IV doses.<sup>14,28</sup> The goal of sustained serum uridine concentrations higher than  $70 \mu\text{mol/L}$ , which are needed to expand intestinal and bone marrow nucleotide pools and to prevent toxicity,<sup>26,31</sup> was explored in several pharmacokinetic evaluations. Continuous uridine infusions of 1 and  $2.5 \text{ g/m}^2/\text{hour}$  increased plasma uridine concentrations to steady-state concentrations of 500 and  $1,000 \mu\text{mol/L}$ , respectively.<sup>42</sup> Intermittent 3-hour dosing of  $3 \text{ g/m}^2$  (the maximum tolerated dose) created peak and nadir concentrations of 846 to  $1,306 \mu\text{mol/L}$  and 138 to  $335 \mu\text{mol/L}$ , respectively.<sup>42</sup>

When uridine was changed to the oral route to mitigate safety concerns with the intravenous product, with single uridine doses from 0.3 to 12 g/m<sup>2</sup>, bioavailability was extremely poor and ranged from only 5.8% to 9.9%.<sup>43</sup> At the maximum tolerated single oral dose of 8 to 12 g/m<sup>2</sup>, plasma uridine concentrations reached 60 to 80 µmol/L; however, at the maximum tolerated multiple-dose regimen of 5 g/m<sup>2</sup>, steady-state concentrations were only approximately 50 µmol/L.<sup>43</sup> Uridine's oral dosing limitations were confirmed in a separate study in which oral dosing of uridine 8 g/m<sup>2</sup> yielded mean trough concentrations of only 42.9±18 µmol/L.<sup>40</sup>

The significant pharmacokinetic limitations of rapid uridine plasma clearance and poor bioavailability, as well as poor oral tolerance and the safety issues surrounding intravenous administration, prompted evaluation of uridine delivery as a uridine triacetate prodrug.<sup>4</sup>

Uridine triacetate has several pharmacokinetic advantages. It is more lipophilic than uridine and does not require the pyrimidine transporter for absorption, which results in enhanced transport across the gastrointestinal mucosa.<sup>19,22</sup> Additionally, uridine triacetate is not a substrate for uridine phosphorylase, thus mitigating catabolism.<sup>19</sup>

Following absorption, uridine triacetate is deacetylated by nonspecific esterases to uridine and acetate. Mouse studies demonstrated that uridine triacetate had decreased first-pass effects that increased uridine bioavailability from 7% to 53% and decreased time to maximum plasma concentrations (ie, to 507 µmol/L at 0.4 hours, compared to only 20 µmol/L at one hour with uridine).<sup>4</sup> Subsequent human evaluations demonstrated that oral uridine triacetate doses of 3.3 g produced average uridine trough values of 37.3 µmol/L and 6.6 g doses produced average trough values of 50.8 µmol/L.<sup>22</sup> With intensive dosing (6 g every 2 hours for 3 doses followed by 6 g every 6 hours for 15 doses), the mean C<sub>max</sub> was 259.33 µmol/L 2 hours after the third intensive dose, and this was then maintained above 100 µmol/L for more than 6 hours.<sup>19</sup> Following single and repeat dosing every 8 hours of a proprietary supplement that contained 0.58 g (1.61% by weight) uridine and 5.4 g uridine triacetate (15.0% by weight), the peak plasma uridine concentrations one to 2 hours later were 150.9±39.3 µmol/L with single dosing and 161.4±31.5 µmol/L with repeat dosing.<sup>46</sup> In clinical trials with current labeled dosing of 10 g for adults and 6 g/m<sup>2</sup> for children, the maximum uridine concentrations occurred after 2 to 3 hours, with a half-life of 2 to 2.6 hours.<sup>21</sup> Plasma uridine concentrations were 99 to 119 µmol/L after the first dose and rose to 153 to 160 µmol/L after the final dose.<sup>6</sup>

## ROLE IN FLUOROPYRIMIDINE TOXICITY

Previous therapy for fluoropyrimidine toxicity was limited to supportive care, included discontinuing drugs that impaired fluoropyrimidine clearance, ECG and cardiovascular monitoring, volume resuscitation, electrolyte repletion, antiemetics and antidiarrheals, colony-stimulating factors, broad-spectrum antibiotics, glutamine enteral supplementation, and ACE inhibitors (for 5-FU-related cardiac dysfunction).<sup>1,2,15</sup> Despite these measures, toxicity was often severe, including bone marrow suppression (with neutropenia, infection, and sepsis), gastrointestinal toxicity (with mucositis, stomatitis, vomiting, transaminitis, and severe diarrhea), volume depletion, acute kidney injury, cardiotoxicity (dysrhythmias, congestive heart failure, and hemorrhagic pericarditis), neurotoxicity, mutisystem organ failure, and death. Uridine triacetate rescue offers a novel antidotal mechanism to mitigate fluoropyrimidine toxicity. Hematopoietic and gastrointestinal mucosal progenitors efficiently incorporate exogenous uridine by the salvage pathway, compared to solid tumors, which favor de novo synthesis, providing an explanation for the effectiveness of exogenous uridine in competing with FUTP in normal tissues.<sup>37</sup>

## Animal Studies

In the first mice studies, intraperitoneal (IP) uridine at 1, 5, or 10 g/kg/day produced 100% survival from previously lethal doses of 5-FU (up to 800 mg/kg), although it was ineffective against higher fluorouracil doses (1,000 or 1,200 mg/kg).<sup>25</sup> With 2 doses of uridine 3.5 g/kg IP, the median lethal dose (LD<sub>50</sub>) of fluorouracil was increased by 68% from 190 to 320 mg/kg.<sup>32</sup>

Furthermore, in mice with tumors given uridine rescue, the maximum tolerated dose of fluorouracil was doubled from 40 to 80 mg/kg without attendant toxicity as well as improved efficacy.<sup>32</sup> In another mouse study using uridine rescue with multiple doses ranging from 1.5 to 3.5 g/kg, high-dose fluorouracil 100 mg/kg/week could be extended to very-high-dose 200 or 225 mg/kg/week, with improved chemotherapeutic efficacy.<sup>34</sup> In mice treated with the maximum tolerated single dose of 5-FU (200 mg/kg) followed in 24 hours by a 5-day rescue uridine infusion of 5 g/kg/day, bone marrow cellularity declines were blunted and recovery was hastened significantly.<sup>24</sup> Mitigation of 5-FU toxicity in doses up to 800 mg/kg with this regimen was also reconfirmed.<sup>24</sup> In combination chemotherapy experiments of methotrexate and 5-FU in which leucovorin intended for methotrexate rescue potentially worsened 5-FU toxicity, uridine rescue permitted an increase in 5-FU doses from 100 mg/kg that was associated with a 60% mortality to 5-FU doses of 150 mg/kg with only 6% mortality.<sup>33</sup> Two IV uridine (3.5 g/kg) doses at 2 and 20 hours after 5-FU dose permitted 5-FU increases from 100 mg/kg to 250 and 300 mg/kg and blunted the leukocyte and erythrocyte nadirs.<sup>35,36</sup> In an attempt to shift to oral regimens, doses of 4 g/kg oral uridine in mice were comparable IP rescue of 5-FU at doses of 150 mg/kg as part of a multidrug chemotherapeutic regimen, which was an increase by more than 50% of the maximum tolerated weekly dose.<sup>31</sup> The addition of a uridine phosphorylase inhibitor in order to sustain uridine concentrations was able to further lower the oral rescue dose to 2 g/kg without compromising efficacy.<sup>31</sup>

The limitations of uridine alone in oral or IV formulation, including its rapid plasma clearance, led to exploration of oral prodrugs in an effort to sustain therapeutic plasma concentrations. Both immediate (at 2 hours) and delayed administration of uridine triacetate (as late as 48 hours) were evaluated, with successful doubling of the maximum tolerated 5-FU dose from 100 mg/kg/week to 200 mg/kg/week.<sup>38</sup> To explore the window of efficacy of uridine triacetate resuscitation, mice were given a lethal dose of 300 mg/kg of 5-FU IP followed by uridine triacetate (2 g/kg orally every 8 hours for 15 doses) at 24, 48, 72, and 96 hours after 5-FU.<sup>9</sup> Survival rates were 90% at 24 hours, which declined to 60%, 30%, and 20% with each subsequent day's delay in administration.<sup>9</sup>

Because many cases of 5-FU toxicity are associated with DPD deficiencies and delayed 5-FU clearance, an animal model was created to mimic DPD deficiency. In mice given the lethal combination of 100 mg/kg 5-FU and the DPD dehydrogenase inhibitor 5-ethynyluracil (2 mg/kg) survival was 80%, 40%, 50%, and 20% after rescue at 24, 48, 72, and 96 hours after 5-FU, respectively.<sup>44</sup> This demonstrated efficacy even in the setting of compromised 5-FU elimination.

## Human Studies

In the first phase 1 study exploring uridine, one or 2 doses of uridine 5 to 6 g/m<sup>2</sup> as a one-hour infusion after fluorouracil administration provided insufficient uridine to eliminate 5-FU toxicity as the 5-FU dose was increased from 550 to 800 mg/m<sup>2</sup>.<sup>28</sup> The second phase 1 uridine trial included 20 patients treated with methotrexate (250 mg/m<sup>2</sup>), 5-FU, leucovorin, and PALA, an inhibitor of the de novo pathway for the pyrimidine biosynthesis.<sup>23</sup> Fluorouracil doses started at 600 mg/m<sup>2</sup> (the prior maximum tolerated dose) and were escalated by 50 mg/m<sup>2</sup> until toxicity was reached. Because of high fevers with continuous uridine, uridine was given at 3 g/m<sup>2</sup> per hour for 3 hours on and then 3 hours off for a total of 72 hours of infusion. With the concomitant chemotherapy, the 5-FU dose could be increased to 750 mg/m<sup>2</sup> with uridine rescue with severe mucositis in only one patient and no decrease in functional status.<sup>23</sup> The oral route and additional supplementation were later explored in the last phase 1 uridine study with doses of 8 g/m<sup>2</sup> provided every 6 hours for 12 doses.<sup>40</sup> With this oral uridine schedule, the maximum tolerated dose of 5-FU could be increased 45% from 1.1 to 1.6 g/m<sup>2</sup> in patients also receiving methotrexate, and by 33% from 0.9 to 1.2 g/m<sup>2</sup> in patients receiving both methotrexate and doxorubicin.<sup>40</sup>

In the first phase 1 trial of uridine triacetate, in which 38 patients were rescued at 24 hours with 6 g as a tablet or 6.6 g as a suspension every 6 hours for 10 doses, the tolerated 5-FU dose could be increased from 0.6 to 1 g/m<sup>2</sup>.<sup>22</sup>

In a second phase 1 trial, 6 g of uridine triacetate was given as a rescue at 8 hours after 5-FU administration and then every 8 hours for 8 doses (48 g). When 5-FU dose-limiting toxicity was reached, intensive uridine triacetate (6 g) was given every 2 hours for 3 doses, and then every 6 hours for 15 doses.<sup>19</sup> Fluorouracil at 1.0 g/m<sup>2</sup> was tolerated without toxicity with uridine triacetate rescue, and the 5-FU dose could be consistently elevated further to 1.25 g/m<sup>2</sup> with intensive rescue. Fluorouracil doses as high as 1.95 g/m<sup>2</sup> were possible, but with hematologic toxicity occurring at this dose.<sup>19</sup> In a phase 2 trial, 65 patients with gastric carcinoma were administered 1.2 g/m<sup>2</sup> of 5-FU (twice the usual dose) with leucovorin, followed by 6 g of uridine triacetate every 8 hours, with rescue at 8 hours after 5-FU, for a total of 8 doses (48 g).<sup>16</sup> This normally toxic 5-FU dose, which leads to 3- to 5-fold increases in 5-FU systemic exposure, was tolerated with no episodes of severe stomatitis or diarrhea, and only a 20% incidence of moderate or severe neutropenia.<sup>16</sup>

