## **EDITORS**

### **First Edition**

Lewis R. Goldfrank, MD, Robert Kirstein, MD

### **Second Edition**

Lewis R. Goldfrank, MD, Neal E. Flomenbaum, MD, Neal A. Lewin, MD, Richard S. Weisman, PharmD

### **Third Edition**

Lewis R. Goldfrank, MD, Neal E. Flomenbaum, MD, Neal A. Lewin, MD, Richard S. Weisman, PharmD, Mary Ann Howland, PharmD, Alan G. Kulberg, MD

### **Fourth Edition**

Lewis R. Goldfrank, MD, Neal E. Flomenbaum, MD, Neal A. Lewin, MD, Richard S. Weisman, PharmD, Mary Ann Howland, PharmD

### **Fifth Edition**

Lewis R. Goldfrank, MD, Neal E. Flomenbaum, MD, Neal A. Lewin, MD, Richard S. Weisman, PharmD, Mary Ann Howland, PharmD, Robert S. Hoffman, MD

### **Sixth Edition**

Lewis R. Goldfrank, MD, Neal E. Flomenbaum, MD, Neal A. Lewin, MD, Richard S. Weisman, PharmD, Mary Ann Howland, PharmD, Robert S. Hoffman, MD

### **Seventh Edition**

Lewis R. Goldfrank, MD, Neal E. Flomenbaum, MD, Neal A. Lewin, MD, Mary Ann Howland, PharmD, Robert S. Hoffman, MD, Lewis S. Nelson, MD

### **Eighth Edition**

Neal E. Flomenbaum, MD, Lewis R. Goldfrank, MD, Robert S. Hoffman, MD, Mary Ann Howland, PharmD, Neal A. Lewin, MD, Lewis S. Nelson, MD

### **Ninth Edition**

Lewis S. Nelson, MD, Neal A. Lewin, MD, Mary Ann Howland, PharmD, Robert S. Hoffman, MD, Lewis R. Goldfrank, MD, Neal E. Flomenbaum, MD

### **Tenth Edition**

Robert S. Hoffman, MD, Mary Ann Howland, PharmD, Neal A. Lewin, MD, Lewis S. Nelson, MD, Lewis R. Goldfrank, MD, Neal E. Flomenbaum, MD (Editor Emeritus)

# GOLDFRANK'S TOXICOLOGIC EMERGENCIES

Eleventh Edition

## **LEWIS S. NELSON, MD, FAACT, FACEP, FACMT, FAAEM, FASAM**

Professor and Chair of Emergency Medicine  
Department of Emergency Medicine  
Director, Division of Medical Toxicology  
Rutgers New Jersey Medical School  
Chief of Service, Emergency Department  
University Hospital of Newark  
New Jersey Poison Information & Education  
System  
Newark, New Jersey

## **MARY ANN HOWLAND, PharmD, DABAT, FAACT**

Clinical Professor of Pharmacy  
St. John's University College of Pharmacy and  
Health Sciences  
Adjunct Professor of Emergency Medicine  
Ronald O. Perelman Department of Emergency  
Medicine  
New York University School of Medicine  
Bellevue Hospital Center and New York  
University Langone Health  
Senior Consultant in Residence  
New York City Poison Control Center  
New York, New York

## **NEAL A. LEWIN, MD, FACEP, FACMT, FACP**

Druckenmiller Professor of Emergency Medicine  
and Medicine  
Ronald O. Perelman Department of Emergency  
Medicine  
New York University School of Medicine  
Director, Didactic Education  
Emergency Medicine Residency  
Attending Physician, Emergency Medicine and  
Internal Medicine  
Bellevue Hospital Center and New York  
University Langone Health  
New York, New York

## **SILAS W. SMITH, MD, FACEP, FACMT**

JoAnn G. and Kenneth Wellner Associate  
Professor of Emergency Medicine  
Ronald O. Perelman Department of Emergency  
Medicine  
New York University School of Medicine  
Section Chief, Quality, Safety, and Practice  
Innovation  
Attending Physician, Emergency Medicine  
Bellevue Hospital Center and New York  
University Langone Health  
New York, New York

## **LEWIS R. GOLDFRANK, MD, FAAEM, FAACT, FACEP, FACMT, FACP**

Herbert W. Adams Professor of Emergency  
Medicine  
Ronald O. Perelman Department of Emergency  
Medicine  
New York University School of Medicine  
Attending Physician, Emergency Medicine  
Bellevue Hospital Center and New York  
University Langone Health  
Medical Director, New York City Poison Control  
Center  
New York, New York

## **ROBERT S. HOFFMAN, MD, FAACT, FACMT, FRCP Edin, FEAPCCT**

Professor of Emergency Medicine and Medicine  
Ronald O. Perelman Department of Emergency  
Medicine  
New York University School of Medicine  
Director, Division of Medical Toxicology  
Attending Physician, Emergency Medicine  
Bellevue Hospital Center and New York  
University Langone Health  
New York, New York

## **Editor Emeritus**

## **NEAL E. FLOMENBAUM, MD, FACP, FACEP**

Professor of Clinical Medicine  
Weill Cornell Medical College of Cornell  
University  
Physician-in-Chief, Emergency Medical  
Services  
Emergency Physician-in-Chief (1996-2016)  
New York-Presbyterian Hospital  
Weill Cornell Medical Center  
New York, New York

## NOTICE

Medicine is an ever-changing science. As new research and clinical experience broaden our knowledge, changes in treatment and drug therapy are required. The authors and the publisher of this work have checked with sources believed to be reliable in their efforts to provide information that is complete and generally in accord with the standards accepted at the time of publication. However, in view of the possibility of human error or changes in medical sciences, neither the authors nor the publisher nor any other party who has been involved in the preparation or publication of this work warrants that the information contained herein is in every respect accurate or complete, and they disclaim all responsibility for any errors or omissions or for the results obtained from use of the information contained in this work. Readers are encouraged to confirm the information contained herein with other sources. For example and in particular, readers are advised to check the product information sheet included in the package of each drug they plan to administer to be certain that the information contained in this work is accurate and that changes have not been made in the recommended dose or in the contraindications for administration. This recommendation is of particular importance in connection with new or infrequently used drugs.

## TERMS OF USE

McGraw-Hill Education and its licensors do not warrant or guarantee that the functions contained in the work will meet your requirements or that its operation will be uninterrupted or error free. Neither McGraw-Hill Education nor its licensors shall be liable to you or anyone else for any inaccuracy, error or omission, regardless of cause, in the work or for any damages resulting therefrom. McGraw-Hill Education has no responsibility for the content of any information accessed through the work. Under no circumstances shall McGraw-Hill Education and/or its licensors be liable for any indirect, incidental, special, punitive, consequential or similar damages that result from the use of or inability to use the work, even if any of them has been advised of the possibility of such damages. This limitation of liability shall apply to any claim or cause whatsoever whether such claim or cause arises in contract, tort or otherwise.

## Neal E. Flomenbaum, MD, FACP, FACEP

*Editor Emeritus*

With the publication of the ninth edition of *Goldfrank's Toxicologic Emergencies*, Neal Flomenbaum informed us of his decision to step down as an editor in order to be able to devote more time to his growing interests in geriatric emergency medicine and prehospital care, while continuing to fulfill his clinical and administrative responsibilities as Chief of Emergency Medicine at New York Presbyterian Hospital-Weill Cornell Medical Center and as Medical Director of its extensive prehospital care system.

In 1979, Dr. Flomenbaum accepted an offer from Lewis Goldfrank to join him at New York University Bellevue Hospital as Associate Director of Emergency Services and Consultant (later, Chief Consultant) to the New York City Poison Control Center, and their subsequent collaborations resulted in many of the outstanding features of this textbook. Frequently, ideas and concepts Neal and Lewis developed for presenting clinical toxicology were recognized for their value to the textbook and then developed further by both, with considerable input and efforts by Neal Lewin, Richard Weisman, Mary Ann Howland, Robert Hoffman, and Lewis Nelson. Thus, an idea for a 1984 review article entitled "Newer Antidotes and Controversies in Antidotal Therapy," written to familiarize clinicians with the appropriate use of antidotes in patient management, became "Antidotes in Depth," a signature feature of this book.

Similarly, the idea for an organ system track in the NYU postgraduate toxicology courses that Neal and Lewis codirected in the early 1980s became "The Pathophysiologic Basis of Medical Toxicology: The Organ System Approach" in the textbook. This section, in turn, suggested another section entitled "The Biochemical and Molecular Basis of Medical Toxicology."

Additional ideas followed for making *Goldfrank's Toxicologic Emergencies* more accessible both as a teaching and a reference resource. A monthly case-based consultants' meeting at the New York City Poison Control Center was modeled after the successful format originated in the first edition of this book, and many of the cases discussed there were adapted for the text and related review books. Placing essential reference tables on the inside front and back covers of the textbook proved to be another useful feature, and Neal is particularly proud of the unique way the textbook acknowledges previous authors at the end of chapters. In addition to his ideas and his organizational and editorial contributions, Neal has written, coauthored, or contributed to dozens of chapters since 1982, including those on salicylates, rodenticides, and managing the acutely poisoned or overdosed patient.

In 1996, Neal Flomenbaum became the first Emergency Physician-in-Chief at New York Presbyterian Hospital/Weill Cornell Medical Center and built a multidisciplinary emergency department of over 50 attending emergency physicians, residents, nurses, nurse practitioners, physician assistants, paramedics, and EMTs. He created, developed, and supported traditional and nontraditional subspecialties and fellowships in pediatric emergency medicine, medical toxicology, prehospital care, global emergency medicine, geriatric emergency medicine, wilderness and environmental emergency medicine, and EM/critical care, each of which was heavily infused with the knowledge and information of age-specific poisonings, overdoses, adverse effects and drug interactions, polypharmacy, and environmental hazards found in these pages. Many of the faculty, in turn, have contributed to chapters in this textbook and peer-reviewed research papers in medical toxicology. These activities culminated in the establishment of an academic department of emergency medicine at Weill Cornell in early 2016. That same year, Neal received the Lifetime Achievement award from his alma mater, the Albert Einstein College of Medicine and, in 2015, the annual "Neal Flomenbaum, MD Prize for Excellence in Emergency Medicine" was established at Weill Cornell commencements.

Neal Flomenbaum first became interested in medical toxicology because of the clinical challenges it presented to emergency physicians, internists, and pediatricians, and he has remained focused on these clinical aspects. His creative energies, talents, and contributions to the second through ninth editions of this book have helped transform a case-based introduction to clinical toxicology into the 2000-page textbook it is today, and these contributions will remain an important part of future editions.

The cover image is the *Papaver somniferum* and is the source of opium. The plant is native to Southwestern Asia, but now grown around the globe. Its products have been used medicinally and recreationally for thousands of years. The beautiful flowers lose their petals with a resultant green capsule, which when lanced exudes the highly viscous opium. Opium contains numerous alkaloids of which morphine, codeine, papaverine, and thebaine are the most medically consequential. Morphine is an opioid agonist analgesic, which when diacetylated produces heroin. Naloxone, a pure opioid antagonist and derivative of thebaine, reverses most of the clinical effects of opioid agonists. Opioids in almost all forms are used with remarkable success for acute pain and conversely, misused and abused with tragic implications for patients, families, and society. The safe and appropriate use of the products and derivatives of *Papaver somniferum* will define much of the work of toxicologists in the twenty-first century.

## DEDICATION

To the staffs of our hospitals, emergency departments, intensive care units, and outpatient sites, who have worked with remarkable courage, concern, compassion, and understanding in treating the patients discussed in this text and many thousands more like them.

To the Emergency Medical Services personnel who have worked so faithfully and courageously to protect our patients' health and who have assisted us in understanding what happens in the home and the field.

To the staff of the New York City Poison Control Center, who have quietly and conscientiously integrated their skills with ours to serve these patients and prevent many patients from ever requiring a hospital visit.

To all the faculty, fellows, residents, nurses, nurse practitioners, physician assistants, and medical and pharmacy students who have studied toxicology with us, whose inquisitiveness has helped us continually strive to understand complex and evolving problems and develop methods to teach them to others. (Editors)

To my wife Laura for her unwavering support; to my children Daniel, Adina, and Benjamin for their fresh perspective, youthful insight, and appreciation of my passion; to my parents Myrna of blessed memory and Dr. Irwin Nelson for the foundation they provided; and to my family, friends, and colleagues who keep me focused on what is important in life. (L.N.)

To my husband Bob; to my children Robert, Marcy and Doug and my grandchildren Joey and Mackenzie; to my mother and to the loving memory of my father; and to family, friends, colleagues, and students for all their help and continuing inspiration. (M.A.H.)

To my wife Gail Miller; my sons Jesse Miller Lewin, MD and Justin Miller Lewin, MD and my daughters-in-law Alana Amarosa Lewin, MD and Alice Tang, MD; my granddaughter Isabelle Rose Lewin; and in memory of my parents. To all my patients, students, residents, fellows, and colleagues who constantly stimulate my being a perpetual student. (N.L.)

To my wife Helen, for her resolute support and understanding; to my children Addison and Alston, for their boundless enthusiasm and inquisitiveness; and to my parents. (S.W.S.)

To my children Rebecca and Ryan, Jennifer, Andrew and Joan, Michelle and James; to my grandchildren Benjamin, Adam, Sarah, Kay, Samantha, Herbert, Jonah, Susie, and Sasha, who have kept me acutely aware of the ready availability of possible poisons; and to my wife, partner, and best friend Susan (deceased) whose support was essential to help me in the development of the first ten editions and whose contributions continue to inspire me and will be found throughout the text. (L.G.)

To my wife Ali; my children Casey and Jesse; my parents; and my friends, family, and colleagues for their never-ending patience and forgiveness for the time I have spent away from them; to the many close colleagues and committee members who have helped me understand the fundamentals of evidence-based medicine and challenged me to be clear, precise, and definitive when making treatment recommendations. (R.S.H.)

To the memory of Louis R. Cantilena, MD, PhD. Lou was a wonderful collaborator, thoughtful intellectual, clinical pharmacologist and medical toxicologist who was a critical author for the previous five editions of our textbook. His warmth, enthusiasm and intellect will be missed.

# ANTIDOTES IN DEPTH

Editors: Mary Ann Howland and Silas W. Smith

Readers of previous editions of *Goldfrank's Toxicologic Emergencies* are undoubtedly aware that the editors have always felt that an emphasis on general management of patients who are poisoned or overdosed coupled with sound medical management is as important as the selection and use of a specific antidote. Nevertheless, there are some instances when nothing other than the timely use of a specific antidote is an essential lifesaving

intervention. For this reason, and also because the use of such strategies are often problematic, controversial, or unfamiliar to the practitioner as new therapeutic approaches continue to emerge and old standards are reevaluated, we have included a section (or sections) at the end of appropriate chapters in which an in-depth discussion of such material is relevant.

## TABLE OF ANTIDOTES IN DEPTH

<b>N-ACETYLCYSTEINE</b> .....492 <i>Robert G. Hendrickson and Mary Ann Howland</i>	<b>EDETATE CALCIUM DISODIUM (CaNa<sub>2</sub>EDTA)</b> ..... 1315 <i>Mary Ann Howland</i>	<b>PENTETIC ACID OR PENTETATE (ZINC OR CALCIUM) TRISODIUM (DTPA)</b> ..... 1779 <i>Joseph G. Rella</i>
<b>ACTIVATED CHARCOAL</b> .....76 <i>Silas W. Smith and Mary Ann Howland</i>	<b>ETHANOL</b> ..... 1440 <i>Mary Ann Howland</i>	<b>PHYSOSTIGMINE SALICYLATE</b> .....755 <i>Mary Ann Howland</i>
<b>ANTIVENOM FOR NORTH AMERICAN VENOMOUS SNAKES (CROTALINE AND ELAPID)</b> ..... 1627 <i>Anthony F. Pizon and Anne-Michelle Ruha</i>	<b>FLUMAZENIL</b> ..... 1094 <i>Mary Ann Howland</i>	<b>POTASSIUM IODIDE</b> ..... 1775 <i>Joseph G. Rella</i>
<b>ANTIVENOM: SCORPION</b> ..... 1563 <i>Michael A. Darracq and Richard F. Clark</i>	<b>FOLATES: LEUCOVORIN (FOLINIC ACID) AND FOLIC ACID</b> .....775 <i>Silas W. Smith and Mary Ann Howland</i>	<b>PRALIDOXIME</b> ..... 1508 <i>Mary Ann Howland</i>
<b>ANTIVENOM: SPIDER</b> ..... 1559 <i>Michael A. Darracq and Richard F. Clark</i>	<b>FOMEPIZOLE</b> ..... 1435 <i>Mary Ann Howland</i>	<b>PROTAMINE</b> .....919 <i>Mary Ann Howland</i>
<b>ATROPINE</b> ..... 1503 <i>Mary Ann Howland</i>	<b>GLUCAGON</b> .....941 <i>Mary Ann Howland and Silas W. Smith</i>	<b>PROTHROMBIN COMPLEX CONCENTRATES AND DIRECT ORAL ANTICOAGULANT ANTIDOTES</b> .....908 <i>Betty C. Chen and Mark K. Su</i>
<b>BENZODIAZEPINES</b> ..... 1135 <i>Fiona Garlich Horner, Robert S. Hoffman, Lewis S. Nelson, and Mary Ann Howland</i>	<b>GLUCARPIDASE (CARBOXYPEPTIDASE G<sub>2</sub>)</b> .....782 <i>Silas W. Smith</i>	<b>PRUSSIAN BLUE</b> ..... 1357 <i>Robert S. Hoffman</i>
<b>BOTULINUM ANTITOXIN</b> .....586 <i>Silas W. Smith and Howard L. Geyer</i>	<b>HIGH-DOSE INSULIN (HDI)</b> .....953 <i>Samuel J. Stelpflug and William Kerns II</i>	<b>PYRIDOXINE</b> .....862 <i>Mary Ann Howland</i>
<b>CALCIUM</b> ..... 1403 <i>Silas W. Smith and Mary Ann Howland</i>	<b>HYDROXOCOBALAMIN</b> ..... 1694 <i>Mary Ann Howland</i>	<b>SODIUM BICARBONATE</b> .....567 <i>Paul M. Wax and Ashley Haynes</i>
<b>L-CARNITINE</b> .....732 <i>Mary Ann Howland</i>	<b>HYPERBARIC OXYGEN</b> ..... 1676 <i>Stephen R. Thom</i>	<b>SUCCIMER (2,3-DIMERCAPTOSUCCINIC ACID) AND DMPS (2,3-DIMERCAPTO-1-PROPANESULFONIC ACID)</b> ..... 1309 <i>Mary Ann Howland</i>
<b>DANTROLENE SODIUM</b> ..... 1029 <i>Caitlin J. Guo and Kenneth M. Sutin</i>	<b>LIPID EMULSION</b> ..... 1004 <i>Sophie Gosselin and Theodore C. Bania</i>	<b>THIAMINE HYDROCHLORIDE</b> ..... 1157 <i>Robert S. Hoffman</i>
<b>DEFEROXAMINE</b> .....676 <i>Mary Ann Howland</i>	<b>MAGNESIUM</b> .....876 <i>Silas W. Smith</i>	<b>URIDINE TRIACETATE</b> .....789 <i>Silas W. Smith</i>
<b>DEXTROSE (D-GLUCOSE)</b> .....707 <i>Vincent Nguyen and Larissa I. Velez</i>	<b>METHYLENE BLUE</b> ..... 1713 <i>Mary Ann Howland</i>	<b>VITAMIN K<sub>1</sub></b> .....915 <i>Mary Ann Howland</i>
<b>DIGOXIN-SPECIFIC ANTIBODY FRAGMENTS</b> .....977 <i>Silas W. Smith and Mary Ann Howland</i>	<b>NITRITES (AMYL AND SODIUM) AND SODIUM THIOSULFATE</b> ..... 1698 <i>Mary Ann Howland</i>	<b>WHOLE-BOWEL IRRIGATION AND OTHER INTESTINAL EVACUANTS</b> .....83 <i>Silas W. Smith and Mary Ann Howland</i>
<b>DIMERCAPROL (BRITISH ANTI-LEWISITE OR BAL)</b> ..... 1251 <i>Mary Ann Howland</i>	<b>OCTREOTIDE</b> .....713 <i>Silas W. Smith and Mary Ann Howland</i>	
	<b>OPIOID ANTAGONISTS</b> .....538 <i>Lewis S. Nelson and Mary Ann Howland</i>	

# CONTENTS

Contributors .....	xiv
Preface .....	xxv
Acknowledgments .....	xxvi

1. Historical Principles and Perspectives ..... 1  
*Paul M. Wax*
2. Toxicologic Misfortunes and Catastrophes in History ..... 16  
*Paul M. Wax*

## PART A THE GENERAL APPROACH TO THE PATIENT 27

### CASE STUDY 1 ..... 27

3. Initial Evaluation of the Patient: Vital Signs and Toxic Syndromes ..... 28  
*Lewis S. Nelson, Mary Ann Howland, Neal A. Lewin, Silas W. Smith, Lewis R. Goldfrank, and Robert S. Hoffman*

### CASE STUDY 2 ..... 32

4. Principles of Managing the Acutely Poisoned or Overdosed Patient ..... 33  
*Lewis S. Nelson, Mary Ann Howland, Neal A. Lewin, Silas W. Smith, Lewis R. Goldfrank, and Robert S. Hoffman*

### SC1. PRINCIPLES OF ANTIDOTE STOCKING ..... 42

*Silas W. Smith, Lewis R. Goldfrank, and Mary Ann Howland*

5. Techniques Used to Prevent Gastrointestinal Absorption ..... 48  
*Lotte C. G. Hoegberg*

### SC2. DECONTAMINATION PRINCIPLES: PREVENTION OF DERMAL, OPTHALMIC, AND INHALATIONAL ABSORPTION ..... 71

*Scott Lucyk*

### A1. ACTIVATED CHARCOAL ..... 76

*Silas W. Smith and Mary Ann Howland*

### A2. WHOLE-BOWEL IRRIGATION AND OTHER INTESTINAL EVACUANTS ..... 83

*Silas W. Smith and Mary Ann Howland*

6. Principles and Techniques Applied to Enhance Elimination ..... 90  
*David S. Goldfarb and Marc Ghannoum*

7. Laboratory Principles ..... 101  
*Ami M. Grunbaum and Petrie M. Rainey*

8. Principles of Diagnostic Imaging ..... 114  
*David T. Schwartz*

9. Pharmacokinetic and Toxicokinetic Principles ..... 140  
*Mary Ann Howland*

## PART B THE FUNDAMENTAL PRINCIPLES OF MEDICAL TOXICOLOGY 155

### SECTION I

#### BIOCHEMICAL AND MOLECULAR CONCEPTS

10. Chemical Principles ..... 155  
*Stephen J. Traub and Lewis S. Nelson*
11. Biochemical and Metabolic Principles ..... 167  
*James D. Cao and Kurt C. Kleinschmidt*
12. Fluid, Electrolyte, and Acid–Base Principles ..... 189  
*Alan N. Charney and Robert S. Hoffman*
13. Neurotransmitters and Neuromodulators ..... 203  
*Steven C. Curry, Ayrn D. O'Connor, Kimberlie A. Graeme, and A. Min Kang*

14. Withdrawal Principles ..... 236  
*Nicholas J. Connors and Richard J. Hamilton*

### SECTION II

#### PATHOPHYSIOLOGIC BASIS: ORGAN SYSTEMS

### CASE STUDY 3 ..... 242

15. Cardiologic Principles I: Electrophysiologic and Electrocardiographic Principles ..... 244  
*Cathleen Clancy*

16. Cardiologic Principles II: Hemodynamics ..... 260  
*Rachel S. Wightman and Robert A. Hessler*

### CASE STUDY 4 ..... 268

17. Dermatologic Principles ..... 269  
*Jesse M. Lewin, Neal A. Lewin, and Lewis S. Nelson*

### SC3. TRANSDERMAL TOXICOLOGY ..... 284

*Lewis S. Nelson*

18. Gastrointestinal Principles ..... 287  
*Matthew D. Zuckerman and Richard J. Church*

19. Genitourinary Principles ..... 297  
*Jason Chu*

20. Hematologic Principles ..... 310  
*Marco L. A. Sivilotti*

21. Hepatic Principles ..... 327  
*Kathleen A. Delaney and Jakub Furmaga*

# CONTRIBUTORS

**Judith C. Ahronheim, MD**

Clinical Professor of Medicine  
New York Medical College  
Valhalla, New York  
*Chapter 32, "Geriatric Principles"*

**Theodore C. Bania, MD, MS**

Assistant Professor of Emergency Medicine  
Director of Research and Toxicology  
Mt. Sinai West and Mt. Sinai St. Luke's Hospitals  
Department of Emergency Medicine  
Associate Dean for Human Subject Research  
Associate Director Program for the Protection  
of Human Subjects  
Icahn School of Medicine at Mount Sinai  
New York, New York  
*Antidotes in Depth: A23, "Lipid Emulsion"*

**Fermin Barrueto Jr., MD, MBA, FACEP**

Volunteer Associate Professor of Emergency  
Medicine  
University of Maryland School of Medicine  
Baltimore, Maryland  
Senior Vice President  
Chief Medical Officer  
University of Maryland Upper Chesapeake Health  
Bel Air, Maryland  
*Chapter 113, "Sodium Monoﬂuoroacetate and  
Fluoroacetamide"*

**James David Barry, MD**

Clinical Professor of Emergency Medicine  
University of California, Irvine School of Medicine  
Irvine, California  
Associate Director, Emergency Department  
Long Beach VA Medical Center  
Long Beach, California  
*Chapter 55, "Antimalarials"*

**Michael C. Beuhler, MD**

Professor of Emergency Medicine  
Carolinas HealthCare System  
Medical Director, Carolinas Poison Center  
Charlotte, North Carolina  
*Chapter 112, "Phosphorus"*

**Rana Biary, MD**

Assistant Professor of Emergency Medicine  
New York University School of Medicine  
Program Director, Medical Toxicology Fellowship  
Emergency Physician  
Ronald O. Perelman Department of Emergency  
Medicine  
Bellevue Hospital Center and NYU Langone  
Health  
New York, New York  
*Case Studies*

**Steven B. Bird, MD**

Professor of Emergency Medicine  
University of Massachusetts Medical School  
UMass Memorial Medical Center  
Worcester, Massachusetts  
*Chapter 90, "Chromium"*

**Eike Blohm, MD**

Assistant Professor of Surgery  
Division of Emergency Medicine  
Toxicology Consultant Northern New England  
Poison Center  
University of Vermont Larner College of Medicine  
University of Vermont Medical Center  
Burlington, Vermont  
*Chapter 116, "Marine Envenomations"*

**Keith J. Boesen, PharmD, FAZPA**

Instructor, University of Arizona College of  
Pharmacy  
Director, Arizona Poison and Drug Information  
Center  
Tucson, Arizona  
*Special Considerations: SC10, "Exotic Nonnative  
Snake Envenomations"*

**Kelly A. Green Boesen, PharmD**

Clinical Pharmacist  
Tucson, Arizona  
*Special Considerations: SC10, "Exotic Nonnative  
Snake Envenomations"*

**George M. Bosse, MD**

Professor of Emergency Medicine  
University of Louisville School of Medicine  
Medical Director, Kentucky Poison Center  
Louisville, Kentucky  
*Chapter 47, "Antidiabetics and Hypoglycemics/  
Antiglycemics"*

**Nicole C. Bouchard, MD, FACMT, FRCPC**

Assistant Clinical Professor of Emergency  
Medicine  
Donald and Barbara Zucker School of Medicine  
at Hofstra/Northwell  
Emergency Physician  
Lenox Health in Greenwich Village, Northwell  
Health  
New York, New York  
*Chapter 53, "Thyroid and Antithyroid Medications"*

**Jeffrey R. Brubacher, MD, MSc, FRCPC**

Associate Professor of Emergency Medicine  
University of British Columbia  
Emergency Physician  
Vancouver General Hospital  
Vancouver, British Columbia, Canada  
*Chapter 59, "β-Adrenergic Antagonists"*

**D. Eric Brush, MD, MHCM**

Clinical Associate Professor of Emergency  
Medicine  
University of Massachusetts Medical School  
Division of Toxicology  
Director of Clinical Operations  
UMass Memorial Medical Center  
Worcester, Massachusetts  
*Chapter 116, "Marine Envenomations"*

Assistant Professor of Pediatrics and Emergency  
Medicine  
Harvard Medical School  
Director, Medical Toxicology Fellowship  
Medical Director, Regional Center for Poison  
Control and Prevention  
Attending Physician, Pediatric Emergency  
Medicine  
Boston Children's Hospital  
Boston, Massachusetts  
*Chapter 98, "Silver"*

**Diane P. Calello, MD**

Associate Professor of Emergency Medicine  
Rutgers New Jersey Medical School  
Executive and Medical Director  
New Jersey Poison Information and Education  
System  
Newark, New Jersey  
*Chapter 93, "Lead"*  
*Chapter 97, "Selenium"*

**Louis R. Cantilena, MD, PhD (Deceased)**

Professor of Medicine and Pharmacology  
Director, Division of Clinical Pharmacology and  
Medical Toxicology  
Department of Medicine  
Uniformed Services University  
Bethesda, Maryland  
*Chapter 135, "Drug Development, Adverse Drug  
Events, and Postmarketing Surveillance"*

**James D. Cao, MD**

Assistant Professor of Emergency Medicine  
Division of Medical Toxicology  
University of Texas Southwestern Medical School  
Program Director, Medical Toxicology  
University of Texas Southwestern Medical Center  
Dallas, Texas  
*Chapter 11, "Biochemical and Metabolic  
Principles"*

**Jennifer L. Carey, MD**

Assistant Professor of Emergency Medicine  
Division of Medical Toxicology  
University of Massachusetts Medical School  
UMass Memorial Medical Center  
Worcester, Massachusetts  
*Chapter 79, "Hallucinogens"*

**Gar Ming Chan, MD, FACEM**

Emergency Medicine Specialist  
Calvary Health Care, Lenah Valley  
Tasmania, Australia  
*Chapter 91, "Cobalt"*

**Yiu-Cheung Chan, MD, MBBS, FRCS (Ed), FHKCEM, FHKAM**

Consultant, Accident and Emergency  
Department,  
United Christian Hospital  
Hong Kong Poison Information Centre  
Hong Kong SAR, China  
*Chapter 114, "Strychnine"*

**Nathan P. Charlton, MD**

Associate Professor of Emergency Medicine  
Program Director, Medical Toxicology  
University of Virginia School of Medicine  
Charlottesville, Virginia  
*Chapter 120, "Smoke Inhalation"*

**Alan N. Charney, MD**

Professor of Medicine  
New York University School of Medicine  
New York, New York  
*Chapter 12, "Fluid, Electrolyte, and Acid-Base Principles"*

**Betty C. Chen, MD**

Assistant Professor of Emergency Medicine  
University of Washington School of Medicine  
Harborview Medical Center  
Toxicology Consultant, Washington Poison  
Center  
Seattle, Washington  
*Chapter 58, "Antithrombotics"*  
*Antidotes in Depth: A17, "Prothrombin Complex Concentrates and Direct Oral Anticoagulant Antidotes"*

Professor of Emergency Medicine  
New York University School of Medicine  
Emergency Physician  
Ronald O. Perelman Department of Emergency  
Medicine  
Bellevue Hospital Center and NYU Langone  
Health  
New York, New York  
*Chapter 25, "Otolaryngologic Principles"*

**Jason Chu, MD**

Associate Professor of Emergency Medicine  
Icahn School of Medicine at Mount Sinai  
Emergency Physician and Medical Toxicologist  
Mt. Sinai West and Mt. Sinai St. Luke's Hospitals  
New York, New York  
*Chapter 19, "Genitourinary Principles"*  
*Chapter 52, "Antimigraine Medications"*

**Richard J. Church, MD, FACEP, FACMT**

Associate Professor of Emergency Medicine and  
Medical Toxicology  
Assistant Program Director, Emergency Medicine  
Residency  
University of Massachusetts Medical School  
UMass Memorial Medical Center  
Worcester, Massachusetts  
*Chapter 18, "Gastrointestinal Principles"*

**Cathleen Clancy, MD**

Associate Professor of Emergency Medicine  
The George Washington University Medical  
Center  
Emergency Physician  
Walter Reed National Military Medical Center  
Associate Medical Director  
Program Director, Medical Toxicology Fellowship  
National Capital Poison Center  
Washington, District of Columbia  
*Chapter 15, "Cardiologic Principles I:  
Electrophysiologic and Electrocardiographic  
Principles"*

**Richard F. Clark, MD**

Professor of Emergency Medicine  
Director, Division of Medical Toxicology  
University of California, San Diego  
San Diego, California  
*Antidotes in Depth: A37, "Antivenom: Spider"*  
*Antidotes in Depth: A38, "Antivenom: Scorpion"*

**Nicholas J. Connors, MD**

Associate Professor of Emergency Medicine  
Medical University of South Carolina  
Charleston, South Carolina  
Medical Toxicologist  
Palmetto Poison Center  
Columbia, South Carolina  
*Chapter 14, "Withdrawal Principles"*

**Steven C. Curry, MD**

Professor of Medicine and Emergency Medicine  
Division of Medical Toxicology and Precision  
Medicine  
Division of Clinical Data Analytics and Decision  
Support  
Center for Toxicology and Pharmacology  
Education and Research

Medicine  
University of California, San Francisco  
(UCSF)-Fresno  
Medical Education Program  
Department of Emergency Medicine  
Division of Medical Toxicology  
Fresno, California  
*Antidotes in Depth: A37, "Antivenom: Spider"*  
*Antidotes in Depth: A38, "Antivenom: Scorpion"*

**Andrew H. Dawson, MBBS, FRACP, FRCP, FCCP**

Clinical Professor of Medicine, University of  
Sydney  
Clinical Director, NSW Poisons Information  
Centre  
Director, Clinical Toxicology  
Royal Prince Alfred Hospital  
Sydney, Australia  
*Chapter 107, "Barium"*

**Kathleen A. Delaney, MD, FACP, FACMT**

Academic Chair of Emergency Medicine,  
Emeritus  
John Peter Smith Health Science Center  
Fort Worth, Texas  
*Chapter 21, "Hepatic Principles"*  
*Chapter 29, "Thermoregulatory Principles"*

**Francis Jerome DeRoos, MD**

Associate Professor of Emergency Medicine  
Perelman School of Medicine at the University of  
Pennsylvania  
Hospital of the University of Pennsylvania  
Philadelphia, Pennsylvania  
*Chapter 61, "Miscellaneous Antihypertensives and  
Pharmacologically Related Agents"*

**Suzanne Doyon, MD, MPH, ACEP, FACMT, FASAM**

Assistant Professor of Emergency Medicine  
Medical Director, Connecticut Poison Control  
Center  
University of Connecticut School of Medicine  
Farmington, Connecticut  
*Chapter 48, "Antiepileptics"*

**Michael Eddleston, BM, ScD**

Professor of Clinical Toxicology  
University of Edinburgh  
Consultant Clinical Toxicologist  
Royal Infirmary of Edinburgh and National  
Poisons Information Service, Edinburgh  
Edinburgh, United Kingdom  
*Chapter 110, "Insecticides: Organic Phosphorus  
Compounds and Carbamates"*

**Brenna M. Farmer, MD**

Assistant Professor of Clinical Medicine  
Weill Cornell Medical College of Cornell  
University  
Emergency Physician  
Assistant Program Director of Emergency  
Medicine  
New York–Presbyterian Hospital  
Director of Patient Safety  
Weill Cornell Emergency Department  
New York, New York  
*Chapter 80, “ $\gamma$ -Hydroxybutyric Acid  
( $\gamma$ -Hydroxybutyrate)”*  
*Chapter 84, “Aluminum”*  
*Chapter 134, “Medication Safety and Adverse Drug  
Events”*

**Brandy Ferguson, MD**

Assistant Professor of Emergency Medicine  
New York University School of Medicine  
Emergency Physician  
Ronald O. Perelman Department of Emergency  
Medicine  
Bellevue Hospital Center and NYU Langone  
Health  
New York, New York  
*Chapter 132, “Hazardous Materials Incident  
Response”*

**Denise Fernández, MD**

Assistant Professor of Emergency Medicine  
Albert Einstein College of Medicine  
Medical Toxicologist  
Emergency Physician  
Jacobi Medical Center/North Central Bronx  
Hospital  
Bronx, New York  
*Chapter 82, “Nicotine”*

**Laura J. Fil, DO, MS**

Adjunct Professor  
Department of Primary Care  
Touro College of Osteopathic Medicine  
Middletown, New York  
Emergency Physician  
Department of Emergency Medicine  
Vassar Brothers Medical Center  
Poughkeepsie, New York  
*Chapter 39, “Food Poisoning”*

**Jeffrey S. Fine, MD**

Associate Professor of Emergency Medicine and  
Pediatrics  
New York University School of Medicine  
Emergency Physician  
Ronald O. Perelman Department of Emergency  
Medicine  
Bellevue Hospital Center and NYU Langone  
Health  
New York, New York  
*Chapter 30, “Reproductive and Perinatal  
Principles”*  
*Chapter 31, “Pediatric Principles”*

**Mark A. Flomenbaum, MD, PhD**

Chief Medical Examiner, State of Maine  
Augusta, Maine  
*Chapter 140, “Postmortem Toxicology”*

**Lindsay M. Fox, MD**

Assistant Professor of Emergency Medicine  
Rutgers New Jersey Medical School  
University Hospital  
Toxicology Consultant, New Jersey Poison  
Information and Education System  
Newark, New Jersey  
*Chapter 43, “Plant- and Animal-Derived Dietary  
Supplements”*

**Jessica A. Fulton, DO**

Emergency Physician  
Grandview Hospital  
Sellersville, Pennsylvania  
*Chapter 103, “Caustics”*

**Jakub Furmaga, MD**

Assistant Professor of Emergency Medicine  
University of Texas Southwestern Medical School  
Division of Medical Toxicology  
University of Texas Southwestern Medical Center  
Dallas, Texas  
*Chapter 21, “Hepatic Principles”*

**Howard L. Geyer, MD, PhD**

Assistant Professor of Neurology  
Director, Division of Movement Disorders  
Montefiore Medical Center  
Albert Einstein College of Medicine  
Bronx, New York  
*Chapter 38, “Botulism”*  
*Antidotes in Depth: A6, “Botulinum Antitoxin”*

**Marc Ghannoum, MD, MSc**

Associate Professor of Medicine  
University of Montreal  
Nephrology and Internal Medicine  
Verdun Hospital  
Montreal, Québec, Canada  
*Chapter 6, “Principles and Techniques Applied to  
Enhance Elimination”*  
*Chapter 27, “Renal Principles”*

**Beth Y. Ginsburg, MD**

Assistant Professor of Emergency Medicine  
Icahn School of Medicine at Mount Sinai  
New York, New York  
Emergency Physician  
Elmhurst Hospital Center  
Elmhurst, New York  
*Chapter 44, “Vitamins”*

**Jeffrey A. Gold, MD**

Professor of Medicine  
Chief, Division of Pulmonary and Critical Care  
(Interim)  
Associate Director, Adult Cystic Fibrosis Center  
Oregon Health and Science University  
Portland, Oregon  
*Chapter 77, “Alcohol Withdrawal”*

**David S. Goldfarb, MD, FASN**

Professor of Medicine and Physiology  
New York University School of Medicine  
Clinical Chief, Nephrology Division  
NYU Langone Health  
Chief, Nephrology Section  
New York Harbor VA Healthcare System  
Consultant, New York City Poison Control Center  
New York, New York  
*Chapter 6, “Principles and Techniques Applied to  
Enhance Elimination”*  
*Chapter 27, “Renal Principles”*

**Lewis R. Goldfrank, MD, FAAEM, FAACT,  
FACEP, FACMT, FACP**

Herbert W. Adams Professor of Emergency  
Medicine  
New York University School of Medicine  
Emergency Physician  
Ronald O. Perelman Department of Emergency  
Medicine  
Bellevue Hospital Center and NYU Langone  
Health  
Medical Director, New York City Poison Control  
Center  
New York, New York  
*Chapter 3, “Initial Evaluation of the Patient: Vital  
Signs and Toxic Syndromes”*  
*Chapter 4, “Principles of Managing the Acutely  
Poisoned or Overdosed Patient”*  
*Chapter 117, “Mushrooms”*  
*Chapter 118, “Plants”*  
*Special Considerations: SC1, “Principles of  
Antidote Stocking”*

**Sophie Gosselin, MD, CSPQ, FRCPC, FAACT,  
FACMT**

Associate Professor, Department of Medicine  
McGill University  
Emergency Physician  
McGill University Health Center & Hôpital  
Charles-Lemoyne  
Montréal, Québec, Canada  
Medical Toxicologist  
Centre Antipoison du Québec  
Québec City, Québec, Canada  
*Chapter 49, “Antihistamines and Decongestants”*  
*Antidotes in Depth: A23, “Lipid Emulsion”*

**Kimberlie A. Graeme, MD**

Clinical Associate Professor of Emergency  
Medicine  
University of Arizona College of  
Medicine—Phoenix  
Department of Medical Toxicology  
Banner—University Medical Center Phoenix  
Phoenix, Arizona  
*Chapter 13, “Neurotransmitters and  
Neuromodulators”*

**Howard A. Greller, MD, FACEP, FACMT**

Department of Clinical Medicine,  
 Affiliated Medical Professor  
 City University of New York School of Medicine  
 Director of Research and Medical Toxicology  
 SBH Health System Department of Emergency  
 Medicine  
 St. Barnabas Hospital  
 Bronx, New York  
*Chapter 70, "Lithium"*

**Ami M. Grunbaum, MD, FRCPC**

Adjunct Professor of Medicine  
 Medical Biochemist, MUHC and CISSS-Laval  
 McGill University  
 Montreal, Québec, Canada  
*Chapter 7, "Laboratory Principles"*

**Hallam Melville Gugelmann, MD, MPH**

Assistant Clinical Professor  
 Division of Clinical Pharmacology and Medical  
 Toxicology, Department of Medicine,  
 University of California, San Francisco  
 Emergency Physician, CPMC St. Luke's Hospital  
 Emergency Department  
 Assistant Medical Director, California Poison  
 Control System-San Francisco Division  
 San Francisco, California  
*Chapter 61, "Miscellaneous Antihypertensives and  
 Pharmacologically Related Agents"*

**David D. Gummin, MD, FAACP, FACEP, FACMT**

Professor of Emergency Medicine, Pediatrics,  
 Pharmacology and Toxicology  
 Section Chief, Medical Toxicology  
 Medical College of Wisconsin  
 Medical Director, Wisconsin Poison Center  
 Milwaukee, Wisconsin  
*Chapter 105, "Hydrocarbons"*

**Caitlin J. Guo, MD, MBA**

Assistant Professor of Anesthesiology,  
 Perioperative Care and Pain Medicine  
 New York University School of Medicine  
 Attending Physician  
 Bellevue Hospital Center and NYU Langone  
 Health  
 New York, New York  
*Chapter 65, "Inhalational Anesthetics"*  
*Chapter 66, "Neuromuscular Blockers"*  
*Antidotes in Depth: A24, "Dantrolene Sodium"*

**Amit K. Gupta, MD**

Assistant Professor of Emergency Medicine  
 Seton Hall Medical School  
 Assistant Residency Director, Department of  
 Emergency Medicine  
 Hackensack University Medical Center  
 Hackensack, New Jersey  
*Chapter 78, "Disulfiram and Disulfiramlike  
 Reactions"*

**Jason B. Hack, MD**

Professor of Emergency Medicine  
 Program Director, Division of Medical Toxicology  
 The Warren Alpert Medical School of Brown  
 University  
 Rhode Island Hospital  
 Providence, Rhode Island  
*Chapter 62, "Cardioactive Steroids"*

**In-Hei Hahn, MD, FACEP, FACMT**

Expedition Medical Officer  
 Research Associate  
 Division of Paleontology  
 American Museum of Natural History  
 New York, New York  
*Chapter 115, "Arthropods"*

**Richard J. Hamilton, MD, FAAEM, FACEP, FACMT**

Professor and Chair of Emergency Medicine  
 Drexel University College of Medicine  
 Philadelphia, Pennsylvania  
*Chapter 14, "Withdrawal Principles"*

**Stephen A. Harding, MD**

Assistant Professor of Emergency Medicine  
 Henry J. N. Taub Department of Emergency  
 Medicine  
 Baylor College of Medicine  
 Houston, Texas  
*Chapter 84, "Aluminum"*

**Rachel Haroz, MD**

Assistant Professor of Emergency Medicine  
 Cooper University Health Care  
 Camden, New Jersey  
*Chapter 80, "γ-Hydroxybutyric Acid  
 (γ-Hydroxybutyrate)"*

**Ashley Haynes, MD, FACEP**

Assistant Professor of Emergency Medicine  
 Division of Toxicology  
 University of Texas Southwestern Medical School  
 Attending Physician  
 Parkland Hospital  
 Clements University Hospital  
 Children's Medical Center  
 Dallas, Texas  
*Chapter 101, "Antiseptics, Disinfectants, and  
 Sterilants"*  
*Antidotes in Depth: A5, "Sodium Bicarbonate"*

**Robert G. Hendrickson, MD, FACMT, FAACP**

Professor of Emergency Medicine  
 Program Director, Fellowship in Medical  
 Toxicology  
 Associate Medical Director, Oregon Poison  
 Center  
 Oregon Health and Science University  
 Portland, Oregon  
*Chapter 33, "Acetaminophen"*  
*Antidotes in Depth: A3, "N-Acetylcysteine"*

**Fred M. Henretig, MD, FAAP, FACMT**

Professor Emeritus of Pediatrics  
 Perelman School of Medicine, University of  
 Pennsylvania  
 Senior Toxicologist, The Poison Control Center at  
 the Children's Hospital of Philadelphia  
 Philadelphia, Pennsylvania  
*Chapter 93, "Lead"*

**Christina H. Herson, MD**

Lecturer in Emergency Medicine  
 Harvard Medical School  
 Department of Emergency Medicine  
 Division of Medical Toxicology  
 Cambridge Health Alliance  
 Cambridge, Massachusetts  
*Chapter 56, "Antituberculous Medications"*

**Robert A. Hessler, MD, PhD**

Associate Professor of Emergency Medicine  
 New York University School of Medicine  
 Emergency Physician  
 Ronald O. Perelman Department of Emergency  
 Medicine  
 Bellevue Hospital Center, NYU Langone Health  
 and VA NY Harbor Healthcare System  
 New York, New York  
*Chapter 16, "Cardiologic Principles II:  
 Hemodynamics"*

**Elizabeth Quaal Hines, MD**

Clinical Assistant Professor of Pediatrics  
 Division of Pediatric Emergency Medicine  
 University of Maryland School of Medicine  
 Toxicology Consultant, Maryland Poison Center  
 Baltimore, Maryland  
*Chapter 31, "Pediatric Principles"*  
*Chapter 94, "Manganese"*

**Lotte C. G. Hoegberg, MS (Pharm), PhD, FEAPCCT**

Pharmacist, Medical Toxicologist  
 The Danish Poisons Information Centre  
 Department of Anesthesia and Intensive Care  
 Copenhagen University Hospital Bispebjerg  
 Copenhagen, Denmark  
*Chapter 5, "Techniques Used to Prevent  
 Gastrointestinal Absorption"*

**Robert J. Hoffman, MD, MS, FACMT, FACEP**

Medical Director, Qatar Poison Center  
 Sidra Medicine  
 Doha, Qatar  
*Chapter 63, "Methylxanthines and Selective  
 β<sub>2</sub>-Adrenergic Agonists"*

**Robert S. Hoffman, MD, FAACT, FACMT,  
FRCP Edin, FEAPCCT**

Professor of Emergency Medicine and Medicine  
New York University School of Medicine  
Director, Division of Medical Toxicology  
Ronald O. Perelman Department of Emergency  
Medicine  
Emergency Physician  
Bellevue Hospital Center and NYU Langone  
Health  
New York, New York

*Chapter 3, "Initial Evaluation of the Patient: Vital  
Signs and Toxic Syndromes"*

*Chapter 4, "Principles of Managing the Acutely  
Poisoned or Overdosed Patient"*

*Chapter 12, "Fluid, Electrolyte, and Acid-Base  
Principles"*

*Chapter 28, "Respiratory Principles"*

*Chapter 75, "Cocaine"*

*Chapter 88, "Cadmium"*

*Chapter 99, "Thallium"*

*Chapter 130, "Poison Control Centers and Poison  
Epidemiology"*

*Antidotes in Depth: A26, "Benzodiazepines"*

*Antidotes in Depth: A27, "Thiamine Hydrochloride"*

*Antidotes in Depth: A31, "Prussian Blue"*

**Michael G. Holland, MD, FEAPCCT, FAACT,  
FACMT, FACOEM, FACEP**

Clinical Professor of Emergency Medicine  
SUNY Upstate Medical University  
Syracuse, New York

Medical Toxicologist, Upstate New York Poison  
Center  
Syracuse, New York

Director of Occupational Medicine, Glens Falls  
Hospital Center for Occupational Health  
Glens Falls, New York

Senior Medical Toxicologist, Center for  
Toxicology and Environmental Health  
North Little Rock, Arkansas

*Chapter 111, "Insecticides: Organic Chlorines,  
Pyrethrins/Pyrethroids and Insect Repellents"*

**Christopher P. Holstege, MD**

Professor of Emergency Medicine and Pediatrics  
Chief, Division of Medical Toxicology  
University of Virginia School of Medicine  
Medical Director, Blue Ridge Poison Center  
University of Virginia Health System  
Charlottesville, Virginia

*Chapter 123, "Cyanide and Hydrogen Sulfide"*

**William J. Holubek, MD, MPH, CPE,  
FACEP, FACMT**

Vice President of Medical Affairs  
WellStar Atlanta Medical Center  
Atlanta, Georgia

*Chapter 35, "Nonsteroidal Antiinflammatory  
Drugs"*

**Fiona Garlich Horner, MD**

Clinical Assistant Professor of Emergency  
Medicine  
Keck School of Medicine of the University of  
Southern California  
Los Angeles, California

*Antidotes in Depth: A26, "Benzodiazepines"*

**Mary Ann Howland, PharmD, DABAT, FAACT**

Clinical Professor of Pharmacy  
St. John's University College of Pharmacy and  
Health Sciences

Adjunct Professor of Emergency Medicine  
New York University School of Medicine

Ronald O. Perelman Department of Emergency  
Medicine

Bellevue Hospital Center and NYU Langone  
Health

Senior Consultant in Residence

New York City Poison Control Center  
New York, New York

*Chapter 3, "Initial Evaluation of the Patient: Vital  
Signs and Toxic Syndromes"*

*Chapter 4, "Principles of Managing the Acutely  
Poisoned or Overdosed Patient"*

*Chapter 9, "Pharmacokinetic and Toxicokinetic  
Principles"*

*Chapter 32, "Geriatric Principles"*

*Antidotes in Depth: A1, "Activated Charcoal"*

*Antidotes in Depth: A2, "Whole-Bowel Irrigation  
and Other Intestinal Evacuants"*

*Antidotes in Depth: A3, "N-Acetylcysteine"*

*Antidotes in Depth: A4, "Opioid Antagonists"*

*Antidotes in Depth: A7, "Deferoxamine"*

*Antidotes in Depth: A9, "Octreotide"*

*Antidotes in Depth: A10, "L-Carnitine"*

*Antidotes in Depth: A11, "Physostigmine Salicylate"*

*Antidotes in Depth: A12, "Folates: Leucovorin  
(Folinic Acid) and Folic Acid"*

*Antidotes in Depth: A15, "Pyridoxine"*

*Antidotes in Depth: A18, "Vitamin K<sub>1</sub>"*

*Antidotes in Depth: A19, "Protamine"*

*Antidotes in Depth: A20, "Glucagon"*

*Antidotes in Depth: A22, "Digoxin-Specific  
Antibody Fragments"*

*Antidotes in Depth: A25, "Flumazenil"*

*Antidotes in Depth: A26, "Benzodiazepines"*

*Antidotes in Depth: A28, "Dimercaprol (British  
Anti-Lewisite or BAL)"*

*Antidotes in Depth: A29, "Succimer  
(2,3-dimercaptosuccinic acid) and DMPS  
(2,3-dimercapto-1-propanesulfonic acid)"*

*Antidotes in Depth: A30, "Edetate Calcium  
Disodium (CaNa<sub>2</sub>EDTA)"*

*Antidotes in Depth: A32, "Calcium"*

*Antidotes in Depth: A33, "Fomepizole"*

*Antidotes in Depth: A34, "Ethanol"*

*Antidotes in Depth: A35, "Atropine"*

*Antidotes in Depth: A36, "Pralidoxime"*

*Antidotes in Depth: A41, "Hydroxocobalamin"*

*Antidotes in Depth: A42, "Nitrites (Amyl and  
Sodium) and Sodium Thiosulfate"*

*Antidotes in Depth: A43, "Methylene Blue"*  
*Special Considerations: SC1, "Principles of  
Antidote Stocking"*

**Nicholas B. Hurst, MD, MS, FAAEM**

Assistant Professor of Emergency Medicine  
Medical Toxicology Consultant

Arizona Poison and Drug Information Center  
University of Arizona College of Medicine-Tucson  
Tucson, Arizona

*Special Considerations: SC10, "Exotic Nonnative  
Snake Envenomations"*

**David H. Jang, MD, MSc, FACMT**

Assistant Professor of Emergency Medicine  
Divisions of Medical Toxicology and Critical Care  
Medicine (ResCCU)

Perelman School of Medicine, University of  
Pennsylvania

Philadelphia, Pennsylvania

*Chapter 60, "Calcium Channel Blockers"*

*Chapter 73, "Amphetamines"*

**David N. Juurlink, MD, PhD, FRCPC,  
FAACT, FACMT**

Professor of Medicine, Pediatrics and Health  
Policy, Management and Evaluation

Director, Division of Clinical Pharmacology and  
Toxicology

University of Toronto

Senior Scientist, Institute for Clinical Evaluative  
Sciences

Medical Toxicologist, Ontario Poison Centre  
Toronto, Ontario, Canada

*Chapter 67, "Antipsychotics"*

**A. Min Kang, MD, MPhil, FAAP, FASAM**

Assistant Professor of Child Health and Medicine  
University of Arizona College of  
Medicine—Phoenix

Section Chief, Toxicology, Phoenix Children's  
Hospital

Medical Toxicologist, Banner—University

Medical Center Phoenix

Associate Medical Director, Banner Poison and  
Drug Information Center

Phoenix, Arizona

*Chapter 13, "Neurotransmitters and  
Neuromodulators"*

**Bradley J. Kaufman, MD, MPH, FACEP, FAEMS**

Associate Professor of Emergency Medicine  
Donald and Barbara Zucker School of Medicine  
at Hofstra/Northwell

Hempstead, New York

Emergency Physician

Long Island Jewish Medical Center

New Hyde Park, New York

First Deputy Medical Director

Fire Department of the City of New York

New York, New York

*Chapter 132, "Hazardous Materials Incident  
Response"*

**Brian S. Kaufman, MD**

Professor of Medicine, Anesthesiology, Neurology  
and Neurosurgery

New York University School of Medicine

NYU Langone Health

New York, New York

*Chapter 65, "Inhalational Anesthetics"*

**William Kerns II, MD, FACEP, FACMT**

Professor of Emergency Medicine and Medical Toxicology  
 Division of Medical Toxicology  
 Department of Emergency Medicine  
 Carolinas Medical Center  
 Charlotte, North Carolina  
*Antidotes in Depth: A21, "High-Dose Insulin (HDI)"*

**Hong K. Kim, MD, MPH**

Assistant Professor of Emergency Medicine  
 University of Maryland School of Medicine  
 Baltimore, Maryland  
*Chapter 102, "Camphor and Moth Repellents"*

**Mark A. Kirk, MD**

Associate Professor of Emergency Medicine  
 University of Virginia  
 Charlottesville, Virginia  
 Director, Chemical Defense  
 Countering Weapons of Mass Destruction  
 Department of Homeland Security  
 Washington, District of Columbia  
*Chapter 120, "Smoke Inhalation"*  
*Chapter 123, "Cyanide and Hydrogen Sulfide"*

**Barbara M. Kirrane, MD, MPH**

Medical Toxicology Consultant, Department of  
 Emergency Medicine  
 Physician Advisor, Department of Case  
 Management  
 Saint Barnabas Medical Center  
 Livingston, New Jersey  
*Chapter 138, "Risk Management and Legal  
 Principles"*

**Kurt C. Kleinschmidt, MD, FACMT, DABAM**

Professor of Emergency Medicine  
 Division Chief, Medical Toxicology  
 University of Texas Southwestern Medical School  
 Medical Director, Perinatal Intervention Program  
 Parkland Health and Hospital System  
 Dallas, Texas  
*Chapter 11, "Biochemical and Metabolic  
 Principles"*

**Cathy A. Kondas, MD, MBS**

Assistant Professor of Psychiatry  
 New York University School of Medicine  
 Attending Psychiatrist  
 Director, Women's Mental Health Fellowship  
 Associate Director, Consultation-Liaison  
 Psychiatry  
 Bellevue Hospital Center  
 New York, New York  
*Chapter 26, "Psychiatric Principles"*  
*Special Considerations: SC4, "Patient Violence"*

**Andrea Martinez Kondracke, MD**

Assistant Professor of Psychiatry and Internal  
 Medicine  
 New York University School of Medicine  
 Division Chief, Department of Medical Psychiatry  
 and Consultation Liaison Psychiatry  
 Bellevue Hospital Center  
 New York, New York  
*Chapter 26, "Psychiatric Principles"*  
*Special Considerations: SC4, "Patient Violence"*

**Jeffrey T. Lai, MD**

Assistant Professor of Emergency Medicine  
 Department of Emergency Medicine  
 University of Massachusetts Medical School  
 UMass Memorial Medical Center  
 Worcester, Massachusetts  
*Chapter 56, "Antituberculous Medications"*

**Melisa W. Lai-Becker, MD, FACEP, FAAEM**

Instructor in Emergency Medicine  
 Harvard Medical School  
 Chief, CHA Everett Hospital Emergency  
 Department  
 Director, CHA Division of Medical Toxicology  
 Cambridge Health Alliance  
 Boston, Massachusetts  
*Chapter 98, "Silver"*

**Jeff M. Lapoint, DO**

Director, Division of Medical Toxicology  
 Department of Emergency Medicine  
 Southern California Permanente Group  
 San Diego, California  
*Chapter 74, "Cannabinoids"*

**David C. Lee, MD**

Professor of Emergency Medicine  
 Donald and Barbara Zucker School of Medicine  
 at Hofstra/Northwell  
 Hempstead, New York  
 Chair, Department of Emergency Medicine  
 WellSpan York Hospital  
 York, Pennsylvania  
*Chapter 72, "Sedative-Hypnotics"*

**Joshua D. Lee, MD**

Associate Professor of Population Health  
 New York University School of Medicine  
 New York, New York  
*Special Considerations: SC6, "Prevention,  
 Treatment, and Harm Reduction Approaches to  
 Opioid Overdoses"*

**Jesse M. Lewin, MD, FAAD**

Mohs Micrographic and Dermatologic Surgery  
 Director of Dermatologic Surgery Education  
 Assistant Professor of Dermatology  
 Department of Dermatology  
 Columbia University Irving Medical Center  
 New York, New York  
*Chapter 17, "Dermatologic Principles"*

**Justin M. Lewin, MD**

Assistant Professor of Psychiatry  
 New York University School of Medicine  
 Comprehensive Psychiatric Emergency Program  
 Consultation-Liaison Psychiatry  
 Bellevue Hospital Center  
 New York, New York  
*Chapter 26, "Psychiatric Principles"*  
*Special Considerations: SC4, "Patient Violence"*

**Neal A. Lewin, MD, FACEP, FACMT, FACP**

Druckenmiller Professor of Emergency Medicine  
 and Professor of Medicine  
 New York University School of Medicine  
 Ronald O. Perelman Department of Emergency  
 Medicine  
 Director, Didactic Education  
 Emergency Medicine Residency  
 Attending Physician, Emergency Medicine and  
 Internal Medicine  
 Bellevue Hospital Center and NYU Langone  
 Health  
 New York, New York  
*Chapter 3, "Initial Evaluation of the Patient: Vital  
 Signs and Toxic Syndromes"*  
*Chapter 4, "Principles of Managing the Acutely  
 Poisoned or Overdosed Patient"*  
*Chapter 17, "Dermatologic Principles"*

**Erica L. Liebelt, MD, FACMT**

Clinical Professor of Pediatrics and Emergency  
 Medicine  
 University of Washington School of Medicine  
 Medical/Executive Director  
 Washington Poison Center  
 Seattle, Washington  
*Chapter 68, "Cyclic Antidepressants"*

**Zhanna Livshits, MD**

Assistant Professor of Medicine  
 Weill Cornell Medical College of Cornell  
 University  
 Emergency Physician and Medical Toxicologist  
 New York Presbyterian Weill Cornell Medical  
 Center  
 New York, New York  
*Chapter 89, "Cesium"*

**Heather Long, MD**

Associate Professor of Emergency Medicine  
 Director, Medical Toxicology  
 Albany Medical Center  
 Albany, New York  
*Chapter 81, "Inhalants"*

**Scott Lucyk, MD, FRCPC**

Clinical Assistant Professor of Emergency  
 Medicine  
 Medical Toxicologist  
 Associate Medical Director, Poison and Drug  
 Information Service (PADIS)  
 Program Director, Clinical Pharmacology and  
 Toxicology  
 Alberta Health Services  
 Calgary, Alberta, Canada  
*Special Considerations: SC2, "Decontamination  
 Principles: Prevention of Dermal, Ophthalmic  
 and Inhalational Absorption"*

**Daniel M. Lugassy, MD**

Assistant Professor of Emergency Medicine  
 Medical Director, New York Simulation Center for  
 the Health Sciences (NYSIM)  
 New York University School of Medicine  
 Division of Medical Toxicology  
 Ronald O. Perelman Department of Emergency  
 Medicine  
 Emergency Physician, Bellevue Hospital Center  
 and NYU Langone Health  
 Toxicology Consultant  
 New York City Poison Control Center  
 New York, New York  
*Chapter 37, "Salicylates"*

**Nima Majlesi, DO**

Assistant Professor of Emergency Medicine  
 Donald and Barbara Zucker School of Medicine  
 at Hofstra/Northwell  
 Director of Medical Toxicology  
 Staten Island University Hospital  
 Staten Island, New York  
*Chapter 100, "Zinc"*

**Alex F. Manini, MD, MS, FACMT, FAACT**

Professor of Emergency Medicine  
 Division of Medical Toxicology  
 Icahn School of Medicine at Mount Sinai  
 Elmhurst Hospital Center  
 New York, New York  
*Chapter 71, "Monoamine Oxidase Inhibitors"*  
*Chapter 137, "Principles of Epidemiology and  
 Research Design"*

**Jeanna M. Marraffa, PharmD, DABAT, FAACT**

Associate Professor of Emergency Medicine  
 Clinical Toxicologist  
 Assistant Clinical Director, Upstate New York  
 Poison Center  
 Upstate Medical University  
 Syracuse, New York  
*Chapter 40, "Dieting Xenobiotics and Regimens"*

**Maryann Mazer-Amirshahi, PharmD,  
MD, MPH**

Associate Professor of Emergency Medicine  
 Georgetown University School of Medicine  
 Emergency Physician,  
 Department of Emergency Medicine  
 MedStar Washington Hospital Center  
 Washington, District of Columbia  
*Chapter 57, "Antidysrhythmics"*

**Charles A. McKay, MD, FACMT, FACEP**

Associate Clinical Professor of Emergency  
 Medicine  
 University of Connecticut School of Medicine  
 Consulting Toxicologist  
 Division of Medical Toxicology  
 Hartford Hospital and University of Connecticut  
 Health Center  
 Associate Medical Director  
 Connecticut Poison Control Center  
 Farmington, Connecticut  
*Chapter 133, "Risk Assessment and Risk  
 Communication"*

**Nathanael J. McKeown, DO, FACMT**

Assistant Professor of Emergency Medicine  
 Oregon Health & Science University  
 Medical Toxicologist  
 Oregon Poison Center  
 Chief, Emergency Medicine Service  
 VA Portland Health Care System  
 Portland, Oregon  
*Chapter 33, "Acetaminophen"*

**Maria Mercurio-Zappala, RPh, MS**

Assistant Professor of Emergency Medicine  
 New York University School of Medicine  
 Ronald O. Perelman Department of Emergency  
 Medicine  
 Associate Director  
 New York City Poison Control Center  
 New York, New York  
*Chapter 99, "Thallium"*

**Robert A. Middleberg, PhD, F-ABFT,  
DABCC(TC)**

Adjunct Assistant Professor of Pharmacology and  
 Experimental Therapeutics  
 Thomas Jefferson University  
 Philadelphia, Pennsylvania  
 Laboratory Director  
 NMS Labs  
 Willow Grove, Pennsylvania  
*Chapter 139, "Medicolegal Interpretive Toxicology"*

**Stephen W. Munday, MD, MPH, MS**

Chair, Department of Occupational Medicine and  
 Chief Medical Toxicologist  
 Sharp Rees-Stealy Medical Group  
 San Diego, California  
*Chapter 86, "Arsenic"*

**Mark J. Neavyn, MD**

Assistant Professor of Emergency Medicine  
 Program Director, Fellowship in Medical  
 Toxicology  
 University of Massachusetts Medical School  
 UMass Memorial Medical Center  
 Worcester, Massachusetts  
*Chapter 79, "Hallucinogens"*

**Lewis S. Nelson, MD, FAACT, FACEP, FACMT,  
FAAEM, FASAM**

Professor and Chair of Emergency Medicine  
 Director, Division of Medical Toxicology  
 Rutgers New Jersey Medical School  
 Chief of Service, Emergency Department  
 University Hospital of Newark  
 New Jersey Poison Information and Education  
 System  
 Newark, New Jersey  
*Chapter 3, "Initial Evaluation of the Patient: Vital  
 Signs and Toxic Syndromes"*  
*Chapter 4, "Principles of Managing the Acutely  
 Poisoned or Overdosed Patient"*  
*Chapter 10, "Chemical Principles"*  
*Chapter 17, "Dermatologic Principles"*  
*Chapter 36, "Opioids"*  
*Chapter 57, "Antidysrhythmics"*  
*Chapter 77, "Alcohol Withdrawal"*  
*Chapter 92, "Copper"*  
*Chapter 118, "Plants"*  
*Chapter 121, "Simple Asphyxiants and Pulmonary  
 Irritants"*  
*Antidotes in Depth: A4, "Opioid Antagonists"*  
*Antidotes in Depth: A26, "Benzodiazepines"*  
*Special Considerations: SC3, "Transdermal  
 Toxicology"*

**Vincent Nguyen, MD**

Assistant Professor of Emergency Medicine  
 Medical Toxicologist  
 Albert Einstein College of Medicine  
 Jacobi Medical Center/North Central Bronx  
 Medical Center  
 The Bronx, New York  
*Antidotes in Depth: A8, "Dextrose (D-Glucose)"*

**Sean Patrick Nordt, MD, PharmD, DABAT,  
FAACT, FAAEM, FACMT**

Associate Dean, Academic Affairs  
 Gavin Herbert Endowed Professor of Pharmacy  
 Chief Medical Officer  
 Chapman University School of Pharmacy  
 Crean College of Health and Behavioral Sciences  
 Chapman University  
 Adjunct Associate Professor of Emergency  
 Medicine  
 Department of Emergency Medicine  
 University of California, Irvine  
 Irvine, California  
*Chapter 46, "Pharmaceutical Additives"*

**Ayrn D. O'Connor, MD**

Associate Professor of Emergency Medicine  
 Program Director, Medical Toxicology Fellowship  
 University of Arizona College of Medicine  
 Phoenix  
 Department of Medical Toxicology  
 Banner—University Medical Center Phoenix  
 Phoenix, Arizona  
*Chapter 13, "Neurotransmitters and  
 Neuromodulators"*

**Ruben E. Olmedo, MD**

Associate Clinical Professor of Emergency  
Medicine  
Icahn School of Medicine at Mount Sinai  
Director, Division of Toxicology  
Mount Sinai Hospital  
New York, New York  
*Chapter 83, "Phencyclidine and Ketamine"*

**Dean Olsen, DO**

Assistant Professor of Emergency Medicine and  
Toxicology  
NYIT College of Osteopathic Medicine  
Old Westbury, New York  
Director, Residency in Emergency Medicine  
Nassau University Medical Center  
East Meadow, New York  
*Chapter 36, "Opioids"*

**Robert B. Palmer, PhD, DABAT, FAACT**

Assistant Clinical Professor of Emergency  
Medicine (Medical Toxicology)  
University of Colorado School of Medicine  
Attending Toxicologist  
Medical Toxicology Fellowship Program  
Rocky Mountain Poison and Drug Center  
Denver, Colorado  
*Special Considerations: SC11, "Assessment of  
Ethanol-Induced Impairment"*

**Jeanmarie Perrone, MD, FACMT**

Professor of Emergency Medicine  
Director of Medical Toxicology  
Perelman School of Medicine, University of  
Pennsylvania  
Philadelphia, Pennsylvania  
*Chapter 45, "Iron"*

**Anthony F. Pizon, MD**

Associate Professor of Emergency Medicine  
University of Pittsburgh School of Medicine  
Chief, Division of Medical Toxicology  
University of Pittsburgh Medical Center  
Pittsburgh, Pennsylvania  
*Chapter 119, "Native (US) Venomous Snakes and  
Lizards"*  
*Antidotes in Depth: A39, "Antivenom for North  
American Venomous Snakes (Crotaline and  
Elapid)"*

**Dennis P. Price, MD**

Assistant Professor of Emergency Medicine  
New York University School of Medicine  
Emergency Physician  
Ronald O. Perelman Department of Emergency  
Medicine  
Bellevue Hospital Center and NYU Langone  
Health  
New York, New York  
*Chapter 124, "Methemoglobin Inducers"*

**Jane M. Prosser, MD**

Medical Toxicologist  
Emergency Physician  
Department of Emergency Medicine  
Kaiser Permanente Northern California  
Kaiser Permanente  
Vallejo, California  
*Special Considerations: SC5, "Internal  
Concealment of Xenobiotics"*

**Petrie M. Rainey, MD, PhD, FACMT**

Professor Emeritus of Laboratory Medicine  
University of Washington School of Medicine  
University of Washington Medical Center  
Seattle, Washington  
*Chapter 7, "Laboratory Principles"*

**Rama B. Rao, MD, FACMT**

Associate Professor of Medicine  
Weill Cornell Medical College of Cornell  
University  
Chief, Division of Medical Toxicology  
Emergency Physician  
New York-Presbyterian Hospital  
New York, New York  
*Chapter 22, "Neurologic Principles"*  
*Chapter 87, "Bismuth"*  
*Chapter 140, "Postmortem Toxicology"*  
*Special Considerations: SC7, "Intrathecal  
Administration of Xenobiotics"*  
*Special Considerations: SC12, "Organ Procurement  
from Poisoned Patients"*

**Joseph G. Rella, MD**

Assistant Professor of Medicine  
Weill Cornell Medical College of Cornell  
University  
Emergency Physician  
New York-Presbyterian Hospital  
New York, New York  
*Chapter 128, "Radiation"*  
*Antidotes in Depth: A44, "Potassium Iodide"*  
*Antidotes in Depth: A45, "Pentetic Acid or  
Pentetate (Zinc or Calcium) Trisodium  
(DTPA)"*

**Daniel J. Repplinger, MD**

Assistant Clinical Professor of Emergency  
Medicine  
University of California, San Francisco  
Zuckerberg San Francisco General Hospital  
San Francisco, California  
*Chapter 115, "Arthropods"*

**Morgan A. A. Riggan, MD, FRCPC**

Assistant Professor of Emergency Medicine  
Western University  
Emergency Physician  
London Health Sciences Centre  
London, Ontario, Canada  
Medical Toxicologist  
Poison and Drug Information Service (PADIS)  
Alberta Health Services  
Calgary, Alberta, Canada  
*Chapter 105, "Hydrocarbons"*

**Darren M. Roberts, MBBS, PhD, FRACP**

Conjoint Associate Professor  
University of New South Wales  
Consultant Physician and Clinical Toxicologist  
St. Vincent's Hospital and New South Wales  
Poisons Information Centre  
Sydney, Australia  
*Chapter 109, "Herbicides"*

**Anne-Michelle Ruha, MD**

Professor of Internal Medicine and Emergency  
Medicine  
Departments of Internal Medicine and  
Emergency Medicine  
University of Arizona College of  
Medicine—Phoenix  
Department of Medical Toxicology  
Banner—University Medical Center Phoenix  
Phoenix, Arizona  
*Chapter 119, "Native (US) Venomous Snakes and  
Lizards"*  
*Antidotes in Depth: A39, "Antivenom for North  
American Venomous Snakes (Crotaline and Elapid)"*

**Cynthia D. Santos, MD**

Assistant Professor of Emergency Medicine  
Emergency Physician  
University Hospital of Newark  
Rutgers New Jersey Medical School  
Toxicology Consultant  
New Jersey Poison Information and Education  
System  
Newark, New Jersey  
*Chapter 34, "Colchicine, Podophyllin, and the  
Vinca Alkaloids"*

**Daniel Schatz, MD**

Addiction Medicine Fellow  
Department of Medicine  
New York University School of Medicine  
Bellevue Hospital Center  
New York, New York  
*Special Considerations: SC6, "Prevention,  
Treatment, and Harm Reduction Approaches to  
Opioid Overdoses"*

**Capt. Joshua G. Schier, MD, MPH, USPHS**

Lead, Environmental Toxicology Team  
Centers for Disease Control and Prevention  
Assistant Professor of Emergency Medicine  
Emory University School of Medicine  
Associate Director, Emory/CDC Medical  
Toxicology Fellowship  
Consultant, Georgia Poison Center  
Atlanta, Georgia  
*Chapter 34, "Colchicine, Podophyllin, and the  
Vinca Alkaloids"*  
*Special Considerations: SC9, "Diethylene Glycol"*

**David T. Schwartz, MD**

Associate Professor of Emergency Medicine  
New York University School of Medicine  
Emergency Physician  
Ronald O. Perelman Department of Emergency  
Medicine  
Bellevue Hospital Center and NYU Langone  
Health  
New York, New York

# PREFACE

*Goldfrank's Toxicologic Emergencies* is a multiauthored text of approximately 2,000 pages prepared by using the educational and management principles we apply at the New York City Poison Control Center, New Jersey Poison Information & Education System, and at our clinical sites. In this eleventh edition of *Goldfrank's Toxicologic Emergencies*, we proudly offer readers an approach to medical toxicology using evidence-based principles viewed through the lens of an active bedside clinical practice.

Some would ask why create textbooks and e-books in an era when podcasts and blogs appear so successful. We still believe that the slow, thoughtful, rigorous investigation of all available information by a team of authors and editors required to create and revise this text is essential to analyze the complex problems that challenge our daily practices. Although in our field we have made great progress, the level of uncertainty remains substantial. We have attempted to integrate the collaborative wisdom of experts from diverse backgrounds in order to provide the information necessary to achieve excellence. We offer our readers the evidence, shared thoughts, and structured analysis necessary to arrive at a decision. Evidence is created not only with randomized clinical trials, observational studies, case control studies, and case reports, but also with the insights of six toxicologists who work together continuously, along with the gifted scholars we selected as authors. We have worked together defining and redefining the scope and context of chapters, Antidotes in Depth, and Special Considerations. We then shared our ideas with many respected local, national, and international toxicologists, thus creating new chapters that these toxicologists have revised by adding information and insight that has come to light since the publication of the tenth edition of the text. In this way, knowledge from their experience as toxicologists and related disciplines is merged with ours, allowing us to create chapters that represent our collective thoughts. This iterative process is continued until the authors and editors are satisfied that we have closely approximated the best strategy to evaluate and care for poisoned or overdosed patients. This is a fascinating process. In this edition, we have tried to enhance our rigor focusing on as precise an analysis of the literature as we

can all do and an attempt to tell you as clearly as possible what we and our authors think and how we practice. Because we occasionally disagree, we then reread, research, look for special cases, and reflect on a final version with our authors.

In this edition, we have asked Rana Biary, MD to expand the concept of the patient narrative in the Case Studies section. These are the patients who challenge us to be vigilant as toxicologists. Such patients, whose signs and symptoms are related to the whole book or to several chapters, serve to return us to focus on the unknown, the differential diagnosis, and problem solving and include contextual cases representative of our work. Patients with a pesticide exposure, bradycardia, metabolic acidosis, medication error, seizures, coma or agitation, and hyperthermia are offered as examples for contemplation. We believe that analyzing the care of these complex, undifferentiated patients will help you as much as they have helped us and those who read the first edition of this book. These cases act as the building blocks for chapters in this edition and represent provocative introductions to several sections of this text. We have demonstrated our thought processes so that you can understand our approach to patient management. This classic Socratic development of knowledge and improvement of clinical decision making will improve problem solving, stimulate creative investigation, and enhance care. We hope to facilitate your participation in the intellectual processes that we believe to be essential in order to create a fine book for thoughtful readers who desire to render excellent attention to their patients. The cases serve as the transition between the patient and population as you diminish the gap between your roles as a medical or clinical toxicologist at the bedside and that of a toxicologist serving the needs of the community. Our hope is that these cases re-create the clinicians' thoughts prior to, during, and after care is initiated.

In this eleventh edition, Silas W. Smith, MD, became an editor reflecting his superior work on prior editions. We are sure that his knowledge and thoughtfulness will be appreciated by all.