The pivotal efficacy trials of uridine triacetate were 2 compassionate-use studies that were summarized in 2 publications and analyses by the FDA. Those included WELL401, an open-label, single-arm, multicenter emergency use study and collection of single-patient INDs, and 401.10.001, an open-label expanded access protocol.<sup>7,8,21,29</sup> In these trials of 173 total patients, 142 patients had documented overdose (136 by 5-FU at 1.9 to 576 times the planned infusion rate or doses up to 10 times the intended dose and 6 by capecitabine 7,000 to 2,800 mg), an additional 26 patients had rapid onset of toxicity (severe or life-threatening toxicities within 96 hours following the end of 5-FU administration), at least one of whom was DPD deficient, and 5 were lost to follow-up.<sup>29</sup> There were 6 pediatric patients, of whom 3 had ingested capecitabine unintentionally. Treatment included uridine triacetate 10 g or 6.2 g/m<sup>2</sup> orally every 6 hours for 20 doses. Historical controls—albeit confounded by publication, reporting, and litigation bias—included 47 cases from the FDA (eg, the Manufacturers and User Facility Device Experience Database and Adverse Event Databases), ISMP (Institute for Safe Medication Practices), the medical and gray literature, and forensic cases, which included 25 patients with available data for 5-FU administered dose, 5-FU time and rate of administration, and the patient outcomes.<sup>29</sup> The primary outcome, survival to 30 days or chemotherapy resumption, was achieved overall in 158 of 168 patients (94%), with an additional 5 lost to follow-up, which included 137 of 142 patients (96%) with overdose and 21 of 26 (81%) with early-onset toxicity. Not all of these patients had expected lethality based on the infusion rate and dose. Efficacy in late administration after more than 96 hours was significantly diminished. In the 8 patients in the early toxicity cohort who had therapy initiated after 96 hours following 5-FU exposure, only 3 survived (37.5% survival).<sup>29</sup> Acknowledging the aforementioned limitations of historical controls, the historical cohort patients—who appeared to be comparable to the overdose patients treated with uridine triacetate as ascertained in the FDA medical review—experienced only a 16% survival (4 of 25 patients) when treated with supportive care alone.<sup>8,21</sup> The FDA separately reviewed the Adverse Event Reporting System for postmarketing fatal cases of fluoropyrimidine toxicity. There were 203 cases in the past 50 years (58 5-FU cases and 145 capecitabine cases), many of which were similar in their early-onset, severe, or life-threatening toxicity presentation, which ultimately all resulted in death despite supportive care.<sup>21</sup> In a separate phase 3 trial for which outcomes data are not yet available (NCT00024427), 2 patients with DPD deficiency were identified who had received high-dose 1.4 g/m<sup>2</sup> 5-FU followed by 8 doses of uridine triacetate every 8 hours.<sup>37</sup> One patient developed severe thrombocytopenia and rash and survived, whereas the other patient died with a perforated duodenal ulcer and candidemia, highlighting the risk that the DPD genetic deficiency presents to patients.<sup>37</sup> There are no data on uridine triacetate efficacy in overdose of tegafur, a 5-FU prodrug, although it would be reasonable to provide uridine triacetate in this circumstance.

## ADVERSE EFFECTS AND SAFETY ISSUES

The most common adverse events observed in the clinical trials of uridine triacetate were vomiting (8.1%), nausea (4.6%), and diarrhea (3.5%).<sup>29</sup> These adverse effects are also consistent with those in patients receiving fluoropyrimidine chemotherapy both therapeutically and in overdose.<sup>29</sup> Of 135

patients in the pivotal studies, 3 patients had to discontinue uridine triacetate because of adverse effects within 30 days.<sup>8</sup> Safety data can also be gathered from use of uridine triacetate in additional patient populations. FDA reviews identified uridine triacetate use in 4 patients with hereditary orotic aciduria (HOA), 53 adults with diabetic neuropathy; 30 patients (22 children and 8 adults) with mitochondrial and metabolic disorders; 46 healthy subjects, 148 patients (6 children and 142 adults) at risk of 5-fluorouracil (5-FU) toxicity, and 288 subjects receiving high-dose 5-FU.<sup>12,13</sup> Providing boundaries for safe dosing regimens, the doses studied included 120 mg/kg/day for 9 months in HOA; 4 or 8 g/day for 6 to 12 months in diabetic neuropathy; 33 to 300 mg/kg/day for up to 18 years in patients with mitochondrial and metabolic disorders; and doses of 6 to 40 g/day for 5 days in 5-FU toxicity.<sup>13</sup> Only “non-serious” gastrointestinal adverse effects were identified, which were attributed to an undisclosed excipient that was demonstrated to be in an earlier uridine triacetate formulation.<sup>11</sup> No treatment discontinuations occurred in HOA clinical trials for adverse events or for any other reason. Diarrhea was reported in patients administered doses of uridine triacetate greater than 4 g/day.<sup>11</sup> Regarding QT interval prolongation hERG potassium channel current inhibition was reported in vitro with uridine triacetate but not with uridine, but not at physiologically relevant concentrations, and no cardiac toxicity was observed in dog or rat studies.<sup>8,9,13</sup> In vitro, no significant CYP450 enzyme interactions were found with uridine or uridine triacetate.<sup>7,10</sup> Uridine triacetate is a weak P-glycoprotein substrate and inhibitor in vitro, and the potential for local inhibition at the gut level could not be excluded.<sup>13</sup>

## PREGNANCY AND LACTATION

There are insufficient data on the use of uridine triacetate during pregnancy to inform the risks of birth defects or miscarriage. Animal studies did not demonstrate toxicity when uridine triacetate was provided at one-half the human dose.<sup>6</sup> The presence of uridine triacetate in human milk is unstudied.

## DOSING AND ADMINISTRATION

Uridine triacetate dosing in adults is 10 g (1 packet) orally every 6 hours for a total of 20 doses, without regard to meals.<sup>6</sup> The pediatric dose is 6.2 g/m<sup>2</sup> up to the adult maximum, and a table for the conversion of grams to graduated teaspoons for children is provided in the prescribing information.<sup>6</sup> Uridine triacetate is mixed with 3 to 4 ounces of soft foods (such as applesauce, pudding, or yogurt) and ingested within 30 minutes, along with 4 ounces of water.<sup>6</sup> We recommend that a 5-HT<sub>3</sub>-receptor antagonist be given an antiemetic such as ondansetron, 20 to 30 minutes prior to each dose to prevent vomiting. If vomiting occurs within 2 hours of the last dose, the entire dose is given within 15 minutes of vomiting and the next dose is given at the next scheduled interval. In the event the patient cannot tolerate the oral route (eg, severe mucositis), then we recommend that uridine triacetate be given by nasogastric or gastrostomy tube. If provided via this route, then 4 ounces of a food starch-based thickening product in water should be stirred briskly until the thickener has dissolved, and the contents of one full 10-g packet of uridine triacetate granules that have been crushed to a fine powder added to the reconstituted food starch-based thickening product.<sup>6</sup> For pediatric patients receiving less than 10 g, the mixture should be prepared at a ratio of no greater than 1 g per 10 mL of reconstituted food starch-based thickening product and mix thoroughly.<sup>6</sup> The nasogastric or gastrostomy tube should be flushed with water following administration. Although uridine triacetate absorption is unaffected by food, medicines such as bismuth, cholestyramine, Kaopectol, and sucralfate interfere with absorption.<sup>8</sup>

## FORMULATION AND ACQUISITION

Uridine triacetate granules contain 10 g of orange-flavored, white to off-white oral granules in single-dose packets. Inactive ingredients include ethylcellulose (0.309 g), Opadry Clear (a proprietary dispersion of hydroxypropylmethylcellulose and Macrogol, 0.077 g), and natural orange juice flavor (0.131 g). Uridine triacetate is supplied as a full course of therapy with 20 single-dose packets per carton, as well as a “24-Hour Pack” containing 4 single-dose

packets per carton. The manufacturer-supplied contact number for ordering uridine triacetate is 1-844-293-0007.<sup>20</sup>

## SUMMARY

- Uridine triacetate is a uridine prodrug that is the recommended treatment for toxicity from fluoropyrimidines such as fluorouracil and its prodrugs capecitabine and Tegafur.
- Uridine triacetate should be started as early as possible after recognition of overdose or early toxicity, as efficacy declines with delay to administration.
- The antidote must be given orally or by nasogastric or gastrostomy tube.

# INTRATHECAL ADMINISTRATION OF XENOBIOTICS

Rama B. Rao

Cerebrospinal fluid (CSF) is produced by the choroid plexus that lines the cerebral ventricles at a rate of 15 to 30 mL/h, or approximately 500 mL/day in adults.<sup>57</sup> Cerebrospinal fluid flows in a rostral to caudal direction and is reabsorbed through the arachnoid villi directly into the venous circulation. The estimated total volume of CSF is 130 to 150 mL in healthy adults and 35 mL in infants.<sup>57,74,99</sup>

For more than 100 years, a variety of experimental and therapeutic xenobiotics have been delivered directly into the CSF<sup>64,127</sup> (Table SC7-1). The most common current indications for intrathecal administration include the instillation of analgesics or anesthetics and the treatment of spasticity or central nervous system (CNS) neoplasms. The clinical advantages of this route of administration include targeted delivery and lower medication dosages with fewer systemic effects. Medications are usually administered via a spinal needle or an indwelling intrathecal catheter. Catheters can be attached to either an external or subcutaneous pump. Less commonly, medications are administered into a reservoir of an intraventricular shunt. The distribution of intrathecal xenobiotics is determined by a variety of factors. Some authors speculate that the xenobiotic movement is often attributed to both diffusion and convection, and they suggest that the dilution of xenobiotics administered via a lumbar catheter is attributed to the outflow of CSF from the fourth ventricle.<sup>92</sup> In a radiolabeled tracer study of 5 patients with lumbar catheters, individuals received the hydrophilic radiolabeled diethylene triamine pentaacetic acid (<sup>111</sup>In-DTPA) intrathecally. Neuroimaging revealed a drop in concentration of the tracer as the fluid moved rostrally.<sup>66</sup> The steady-state lumbar to cervical concentration for hydrophilic xenobiotics is 4:1 with marked interindividual variability.<sup>96</sup> Depending on the lipophilicity, the xenobiotic reaches the brain within a few minutes to 1 hour. Patient position and interindividual variations in lumbosacral CSF volume affect xenobiotic distribution and account for the differences in the level of spinal anesthesia among patients administered the same local anesthetic dosages.<sup>55</sup> Baricity, which is the ratio of the specific gravity of the xenobiotic to the specific gravity of CSF at 98.6°F (37°C), is also a consequential variable. Hyperbaric xenobiotics typically distribute in accordance with gravitational forces.<sup>55</sup> However, in overdose or administration of xenobiotics unintended for intrathecal administration, distribution, reabsorption, and clinical effects are unpredictable.

Complications occur from preparation and dosing errors or inadvertent penetration of the dura and admixture with the CSF during epidural anesthesia or analgesia.<sup>27,54,55</sup> Medications intended for intrathecal delivery are occasionally administered inadvertently into the wrong port of a pump delivery system, resulting in a massive overdose (see Pump Malfunction and Errors). Another potentially fatal error involves inadvertent administration of the wrong medication into the CSF.<sup>60</sup> This error occurs with misidentification or mislabeling of medications during pharmacy preparation or at the bedside. For patients with indwelling devices, medications intended for intravenous delivery are occasionally connected inadvertently to the intrathecal catheter, which also currently operates utilizing the same Luer lock system.