## The Editors

## ACKNOWLEDGMENTS

We are grateful to Joan Demas, who worked extensively with the local, national, and international authors to ensure that their ideas were effectively expressed. She has assisted all of us in checking the facts, finding essential references, and improving the structure and function of our text, while dedicating her efforts to ensuring the precision and rigor of the text for her fifth consecutive edition. She has helped authors new and old achieve their commitment with the skill of an exceptional publishing professional. The authors' and editors' work is better because of her devotion to excellence, calm demeanor in the face of editorial chaos, and consistent presence throughout each stage of the production of this text. We are deeply appreciative of the wonderful effort she provides for our readers and colleagues.

The many letters and verbal communications we have received with the reviews of the previous editions of this book continue to improve our efforts. We are deeply indebted to our friends, associates, residents, fellows, and students, who stimulated us to begin this book with their questions and then faithfully criticized our answers.

We appreciate the assistance of Dorice Vieira, Associate Curator, Medical Library, and Clinical Outreach and Graduate Medical Education Librarian, in her commitment to helping us find essential information.

We thank the many volunteers, students, librarians, and particularly the St. John's University College of Pharmacy and Health Sciences students and drug information staff who provide us with vital technical assistance in our daily attempts to deal with toxicologic emergencies.

No words can adequately express our indebtedness to the many authors who worked on earlier editions of many of the chapters in this book. As different authors write and rewrite topics with each new edition, we recognize that without the foundational work of their predecessors this book would not be what it is today.

We appreciate the creative skills in design and scientific art that the McGraw-Hill team, led by Armen Ovsepyan, have added to the text. The devotion to the creation of high-quality art graphics and tables is greatly appreciated. The support for excellence in this edition was facilitated by the constant vigilance of our longstanding collaborator Senior Content Acquisitions Editor Karen Edmonson whose thoughtful, and cooperative spirit persists after all these years. Her intelligence and ever vigilant commitment to our efforts has been wonderful. We are pleased with the creative developmental editorial efforts of Robert Pancotti. The organized project management by Revathi Viswanathan has found errors hiding throughout our pages. Her carefully posed questions have facilitated the process of correcting the text. It has been a pleasure to have her assistance. We greatly appreciate the compulsion that Maria van Beuren has applied to make the index of this edition one of unique value. She demonstrated exceptional rigor with a twist of copy editing to find many unseen errors, saving the reader confusion and us embarrassment. We appreciate the work of Catherine Saggese in ensuring the quality of production in the finished work.

# HISTORICAL PRINCIPLES AND PERSPECTIVES

Paul M. Wax

The term *poison* first appeared in the English literature around 1225 A.D. to describe a potion or draught that was prepared with deadly ingredients.<sup>8,155</sup> The history of poisons and poisoning, however, dates back thousands of years. Throughout the millennia, poisons have played an important role in human history—from political assassination in Roman times, to weapons of war, to contemporary environmental concerns, and to weapons of terrorism.

This chapter offers a perspective on the impact of poisons and poisoning on history. It also provides a historic overview of human understanding of poisons and the development of toxicology from antiquity to the present. The development of the modern poison control center, the genesis of the field of medical toxicology, and the increasing focus on medication errors are examined. Chapter 2 describes poison plagues and unintentional disasters throughout history and examines the societal consequences of these unfortunate events. An appreciation of past failures and mistakes in dealing with poisons and poisoning promotes a keener insight and a more critical evaluation of present-day toxicologic issues and helps in the assessment and management of future toxicologic problems.

## POISONS, POISONERS, AND ANTIDOTES OF ANTIQUITY

The earliest poisons consisted of plant extracts, animal venoms, and minerals. They were used for hunting, waging war, and sanctioned and unsanctioned executions. The *Ebers Papyrus*, an ancient Egyptian text written circa 1500 B.C. that is considered to be among the earliest medical texts, describes many ancient poisons, including aconite, antimony, arsenic, cyanogenic glycosides, hemlock, lead, mandrake, opium, and wormwood.<sup>102,155</sup> These poisons were thought to have mystical properties, and their use was surrounded by superstition and intrigue. Some agents, such as the Calabar bean (*Physostigma venenosum*) containing physostigmine, were referred to as “ordeal poisons.” Ingestion of these substances was believed to be lethal to the guilty and harmless to the innocent.<sup>130</sup> The “penalty of the peach” involved the administration of peach pits, which we now know contain the cyanide precursor amygdalin, as an ordeal poison. Magicians, sorcerers, and religious figures were the toxicologists of antiquity. The Sumerians, in circa 4500 B.C., were said to worship the deity Gula, who was known as the “mistress of charms and spells” and the “controller of noxious poisons” (Table 1-1).<sup>155</sup>

### Arrow and Dart Poisons

The prehistoric Masai hunters of Kenya, who lived 18,000 years ago, used arrow and dart poisons to increase the lethality of their weapons.<sup>20</sup> One of these poisons appears to have consisted of extracts of *Strophanthus* species, an indigenous plant that contains strophanthin, a digitalislike substance.<sup>102</sup> Cave paintings of arrowheads and spearheads reveal that these weapons were crafted with small depressions at the end to hold the poison.<sup>156</sup> In fact, the term *toxicology* is derived from the Greek terms *toxikos* (“bow”) and *toxikon* (“poison into which arrowheads are dipped”).<sup>6,156</sup>

References to arrow poisons are cited in a number of other important literary works. The ancient Indian text *Rig Veda*, written in the 12th century B.C., refers to the use of *Aconitum* species for arrow poisons.<sup>20</sup> In the *Odyssey*, Homer (ca. 850 B.C.) wrote that Ulysses anointed his arrows with a variety of poisons, including extracts of *Helleborus orientalis* and snake venoms. The writings of Ovid (43 B.C.–18 A.D.), describe weapons poisoned with the blood of serpents.<sup>164</sup>

### Classification of Poisons

The first attempts at poison identification and classification and the introduction of the first antidotes took place during Greek and Roman times.

An early categorization of poisons divided them into fast poisons, such as strychnine, and slow poisons, such as arsenic. In his treatise, *Materia Medica*, the Greek physician Dioscorides (40–80 A.D.) categorized poisons by their origin—animal, vegetable, or mineral.<sup>156</sup> This categorization remained the standard classification for the next 1,500 years.<sup>156</sup>

### Animal Poisons

Animal poisons usually referred to the venom from poisonous animals. Although the venom from poisonous snakes has always been among the most commonly feared poisons, poisons from toads, salamanders, jellyfish, sting-rays, and sea hares are often as lethal. Nicander of Colophon (204–135 B.C.), a

TABLE 1-1 Important Early People in the History of Toxicology

Person	Date	Importance
Gula	ca. 4500 B.C.	First deity associated with poisons
Shen Nung	ca. 2000 B.C.	Chinese emperor who experimented with poisons and antidotes and wrote treatise on herbal medicine
Homer	ca. 850 B.C.	Wrote how Ulysses anointed arrows with the venom of serpents
Aristotle	384–322 B.C.	Described the preparation and use of arrow poisons
Theophrastus	ca. 370–286 B.C.	Referred to poisonous plants in <i>De Historia Plantarum</i>
Socrates	ca. 470–399 B.C.	Executed by poison hemlock
Nicander	204–135 B.C.	Wrote two poems, “Theriaca” and “Alexipharmaca,” that are among the earliest works on poisons
King Mithridates VI	ca. 132–63 B.C.	Fanatical fear of poisons; developed mithridatum, one of the universal antidotes
Sulla	81 B.C.	Issued <i>Lex Cornelia</i> , the first antipoisoning law
Cleopatra	69–30 B.C.	Committed suicide with deliberate cobra envenomation
Andromachus	37–68 A.D.	Refined mithridatum; known as the Theriac of Andromachus
Dioscorides	40–80 A.D.	Wrote <i>Materia Medica</i> , which classified poisons by animal, vegetable, and mineral
Galen	ca. 129–200 A.D.	Prepared “nut theriac” for Roman emperors, a remedy against bites, stings, and poisons; wrote <i>De Antidotis I</i> and <i>II</i> , which provided recipes for different antidotes, including mithridatum and panacea
Ibn Wahshiya	9th century	Famed Arab toxicologist; wrote toxicology treatise <i>Book on Poisons</i> , combining contemporary science, magic, and astrology
Moses Maimonides	1135–1204	Wrote <i>Treatise on Poisons and Their Antidotes</i>
Petrus Abbonus	1250–1315	Wrote <i>De Venenis</i> , major work on poisoning

Greek poet and physician who is considered to be one of the earliest toxicologists, experimented with animal poisons on condemned criminals.<sup>142</sup> Nicander's poems *Theriaca* and *Alexipharmaca* are considered to be the earliest extant Greek toxicologic texts, describing the presentations and treatment of poisonings from animal xenobiotics.<sup>155</sup> A notable fatality from the effects of an animal xenobiotic was Cleopatra (69–30 B.C.), who reportedly committed suicide by deliberately falling on an asp.<sup>76</sup>

### Vegetable Poisons

Theophrastus (ca. 370–286 B.C.) described vegetable poisons in his treatise *De Historia Plantarum*.<sup>77</sup> Notorious poisonous plants included *Aconitum* species (monkshood, aconite), *Conium maculatum* (poison hemlock), *Hyoscyamus niger* (henbane), *Mandragora officinarum* (mandrake), *Papaver somniferum* (opium poppy), and *Veratrum album* (hellebore). Aconite was among the most frequently encountered poisonous plants and was described as the “queen mother of poisons.”<sup>155</sup> Hemlock was the official poison used by the Greeks and was used in the execution of Socrates (ca. 470–399 B.C.) and many others.<sup>144</sup> Poisonous plants used in India at this time included *Cannabis indica* (marijuana), *Croton tiglium* (croton oil), and *Strychnos nux vomica* (poison nut, strychnine).<sup>77</sup>

### Mineral Poisons

The mineral poisons of antiquity consisted of the metals antimony, arsenic, lead, and mercury. Undoubtedly, the most famous of these was lead. Lead was discovered as early as 3500 B.C. Although controversy continues about whether an epidemic of lead poisoning among the Roman aristocracy contributed to the fall of the Roman Empire, lead was certainly used extensively during this period.<sup>55,118</sup> In addition to its considerable use in plumbing,<sup>44</sup> lead was also used in the production of food and drink containers.<sup>62</sup> It was common practice to add lead directly to wine or to intentionally prepare the wine in a lead kettle to improve its taste. Not surprisingly, chronic lead poisoning became widespread. Nicander described the first case of lead poisoning in the 2nd century B.C.<sup>159</sup> Dioscorides, writing in the 1st century A.D., noted that fortified wine was “most hurtful to the nerves.”<sup>159</sup> Lead-induced gout (“saturnine gout”) may have also been widespread among the Roman elite.<sup>118</sup>

### Gases

Although not animal, vegetable, or mineral in origin, the toxic effects of gases were also appreciated during antiquity. In the 3rd century B.C., Aristotle commented that “coal fumes lead to a heavy head and death,”<sup>74</sup> and Cicero (106–43 B.C.) referred to the use of coal fumes in suicides and executions.

### Poisoners of Antiquity

Given the increasing awareness of the toxic properties of some naturally occurring xenobiotics and the lack of analytical detection techniques, homicidal poisoning was common during Roman times. During this period, members of the aristocracy commonly used “tasters” to shield themselves from potential poisoners, a practice also in vogue during the reign of Louis XIV in 17th-century France.<sup>164</sup>

One of the most infamous poisoners of ancient Rome was Locusta, who was known to experiment on slaves with poisons that included aconite, arsenic, belladonna, henbane, and poisonous fungi. In 54 A.D., Nero's mother, Agrippina, hired Locusta to poison Emperor Claudius (Agrippina's husband and Nero's stepfather) as part of a scheme to make Nero emperor. As a result of these activities, Claudius, who was a great lover of mushrooms, died from *Amanita phalloides* poisoning,<sup>18</sup> and in the next year, Britannicus (Nero's stepbrother) also became one of Locusta's victims. In this case, Locusta managed to fool the taster by preparing unusually hot soup that required additional cooling after the soup had been officially tasted. At the time of cooling, the poison was surreptitiously slipped into the soup. Almost immediately after drinking the soup, Britannicus collapsed and died. The exact poison remains in doubt, although some authorities suggest that it was a cyanogenic glycoside.<sup>147</sup>

### Early Quests for the Universal Antidote

The recognition, classification, and use of poisons in ancient Greece and Rome were accompanied by an intensive search for a universal antidote. In fact, many of the physicians of this period devoted significant parts of their careers to this endeavor.<sup>155</sup> Mystery and superstition surrounded the origins and sources of these proposed antidotes. One of the earliest specific references to a protective therapy can be found in Homer's *Odyssey*, when Ulysses is advised to protect himself by taking the antidote “moli.” Recent speculation suggests that moli referred to *Galanthus nivalis*, which contains a cholinesterase inhibitor. Moli could have been used as an antidote against poisonous plants such as *Datura stramonium* (jimsonweed) that contain the anticholinergic alkaloids scopolamine, atropine, and hyoscyamine.<sup>127</sup>

### Theriacs and the Mithridatum

The Greeks referred to the universal antidote as the *alexipharmaca* or *theriac*.<sup>79,155</sup> The term *alexipharmaca* was derived from the words *alexipharmakos* (“which keeps off poison”) and *antipharmakon* (“antidote”). Over the years, *alexipharmaca* was increasingly used to refer to a method of treatment, such as the induction of emesis by using a feather. Theriac, which originally had referred to poisonous reptiles or wild beasts, was later used to refer to the antidotes. Consumption of the early theriacs (ca. 200 B.C.) was reputed to make people “poison proof” against bites of all venomous animals except the asp. Their ingredients included aniseed, anmi, apoponax, fennel, meru, parsley, and wild thyme.<sup>155</sup>

The quest for the universal antidote was epitomized by the work of King Mithridates VI of Pontus (135–63 B.C.).<sup>75</sup> After repeatedly being subjected to poisoning attempts by his enemies during his youth, Mithridates sought protection by the development of universal antidotes. To find the best antidote, he performed acute toxicity experiments on criminals and slaves. The theriac he concocted, known as the “mithridatum,” contained a minimum of 36 ingredients and was thought to be protective against aconite, scorpions, sea slugs, spiders, vipers, and all other poisonous substances. Mithridates took his concoction every day. Ironically, when an old man, Mithridates attempted suicide by poison but supposedly was unsuccessful because he had become poison proof. Having failed at self-poisoning, Mithridates was compelled to have a soldier kill him with a sword. Galen described Mithridates' experiences in a series of three books: *De Antidotis I*, *De Antidotis II*, and *De Theriaca ad Pisonem*.<sup>75,160</sup>

The Theriac of Andromachus, also known as the “Venice treacle” or “galene,” is probably the most well-known theriac.<sup>64</sup> According to Galen, this preparation, formulated during the 1st century A.D., was considered an improvement over the mithridatum.<sup>146</sup> It was prepared by Andromachus (37–68 A.D.), physician to Emperor Nero. Andromachus added to the mithridatum ingredients such as the flesh of vipers, squills, and generous amounts of opium.<sup>167</sup> Other ingredients were removed. Altogether, 73 ingredients were required. It was advocated to “counteract all poisons and bites of venomous animals,” as well as a host of other medical problems, such as colic, dropsy, and jaundice, and it was used both therapeutically and prophylactically.<sup>155,160</sup> As evidence of its efficacy, Galen demonstrated that fowl receiving poison followed by theriac had a higher survival rate than fowl receiving poison alone.<sup>155</sup> It is likely, however, that the scientific rigor and methodology used differed from current scientific practice.

By the Middle Ages, the Theriac of Andromachus contained more than 100 ingredients. Its synthesis was quite elaborate; the initial phase of production lasted months followed by an aging process that lasted years, somewhat similar to that of vintage wine.<sup>98</sup> The final product was often more solid than liquid in consistency.

Other theriac preparations were named after famous physicians (Damocrates, Nicolaus, Amando, Arnauld, and Abano) who contributed additional ingredients to the original formulation. Over the centuries, certain localities were celebrated for their own peculiar brand of theriac. Notable centers of theriac production included Bologna, Cairo, Florence, Genoa, Istanbul, and Venice. At times, theriac production was accompanied by great fanfare. For example, in Bologna, the mixing of the theriac could take place only under the direction of the medical professors at the university.<sup>155</sup>

Whether these preparations were of actual benefit is uncertain. Some suggest that the theriac had an antiseptic effect on the gastrointestinal (GI) tract, but others state that the sole benefit of the theriac derived from its formulation with opium.<sup>98</sup> Theriacs remained in vogue throughout the Middle Ages and Renaissance, and it was not until 1745 that their efficacy was finally questioned by William Heberden in *Antitheriaca: An Essay on Mithridatum and Theriaca*.<sup>75</sup> Nonetheless, pharmacopeias in France, Spain, and Germany continued to list these preparations until the last quarter of the 19th century, and theriac was still available in Italy and Turkey in the early 20th century.<sup>19,98</sup>

### Sacred Earth

Beginning in the 5th century B.C., an adsorbent agent called *terra sigillata* was promoted as a universal antidote. This xenobiotic, also known as the “sacred sealed earth,” consisted of red clay that could be found on only one particular hill on the Greek island of Lemnos. Perhaps somewhat akin to the 20th-century “universal antidote,” it was advocated as effective in counteracting all poisons.<sup>155</sup> With great ceremony, once per year, the *terra sigillata* was retrieved from this hill and prepared for subsequent use. According to Dioscorides, this clay was formulated with goat’s blood to make it into a paste. At one time, it was included as part of the Theriac of Andromachus. Demand for *terra sigillata* continued into the 15th century. Similar antidotal clays were found in Italy, Malta, Silesia, and England.<sup>155</sup>

### Charms

Charms, such as toadstones, snakestones, unicorn horns, and bezoar stones, were also promoted as universal antidotes. Toadstones, found in the heads of old toads, were reputed to have the capability to extract poison from the site of a venomous bite or sting. In addition, the toadstone was supposedly able to detect the mere presence of poison by producing a sensation of heat upon contact with a poisonous substance.<sup>155</sup>

Similarly, snakestones extracted from the heads of cobras (known as *piedras della cobra de Capelos*) were also reported to have magical qualities.<sup>14</sup> The 17th-century Italian philosopher Athanasius Kircher (1602–1680) became an enthusiastic supporter of snakestone therapy for the treatment of snakebite after conducting experiments, demonstrating the antidotal attributes of these charms “in front of amazed spectators.” Kircher attributed the efficacy of the snakestone to the theory of “attraction of like substances.” Francesco Redi (1626–1698), a court physician and contemporary of Kircher, debunked this quixotic approach. A harbinger of future experimental toxicologists, Redi was unwilling to accept isolated case reports and field demonstrations as proof of the utility of the snakestone. Using a considerably more rigorous approach, *provando et riprovando* (by testing and retesting), Redi assessed the antidotal efficacy of snakestone on different animal species and different xenobiotics and failed to confirm any benefit.<sup>14</sup>

Much lore has surrounded the antidotal effects of the mythical unicorn horn. Ctesias, writing in 390 B.C., was the first to chronicle the wonders of the unicorn horn, claiming that drinking water or wine from the “horn of the unicorn” would protect against poison.<sup>155</sup> The horns were usually narwhal tusks or rhinoceros horns, and during the Middle Ages, the unicorn horn may have been worth as much as 10 times the price of gold. Similar to the toadstone, the unicorn horn was used both to detect poisons and to neutralize them. Supposedly, a cup made of unicorn horn would sweat if a poisonous substance was placed in it.<sup>96</sup> To give further credence to its use, a 1593 study on dogs poisoned by arsenic reportedly showed that the horn was protective.<sup>96</sup>

Bezoar stones, also touted as universal antidotes, consisted of stomach or intestinal calculi formed by the deposition of calcium phosphate around a hair, fruit pit, or gallstone. They were removed from wild goats, cows, and apes and administered orally to humans. The Persian name for the bezoar stone was *pad zahr* (“expeller of poisons”); the ancient Hebrews referred to the bezoar stone as *bel Zaard* (“every cure for poisons”). Over the years, regional variations of bezoar stones were popularized, including an Asian variety from wild goat of Persia, an Occidental variety from llamas of Peru, and a European variety from chamois of the Swiss mountains.<sup>50,155</sup>

## OPIUM, COCA, CANNABIS, AND HALLUCINOGENS IN ANTIQUITY

Although it was not until the mid-19th century that the true perils of opioid addiction were first recognized, juice from the *Papaver somniferum* was known for its medicinal value in Egypt at least as early as the writing of the *Ebers Papyrus* in 1500 B.C. Egyptian pharmacologists of that time reportedly recommended opium poppy extract as a pacifier for children who exhibited incessant crying.<sup>141</sup> In Ancient Greece, Dioscorides and Galen were early advocates of opium as a therapeutic xenobiotic. During this time, it was also used as a means of suicide. Mithridates’ lack of success in his own attempted suicide by poisoning may have been the result of an opium tolerance that had developed from previous repetitive use.<sup>141</sup> One of the earliest descriptions of the abuse potential of opium is attributed to Epistratos (304–257 B.C.), who criticized the use of opium for earache because it “dulled the sight and is a narcotic.”<sup>141</sup>

Cocaine use dates back to at least 300 B.C., when South American Indians reportedly chewed coca leaves during religious ceremonies.<sup>112</sup> Chewing coca to increase work efficacy and to elevate mood has remained commonplace in some South American societies for thousands of years. An Egyptian mummy from about 950 B.C. revealed significant amounts of cocaine in the stomach and liver, suggesting oral use of cocaine occurred during this time period.<sup>116</sup> Large amounts of tetrahydrocannabinol (THC) were also found in the lung and muscle of the same mummy. Another investigation of 11 Egyptian (1079 B.C.–395 A.D.) and 72 Peruvian (200–1500 A.D.) mummies found cocaine, thought to be indigenous only to South America, and hashish, thought to be indigenous only to Asia, in both groups.<sup>126</sup>

Cannabis use in China dates back even further, to around 2700 B.C., when it was known as the “liberator of sin.”<sup>112</sup> In India and Iran, cannabis was used as early as 1000 B.C. as an xenobiotic known as *bhanga*.<sup>115</sup> Other currently abused xenobiotics that were known to the ancients include cannabis, hallucinogenic mushrooms, nutmeg, and peyote. As early as 1300 B.C., Peruvian Indian tribal ceremonies included the use of mescaline-containing San Pedro cacti.<sup>112</sup> The hallucinogenic mushroom, *Amanita muscaria*, known as “fly agaric,” was used as a ritual drug and may have been known in India as “soma” around 2000 B.C.

## EARLY ATTEMPTS AT GASTROINTESTINAL DECONTAMINATION

Nicander’s *Alexipharmaca* (*Antidotes for Poisons*) recommended induction of emesis by one of several methods: (a) ingesting warm linseed oil, (b) tickling the hypopharynx with a feather, or (c) “emptying the gullet with a small twisted and curved paper.”<sup>98</sup> Nicander also advocated the use of suction to limit envenomation.<sup>156</sup> The Romans referred to the feather as the “vomiting feather” or “pinna.” Most commonly, the feather was used after a hearty feast to avoid the GI discomfort associated with overeating. At times, the pinna was dipped into a nauseating mixture to increase its efficacy.<sup>101</sup>

## TOXICOLOGY DURING THE MEDIEVAL AND RENAISSANCE PERIODS

After Galen (ca. A.D. 129–200), there is relatively little documented attention to the subject of poisons until the works of Ibn Wahshiya in the 9th century. Citing Greek, Persian, and Indian texts, Wahshiya’s work, titled *Book of Poisons*, combined contemporary science, magic, and astrology during his discussion of poison mechanisms (as they were understood at that time), symptomatology, antidotes (including his own recommendation for a universal antidote), and prophylaxis. He categorized poisons as lethal by sight, smell, touch, and sound, as well as by drinking and eating. For victims of an aconite-containing dart arrow, Ibn Wahshiya recommended excision followed by cauterization and topical treatment with onion and salt.<sup>93</sup>

Another significant medieval contribution to toxicology can be found in Moses Maimonides’ (1135–1204) *Treatise on Poisons and Their Antidotes* (1198). In part one of this treatise, Maimonides discussed the bites of snakes and mad dogs and the stings of bees, wasps, spiders, and scorpions.<sup>139</sup> He also discussed the use of cupping glasses for bites (a progenitor of the modern suctioning device) and was one of the first to differentiate the hematotoxic

(hot) from the neurotoxic (cold) effects of poison. In part two, he discussed mineral and vegetable poisons and their antidotes. He described belladonna poisoning as causing a “redness and a sort of excitation.”<sup>139</sup> He suggested that emesis should be induced by hot water, *Anethum graveolens* (dill), and oil, followed by fresh milk, butter, and honey. Although he rejected some of the popular treatments of the day, he advocated the use of the great theriac and the mithridatum as first- and second-line xenobiotics in the management of snakebite.<sup>139</sup>

On the subject of oleander poisoning, Petrus Abbonus (1250–1315) wrote that those who drink the juice, spines, or bark of oleander will develop anxiety, palpitations, and syncope.<sup>22</sup> He described the clinical presentation of opium overdose as someone who “will be dull, lazy, and sleepy, without feeling, and he will neither understand nor feel anything, and if he does not receive succor, he will die.” Although this “succor” is not defined, he recommended that treatment of opium toxicity include drinking the strongest wine, rubbing the extremities with alkali and soap, and olfactory stimulation with pepper. To treat snakebite, Abbonus suggested the immediate application of a tourniquet, as well as oral suctioning of the bite wound, preferably performed by a servant. Interestingly, from a 21st-century perspective, Abbonus also suggested that St. John’s wort had the magical power to free anything from poisons and attributed this virtue to the influence of the stars.<sup>22</sup>

### The Scientists

Paracelsus’ (1493–1541) study on the dose–response relationship is usually considered the beginning of the scientific approach to toxicology (Table 1–2). He was the first to emphasize the chemical nature of toxic xenobiotics.<sup>123</sup> Paracelsus stressed the need for proper observation and experimentation regarding the true response to xenobiotics. He underscored the need to differentiate between the therapeutic and toxic properties of chemicals when he stated in his *Third Defense*, “What is there that is not poison? All things are poison and nothing [is] without poison. Solely, the dose determines that a thing is not a poison.”<sup>43</sup>

Although Paracelsus is the best known Renaissance toxicologist, Ambroise Pare (1510–1590) and William Piso (1611–1678) also contributed to the field. Pare argued against the use of the unicorn horn and bezoar stone.<sup>100</sup> He also wrote an early treatise on carbon monoxide poisoning. Piso is credited as one of the first to recognize the emetic properties of ipecacuanha.<sup>136</sup>

### Medieval and Renaissance Poisoners

Along with these advances in toxicologic knowledge, the Renaissance is mainly remembered as the age of the poisoner, a time when the art of poisoning reached new heights (Table 1–3). In fact, poisoning was so rampant during this time that in 1531, King Henry VIII decreed that convicted poisoners should be boiled alive.<sup>52</sup> From the 15th to 17th centuries, schools of poisoning existed in Venice and Rome. In Venice, poisoning services were provided by a group called the Council of Ten, whose members were hired to perform murder by poison.<sup>164</sup>

Members of the infamous Borgia family were considered to be responsible for many poisonings during this period. They preferred to use a poison called “La Cantarella,” a mixture of arsenic and phosphorus.<sup>157</sup> Rodrigo Borgia (1431–1503), who became Pope Alexander VI, and his son, Cesare Borgia, were reportedly responsible for the poisoning of cardinals and kings.

In the late 16th century, Catherine de Medici, wife of Henry II of France, introduced Italian poisoning techniques to France. She experimented on the poor, the sick, and the criminal. By analyzing the subsequent complaints of her victims, she is said to have learned the sites of action and times of onset, the clinical signs and symptoms, and the efficacies of poisons.<sup>56</sup> Murder by poison remained quite popular during the latter half of the 17th and the early part of the 18th centuries in Italy and France.

The Marchioness de Brinvilliers (1630–1676) tested her poison concoctions on hospitalized patients and on her servants and allegedly murdered her husband, father, and two siblings.<sup>54,147</sup> Among the favorite poisons of the Marchioness were arsenic, copper sulfate, corrosive sublimate (mercury bichloride), lead, and tartar emetic (antimony potassium tartrate).<sup>157</sup>

TABLE 1–2 Important People in the Later History of Toxicology

Person	Date	Importance
Paracelsus	1493–1541	Introduced the dose–response concept to toxicology
Ambroise Pare	1510–1590	Argued against unicorn horns and bezoars as antidotes
William Piso	1611–1678	First to study emetic qualities of ipecacuanha
Bernardino Ramazzini	1633–1714	Father of occupational medicine; wrote <i>De Morbis Artificum Diatriba</i>
Richard Mead	1673–1754	Wrote English-language book about poisoning
Percivall Pott	1714–1788	Wrote the first description of occupational cancer, relating the chimney sweep occupation to scrotal cancer
Felice Fontana	1730–1805	First scientific study of venomous snakes
Philip Physick	1767–1837	Early advocate of orogastric lavage to remove poisons
Baron Guillaume Dupuytren	1777–1835	Early advocate of orogastric lavage to remove poisons
Francois Magendie	1783–1855	Discovered emetine and studied the mechanisms of cyanide and strychnine
Bonaventure Orfila	1787–1853	Father of modern toxicology; wrote <i>Traite des Poisons</i> ; first to isolate arsenic from human organs
James Marsh	1794–1846	Developed reduction test for arsenic
Robert Christison	1797–1882	Wrote <i>Treatise on Poisons</i> , one of the most influential texts of the early 19th century
Grand Marshall Bertrand	1813	Demonstrated the efficacy of charcoal in arsenic ingestion
Claude Bernard	1813–1878	Studied the mechanisms of toxicity of carbon monoxide and curare
Edward Jukes	1820	Self-experimented with orogastric lavage apparatus known as Jukes syringe
Theodore Wormley	1826–1897	Wrote <i>Micro-Chemistry of Poisons</i> , the first American book devoted exclusively to toxicology
Pierre Touery	1831	Demonstrated the efficacy of charcoal in strychnine ingestion
Hugo Reinsch	1842–1884	Developed qualitative tests for arsenic and mercury
Alfred Garrod	1846	Conducted the first systematic study of charcoal in an animal model
Max Gutzeit	1847–1915	Developed method to quantitate small amounts of arsenic
Benjamin Howard Rand	1848	Conducted the first study of the efficacy of charcoal in humans
O.H. Costill	1848	Wrote the first book on symptoms and treatment of poisoning
Louis Lewin	1850–1929	Studied many toxins, including methanol, chloroform, snake venom, carbon monoxide, lead, opioids, and hallucinogenic plants
Rudolf Kobert	1854–1918	Studied digitalis and ergot alkaloids
Albert Niemann	1860	Isolated cocaine alkaloids
Alice Hamilton	1869–1970	Conducted landmark investigations associating worksite chemical hazards with disease; led reform movement to improve worker safety

TABLE 1–3 Notable Poisoners from Antiquity to the Present

Poisoner	Date	Victim(s)	Poison(s)
Locusta	54–55 A.D.	Claudius and Britannicus	<i>Amanita phalloides</i> , cyanide
Cesare Borgia	1400s	Cardinals and kings	La Cantarella (arsenic and phosphorus)
Catherine de Medici	1519–1589	Poor, sick, criminals	Unknown
Hieronyma Spara	Died 1659	Taught women how to poison their husbands	Mana of St. Nicholas of Bari (arsenic trioxide)
Marchioness de Brinvilliers	Died 1676	Hospitalized patients, husband, father	Antimony, arsenic, copper, lead, mercury
Catherine Deshayes	Died 1680	>2,000 infants, many husbands	La poudre de succession (arsenic mixed with aconite, belladonna, and opium)
Madame Giulia Toffana	Died 1719	>600 people	Aqua toffana (arsenic trioxide)
Mary Blandy	1752	Father	Arsenic
Anna Maria Zwanizer	1807	Random people	Antimony, arsenic
Marie Lefarge	1839	Husband	Arsenic (first use of Marsh test)
John Tawell	1845	Mistress	Cyanide
William Palmer, MD	1855	Fellow gambler	Strychnine
Madeline Smith (acquitted)	1857	Lover	Arsenic
Edmond de la Pommerais, MD	1863	Patient and mistress	Digitalis
Edward William Pritchard, MD	1865	Wife and mother-in-law	Antimony
George Henry Lamson, MD	1881	Brother-in-law	Aconite
Adelaide Bartlett (acquitted)	1886	Husband	Chloroform
Florence Maybrick	1889	Husband	Arsenic
Thomas Neville Cream, MD	1891	Prostitutes	Strychnine
Johann Hoch	1892–1905	Serial wives	Arsenic
Cordelia Botkin	1898	Rival woman	Arsenic (in chocolate candy)
Roland Molineux	1898	Acquaintance	Cyanide of mercury
Hawley Harvey Crippen, MD	1910	Wife	Hyoscine
Frederick Henry Seddon	1911	Boarder	Arsenic (fly paper)
Henri Girard Landru	1912	Acquaintances	<i>Amanita phalloides</i>
Robert Armstrong	1921	Wife	Arsenic (weed killer)
Landru	1922	Many women	Cyanide
Suzanne Fazekas	1929	Supplied poison to 100 wives to kill husbands	Arsenic
Sadamichi Hirasawa	1948	Bank employees	Potassium cyanide
Christa Ambros Lehmann	1954	Friend, husband, father-in-law	E-605 (parathion)
Nannie Doss	1954	11 relatives, including five husbands	Arsenic
Carl Coppolino, MD	1965	Wife	Succinylcholine
Graham Frederick Young	1971	Stepmother, coworkers	Antimony, thallium
Judias V. Buonoano	1971	Husband, son	Arsenic
Ronald Clark O'Bryan	1974	Son and neighborhood children	Cyanide (in Halloween candy)
Governmental	1978	Georgi Markov, Bulgarian dissident	Ricin
Jim Jones	1978	>900 people in mass suicide	Cyanide
Harold Shipman, MD	1974–1998	>100 patients	Heroin
Unidentified	1982	Seven random people	Extra Strength Tylenol mixed with cyanide

(Continued)

TABLE 1-3 Notable Poisoners from Antiquity to the Present (Continued)

Poisoner	Date	Victim(s)	Poison(s)
Donald Harvey	1983–1987	Patients	Arsenic
George Trepal	1988	Neighbors	Thallium
Michael Swango, MD	1980s–1990s	Hospitalized patients	Arsenic, potassium chloride, succinylcholine
Charles Cullen, RN	1990s–2003	Hospitalized patients	Digoxin
State sponsored	2004	Viktor Yushchenko, Ukrainian presidential candidate	Dioxin
State sponsored	2006	Alexander Litvinenko	Polonium-210
State sponsored	2017	Kim Jong-nam	VX

Catherine Deshayes (1640–1680), a fortuneteller and sorceress, was one of the last “poisoners for hire” and was implicated in countless poisonings, including the killing of more than 2,000 infants.<sup>56</sup> Better known as “La Voisine,” she reportedly sold poisons to women wishing to rid themselves of their husbands. Her particular brand of poison was a concoction of aconite, arsenic, belladonna, and opium known as “la poudre de succession.”<sup>157</sup> Ultimately, de Brinvilliers was beheaded, and Deshayes was burned alive for her crimes. In an attempt to curtail these rampant poisonings, Louis XIV issued a decree in 1662 banning the sale of arsenic, mercury, and other poisons to customers not known to apothecaries and requiring buyers to sign a register declaring the purpose for their purchase.<sup>147</sup>

A major center for poison practitioners was Naples, the home of the notorious Madame Giulia Toffana. She reportedly poisoned more than 600 people, preferring a particular solution of white arsenic (arsenic trioxide), better known as “aqua toffana,” and dispensed under the guise of a cosmetic. Eventually convicted of poisoning, Madame Toffana was executed in 1719.<sup>21</sup>

## EIGHTEENTH- AND NINETEENTH-CENTURY DEVELOPMENTS IN TOXICOLOGY

The development of toxicology as a distinct specialty began during the 18th and 19th centuries (Table 1-2).<sup>125</sup> The mythological and magical mystique of poisoners began to be gradually replaced by an increasingly rational, scientific, and experimental approach to these xenobiotics. Much of the poison lore that had survived for almost 2,000 years was finally debunked and discarded. The 18th-century Italian Felice Fontana was one of the first to usher in the modern age. He was an early experimental toxicologist who studied the venom of the European viper and wrote the classic text *Traite sur le Venin de la Vipere* in 1781.<sup>82</sup> Through his exacting experimental study on the effects of venom, Fontana brought a scientific insight to toxicology previously lacking and demonstrated that clinical symptoms resulted from the poison (venom) acting on specific target organs. During the 18th and 19th centuries, attention focused on the detection of poisons and the study of toxic effects of xenobiotics in animals.<sup>117</sup> Issues relating to adverse effects of industrialization and unintentional poisoning in the workplace and home environment were raised. Also during this time, early experience and experimentation with methods of GI decontamination took place.

### Development of Analytical Toxicology and the Study of Poisons

The French physician Bonaventure Orfila (1787–1853) is often called the father of modern toxicology.<sup>117</sup> He emphasized toxicology as a distinct, scientific discipline, separate from clinical medicine and pharmacology.<sup>11</sup> He was also an early medicolegal expert who championed the use of chemical analysis and autopsy material as evidence to prove that a poisoning had occurred. His treatise *Traite des Poisons* (1814)<sup>122</sup> evolved over five editions and was regarded as the foundation of experimental and forensic toxicology.<sup>163</sup> This text classified poisons into six groups: acrids, astringents, corrosives, narcoticoacrids, septic and putrefiants, and stupeficients and narcotics.

A number of other landmark works on poisoning also appeared during this period. In 1829, Robert Christison (1797–1882), a professor of medical jurisprudence and Orfila’s student, wrote *A Treatise on Poisons*.<sup>32</sup> This work simplified Orfila’s poison classification schema by categorizing poisons into three groups: irritants, narcotics, and narcoticoacrids. Less concerned with jurisprudence than with clinical toxicology, O.H. Costill’s *A Practical Treatise on Poisons*, published in 1848, was the first modern clinically oriented text to emphasize the symptoms and treatment of poisoning.<sup>36</sup> In 1867, Theodore Wormley (1826–1897) published the first American book written exclusively on poisons titled the *Micro-Chemistry of Poisons*.<sup>48,166</sup>

During this time, important breakthroughs in the chemical analysis of poisons resulted from the search for a more reliable assay for arsenic.<sup>66,162</sup> Arsenic was widely available and was the suspected cause of a large number of deaths. In one study, arsenic was used in 31% of 679 homicidal poisonings.<sup>157</sup> A reliable means of detecting arsenic was much needed by the courts.

Until the 19th century, poisoning was mainly diagnosed by its resultant symptoms rather than by analytic tests. The first use of a chemical test as evidence in a poisoning trial occurred in the 1752 trial of Mary Blandy, who was accused of poisoning her father with arsenic.<sup>104</sup> Although Blandy was convicted and hanged publicly, the test used in this case was not very sensitive and depended in part on eliciting a garlic odor upon heating the gruel that the accused had fed to her father.

During the 19th century, James Marsh (1794–1846), Hugo Reinsch (1842–1884), and Max Gutzeit (1847–1915) each worked on this problem. Assays bearing their names are important contributions to the early history of analytic toxicology.<sup>105,117</sup> The “Marsh test” to detect arsenic was first used in a criminal case in 1839 during the trial of Marie Lefarge, who was accused of using arsenic to murder her husband.<sup>147</sup> Orfila’s trial testimony that the victim’s viscera contained minute amounts of arsenic helped to convict the defendant, although subsequent debate suggested that contamination of the forensic specimen may have also played a role.

In a further attempt to curtail criminal poisoning by arsenic, the British Parliament passed the Arsenic Act in 1851. This bill, which was one of the first modern laws to regulate the sale of poisons, required that the retail sale of arsenic be restricted to chemists, druggists, and apothecaries and that a poison book be maintained to record all arsenic sales.<sup>15</sup>

Homicidal poisonings remained common during the 19th century and early 20th century. Infamous poisoners of that time included William Palmer, Edward Pritchard, Harvey Crippen, and Frederick Seddon.<sup>157</sup> Many of these poisoners were physicians who used their knowledge of medicine and toxicology in an attempt to solve their domestic and financial difficulties by committing the “perfect” murder. Some of the poisons used were aconitine (by Lamson, who was a classmate of Christison), *Amanita phalloides* (by Girard), arsenic (by Maybrick, Seddon, and others), antimony (by Pritchard), cyanide (by Molineux and Tawell), digitalis (by Pommerais), hyoscyne (by Crippen), and strychnine (by Palmer and Cream) (Table 1-3).<sup>24,91,155,157</sup>

In the early 20th century, forensic investigation into suspicious deaths, including poisonings, was significantly advanced with the development of

the medical examiner system replacing the much-flawed coroner system that was subject to widespread corruption. In 1918, the first centrally controlled medical examiner system was established in New York City. Alexander Gettler, considered the father of forensic toxicology in the United States, established a toxicology laboratory within the newly created New York City Medical Examiner's Office. Gettler pioneered new techniques for the detection of a variety of substances in biologic fluids, including carbon monoxide, chloroform, cyanide, and heavy metals.<sup>49,117</sup>

Systematic investigation into the underlying mechanisms of toxic substances also commenced during the 19th century. Francois Magendie (1783–1855) studied the mechanisms of toxicity and sites of action of cyanide, emetine, and strychnine.<sup>47</sup> Claude Bernard (1813–1878), a pioneering physiologist and a student of Magendie, made important contributions to the understanding of the toxicity of carbon monoxide and curare.<sup>90</sup> Rudolph Kobert (1854–1918) studied digitalis and ergot alkaloids and authored a textbook on toxicology for physicians and students.<sup>87,120</sup> Louis Lewin (1850–1929) was the first person to intensively study the differences between the pharmacologic and toxicologic actions of xenobiotics. Lewin studied chronic opium intoxication, as well as the toxicity of carbon monoxide, chloroform, lead, methanol, and snake venom. He also developed a classification system for psychoactive drugs, dividing them into euphorics, phantastics, inebriants, hypnotics, and excitants.<sup>99</sup>

### The Origin of Occupational Toxicology

The origins of occupational toxicology can be traced to the early 18th century and to the contributions of Bernardino Ramazzini (1633–1714). Considered the father of occupational medicine, Ramazzini wrote *De Morbis Artificum Diatriba (Diseases of Workers)* in 1700, which was the first comprehensive text discussing the relationship between disease and workplace hazards.<sup>53</sup> Ramazzini's essential contribution to patient care is epitomized by the addition of a standard question to a patient's medical history: "What occupation does the patient follow?"<sup>51</sup> Altogether Ramazzini described diseases associated with 54 occupations, including hydrocarbon poisoning in painters, mercury poisoning in mirror makers, and pulmonary diseases in miners.

In 1775, Sir Percivall Pott proposed the first association between workplace exposure and cancer when he noticed a high incidence of scrotal cancer in English chimney sweeps. Pott's belief that the scrotal cancer was caused by prolonged exposure to tar and soot was confirmed by further investigation in the 1920s, indicating the carcinogenic nature of the polycyclic aromatic hydrocarbons contained in coal tar (including benzo[*a*]pyrene).<sup>73</sup>

Dr. Alice Hamilton (1869–1970) was another pioneer in occupational toxicology, whose rigorous scientific inquiry had a profound impact on linking chemical xenobiotics with human disease. A physician, scientist, humanitarian, and social reformer, Hamilton became the first female professor at Harvard University and conducted groundbreaking studies of many different occupational exposures and problems, including carbon monoxide poisoning in steelworkers, mercury poisoning in hatters, and wrist drop in lead workers. Hamilton's overriding concerns about these "dangerous trades" and her commitment to improving the health of workers led to extensive voluntary and regulatory reforms in the workplace.<sup>60,65</sup>

### Advances in Gastrointestinal Decontamination

Using gastric lavage and charcoal to treat poisoned patients was introduced in the late 18th and early 19th century. A stomach pump was first designed by Munro Secundus in 1769 to administer neutralizing substances to sheep and cattle for the treatment of bloat.<sup>25</sup> The American surgeon Philip Physick (1768–1837) and the French surgeon Baron Guillaume Dupuytren (1777–1835) were two of the first physicians to advocate gastric lavage for the removal of poisons.<sup>25</sup> As early as 1805, Physick demonstrated the use of a "stomach tube" for this purpose. Using brandy and water as the irrigation fluid, he performed stomach washings in twins to wash out excessive doses of tincture of opium.<sup>25</sup> Dupuytren performed gastric emptying by first introducing warm water into the stomach via a large syringe attached to a long flexible sound and then withdrawing the "same water charged with

poison."<sup>25</sup> Edward Jukes, a British surgeon, was another early advocate of poison removal by gastric lavage. Jukes first experimented on animals, performing gastric lavage after the oral administration of tincture of opium. Attempting to gain human experience, he experimented on himself, by first ingesting 10 drams (600 g) of tincture of opium and then performing gastric lavage using a 25-inch-long, 0.5-inch-diameter tube, which became known as Jukes syringe.<sup>111</sup> Other than some nausea and a 3-hour sleep, he suffered no ill effects, and the experiment was deemed a success.

The principle of using charcoal to adsorb xenobiotics was first described by Scheele (1773) and Lowitz (1785), but the medicinal use of charcoal dates to ancient times.<sup>35</sup> The earliest reference to the medicinal uses of charcoal is found in Egyptian papyrus from about 1500 B.C.<sup>35</sup> The charcoal used during Greek and Roman times, referred to as "wood charcoal," was used to treat those with anthrax, chlorosis, epilepsy, and vertigo. By the late 18th century, topical application of charcoal was recommended for gangrenous skin ulcers, and internal use of a charcoal–water suspension was recommended for use as a mouthwash and in the treatment of bilious conditions.<sup>35</sup>

The first hint that charcoal might have a role in the treatment of poisoning came from a series of courageous self-experiments in France during the early 19th century. In 1813, the French chemist Bertrand publicly demonstrated the antidotal properties of charcoal by surviving a 5-g ingestion of arsenic trioxide that had been mixed with charcoal.<sup>69</sup> Eighteen years later, before the French Academy of Medicine, the pharmacist Touery survived an ingestion consisting of 10 times the lethal dose of strychnine mixed with 15 g of charcoal.<sup>69</sup> One of the first reports of charcoal used in a poisoned patient was in 1834 by the American Hort, who successfully treated a mercury bichloride–poisoned patient with large amounts of powdered charcoal.<sup>3</sup>

In the 1840s, Garrod performed the first controlled study of charcoal when he examined its utility on a variety of poisons in animal models.<sup>69</sup> Garrod used dogs, cats, guinea pigs, and rabbits to demonstrate the potential benefits of charcoal in the management of strychnine poisoning. He also emphasized the importance of early use of charcoal and the proper ratio of charcoal to poison. Other toxic substances, such as aconite, hemlock, mercury bichloride, and morphine, were also studied during this period. The first charcoal efficacy studies in humans were performed by the American physician B. Rand in 1848.<sup>69</sup>

But it was not until the early 20th century that an activation process was added to the manufacture of charcoal to increase its effectiveness. In 1900, the Russian Ostrejko demonstrated that treating charcoal with superheated steam significantly enhanced its adsorbing power.<sup>35</sup> Despite this improvement and the favorable reports mentioned, charcoal was only occasionally used in GI decontamination until the early 1960s, when Holt and Holz repopularized its use.<sup>63</sup>

### The Increasing Recognition of the Perils of Drug Abuse

#### Opioids

Although the medical use of opium was promoted by Paracelsus in the 16th century, its popularity was given a significant boost when the distinguished British physician Thomas Sydenham (1624–1689) formulated laudanum, which was a tincture of opium containing cinnamon, cloves, saffron, and sherry. Sydenham also formulated a different opium concoction known as "syrup of poppies."<sup>86</sup> A third opium preparation called Dover's powder was designed by Sydenham's protégé, Thomas Dover; this preparation contained ipecac, licorice, opium, salt-peter, and tartaric acid.

John Jones, the author of the 18th-century text *The Mysteries of Opium Revealed*, was another enthusiastic advocate of its "medicinal" uses.<sup>86</sup> A well-known opium user himself, Jones provided one of the earliest descriptions of opioid addiction. He insisted that opium offered many benefits if the dose was moderate but that discontinuation or a decrease in dose, particularly after "leaving off after long and lavish use," would result in such symptoms as sweating, itching, diarrhea, and melancholy. His recommendation for the treatment of these withdrawal symptoms included decreasing the dose of opium by 1% each day until the drug was totally withdrawn. During this period, a number of English writers became well-known opium

addicts including Elizabeth Barrett Browning, Samuel Taylor Coleridge, and Thomas De Quincey. De Quincey, author of *Confessions of an English Opium Eater*, was an early advocate of the recreational use of opioids. The famed Coleridge poem *Kubla Khan* referred to opium as the “milk of paradise,” and De Quincey’s *Confessions* suggested that opium held the “key to paradise.” In many of these cases, the initiation of opium use for medical reasons led to recreational use, tolerance, and dependence.<sup>86</sup>

Although opium was first introduced to Asian societies by Arab physicians some time after the fall of the Roman Empire, the use of opium in Asian countries grew considerably during the 18th and 19th centuries. The growing dependence of China on opium was spurred on by the English desire to establish and profit from a flourishing drug trade.<sup>141</sup> Opium was grown in India and exported east. Despite Chinese protests and edicts against this practice, the importation of opium persisted throughout the 19th century, with the British going to war twice to maintain their right to sell opium. Not surprisingly, by the beginning of the 20th century, opium abuse in China was endemic.

In England, opium use continued to increase during the first half of the 19th century. During this period, opium was legal and freely available from the neighborhood grocer. To many, its use was considered no more problematic than alcohol use.<sup>58</sup> The Chinese usually self-administered opium by smoking, a custom that was brought to the United States by Chinese immigrants in the mid-19th century; the English use of opium was more often by ingestion, that is, “opium eating.”

The liberal use of opioids as infant-soothing xenobiotics was one of the most unfortunate aspects of this period of unregulated opioid use.<sup>87</sup> Godfrey’s Cordial, Mother’s Friend, Mrs. Winslow’s Soothing Syrup, and Quietness were among the most popular opioids for children.<sup>94</sup> They were advertised as producing a natural sleep and recommended for teething and bowel regulation, as well as for crying. Because of the wide availability of opioids during this period, the number of acute opioid overdoses in children was consequential and would remain problematic until these unsavory remedies were condemned and removed from the market.

With the discovery of morphine in 1805 and Alexander Wood’s invention of the hypodermic syringe in 1853, parenteral administration of morphine became the preferred route of opioid administration for therapeutic use and abuse.<sup>71</sup> A legacy of the generous use of opium and morphine during the US Civil War was “soldiers’ disease,” referring to a rather large veteran population that returned from the war with a lingering opioid habit.<sup>133</sup> One hundred years later, opioid abuse and addiction would again become common among US military serving during the Vietnam War. Surveys indicated that as many as 20% of American soldiers in Vietnam were addicted to opioids during the war—in part because of their widespread availability and high purity there.<sup>138</sup>

Growing concerns about opioid abuse in England led to the passing of the Pharmacy Act of 1868, which restricted the sale of opium to registered chemists. But in 1898, the Bayer Pharmaceutical Company of Germany synthesized heroin from opium and also introduced aspirin in the late 1890s.<sup>148</sup> Although initially touted as a nonaddictive morphine substitute, problems with heroin use quickly became evident in the United States. Illicit heroin use reached epidemic proportions after World War II and again in the late 1960s.<sup>72</sup> Although heroin use appeared to have leveled off by the end of the 20th century, an epidemic of prescription opioid abuse followed by a resurgence in heroin use occurred during the first years of the 21st century.<sup>85</sup>

## Cocaine

Ironically, during the later part of the 19th century, Sigmund Freud and Robert Christison, among others, promoted cocaine as a treatment for opioid addiction. After Albert Niemann’s isolation of cocaine alkaloid from coca leaf in 1860, growing enthusiasm for cocaine as a panacea ensued.<sup>80</sup> Some of the most important medical figures of the time, including William Halsted, the famed Johns Hopkins surgeon, also extolled the virtues of cocaine use. Halsted championed the anesthetic properties of this drug, although his own use of cocaine and subsequent morphine use in an attempt to overcome his cocaine dependency would later take a considerable toll.<sup>121</sup> In 1884, Freud

wrote *Über Cocaine*,<sup>27</sup> advocating cocaine as a cure for opium and morphine addiction and as a treatment for fatigue and hysteria.

During the last third of the 19th century, cocaine was added to many popular nonprescription tonics. In 1863, Angelo Mariani, a Frenchman, introduced a new wine, “Vin Mariani,” that consisted of a mixture of cocaine and wine (6 mg of cocaine alkaloid per ounce) and was sold as a digestive aid and restorative.<sup>112</sup> In direct competition with the French tonic was the American-made Coca-Cola, developed by J.S. Pemberton. It was originally formulated with coca and caffeine and marketed as a headache remedy and invigorator. With the public demand for cocaine increasing, patent medication manufacturers were adding cocaine to thousands of products. One such asthma remedy was “Dr. Tucker’s Asthma Specific,” which contained 420 mg of cocaine per ounce and was applied directly to the nasal mucosa.<sup>80</sup> By the end of the 19th century, the first American cocaine epidemic was underway.<sup>114</sup>

Similar to the medical and societal adversities associated with opioid use, the increasing use of cocaine led to a growing concern about comparable adverse effects. In 1886, the first reports of cocaine-related cardiac arrest and stroke were published.<sup>134</sup> Reports of cocaine habituation occurring in patients using cocaine to treat their underlying opioid addiction also began to appear. In 1902, a popular book, *Eight Years in Cocaine Hell*, described some of these problems. *Century Magazine* called cocaine “the most harmful of all habit-forming drugs,” and a report in *The New York Times* stated that cocaine was destroying “its victims more swiftly and surely than opium.”<sup>42</sup> In 1910, President William Taft proclaimed cocaine to be “public enemy number 1.”

In an attempt to curb the increasing problems associated with drug abuse and addiction, the 1914 Harrison Narcotics Act mandated stringent control over the sale and distribution of narcotics (defined as opium, opium derivatives, and cocaine).<sup>42</sup> It was the first federal law in the United States to criminalize the nonmedical use of drugs. The bill required doctors, pharmacists, and others who prescribed narcotics to register and to pay a tax. A similar law, the Dangerous Drugs Act, was passed in the United Kingdom in 1920.<sup>58</sup> To help enforce these drug laws in the United States, the Narcotics Division of the Prohibition Unit of the Internal Revenue Service (a progenitor of the Drug Enforcement Agency) was established in 1920. In 1924, the Harrison Act was further strengthened with the passage of new legislation that banned the importation of opium for the purpose of manufacturing heroin, essentially outlawing the medicinal uses of heroin. With the legal venues to purchase these drugs now eliminated, users were forced to buy from illegal street dealers, creating a burgeoning black market that still exists today.

## Sedative–Hypnotics

The introduction to medical practice of the anesthetics nitrous oxide, ether, and chloroform during the 19th century was accompanied by the recreational use of these anesthetics and the first reports of volatile substance abuse. Chloroform “jags,” ether “frolics,” and nitrous parties became a new type of entertainment. Humphry Davy was an early self-experimenter with the exhilarating effects associated with nitrous oxide inhalation. In certain Irish towns, especially where the temperance movement was strong, ether drinking became quite popular.<sup>107</sup> Horace Wells, the American dentist who introduced chloroform as an anesthetic, became dependent on this volatile solvent and later committed suicide.

Until the last half of the 19th century aconite, alcohol, hemlock, opium, and prussic acid (cyanide) were the primary xenobiotics used for sedation.<sup>33</sup> During the 1860s, new, more specific sedative–hypnotics, such as chloral hydrate and potassium bromide, were introduced into medical practice. In particular, chloral hydrate was hailed as a wonder drug that was relatively safe compared with opium and was recommended for insomnia, anxiety, and delirium tremens, as well as for scarlet fever, asthma, and cancer. But within a few years, problems with acute toxicity of chloral hydrate, as well as its potential to produce tolerance and physical dependence, became apparent.<sup>33</sup> Mixing chloral hydrate with ethanol, both of which inhibit each other’s metabolism by competing with alcohol dehydrogenase, was noted to produce a rather powerful “knockout” combination that would become known as a “Mickey Finn,” allegedly named after a Chicago saloon proprietor.<sup>16</sup> Abuse of chloral

hydrate, as well as other new sedatives such as potassium bromide, would prove to be a harbinger of 20th-century sedative–hypnotic abuse.

Absinthe, an ethanol-containing beverage that was manufactured with an extract from wormwood (*Artemisia absinthium*), was very popular during the last half of the 19th century.<sup>89</sup> This emerald-colored, very bitter drink was memorialized in the paintings of Degas, Toulouse-Lautrec, and Van Gogh and was a staple of French society during this period.<sup>12</sup>  $\alpha$ -Thujone, a psychoactive component of wormwood and a noncompetitive  $\gamma$ -aminobutyric acid type A (GABA<sub>A</sub> antagonist), is thought to be responsible for the pleasant feelings, hyperexcitability, and significant neurotoxicity associated with this drink.<sup>68</sup> Van Gogh's debilitating episodes of psychosis were likely exacerbated by absinthe drinking.<sup>152</sup> Because of the medical problems associated with its use, absinthe was banned throughout most of Europe by the early 20th century.

### Hallucinogens

Native Americans used peyote in religious ceremonies since at least the 17th century. Hallucinogenic mushrooms, particularly *Psilocybe* mushrooms, were also used in the religious life of Native Americans. These were called “teonanacatl,” which means “God's sacred mushrooms” or “God's flesh.”<sup>128</sup> Interest in the recreational use of cannabis also accelerated during the 19th century after Napoleon's troops brought the drug back from Egypt, where its use among the lower classes was widespread. In 1843, several French Romantics, including Balzac, Baudelaire, Gautier, and Hugo, formed a hashish club called “Le Club des Hachichins” in the Parisian apartment of a young French painter. Fitz Hugh Ludlow's *The Hashesh Eater*, published in 1857, was an early American text espousing the virtues of marijuana.<sup>97</sup>

A more recent event that had significant impact on modern-day hallucinogen use was the synthesis of lysergic acid diethylamide (LSD) by Albert Hofmann in 1938.<sup>67</sup> Working for Sandoz Pharmaceutical Company, Hofmann synthesized LSD while investigating the pharmacologic properties of ergot alkaloids. Subsequent self-experimentation by Hofmann led to the first description of its hallucinogenic effects and stimulated research into the therapeutic use of LSD. Hofmann is also credited with isolating psilocybin as the active ingredient in *Psilocybe mexicana* mushrooms in 1958.<sup>112</sup>

## TWENTIETH- AND TWENTY-FIRST-CENTURY EVENTS

### Early Regulatory Initiatives

The development of medical toxicology as a medical subspecialty and the important role of poison control centers began shortly after World War II. Before then, serious attention to the problem of household poisonings in the United States was limited to a few federal legislative antipoisoning initiatives (Table 1–4). The 1906 Pure Food and Drug Act was the first federal legislation that sought to protect the public from problematic and potentially unsafe drugs and food. The driving force behind this reform was Harvey Wiley, the chief chemist at the Department of Agriculture. Beginning in the 1880s, Wiley investigated the problems of contaminated food. In 1902, he organized the “poison squad,” which consisted of a group of volunteers who did self-experiments with food preservatives.<sup>4</sup> Revelations from the “poison squad,” as well as the publication of Upton Sinclair's muckraking novel *The Jungle*<sup>146</sup> in 1906, exposed unhygienic practices of the meatpacking industry and led to growing support for legislative intervention. Samuel Hopkins Adams' reports about the patent medicine industry revealed that some drug manufacturers added opioids to soothing syrups for infants and led to the call for reform.<sup>135</sup> Although the 1906 regulations were mostly concerned with protecting the public from adulterated food, regulations protecting against misbranded patent medications were also included.

The Federal Caustic Poison Act of 1927 was the first federal legislation to specifically address household poisoning. As early as 1859, bottles clearly demarcated “poison” were manufactured in response to a rash of unfortunate dispensing errors that occurred when oxalic acid was unintentionally substituted for a similarly appearing Epsom salts solution.<sup>28</sup> Before 1927, however, “poison” warning labels were not required on chemical containers, regardless of toxicity or availability. The 1927 Caustic Act was spearheaded

by the efforts of Chevalier Jackson, an otolaryngologist, who showed that unintentional exposures to household caustics were an increasingly frequent cause of severe oropharyngeal and GI burns. Under this statute, for the first time, alkali- and acid-containing products had to clearly display a “poison” warning label.<sup>78,154</sup>

The most pivotal regulatory initiative in the United States before World War II—and perhaps the most significant American toxicologic regulation of the 20th century—was the Federal Food, Drug, and Cosmetic Act of 1938. Although the Food and Drug Administration (FDA) had been established in 1930 and legislation to strengthen the 1906 Pure Food and Drug Act was considered by Congress in 1933, the proposed revisions still had not been passed by 1938. Then the elixir of sulfanilamide tragedy in 1938 (Chap. 2) claimed the lives of 105 people who had ingested a prescribed liquid preparation of the antibiotic sulfanilamide inappropriately dissolved in diethylene glycol. This event finally provided the catalyst for legislative intervention.<sup>109,161</sup> Before the elixir disaster, proposed legislation called only for the banning of false and misleading drug labeling and for the outlawing of dangerous drugs without mandatory drug safety testing. After the tragedy, the proposal was strengthened to require assessment of drug safety before marketing, and the legislation was ultimately passed.

### The Development of Poison Control Centers

World War II led to the rapid proliferation of new xenobiotics in the marketplace and in the household.<sup>39</sup> At the same time, suicide was recognized as a leading cause of death from these xenobiotics.<sup>9</sup> Both of these factors led the medical community to develop a response to the serious problems of unintentional and intentional poisonings. In Europe during the late 1940s, special toxicology wards were organized in Copenhagen and Budapest,<sup>59</sup> and a poison information service was begun in the Netherlands (Table 1–5).<sup>158</sup> A 1952 American Academy of Pediatrics study revealed that more than 50% of childhood “accidents” in the United States were the result of unintentional poisonings.<sup>61</sup> This study led Edward Press to open the first US poison control center in Chicago in 1953.<sup>129</sup> Press believed that it was extremely difficult for individual physicians to keep abreast of product information, toxicity, and treatment for the rapidly increasing number of potentially poisonous household products. His initial center was organized as a cooperative effort among the departments of pediatrics at several Chicago medical schools, with the goal of collecting and disseminating product information to inquiring physicians, mainly pediatricians.<sup>132</sup>

By 1957, 17 poison control centers were operating in the United States.<sup>39</sup> With the Chicago center serving as a model, these early centers responded to physician callers by providing ingredient and toxicity information about drug and household products and making treatment recommendations. Records were kept of the calls, and preventive strategies were introduced into the community. As more poison control centers opened, a second important function, providing information to calls from the general public, became increasingly common. The physician pioneers in poison prevention and poison treatment were predominantly pediatricians who focused on unintentional childhood ingestions.<sup>137</sup>

During these early years in the development of poison control centers, each center had to collect its own product information, which was a laborious and often redundant task.<sup>38</sup> In an effort to coordinate its operations and to avoid unnecessary duplication, Surgeon General James Goddard responded to the recommendation of the American Public Health Service and established the National Clearinghouse for Poison Control Centers in 1957.<sup>106</sup> This organization, placed under the Bureau of Product Safety of the Food and Drug Administration, disseminated 5-inch by 8-inch index cards containing poison information to each center to help standardize poison control center information resources. The Clearinghouse also collected and tabulated poison data from each of the centers.

Between 1953 and 1972, a rapid, uncoordinated proliferation of poison control centers occurred in the United States.<sup>103</sup> In 1962, there were 462 poison control centers. By 1970, this number had risen to 590,<sup>95</sup> and by 1978, there were 661 poison control centers in the United States, including 100 centers

TABLE 1–4 Protecting Our Health: Important US Regulatory Initiatives Pertaining to Xenobiotics

<i>Date</i>	<i>Federal Legislation</i>	<i>Intent</i>
1906	Pure Food and Drug Act	Early regulatory initiative; prohibits interstate commerce of misbranded and adulterated foods and drugs.
1914	Harrison Narcotics Act	First federal law to criminalize the nonmedical use of drugs. Taxed and regulated distribution and sale of narcotics (opium, opium derivatives, and cocaine).
1927	Federal Caustic Poison Act	Mandated labeling of concentrated caustics.
1930	Food and Drug Administration (FDA)	Established successor to the Bureau of Chemistry; promulgation of food and drug regulations.
1937	Marijuana Tax Act	Applied controls to marijuana similar to those applied to narcotics.
1938	Federal Food, Drug, and Cosmetic Act	Required toxicity testing of pharmaceuticals before marketing.
1948	Federal Insecticide, Fungicide, and Rodenticide Act	Provided federal control for pesticide sale, distribution, and use.
1951	Durham-Humphrey Amendment	Restricted many therapeutic drugs to sale by prescription only.
1960	Federal Hazardous Substances Labeling Act	Mandated prominent labeling warnings on hazardous household chemical products.
1962	Kefauver-Harris Drug Amendments	Required drug manufacturers to demonstrate efficacy before marketing.
1963	Clean Air Act	Regulated air emissions by setting maximum pollutant standards.
1966	Child Protection Act	Banned hazardous toys when adequate label warnings could not be written.
1970	Comprehensive Drug Abuse and Control Act	Replaced and updated all previous laws concerning narcotics and other dangerous drugs.
1970	Environmental Protection Agency (EPA)	Established and enforced environmental protection standards.
1970	Occupational Safety and Health Act (OSHA)	Enacted to improve worker and workplace safety. Created National Institute for Occupational Safety and Health (NIOSH) as research institution for OSHA.
1970	Poison Prevention Packaging Act	Mandated child-resistant safety caps on certain pharmaceutical preparations to decrease unintentional childhood poisoning.
1972	Clean Water Act	Regulated discharge of pollutants into US waters.
1972	Consumer Product Safety Act	Established Consumer Product Safety Commission (CPSC) to reduce injuries and deaths from consumer products.
1972	Hazardous Material Transportation Act	Authorized the Department of Transportation to develop, promulgate, and enforce regulations for the safe transportation of hazardous materials.
1973	Drug Enforcement Administration (DEA)	Successor to the Bureau of Narcotics and Dangerous Drugs; charged with enforcing federal drug laws.
1973	Lead-based Paint Poison Prevention Act	Regulated the use of lead in residential paint. Lead in some paints was banned by Congress in 1978.
1974	Safe Drinking Water Act	Set safe standards for water purity.
1976	Resource Conservation and Recovery Act (RCRA)	Authorized EPA to control hazardous waste from the “cradle to grave,” including the generation, transportation, treatment, storage, and disposal of hazardous waste.
1976	Toxic Substances Control Act	Emphasis on law enforcement. Authorized EPA to track 75,000 industrial chemicals produced or imported into the United States. Required testing of chemicals that pose environmental or human health risk.
1980	Comprehensive Environmental Response Compensation and Liability Act (CERCLA)	Set controls for hazardous waste sites. Established trust fund (Superfund) to provide cleanup for these sites. Agency for Toxic Substances and Disease Registry (ATSDR) created.
1983	Federal Anti-Tampering Act	Response to cyanide laced Tylenol deaths. Outlawed tampering with packaged consumer products.
1986	Controlled Substance Analogue Enforcement Act	Instituted legal controls on analog (designer) drugs with chemical structures similar to controlled substances.
1986	Drug-Free Federal Workplace Program	Executive order mandating drug testing of federal employees in sensitive positions.
1986	Superfund Amendments and Reauthorization Act (SARA)	Amendment to CERCLA. Increased funding for the research and cleanup of hazardous waste (SARA) sites.
1988	Labeling of Hazardous Art Materials Act	Required review of all art materials to determine hazard potential and mandated warning labels for hazardous materials.
1994	Dietary Supplement Health and Education Act	Permitted dietary supplements including many herbal preparations to bypass FDA scrutiny.
1997	FDA Modernization Act	Accelerated FDA reviews, regulated advertising of unapproved uses of approved drugs.
2002	The Public Health Security and Bioterrorism Preparedness and Response Act	Tightened control on biologic agents and toxins; increased safety of the US food and drug supply and drinking water; and strengthened the Strategic National Stockpile.
2005	Combat Methamphetamine Epidemic Act	Part of the Patriot Act, this legislation restricted nonprescription sale of the methamphetamine precursor drugs ephedrine and pseudoephedrine used in the home production of methamphetamine.
2009	Family Smoking Prevention and Tobacco Control Act	Empowered FDA to set standards for tobacco products.
2016	Comprehensive Addiction and Recovery Act (CARA)	Federal response to prescription opioid and heroin epidemic providing for expansion of medication-assisted treatment with buprenorphine and methadone and expanded use of naloxone by first responders and community members.

**TABLE 1-5** Milestones in the Development of Medical Toxicology in the United States

Year	Milestone
1952	American Academy of Pediatrics study shows that 51% of children's "accidents" are the result of the ingestion of potential poisons
1953	First US poison control center opens in Chicago
1957	National Clearinghouse for Poison Control Centers established
1958	American Association of Poison Control Centers (AAPCC) founded
1961	First Poison Prevention Week
1963	Initial call for development of regional Poison Control Centers (PCCs)
1964	Creation of European Association for PCCs
1968	American Academy of Clinical Toxicology (AACT) established
1972	Introduction of microfiche technology to poison information
1974	American Board of Medical Toxicology (ABMT) established
1978	AAPCC introduces standards of regional designation
1983	First examination given for Specialist in Poison Information (SPI)
1985	American Board of Applied Toxicology (ABAT) established
1992	Medical Toxicology recognized by American Board of Medical Specialties (ABMS)
1993	American College of Medical Toxicology established
1994	First ABMS examination in Medical Toxicology
2000	Accreditation Council for Graduate Medical Education (ACGME) approval of residency training programs in Medical Toxicology
2000	Poison Control Center Enhancement and Awareness Act
2004	Institute of Medicine (IOM) report on the future of poison control centers is released, calling for a greater integration between public health sector and poison control services

in the state of Illinois alone.<sup>143</sup> The nature of calls to centers changed as lay public-generated calls began to outnumber physician-generated calls. Recognizing the public relations value and strong popular support associated with poison control centers, some hospitals started poison control centers without adequately recognizing or providing for the associated responsibilities. Unfortunately, many of these centers offered no more than a part-time telephone service located in the back of the emergency department or pharmacy, staffed by poorly trained personnel.<sup>143</sup>

Despite the "growing pains" of these poison services during this period, many significant achievements were made. A dedicated group of physicians and other health care professionals began devoting an increasing proportion of their time to poison related matters. In 1958, the American Association of Poison Control Centers (AAPCC) was founded to promote closer cooperation between poison control centers, to establish uniform standards, and to develop educational programs for the general public and health care professionals.<sup>61</sup> Annual research meetings were held, and important legislative initiatives were stimulated by the organization.<sup>106</sup> Examples of such legislation include the Federal Hazardous Substances Labeling Act of 1960, which improved product labeling; the Child Protection Act of 1966, which extended labeling statutes to pesticides and other hazardous xenobiotics; and the Poison Prevention Packaging Act of 1970, which mandated safety packaging. In 1961, in an attempt to heighten public awareness of the dangers of unintentional poisoning, the third week of March was designated as the Annual National Poison Prevention Week.

Another organization that would become important, the American Academy of Clinical Toxicology (AACT), was founded in 1968 by a diverse group of toxicologists.<sup>34</sup> This group was "interested in applying principles of rational toxicology to patient treatment" and in improving the standards of care on a national basis.<sup>140</sup> The first modern textbooks of clinical toxicology began to appear in the mid-1950s with the publication of Dreisbach's *Handbook of Poisoning* (1955);<sup>45</sup> Gleason, Gosselin, and Hodge's *Clinical Toxicology of Commercial Products* (1957);<sup>57</sup> and Arena's *Poisoning* (1963).<sup>10</sup> Major advancements in the storage and retrieval of poison information were also instituted during these years. Information as noted earlier on consumer products initially appeared on index cards distributed regularly to poison control centers by the National Clearinghouse, and by 1978, more than 16,000 individual product cards had been issued.<sup>143</sup> The introduction of microfiche technology in 1972 enabled the storage of much larger amounts of data in much smaller spaces at the individual poison control centers. Toxifile and POISINDEX, two large drug and poison databases using microfiche technology, were introduced and gradually replaced the much more limited index card system.<sup>143</sup> During the 1980s, POISINDEX, which had become the standard database, was made more accessible by using CD-ROM technology. Sophisticated information about the most obscure xenobiotics was now instantaneously available by computer at every poison control center.

In 1978, the poison control center movement entered an important new stage in its development when the AAPCC introduced standards for regional poison control center designation.<sup>103</sup> By defining strict criteria, the AAPCC sought to improve poison control center operations significantly and to offer a national standard of service. These criteria included using poison specialists dedicated exclusively to operating the poison control center 24 hours per day and serving a catchment area of between 1 and 10 million people. Not surprisingly, this professionalization of the poison control center movement led to a rapid consolidation of services. An AAPCC credentialing examination for poison information specialists was inaugurated in 1983 to help ensure the quality and standards of poison control center staff.<sup>7</sup>

In 2000, the Poison Control Center Enhancement and Awareness Act was passed by Congress and signed into law by President Clinton. For the first time, federal funding became available to provide assistance for poison prevention and to stabilize the funding of regional poison control centers. This federal assistance permitted the establishment of a single nationwide toll-free phone number (800-222-1222) to access poison control centers. At present, 55 centers contribute data to a National Poison Database System (NPDS), which from 1983 to 2006 was known as Toxic Exposure Surveillance System (TESS). The Centers for Disease Control and Prevention (CDC) collaborates with the AAPCC to conduct real-time surveillance of these data to help facilitate the early detection of chemical exposures of public health importance.<sup>165</sup>

A poison control center movement has also grown and evolved in Europe over the past 35 years, but unlike the movement in the United States, it focused from the beginning on establishing strong centralized toxicology treatment centers.<sup>131</sup> In the late 1950s, Gaultier in Paris developed an inpatient unit dedicated to the care of poisoned patients.<sup>59</sup> In the United Kingdom, the National Poison Information Service developed at Guys Hospital in 1963 under Roy Goulding. Henry Matthew initiated a regional poisoning treatment center in Edinburgh about the same time.<sup>131</sup> In 1964, the European Association for Poison Control Centers was formed at Tours, France.<sup>59</sup>

### The Rise of Environmental Toxicology and Further Regulatory Protection from Toxic Substances

The rise of the environmental movement during the 1960s can be traced, in part, to the publication of Rachel Carson's *Silent Spring* in 1962, which revealed the perils of an increasingly toxic environment.<sup>29</sup> The movement also benefited from the new awareness by those involved with the poison movement of the growing menace of xenobiotics in the home environment.<sup>26</sup> Battery casing fume poisoning, resulting from the burning of discarded lead battery cases, and acrodynia, resulting from exposure to a variety of mercury-containing products,<sup>41</sup> both demonstrated that young children are

particularly vulnerable to low-dose exposures from certain xenobiotics. Worries about the persistence of pesticides in the ecosystem and the increasing number of chemicals introduced into the environment added to concerns of the environment as a potential source of illness, heralding a drive for additional regulatory protection.

Starting with the Clean Air Act in 1963, laws were passed to help reduce the toxic burden on our environment (Table 1–4). The establishment of the Environmental Protection Agency (EPA) in 1970 spearheaded this attempt at protecting our environment, and during the next 10 years, numerous protective regulations were introduced. Among the most important initiatives was the Occupational Safety and Health Act of 1970, which established the Occupational Safety and Health Administration (OSHA). This act mandates that employers provide safe work conditions for their employees. Specific exposure limits to toxic chemicals in the workplace were promulgated. The Consumer Product Safety Commission was created in 1972 to protect the public from consumer products that posed an unreasonable risk of illness or injury. Cancer-producing xenobiotics, such as asbestos, benzene, and vinyl chloride, were banned from consumer products as a result of these new regulations. Toxic waste disasters such as those at Love Canal, New York, and Times Beach, Missouri, led to the passing of the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, also known as the Superfund) in 1980. This fund is designed to help pay for cleanup of hazardous substance releases posing a potential threat to public health. The Superfund legislation also led to the creation of the Agency for Toxic Substances and Disease Registry (ATSDR), a federal public health agency charged with determining the nature and extent of health problems at Superfund sites and advising the US EPA and state health and environmental agencies on the need for cleanup and other actions to protect the public's health. In 2003, the ATSDR became part of the National Center for Environmental Health of the CDC.

### Medical Toxicology Comes of Age

Over the past 50 years, the primary specialties of medical toxicologists have changed. The development of emergency medicine and preventive medicine as medical specialties led to the training of more physicians with a dedicated interest in toxicology. By the early 1990s, emergency physicians accounted for more than half the number of practicing medical toxicologists. The increased diversity of medical toxicologists with primary training in emergency medicine, pediatrics, preventive medicine, or internal medicine has helped broaden the goals of poison control centers and medical toxicologists beyond the treatment of acute unintentional childhood ingestions. The scope of medical toxicology now includes a much wider array of toxic exposures, including acute and chronic, adult and pediatric, unintentional and intentional, and occupational and environmental exposures.