Several factors affect the clinical toxicity of intrathecal medication errors.<sup>128</sup> The properties of the medication are important. Ionized xenobiotics are likely to disrupt normal neurotransmission and cause toxicity, as do hyperosmolar or lipophilic xenobiotics. The site of administration is important as well. Patients administered the wrong xenobiotic into an Ommaya

reservoir (an intraventricular catheter with a subcutaneous access port on the scalp) often suffer immediate alterations in mental status depending upon the xenobiotic administered. Although intrathecal administration of preservatives and excipients were investigated in animal models, the characteristics of these adjuvants in medication errors are not likely to be of value in predicting clinical effect.<sup>56</sup>

Patients often present with exaggerated symptoms and findings typically associated with the xenobiotic. For example, patients with intrathecal morphine overdose present with symptoms of opioid toxicity.<sup>62</sup> Other manifestations of intrathecal errors, regardless of the xenobiotic, include pain and paresthesias, often ascending in nature; autonomic instability, especially with extremes of blood pressure and hyperreflexic myoclonic spasms similar to those that occur in patients with tetanus. Seizures or a depressed level of consciousness also occur. The time of onset of these life-threatening symptoms is determined by the dose and characteristics of the xenobiotic. For example, a woman inadvertently administered intrathecal potassium chloride complained immediately of severe back pain.<sup>82</sup> Myoclonic spasms, seizures, and coma followed, and the patient died within 3 hours despite a normal serum potassium concentration. Patients with inadvertent vincristine exposures will be asymptomatic for many hours and die within a few days to a few weeks. In another example, a patient with an inadvertent intrathecal administration of aminophylline immediately developed leg cramps. He recovered and was discharged, only to return 24 hours later with leg weakness that progressed to irreversible paraplegia.<sup>7</sup>

**TABLE SC7-1** Xenobiotics Intentionally Administered Intrathecally<sup>a</sup>

Analgesics/anesthetics	Antiinflammatory
Anesthetics (local)	Corticosteroids <sup>100</sup>
Ketamine <sup>53</sup>	Antispasmodic
Morphine <sup>70</sup>	Baclofen <sup>124</sup>
Opioids <sup>80</sup>	Chemotherapeutics
Ziconitide <sup>19</sup>	Cytarabine (liposomal) <sup>18</sup>
Antimicrobials	Methotrexate <sup>3</sup>
Amikacin <sup>15,28</sup>	Vasoactive
Amphotericin B <sup>48</sup>	Epinephrine <sup>49</sup>
Arbekacin <sup>42</sup>	Papaverine <sup>106</sup>
Cefotiam <sup>20</sup>	Phenylephrine <sup>31</sup>
Ceftriaxone <sup>24</sup>	Other
Colistin <sup>123</sup>	Bethanecol <sup>94</sup>
Gentamicin <sup>112</sup>	Clonidine <sup>23</sup>
Levofloxacin <sup>15</sup>	Midazolam <sup>130</sup>
Penicillin <sup>11</sup>	Neostigmine <sup>70</sup>
Polymyxin E <sup>14</sup>	Octreotide <sup>89,96</sup>
Vancomycin <sup>1,81</sup>	Tetanus immunoglobulin <sup>2</sup>

<sup>a</sup>Few of these xenobiotics are approved by the US Food and Drug Administration for intrathecal administration. Most were utilized in clinical trials or as rescue therapy for refractory central nervous system disorders.

## XENOBIOTIC RECOVERY FROM CEREBROSPINAL FLUID

Once a medication delivery error is identified, rapid intervention is mandatory, especially for ionized xenobiotics, chemotherapeutics, or iodinated water-soluble contrast agents because these xenobiotics usually reach the brain within an hour. In cases in which outcome is uncertain or not previously described, the exposure should be treated as potentially fatal. Any existing access to the CSF, ideally in the lumbosacral area, should be maintained.<sup>121</sup> Immediate withdrawal of CSF, in volumes as high as 75 mL in adults, is indicated. This can be replaced with isotonic solutions: lactated Ringer, 0.9% normal sodium chloride, or Plasma-Lyte, or a combination of these. Older cases utilized Elliot B solution, which is not readily available or advised. Some authors recommend the initial volume removal of 100 mL be performed in 20- to 30-mL aliquots. This is a reasonable initial intervention for fatal intrathecal exposures. For children, multiple aliquots of 5 to 10 mL can be removed and replaced with isotonic fluid. If the patient can tolerate an upright position, this has the potential to limit cephalad movement of xenobiotics, but positioning for any critical life support measures should take precedence.

Delays to initial CSF drainage should be minimized as the interval between the exposure and CSF drainage affects the total xenobiotic recovered (see below). In the interim, a neurosurgical consultation should be obtained to consider the placement of cerebral ventricular access for the performance of continuous CSF lavage. This procedure, also known as ventriculolumbar perfusion, involves continuous instillation of an isotonic solution into the cerebral ventricular system with CSF drainage through a lumbar site. Another intervention involves placement of an epidural catheter into the intrathecal space at a space above the lumbar drainage site so that an isotonic solution can be perfused through the catheter and drained caudally. This serves as a readily available, rapid intervention for patients awaiting placement of an emergent ventriculostomy.<sup>84,114</sup>

For ventriculolumbar perfusion, lavage flow rates can be as great as 150 mL/h. One author advised the addition of fresh-frozen plasma to lavage fluid after several hours to increase the CSF protein content. The ideal lavage fluid, protein components, and infusion rates are not known.<sup>51</sup> As multiple successful perfusions have been reported without use of this intervention, and there is unlikely to be high-quality data, the use of fresh-frozen plasma in lavage fluid is not recommended unless brain edema is already present. Some protocols previously utilized are listed in [Table SC7-2](#). Although artificial CSF formulations exist, their role in the treatment of such medication errors is not evaluated.<sup>86</sup>

Depending on the xenobiotic exposure, specific antidotes or rescue xenobiotics can be employed. With most intrathecal exposures, these therapeutics will be administered via oral, intramuscular, or intravenous routes. Extreme caution should be undertaken to avoid delivery of antidotes directly into the CSF, unless specific data support their use. Immediate, aggressive CSF removal and lavage resulted in nearly 95% recovery of vincristine in the lavage fluid of a patient with inadvertent exposure. Of the published cases in which xenobiotic recovery is reported, percentages relate to both the lavage method and quantity of CSF removed. For example, withdrawal of 10 mL of CSF 45 minutes after a methotrexate overdose in a 4-year-old patient recovered 20% of the initial dose.<sup>3</sup> Withdrawal of 200 mL of CSF in aliquots 45 minutes after methotrexate overdose in a 9-year-old patient recovered 78% of the initial dose.<sup>35</sup> The specific xenobiotic affects recovery as well. For example, a patient underwent withdrawal of 30 mL of CSF 18 minutes after an overdose of simultaneously administered lidocaine, epinephrine, and fentanyl. Approximately 39% of lidocaine was recovered, whereas the recovery of fentanyl was only 7%.<sup>113</sup>

## SPECIFIC EXPOSURES

### Ionic Contrast

Several xenobiotics were utilized historically for contrast myelography. Many of these xenobiotics were abandoned because of their propensity to cause adhesive arachnoiditis chronic pain syndromes or other complications (Thorotrast). Low osmolar, nonionic contrast media are currently utilized,

but unfortunately, other hyperosmolar ionic media are readily available in radiographic suites and sometimes inadvertently administered. Patients develop cranial neuropathies.<sup>40</sup> Exposed patients become symptomatic within 30 minutes to 6 hours after administration, with hyperreflexia and myoclonic spasms following minimal stimulation.<sup>102,104,118</sup> Clinical symptoms and effects typically begin in the lower extremities and move in a cephalad direction, sometimes progressing to opisthotonos. This is likely due to alterations in inhibitory neurotransmission occurring in patients with tetanus; this condition is called ascending tonic-clonic syndrome (ATCS). In one review, 3 of 7 patients with ATCS died as a result of their exposures.<sup>102</sup> Immediate large-volume (>100 mL) CSF drainage should be performed in 20-mL utilizing the same catheter aliquots with isotonic fluid replacement. Ventriculolumbar perfusion should be performed in severe cases.

### Chemotherapeutics

Methotrexate is administered intrathecally for the prevention and treatment of leukemic meningitis or other CNS neoplasms.<sup>9</sup> Errors are generally dose related.<sup>3,33-35,51,58,69,101,119</sup> In most reported cases, aggressive drainage of as great as 250 mL of CSF in aliquots with isotonic fluid replacement was utilized without ventriculolumbar perfusion. Experimental treatment of patients with intrathecal glucarpidase was described without obvious adverse events.<sup>87,125</sup> The patients underwent lumbar drainage followed by intrathecal glucarpidase. Drainage removed between 32% and 58% of the methotrexate, and the antidote reduced the methotrexate concentrations by 98%. The patients received 2,000 units of intrathecal glucarpidase in 12 mL of 0.9% sodium chloride solution over 5 minutes (Antidotes in Depth: A13).

Intrathecal leucovorin is *absolutely contraindicated* as its use results in fatalities. Following intrathecal methotrexate overdose, the intravenous administration of leucovorin is appropriate<sup>59,120</sup> (Antidotes in Depth: A12).

Vincristine is typically administered intravenously and does not cross the blood-brain barrier. There are no therapeutic indications for intrathecal vincristine, and such errors are almost invariably fatal.<sup>4-6,17,29,39,43,46,67</sup> In most cases, the error is the result of confusion of either syringes or catheter access. As soon as the exposure is identified, immediate CSF drainage should be instituted, and rapid neurosurgical consultation should be obtained. The few known survivors with cognitive function underwent early neurosurgical intervention for ventriculolumbar perfusion.<sup>5,33,84,97,134</sup> One of the patients had an epidural catheter placed intrathecally above the drainage site for lumbolumbar perfusion while awaiting ventriculostomy. This method of intrathecal perfusion is recommended in all patients with intrathecal vincristine exposures until definitive ventriculolumbar perfusion can be established. Ideally, tubing systems should be readily available and prepared for use to prevent intrathecal medication errors.<sup>90,116</sup> Other rescue medications are discussed in Chaps. 34 and 51.

## PUMP MALFUNCTIONS AND ERRORS

Pump malfunctions cause a sudden decrease or increase in the amount of drug delivered to the intrathecal space.

Insufficient drug delivery will result in withdrawal especially in pumps containing opioids, baclofen, or clonidine.<sup>72</sup> This occurs from either pump malfunction<sup>98</sup> or impairment of flow through the intrathecal catheter. Catheters infrequently kink, migrate, or become obstructed by an inflammatory mass.<sup>25,26,60,91</sup> In some devices, an impaired or reduced delivery of drug is indicated by an audible alarm.<sup>72</sup> Such alarms should be heeded and consultation with the implanting service is warranted to avert withdrawal.<sup>72</sup> Patients on chronic therapy are at highest risk of severe withdrawal signs and symptoms.<sup>124</sup> As intrathecal doses are 100 to 1,000 times more potent than the equivalent dose administered intravenously,<sup>63</sup> patients will require very high oral or intravenous doses to treat withdrawal until intrathecal delivery can be re-established. A thorough neurologic examination should be performed to evaluate for spinal cord compression symptoms that indicates a catheter-related complication.<sup>60</sup> An anteroposterior and lateral radiograph should be obtained to assess for kinking or fracture of the catheter.