The development of medical toxicology as a medical subspecialty began in 1974, when the AACT created the American Board of Medical Toxicology (ABMT) to recognize physician practitioners of medical toxicology.<sup>5</sup> From 1974 to 1992, 209 physicians obtained board certification, and formal subspecialty recognition of medical toxicology by the American Board of Medical Specialties (ABMS) was granted in 1992. In that year, a conjoint subboard with representatives from the American Board of Emergency Medicine, American Board of Pediatrics, and American Board of Preventive Medicine was established, and the first ABMS-sanctioned examination in medical toxicology was offered in 1994. By 2016, a total of more than 600 physicians were board certified in medical toxicology. The American College of Medical Toxicology (ACMT) was founded in 1994 as a physician-based organization designed to advance clinical, educational, and research goals in medical toxicology. In 1999, the Accreditation Council of Graduate Medical Education (ACGME) in the United States formally recognized postgraduate education in medical toxicology, and by 2018, 27 fellowship training programs were approved. During the 1990s in the United States, some medical toxicologists began to work on establishing regional toxicology treatment centers. Adapting the European model, such toxicology treatment centers could serve as referral centers for patients requiring advanced toxicologic evaluation and treatment. Goals of such inpatient regional centers included enhancing care

of poisoned patients, strengthening toxicology training, and facilitating research. The evaluation of the clinical efficacy and fiscal viability of such programs is ongoing. More recently, an increasing number of medical toxicologists have expanded their practice into addiction medicine responding to the prescription opioid crisis.<sup>88</sup>

The professional maturation of advanced practice pharmacists and nurses with primary interests in clinical toxicology occurred over the past two decades. In 1985, the AACT established the American Board of Applied Toxicology (ABAT) to administer certifying examinations for nonphysician practitioners of medical toxicology who meet their rigorous standards.<sup>4</sup> By 2017, more than 115 toxicologists, who mostly held either a PharmD or a PhD in pharmacology or toxicology, were certified by this board.

### Recent Poisonings and Poisoners

Although accounting for just a tiny fraction of all homicidal deaths (0.16% in the United States), notorious lethal poisonings continued throughout the 20th and 21st centuries (Table 1–3).<sup>1</sup>

In England, Graham Frederick Young developed a macabre fascination with poisons.<sup>30</sup> In 1971, at age 14 years, he killed his stepmother and other family members with arsenic and antimony. Sent away to a psychiatric hospital, he was released at age 24 years, when he was no longer considered to be a threat to society. Within months of his release, he again engaged in lethal poisonings, killing several of his coworkers with thallium. Ultimately, he died in prison in 1990.

In 1978, Georgi Markov, a Bulgarian defector living in London, developed multisystem failure and died 4 days after having been stabbed by an umbrella carried by an unknown assailant. The postmortem examination revealed a pinhead-sized metal sphere embedded in his thigh where he had been stabbed. Investigators hypothesized that this sphere had most likely carried a lethal dose of ricin into the victim.<sup>37</sup> This theory was greatly supported when ricin was isolated from the pellet of a second victim who was stabbed under similar circumstances.

In 1982, deliberate tampering with nonprescription Tylenol preparations with potassium cyanide caused seven deaths in Chicago.<sup>46</sup> Because of this tragedy, packaging of nonprescription medications was changed to decrease the possibility of future product tampering.<sup>113</sup> The perpetrator(s) were never apprehended, and other deaths from nonprescription product tampering were reported in 1991.<sup>31</sup>

In 1998, Judias Buenoano, known as the “black widow,” was executed for murdering her husband with arsenic in 1971 to collect insurance money. She was the first woman executed in Florida in 150 years. The fatal poisoning had remained undetected until 1983, when Buenoano was accused of trying to murder her fiancé with arsenic and by car bombing. Exhumation of the husband's body, 12 years after he died, revealed substantial amounts of arsenic in the remains.<sup>2</sup>

Health care providers continue to be implicated in several poisoning homicides as well. An epidemic of mysterious cardiopulmonary arrests at the Ann Arbor Veterans Administration Hospital in Michigan in July and August 1975 was attributed to the homicidal use of pancuronium by two nurses.<sup>153</sup> Intentional digoxin poisoning by hospital personnel may have explained some of the increased number of deaths on a cardiology ward of a Toronto pediatric hospital in 1981, but the cause of the high mortality rate remained unclear.<sup>23</sup> In 2000, an English general practitioner Harold Shipman was convicted of murdering 15 female patients with heroin and may have murdered as many as 297 patients during his 24 year career. These recent revelations prompted calls for strengthening the death certification process, improving preservation of case records, and developing better procedures to monitor controlled drugs.<sup>70</sup>

Also in 2000, Michael Swango, an American physician, pleaded guilty to the charge of poisoning a number of patients under his care during his residency training. Succinylcholine, potassium chloride, and arsenic were used to kill his patients.<sup>151</sup> Attention to more careful physician credentialing and to maintenance of a national physician database arose from this case because the poisonings occurred at multiple hospitals across the country. Continuing concerns about health care providers acting as serial killers is

highlighted by a recent case in New Jersey in which a nurse, Charles Cullen, was found responsible for killing patients with digoxin.<sup>17</sup>

By the end of the 20th century, 24 centuries after Socrates was executed by poison hemlock, the means of implementing capital punishment had come full circle. Government-sanctioned execution in the United States again favored the use of a “state” poison—this time, employing single drug and multiple drug protocols using sodium thiopental, pentobarbital, midazolam, hydromorphone, pancuronium, and potassium chloride.<sup>81</sup>

The use of a poison to achieve political ends has again resurfaced in several incidents from the former Soviet Union and its allies. In December 2004, it was announced that the Ukrainian presidential candidate Viktor Yushchenko was poisoned with 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), a potent dioxin.<sup>149</sup> The dramatic development of chloracne over the face of this public person during the previous several months suggested dioxin as a possibly culprit. Given the paucity of reports of acute dioxin poisoning, however, it was not until laboratory tests confirmed that Yushchenko’s dioxin concentrations were more than 6,000 times normal that this diagnosis was confirmed. In another case, a former KGB agent and Russian dissident Alexander Litvinenko was murdered with polonium-210. Initially thought to be a possible case of heavy metal poisoning, Litvinenko developed acute radiation syndrome manifested by GI symptoms followed by alopecia and pancytopenia before he died.<sup>108</sup> In February 2017, the nerve agent VX was believed responsible for the death of the North Korean leader’s elder brother Kim Jong-nam.<sup>124</sup>

## Other Developments

### Medical Errors

Beginning in the 1980s, several highly publicized medication errors received considerable public attention and provided a stimulus for the initiation of change in policies and systems. Ironically, all of the cases occurred at nationally preeminent university teaching hospitals. In 1984, 18-year-old Libby Zion died from severe hyperthermia soon after hospital admission. Although the cause of her death was likely multifactorial, drug–drug interactions and the failure to recognize and appropriately treat her agitated delirium also contributed to her death.<sup>13</sup> State and national guidelines for closer house staff supervision, improved working conditions, and a heightened awareness of consequential drug–drug interactions resulted from the medical, legislative, and legal issues of this case. In 1994, a prominent health journalist for the *Boston Globe*, Betsy Lehman, was the unfortunate victim of another preventable dosing error when she inadvertently received four times the dose of the chemotherapeutic cyclophosphamide as part of an experimental protocol.<sup>83</sup> Despite treatment at a world-renowned cancer center, multiple physicians, nurses, and pharmacists failed to notice this erroneous medication order. An overhaul of the medication-ordering system was implemented at that institution after this tragic event.

Another highly publicized death occurred in 1999, when 18-year-old Jesse Gelsinger died after enrolling in an experimental gene-therapy study. Gelsinger, who had ornithine transcarbamylase deficiency, died from multiorgan failure 4 days after receiving, by hepatic infusion, the first dose of an engineered adenovirus containing the normal gene. Although this unexpected death was not the direct result of a dosing or drug–drug interaction error, the FDA review concluded that major research violations had occurred, including failure to report adverse effects with this therapy in animals and earlier clinical trials and to properly obtain informed consent.<sup>145</sup> In 2001, Ellen Roche, a 24-year-old healthy volunteer in an asthma study at John Hopkins University, developed a progressive pulmonary illness and died 1 month after receiving 1 g of hexamethonium by inhalation as part of the study protocol.<sup>150</sup> Hexamethonium, a ganglionic blocker, was once used to treat hypertension but was removed from the market in 1972. The investigators were cited for failing to indicate on the consent form that hexamethonium was experimental and not FDA approved. Calls for additional safeguards to protect patients in research studies resulted from these cases.

In late 1999, the problems of medical errors finally received the high visibility and deserved attention in the United States with the publication and

subsequent reaction to an Institute of Medicine (IOM) report suggesting that 44,000 to 98,000 fatalities each year were the result of medical errors.<sup>84</sup> Many of these errors were attributed to preventable medication errors. The IOM report focused on its findings that errors usually resulted from system faults and not solely from the carelessness of individuals.

## Toxicology in the Twenty-First Century

As new challenges and opportunities arise in the 21st century, new toxicologic disciplines have emerged such as toxicogenomics, precision medicine, and nanotoxicology.<sup>40,92,119</sup> These nascent fields constitute the toxicologic responses to rapid advances in genetics and material sciences. Toxicogenomics combines toxicology with genomics dealing with how genes and proteins respond to toxic substances. The study of toxicogenomics attempts to better decipher the molecular events underlying toxicologic mechanisms, develop predictors of toxicity through the establishment of better molecular biomarkers, and better understand genetic susceptibilities that pertain to toxic substances such as unanticipated idiosyncratic drug reactions. Applying the principles of toxicogenomics has given birth to the field of precision medicine, also known as personalized medicine. Using such an approach drug therapy may be able to be individually tailored improving the prediction of drug efficacy and safety by accounting for genomic and metabolomics factors.<sup>110</sup>

*Nanotoxicology* refers to the toxicology of engineered tiny particles, usually smaller than 100 nm. Given the extremely small size of nanoparticles, typical barriers at portals of entry may not prevent absorption or may themselves be adversely affected by the nanoparticles. Ongoing studies focus on the translocation of these particles to sensitive target sites such as the central nervous system or bone marrow (Chap. 125).<sup>119,168</sup>

## SUMMARY

- Since the dawn of recorded history, toxicology has impacted greatly on human events and our ecosystem.
- Over the millennia, although the important poisons of the day have changed to some degree, toxic xenobiotics continue to challenge our safety.
- The era of poisoners for hire may have long ago reached its pinnacle, but problems with drug abuse, intentional self-poisoning, and exposure to environmental chemicals continue to challenge us.
- Knowledge acquired by one generation is often forgotten or discarded inappropriately by the next generation, leading to a cyclical historic course.

# TOXICOLOGIC MISFORTUNES AND CATASTROPHES IN HISTORY

Paul M. Wax

Throughout history, mass poisonings have caused suffering and misfortune. From the ergot epidemics of the Middle Ages to contemporary industrial disasters, these mass events have had great political, economic, social, and environmental ramifications. Particularly within the past 100 years, as the number of toxins and potential toxins has risen dramatically, toxic disasters have become increasingly common events. The sites of some of these events—Bhopal (India), Chernobyl (Ukraine), Jonestown (Guyana), Love Canal (New York), Minamata Bay (Japan), Seveso (Italy), West Bengal (India)—have come to symbolize our increasing potential for environmental toxicity. Globalization has led to the proliferation and rapid distribution of toxic chemicals throughout the world. Many factories that store large amounts of potentially lethal chemicals are not secure. Given the increasing attention to terrorism preparedness, an appreciation of chemicals as agents of opportunity for terrorists has suddenly assumed great importance. This chapter provides an overview of some of the most consequential and historically important toxin-associated mass poisonings that represent human and environmental disasters.

## GAS DISASTERS

Inhalation of toxic gases and oral ingestions resulting in food poisoning tend to subject the greatest number of people to adverse consequences of a toxic exposure. Toxic gas exposures may be the result of a natural disaster (volcanic eruption), industrial mishap (fire, chemical release), chemical warfare, or an intentional homicidal or genocidal endeavor (concentration camp gas chamber). Depending on the toxin, the clinical presentation may be acute, with a rapid onset of toxicity (cyanide), or subacute or chronic, with a gradual onset of toxicity (air pollution).

One of the earliest recorded toxic gas disasters resulted from the eruption of Mount Vesuvius near Pompeii, Italy, in 79 A.D. (Table 2-1). Poisonous gases generated from the volcanic activity reportedly killed thousands of people.<sup>35</sup> A more recent natural disaster occurred in 1986 in Cameroon, when excessive amounts of carbon dioxide spontaneously erupted from Lake Nyos, a volcanic crater lake.<sup>19</sup> Approximately 1,700 human and countless animal fatalities resulted from exposure to this asphyxiant.

A toxic gas leak at the Union Carbide pesticide plant in Bhopal, India, in 1984 resulted in one of the greatest civilian toxic disasters in modern history.<sup>144</sup> An unintended exothermic reaction at this carbaryl-producing plant caused the release of more than 24,000 kg of methyl isocyanate. This gas was quickly dispersed through the air over the densely populated area surrounding the factory where many of the workers lived, resulting in at least 2,500 deaths and 200,000 injuries.<sup>88</sup> The initial response to this disaster was greatly limited by a lack of pertinent information about the toxicity of this chemical as well as the poverty of the residents. A follow-up study 10 years later showed persistence of small-airway obstructive disease among survivors as well as chronic ophthalmic problems.<sup>31</sup> Calls for improvement in disaster preparedness and strengthened “right-to-know” laws regarding potential toxic exposures resulted from this tragedy.<sup>50,144</sup>

The release into the atmosphere of 26 tons of hydrofluoric acid at a petrochemical plant in Texas in October 1987 resulted in 939 people seeking medical attention at nearby hospitals. Ninety-four people were hospitalized, but there were no deaths.<sup>154</sup>

More than any other single toxin, carbon monoxide is involved in the largest number of toxic disasters. Catastrophic fires, such as the Cocoanut Grove Nightclub fire in 1943, have caused hundreds of deaths at a time, many of them from carbon monoxide poisoning.<sup>37</sup> A 1990 fire deliberately started at the Happy Land Social Club in the Bronx, New York, claimed 87 victims,

including a large number of nonburn deaths,<sup>78</sup> and the 2003 fire at the Station nightclub in West Warwick, Rhode Island, killed 98 people.<sup>128</sup> Carbon monoxide poisoning was a major determinant in many of these deaths, although hydrogen cyanide gas and simple asphyxiation may have also contributed to the overall mortality.

Another notable toxic gas disaster involving a fire occurred at the Cleveland Clinic in Cleveland, Ohio, in 1929, where a fire in the radiology department resulted in 125 deaths.<sup>34</sup> The burning of nitrocellulose radiographs produced nitrogen dioxide, cyanide, and carbon monoxide gases held responsible for many of the fatalities. In 2003, at least 243 people died and 10,000 became ill after a drilling well exploded in Xiaoyang, China, releasing hydrogen sulfide and natural gas into the air.<sup>159</sup> A toxic gas cloud covered 25 square kilometers. Ninety percent of the villagers who lived in the village adjoining the gas well died.

The release of a dioxin-containing chemical cloud into the atmosphere from an explosion at a hexachlorophene production factory in Seveso, Italy

TABLE 2-1 Gas Disasters

<i>Xenobiotic</i>	<i>Location</i>	<i>Date</i>	<i>Significance</i>
Poisonous volcanic gases	Pompeii, Italy	79 A.D.	>2,000 deaths from eruption of Mt. Vesuvius
Smog (SO <sub>2</sub> )	London, England	1873	268 deaths from bronchitis
NO <sub>2</sub> , CO, CN	Cleveland Clinic, Cleveland, OH	1929	Fire in radiology department; 125 deaths
Smog (SO <sub>2</sub> )	Meuse Valley, Belgium	1930	64 deaths
CO, CN	Cocoanut Grove Lounge, Boston, Mass	1942	498 deaths from fire
CO	Salerno, Italy	1944	>500 deaths on a train stalled in a tunnel
Smog (SO <sub>2</sub> )	Donora, PA	1948	20 deaths; thousands ill
Smog (SO <sub>2</sub> )	London, England	1952	4,000 deaths attributed to the fog and smog
Dioxin	Seveso, Italy	1976	Unintentional industrial release of dioxin into environment; chloracne
Methyl isocyanate	Bhopal, India	1984	>2,500 deaths; 200,000 injuries
Carbon dioxide	Cameroon, Africa	1986	>1,700 deaths from release of gas from Lake Nyos
Hydrofluoric acid	Texas City, TX	1987	Atmospheric release; 94 hospitalized
CO, CN	Happy Land Social Club, Bronx, NY	1990	87 deaths in fire from toxic smoke
Hydrogen sulfide	Xiaoyang, China	2003	243 deaths and 10,000 became ill from gas poisoning after a gas well exploded
CO, CN	West Warwick, RI	2003	98 deaths in fire

in 1976, resulted in one of the most serious exposures to dioxin (2,3,7,8-tetrachlorodibenzo-*p*-dioxin {TCDD}).<sup>49</sup> The lethality of this xenobiotic in animals has caused considerable concern for acute and latent injury from human exposure. Although chloracne was the only significant clinical finding related to the dioxin exposure at 5-year follow-up<sup>9</sup> more recent data after 30 years suggest a positive correlation between TCDD serum concentration and cancer incidence.<sup>147</sup>

Air pollution is another source of toxic gases that causes significant disease and death. Complaints about smoky air date back to at least 1272, when King Edward I banned the burning of mineral coal.<sup>142</sup> By the 19th century, the era of rapid industrialization in England, winter “fogs” became increasingly problematic. An 1873 London fog was responsible for 268 deaths from bronchitis. Excessive smog (a portmanteau of smoke and fog) in the Meuse Valley of Belgium in 1930 and in Donora, Pennsylvania, in 1948, was also blamed for excess morbidity and mortality. In 1952, another dense sulfur dioxide-laden smog in London was responsible for 4,000 deaths.<sup>74</sup> Both the initiation of long-overdue air pollution reform in England and the passing of the 1956 Clean Air Act by Parliament resulted from this latter “fog.”

## WARFARE AND TERRORISM

Exposure to xenobiotics with the deliberate intent to inflict harm claimed an extraordinary number of victims during the 20th century (Table 2–2). During World War I, chlorine, phosgene, and the liquid vesicant mustard were used as battlefield weapons, with mustard causing approximately 80% of the chemical casualties.<sup>130</sup> Reportedly, 100,000 deaths and 1.2 million casualties were attributable to these chemical attacks.<sup>37</sup> The toxic exposures resulted in severe airway irritation, acute respiratory distress syndrome, hemorrhagic pneumonitis, skin blistering, and ophthalmic damage. Mustard was used again in the 1980s during the war between Iran and Iraq.

The Nazis used poisonous gases during World War II to commit genocide. Initially, the Nazis used carbon monoxide to kill. To expedite the killing process, Nazi scientists developed Zyklon-B gas (hydrogen cyanide gas). As many as 10,000 people per day were killed by the rapidly acting cyanide, and millions of deaths were attributable to the use of these gases.

Agent Orange was widely used as a defoliant during the Vietnam War. This herbicide consisted of a mixture of 2,4,5-trichlorophenoxy-acetic acid (2,4,5-T) and 2,4-dichlorophenoxyacetic acid (2,4-D), as well as small amounts of a contaminant, TCDD. Over the years, a large number of adverse health effects have been attributed to Agent Orange exposure. Although a 2002 Institute of Medicine study concluded that among Vietnam veterans, there was sufficient evidence to demonstrate an association between this

herbicide exposure and chronic lymphocytic leukemia, soft tissue sarcomas, non-Hodgkin lymphomas, Hodgkin disease, and chloracne,<sup>55</sup> a 2015 critical review concluded that causation has yet to be established.<sup>123</sup>

Mass exposure to the very potent organic phosphorus compound sarin occurred in March 1995, when terrorists released this chemical weapon in three separate Tokyo subway lines.<sup>104</sup> Eleven people were killed, and 5,510 people sought emergency medical evaluation at more than 200 hospitals and clinics in the area.<sup>131</sup> This calamity introduced the spectra of terrorism to the modern emergency medical services system, resulting in a greater emphasis on hospital preparedness, including planning for the psychological consequences of such events. Sarin exposure also resulted in several deaths and hundreds of casualties in Matsumoto, Japan, in June 1994.<sup>93,101</sup> During the Syrian Civil War, sarin and chlorine were used on multiple occasions.<sup>75</sup>

After the terrorist attacks on New York City in September 11, 2001, that resulted in the collapse of World Trade Center, persistent cough and increased bronchial responsiveness were noted among 8% of New York City Fire Department workers who were exposed to large amounts of dust and other particulates during the clean-up.<sup>110,111</sup> This condition, known as World Trade Center cough syndrome, is characterized by upper airway (chronic rhinosinusitis) and lower airway findings (bronchitis, asthma, or both) as well as, at times, gastroesophageal reflux dysfunction. The risk of development of hyperreactivity and reactive airways dysfunction was clearly associated with the intensity of exposure.<sup>16</sup> A World Trade Center health registry was established to investigate and care for those exposed workers who may be at increased risk for development of cancer and other chronic diseases.<sup>72,98</sup> Registry data suggest that some workers appear to be at an increased risk for development of sarcoidosis<sup>58</sup> and persistent lower respiratory tract symptoms.<sup>57</sup>

The Russian military used a mysterious “gas” to incapacitate Chechen rebels at a Moscow theatre in 2002, resulting in the deaths of more than 120 hostages. One report suggested that the gas contained a mixture of the highly potent aerosolized fentanyl derivatives carfentanil and remifentanil.<sup>115</sup> Better preparation of the rescuers with suitable amounts of naloxone might have helped prevent some of these seemingly unanticipated casualties.<sup>148</sup>

Ricin was found in several government buildings, including a mail processing plant in Greenville, South Carolina, in 2003 and the Dirksen Senate Office Building in Washington, DC, in 2004. Although no cases of ricin-associated illness ensued, increased concern was generated because the method of delivery was thought to be the mail, and irradiation procedures designed to kill microbials such as anthrax would not inactivate chemical toxins such as ricin.<sup>14,124</sup>

**TABLE 2–2** Warfare and Terrorism Disasters

Toxin	Location	Date	Significance
Chlorine, mustard gas, phosgene	Ypres, Belgium	1915–1918	100,000 dead and 1.2 million casualties from chemicals during World War I
Cyanide, Carbon Monoxide	Europe	1939–1945	Millions murdered by Zyklon-B (HCN) gas
Agent Orange	Vietnam	1960s	Contained dioxin; excess skin cancer
Mustard gas	Iraq–Iran	1982	New cycle of war gas casualties
Yet to be determined	Persian Gulf	1991	Gulf War syndrome
Sarin	Matsumoto, Japan	1994	First terrorist attack in Japan using sarin
Sarin	Tokyo, Japan	1995	Subway exposure; 5,510 people sought medical attention
Dust and other particulates	New York, NY	2001	World Trade Center collapse from terrorist air strike
Carfentanil & Remifentanil	Moscow, Russia	2002	Used by the Russian military to subdue terrorists in Moscow theater
Ricin	Washington, DC	2004	Detected in Dirksen Senate Office Building; no illness reported
Chlorine	Iraq	2007	Used against US troops and Iraqi civilians
Sarin	Syria	2013, 2017	Used against Syrian civilians

## FOOD DISASTERS

Unintentional contamination of food and drink has led to numerous toxic disasters (Table 2–3). Ergot, produced by the fungus *Claviceps purpurea*, caused epidemic ergotism as the result of eating breads and cereals made from rye contaminated by *C. purpurea*. In some epidemics, convulsive manifestations predominated, and in others, gangrenous manifestations predominated.<sup>90</sup> Ergot-induced severe vasospasm was thought to be responsible for both presentations.<sup>89,90</sup> In 994 A.D., 40,000 people died in Aquitania, France, in one such epidemic.<sup>70</sup> Convulsive ergotism was initially described as a “fire which twisted the people,” and the term “St. Anthony’s fire” (*ignis sacer*) was used to refer to the excruciating burning pain experienced in the extremities that is an early manifestation of gangrenous ergotism. The events surrounding the Salem, Massachusetts, witchcraft trials have also been attributed to the ingestion of contaminated rye. The bizarre neuropsychiatric manifestations exhibited by some of the individuals associated with this event may have been caused by the hallucinogenic properties of ergotamine, a lysergic acid diethylamide (LSD) precursor.<sup>23,84</sup>

During the last half of the 20th century, unintentional mass poisoning from food and drink contaminated with toxic chemicals became all too common. One of the more unusual poisonings occurred in Turkey in 1956 when wheat seed intended for planting was treated with the fungicide hexachlorobenzene and then inadvertently used for human consumption. Approximately 4,000 cases of porphyria cutanea tarda were attributed to the ingestion of this toxic wheat seed.<sup>125</sup>

Another example of chemical food poisoning took place in Epping, England, in 1965. In this incident, a sack of flour became contaminated with

methylenedianiline when the chemical unintentionally spilled onto the flour during transport to a bakery. Subsequent ingestion of bread baked with the contaminated flour produced hepatitis in 84 people. This outbreak of toxic hepatitis became known as Epping jaundice.<sup>63</sup>

The manufacture of polybrominated biphenyls (PBBs) in a factory that also produced food supplements for livestock resulted in the unintentional contamination of a large amount of livestock feed in Michigan in 1973.<sup>24</sup> Significant morbidity and mortality among the livestock population resulted, and increased human tissue concentrations of PBBs were reported,<sup>155</sup> although human toxicity seemed limited to vague constitutional symptoms and abnormal liver function test results.

The chemical contamination of rice oil in Japan in 1968 caused a syndrome called Yusho (“rice oil disease”). This occurred when heat-exchange fluid containing polychlorinated biphenyls (PCBs) and polychlorinated dibenzofurans (PCDFs) leaked from a heating pipe into the rice oil. More than 1,600 people developed chloracne, hyperpigmentation, an increased incidence of liver cancer, or adverse reproductive effects. In 1979 in Taiwan, 2,000 people developed similar clinical manifestations after ingesting another batch of PCB-contaminated rice oil. This latter epidemic was referred to as Yu-Cheng (“oil disease”).<sup>56</sup> These polychlorinated chemicals are very biopersistent, with follow-up testing 40 years later demonstrating blood half-lives approaching infinity in some patients.<sup>85</sup>

In another oil contamination epidemic, consumption of illegally marketed cooking oil in Spain in 1981 was responsible for a mysterious poisoning epidemic that affected more than 19,000 people and resulted in at least 340 deaths. Exposed patients developed a multisystem disorder referred to as

**TABLE 2–3** Food Disasters

Xenobiotic	Location	Date	Significance
Ergot	Aquitania, France	994 A.D.	40,000 died in the epidemic
Ergot	Salem, MA	1692	Neuropsychiatric symptoms may be attributable to ergot
Lead	Devonshire, England	1700s	Colic from cider contaminated during production
Lead	Canada	1846	134 men died during the Franklin expedition, possibly because of contamination of food stored in lead cans
Cadmium	Japan	1939–1954	Itai-Itai (“ouch-ouch”) disease
Hexachlorobenzene	Turkey	1956	4,000 cases of porphyria cutanea tarda
Methyl mercury	Minamata Bay, Japan	1950s	Consumption of organic mercury poisoned fish
Triorthocresyl phosphate	Meknes, Morocco	1959	Cooking oil adulterated with turbojet lubricant
Methylenedianiline	Epping, England	1965	Jaundice
Polychlorinated biphenyls	Japan	1968	Yusho (“rice oil disease”)
Methyl mercury	Iraq	1971	>400 deaths from contaminated grain
Polybrominated biphenyls	Michigan	1973	97% of Michigan residents contaminated through food chain
Polychlorinated biphenyls	Taiwan	1979	Yu-Cheng (“oil disease”)
Rapeseed oil (denatured)	Spain	1981	Toxic oil syndrome affected 19,000 people
Arsenic	Buenos Aires	1987	Malicious contamination of meat; 61 people underwent chelation
Arsenic	Bangladesh and West Bengal, India	1990s–present	Contaminated ground water; millions exposed; 100,000s with symptoms; greatest mass poisoning in history
Tetramine	China	2002	Snacks deliberately contaminated, resulting in 42 deaths and 300 people with symptoms
Arsenic	Maine	2003	Intentional contamination of coffee; one death and 16 cases of illness
Nicotine	Michigan	2003	Deliberate contamination of ground beef; 92 people became ill
Melamine	China	2008	50,000 hospitalized from tainted infant formula

toxic oil syndrome (or toxic epidemic syndrome), characterized by pneumonitis, eosinophilia, pulmonary hypertension, scleroderma-like features, and neuromuscular changes. Although this syndrome was associated with the consumption of rapeseed oil denatured with 2% aniline, the exact etiology was not definitively identified at the time. Subsequent investigations suggest that the fatty acid oleyl anilide may have been the putative xenobiotic.<sup>59,60,108</sup>

In 1999, an outbreak of health complaints related to consuming Coca-Cola occurred in Belgium, when 943 people, mostly children, complained of gastrointestinal (GI) symptoms, malaise, headaches, and palpitations after drinking Coca-Cola.<sup>102</sup> Many of those affected complained of an “off taste” or bad odor to the soft drink. In some of the Coca-Cola bottles, the carbon dioxide was contaminated with small amounts of carbonyl sulfide, which hydrolyzes to hydrogen sulfide, and may have been responsible for odor-triggered reactions. Mass psychogenic illness may have contributed to the large number of medical complaints because the concentrations of the carbonyl sulfide and hydrogen sulfide were very low and unlikely to cause systemic toxicity.<sup>39</sup>

Epidemics of heavy metal poisoning from contaminated food and drink have also occurred throughout history. Epidemic lead poisoning is associated with many different vehicles of transmission, including leaden bowls, kettles, and pipes. A famous 18th-century epidemic was known as the Devonshire colic. Although the exact etiology of this disorder was unknown for many years, later evidence suggested that the ingestion of lead-contaminated cider was responsible.<sup>145</sup>

Intentional chemical contamination of food may also occur. Multiple cases of metal poisoning occurred in Buenos Aires in 1987, when vandals broke into a butcher’s shop and poured an unknown amount of a 45% sodium arsenite solution over 200 kg of partly minced meat.<sup>117</sup> The contaminated meat was purchased by 718 people. Of 307 meat purchasers who submitted to urine sampling, 49 had urine arsenic concentrations of 76 to 500 mcg/dL, and 12 had urine arsenic concentrations above 500 mcg/dL (normal urine arsenic concentration is <50–100 mcg/dL).

Cases of deliberate mass poisoning have heightened concerns about food safety and security. In China in 2002, a jealous food vendor adulterated fried dough sticks, sesame cakes, and rice prepared in a rival’s snack bar by surreptitiously putting a large amount of tetramine (tetramethylene disulfotetramine) into the raw pastry material. More than 300 people who consumed these adulterated snacks became ill, and 42 died.<sup>30</sup> In Maine in 2003, a disillusioned parishioner contaminated the communal coffee pot at a church bake sale with arsenic. One victim died within 12 hours, and five others developed hypotension.<sup>156</sup> In 2003 in Michigan, 92 people became ill after ingesting contaminated ground beef deliberately contaminated with a nicotine pesticide by a supermarket employee.<sup>6</sup>

At the end of the 20th century and beginning of the 21st century, what may be the greatest mass poisoning in history occurred in Bangladesh and India’s West Bengal State<sup>33,95,112,135</sup> (Chap. 86). In Bangladesh alone, 60 million people routinely drank arsenic-contaminated ground water, and at least 220,000 inhabitants of India’s West Bengal were diagnosed with arsenic poisoning.<sup>94</sup> Symptoms reported include melanosis, depigmentation, hyperkeratosis, hepatomegaly, splenomegaly, squamous cell carcinoma, intraepidermal carcinoma, and gangrene.<sup>33</sup> In a country long plagued by dysentery, attempts to purify the water supply led to the drilling of millions of wells into the superficial water table. Unknown to the engineers, this water was naturally contaminated with arsenic, creating several thousand tube wells with extremely high concentrations of arsenic—up to 40 times the acceptable concentration. Although toxicity from arsenic-contaminated groundwater was previously reported from other areas of the world, including Argentina, China, Mexico, Taiwan (black foot disease), and Thailand, the number of people at risk in Bangladesh and West Bengal is by far the largest. A 2016 report suggests that 40 million people in Bangladesh may still be exposed to unsafe concentrations of arsenic in the water with tens of thousands of deaths per year attributed to arsenic exposure.<sup>73</sup>

Methyl mercury is responsible for several poisoning epidemics in the past half century. During the 1950s, a Japanese chemical factory that manufactured vinyl chloride and acetaldehyde routinely discharged mercury into

Minamata Bay, resulting in contamination of the aquatic food chain. An epidemic of methyl mercury poisoning ensued as the local people ate the poisoned fish.<sup>109,141</sup> Chronic brain damage, tunnel vision, deafness, and severe congenital defects were associated with this mass poisoning.<sup>109</sup> Another mass epidemic of methyl mercury poisoning occurred in Iraq in 1971, when the local population consumed homemade bread prepared from wheat seed treated with a methyl mercury fungicide.<sup>15</sup> Six thousand hospital admissions and more than 400 deaths were associated with this mass poisoning. As was the case of the hexachlorobenzene exposure in Turkey 15 years previously, the treated grain, intended for use as seed, was instead utilized as food.

From 1939 to 1954, contamination of the local water supply with the wastewater runoff from a zinc–lead–cadmium mine in Japan was believed responsible for causing Itai-Itai (“ouch-ouch”) disease, an unusual chronic syndrome manifested by extreme bone pain and osteomalacia. The local water was used for drinking and irrigation of the rice fields. Approximately 200 people who lived along the banks of the Jintsu River developed these peculiar symptoms, which were thought most likely to be caused by the cadmium.<sup>2</sup>

More than 50,000 infants were hospitalized in China in 2008 from the ill effects of melamine-contaminated powdered infant formulae.<sup>54</sup> Melamine (1,3,5-triazine–2,4,6-triamine) is a component in many adhesives, glues, plastics, and laminated products (eg, plywood, cleaners, cement, cleansers, fire-retardant paint). More than 20 Chinese companies produced the tainted formula. Analysis of these formulas found melamine concentrations as high as 2,500 ppm. Clinically, exposure to high doses of melamine has been associated with the development of nephrolithiasis, obstructive uropathy, and in some cases acute kidney failure.<sup>146</sup> Melamine contamination of pet food resulting in deaths in dogs and cats was previously reported.<sup>22</sup> The melamine disaster also demonstrates that globalization and international agribusiness may facilitate worldwide distribution of contaminated foodstuffs. After the initial reports of melamine contamination in China, investigation in the United States revealed that certain brands of cookies, biscuits, candies, and milk sold in this country were also tainted with melamine, some of which was traced to an origin in China.<sup>54</sup>

## MEDICINAL DRUG DISASTERS

Illness and death as a consequence of therapeutic drug use occur as sporadic events, usually affecting individual patients, or as mass poisoning, affecting multiple (sometimes hundreds or thousands) patients. Sporadic single-patient medication-induced tragedies usually result from errors (Chaps. 1 and 135) or unforeseen idiosyncratic reactions. Mass therapeutic drug disasters have generally occurred secondary to poor safety testing, a lack of understanding of diluents and excipients, drug contamination, or problems with unanticipated drug–drug interactions or drug toxicity (Table 2–4).

In September and October 1937, more than 105 deaths were associated with the use of one of the early sulfa preparations—elixir of sulfanilamide–Massengill—that contained 72% diethylene glycol as the vehicle for drug delivery. Little was known about diethylene glycol toxicity at the time, and many cases of acute kidney failure and death occurred.<sup>41</sup> To avoid similar tragedies in the future, animal drug testing was mandated by the Food, Drug, and Cosmetic Act of 1938.<sup>149</sup> Unfortunately, diethylene glycol continues to be sporadically used in other countries as a medicinal diluent, resulting in deaths in South Africa (1969), India (1986), Nigeria (1990), Bangladesh (1990–1992), and Haiti (1995–1996).<sup>150</sup> In 1996 in Haiti, at least 88 Haitian children died (case fatality rate of 98% for those who remained in Haiti) after ingesting an acetaminophen (APAP) elixir formulated with diethylene glycol–contaminated glycerin.<sup>103,122</sup> In Panama in 2006, glycerin contaminated with diethylene glycol found in prescription liquid cough syrup resulted in at least 121 cases of poisoning and 78 deaths (case fatality rate, 65.5%).<sup>18,114</sup> Investigators of this last outbreak discovered that the contaminated glycerin was imported to Panama from China via a European broker, demonstrating that improprieties in pharmaceutical manufacturing may have worldwide implications. In Nigeria in 2009, a tainted teething formula was responsible for 84 deaths in children.<sup>7</sup> The pharmaceutical manufacturers intended to

TABLE 2–4 Medicinal Disasters

<i>Xenobiotic</i>	<i>Location</i>	<i>Date</i>	<i>Significance</i>
Thallium	United States	1920s–1930s	Treatment of ringworm; 31 deaths
Diethylene glycol	United States	1937	Elixir of sulfanilamide; kidney failure
Thorotrast	United States	1930s–1950s	Hepatic angiosarcoma
Phenobarbital	United States	1940–1941	Contaminated sulfathiazole: 82 deaths
Diethylstilbestrol	United States, Europe	1940s–1970s	Vaginal adenocarcinomas in patients' daughters and urogenital abnormalities in sons
Stalinon	France	1954	Severe neurotoxicity from triethyltin
Clioquinol	Japan	1955–1970	Subacute myelo optic neuropathy; 10,000 symptomatic
Thalidomide	Europe	1960s	5,000 cases of phocomelia
Isoproterenol 30%	Great Britain	1961–1967	3,000 excess asthma deaths
Pentachlorophenol	United States	1967	Used in hospital laundry; nine neonates ill, two deaths
Benzyl alcohol	United States	1981	Neonatal gasping syndrome
Tylenol–cyanide	Chicago	1982	Tampering incident resulted in seven homicides
L-Tryptophan	United States	1989	Eosinophilia myalgia syndrome
Diethylene glycol	Haiti	1996	Contaminated acetaminophen elixir; kidney failure; >88 pediatric deaths
Diethylene glycol	Panama	2006	Contaminated cough preparation, causing 78 deaths
Diethylene glycol	Nigeria	2009	Contaminated teething formula, causing 84 deaths

purchase propylene glycol, a component of the teething formula, but had bought the diluent in a jerrycan instead of the original container, and the chemical contained diethylene glycol (Special Considerations: SC9).