**TABLE SC7-2** Inadvertent Intrathecal Overdoses and Unintentional Exposures

<i>Xenobiotic</i>	<i>Age/Sex</i>	<i>Mechanism</i>	<i>Clinical Findings/Effects</i>	<i>Intervention</i>	<i>Outcome</i>
Aminophylline <sup>7</sup>	64/M	Medication error	Muscle cramps initially Paraplegia at 24 hours	Observation	Paraplegia Death in 2 years
Baclofen <sup>132</sup>	8/M	Probable pump malfunction	Coma, vomiting, bradycardia	20 mL CSF removed at undetermined time	Survived
Bortezomib <sup>36,47</sup>	Unknown	Medication error	Not reported	Not described	Three deaths
Bupivacaine <sup>38</sup>	34/M	Inadvertent dural puncture	Hypotension Ascending paralysis at 10 minutes	Not described	Survived
Cefotiam <sup>20</sup>	66/M	Catheter misconnection	Dyspnea, hypotension, myoclonic spasm, pain at 2 hours	10 mL CSF removed at 20 hours	Rhabdomyolysis Survived
Ceftriaxone <sup>24</sup>	74/F	Overdose	Bilateral lower extremity pain	240 mL CSF removed in 20-mL aliquots, with 0.9% NaCl replacement therapy Started at unknown time	Survived
Cytarabine <sup>68</sup>	4/M	Overdose	Mydriasis, delayed onset, gait impairment, tremor	50 mL CSF removed in 5-mL aliquots, with 0.9% NaCl replacement therapy Started at 65 minutes Estimated 27%–36% cytarabine recovery	Died of unknown cause
Cytarabine <sup>77</sup>	45/F	Overdose	Headache, vomiting	CSF removal of 54 mL from Ommaya at 2 hours	Asymptomatic at 6 hours
Dactinomycin <sup>65</sup>	5/F	Medication error	Hypotonia, fasciculations, hyperreflexia at 2 hours	50 mL CSF removed with 0.9% NaCl replacement at 1 hour, then VL perfusion started at 1.5 hours using 0.9% NaCl 100 mL/h with 2.5 mg/mL hydrocortisone for 26 hours Other adjuncts	Ascending paraplegia, obstructive hydrocephalus Survived
Doxorubicin <sup>8</sup>	12/F	Medication error	Fever, headache, vomiting at 12 hours, seizures, hydrocephalus	No attempt at removal	Survived without sequelae at 56 days
Doxorubicin <sup>61</sup>	31/F	Medication error	Hypoesthesia, paraparesis, incontinence over 7 days, T8 sensory level, bowel, bladder incontinence, meningismus, adhesive arachnoiditis at 3 weeks	CSF exchange at 20 mL/h for 500 cm <sup>3</sup> per publication; methyl prednisolone 500 mg/d and immunoglobulin 22 g/d initiated at 1 week Treatment of arachnoiditis with VP shunt placement	Lower extremity weakness 3/5 at 8 months, eventual ambulation with resolution of incontinence at 14 months
Furosemide <sup>22</sup>	36/M	Medication error	None	No attempt at removal	Survived
Gadolinium <sup>9</sup>	64/M	Medication error: gadopentetate dimeglumine	Confusion, nausea, vomiting, ataxia, nystagmus, hallucinations, blurred vision, depressed mental status	Not described	Survived
Gallamine <sup>50</sup>	48/M	Medication error	Hyperreflexic myoclonic spasm, onset 1 hour 45 minutes; fever, hypertension, tachycardia, miosis, coma at 3 hours	15 mL CSF drainage started at 6 hours	Survived
Iohexol <sup>103</sup>	52/M	Dural perforation	ATCS at 30 minutes, coma, hypoxia, fever	Not described	Survived
Ionic contrast media cases <sup>102</sup>	Various	Medication error	ATCS starting at 30 minutes to 6 hours	Variable	3/7 patients died; fractures, rhabdomyolysis
Iopamidol <sup>40</sup>	Various	Medication error	Cranial neuropathy	Not described	Survived
Ioxithalamate Contrast <sup>122</sup>	48/M	Medication error	ATCS, opisthotonos	Sitting position, intubation 145 mL CSF removal in 10–20-mL aliquots Other adjuncts	Survived
Labetolol <sup>16</sup>	32/F	Medication error	Mild drop in BP and HR	Fluid bolus	Recovered
Leucovorin <sup>59</sup>	11/M	Therapeutic error	Seizures	Not described	Died day 5

(Continued)

TABLE SC7-2 Inadvertent Intrathecal Overdoses and Unintentional Exposures (Continued)

Xenobiotic	Age/Sex	Mechanism	Clinical Findings/Effects	Intervention	Outcome
Lidocaine, epinephrine, fentanyl <sup>113</sup>					
Patient 1	28/F	Dural perforation	Hypotension, numbness at 5 minutes	20 mL CSF drained within 5 minutes; 51% lidocaine recovery, 4% fentanyl recovery	Survived
Patient 2	68/F	Dural perforation	C <sub>5</sub> –C <sub>8</sub> sensory impairment at 18 minutes	30 mL CSF drained at 18 minutes; 39% lidocaine recovery; 7% fentanyl recovery	Survived
Magnesium sulfate <sup>73</sup>	23/F	Medication error	Backache, lower extremity weakness, intact sensation, normotension	Fowler position	Recovery within 7 hours
Mercury <sup>115</sup>	69/F	Inadvertent (Mercurochrome) injection into CSF fistula	Local pain, nuchal rigidity, coma at 24 hours	Lumbar drain, parenteral chelation	Sensorimotor polyneuropathy Survived
Methotrexate <sup>34</sup>	2/F	Overdose	Headaches	Varied	Survived
Methotrexate <sup>41</sup>	34/M	Overdose	Confusion, seizures, ARDS, coma at 2 hours	200 mL CSF drained and replaced with 0.9% NaCl started at 6 hours in aliquots over 48 hours, then another 150 mL CSF exchange over 36 hours (patient also inappropriately received an intrathecal leucovorin)	Cognitive and motor deficits
Methotrexate <sup>35</sup>	9/M	Overdose	Lower extremity numbness, seizures, flaccid paralysis, cranial neuropathy, posturing	200 mL CSF drained in 30–40-mL aliquots, replacement with Elliotts B solution Started at 45 minutes 78% drug recovery	Died
Methotrexate series I <sup>3</sup>		Overdose			
Patient 1	12/M		Headache, vomiting at 45 minutes	30 mL CSF drained and replacement with 20-mL of Elliotts B solution started at 2 hours; 28% drug recovery	Survived until relapse leukemia
Patient 2	4/M			10 mL CSF drained at 45 minutes; 20% drug recovery	Survived
Methotrexate series II <sup>58</sup>					
Patient 1	4/M			250 mL CSF drained in 20-mL aliquots, replacement with 0.9% NaCl started at 5 hours	Survived
Patient 2	11/M			20 mL CSF withdrawn then 210 mL CSF drained in 5-mL aliquots, replacement with 0.9% NaCl started at 3 hours; 31% drug recovery	Survived
Methotrexate <sup>71</sup>	3/F	Medication error: 125 mg	Seizures at 3 hours	No CSF exchange; IV leucovorin rescue and dexamethasone	Survived
Methotrexate <sup>114</sup>	26/M	Medication error: 625 mg	Immediate pain in leg, followed by coma and flaccid paralysis, renal failure	70 mL CSF drained at 2 hours; VL perfusion with 240 mL 0.9% NaCl over 3 hours; intrathecal administration of 1,000 units CPDG <sub>2</sub> at 8.5 hours; 32% recovery in initial drainage fluid; 58% recovery from perfusion drainage	Survived
Methotrexate <sup>125</sup>	Case series, n = 7	Medication errors: 155–600 mg	5/7 patients with seizures, some with headache, nausea, vomiting	Various interventions including VL perfusion started within 1 hour with 500 mL 0.9% NaCl over 4 hours	All survived
Methylene blue <sup>37</sup>	Case series, n = 14	Direct toxicity due to dye or pH: 10–100 mg	Pain headache, paralysis	Not described	11/14 residual paraplegia or weakness
Methylene blue <sup>109</sup>	59/M	6 mL 1% solution; as above	Vomiting, hypotension day 1; paralysis and urinary retention	Not described	Paraplegia and death at 5 years
Morphine <sup>105</sup>	45/F	Inadvertent filling of wrong port of subcutaneous infusion pump; 450 mg	Seizures, hypertension, subarachnoid hemorrhage	12 mL CSF withdrawn, then 550 mL CSF drained at 10 mL/h by gravity over 2–3 days	Survived
Morphine <sup>62</sup>	81/M	Inadvertent: 5 mg	Coma at 4 hours	50 mL CSF drained over 6 minutes, replacement with 50 mL 0.9% NaCl	Survived

(Continued)

**TABLE SC7-2** Inadvertent Intrathecal Overdoses and Unintentional Exposures (Continued)

<i>Xenobiotic</i>	<i>Age/Sex</i>	<i>Mechanism</i>	<i>Clinical Findings/Effects</i>	<i>Intervention</i>	<i>Outcome</i>
Morphine <sup>133</sup>	47/F	510 mg into wrong port of pump	Myoclonic spasms, coma, seizures, cranial neuropathy, hypertension then hypotension	No CSF interventions	Survived
Neostigmine <sup>75</sup>	26/M	Medication error	????	None	Survived
PEG asparaginase <sup>85</sup>	12/M	Wrong route	None	None	Survived
Penicillin <sup>21</sup>	22/M	Dosing error into Ommaya reservoir	Coma, hyporeflexia, tonic-clonic seizures, absence seizures, hypotension at 30 minutes	10 mL CSF withdrawal, then VL CSF drainage; replacement with LR over 30 minutes	Survived
Potassium chloride <sup>82</sup>	42/F	Medication error during labor	Immediate cramps, pain, seizures, normal serum potassium	None	Maternal-fetal death at 3 hours
Potassium chloride <sup>30</sup>	62/M	Medication error during anesthesia	Pain, cramps, hypertension, tachycardia, weakness, paresthesia, paraplegia	Removal of 50 mL CSF replaced with saline then removal of 20 mL CSF replaced with saline	Recovery beginning at 8 hours with no sequelae at 2 months
Tramadol <sup>12</sup>	75/F	Connection error	Diaphoresis, hypotension at 10 minutes; myoclonic spasms, opisthotonos	None	Fatal at 48 hours
Tranexamic acid <sup>131</sup>	49/F	Medication error, wrong route	Immediate back pain, hypertension; seizure at 2 minutes; ventricular fibrillation	None	Fatal at 1.5 hours
Vincristine <sup>78</sup>	5/F	Medication error: 0.9 mg	Headache at 10 hours, opisthotonos, nystagmus, flaccidity	None	Fatal on day 18
Vincristine <sup>106</sup>	2.5/F	Medication error: 3 mg	Opisthotonos day 2	200 mL CSF drainage in 10-mL aliquots; replacement with 0.9% NaCl	Fatal on day 3
Vincristine <sup>69</sup>	27/F	Medication error into Ommaya reservoir	Ascending paralysis	Detail limited: CNS "washout" FFP and "lactate solution" in undefined quantities; timing not described	Fatal on day 10
Vincristine <sup>126</sup>	16/M	Mislabeled	Ascending paralysis at 2 hours, fever, coma	None	Fatal
Vincristine <sup>33</sup>	Adult	Medication error	Ascending paralysis	CSF drainage of unreported quantity and replacement with LR immediately; VL perfusion 150 mL/h for >24 hours, then 25 mL FFP in 1 L isotonic solution at 75 mL/h for undefined time; 95% recovery of vincristine	Lower extremity neuropathy
Vincristine <sup>39</sup>	4/F	Medication error: 1.5 mg	Nystagmus, encephalopathy, ascending paralysis, transient improvement	Immediate drainage of 18 mL CSF in 3-mL aliquots, replacement 0.9% NaCl; an additional 30-40 mL drained over 30 minutes, starting at 10 minutes; VL perfusion using Plasma-Lyte to replace 200 mL CSF over an unknown rate, then 6 mL FFP in 250 mL Plasma-Lyte at 50 mL/h for 4 hours	Fatal on day 13
Vincristine <sup>4</sup>	1.25/M	Medication error: 0.7 mg	Febrile and irritable at 10 hours then lower extremity pain, nuchal rigidity, opisthotonos, ileus, hypotonia at day 2; ascending paralysis, encephalopathy by day 5; respiratory arrest at day 7	Intrathecal corticosteroids at 10 hours	Death on day 75 (withdrawal of life support)
Vincristine <sup>5</sup>	7/F	Medication error: 0.5 mg	Ascending weakness, pain, paraplegia	Upright position; immediate drainage 75 mL CSF within 15 min, replaced with LR; VL perfusion started within 2 hours with 150 mL/h of LR for 10 hours, then FFP 15 mL in 1 L LR as irrigant at 55 mL/h for 24 hours Other efforts	Paraplegia, neurogenic bladder Survived

(Continued)

TABLE SC7-2 Inadvertent Intrathecal Overdoses and Unintentional Exposures (Continued)

Xenobiotic	Age/Sex	Mechanism	Clinical Findings/Effects	Intervention	Outcome
Vincristine <sup>6</sup>	12/F	Medication error: 2 mg	Asymptomatic for 48 hours, then ascending paralysis, hiccups, cranial neuropathy, coma	35 mL CSF drained at 30 min, then additional drainage of 15 mL CSF replaced with LR; VL perfusion at 3 hours using FFP 15 mL in 1 L LR for total drainage of 615 mL CSF over 10 hours; 0.785 mg recovered	Death on day 83
Vincristine <sup>17</sup>	23/M	Medication error: 2 mg	Headache day 1; leg weakness day 2–3; ascending myeloencephalopathy with coma at day 10; seizures	Drainage of 100 mL CSF at 10 minutes, “large volume lumbar punctures” on day 2 and 3	Prolonged coma, death at 11 months
Vincristine series <sup>29</sup>		Medication error			
Patient 1	5/F		Ascending paralysis, opisthotonos, coma	Not described	Death on day 7
Patient 2	57/M		Ascending paralysis	“Flushing the subarachnoid space”	Death at 4 weeks
Vincristine <sup>67</sup>	3/M	Medication error	Day 1: leg pain Day 2: headache, nuchal rigidity Day 3: bladder dysfunction, fever, lower extremity paralysis, opisthotonos and coma	Not described	Death on day 6
Vincristine <sup>83</sup>	59/F	Medication error into Ommaya reservoir: 2 mg	Nausea, vomiting day 1; altered mental status, tremor, chills, hiccups, nystagmus, coma over 1 week	50 mL CSF drainage at 10 minutes followed by 75 mL CSF drainage at 30 minutes; VL perfusion with LR and FFP over 24 hours	Death on day 40
Vincristine <sup>84</sup>	10/F	Medication error	Asymptomatic for 6 days, then ascending paralysis with incontinence	Immediate drainage of CSF for 15 minutes; epidural catheter above the lumbar drainage site with lumbolumbar irrigation using 12.5 mL FFP in 500 mL LR with 96 mL drained; VL perfusion within 90 minutes for 24 hours	Survived with sensory-motor deficits of the extremities and urinary incontinence
Vincristine <sup>110</sup>	5.5	1.2 mg	Headache, vomiting, and backache at 3 hours, nystagmus, extremity weakness at 72 hours, autonomic instability, hiccups, encephalopathy	Drainage of 20 mL CSF at 30 minutes, repeated on day 2, intrathecal corticosteroids, 23% recovery of dose	Death on day 12
Vincristine <sup>111</sup>	29/F	2 mg	Headache, ascending paraplegia, cranial neuropathy, coma	Intrathecal infusion 5 mL 0.9% NaCl with drainage of 10 mL CSF, positioned upright, additional 60 mL CSF drained at 3 hours	Death on day 14, pulmonary embolus at autopsy
Ziconotide series <sup>95</sup>		Overtitration of therapeutic dosage in each case		Stopped medication in each case	Improved days to weeks later
Patient 1	47/M		Nystagmus, auditory and visual hallucinations, dysmetria, ataxia		Retrograde amnesia Resolution with discontinuation of medication
Patient 2	62/M for pain of multiple sclerosis		Agitation, disorientation, waxing and waning mental status, hallucinations, allodynia, bradycardia		Resolution with discontinuation of medication; worsening multiple sclerosis at 1 year
Patient 3	45/M		Nausea, lightheadedness, nystagmus, bradycardia, agitation		Resolution with discontinuation

ATCS = ascending tonic-clonic syndrome (myoclonus, hyperreflexia on minimal stimulation, beginning in the lower extremities); CNS = central nervous system; CPDG2 = carboxypeptidase G<sub>2</sub>; CSF = cerebrospinal fluid; FFP = fresh-frozen plasma; LR = lactated Ringer solution; VL = ventriculolumbar; VP = ventriculoperitoneal.

Pump failures also result in overinfusion. The tubing and gears can be compromised by manufacturing issues, time since implantation, or use of medications not specifically approved for the device. These unapproved drugs can leak or corrode the device and impair responsiveness of the controls on delivery rates. The combination of device age and use of drugs not specifically approved for the device substantially increased the risk of device failure from one major manufacturer.<sup>44,76</sup>

Intrathecal pump overdoses also occur with errors in refilling pumps that are otherwise intact. Some pumps contain 2 access sites, one of which is contiguous with the intrathecal space and allows for CSF withdrawal or injection of nonionic contrast media for imaging. The other access site is a

depot port that is intermittently filled with concentrated amounts of drug (usually an opioid or baclofen) to be delivered through a programmable pump. In some patients, a template must be placed on the skin overlying subcutaneous pumps to ascertain the proper medication port. Errors occur when a concentrated bolus is inadvertently injected into the wrong port, resulting in a massive, sometimes fatal, overdose.<sup>60,129</sup> Massive intrathecal morphine overdose can have severe rapid symptoms, including adrenergic crisis.

When intrathecal overdose is suspected from either a refill error or pump malfunction, the clinical service that placed and manages the pump should be consulted. They can assist in device interrogation and gaining CSF

access.<sup>32</sup> Either re-accessing the CSF port immediately or placing a spinal needle into the intrathecal space at another site is critical for the withdrawal of CSF. Large-volume drainage (>100 mL in adults in 20–30-mL aliquots) with isotonic fluid replacement is required, as well as other supportive measures such as intravenous naloxone if opioid toxicity is present. Some of these patients will require intubation and care in an intensive care unit.

If the consultant is not readily available, emptying the depot port will automatically cause the pump motor to stop. Any removed product should be carefully measured and preserved. Based on the programmed rate of delivery and time and volume of last refill, the volume expected from emptying the pump reservoir can be calculated. In suspected device failure, retrieval of a volume less than expected confirms an overinfusion into the intrathecal space. Medical care will often be specific to the xenobiotic delivered. Ideally pumps with erratic delivery or confirmed overinfusion should be replaced and the failed pump sent to the manufacturer for analysis.<sup>44,76</sup>

## ERROR PREVENTION

All intrathecal medication errors are preventable.<sup>47</sup> Mechanisms for prevention are well described.<sup>36,79</sup> They include trained pharmacists and administering physicians, specialized packaging and handling, use of minibags for intrathecal medications whenever feasible, preadministration of any intravenous medications, removal of all syringes and other medications from the area, and a checklist and time out, with 2 persons reviewing all labels. Non-Luer lock systems are being adopted in the United Kingdom to limit connection errors, by assuring incompatibility<sup>88</sup> and recently FDA final guidelines has occurred on the topic in the United States. Any adopted system of prevention should include steps for intrathecal administration of required xenobiotics in all settings, including treatment wards, outpatient clinics, radiology suites, and the operating room, as well as by all intrathecal routes such as implantable pumps, Ommaya reservoirs, and lumbar or other access points.

## SUMMARY

- Intrathecal medication errors can be life-threatening.
- Errors occur during preparation or administration.
- Rapid intervention with CSF drainage should be considered when a dosing or medication error occurs.
- Some intrathecal chemotherapeutic errors are fatal, and time to CSF drainage is critical to outcome.
- Pump failures precipitate either withdrawal or overdose depending on the malfunction.
- Any drug removed from a pump reservoir should be carefully measured and preserved

## EXTRAVASATION OF XENOBIOTICS

Richard Y. Wang

Extravasation injuries are among the most consequential local toxic events. When the vesicant chemotherapeutics leak into the perivascular space, significant necrosis of skin, muscles, and tendons occurs, with resultant loss of function, infection, and deformity. Typical initial manifestations include swelling, pain, and a burning sensation that can last for hours. Days later, the area becomes erythematous and indurated, followed by resolution or progression to ulceration and necrosis. These early findings are often difficult to distinguish from other forms of local drug toxicity, such as irritation and hypersensitivity, which can result from the chemotherapeutic or its vehicle (ethanol, propylene glycol) and do not progress to ulceration and necrosis. For example, fluorouracil, carmustine, cisplatin, and dacarbazine are local irritants. The local irritation and hypersensitivity manifestations are self-limiting and typified by an immediate onset of a burning sensation, pruritus, erythema, and a flare reaction of the vein receiving the infused. The extravasation of monoclonal antibodies causes minimal discomfort and inflammation.<sup>15,37,49</sup> When a hypersensitivity reaction or an irritation to the vessel cannot be differentiated from extravasation, it is prudent to presume extravasation and manage the situation accordingly.

The occurrence of extravasations appears to be more frequent with inexperienced clinicians.<sup>19</sup> Factors associated with extravasation injuries from peripheral intravenous lines include (1) poor vessel integrity and blood flow, such as those found in the elderly and in patients with numerous venipuncture attempts or who have received radiation therapy to the site; (2) limited venous and lymphatic drainage caused by either obstruction or surgical resection; and (3) the use of venous access overlying a joint, which increases the risk of dislodgments because of movement.<sup>18,40</sup>

In children, the use of a steel needle (butterfly) or a small catheter that easily allows blood to flow around the catheter increases the risk for an extravasation.<sup>10</sup> Children require frequent monitoring of the intravenous site for possible extravasation. Extravasation injuries from implanted ports in central veins occurs from inadequate placement of the needle, needle dislodgment, damaged septum, fibrin sheath formation around the catheter, perforation of the superior vena cava, and fracture of the catheter.<sup>44</sup> When extravasation from a central venous access device is suspected and plain radiographic studies are not diagnostic, a contrast-enhanced CT scan of the anatomic location is necessary for evaluation because the extent of the injury is often underestimated at the bedside.<sup>1,2,37</sup>

The factors associated with a poor outcome from extravasation injuries include (1) areas of the body with little subcutaneous tissue, such as the dorsum of the hand, volar surface of the wrist, and the antecubital fossa, where healing is poor and vital structures are more likely to be involved; (2) increased concentrations of extravasate; (3) increased volume and duration of contact with tissue; and (4) the type of chemotherapeutic.<sup>40,41</sup>

Vesicants, such as doxorubicin, daunorubicin, dactinomycin, epirubicin, idarubicin, mechlorethamine, mitomycin, and the vinca alkaloids produce more significant local tissue destruction than other types of chemotherapeutics, such as irritants. Mitomycin infusions cause dermal ulcerations at venipuncture sites remote from the location of administration.<sup>36</sup> The anthracycline antibiotics are associated with a higher incidence of significant injuries and delayed healing, which likely result from their slow release from bound tissue into surrounding viable tissue. Doxorubicin extravasation is associated with local tissue necrosis in approximately 25% of reported cases. The extravasation injuries from

taxanes appear similar to the vesicants, but are less severe in response and more delayed in presentation.<sup>3,38</sup>