A lesser known drug manufacturing event, also involving an early sulfa antimicrobial, occurred in 1940 to 1941, when at least 82 people died from the therapeutic use of sulfathiazole that was contaminated with phenobarbital (Luminal).<sup>136</sup> The responsible pharmaceutical company, Winthrop Chemical, produced both sulfathiazole and phenobarbital, and the contamination likely occurred during the tableting process because the tableting machines for the two medications were adjacent to each other and were used interchangeably. Each contaminated sulfathiazole tablet contained about 350 mg of phenobarbital (and no sulfathiazole), and the typical sulfathiazole dosing regimen was several tablets within the first few hours of therapy. Twenty-nine percent of the production lot was contaminated. Food and Drug Administration (FDA) intervention was required to assist with the recovery of the tablets, although 22,000 contaminated tablets were never found.<sup>136</sup>

In the early 1960s, one of the worst drug-related modern-day events occurred with the release of thalidomide as an antiemetic and sedative-hypnotic.<sup>32</sup> Its use as a sedative-hypnotic by pregnant women caused about 5,000 babies to be born with severe congenital limb anomalies.<sup>90</sup> This tragedy was largely confined to Europe, Australia, and Canada, where the drug was initially marketed. The United States was spared because of the length of time required for review and the rigorous scrutiny of new drug applications by the FDA.<sup>86</sup>

A major therapeutic drug event that did occur in the United States involved the recommended and subsequent widespread use of diethylstilbestrol (DES) for the treatment of threatened and habitual abortions. Despite the lack of convincing efficacy data, as many as 10 million Americans received DES during pregnancy or in utero during a 30-year period, until the drug was prohibited for use during pregnancy in 1971. Adverse health effects associated with DES use include increased risk for breast cancer in “DES mothers” and increased risk of a rare form of vaginal cancer, reproductive tract anomalies, and premature births in “DES daughters.”<sup>43,48</sup>

Thorotrast (thorium dioxide 25%) is an intravenous radiologic contrast medium that was widely used between 1928 and 1955. Its use was associated

with the delayed development of hepatic angiosarcomas, as well as skeletal sarcomas, leukemia, and “thorotrastomas” (malignancies at the site of extravasated thorotrast).<sup>134,151</sup>

The use of thallium to treat ringworm infections in the 1920s and 1930s also led to needless morbidity and mortality.<sup>44</sup> Understanding that thallium caused alopecia, dermatologists and other physicians prescribed thallium acetate, both as pills and as a topical ointment (Koremlu), to remove the infected hair. A 1934 study found 692 cases of thallium toxicity after oral and topical application and 31 deaths after oral use.<sup>97</sup> “Medicinal” thallium was subsequently removed from the market.

The “Stalinon affair” in France in 1954 involved the unintentional contamination of a proprietary oral medication that was marketed for the treatment of staphylococcal skin infections, osteomyelitis, and anthrax. Although it was supposed to contain diethyltin diiodide and linoleic acid, triethyltin, a potent neurotoxin and the most toxic of organotin compounds, and trimethyltin were present as impurities. Of the approximately 1,000 people who received this medication, 217 patients developed symptoms, and 102 patients died.<sup>10,17</sup>

An unusual syndrome, featuring a constellation of abdominal symptoms (pain and diarrhea) followed by neurologic symptoms (peripheral neuropathy and visual disturbances, including blindness) was experienced by approximately 10,000 Japanese people between 1955 and 1970, resulting in several hundred deaths.<sup>66</sup> This presentation, subsequently labeled subacute myelo optic neuropathy (SMON), was associated with the use of the GI disinfectant clioquinol, known in the West as Entero-Vioform and most often used for the prevention of travelers' diarrhea.<sup>100</sup> In Japan, this drug was referred to as “sei-cho-zai” (“active in normalizing intestinal function”). It was incorporated into more than 100 nonprescription medications and was used by millions of people, often for weeks or months. The exact mechanism of toxicity has not been determined, but recent investigators theorize that clioquinol may enhance the cellular uptake of certain metals, particularly zinc, and that the clioquinol–zinc chelate may act as a mitochondrial toxin, causing this syndrome.<sup>13</sup> New cases declined rapidly when clioquinol was banned in Japan.

In 1981, a number of premature neonates died with a “gasping syndrome,” manifested by severe metabolic acidosis, respiratory depression with

gassing, and encephalopathy.<sup>42</sup> Before the development of these findings, the infants had all received multiple injections of heparinized bacteriostatic sodium chloride solution (to flush their indwelling catheters) and bacteriostatic water (to mix medications), both of which contained 0.9% benzyl alcohol. Accumulation of large amounts of benzyl alcohol and its metabolite benzoic acid in the blood was thought to be responsible for this syndrome.<sup>42</sup>

In 1989 and 1990, eosinophilia-myalgia syndrome, a debilitating syndrome somewhat similar to toxic oil syndrome, developed in more than 1,500 people who had used the dietary supplement L-tryptophan.<sup>143</sup> These patients presented with disabling myalgias and eosinophilia, often accompanied by extremity edema, dyspnea, and arthralgias. Skin changes, neuropathy, and weight loss sometimes developed. Intensive investigation revealed that all affected patients had ingested L-tryptophan produced by a single manufacturer that had recently introduced a new process involving genetically altered bacteria to improve L-tryptophan production. A contaminant produced by this process probably was responsible for this syndrome.<sup>20</sup> The banning of L-tryptophan by the FDA set in motion the passage of the Dietary Supplement Health and Education Act of 1994. This legislation, which attempted to regulate an uncontrolled industry, facilitated industry marketing of dietary supplements bypassing FDA scrutiny. In 2001, the FDA loosened the restrictions on the marketing of tryptophan, which is now sold through some compounding pharmacies.

A number of pharmaceuticals previously approved by the FDA have been withdrawn from the market because of concerns about health risks.<sup>158</sup> Many

more drugs have been given “black box warnings” by the FDA because of their propensity to cause serious or life-threatening adverse effects.<sup>83</sup> Some of the withdrawn drugs were responsible for causing serious drug–drug interactions (astemizole, cisapride, mibefradil, terfenadine).<sup>96</sup> Other drugs were withdrawn because of a propensity to cause hepatotoxicity (troglitazone), anaphylaxis (bromfenac sodium), valvular heart disease (fenfluramine, dexfenfluramine), rhabdomyolysis (cerivastatin), hemorrhagic stroke (phenylpropanolamine), and other adverse cardiac and neurologic effects (ephedra, rofecoxib). One of the more disconcerting drug problems to arise was the development of cardiac valvulopathy and pulmonary hypertension in patients taking the weight-loss drug combination fenfluramine and phentermine (fen-phen) or dexfenfluramine.<sup>28,129</sup> The histopathologic features observed with this condition were similar to the valvular lesions associated with ergotamine and carcinoid syndrome. Interestingly, appetite suppressant medications, as well as ergotamine and the carcinoid syndrome, all increase available serotonin.

## ALCOHOL AND ILLICIT DRUG DISASTERS

Unintended toxic disasters have also involved the use of alcohol and other drugs of abuse (Table 2–5). Arsenical neuropathy developed in an estimated 40,000 people in France in 1828, when wine and bread were unintentionally contaminated by arsenious acid.<sup>82</sup> The use of arsenic-contaminated sugar in the production of beer in England in 1900 resulted in at least 6,000 cases of peripheral neuropathy and 70 deaths (Staffordshire beer epidemic).<sup>5</sup>

**TABLE 2–5 Alcohol and Illicit Drug Disasters**

<i>Xenobiotic</i>	<i>Location</i>	<i>Date</i>	<i>Significance</i>
Arsenious acid	France	1828	40,000 cases of polyneuropathy from contaminated wine and bread
Arsenic	Staffordshire, England	1900	Contaminated sugar used in beer production
Triorthocresyl phosphate	United States	1930–1931	Ginger Jake paralysis
Methanol	Atlanta, GA	1951	Epidemic from ingesting bootleg whiskey
Cobalt	Quebec City, Canada and others	1960s	Beer cardiomyopathy
Methanol	Jackson, MI	1979	Occurred in a prison
MPTP	San Jose, CA	1982	Illicit meperidine manufacturing resulting in drug-induced parkinsonism
Heroin heated on aluminum foil	Netherlands	1982	Spongiform leukoencephalopathy
3-Methyl fentanyl	Pittsburgh, PA	1988	“China-white” epidemic
Methanol	Baroda, India	1989	Moonshine contamination; 100 deaths
Fentanyl	New York City	1990	“Tango and Cash” epidemic
Methanol	New Delhi, India	1991	Antidiarrheal medication contaminated with methanol; >200 deaths
Methanol	Cuttack, India	1992	Methanol-tainted liquor; 162 deaths
Scopolamine	US East Coast	1995–1996	325 cases of anticholinergic poisoning in heroin users
Methanol	Cambodia	1998	>60 deaths
Opioids	United States	1999–present	Epidemic of opioid fatalities from prescription opioids and heroin with >42,420 opioid deaths in 2016
Methanol	Nicaragua	2006	800 ill, 15 blind, 45 deaths
Methanol	India	2011	>143 deaths
Methanol	Czech Republic	2012	121 ill; 41 deaths
Methanol	Libya	2013	1066 ill; 101 deaths
Methanol	Kenya	2014	Two outbreaks: 341 ill and 100 deaths; 126 ill and 26 deaths
Fentanyl and analogs	United States	2015–present	Dramatic increase in opioid deaths from fentanyl and analogs such as carfentanil

MPTP = 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine.

During the early 20th century, particularly during Prohibition, the ethanolic extract of Jamaican ginger (sold as “the Jake”) was a popular ethanol substitute in the southern and Midwestern United States.<sup>91</sup> It was sold legally because it was considered a medical supplement to treat headaches and aid digestion and was not subject to Prohibition. For years, the Jake was sold adulterated with castor oil, but in 1930, as the price of castor oil rose, the Jake was reformulated with an alternative adulterant, triorthocresyl phosphate (TOCP). Little was previously known about the toxicity of this compound, and TOCP proved to be a potent neurotoxin. From 1930 to 1931, at least 50,000 people who drank the Jake developed TOCP poisoning, manifested by upper and lower extremity weakness (“ginger Jake paralysis”) and gait impairment (“Jake walk” or “Jake leg”).<sup>91</sup> A quarter century later, in Morocco, the dilution of cooking oil with a turbojet lubricant containing TOCP caused an additional 10,000 cases of TOCP-induced paralysis.<sup>132</sup>

In the 1960s, cobalt was added to several brands of beer as a foam stabilizer. Certain local breweries in Quebec City, Canada; Minneapolis, Minnesota; Omaha, Nebraska; and Louvain, Belgium, added 0.5 to 5.5 ppm of cobalt to their beer. This resulted in epidemics of fulminant heart failure among heavy beer drinkers (named cobalt-beer cardiomyopathy).<sup>1,92</sup>

Epidemic methanol poisoning among those seeking ethanol and other inebriants is well described. In one such incident in Atlanta, Georgia, in 1951, the ingestion of methanol-contaminated bootleg whiskey caused 323 cases of methanol poisoning, including 41 deaths.<sup>21</sup> In another epidemic in 1979, 46 prisoners became ill after ingesting a methanol-containing diluent used in copy machines.<sup>137</sup>

In recent years, major mass methanol poisonings have continued to occur in developing countries, where store-bought alcohol is often prohibitively expensive. In Baroda, India, in 1989, at least 100 people died, and another 200 became ill after drinking a homemade liquor that was contaminated with methanol.<sup>4</sup> In New Delhi, India, in 1991, an inexpensive antidiarrheal medicine, advertised to contain large amounts of ethanol, was instead contaminated with methanol, causing more than 200 deaths.<sup>27</sup> The following year, in Cuttack, India, 162 people died, and an additional 448 were hospitalized after drinking methanol-tainted liquor.<sup>11</sup> A major epidemic of methanol poisoning occurred in 1998 in Cambodia, when rice wine was contaminated with methanol.<sup>3</sup> At least 60 deaths and 400 cases of illness were attributed to the methanol. In 2011 in Sangrampur, India, more than 143 died from drinking methanol-tainted bootleg alcohol.<sup>77</sup> A mass methanol poisoning in the Czech Republic in 2012 in 121 people resulted in a fatality rate of 34%.<sup>160</sup> Most recently in 2013 in Libya, more than 1,000 people were poisoned with methanol with a fatality rate of 10%, and in 2014 in Kenya, two outbreaks of methanol poisoning occurred among 341 and 126 people with fatality rates of 29% and 21% respectively.<sup>118</sup>

So-called designer drugs are responsible for several toxicologic disasters. In 1982, several injection drug users living in San Jose, California, who were attempting to use a meperidine analog, MPPP (1-methyl-4-phenyl-4-propionoxy-piperidine), developed a peculiar, irreversible neurologic disease closely resembling Parkinson disease.<sup>68</sup> Investigation revealed that these patients had unknowingly injected trace amounts of MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), which was present as an inadvertent product of the clandestine MPPP synthesis. The subsequent metabolism of MPTP to MPP<sup>+</sup> resulted in a toxic compound that selectively destroyed cells in the substantia nigra, depleting dopamine stores or products and causing severe and irreversible parkinsonism. The vigorous pursuit of the cause of this disaster led to a better understanding of the pathophysiology of parkinsonism.

Another example of a “designer drug” poisoning occurred in the New York City metropolitan area in 1991, when a sudden epidemic of opioid overdoses occurred among heroin users who bought envelopes labeled “Tango and Cash.”<sup>38</sup> Expecting to receive a new brand of heroin, the drug users instead purchased the much more potent fentanyl. Increased and unpredictable toxicity resulted from the inability of the dealer to adjust (“cut”) the fentanyl dose properly. Some purchasers presumably received little or no fentanyl, but others received potentially lethal doses.

A similar epidemic involving 3-methylfentanyl occurred in 1988 in Pittsburgh, Pennsylvania.<sup>80</sup>

At least 325 cases of anticholinergic poisoning occurred among heroin users in New York City; Newark, New Jersey; Philadelphia, Pennsylvania; and Baltimore, Maryland, from 1995 to 1996.<sup>8</sup> The “street drug” used in these cases was adulterated with scopolamine. Whereas naloxone treatment was associated with increased agitation and hallucinations, physostigmine administration resulted in resolution of symptoms. Why the heroin was adulterated was unknown, although the use of an opiate–scopolamine mixture was reminiscent of the morphine–scopolamine combination therapy known as “twilight sleep” that was extensively used in obstetric anesthesia during the early 20th century.<sup>106</sup> Another unexpected complication of heroin use was observed in the Netherlands in the 1980s, when 47 heroin users developed mutism and spastic quadriplegia that was pathologically demonstrated to be spongiform leukoencephalopathy.<sup>157</sup> In these and subsequent cases in Europe and the United States, the users inhaled heroin vapors after the heroin powder had been heated on aluminum foil, a drug administration technique known as “chasing the dragon.”<sup>64,157</sup> The exact toxic mechanism has not been elucidated.

Since 1999, an epidemic of opioid deaths has occurred in the United States. Described by the Centers for Disease Control and Prevention (CDC) as the worst drug overdose epidemic in US history,<sup>62</sup> from 1999 to 2014, the number of drug overdose deaths nearly tripled in the United States.<sup>119</sup> Drug overdose deaths now surpass the number of fatalities from motor vehicle collisions and are similar in number to the annual mortality at the height of the HIV/AIDS epidemic in the US. According to the CDC, in 2016, of the 63,632 drug overdose deaths in the United States, opioids were implicated in approximately 42,420 (66.4%) deaths.<sup>119</sup> This opioid overdose epidemic was fueled by an exponential increase in prescription opioid consumption, including a 500% increase in oxycodone consumption. Accompanying this epidemic has been a 900% increase in individuals seeking treatment for opioid use disorders.<sup>62</sup> What began as an epidemic of prescription opioid overdose deaths has now been associated with an epidemic of heroin overdose deaths as prescription opioid abusers switched to easier-to-obtain heroin as their opioid of choice. In 2015 and 2016, an increase in designer opioid overdose deaths emerged, including deaths attributed to fentanyl and fentanyl analogs such as carfentanil.<sup>121,133</sup>

## OCCUPATION-RELATED CHEMICAL DISASTERS

Unfortunately, occupation-related toxic epidemics have become increasingly common (Table 2–6). Such poisoning syndromes tend to have an insidious onset and may not be recognized clinically until years after the exposure. A specific xenobiotic may cause myriad problems, among the most worrisome being the carcinogenic and mutagenic potentials.

Although the 18th-century observations of Ramazzini and Pott introduced the concept of certain diseases as a direct result of toxic exposures in the workplace, it was not until the height of the 19th-century industrial revolution that the problems associated with the increasingly hazardous workplace became apparent.<sup>53</sup> During the 1860s, a peculiar disorder, attributed to the effects of inhaling mercury vapor, was described among manufacturers of felt hats in New Jersey.<sup>152</sup> Mercury nitrate was used as an essential part of the felting process at the time. “Hatter’s shakes” refers to the tremor that developed in an estimated 10% to 60% of hatters surveyed.<sup>152</sup> Extreme shyness, another manifestation of mercurialism, also developed in many hatters in later studies. Five percent of hatters during this period died from renal failure.

Other notable 19th-century and early 20th-century occupational tragedies included an increased incidence of mandibular necrosis (phossy jaw) among workers in the matchmaking industry who were exposed to white phosphorus,<sup>51</sup> an increased incidence of bladder tumors among synthetic dye makers who used β-naphthylamine,<sup>45</sup> and an increased incidence of aplastic anemia among artificial leather manufacturers who used benzene.<sup>127</sup> The epidemic of phossy jaw among matchmakers had a latency period of 5 years and a mortality rate of 20% and has been called the “greatest tragedy

**TABLE 2-6** Occupational Disasters

<i>Xenobiotic</i>	<i>Location</i>	<i>Date</i>	<i>Significance</i>
Polycyclic aromatic hydrocarbons	England	1700s	Scrotal cancer among chimney sweeps; first description of hydrocarbons occupational cancer
Mercury	New Jersey	Mid to late 1800s	Outbreak of mercurialism in hatters
White phosphorus	Europe	Mid to late 1800s	Phossy jaw in matchmakers
β-Naphthylamine	Worldwide	Early 1900s	Bladder cancer in dye makers
Benzene	Newark, NJ	1916–1928	Aplastic anemia among artificial leather manufacturers
Asbestos	Worldwide	20th century	Millions at risk for asbestos-related disease
Vinyl chloride	Louisville, KY	1960s–1970s	Hepatic angiosarcoma among plastics workers
Chlordecone	James River, VA	1973–1975	Neurologic abnormalities among insecticide workers
1,2-Dibromochloropropane	California	1974	Infertility among pesticide makers
Lead	Zamfara, Nigeria	2010	400 deaths in children exposed to lead from artisanal mining operation

in the whole story of occupational disease.”<sup>25</sup> The problem continued in the United States until Congress passed the White Phosphorus Match Act in 1912, which established a prohibitive tax on white phosphorus matches.

Since antiquity, occupational lead poisoning has been a constant threat. Workplace exposure to lead was particularly problematic during the 19th century and early 20th century because of the large number of industries that relied heavily on lead. One of the most notorious of the “lead trades” was the actual production of white lead and lead oxides. Palsies, encephalopathy, and deaths from severe poisoning were reported.<sup>47</sup> Other occupations that resulted in dangerous lead exposures included pottery glazing, rubber manufacturing, pigment manufacturing, painting, printing, and plumbing.<sup>79</sup> Given the increasing awareness of harm suffered in the workplace, the British Factory and Workshop Act of 1895 required governmental notification of occupational diseases caused by lead, mercury, and phosphorus poisoning, as well as of occupational diseases caused by anthrax.<sup>69</sup>

In 2010, an outbreak of fatal lead poisoning in children who were environmentally exposed to lead from an artisanal gold mining operation in Zamfara, Nigeria, was reported.<sup>46</sup> Approximately 400 deaths from lead poisoning occurred over a 3-month period. As a result of this mass lead poisoning outbreak, 1,156 children underwent chelation therapy. Of 3,180 treatment courses administered, 36% commenced with venous blood lead concentrations greater than 80 mcg/dL, and 6% had concentrations greater than 120 mcg/dL.<sup>140</sup>

Exposures to asbestos during the 20th century have resulted in continuing extremely consequential occupational and environmental disasters.<sup>29,99</sup> Even though the first case of asbestosis was reported in 1907, asbestos was heavily used in the shipbuilding industries in the 1940s as an insulating and fireproofing material. Since the early 1940s, 8 to 11 million individuals were occupationally exposed to asbestos,<sup>71</sup> including 4.5 million individuals who worked in the shipyards. Asbestos-related diseases include mesothelioma, lung cancer, and pulmonary fibrosis (asbestosis). A threefold excess of cancer deaths, primarily of excess lung cancer deaths, has been observed in asbestos-exposed insulation workers.<sup>126</sup>

The manufacture and use of a variety of newly synthesized chemicals has also resulted in mass occupational poisonings. In Louisville, Kentucky, in 1974, an increased incidence of angiosarcoma of the liver was first noticed among polyvinyl chloride polymerization workers who were exposed to vinyl chloride monomer.<sup>36</sup> In 1975, chemical factory workers exposed to the organochlorine insecticide chlordecone (Kepone) experienced a high incidence of neurologic abnormalities, including tremor and chaotic eye movements.<sup>138</sup> An increased incidence of infertility among male Californian pesticide workers exposed to 1,2-dibromochloropropane (DBCP) was noted in 1977.<sup>153</sup>

## RADIATION DISASTERS

A discussion of mass poisonings is incomplete without mention of the large number of radiation disasters that have characterized the 20th century (Table 2-7). The first significant mass exposure to radiation occurred among several thousand teenage girls and young women employed in the dial-painting industry.<sup>26</sup> These workers painted luminous numbers on watch and instrument dials with paint that contained radium. Exposure occurred by licking the paint brushes and inhaling radium-laden dust. Studies showed an increase in bone-related cancers, as well as aplastic anemia and leukemia, in exposed workers.<sup>81,107</sup>

At the time of the “watch” disaster, radium was also being sold as a nostrum touted to cure all sorts of ailments, including rheumatism, syphilis, multiple sclerosis, and sexual dysfunction. Referred to as “mild radium therapy” to differentiate it from the higher dose radium that was used in the treatment of cancer at that time, such particle-emitting isotopes were hailed as powerful natural elixirs that acted as metabolic catalysts to deliver direct energy transfusions.<sup>76</sup>

During the 1920s, dozens of patent medications containing small doses of radium were sold as radioactive tablets, liniments, or liquids. One of the most infamous preparations was Radithor. Each half-ounce bottle contained slightly more than one curie of radium (<sup>228</sup>Ra and <sup>226</sup>Ra). This radioactive

**TABLE 2-7** Radiation Disasters

<i>Xenobiotic</i>	<i>Location</i>	<i>Date</i>	<i>Significance</i>
Radium	Orange, NJ	1910s–1920s	Increase in bone cancer in dial-painting workers
Radium	United States	1920s	“Radithor” (radioactive water) sold as radium-containing patent medication
Radiation	Hiroshima and Nagasaki, Japan	1945	First atomic bombs dropped at the end of World War II; clinical effects still evident today
Radiation	Chernobyl, Ukraine	1986	Unintentional radioactive release; acute radiation sickness
Cesium	Goiania, Brazil	1987	Acute radiation sickness and radiation burns
Cesium, iodine	Fukushima, Japan	2011	Unintentional radioactive release after earthquake and tsunami

water was sold all over the world “as harmless in every respect” and was heavily promoted as a sexual stimulant and aphrodisiac, taking on the glamour of a recreational drug for the wealthy.<sup>76</sup> More than 400,000 bottles were sold. The 1932 death of Eben Byers a Radithor connoisseur, from chronic radiation poisoning drew increased public and governmental scrutiny to this unregulated radium industry and helped end the era of radioactive patent medications.<sup>76</sup>

Concerns about the health effects of radiation have continued to escalate since the dawn of the nuclear age in 1945. Long-term follow-up studies 50 years after the atomic bombings at Hiroshima and Nagasaki demonstrate an increased incidence of leukemia, other cancers, radiation cataracts, hyperparathyroidism, delayed growth and development, and chromosomal anomalies in exposed individuals.<sup>61</sup>

The unintentional nuclear disaster at Chernobyl, Ukraine, in April 1986 again forced the world to confront the medical consequences of 20th-century scientific advances that created the atomic age.<sup>40</sup> The release of radioactive material resulted in 31 deaths and the hospitalization of more than 200 people for acute radiation sickness. By 2003, the predominant long-term effects of the event appeared to be childhood thyroid cancer and psychological consequences.<sup>113</sup> In some areas of heavy contamination, the increase in childhood thyroid cancer has increased 100-fold.<sup>120</sup>

Another serious radiation event occurred in Goiânia, Brazil, in 1987 when an abandoned radiotherapy unit was opened in a junkyard and 244 people were exposed to cesium (<sup>137</sup>Cs). Of those exposed, 104 showed evidence of internal contamination, 28 had local radiation injuries, and 8 developed acute radiation syndrome. There were at least 4 deaths.<sup>105,116</sup>

In September 1999, a nuclear event at a uranium-processing plant in Japan set off an uncontrolled chain reaction, exposing 49 people to radiation.<sup>65</sup> Radiation measured outside the facility reached 4,000 times the normal ambient level. Two workers died from the effects of the radiation.

A 9.0 magnitude earthquake and tsunami in Japan in March 2011 caused equipment failure at the Fukushima Daiichi nuclear plant resulted in a release of radioactive material into the atmosphere and seawater. Nearby foodstuff and drinking water was contaminated with cesium (<sup>137</sup>Cs) and iodine (<sup>131</sup>I).<sup>139</sup> Although there were no cases of acute radiation syndrome, significant psychological and social effects resulted from this incident.<sup>87</sup>

## MASS SUICIDE BY POISON

Mass poisonings have also manifested themselves as events of mass suicide. In 1978 in Jonestown, Guyana, 911 members of the Peoples Temple died after drinking a beverage containing cyanide.<sup>12</sup> In 1997, phenobarbital and ethanol (sometimes assisted by physical asphyxiation) was the suicidal method favored by 39 members of the Heavens Gate cult in Rancho Santa Fe, California, a means of suicide recommended in the book *Final Exit*.<sup>52</sup> Apparently, the cult members committed suicide to shed their bodies in hopes of hopping aboard an alien spaceship they believed was in the wake of the Hale-Bopp comet.<sup>67</sup>

## SUMMARY

- There are significant lessons to be learned from mass poisonings.
- An understanding of the pathogenesis of these mass poisonings pertaining to drug, food, and occupational safety is critically important to prevent future disasters.
- Such events make us aware that many of the toxic xenobiotics involved are potential agents of opportunity for terrorists and nonterrorists who seek to harm others.
- Given the practical and ethical limitations in studying the effects of many specific xenobiotics in humans, lessons from these unfortunate tragedies must be fully mastered and retained for future generations.

## CASE STUDY 1

**History** Police were called to a public area where a young man was shirtless and acting bizarrely. It was a hot summer day with a temperature of 92°F (33°C) and a dew point of 75°F (24°C). The man, who appeared confused, was pacing and gesturing as if he was hallucinating. When the police approached him, he began to run away, but after a struggle, he was subdued. The paramedics were called because of his behavior. When they arrived, they found an agitated and confused man whose arms and legs were restrained and in a full-body bag. He was diaphoretic with 6 to 7 mm pupils, and he was breathing rapidly and had a pulse of 180 beats/min. Because of the restraints, no other vital signs were obtained, and the patient was transported to the emergency department (ED).

**Physical Examination** On arrival to the ED, a team of physicians, nurses, and hospital security personnel removed the patient from the body bag, restrained him, and transferred him to a hospital stretcher. An arm was held in place, and an intravenous (IV) line was administered. Blood was obtained for analysis, and midazolam (10 mg IV) was given. Within a few moments, the patient became calmer, and the following vital signs were obtained: blood pressure, 198/122 mm Hg; pulse, 188 beats/min; respiratory rate, 38 breaths/min; tympanic temperature, 104.6°F (40.3°C); oxygen saturation, 98% on room air; and glucose, 187 mg/dL. Physical examination revealed a diaphoretic young man who was mumbling incoherently and was hot to the touch. There were no signs of trauma, and his pupils were 7 mm and reactive to light. His chest was clear, and his heart rate was regular and tachycardic without extra sounds. His abdomen was soft and nontender with normal bowel sounds. A complete neurologic assessment could not be performed, as he was disoriented, distracted, and unable to follow commands. His pupils were reactive, and oculocephalic reflexes were present. Muscle tone was increased symmetrically, and reflexes were brisk, with three to four beats of clonus noted at both ankles. His toes were downgoing.

**What Is the Toxicologic Differential Diagnosis?** This patient presents with agitation, tachycardia, hypertension, hyperthermia, diaphoresis, mydriasis, and disorientation. Although this presentation

is fairly characteristic of a sympathomimetic toxic syndrome (Chaps. 3, 73, and 75) additional considerations must include alcohol and sedative-hypnotic withdrawal (Chaps. 14 and 77), hallucinogens (Chap. 79), and phencyclidine (Chap. 83). These and other etiologies for the hyperthermia are listed in [Table CS1-1](#).

**Initial Management** A rectal probe was inserted, and the patient's core temperature was noted to be 109.2°F (42.9°C). This single vital sign abnormality takes precedence over the others and requires emergent intervention, regardless of the etiology. An additional 5 mg of IV midazolam was administered (Antidotes in Depth: A26) to further control the agitation, and the patient was placed in an ice-water bath (Chap. 29). While in the bath, another 5 mg of midazolam was needed to control his behavior. One liter of 0.9 sodium chloride was infused through the peripheral IV line, and a Foley catheter was inserted, which drained a scant amount of dark yellow urine.

Within 15 minutes, the patient's core temperature fell to 101.4°F (38.6°C); he was removed from the ice bath, dried, and placed on a clean, dry stretcher. At that time, the following vital signs were obtained: blood pressure, 148/94 mm Hg; pulse, 120 beats/min; respiratory rate, 24 breaths/min; core temperature, 99.2°F (37.3°C); oxygen saturation, 96% on room air; and end-tidal carbon dioxide, 46 mm Hg.

**What Clinical and Laboratory Analyses Can Help Exclude Life-Threatening Consequences of This Patient's Presentation?** The consequences of hyperthermia include injury to many organ systems as outlined in [Table CS1-2](#). An electrocardiogram (ECG) should be obtained because it can rapidly detect critical myocardial injury and

life-threatening electrolyte abnormalities. A rapid assessment of electrolytes, kidney and liver function, coagulation status, acid-base balance, creatine kinase, troponin, and a urinalysis are all indicated. Severe abnormalities should be addressed as detected. In this case, although the urine dipstick showed the large presence of blood, no red blood cells were seen or microscopic analysis leading to a clinical suspicion of rhabdomyolysis. The patient was started on fluids at twice his maintenance requirement as well as a bicarbonate infusion (Antidotes in Depth: A5).

**Further Diagnosis and Treatment** The patient remained calm and began to answer questions a few hours later. The ECG showed sinus tachycardia with normal intervals and no pattern of injury. However, the laboratory results were remarkable for a creatinine of 3.4 mg/dL, a bicarbonate of 12 mEq/L, an anion gap of 30 mEq/L, and a creatine kinase of greater than 100,000 IU/L, compatible with an acute kidney injury to rhabdomyolysis. Although repeat electrolytes showed a rapid correction of the bicarbonate and anion gap, the creatinine continued to rise, and the creatine kinase remained greater than 100,000 IU/L. A nephrology consult was obtained because of the potential need for hemodialysis, but the patient continued to have an adequate urine output, and urine electrolytes demonstrated a retained ability to concentrate the urine.

The patient regained a normal mental status and related that the last thing he remembered was smoking crack cocaine. Over the course of one week, the creatine kinase fell, and the serum creatinine stabilized at 1.7 mg/dL. Referrals were made to an outpatient detoxification center and a primary physician, and the patient was discharged.

**TABLE CS1-1** Xenobiotics, Potentiators and Interactions Associated with Life-Threatening Hyperthermia

- Alcohol withdrawal
- Anticholinergics (atropine, antihistamines)
- Malignant hyperthermia
- Monoamine oxidase inhibitor overdose
- Neuroleptic malignant syndrome
- Oxidative phosphorylation uncouplers (dinitrophenol, salicylates)
- Phencyclidine
- Sedative-hypnotic withdrawal
- Serotonin toxicity
- Sympathomimetics (cocaine, amphetamines)
- Thyrotoxicosis factitia

**TABLE CS1-2** Major Organ System Complications of Hyperthermia

Organ System	Complication
Brain	Cerebral edema
Lungs	Acute respiratory distress syndrome
Heart	Myocardial stunning, myocardial infarction, dysrhythmias
Gastrointestinal	Hepatic injury
Kidneys	Acute kidney injury
Hematological	Coagulopathy
Muscle	Rhabdomyolysis

# INITIAL EVALUATION OF THE PATIENT: VITAL SIGNS AND TOXIC SYNDROMES

Lewis S. Nelson, Mary Ann Howland, Neal A. Lewin, Silas W. Smith,  
Lewis R. Goldfrank, and Robert S. Hoffman

For more than 200 years, American health care providers have attempted to standardize their approach to the assessment of patients. At the New York Hospital in 1865, pulse rate, respiratory rate, and temperature were incorporated into the bedside chart and called “vital signs.”<sup>9</sup> It was not until the early part of the 20th century, however, that blood pressure determination also became routine. Additional components of the present standard emergency assessment, such as oxygen saturation by pulse oximetry, capillary blood glucose, and pain severity, are sometimes considered vital signs. Although they are essential components of the clinical evaluation and are important considerations throughout this text, they are not discussed in this chapter. Similarly, invasive and noninvasive modalities for the bedside assessment of organ function, such as capnometry, focused ultrasonography, arterial Doppler analysis, arterial catheterization, and tissue oxygen saturation, are not discussed here but appear in relevant sections of this textbook.<sup>1</sup>

In the practice of medical toxicology, vital signs play an important role beyond assessing and monitoring the overall status of a patient, because they frequently provide valuable physiologic clues to the toxicologic etiology and severity of an illness. The vital signs also are a valuable parameter used to assess and monitor a patient’s response to treatment and antidotal therapy.

Table 3–1 presents the normal vital signs for various age groups. However, this broad range of values considered normal should serve merely as a guide. Only a complete assessment of a patient can determine whether or not a particular vital sign is truly clinically normal in the particular clinical setting. This table of normal vital signs is useful in assessing children because normal values for children vary considerably with age, and knowing the range of normal variation is essential. Normal rectal temperature in adults is defined as 96.8° to 100.4°F (35°–38°C), and, although less reliable, a normal oral temperature is considered 95.0° to 99.6°F (36.4°–37.5°C).

The difficulty in defining what constitutes “normal” vital signs in an emergency setting is inadequately addressed and may prove to be an impossible undertaking. Published normal values likely have little relevance for an acutely ill or anxious patient in the emergency setting, yet that is precisely the environment in which abnormal vital signs must be identified and addressed. Even in nonemergent situations, “normalcy” of vital signs depends on the clinical condition of the patient. A sleeping or comatose patient may have physiologic bradycardia, although a slow heart rate is often appropriate for this low energy requiring state. For these reasons, descriptions of vital signs as “normal” or “stable” are too nonspecific to be meaningful and therefore should never be accepted as defining normalcy in an individual patient. Conversely, no patient should be considered too agitated, too young, or too gravely ill for the practitioner to obtain a complete set of vital signs; indeed, these patients urgently need a thorough evaluation that includes all of the vital signs. Also, the vital signs must be recorded as accurately as possible, first in the prehospital setting, again, with precision and accuracy, as soon as a patient arrives in the emergency department (ED), and continuously thereafter as clinically indicated to identify trends.

Many xenobiotics affect the autonomic nervous system, which in turn affects the vital signs via the sympathetic pathway, the parasympathetic pathway, or both. Meticulous attention to both the initial and repeated determinations of vital signs is of extreme importance in identifying a pattern of changes suggesting a particular xenobiotic or group of xenobiotics. The value of serial monitoring of the vital signs is demonstrated by the patient who presents with anticholinergic toxicity and receives the antidote, physostigmine. In this situation, it is important to recognize when tachycardia

becomes bradycardia (eg, anticholinergic syndrome followed by physostigmine excess). Meticulous attention to these changes ensures that the therapeutic interventions should be modified or adjusted accordingly.

Similarly, a patient who has opioid-induced bradypnea (a decreased rate of breathing) will either normalize or develop tachypnea (an increased rate of breathing) after the administration of the opioid antagonist naloxone. The analysis becomes exceedingly complicated when that patient is potentially exposed to two or more xenobiotics, such as an opioid combined with cocaine. In this situation, the effects of cocaine become “unmasked” by the naloxone used to counteract the opioid, and the clinician must then differentiate naloxone-induced opioid withdrawal from cocaine toxicity. The assessment starts by analyzing diverse information, including vital signs, history, and physical examination.

Table 3–2 describes the most typical toxic syndromes. This table includes only vital signs that are thought to be characteristically abnormal or pathognomonic and directly related to the toxicologic effect of the xenobiotic. The primary purpose of the table, however, is to include many findings, in addition to the vital signs, that together constitute a toxic syndrome. Mofenson and Greensher<sup>8</sup> coined the term *toxidromes* from the words *toxic syndromes* to describe the groups of signs and symptoms that consistently result from particular toxins. These syndromes are usually best described by a combination of the vital signs and clinically apparent end-organ manifestations. The signs that prove most clinically useful are those involving the central nervous system (CNS; mental status), ophthalmic system (pupil size), gastrointestinal system (peristalsis), dermatologic system (skin dryness versus diaphoresis), mucous membranes (moistness versus dryness), and genitourinary system (urinary retention versus incontinence).

Table 3–2 includes some of the most important signs and symptoms and the xenobiotics most commonly responsible for these manifestations.

TABLE 3–1 Normal Vital Signs by Age<sup>a</sup>

Age	Systolic BP (mm Hg)	Diastolic BP (mm Hg)	Pulse (beats/min)	Respirations (breaths/min) <sup>b</sup>
Adult	120	80	50–90	16–24
16 years	≤120	<80	80	16–30
12 years	119	76	85	16–30
10 years	115	74	90	16–30
6 years	107	69	100	20–30
4 years	104	65	110	20–30
4 months	90	50	145	30–35
2 months	85	50	145	30–35
Newborn	65	50	145	35–40

<sup>a</sup>The normal rectal temperature is defined as 96.8°F to 100.4°F (35°–38°C) for all ages. For children 1 year of age or younger, these values are the mean values for the 50th percentile. For older children, these values represent the 90th percentile at a specific age for the 50th percentile of weight in that age group.

<sup>b</sup>These respiration values were determined in the emergency department and may be environment and situation dependent.

BP = blood pressure.