Prevention is the best therapy for extravasation injuries. Clinicians qualified for chemotherapy administration, the development and implementation of procedures for the management of extravasations, and the safe administration of chemotherapeutics can limit the extent of these injuries.<sup>8,32,33</sup>

**MANAGEMENT**

The treatment for extravasation injuries varies by locality based on controversial practices, such as the use of selective antidotes, the use of surgical irrigation, and the timing of surgical wound debridement. This uncertainty is a result of the limited number of clinical cases available for study and the discordance between animal studies and human experience. However, the general and specific management recommendations derived from the literature and their theoretical foundations exist (Table SC8-1).<sup>5,9,24,37,49</sup> Clinical centers should develop and implement procedures for the management of extravasation injuries that are consistent with the current literature and guidelines.<sup>32</sup>

Once extravasation is suspected, the infusion should be immediately halted. A physician should be notified and the xenobiotic, its concentration, and the approximate amount infused should be noted. The venous access should be maintained to permit aspiration of as much of the infusate as possible and administration of an antidote, if indicated. The early surgical irrigation of the extravasation site is recommended by some centers for an extravasation containing more than 5 mL of a vesicant.<sup>49</sup> Irrigation should be initiated within 6 hours of the incident, although it has been used in patients with pain, swelling, and no ulcerations at the site when it was beyond 6 hours.<sup>13,16,49</sup>

The intermittent local application of a dry cold compress and elevation of the extremity is recommended for 48 to 72 hours to limit further progression of the xenobiotic and the development of dependent edema. Cooling the affected area reduces the amount of xenobiotic absorbed by the tissue and lowers the cellular metabolic rate, which limits further tissue damage and cell injury.<sup>23,48</sup> With just the application of a cold compress and strict elevation, only 13 (11%) of 119 patients with mild extravasations required surgical intervention for their injuries in a retrospective review of patients at one center.<sup>28</sup> In the past, heat was recommended to disperse the xenobiotic, but investigations with animals treated with intradermal doxorubicin demonstrated increase in the area of skin ulceration.<sup>12,27</sup> However, dry, warm compresses to promote systemic uptake of the vinca alkaloids (vincristine and vinblastine) and etoposide are recommended.

A warm compress is combined with the immediate local infiltration of hyaluronidase to enhance absorption of an extravasation with a vinca alkaloid or etoposide (Table SC8-1).<sup>6</sup> Hyaluronidase hydrolyzes the beta-1,4-glycosidic bond between *N*-acetyl-D-glucosamine and D-glucuronic acid in the glycosaminoglycan hyaluronate (hyaluronic acid). Hyaluronate is a natural polymer consisting of the above disaccharide unit, and it contains alternating beta-1,4-glycosidic and beta-1,3-glycosidic bonds. Hyaluronate is produced in the plasma membrane of the cell and it provides structural integrity to the extracellular matrix of soft tissues, such as connective tissue. The enzymatic hydrolysis of hyaluronate promotes the distribution of the chemotherapeutic in the soft tissue space.

Hyaluronidase is also used in the treatment of extravasations with a hyperosmotic infusate (eg, total parenteral nutrition, calcium, potassium, 10%–50% dextrose, and nafcillin).<sup>39</sup>

TABLE SC8-1 Management of Extravasation Injuries

	Therapy	Purpose/Mechanism
<b>General</b>	Stop infusion and maintain intravenous cannula at the site	Decrease further extravasation
	Aspirate extravasate from the site by accessing the original intravenous cannula	Minimizes amount of chemotherapeutic localized at the site
	Apply dry cool compresses for 1 hour, every 8 hours for 3 days	Localizes area of involvement and diminishes cellular uptake of the chemotherapeutic
	Elevate extremity and administer analgesia	Promotes drainage, prevents dependent edema, and provides comfort
	For vinca alkaloids and epipodophyllotoxins, apply dry warm compresses for 1 hour, every 8 hours for 3 days (see specific management)	Promotes systemic absorption of the chemotherapeutic
<b>Chemotherapeutic Specific</b>		
Anthracyclines	Dexrazoxane 1,000 mg/m <sup>2</sup> , administered daily by IV (max. 2,000 mg per day), on days 1 and 2, and 500 mg/m <sup>2</sup> on day 3 (max. 1,000 mg); dose is decreased for patients with kidney disease	Limits free radical formation
Mechlorethamine	Add 1.6 mL of 25% sodium thiosulfate to 8.4 mL of sterile water for injection to make a 4% solution Infiltrate the site of extravasation with 2 mL of 4% sodium thiosulfate per milligram of mechlorethamine at the site	Prevents tissue alkylation
Mitomycin	Dimethyl sulfoxide (DMSO): 55%–99% (w/v) applied topically and allowed to air dry	Free radical scavenger
Vinca alkaloids and epipodophyllotoxins	Hyaluronidase: Inject subcutaneously, 150 units/mL into the site as 5 separate and equally spaced injections of 0.2 mL using a 25-gauge or smaller needle at the leading edge of the infiltrate	Degrades hyaluronic acid to enhance systemic absorption of the chemotherapeutic

Human recombinant hyaluronidase (Hyalenex) is available as 150 units/mL, and recommendations are to administer it as 5 separate and equally spaced subcutaneous injections of 0.2 mL (30 units) using a 25-gauge or smaller needle at the leading edge of the infiltrate.<sup>17,42,43</sup> Wounds that are either cancerous or infected should not be treated with hyaluronidase. Patients treated with hyaluronidase require monitoring for allergic reactions, such as anaphylaxis, although the newer human recombinant form is less allergenic than animal-derived hyaluronidase.

The wound should be observed closely for the first 7 days, and a surgeon consulted if either pain persists or evidence of ulceration appears.<sup>40</sup> However, in patients with severe extravasations—where there is a high likelihood of necrosis because of the chemotherapeutic (doxorubicin), the volume or concentration, and any area where there may be significant potential for long-term morbidity such as over joints, early surgical consultation is recommended. If tissue ulceration occurs, initial management is often restricted to sterile dressings to prevent secondary infections. Once the area of necrotic skin can be clearly delineated from surviving tissue, surgical debridement is reasonable to limit secondary infection. Some patients require surgical reconstruction or skin grafts depending on the extent of the injury.

## ANTIDOTES

Antidotal therapy, when available, is indicated when the extravasated xenobiotic is known to respond poorly to conservative care. The antidotal treatments are categorized by their mechanism of action. Topical steroids were used to reduce the inflammatory response, including hypersensitivity reactions, from extravasated xenobiotics.<sup>22,49</sup> However, this therapy remains a controversial practice for chemotherapeutics that are known to cause direct tissue necrosis, such as doxorubicin and the vinca alkaloids,<sup>4,19,29,46</sup> because inflammatory cells do not predominate at the wound site, and not currently recommended.<sup>7</sup> Sodium thiosulfate is recommended for mechlorethamine extravasation and is believed to inactivate the xenobiotic by reacting with the active ethylenimmonium ring.<sup>18,35</sup> The site should be infiltrated with 2 mL of a sterile 4% (isotonic) sodium thiosulfate solution for each milligram of mechlorethamine, followed by intermittent dry cold compresses for 48 to 72 hours.<sup>6</sup>

Finally, there are antidotes for anthracycline extravasations, such as dimethyl sulfoxide (DMSO) and dexrazoxane. Because dexrazoxane was

approved by the FDA for the treatment of anthracycline extravasations in adults, the role for DMSO in the treatment of anthracycline extravasations has become secondary.<sup>21,49</sup> Dimethyl sulfoxide scavenges free radicals that cause tissue damage from chemotherapeutics, such as doxorubicin. Dimethyl sulfoxide was beneficial for anthracycline extravasations in both animal and human clinical trials.<sup>6,12,29,35,45</sup> Dimethyl sulfoxide was used at concentrations varying from 55% to 99% (w/v) and it was applied topically and then followed with intermittent cold compresses.<sup>6,14,29,34</sup> Additional beneficial properties of DMSO are its antiinflammatory, analgesic, and vasodilatory effects, as well as its ability to promote systemic absorption of the chemotherapeutic at local sites.<sup>30</sup> Dimethyl sulfoxide is also recommended for extravasations with mitomycin.

Dexrazoxane limits free radical cellular damage by chelating iron and directly acting as an antioxidant. The systemic administration of dexrazoxane limited anthracycline-induced skin lesions in a murine model<sup>25</sup> and was used successfully in patients following doxorubicin<sup>11,26,47</sup> and epirubicin<sup>20,25</sup> extravasations. In 2 prospective, open-label, single-arm, multicenter clinical trials, the systemic administration of dexrazoxane within 6 hours of anthracycline extravasation resulted in the need for surgical resection of the wound site in only 1 of 54 (1.8%) patients.<sup>31</sup> Dexrazoxane was given to these patients over 3 days intravenously at a starting dose of 1,000 mg/m<sup>2</sup>, which was infused over 15 to 30 minutes at a site distant to that of the extravasation because of its irritating properties. Dry cold compresses at the site of the extravasation were discontinued for 15 minutes prior to therapy to promote perfusion of the antidote at the site. The dose of dexrazoxane (Table SC8-1) is decreased for patients with diminished kidney function (creatinine clearance < 40 mL/min). Patients need to be monitored with CBC and serum aminotransferases because dexrazoxane can cause reversible bone marrow suppression and result in hepatotoxicity. Additional clinical evidence needs to be gathered to better define the medical management of other chemotherapeutic extravasations. The overall incidence of extravasations with chemotherapeutics is likely small, the associated morbidity is significant.

## SUMMARY

- Prevention is the best form of therapy for these injuries.
- Immediately stop the infusion following a suspected extravasation.
- Aspirate, apply dry cool compresses, elevate the extremity, and administer analgesia.

## ANTIMIGRAINE MEDICATIONS

Jason Chu

### PATHOPHYSIOLOGY OF MIGRAINE HEADACHES

A migraine headache is a neurovascular disorder often initiated by a trigger and characterized by a headache, which is preceded by an aura 20% of the time. The aura is either unilateral (40%) or bilateral (60%), reversible visual, sensory or other central nervous system symptom that gradually develops and last for minutes preceding the headache. The headache lasts 4 to 72 hours in adults and 1 to 48 hours in children and is typically a pulsatile headache of moderate to severe intensity with associated nausea, photophobia, and/or phonophobia and is typically worsened by routine physical activity. The International Headache Society establishes the diagnostic criteria for the various types of migraine, which are divided into multiple groups: migraine without aura (“common migraine”), migraine with aura (“classic migraine”), chronic migraine, complications of migraine, probable migraine, and episodic syndromes that may be associated with migraine. Further subdivisions of migraine with aura include migraine with typical aura with or without headache, migraine with brain stem aura, hemiplegic migraine, and retinal or ophthalmic migraine.<sup>41</sup>

The origin of migraine pain evolved from a vascular theory to a neurogenic theory but is still not fully elucidated. Migraine pain involves the trigemino-vascular system as well as brain stem and diencephalic nuclei. Although the brain is insensate, the cerebral blood vessels, arteries, veins, and sinuses are innervated by C-fibers and A- $\delta$ -fibers of the trigeminal ganglion, and the dura mater is innervated by neurons from cervical dorsal root ganglia. Activation of these *first-order neurons* releases inflammatory neuropeptides such as calcitonin gene-related polypeptide (CRGP), vasoactive intestinal peptide (VIP), neurokinin A, substance P, and pituitary adenylate cyclase-activating peptide (PACAP). Pain impulses are relayed to the trigeminocervical complex composed of the trigeminal nucleus caudalis in lower medulla and the C1 and C2 region of the spinal cord. From there, nociceptive signals are relayed via *second-order neurons* via the trigeminothalamic tract to third-order neurons in the ventroposteromedial thalamus as well as the locus coeruleus, periaqueductal gray area, and hypothalamus. Thalamic *third-order neurons* in turn synapse with multiple higher and diffuse cortical areas. The trigeminocervical complex also produces retrograde parasympathetic impulses from the sphenopalatine ganglion and the superior salivatory nucleus in the pons through the sphenopalatine ganglion to the cerebral vessels.<sup>38</sup>

Migraine has a strong genetic component and particularly involving genetic abnormalities in the central nervous system (CNS) ion channels, namely, the P/Q calcium channels that predispose patients to specific triggers. Familial hemiplegic migraine is an autosomal dominant disorder with mutations affecting neuronal ion channels, leading to increased neuronal excitability. Four genes are known to be involved, three of these are involved in ion transport and the fourth is an axonal protein complex. Genomewide association studies have identified genes potentially involved in migraine susceptibility.<sup>34</sup>

Migraine auras are transient focal neurologic symptoms, which are present in about 25% to 30% of migraine patients and are typically visual although sensory, motor, speech or brain stem deficits are also described.<sup>38</sup> Usually auras precede the headache but can extend into the headache and postdromal phase. Visual auras are caused by a wave of neuronal depolarization, termed cortical spreading depression, at the visual cortex from a caudal to rostral fashion initially causing oligemia followed by hyperemia known as the spreading wave of oligemia. This in turn can activate the trigeminovascular system. Although cortical spreading depression accounts for migraine auras as well as the headache itself, it is still debated whether cortical spreading depression is a trigger for the initiation of migraine.<sup>38</sup>

Treatment of migraines encompasses a wide variety of xenobiotics that can be broadly classified either as prophylactic or abortive therapies (Table 52–1).<sup>75</sup> Triptans are considered the drugs of choice for abortive migraine therapy.

### ERGOT ALKALOIDS

#### History and Epidemiology

Ergot is the product of *Claviceps purpurea*, a fungus that contaminates rye and other grains. The spores of the fungus are both windborne and transported by insects to young rye, where they germinate into hyphal filaments. When a spore germinates, it destroys the grain and hardens into a curved body called the sclerotium, which remains the major commercial source of ergot alkaloids.<sup>11</sup> The *C. purpurea* fungus produces diverse substances, including ergotamine, histamine, lysergic acid, tyramine, isomylamine, acetylcholine, and acetaldehyde.

In 600 B.C. an Assyrian tablet mentioned grain contamination believed to be by *C. purpurea*. In the Middle Ages, epidemics causing gangrene of the

TABLE 52–1 Xenobiotics Used in Migraine Treatment<sup>a</sup>

Prophylactic	Abortive
$\beta$ -Adrenergic antagonists	Acetaminophen
ACE inhibitors	Antiemetics: metoclopramide, prochlorperazine
Acetazolamide	Aspirin
Angiotensin II receptor antagonist	Butalbital
Antiepileptics: Carbamazepine, gabapentin, levetiracetam, topiramate, valproic acid, zonisamide	Butyrophenones: Droperidol, haloperidol
Antipsychotics: Aripiprazole, olanzapine, quetiapine	Caffeine
Benzodiazepines	Corticosteroids
Butterbur root	Ergots
Calcium channel blockers	Lidocaine (intranasal)
Coenzyme Q10	Magnesium (intravenous)
Cyclic antidepressants	Nonsteroidal antiinflammatory drugs
Cyproheptadine	Opioids
Feverfew	Oxygen
Flunarizine	Sedative–hypnotics
Hormonal contraceptives	Triptans
Isometheptene/dichloralphenazone/acetaminophen (Midrin)	Valproic acid
Magnesium (oral)	
Monoamine oxidase inhibitors	
Melatonin	
Memantine	
Nefazodone	
OnabotulinumtoxinA (Botox A)	
Pizotifen	
Riboflavin	
Selective serotonin reuptake inhibitors	

<sup>a</sup>Prophylactic xenobiotics are usually taken to prevent triggering of migraines, and abortive xenobiotics are usually taken to stop the clinical manifestations of migraines once they are triggered. However, the separation between the two groups of xenobiotics is not strict, and some xenobiotics may be used in both roles. Triptans are currently considered the drug class of choice to abort moderate to severe migraine headache. ACE = angiotensin-converting enzyme inhibitors.

extremities, with mummification of limbs, were depicted in the literature as blackened limbs resembling the charring from fire and caused a burning sensation expressed by its victims. The disease was called *holy fire* or *St. Anthony's fire*, but the improvement that reportedly occurred when victims went to visit the shrine of St. Anthony was probably the result of a diet free of contaminated grain on the journey.<sup>82</sup> Abortion and seizures were also reported to result from this poisoning. On the other hand, as early as 1582, midwives used ergot to assist in the childbirth process. In 1818, Desgranges was the first physician to use ergot for obstetric care, and in 1822 Hosack reported that ergot could be used for the control of postpartum hemorrhage.<sup>82</sup> In the twentieth century, ergot derivatives were almost entirely limited to the treatment of vascular headaches whereas today they are rarely employed. Ergonovine, another ergot derivative, is used in obstetric care for its stimulant effect on uterine smooth muscle and was formerly used in cardiac stress tests. Methylergonovine is used for postpartum uterine atony and hemorrhage. Cabergoline is used for hyperprolactinemia. Pergolide was used for Parkinson disease but was withdrawn from the United States in 2007. Ergot derivatives were also used as "cognition enhancers,"<sup>85</sup> to help manage orthostatic hypotension,<sup>77</sup> and to prevent the secretion of prolactin.<sup>68</sup>

The United States, Australia, Canada, European Union, Japan, New Zealand, Switzerland, and the United Kingdom regulate the ergot level in grains, ranging from no ergots in grains in the United Kingdom to 0.03% ergot in US grain.<sup>11</sup> Elsewhere in the world, ergot toxicity remains a problem predominantly in poorly developed areas without ergot regulation and in animals.<sup>11,12</sup>

### Pharmacology and Pharmacokinetics

All ergot alkaloids are derivatives of the tetracyclic compound 6-methylergoline. They are divided into 3 groups: amino acid alkaloids (ergotamine, ergotoxine), dihydrogenated amino acid alkaloids, and amine alkaloids (Fig. 52-1).

The pharmacokinetics of the ergot alkaloids are well defined by controlled human volunteer studies, whereas the toxicokinetics are essentially unknown (Table 52-2). Almost all of the ergots are poorly absorbed orally and there is considerable first-pass hepatic metabolism, resulting in highly variable bioavailability.

The pharmacologic effects of the ergot alkaloids can be subdivided into central and peripheral effects (Table 52-2). In the CNS, ergotamine stimulates serotonergic receptors, potentiates serotonergic effects, blocks

neuronal serotonin reuptake, and has central sympatholytic actions.<sup>19</sup> Ergots interact with the 1A, 1B, 1D, 1F, 2A, 2C, 3, and 4 serotonin receptor subtypes, dopamine receptors and adrenergic receptors.<sup>7</sup> Stimulation of 5HT<sub>1B</sub> receptors on cranial arteries causes vasoconstriction. 5-Hydroxytryptamine<sub>1D</sub> receptors are located presynaptically at trigeminal nerve endings and central nervous system neurons. Stimulation blocks the release of substance P and calcitonin gene-related peptide (CGRP) from trigeminal nerve endings and blocks the activation of second-order neurons of the trigeminal nucleus caudalis.<sup>75,76</sup> Ergotamine and dihydroergotamine decrease the neuronal firing rate and stabilize the cerebrovascular smooth musculature, which made them useful drugs for both abortive and prophylactic treatment of migraine headaches; however, newer medications with fewer adverse effects have replaced them clinically.

Peripherally, ergotamine and dihydroergotamine are  $\alpha$ -adrenergic, 5-HT<sub>2A</sub> and 5-HT<sub>1B</sub> agonists, and vasoconstrictors.<sup>71</sup> The amino acid ergot alkaloids (ergotamine, ergotoxine) exhibit  $\alpha$ -adrenergic agonism, and dehydrogenation (dihydroergotamine) of the lysergic acid nucleus increases the potency of this effect.<sup>68</sup> Ergotamine is a potent constrictor of peripheral arteries and veins, whereas dihydroergotamine constricts veins more than arteries.<sup>19</sup>

In the CNS, ergotamine and dihydroergotamine cause vasoconstriction via 5HT<sub>1B</sub> and  $\alpha$ -adrenergic agonism, with both medications having similar 5-HT receptor agonist activity. As noted above, ergotamine has more peripheral arterial vasoconstriction, constricts larger cranial arteries, and possibly increases norepinephrine-induced vasoconstriction. Dihydroergotamine constricts larger cranial arteries as well but has more  $\alpha$ -receptor antagonist activity and inhibits norepinephrine-induced vasoconstriction. Neither medication affects cranial resistance vessels nor changes cerebral blood flow.<sup>2,69</sup> Ergot stimulation of central 5HT<sub>1A</sub> receptors causes nausea and dysphoria, and stimulation of dopamine D<sub>2</sub> receptors cause nausea and vomiting.<sup>76</sup>

Table 52-2 summarizes the pharmacologic actions of selected ergot alkaloids currently used in clinical medicine. The spectrum of effects depends on dose, host response, and physiologic conditions. The clinical effects following overdose are an extension of the therapeutic effects. At toxic doses, extreme vasoconstriction produces the characteristic ischemic changes that occur in ergotism.

### Clinical Manifestations

Ergotism, a toxicologic syndrome resulting from excessive use of ergot alkaloids, is characterized by intense burning of the extremities, hemorrhagic vesiculation, pruritus, formication, nausea, vomiting, and gangrene (Table 52-3). Headache, fixed miosis, hallucinations, delirium, cerebrovascular ischemia, and convulsions are also associated with this condition, which was called "convulsive" ergotism.<sup>40</sup> Chronic ergotism usually presents with peripheral ischemia of the lower extremities, although ischemia of cerebral, mesenteric, coronary, and renal vascular beds are well documented.<sup>3,28,29,66,67</sup> Ergotism also results from interactions of ergot derivatives with CYP3A4 inhibitors such as macrolide antibiotics and protease inhibitors, which increase bioavailability of ergots.<sup>9,10</sup>

The vascular effects ascribed to ergot alkaloids are complex and sometimes conflicting (Table 52-2). Subintimal and medial fibrosis, vasospasm, and arteriolar and venous thrombi (stasis related) are all reported.<sup>55</sup> Angiography can demonstrate distal, segmental vessel spasm with increased collateralization in patients with chronic ergotism. The coronary, renal, cerebral, ophthalmic, and mesenteric vasculature,<sup>67</sup> as well as the vessels of the extremities, are also affected.<sup>72</sup> Neuropathic changes also occur secondary to ischemia of the vasa nervorum.