**TABLE 3-2 Toxic Syndromes**

Group	Vital Signs				Mental Status	Pupil Size	Peristalsis	Diaphoresis	Other
	BP	P	R	T					
Anticholinergics	-/↑	↑	±	↑	Delirium	↑	↓	↓	Dry mucous membranes, flush, urinary retention
Cholinergics	±	±	±	-	Normal to depressed	±	↑	↑	Salivation, lacrimation, urination, diarrhea, bronchorrhea, fasciculations, paralysis
Ethanol or sedative-hypnotics	↓	↓	↓	-/↓	Depressed, agitated	±	↓	-	Hyporeflexia, ataxia
Opioids	↓	↓	↓	↓	Depressed	↓	↓	-	Hyporeflexia
Serotonin toxicity	↑	↑	-/↑	-/↑	Normal to agitated delirium	-/↑	↑	↑	Clonus, tremor, seizures
Sympathomimetics	↑	↑	↑	↑	Agitated	↑	-/↑	↑	Tremor, seizures diaphoresis
Withdrawal from ethanol or sedative-hypnotics	↑	↑	↑	↑	Agitated, disoriented hallucinations	↑	↑	↑	Tremor, seizures diaphoresis
Withdrawal from opioids	↑	↑	-	-	Normal, anxious	↑	↑	↑	Vomiting, rhinorrhea, piloerection, diarrhea, yawning

↑ = increases; ↓ = decreases; ± = variable; - = change unlikely; BP = blood pressure; P = pulse; R = respirations; T = temperature.

A detailed analysis of each sign, symptom, and toxic syndrome can be found in the pertinent chapters throughout the text. In this chapter, the most typical toxic syndromes are considered to enable the appropriate assessment and differential diagnosis of a poisoned patient.

In considering a toxic syndrome, the reader should always remember that the actual clinical manifestations of a poisoning are far more variable than the syndromes described in Table 3-2. The concept of the toxic syndrome is most useful when thinking about a clinical presentation and formulating a framework for assessment. Although some patients present in a “classic” fashion, others manifest partial toxic syndromes or formes frustes. These incomplete syndromes still provide at least a clue to the correct diagnosis. It is important to understand that incomplete or atypical presentations (particularly in the presence of multiple xenobiotics) do not necessarily imply less severe disease and, therefore, are comparably important to appreciate.

In some instances, an unexpected combination of findings is particularly helpful in identifying a xenobiotic or a combination of xenobiotics. For example, a dissociation between such typically paired changes as an increase in pulse with a decrease in blood pressure (cyclic antidepressants or phenothiazines) or the presentation of a decrease in pulse with an increase in blood pressure (ergot alkaloids) may be extremely helpful in diagnosing a toxic etiology. The use of these unexpected or atypical clinical findings is demonstrated in Chap. 16.

**BLOOD PRESSURE**

Xenobiotics cause hypotension by four major mechanisms: decreased peripheral vascular resistance, decreased myocardial contractility, dysrhythmias, and depletion of intravascular volume. Many xenobiotics initially cause orthostatic hypotension without marked supine hypotension, and any xenobiotic that affects autonomic control of the heart or peripheral capacitance vessels may lead to orthostatic hypotension (Table 3-3). Hypertension from xenobiotics is caused by CNS sympathetic overactivity, increased myocardial contractility, increased peripheral vascular resistance, or a combination thereof.

Blood pressure and pulse rate may vary significantly as a result of changes in receptor responsiveness, degree of physical fitness, and degree of vascular elasticity. Changing patterns of blood pressure often assist in the diagnostic evaluation: overdose with a monoamine oxidase inhibitor characteristically causes an initial normal blood pressure followed by hypertension, which in turn is followed abruptly by severe hypotension (Chap. 71).

**PULSE RATE**

Extremely useful clinical information can be obtained by evaluating the pulse rate (Table 3-4 and Chap. 16). Although the carotid artery is usually easily palpable, for reasons of both safety and reliability, the brachial artery is preferred in infants and the radial artery in adults older than 60 years. The normal heart rate for adults was defined by consensus studies suggesting that 95% of the population has bradycardia and tachycardia thresholds of 50 beats/min and 90 beats/min, making absolute definitions unrealistic, particularly in the ED.

**TABLE 3-3 Common Xenobiotics That Affect the Blood Pressure<sup>a</sup>**

Hypotension	Hypertension
α <sub>1</sub> -Adrenergic antagonists	α <sub>1</sub> -Adrenergic agonists
α <sub>2</sub> -Adrenergic agonists (central)	α <sub>2</sub> -Adrenergic agonists (central) (early)
β-Adrenergic antagonists	α <sub>2</sub> -Adrenergic antagonists
β <sub>2</sub> -Adrenergic agonists	Ergot alkaloids
Angiotensin-converting enzyme inhibitors	Ethanol and sedative-hypnotic withdrawal
Angiotensin receptor blockers	Lead (chronic)
Antidysrhythmics	Monoamine oxidase inhibitors (overdose early and drug-food interaction)
Calcium channel blockers	Nicotine (early)
Cyanide	Phencyclidine
Cyclic antidepressants	Sympathomimetics
Ethanol and other alcohols	
Iron	
Methylxanthines	
Nitrates and nitrites	
Nitroprusside	
Opioids	
Phenothiazines	
Phosphodiesterase-5 inhibitors	
Sedative-hypnotics	

<sup>a</sup>Chapter 16 lists additional xenobiotics that affect hemodynamic function.

TABLE 3–4 Common Xenobiotics That Affect the Pulse Rate<sup>a</sup>

Bradycardia	Tachycardia
α <sub>2</sub> -Adrenergic agonists (central)	α <sub>1</sub> -Adrenergic antagonists
β-Adrenergic antagonists	Anticholinergics
Baclofen	Antipsychotics
Calcium channel blockers (nondihydropyridine)	β-Adrenergic agonists
Carbamates	Cyclic antidepressants
Cardioactive steroids	Disulfiram–ethanol interaction
Ciguatoxin	Ethanol and sedative–hypnotic withdrawal
Ergot alkaloids	Iron
γ-Hydroxybutyric acid	Methylxanthines
Opioids	Phencyclidine
Organic phosphorus compounds	Sympathomimetics
Synthetic cannabinoids	Thyroid hormone
	Thiamine deficiency
	Yohimbine

<sup>a</sup>Chapter 16 lists additional xenobiotics that affect the heart rate.

Because pulse rate is the net result of a balance between sympathetic (adrenergic) and parasympathetic (muscarinic and nicotinic) tone, many xenobiotics that exert therapeutic or toxic effects or cause pain syndromes, hyperthermia, or volume depletion also affect the pulse rate. Whereas hypotension, such as that related to vasodilation or hypovolemia, generally leads to a reflex tachycardia, abrupt hypertension occasionally causes reflex bradycardia. Additionally, there is a direct correlation between pulse rate and temperature in that pulse rate increases approximately 8 beats/min for each 1.8°F (1°C) elevation in temperature.<sup>7</sup>

The inability to differentiate easily between sympathomimetic and anticholinergic xenobiotic effects by vital signs alone illustrates the principle that no single vital sign abnormality can definitively establish a toxicologic diagnosis. In trying to differentiate between a sympathomimetic and anticholinergic toxic syndrome, it should be understood that although tachycardia commonly results from both sympathomimetic and anticholinergic xenobiotics, when tachycardia is accompanied by diaphoresis or increased bowel sounds, sympathomimetic toxicity is suggested, but when tachycardia is accompanied by decreased sweating, absent bowel sounds, and urinary retention, anticholinergic toxicity is likely.

## RESPIRATORY RATE

Establishment of an airway and evaluation of respiratory status are the initial priorities in patient stabilization. Although respirations are typically assessed initially for rate alone, careful observation of the depth and pattern is essential (Table 3–5) for establishing the etiology of a systemic illness or toxicity.<sup>3</sup> Unfortunately, very few investigators have actually measured

TABLE 3–5 Common Xenobiotics That Affect Respiration<sup>a</sup>

Bradypnea	Tachypnea
α <sub>2</sub> -Adrenergic agonists (central)	Cyanide
Botulinum toxin	Dinitrophenol and congeners
Carbamates	Epinephrine
Elapidae venom	Ethylene glycol
Ethanol and other alcohols	Hydrogen sulfide
γ-Hydroxybutyric acid	Methanol
Magnesium	Methemoglobin producers
Neuromuscular blockers	Methylxanthines
Opioids	Nicotine (early)
Organic phosphorus compounds	Pulmonary irritants
Sedative–hypnotics	Salicylates
Tetanospasmin	Sympathomimetics
Tetrodotoxin	

<sup>a</sup>Chapter 28 lists additional xenobiotics affecting respiratory rate.

the respiratory rate in large populations of normal people, let alone in ED patients. Two papers investigating respiratory rates in ED patients differ substantially in their determinations of normal ranges from the remainder of the literature.<sup>4,5</sup> The combined results of these investigations suggest “normal” respiratory rates are 16 to 24 breaths/min in adults with more rapid rates that are inversely related to age in children.

Hyperventilation means an increase in minute ventilation above normal and it may result from tachypnea, hyperpnea or both. Tachypnea can also produce hypoventilation. When hyperventilation results solely or predominantly from hyperpnea, clinicians may miss this important finding entirely, instead erroneously describing such a hyperventilating patient as normally ventilating or even *hypoventilating* if bradypnea is also present. The ventilatory status of the patient must be viewed in the context of the patient’s physiologic condition. Even in patients admitted to an intensive care unit and therefore with a high likelihood of illness, the sensitivity of clinical assessment on the ability to predict severe respiratory dysfunction was only 70%.<sup>11</sup>

Hyperventilation results from the direct effect of a CNS stimulant, such as salicylates, on the brainstem. However, salicylate poisoning characteristically produces hyperventilation by tachypnea, but it also produces hyperpnea with or without tachypnea. Metabolic acidosis, whether of a toxicologic etiology or not, typically results in an attempt by the patient to normalize her or his blood pH through hyperventilation. Pulmonary injury from any source, including aspiration of gastric contents, may lead to hypoxemia with a resultant tachypnea. Later, tachypnea may change to bradypnea, hypopnea (shallow breathing), or both. Bradypnea may occur when a CNS depressant acts on the brainstem. A progression from fast to slow breathing may also occur in a patient exposed to increasing concentrations of cyanide or carbon monoxide.

## TEMPERATURE

Temperature evaluation and control are critical, yet our ability to recognize abnormal temperatures by clinical examination is limited.<sup>6</sup> However, temperature assessment can be done only if safe and reliable equipment is used. The risks of inaccuracy are substantial when an oral temperature is taken in a tachypneic patient, an axillary temperature or a temporal artery temperature is taken in any patient (especially those found outdoors), or a tympanic temperature is taken in a patient with cerumen impaction.<sup>10</sup> Obtaining rectal temperatures using a nonglass probe is essential for safe and accurate temperature determinations in agitated individuals and is considered the standard method of temperature determination in this textbook. Although concerns for infection control have limited the use of rectal temperatures, screening by other routes is acceptable, but rectal temperature assessments remain the most accurate.<sup>10</sup> Rectal temperatures should be obtained when the temperature obtained by another route is not consistent with the expected clinical findings.

The core temperature or deep internal temperature (T) is relatively stable (98.6° ± 1.08°F; 37° ± 0.6°C) under normal physiologic circumstances. Hypothermia (T <95.0°F; <35°C) and hyperthermia (T >100.4°F; >38°C) are common manifestations of toxicity. Severe or significant hypothermia and hyperthermia, unless immediately recognized and managed appropriately, may result in grave complications and inappropriate or inadequate resuscitative efforts. Life-threatening hyperthermia (T >106°F; >41.1°C) from any cause may lead to extensive rhabdomyolysis, myoglobinuric kidney failure, and direct liver and brain injury and must therefore be identified and corrected immediately.

Hyperthermia often results from a distinct neurologic response to a signal demanding thermal “upregulation.” This signal can be from internal generation of heat beyond the capacity of the body to dissipate heat, such as occurs in association with agitation or mitochondrial uncoupling, or from an externally imposed physical or environmental factor, such as the environmental conditions causing heat stroke or the excessive swaddling in clothing causing hyperthermia in infants. Fever, or pyrexia, is hyperthermia caused by an elevation in the hypothalamic thermoregulatory setpoint.<sup>2</sup>

Regardless of etiology, core temperatures higher than 106°F (41.1°C) are extremely rare unless normal feedback mechanisms are overwhelmed.

**TABLE 3–6 Common Xenobiotics that Affect Temperature<sup>a</sup>**

Hyperthermia	Hypothermia
Anticholinergics	$\alpha_2$ -Adrenergic agonists (central)
Chlorophenoxy herbicides	Anesthetics (general and intravenous)
Dinitrophenol and congeners	Cannabinoids
Malignant hyperthermia	Carbon monoxide
Monoamine oxidase inhibitors	Ethanol
Neuroleptic malignant syndrome	$\gamma$ -Hydroxybutyric acid
Phencyclidine	Hypoglycemics
Salicylates	Opioids
Sedative–hypnotic or ethanol withdrawal	Sedative–hypnotics
Serotonin toxicity	(particularly barbiturates)
Sympathomimetics	Thiamine deficiency
Thyroid hormone	

<sup>a</sup>Chapter 29 lists additional xenobiotics that affect temperature.

Hyperthermia of this extreme nature is usually attributed to environmental heat stroke, extreme psychomotor agitation, or xenobiotic-related temperature disturbances such as malignant hyperthermia, serotonin toxicity, or the neuroleptic malignant syndrome. Numerous medications (anticholinergics, antiepileptics, antihistamines, antihypertensives, antipsychotics and diuretics) can also complicate or contribute to environmental hyperthermia. Xenobiotics, such as ethanol, CNS depressants, and general anesthetics, that render humans poikilothermic—in which body temperature approaches the ambient environmental temperature—present a particular risk. A hot environment, in combination with CNS alteration that precludes movement to a safe locale, requires external monitoring and interventions to address the significant patient temperature excursions that occur.

A common xenobiotic-related hyperthermia pattern that frequently occurs in the ED is the cooling that occurs after an acute temperature elevation resulting from psychomotor agitation or a grand mal seizure. **Table 3–6** is a representative list of xenobiotics that affect body temperature. (Chap. 29 provides greater detail.)

Hypothermia is probably less of an immediate threat to life than hyperthermia, but it requires rapid appreciation, accurate diagnosis, and skilled management because it may suggest energy failure. Hypothermia impairs the metabolism of many xenobiotics, leading to unpredictable delayed and/or prolonged toxicologic effects when the patient is warmed. Many xenobiotics that lead to an alteration of mental status or poikilothermia place patients at great risk for becoming concerningly hypothermic from exposure to cold

climates. Most important, a hypothermic patient should never be declared dead without both an extensive assessment and a full resuscitative effort of adequate duration, taking into consideration the difficulties in resuscitating cold but living patients. This is true whenever the body temperature remains less than 95.0°F (36°C) (Chap. 29).

## SUMMARY

- Early, accurate determinations followed by serial monitoring of the vital signs are as essential in medical toxicology as in any other type of emergency or critical care medicine.
- Careful observation of the vital signs helps to determine appropriate therapeutic interventions and guide the clinician in making necessary adjustments to initial and subsequent therapeutic interventions.
- When pathognomonic clinical and laboratory findings are combined with accurate initial and sometimes changing vital signs, a toxic syndrome may become evident, which aids in both general supportive and specific antidotal treatment.
- Correct identification of toxic syndromes also guides further diagnostic testing.

## CASE STUDY 2

**History** A 22-year-old man was brought to the emergency department after being found unconscious at a movie theater. In the field, the paramedics inserted an intravenous (IV) line, performed a rapid reagent glucose test that was recorded as 88 mg/dL, and administered oxygen via nasal cannula at 4 L/min when his room air pulse oximetry was determined to be 91%. The patient had no medical records at the receiving hospital, and no useful information was found among his belongings.

**Physical Examination** On arrival at the ED, the patient was unconscious, with no response to physical stimuli. Vital signs were: blood pressure, 92/56 mm Hg; pulse, 52 beats/min; respiratory rate, 10 breaths/min; temperature, 97.4°F (36.3°C) {rectal}; and oxygen saturation, 98% on 4 L O<sub>2</sub>/min. A repeat rapid reagent glucose was unchanged. Examination was notable for 2- to 3-mm pupils that responded to light, normal oculocephalic testing, nearly flaccid muscle tone, and downgoing toes bilaterally. His head was without signs of trauma, and his neck was supple. Examination of the chest revealed scattered coarse breath sounds and a regular heart rhythm with normal heart sounds and no murmurs. The abdomen was soft, bowel sounds were present, and no abnormalities were noted on the skin or extremities. When oxygen was removed, his saturation fell to 92%, and a continuous end-tidal CO<sub>2</sub> monitor measured 48 mm Hg.

**Immediate Management** Given the patient's hypoventilation and small pupils, graded doses of naloxone were given (0.04, 0.1, and 2 mg IV) without response (Antidotes in Depth: A4). On further examination, the patient's gag reflex was absent, prompting endotracheal intubation, which was performed without medications, and the patient was attached to a mechanical ventilator. A postintubation arterial blood gas, a complete blood count, electrolytes, and ethanol and acetaminophen (APAP) concentrations were obtained. Electrocardiography (ECG) showed sinus bradycardia with normal axis and intervals, and normal ST segments and

T-waves were observed. A total of 1 L of 0.9% sodium chloride was infused, and his blood pressure increased to 102/60 mm Hg, with no change in his pulse. A nasogastric tube was inserted through which 60 g of activated charcoal was instilled into the stomach.

**What Is the Differential Diagnosis?** This patient was comatose, with remarkable vital signs (hypotension, bradycardia, and hypoventilation) and remarkable physical findings (miosis, coma, flaccid muscles). The differential diagnosis is extensive and includes many xenobiotics from diverse chemical classes. The most common causes are listed in **Table CS2-1**. In many cases, it is not necessary to establish the correct diagnosis but rather to exclude diagnoses that require specialized care or are amenable to specific interventions.

**What Clinical and Laboratory Analyses Help Exclude Life-Threatening Causes of This Patient's Presentation?** Either a rapid reagent glucose determination should be obtained or hypertonic dextrose should be administered in every comatose patient (Chaps. 3 and 4 and Antidotes in Depth: A1 and A8). A normal blood glucose concentration or failure to respond to an appropriate dose of hypertonic dextrose essentially excludes persistent hypoglycemia. When hypoventilation is present, a graded trial of naloxone is indicated recognizing that patients who have overdosed on clonidine and similarly acting antihypertensives may respond

(Antidotes in Depth: A4). A screening ECG is essential and may guide diagnosis and management (Chap. 15). Prolongation of the QRS complex occurs with some antidepressants, antipsychotics, and antiepileptics, and it may indicate the need to administer hypertonic sodium bicarbonate (Antidotes in Depth: A5). In addition, prolongation of the QT interval is commonly recognized with many antipsychotic and antidepressant overdoses (Chaps. 67 and 68). Although metabolic acidosis with an elevated anion gap is not typical of the xenobiotics listed, it might be indicative of a serious coingestant. Similarly, coma is not expected after a typical APAP overdose, but APAP is commonly ingested and coformulated with sedatives and opioids.

When a patient presents with coma, mildly abnormal vital signs, and flaccid muscles and if ECG results and glucose, oxygenation, anion gap, and APAP are normal or can be corrected, then the patient will likely do well with supportive care.

**Further Diagnosis and Treatment** The arterial blood gas and electrolytes showed no evidence of acidosis and a normal anion gap and a normal osmol gap. Other than bradycardia, the ECG was normal. The serum APAP concentration was 162 mcg/mL. Because the time of ingestion was unknown, *N*-acetylcysteine (NAC) was initiated (Antidotes in Depth: A3). After some time, a family member was contacted who disclosed that the patient had several previous suicide attempts and was known to be taking phenobarbital. A serum phenobarbital concentration was obtained on original blood in the laboratory and was reported to be 132 mcg/mL. A bicarbonate infusion was started to alkalinize the urine of the patient (Antidotes in Depth: A5). A 21-hour NAC regimen was completed at which time the patient's APAP was not detectable, and the aminotransferases were within normal limits. Over the next 48 hours, the patient regained consciousness and was extubated. A consultation with a psychiatrist determined the need for involuntary hospitalization, and the patient was transferred to the psychiatric service.

**TABLE CS2-1** Common Causes of Coma with Limited Abnormalities in Vital Signs and the Physical Examination

Antidepressants	Ethanol and other toxic alcohols (early)
Antiepileptics	Gabapentin and pregabalin
Antipsychotics	γ-Hydroxybutyric acid
Baclofen	Inhalants
Clonidine and other centrally acting α-adrenergic agonists	Insulin secretagogues Sedative-hypnotics

# PRINCIPLES OF MANAGING THE ACUTELY POISONED OR OVERDOSED PATIENT

Lewis S. Nelson, Mary Ann Howland, Neal A. Lewin, Silas W. Smith,  
Lewis R. Goldfrank, and Robert S. Hoffman

## OVERVIEW

For more than 5 decades, medical toxicologists and poison information specialists have used a clinical approach to poisoned or overdosed patients that emphasizes treating the patient rather than treating the poison.<sup>3</sup> Too often in the past, patients were initially ignored while attention was focused on the ingredients listed on the containers of the product(s) to which they presumably were exposed. Although astute clinicians must always be prepared to administer a specific antidote immediately in instances when nothing else will save a patient, such as with cyanide poisoning,<sup>7</sup> all poisoned or overdosed patients benefit from an organized, rapid clinical management plan (Fig. 4-1). However, clinicians should use caution when applying management advice from compendia and other non-toxicologic-specific sources because they may contain serious discrepancies with current standard expert advice.<sup>2,10</sup> Consultation with a poison control center or a medical or clinical toxicologist should be obtained if any questions or concerns arise about the management of a potentially poisoned or exposed patient.

Over the past 5 decades, some tenets and long-held beliefs regarding the initial therapeutic interventions in toxicologic management have been questioned and subjected to an “evidence-based” analysis. For example, in the mid-1970s, most medical toxicologists began to advocate a standardized approach to a comatose and possibly poisoned adult patient, typically calling for the intravenous (IV) administration of 50 mL of dextrose 50% in water (D<sub>50</sub>W), 100 mg of thiamine, and 2 mg of naloxone along with 100% oxygen at high flow rates. The rationale for this approach was to compensate for the previously idiosyncratic style of management encountered in different health care settings. It was not unusual then to discover from a laboratory chemistry report more than 1 hour after a supposedly overdosed comatose patient had arrived in the emergency department (ED) that the patient had hypoglycemia—a critical delay in the management of unsuspected and consequently untreated hypoglycemic coma. Today, however, with the widespread availability of accurate rapid bedside testing for capillary blood glucose, pulse oximetry for oxygen saturation, and end-tidal CO<sub>2</sub> monitors coupled with a much greater appreciation by all physicians of what needs to be done for each suspected overdose patient, clinicians can safely provide a more rational, individualized approach to determine the need for, and in some instances more precise amounts of, dextrose, thiamine, naloxone, and oxygen.

A second major approach to providing more rational individualized early treatment for patients with toxicologic emergencies involves a closer examination of the actual risks and benefits of various gastrointestinal (GI) decontamination interventions. Appreciation of the potential for significant adverse effects associated with all types of GI decontamination interventions and recognition of the absence of clear evidence-based support of efficacy have led to abandoning of syrup of ipecac-induced emesis, an almost complete elimination of orogastric lavage, and a significant reduction in the routine use of activated charcoal. The value of whole-bowel irrigation (WBI) with polyethylene glycol electrolyte solution (PEG-ELS) appears to be much more specific and limited than originally thought, and some of the limitations and (uncommon) adverse effects of activated charcoal are now more widely recognized (Chap. 5). However, as with many issues in clinical medicine, properly selected procedures performed in properly selected patients can lead to an acceptable risk benefit profile, and blanket elimination of these GI decontamination procedures is not optimal and will lead to suboptimal care.

Similarly, interventions to eliminate absorbed xenobiotics from the body are now much more narrowly defined or, in some cases, have been abandoned. Multiple-dose activated charcoal (MDAC) is useful for select but not all xenobiotics. Ion trapping in the urine is only beneficial, achievable, and relatively safe when the urine can be maximally alkalinized after a significant salicylate or phenobarbital exposure (Antidotes in Depth: A5 and Table A5-1). Finally, the roles of hemodialysis, hemoperfusion, and other extracorporeal techniques are now much more specifically defined.<sup>5</sup> With the foregoing in mind, this chapter represents our current efforts to formulate a logical and effective approach to managing a patient with probable or actual toxic exposure.

The management of most patients with toxicologic clinical syndromes cannot be based on specific antidotal therapies but rather relies on the application of directed supportive or pharmacologic care. These forms of care include the extension of therapies from the management of related clinical syndromes caused by other xenobiotics or from other nontoxicologic etiologies. Examples include the use of vasopressors to manage hypotension from dihydropyridine calcium channel blockers and the use of anticonvulsants benzodiazepines to manage bupropion induced seizures. Table 4-1 provides a recommended stock list of antidotes and therapeutics for the treatment of poisoned or overdosed patients (Special Considerations: SC1). Consensus antidote stocking guidelines exist as well.<sup>4</sup>

## MANAGING ACUTELY POISONED OR OVERDOSED PATIENTS

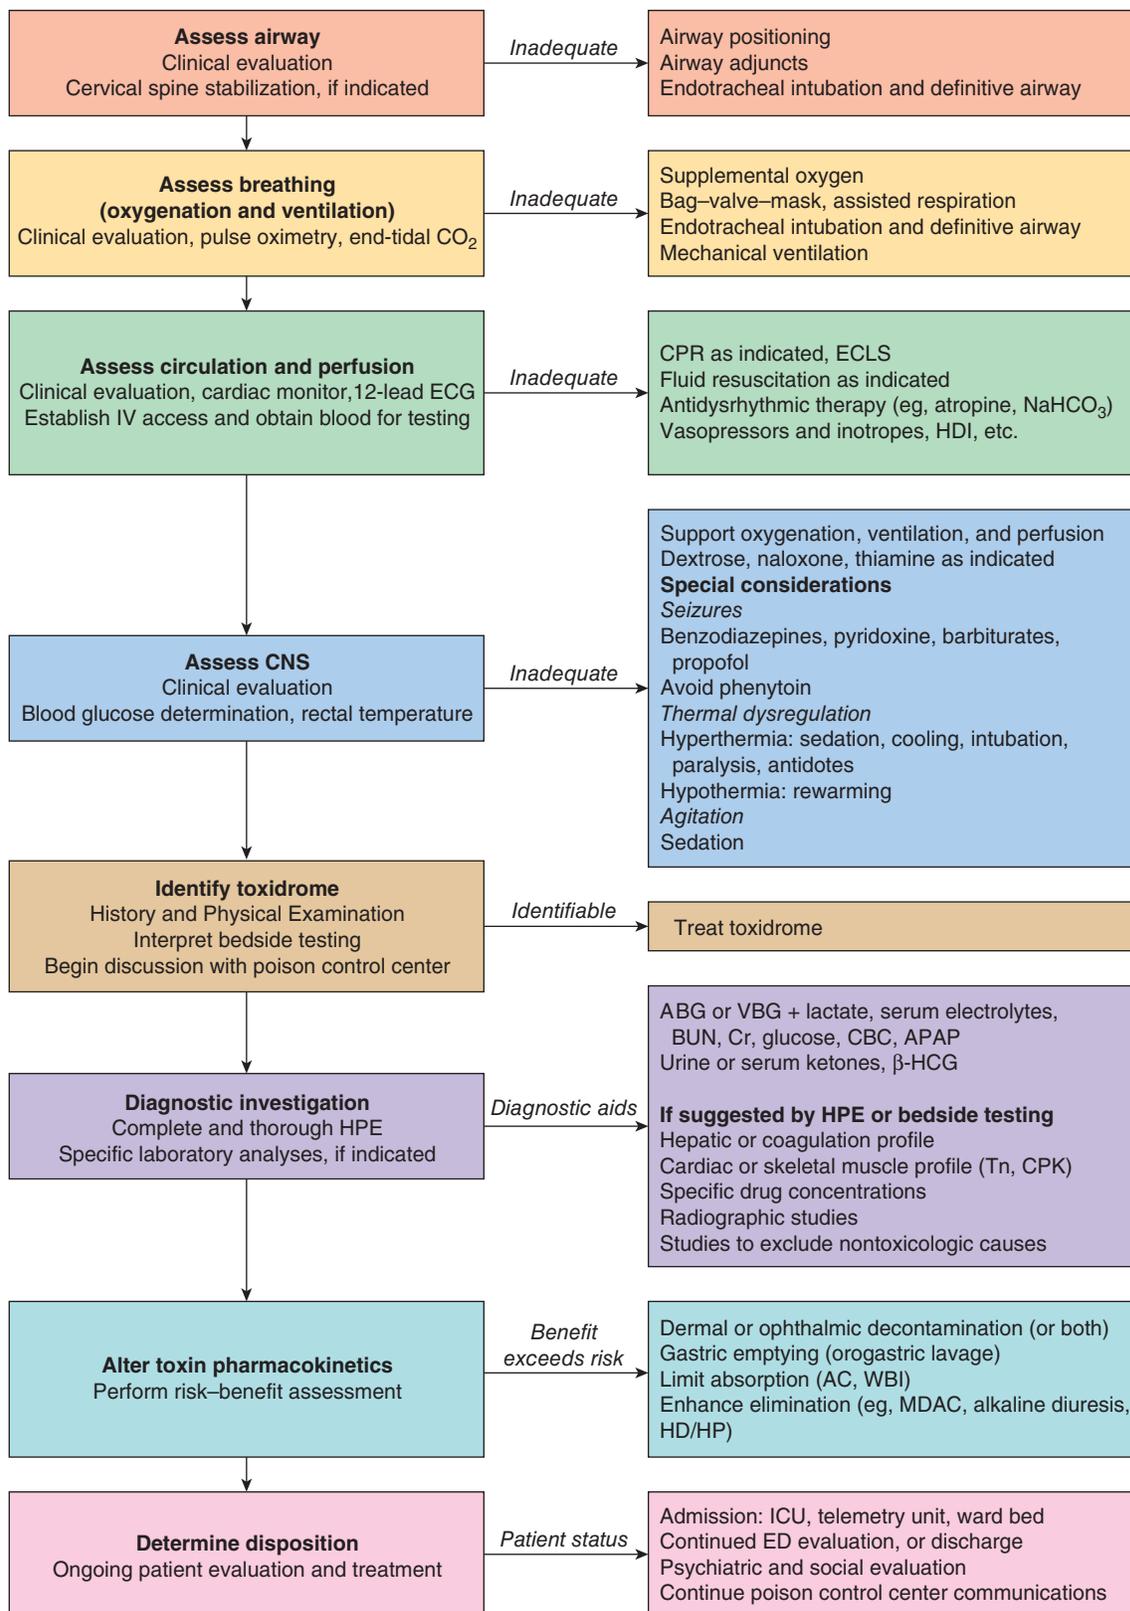

Rarely, if ever, are all of the circumstances involving a poisoned patient known. The history may be incomplete, unreliable, or unobtainable; multiple xenobiotics may be involved; and even when a xenobiotic etiology is identified, it may not be easy to determine whether the problem is an overdose, an allergic or idiosyncratic reaction, or a drug-drug interaction. Similarly, it is sometimes difficult or impossible to differentiate between the adverse effects of a correct dose of medication and the consequences of a deliberate or unintentional overdose. The patient’s presenting signs and symptoms may force an intervention at a time when there is almost no information available about the etiology of the patient’s condition (Table 4-2), and as a result, therapeutics must be thoughtfully chosen empirically to treat or diagnose a condition without exacerbating the situation. See Fig. 4-1 for an algorithmic approach to managing poisoned patients.

### Initial Management of Patients with a Suspected Exposure

Similar to the management of any seriously compromised patient, the clinical approach to the patient potentially exposed to a xenobiotic begins with the recognition and treatment of life-threatening conditions, including airway compromise, breathing difficulties, and circulatory problems such as hemodynamic instability and serious dysrhythmias. After the “ABCs” (airway, breathing, and circulation) are addressed, the patient’s level of consciousness should be assessed because it helps determine the techniques to be used for further management of the exposure.

### Management of Patients with Altered Mental Status

Altered mental status (AMS) is defined as the deviation of a patient’s sensorium from its baseline. Although it is commonly misconstrued as a depression in the patient’s level of consciousness, a patient with agitation, delirium, psychosis, and other deviations from normal is also considered to have an AMS. The spectrum of deviation may range from hyperactive agitated

**FIGURE 4-1.** This algorithm is a basic guide to the management of poisoned patients. A more detailed description of the steps in management may be found in the accompanying text. This algorithm is only a guide to actual management, which must, of course, consider the patient's clinical status. ABG = arterial blood gas; AC = activated charcoal; APAP = acetaminophen; β-HCG = β-human chorionic gonadotropin; CBC = complete blood count; CNS = central nervous system; CPK = creatine phosphokinase; CPR = cardiopulmonary resuscitation; Cr, creatinine; ECG = electrocardiograph; ECLS = extracorporeal life support; HD = hemodialysis; HDI = high dose insulin; HP = hemoperfusion; ICU = intensive care unit; MDAC = multiple-dose activated charcoal; Tn = troponin; VBG = venous blood gas; WBI = whole-bowel irrigation.

**TABLE 4-1** Antidotes and Therapeutics for the Treatment of Poisonings and Overdoses<sup>a</sup>

<i>Therapeutics<sup>b</sup></i>	<i>Indications</i>	<i>Therapeutics<sup>b</sup></i>	<i>Indications</i>
Acetylcysteine (p. 492)	Acetaminophen and other causes of hepatotoxicity	Hydroxocobalamin (p. 1694)	Cyanide
Activated charcoal (p. 76)	Adsorbent xenobiotics in the GI tract	Idarucizumab (p. 911)	Dabigatran
Antivenom ( <i>Centruroides</i> spp) (p. 1563)	Scorpion envenomation	Insulin (p. 953)	β-Adrenergic antagonists, CCBs, hyperglycemia
Antivenom ( <i>Crotalinae</i> ) (p. 1627)	Crotaline snake envenomations	Iodide (SSKI) (p. 1775)	Radioactive iodine ( <sup>131</sup> I)
Antivenom ( <i>Micrurus fulvius</i> ) (p. 1631)	Coral snake envenomations	Lipid emulsion (p. 1004)	Local anesthetics
Antivenom ( <i>Latrodectus mactans</i> ) (p. 1559)	Black widow spider envenomations	Magnesium sulfate injection (p. 876)	Cardioactive steroids, hydrofluoric acid, hypomagnesemia, ethanol withdrawal, torsade de pointes
Antivenom ( <i>Synanceja</i> spp) (p. 1578)	Stonefish envenomation	Methylene blue (1% solution) (p. 1713)	Methemoglobinemia, ifosfamide, vasoplegic syndrome, shock
Atropine (p. 1503)	Bradycardias, cholinesterase inhibitors (organic phosphorus compounds, physostigmine) muscarinic mushrooms ( <i>Clitocybe</i> , <i>Inocybe</i> ) ingestions	Naloxone (p. 538)	Opioids, clonidine
Benzodiazepines (p. 1135)	Seizures, agitation, stimulants, ethanol and sedative-hypnotic withdrawal, cocaine, chloroquine, organic phosphorus compounds	Norepinephrine (p. 950)	Hypotension
Botulinum antitoxin (Heptavalent) (p. 586)	Botulism	Octreotide (p. 713)	Insulin secretagogue induced hypoglycemia
Calcium chloride, calcium gluconate (p. 1403)	Fluoride, hydrofluoric acid, ethylene glycol, CCBs, hypermagnesemia, β-adrenergic antagonists, hyperkalemia	Oxygen (Hyperbaric) (p. 1676)	Carbon monoxide, cyanide, hydrogen sulfide
L-Carnitine (p. 732)	Valproic acid: hyperammonemia	D-Penicillamine (p. 1215)	Copper
Cyanide kit (nitrites, p. 1698; sodium thiosulfate, p. 1698)	Cyanide	Phenobarbital (p. 1087)	Seizures, agitation, stimulants, ethanol and sedative-hypnotic withdrawal
Cyproheptadine (p. 1001)	Serotonin toxicity	Phentolamine (p. 1129)	Vasoconstriction: cocaine, MAOI interactions, epinephrine, and ergot alkaloids
Dantrolene (p. 1029)	Malignant hyperthermia	Physostigmine (p. 755)	Anticholinergics
Deferoxamine (p. 676)	Iron, aluminum	Polyethylene glycol electrolyte lavage solution (p. 83)	Decontamination
Dextrose in water (50% adults; 20% pediatrics; 10% neonates) (p. 707)	Hypoglycemia	Pralidoxime (p. 1508)	Acetylcholinesterase inhibitors (organic phosphorus compounds and carbamates)
Digoxin-specific antibody fragments (p. 977)	Cardioactive steroids	Protamine (p. 919)	Heparin anticoagulation
Dimercaprol (British anti-Lewisite [BAL]) (p. 1251)	Arsenic, mercury, gold, lead	Prussian blue (p. 1357)	Thallium, cesium
Diphenhydramine (p. 741)	Dystonic reactions, allergic reactions	Pyridoxine (vitamin B <sub>6</sub> ) (p. 862)	Isoniazid, ethylene glycol, gyromitrin-containing mushrooms
DTPA (p. 1779) calcium trisodium pentetate	Radioactive isotopes; americium, curium, plutonium	Sodium bicarbonate (p. 567)	Ethylene glycol, methanol, salicylates, cyclic antidepressants, methotrexate, phenobarbital, quinidine, chlorpropamide, class I antidysrhythmics, chlorophenoxy herbicides, sodium channel blockers
Edetate calcium disodium (calcium disodium versenate, CaNa <sub>2</sub> EDTA) (p. 1315)	Lead, other selected metals	Starch (p. 1371)	Iodine
Ethanol (p. 1440)	Ethylene glycol, methanol, diethylene glycol	Succimer (p. 1309)	Lead, mercury, arsenic
Flumazenil (p. 1094)	Benzodiazepines	Thiamine (vitamin B <sub>1</sub> ) (p. 1309)	Thiamine deficiency, ethylene glycol, chronic ethanol consumption (“alcoholism”)
Folinic acid (p. 775)	Methotrexate, methanol	Uridine triacetate (p. 789)	Fluorouracil, capecitabine
Fomepizole (p. 1435)	Ethylene glycol, methanol, diethylene glycol	Vitamin K <sub>1</sub> (p. 915)	Warfarin or rodenticide anticoagulants
Glucagon (p. 941)	β-Adrenergic antagonists, CCBs		
Glucarpidase (p. 782)	Methotrexate		

<sup>a</sup>Each emergency department should have the vast majority of these antidotes immediately available; some of these antidotes may be stored in the pharmacy, and others may be available from the Centers for Disease Control and Prevention, but the precise mechanism for locating each one must be known by each staff member (Special Considerations: SC1).

<sup>b</sup>A detailed analysis of each of these antidotes is found in the text in the Antidotes in Depth section on the page cited to the right of each antidote or therapeutic listed.

CCB = calcium channel blocker; DTPA = diethylenetriaminepentaacetic acid; EDTA = ethylenediamine tetraacetic acid; GI = gastrointestinal; MAOI = monoamine oxidase inhibitor; SSKI = saturated solution of potassium iodide.