Bradycardia is a characteristic effect of the ergot alkaloids and is believed to be a reflex baroreceptor-mediated phenomenon associated with vasoconstriction. However a reduction in sympathetic tone, direct myocardial depression, and increased vagal activity are also factors.<sup>68</sup>

Myocardial valvular abnormalities are reported with ergot alkaloids. Ergotamine, dihydroergotamine methysergide, pergolide, and cabergoline cause mitral and aortic valve leaflet thickening and immobility resulting in valvular regurgitation.<sup>30,66,89</sup> The mitral and aortic valves and pulmonary

arteries have high concentrations of 5HT<sub>2B</sub> receptors. The ergot-derived medications are potent 5HT<sub>2B</sub> receptor agonists, and stimulation activates cellular kinases leading to fibroblast proliferation and collagen synthesis.<sup>25</sup>

### Treatment

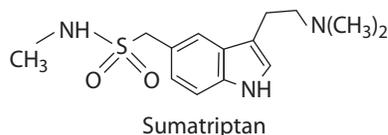

The treatment for a patient with ergot alkaloid toxicity depends on the nature of the clinical findings. Gastric emptying is rarely used, if at all, because vomiting is a common early occurrence, and the ingestion is infrequently

complicated by seizures. After an acute oral overdose, 1 g/kg of oral activated charcoal is recommended. If emesis is present, antiemetics such as ondansetron or metoclopramide are reasonable to be administered intravenously to facilitate the administration of activated charcoal. In mild cases, characterized by minimal pain of the extremities, nausea, or headache, supportive measures such as hydration and analgesia are all that are needed. Immediate-release oral nifedipine is a reasonable therapy for patients with mild symptoms of vasospasm, such as dysesthesias and minimal ischemic pain of the digits.<sup>18</sup> With more serious cases, peripheral vasoconstriction produce ischemic changes that include angina, myocardial infarction, cerebral ischemia, intermittent claudication, and internal organ/mesenteric ischemia. Reasonable therapies include sodium nitroprusside, phentolamine, and intravenous calcium channel blockers, nifedipine, or clevidipine, titrated until resolution of vasoconstriction.<sup>3,15,61</sup> Although methylprednisolone at a dose of 1 mg/kg reversed ergotamine-induced lower extremity arterial vasospasm that was unresponsive to sodium nitroprusside and heparin, there is not enough data to routinely recommend this therapy.<sup>64</sup>

Heparin or low-molecular-weight heparins are reasonable to administer to prevent sludging and subsequent clot formation. Benzodiazepines are recommended therapies to treat ergot- or bromocriptine-associated seizures or hallucinations.<sup>36</sup>

TABLE 52–3 Clinical Manifestations of Ergotism

Central Effects	Peripheral Effects
Agitation	Angina
Cerebrovascular ischemia	Bradycardia
Hallucinations	Gangrene
Headaches	Hemorrhagic vesiculations and skin bullae
Miosis (fixed)	Mesenteric infarction
Nausea	Myocardial infarction
Seizures	Renal infarction
Twitching (facial)	
Vomiting

## TRIPTANS

In 1974, investigations began on a new class of compounds that produced vasoconstrictive effects via 5-HT receptors. The first compound successfully used in this way was 5-carboxamidotryptamine (5-CT). When applied to an isolated dog saphenous vein, 5-CT caused potent venoconstriction and induced significant hypotension in vivo. The next compound developed, AH25086 [(3,2-aminoethyl)-*N*-methyl-1-*H*-indole-5-acetamide], also constricted saphenous veins in dogs but had more 5-HT receptor selectivity. AH25086 was effective against acute migraine in human volunteers, but further research was stopped because it was deemed less suitable for development in humans, possibly owing to the fact that it was highly polar, lipophobic, and unsuitable for oral use.<sup>43,70</sup> In 1984, sumatriptan was synthesized and its clinical success led to the rapid development of 6 other triptans: almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, and zolmitriptan, and one triptan combination medication (sumatriptan/naproxen; Fig. 52-2; Table 52-4).

### Pharmacology

There are numerous interrelated proposed mechanisms of action of 5HT<sub>1</sub> agonists on migraine.<sup>19</sup> The triptans are all primarily 5-HT<sub>1B</sub> and 5-HT<sub>1D</sub> receptor agonists and have less activity at 5-HT<sub>1A</sub> and 5-HT<sub>1F</sub> receptors<sup>31</sup> (Chap. 13). In the CNS, 5-HT<sub>1B</sub> receptors are located on cerebral vessels.<sup>39</sup> Stimulation of these receptors results in cerebral vasoconstriction,<sup>20</sup> reversing abnormal cerebral vasodilation. In contrast, the 5-HT<sub>1D</sub> receptors are located presynaptically on trigeminal neurons, and act as “autoreceptors” to decrease neurotransmitter release from central trigeminal nerve terminals.<sup>47</sup> The triptans also inhibit dural neurogenic inflammation by preventing the release of vasoactive neuropeptides from peripheral trigeminal nerves.<sup>57,73</sup> Centrally, triptans stimulate 5-HT<sub>1B/D/F</sub> receptors in the trigeminal nucleus caudalis to prevent signaling from first order trigeminal neurons to second order neurons in the trigeminal nucleus caudalis. Triptans also stimulate 5-HT<sub>1B/D</sub> receptors to prevent signaling from second-order trigeminal nucleus caudalis neurons to third-order neurons in ventroposteromedial (VPM) thalamus. Both of the latter mechanisms block central sensitization in migraine headaches.<sup>19</sup> Peripherally, triptans cause vasoconstriction systemically through the 5-HT<sub>1B</sub> receptor (Fig. 52-3).<sup>22,51</sup>

**FIGURE 52-3.** Some of the multiple interactive mechanisms of action of triptans. Vasoconstriction of intracranial [1] and peripheral [5] blood vessels via 5-HT<sub>1B</sub> receptor agonism. Inhibition of vasoactive peptide release [2] from trigeminal nerve terminals at dural vessels via 5-HT<sub>1D</sub> agonism. Modulation of nociceptive transmission to trigeminal nucleus caudalis [3] and thalamus [4].

Sumatriptan has poor oral bioavailability but good subcutaneous bioavailability (96%), and is therefore preferentially given by this route. The newer triptans differ substantially from sumatriptan with regard to oral bioavailability, plasma half-life, time to maximum effect, and recurrence rate of headaches. All triptans are pharmacodynamically similar but pharmacokinetically different (Table 52-4).

### Clinical Manifestations

With appropriate therapeutic use, the common adverse effects associated with the triptans are less common and include nausea, vomiting, dyspepsia, esophageal spasm, flushing, and paresthesias.<sup>21,68</sup> The most consequential adverse effects are chest pressure and vasoconstriction. Chest pressure symptoms are reported in up to 15% of sumatriptan users.<sup>14,63</sup> Although triptans reduce coronary artery diameter by 10% to 15%, chest pressure symptoms are not believed to be secondary to cardiac ischemia. Alternate

**TABLE 52-4** Pharmacokinetics of Triptans

Triptan	$t_{1/2}$ (hours)	Duration of Action (hours)	Lipophilicity	Bioavailability O (%)	Metabolism/Elimination
Almotriptan	3.0–3.7	24	Unknown	70–80	CYP3A4, CYP2D6 MAO-A (minor)
Eletriptan	3.6–6.9	14–16	High	50	CYP3A4
Frovatriptan	25	24	Low	24–30	CYP1A2 Kidney
Naratriptan	4.5–6.6	Unknown	High	63–74	Kidney (major) P450
Rizatriptan	1.8–3.0	25	Moderate	40–45	MAO-A
Sumatriptan	2.0–2.5	4	Low	14; 96 (SC)	MAO-A
Zolmitriptan	1.5–3.6	18	Moderate	40–49	CYP1A2 MAO-A (minor)

MAO = monoamine oxidase; Oral = oral unless otherwise stated; PO = oral; SC = subcutaneous.

hypotheses for the chest pressure sensations include a generalized vaso-spastic disorder in migraineurs, esophageal spasm, bronchospasm, alterations of skeletal muscle energy metabolism, and central sensitization of pain pathways.<sup>23</sup>

Triptans can cause ischemia due to vasoconstriction. Therapeutic sumatriptan use is associated with myocardial ischemia and/or infarction, dysrhythmias, renal infarction, splenic infarction, and ischemic colitis.<sup>1,8,17,48,52,58,60,62</sup> Cephalic vasoconstriction is the desired effect of sumatriptan, but there are reports of strokes, hemorrhages, and infarctions.<sup>16,46,50,56</sup> Extrapyramidal symptoms, such as akathisia and dystonia, also occur.<sup>49</sup> Therapeutic use of other triptans is associated with spinal cord infarction, renal infarction, myocardial infarction, ischemic colitis, and seizures.<sup>11,33,54,83,86</sup>

Animal studies showed a wide margin of safety with oral sumatriptan. Subcutaneous administration of 2 g/kg of sumatriptan to rats was lethal. Death was preceded by erythema, inactivity, and tremor.<sup>44</sup> Dogs survived 20 and 100 mg/kg subcutaneous doses, but developed hind limb paralysis, erythema, tremor, salivation, and loss of vocalization.<sup>43</sup> Reactions in other animals include seizures, inactivity, reduced respiratory rate, cyanosis, ptosis, ataxia, mydriasis, salivation, and lacrimation.<sup>44,78</sup>

Excessive triptan use is associated with vasoconstrictive adverse effects as well as tachyphylaxis. A 43-year-old man who used 23 (25 mg) tablets of sumatriptan and 32 tablets of a combination preparation of isometheptene 65 mg, dichloralphenazone 100 mg, and APAP 325 mg over 7 days for headaches developed a left occipital infarction with a right hemianopsia. Digital subtraction angiography revealed segmental narrowing in multiple cerebral vessels. The hemianopsia and vessel findings resolved after cessation of the sumatriptan and Midrin and treatment with nicardipine.<sup>56</sup> A 35-year-old woman who used 300 mg of sumatriptan orally and 12 mg subcutaneously developed ischemic colitis.<sup>4</sup> Two patients who received 4 times and 10 times the recommended dose of naratriptan developed severe hypertension.<sup>6</sup> However, not all triptan overdoses result in toxicity. A 36-year-old man reportedly used 66 (6 mg) doses of sumatriptan subcutaneously over 4 weeks for his cluster headaches and had no adverse effects.<sup>80</sup> The maximum recommended dosage of sumatriptan is 12 mg subcutaneously in a 24-hour period. Patients who took single doses of 100 to 150 mg of almotriptan had no adverse effects.<sup>5</sup>

In 2006, the US Food and Drug Administration (FDA) issued an alert, warning of an increased risk of serotonin toxicity with triptans used in combination with selective serotonin reuptake inhibitors (SSRIs) or selective serotonin-norepinephrine reuptake inhibitors. The alert was based on 27 cases reported to the FDA Adverse Events Reporting System between 1998 and 2002. The cases involved triptan use in conjunction with SSRIs that were coded as serotonin syndrome or symptoms indicative of serotonin toxicity.<sup>26</sup> A case series of serotonin toxicity from migraine medications described 3 cases associated with sumatriptan use alone, sumatriptan with sertraline, and sumatriptan with methysergide, lithium, and sertraline.<sup>53</sup> Other medications that might precipitate serotonin toxicity when used in conjunction with triptans include monoamine oxidase inhibitors (Chaps. 69 and 71).

## Treatment

Treatment of triptan-induced vasoconstriction is dependent on the route of exposure and the organ system affected. Decontamination is not feasible after subcutaneous exposures, but can be effective following overdose of oral preparations. Gastrointestinal decontamination with activated charcoal is a reasonable approach. Because vomiting is not as prominent with triptan exposure compared to ergot alkaloids, gastric emptying procedures, such as orogastric lavage, are appropriate, but only following recent or massive ingestion. The oral forms of rizatriptan and zolmitriptan are formulated to dissolve on the tongue, limiting the effectiveness of gastrointestinal decontamination.

Many reported cases of triptan-induced vasoconstriction compromise responded to intravenous hydration and analgesia.<sup>33,45</sup> It is reasonable to treat triptan-associated myocardial ischemia with aspirin, heparin, and nitroglycerin.<sup>62</sup> Coronary angiography is recommended for transmural myocardial infarctions with ST segment elevations on electrocardiography.<sup>52,60</sup>

## ISOMETHEPTENE