TABLE 4-2 Clinical and Laboratory Findings in Poisoning and Overdose

Agitation	Anticholinergics, <sup>a</sup> hypoglycemia, phencyclidine, sympathomimetics, <sup>b</sup> synthetic cannabinoid receptor agonists, withdrawal from ethanol and sedative–hypnotics
Alopecia	Alkylating agents, radiation, selenium, thallium
Ataxia	Benzodiazepines, carbamazepine, carbon monoxide, ethanol, hypoglycemia, lithium, mercury, nitrous oxide, phenytoin
Blindness or decreased visual acuity	Caustics (direct), cisplatin, cocaine, ethambutol, lead, mercury, methanol, quinine, thallium
Blue skin	Amiodarone, FD&C #1 dye, methemoglobinemia, silver
Constipation	Anticholinergics, <sup>a</sup> botulism, lead, opioids, thallium (severe)
Deafness, tinnitus	Aminoglycosides, carbon disulfide, cisplatin, loop diuretics, macrolides, metals, quinine, quinolones, salicylates
Diaphoresis	Amphetamines, cholinergics, <sup>c</sup> hypoglycemia, opioid withdrawal, salicylates, serotonin toxicity, sympathomimetics, <sup>b</sup> withdrawal from ethanol and sedative–hypnotics
Diarrhea	Arsenic and other metals, boric acid (blue–green), botanical irritants, cathartics, cholinergics, <sup>c</sup> colchicine, iron, lithium, opioid withdrawal, radiation
Dysesthesias, paresthesias	Acrylamide, arsenic, ciguatera, cocaine, colchicine, thallium
Gum discoloration	Arsenic, bismuth, hypervitaminosis A, lead, mercury
Hallucinations	Anticholinergics, <sup>a</sup> dopamine agonists, ergot alkaloids, ethanol, ethanol and sedative–hypnotic withdrawal, LSD, phencyclidine, sympathomimetics, <sup>b</sup> tryptamines
Headache	Carbon monoxide, hypoglycemia, MAOI–food interaction (hypertensive crisis), serotonin toxicity
Metabolic acidosis (elevated anion gap)	Methanol, uremia, ketoacidosis (diabetic, starvation, alcoholic), paraldehyde, metformin, iron, isoniazid, lactic acidosis, cyanide, protease inhibitors, ethylene glycol, salicylates, toluene
Miosis	Cholinergics, <sup>c</sup> clonidine, opioids, phencyclidine, phenothiazines
Mydriasis	Anticholinergics, <sup>a</sup> botulism, opioid withdrawal, sympathomimetics <sup>b</sup>
Nystagmus	Barbiturates, carbamazepine, carbon monoxide, dextromethorphan, ethanol, lithium, MAOIs, phencyclidine, phenytoin, quinine, synthetic cannabinoid receptor agonists
Purpura	Anticoagulant rodenticides, corticosteroids, heparin, pit viper venom, quinine, salicylates, anticoagulants, levamisole
Radiopaque ingestions	Arsenic, halogenated hydrocarbons, iodinated compounds metals (eg, iron, lead), potassium compounds
Red skin	Anticholinergics, <sup>a</sup> boric acid, disulfiram, hydroxocobalamin, scombroid, vancomycin
Rhabdomyolysis	Carbon monoxide, doxylamine, HMG-CoA reductase inhibitors, sympathomimetics, <sup>b</sup> <i>Tricholoma equestre</i> mushrooms
Salivation	Arsenic, caustics, cholinergics, <sup>c</sup> clozapine, ketamine, mercury, phencyclidine, strychnine
Seizures	Bupropion, camphor, carbon monoxide, cyclic antidepressants, <i>Gyromitra</i> mushrooms, hypoglycemia, isoniazid, methylxanthines, ethanol and sedative–hypnotic withdrawal
Tremor	Antipsychotics, arsenic, carbon monoxide, cholinergics, <sup>c</sup> ethanol, lithium, mercury, methyl bromide, sympathomimetics, <sup>b</sup> thyroid hormones
Weakness	Botulism, diuretics, magnesium, paralytic shellfish, steroids, toluene
Yellow skin	APAP (late), pyrrolizidine alkaloids, $\beta$ carotene, amatoxin mushrooms, dinitrophenol

<sup>a</sup>Anticholinergics, including antihistamines, atropine, cyclic antidepressants, and scopolamine.

<sup>b</sup>Sympathomimetics, including adrenergic agonists, amphetamines, cocaine, and ephedrine.

<sup>c</sup>Cholinergics, including muscarinic mushrooms; organic phosphorus compounds and carbamates, including select Alzheimer disease drugs and physostigmine; and pilocarpine and other direct-acting xenobiotics.

APAP = acetaminophen; HMG-CoA = 3-hydroxy-3-methyl-glutaryl-CoA; LSD = lysergic acid diethylamide; MAOI = monoamine oxidase inhibitor.

conditions typified by sympathomimetics such as cocaine or amphetamines to depressed levels of consciousness that typify opioid and sedative hypnotic exposures. “Awake” but “altered” conditions also include delirium or psychoses, such as those induced by lithium, salicylate, or antimuscarinic toxicity.

After airway patency is assured, an initial bedside assessment should be made regarding the adequacy of breathing. Although it is often not possible to assess the adequacy of the depth of ventilation, at least the rate and pattern of breathing should be determined. In this setting, any irregular or slow breathing pattern, particularly with an elevated end-tidal CO<sub>2</sub> measurement, should be considered a possible sign of the incipient apnea, requiring

ventilation using 100% oxygen by bag–valve–mask followed as soon as possible by endotracheal intubation and mechanical ventilation. Endotracheal intubation and mandatory ventilation is often indicated for patients with coma resulting from a toxic exposure to ensure and maintain control of the airway and to enable safe performance of procedures to prevent GI absorption or eliminate previously absorbed xenobiotic.

Although in many instances, the widespread availability of pulse oximetry to determine O<sub>2</sub> saturation and end-tidal CO<sub>2</sub> monitors have made arterial blood gas (ABG) analysis less of an immediate priority, these technical advances have not entirely eliminated the importance of blood gas analysis.

An ABG determination will more accurately define the adequacy not only of oxygenation ( $PO_2$ ,  $O_2$  saturation) and ventilation ( $PCO_2$ ) but may also alert the physician to possible toxic-metabolic etiologies of coma characterized by acid–base disturbances ( $pH$ ,  $PCO_2$ )<sup>11</sup> (Chap. 12). In addition, carboxyhemoglobin determinations are now available by point-of-care testing, and both carboxyhemoglobin and methemoglobin may be determined on either venous or arterial blood specimens (Chaps. 122 and 124). In every patient with an AMS, a bedside rapid glucose concentration should be obtained as soon as possible.

After the patient's respiratory status is assessed and managed appropriately, the strength, rate, and regularity of the pulse should be evaluated and the blood pressure and rectal temperature determined. Both an initial 12-lead electrocardiogram (ECG) and continuous rhythm monitoring are essential. Monitoring will alert the clinician to dysrhythmias that are related to toxic exposures either directly or indirectly via hypoxemia or electrolyte imbalance. For example, a 12-lead ECG demonstrating QRS widening and a right axis deviation might indicate a life-threatening exposure to a cyclic antidepressant or another xenobiotic with sodium channel–blocking properties. In these cases, the physician can anticipate such serious sequelae as ventricular tachydysrhythmias, seizures, and cardiac arrest and plan for both the early use of specific treatment (antidotes), such as IV sodium bicarbonate, and avoidance of medications, such as procainamide and other class IA and IC antidysrhythmics, that could exacerbate toxicity.

Extremes of core body temperature must be addressed early in the evaluation and treatment of a comatose patient. Life-threatening hyperthermia (temperature  $>106^\circ F$ ;  $>41.1^\circ C$ ) is usually appreciated when the patient is touched (although the widespread use of gloves as part of universal precautions has made this less apparent than previously). Individuals with severe hyperthermia, regardless of the etiology, should have their temperatures immediately reduced to about  $101.5^\circ F$  ( $38.7^\circ C$ ) by sedation if they are agitated or displaying muscle rigidity or by ice water immersion (Chap. 29). Hypothermia is probably easier to overlook than hyperthermia, especially in northern regions during the winter months, when most arriving patients feel cold to the touch. Early recognition of hypothermia, however, helps to avoid administering a variety of medications that are ineffective until the patient warms, at which point iatrogenic toxicity may result because of a sudden response to xenobiotics previously administered.

For a hypotensive patient with clear lungs and an unknown overdose, a fluid challenge with IV 0.9% sodium chloride or lactated Ringer solution should be administered. If the patient remains hypotensive or cannot tolerate fluids, an antidote, a vasopressor, or an inotrope is often indicated along with invasive monitoring.

At the time that the IV catheter is inserted, blood samples for glucose, electrolytes, blood urea nitrogen (BUN), a complete blood count (CBC), and any indicated toxicologic analyses should be obtained. A pregnancy test should be obtained in any woman of childbearing age. If the patient has an AMS, there may be a temptation to send blood and urine specimens to identify any central nervous system (CNS) depressants or so-called drugs of abuse in addition to other medications. But the indiscriminate ordering of these tests rarely provides clinically useful information.<sup>1</sup> For a potentially suicidal patient, an APAP concentration should be routinely requested along with tests affecting the management of any specific xenobiotic, such as carbon monoxide (CO), lithium, theophylline, iron, salicylates, and digoxin (or other cardioactive steroids), as suggested by the patient's history, physical examination, or bedside diagnostic tests. In many cases, the blood tests that are most useful in diagnosing toxicologic emergencies are not the toxicologic assays but rather the “nontoxicologic” routine metabolic profile tests such as CBC, BUN, glucose, electrolytes, liver function tests, and blood gas analysis.

Xenobiotic-related seizures are broadly divided into three categories: (1) those that respond to standard antiepileptic treatment (typically using a benzodiazepine); (2) those that either require specific antidotes to control seizure activity or that do not respond consistently to standard anticonvulsant treatment, such as isoniazid-induced seizures requiring pyridoxine administration; and (3) those that may appear to respond to initial treatment

with cessation of tonic–clonic activity but that leave the patient exposed to the underlying, unidentified xenobiotic or to continued electrical seizure activity, as is the case with CO poisoning and hypoglycemia.

Within the first 5 minutes of managing a patient with an AMS, four therapeutic interventions should be administered if indicated and not contraindicated:

1. Supplemental oxygen to treat xenobiotic-induced hypoxia
2. Hypertonic dextrose: 0.5 to 1.0 g/kg of  $D_{50}W$  for an adult or a more dilute dextrose solution ( $D_{10}W$  or  $D_{25}W$ ) for a child; the dextrose is administered as an IV bolus as specific or empiric therapy for hypoglycemia (Antidotes in Depth: A8)
3. Thiamine (100 mg IV for an adult; usually unnecessary for a child) to prevent Wernicke encephalopathy (Antidotes in Depth: A27)
4. Naloxone (0.04 mg IV with upward titration) for an adult or child with opioid-induced respiratory compromise (Antidotes in Depth: A4)

The clinician must be aware that hypoglycemia may be the sole or contributing cause of coma even when the patient manifests focal neurologic findings; therefore, dextrose administration should only be omitted when hypoglycemia can be definitely excluded by accurate rapid bedside testing. Also, while examining a patient for clues to the etiology of a presumably toxic-metabolic form of AMS, it is important to search for any indication that trauma caused, contributed to, or resulted from the patient's condition. Conversely, the possibility of a concomitant xenobiotic ingestion or toxic metabolic disorder in a patient with obvious head trauma should also be assessed.

The remainder of the physical examination should be performed rapidly but thoroughly. In addition to evaluating the patient's level of consciousness, the physician should note abnormal posturing (decorticate or decerebrate), abnormal or unilateral withdrawal responses, and pupil size and reactivity. Pinpoint pupils suggest exposure to opioids or organic phosphorus compounds, and widely dilated pupils suggest anticholinergic or sympathomimetic poisoning. The presence or absence of nystagmus, abnormal reflexes, and any other focal neurologic findings may provide important clues to a structural cause of AMS. For clinicians accustomed to applying the Glasgow Coma Scale (GCS) to all patients with AMS, assigning a score to the overdosed or poisoned patient may provide a useful measure for assessing changes in neurologic status. However, in this situation, the GCS should never be used for prognostic purposes because despite a low GCS score, complete recovery from properly managed toxic-metabolic coma is the rule rather than the exception (Chap. 22).

Characteristic breath or skin odors may identify the etiology of coma. The fruity odor of ketones on the breath suggests diabetic or alcoholic ketoacidosis but also the possible ingestion of acetone or isopropyl alcohol, which is metabolized to acetone. The pungent, minty odor of oil of wintergreen on the breath or skin suggests methyl salicylate poisoning. The odors of other substances such as cyanide (“bitter almonds”), hydrogen sulfide (“rotten eggs”), and organic phosphorus compounds (“garlic”) are described in detail in Chap. 25 and summarized in Table 25–1.

### Further Evaluation of All Patients with Suspected Xenobiotic Exposures

Auscultation of breath sounds, particularly after a fluid challenge, helps to diagnose pulmonary edema, acute respiratory distress syndrome, or aspiration pneumonitis. Coupled with an abnormal breath odor of hydrocarbons or organic phosphorus compounds, for example, crackles and rhonchi may point to a toxic pulmonary etiology instead of a cardiac etiology; this is important because the administration of certain cardioactive medications may be inappropriate or dangerous in the former circumstances.

Heart murmurs in an injection drug user, especially when accompanied by fever, suggest infectious endocarditis. Dysrhythmias suggest overdoses or inappropriate use of cardioactive xenobiotics, such as digoxin and other cardioactive steroids,  $\beta$ -adrenergic antagonists, calcium channel blockers, and cyclic antidepressants.

The abdominal examination often reveals signs of trauma or alcohol-related hepatic disease. The presence or absence of bowel sounds helps to exclude or to diagnose anticholinergic toxicity and is important in considering whether to manipulate the GI tract in an attempt to remove the toxin. A large palpable bladder often signals urinary retention as a further manifestation of anticholinergic toxicity.

Examination of the extremities will reveal clues to current or former drug use (track marks, skin-popping scars); metal poisoning (Mees lines, arsenical dermatitis); and the presence of cyanosis or edema suggesting preexisting cardiac, pulmonary, or kidney disease.

Repeated evaluation of the patient suspected of an overdose is essential for identifying new or developing findings or toxic syndromes and for early identification and treatment of a deteriorating condition. Until the patient is completely recovered or considered no longer at risk for the consequences of a xenobiotic exposure, frequent reassessment must be provided even as the procedures described later are carried out. Toxicologic etiologies of abnormal vital signs and physical findings are summarized in **Tables 3–1 to 3–6**. Toxic syndromes, sometimes called “toxidromes,” are summarized in **Table 3–1**.

Typically, in the management of patients with toxicologic emergencies, there is both a necessity and an opportunity to obtain various diagnostic studies and ancillary tests interspersed with stabilizing the patient’s condition, obtaining the history, and performing the physical examination. Chapters 7, 8, and 15 discuss the timing and indications for qualitative and quantitative diagnostic laboratory studies, diagnostic imaging procedures, and the use and interpretation of the ECG in evaluating and managing poisoned or overdosed patients, respectively.

### The Role of Gastrointestinal Decontamination

A series of highly individualized treatment decisions regarding limiting the exposure to the xenobiotic follow the initial stabilization and assessment of the patient. As noted previously and as discussed in detail in Chap. 5, evacuation of the GI tract or administration of activated charcoal can no longer be considered standard or routine toxicologic care for most patients. Instead, the decision to perform GI decontamination should be based on the specifics of the ingestion, estimated quantity, formulation, and size of the pill or tablet, time since the exposure, concurrent ingestions, coexisting medical conditions, and age and size of the patient. The indications, contraindications, and procedures for performing orogastric lavage and for administering WBI, activated charcoal, MDAC, and cathartics are listed in **Tables 5–1 to 5–7** and are discussed both in Chap. 5 and in the specific Antidotes in Depth sections immediately following Chap. 5.

### Eliminating Absorbed Xenobiotics from the Body

After deciding whether or not an intervention to try to prevent absorption of a xenobiotic is indicated, the clinician must next assess the applicability of techniques available to eliminate xenobiotics already absorbed. Detailed discussions of the indications for and techniques of manipulating urinary pH (ion trapping), diuresis, hemodialysis, hemoperfusion, continuous renal replacement therapy, and exchange transfusion are found in Chap. 6. Briefly, patients who are likely to benefit from these procedures are those who have systemically absorbed xenobiotics amenable to one of these techniques and whose clinical conditions are both serious (or potentially serious) and unresponsive to supportive care or whose physiologic route of elimination (liver–feces, kidney–urine) is impaired.

Alkalinization of the urinary pH to enhance the renal excretion of acidic xenobiotics has only limited applicability. Commonly, sodium bicarbonate is used to alkalinize the urine (as well as the blood) and enhance salicylate elimination (other xenobiotics are discussed in Chap. 6), and sodium bicarbonate also prevents toxicity from methotrexate (Antidotes in Depth: A5). Acidifying the urine to hasten the elimination of alkaline substances is difficult to accomplish, of limited value, and possibly dangerous and therefore has no role in poisoning management. Forced diuresis also has no indication and may endanger the patient by causing pulmonary or cerebral edema.

If extracorporeal elimination is contemplated, hemodialysis is used for patients who overdose with salicylates, methanol, ethylene glycol, lithium, valproic acid, or xenobiotics that are either dialyzable or cause fluid and electrolyte abnormalities. Advances in hemodialysis technology allow the efficient removal of theophylline, phenobarbital, and carbamazepine and have replaced hemoperfusion, which is nearly unavailable in the US. Peritoneal dialysis is too ineffective to be of practical utility, and continuous renal replacement therapies are not as efficacious as hemodialysis or hemoperfusion, although they may play a role between multiple runs of dialysis or in hemodynamically compromised patients who cannot tolerate hemodialysis. In theory, both hemodialysis and hemoperfusion in series is useful for a very few life-threatening overdoses such as thallium or salicylates. Plasmapheresis and exchange transfusion are used to eliminate xenobiotics with large molecular weights that are not dialyzable (Chap. 10).

### AVOIDING PITFALLS

The history alone is not a reliable indicator of which patients require naloxone, hypertonic dextrose, thiamine, and oxygen. Instead, the need for these therapies should be evaluated and performed if indicated (unless specifically contraindicated) only after a clinical assessment for all patients with AMS. The physical examination should be used to guide the use of naloxone. If dextrose or naloxone is indicated, sufficient amounts should be administered to exclude or treat hypoglycemia or opioid toxicity, respectively.

Attributing an AMS to alcohol because of an odor on a patient’s breath is potentially misleading. Small amounts of alcohol or alcoholic beverage congeners generally produce the same breath odor as do intoxicating amounts. Conversely, even when an extremely high blood ethanol concentration is confirmed by laboratory analysis, it is dangerous to ignore other possible causes of an AMS. Because some individuals with chronic alcohol use disorder are alert with ethanol concentrations in excess of 500 mg/dL, a concentration that would result in coma and possibly apnea and death in a nontolerant person, finding a high ethanol concentration does not eliminate the need for further search into the cause of a depressed level of consciousness.

The metabolism of ethanol is fairly constant at 15 to 30 mg/dL/h. Therefore, as a general rule, regardless of the initial blood alcohol concentration, a presumably “inebriated” comatose patient who remains unarousable 3 to 4 hours after initial assessment should be considered to have an intracranial process, such as hemorrhage, or another comorbid medical condition, such as meningitis, as the etiology for the alteration in consciousness until proven otherwise. Careful neurologic evaluation of the completely undressed patient supplemented by a head computed tomography scan is frequently indicated in such cases. A lumbar puncture or additional laboratory testing should be performed based on the need to exclude CNS infection or toxic-metabolic etiologies, respectively. This is especially important in dealing with chronic or heavy users of ethanol given their predisposition to such injuries and diseases.

### ADDITIONAL CONSIDERATIONS IN MANAGING PATIENTS WITH A NORMAL MENTAL STATUS

As in the case of patients with AMS, vital signs must be obtained and recorded. If the patient is alert, talking, and in no respiratory distress, all that remains to document are the respiratory rate and rhythm. Because the patient is alert, additional history should be obtained, keeping in mind that information regarding the number and types of xenobiotics ingested, time elapsed, prior vomiting, and other critical information may be unreliable.

Under certain circumstances, such as when the patient has an AMS or is at risk for self-harm, the history should be privately and independently obtained from a friend or relative after the patient has been initially stabilized. Recent emphasis on compliance with the federal Health Insurance Portability and Accountability Act (HIPAA) may inappropriately discourage clinicians from attempting to obtain information necessary to evaluate and treat patients. Obtaining such information from a friend or relative without unnecessarily giving that person information about the patient is the key to successfully helping such a patient without violating confidentiality.

Speaking to a friend or relative of the patient may provide an opportunity to learn useful and reliable information regarding the exposure, the patient's frame of mind, a history of previous exposures, and the type of support that is available if the patient is discharged from the ED. At times, it is essential to initially separate the patient from any relatives or friends to obtain greater cooperation from the patient and avoid violating confidentiality and because their anxiety may interfere with therapy. Even if the history obtained from a patient with an exposure proves to be unreliable, it may nevertheless provide clues to an overlooked possibility of a second exposure or reveal the patient's mental and emotional condition. As is often true of the history, physical examination, or laboratory assessment in other clinical situations, the information obtained often confirms but rarely excludes possible causes.

At this point in the management of a conscious patient, a focused physical examination should be performed, concentrating on the pulmonary, cardiac, and abdominal examinations. A neurologic survey should emphasize reflexes and any focal findings.

### APPROACHING PATIENTS WITH INTENTIONAL EXPOSURES

Initial efforts at establishing rapport with the patient by indicating to the patient concern about the events that led to the ingestion and the availability of help after the xenobiotic is removed (if such procedures are planned) often facilitates management. If GI decontamination is deemed beneficial, the reason for and nature of the procedure should be clearly explained to the patient together with reassurance that after the procedure is completed, there will be ample time to discuss his or her concerns and provide additional care. These considerations are especially important in managing the patient with an intentional self-harm attempt who is often seeking psychiatric help or emotional support. In deciding on the value of performing GI decontamination, it is important to understand that a resistant patient may transform a procedure of limited benefit into one with serious risks.

### SPECIAL CONSIDERATIONS FOR MANAGING PREGNANT PATIENTS

In general, a successful outcome for both the mother and fetus depends on optimum management of the mother, and proven effective treatment for a potentially serious toxic exposure to the mother should never be withheld based on theoretical concerns regarding the fetus (Chap. 30).

#### Physiologic Factors

A pregnant woman's total blood volume and cardiac output are elevated through the second trimester and into the later stages of the third trimester. This means that signs of hypoperfusion and hypotension manifest later than they would in a woman who is not pregnant, and when they do, uterine blood flow may already be compromised. For these reasons, the possibility of hypotension in a pregnant woman must be more aggressively sought and, if found, more rapidly treated. Maintaining the patient in the left-lateral decubitus position helps prevent supine hypotension resulting from impairment of systemic venous return by compression of the inferior vena cava. The left lateral decubitus position is also the preferred position for orogastric lavage if this procedure is deemed necessary.

Because the tidal volume is increased in pregnancy, the baseline  $PCO_2$  will normally be lower by approximately 10 mm Hg. Appropriate adjustment for this effect should be made when interpreting blood gas results.

#### Use of Antidotes

Limited data are available on the use of antidotes in pregnancy. In general, antidotes should not be used if the indications for use are equivocal. On the other hand, antidotes should not be withheld if they have the potential to reduce potential morbidity and mortality. Risks and benefits of either decision must be assessed. For example, reversal of opioid-induced respiratory depression calls for the use of naloxone, but in an opioid-dependent woman, the naloxone can precipitate acute opioid withdrawal, including uterine contractions and possible induction of labor. Very slow, careful, IV titration starting with 0.04 mg of naloxone is indicated unless apnea is present or cessation of breathing appears imminent. In these instances, it is preferable

to either administer naloxone in higher doses (ie, 0.4–2.0 mg) or manually assist ventilation. A combination of transient assisted ventilation followed by small doses of naloxone optimizes the benefits of both techniques.

An APAP overdose is a serious maternal problem when it occurs at any stage of pregnancy, but the fetus is at greatest risk in the third trimester. Although APAP crosses the placenta easily, acetylcysteine (NAC) has somewhat diminished transplacental passage. During the third trimester, when both the mother and the fetus are at substantial risk from a significant APAP overdose with manifest hepatotoxicity, immediate delivery of a mature or viable fetus has to be considered.

In contrast to the situation with APAP, the fetal risk from iron poisoning is less than the maternal risk. Because deferoxamine is a large charged molecule with little transplacental transport, deferoxamine should never be withheld out of unwarranted concern for fetal toxicity when indicated to treat the mother.

Carbon monoxide poisoning is particularly threatening to fetal survival. The normal  $PO_2$  of the fetal blood is approximately 15 to 20 mm Hg. Oxygen delivery to fetal tissues is impaired by the presence of carboxyhemoglobin, which shifts the oxyhemoglobin dissociation curve to the left, potentially compromising an already tenuous balance. For this reason, hyperbaric oxygen is recommended for much lower carboxyhemoglobin concentrations in a pregnant compared with a nonpregnant woman (Chap. 122 and Antidotes in Depth: A40). Early notification of the obstetrician and close cooperation among involved physicians are essential for the best results in all of these instances.

### MANAGEMENT OF PATIENTS WITH CUTANEOUS EXPOSURE

The xenobiotics that people are commonly exposed to externally include household cleaning materials; organic phosphorus or carbamate mark in color so they can compare from crop dusting, gardening, or pest extermination; acids from leaking or exploding batteries; alkalis, such as lye; and lacrimators that are used in crowd control. In all of these cases, the principles of management are as follows:

1. Avoid secondary exposures by wearing protective (rubber or plastic) gowns, gloves, and shoe covers. Cases of serious secondary poisoning have occurred in emergency personnel after contact with xenobiotics such as organic phosphorus compounds on the victim's skin or clothing.
2. Remove the patient's clothing, place it in plastic bags, and then seal the bags.
3. Wash the patient with soap and copious amounts of water twice regardless of how much time has elapsed since the exposure.
4. Make no attempt to neutralize an acid with a base or a base with an acid. Further tissue damage may result from the heat generated by this exothermic reaction.
5. Avoid using any greases or creams because they will only keep the xenobiotic in close contact with the skin and ultimately make removal more difficult.

Chapter 17 discusses the principles of managing cutaneous exposures, and Special Considerations: SC2 discusses the principles of preventing dermal absorption.

### MANAGEMENT OF PATIENTS WITH OPHTHALMIC EXPOSURES

Although the vast majority of toxicologic emergencies result from ingestion, injection, or inhalation, the eyes are occasionally the routes of systemic absorption or are the organs at risk from ophthalmic exposures. The eyes should be irrigated with the eyelids fully retracted for no less than 20 minutes. To facilitate irrigation, a drop of an anesthetic (proparacaine and tetracaine) in each eye should be used, and the eyelids should be kept open with an eyelid retractor. An adequate irrigation stream is obtained by running 1 L of 0.9% sodium chloride through regular IV tubing held a few inches from the eye or by using an irrigating lens. Checking the eyelid fornices with pH paper strips is important to ensure adequate irrigation; the pH should normally

be 6.5 to 7.6 if accurately tested, although when using paper test strips, the measurement will often be near 8.0. Chapter 24 describes the management of toxic ophthalmic exposures in more detail, and Special Considerations: SC2 discusses the principles of preventing dermal absorption.

## IDENTIFYING PATIENTS WITH NONTOXIC EXPOSURES

Many exposures, whether caused by the nature or quantity of the xenobiotic or the clinical circumstances, are reliably predictable to be nonconsequential. More than 40% of exposures reported to poison control centers annually are nontoxic or minimally toxic. In this patient population, there are considerable risks of needlessly subjecting a patient to potential harm through unnecessarily aggressive treatment. For example, GI decontamination techniques or antidotes that are indicated for patients with serious exposures carry risks that are only acceptable if there is potential to offset the risk with clinical benefit. The following general guidelines for considering an exposure nontoxic or minimally toxic will assist clinical decision making.<sup>6,8,9</sup>

1. Identification of the product and its ingredients is possible.
2. None of the US Consumer Product Safety Commission's "signal words" (CAUTION, WARNING, or DANGER) appear on the product label.
3. The route of exposure is known.
4. A reliable approximation of the maximum exposure quantity is able to be made.
5. Based on the available medical literature and clinical experience, the potential effects related to the exposure are expected to be benign or at worst self-limited and not likely to require the patient to access health care.
6. The patient is asymptomatic or has developed the maximal expected self-limited toxicity.
7. Adequate time has occurred to assess the potential for the development of toxicity.

For any patient in whom there is a question about the nature of the exposure, it is not appropriate to consider that exposure nontoxic. All such patients, and all patients for whom the health care provider is unsure of the risks associated with a given exposure, should be referred either

to the regional poison control center or health care facility for further evaluation.

## DISPOSITION OF PATIENTS

Determining the appropriate transition of care may occur once or several times during the management of a poisoned patient. The poison control center must determine the need for direct medical care in a hospital or whether the patient has had a nontoxic exposure (discussed earlier) and can be managed at home. In the ED, many patients are discharged after their evaluation and treatment and after psychiatric and social services evaluations are obtained as needed. Among clinically ill poisoned patients, the decision is generally simplified based on the relative abilities of the various units within the medical facility. Critical care units expend the highest level of resources to assure both intensive monitoring and the provision of timely care and are necessary for patients who are currently ill or currently stable but likely to decompensate. See Table 4-3 for a description of patients best suited for critical care unit admission. General hospital beds, often called medical/surgical beds, provide only intermittent nursing and medical care and are sufficient for patients unlikely to undergo abrupt concerning changes in the clinical status but who nonetheless need clinical monitoring. The capabilities of medical/surgical beds vary widely by hospital. Stepdown or intermediate care units and telemetry units bridge the divide between these two extremes of care, and variably provide enhanced technological support and monitoring and higher nurse-to-patient ratios. Determining the optimal disposition for a poisoned patient requires an evaluation of the nature of the exposure, the patient, and the capabilities of the community and the institution. Most often such decisions are made conservatively and cautiously, given the unpredictable nature of human poisoning.

## ENSURING AN OPTIMAL OUTCOME

The best way to ensure an optimal outcome for the patient with a suspected toxic exposure is to apply the principles of basic and advanced life support in conjunction with a planned and stepwise approach. Always bear in mind that a toxicologic etiology or co-etiology for any abnormal conditions

**TABLE 4-3** Define the Indications for Intensive Care Unit Admission

Patient Characteristics	Xenobiotic Characteristics	Capabilities of the Inpatient or Observation Unit
Does the patient have any signs of serious end-organ toxicity?	Are there known serious sequelae (eg, cyclic antidepressants, CCBs)?	Does the admitting health care team appreciate the potential seriousness of a toxicologic emergency?
Are the end-organ effects progressing?	Can the patient deteriorate rapidly from its toxic effects?	Is the nursing staff:
Are laboratory data suggestive of serious toxicity?	Is the onset of toxicity likely to be delayed (eg, sustained-release preparation, slowed GI motility, or delayed toxic effects)?	Familiar with this toxicologic emergency?
Is the patient a high risk for complications requiring ICU intervention?	Does the xenobiotic have effects that will require cardiac monitoring?	Familiar with the potential for serious complications?
Seizures	Is the amount ingested a potentially serious or potentially lethal dose?	Is the staffing adequate to monitor the patient?
Unresponsive to verbal stimuli	Are xenobiotic concentrations rising?	What is the ratio of nurses to patients?
Level of consciousness impaired to the point of potential airway compromise	Is the required or planned therapy unconventional (eg, large doses of atropine for treating overdoses of organic phosphorus compounds; or high dose insulin for CCB overdose)?	Are time-consuming nursing activities required and realistic?
PCO <sub>2</sub> >45 mm Hg	Does the therapy have potentially serious adverse effects?	Can a safe environment be provided for a suicidal patient?
Systolic blood pressure <80 mm Hg (in an adult)	Is there insufficient literature to describe the potential human toxic effects?	Can a patient have suicide precautions and monitoring with a medical floor bed?
Cardiac dysrhythmias (ventricular dysrhythmias, high-grade conduction abnormalities)	Are potentially serious coingestants likely (must take into account the reliability of the history)?	Can a one-to-one observer be present in the room with the patient?
Abnormal ECG complexes and intervals (QRS duration ≥0.10 seconds; QT prolongation)		Can the patient be restrained or sedated?
Refractory or recurrent hypoglycemia		
Is the patient at high risk for complications such as aspiration pneumonitis, anoxic brain injury, rhabdomyolysis, or compartment syndrome?		
Does the patient have preexisting medical conditions that could predispose to complications?		
Alcohol or drug dependence		
Liver disease		
Acute kidney injury or chronic kidney disease		
Heart disease		
Pregnancy: Is the xenobiotic or the antidote teratogenic?		
Is the patient suicidal?		

CCB = calcium channel blocker; ECG = electrocardiogram; GI = gastrointestinal; ICU = intensive care unit.

necessitates modifying whatever standard approach is brought to the bedside of a severely ill patient. For example, it is extremely important to recognize that xenobiotic-induced dysrhythmias and cardiac instability require alterations in standard protocols that assume a primary cardiac or nontoxicologic etiology (Chaps. 15 and 16).

Involvement of the expertise of a poison control center, a medical toxicologist, or a clinical toxicologist can help direct both diagnosis and management strategies to improve the efficiency and outcome of the patient.

Typically, only some of the xenobiotics to which a patient is exposed will ever be confirmed by laboratory analysis. The thoughtful combination of stabilization, general management principles, and both empiric and specific treatment when indicated will result in successful outcomes in the majority of patients with actual or suspected exposures.

## SUMMARY

- Patients with a suspected overdose or poisoning and an AMS present some of the most complex initial challenges.
- Pregnant patients with possible xenobiotic exposures raise additional management issues, as do those with toxic cutaneous or ophthalmic exposures.
- Among the most frequent toxicologic emergencies that clinicians must address is a patient with a suspected toxic exposure to an unidentified xenobiotic (medication or substance), sometimes referred to as an unknown overdose.

- Consider self-harm, the use of illicit drugs, and those who are unknowingly exposed to xenobiotics as having the potential for serious adverse consequences because of the limited accurate historical information that can be obtained.

## PRINCIPLES OF ANTIDOTE STOCKING

Silas W. Smith, Lewis R. Goldfrank, and Mary Ann Howland

Most patients with xenobiotic exposures do well with supportive care and close attention to vital physiology. However, one of the fundamental principles of managing an acutely poisoned patient is appropriate and timely antidotal administration when indicated. According to the last available US Poison Control Center data, a therapeutic intervention which includes specific antidotes was used in 18.5% of all poisoning exposures (Chap. 130).<sup>16,41</sup>

Sufficient antidote stocking is a best practice; failure to do so presents a clear and present danger to patient safety. Death and serious harm resulted from the delay to administer appropriate antidotes, reversal agents, and rescue agents.<sup>28</sup> Many poisonings are acute unanticipated emergencies, which would presumably invoke the protections of the Emergency Medical Treatment and Labor Act of 1986, which mandates public access to emergency services regardless of ability to pay. The Joint Commission (TJC) is the accrediting body for hospitals. The Joint Commission's elements of performance require that "emergency medications and their associated supplies are readily available," as well as written criteria determining which medications are available for dispensing or administering to patients.<sup>55,56</sup> The Joint Commission also recognizes the difficulties presented by medication shortages and requires staff communication, written medication substitution protocols approved by leadership and the medical staff, and review of the impact of substitutions (eg, medication errors and adverse drug events).<sup>57</sup> It is an Institute for Safe Medication Practices best practice to "ensure all appropriate antidotes, reversal agents, and rescue agents are readily available."<sup>28</sup> The World Health Organization devotes an entire section to antidotes and other substances used in poisonings that are considered of paramount importance in its model list of essential medicines.<sup>65</sup> Because many antidotes are used in practice to reverse potential medication errors, overdoses, or adverse clinical conditions, the Department of Veterans Affairs (VA) National Center for Patient Safety considers it mandatory that reversal agents such as flumazenil, naloxone, protamine, and others are available in the clinical setting.<sup>60</sup> Antidotes are a fundamental aspect of response (as medical countermeasures) to chemical, biological, and radiologic terrorism. As such, provisioning and antidotal administration are Critical Target Capabilities in the US National Preparedness Guidelines.<sup>59</sup> These national Preparedness Measures include quarterly updates to the federal government on the status of critical items; memoranda of understanding to determine collective inventory accessibility and to ramp up manufacturing capability; and maintenance by pharmaceutical manufacturers and distributors of increased inventory amounts of critical items.<sup>59</sup> Many professional organizations such as the American Heart Association, American Hospital Association, American Medical Association, American College of Medical Toxicology, and American Academy of Clinical Toxicology consider drug and antidote shortages a significant threat to public health and patient outcomes.<sup>5,6,8,9</sup>

### LOCAL AVAILABILITY

Decades of research have consistently documented inadequate stocking of antidotes, which are required at critical instances. In 1986, the lack of any antidotal capacity within a 50-mile radius to treat a case of pyrinuron (Vacor) overdose was reported, with ultimate patient mortality.<sup>26</sup> A 1996 study of Colorado, Montana, and Nevada pharmacies found that only 1 of 108 (0.9%) responding hospitals had adequate supplies of eight antidotes (Crotalidae antivenin, cyanide kit, deferoxamine, digoxin immune Fab, ethanol, naloxone, pralidoxime chloride, and pyridoxine).<sup>17</sup> A 1997 survey of

Massachusetts hospitals found that only 8 of 82 hospitals (9.8%) stocked all of 14 common antidotes.<sup>64</sup> A 1999 study determined that no Alabama hospital had adequate supplies of all nine essential antidotes (digoxin-specific antibody fragments [DSFab], pyridoxine, ethanol, pralidoxime, Crotalidae antivenin, deferoxamine, cyanide antidote, naloxone, and fomepizole).<sup>53</sup> In 1999, a tertiary care New Mexico hospital was unable to adequately respond to three separate poisoning episodes (ethylene glycol, organic phosphorus compounds, and rattlesnake envenomation).<sup>47</sup> Rural hospitals are even more likely to lack antidotes.<sup>15,16,22</sup> To complicate medication management, multiple antidotes, such as bromocriptine, carnitine, cyproheptadine, glucagon, octreotide, and high-dose insulin, are not specifically labeled for use as such or are used at different dosages than that of the labeled indication.

With its small vial size, pyridoxine was particularly problematic in the past. Only half of the hospitals with pediatric emergency medicine (EM) fellowships and only two-thirds of hospitals with EM residencies had adequate pyridoxine stores, and of those that did, more than 70% of the time it was stored away from the emergency department (ED) in the hospital's pharmacy.<sup>49</sup> One isoniazid overdose case depleted the intravenous pyridoxine supply for a significant region of a state (Nebraska).<sup>40</sup> A similar isoniazid overdose case left a patient continually seizing because of an inadequate supply at a treating hospital and three of four surrounding hospitals.<sup>38</sup> In one study of 21 patients, 85% of patients failed to receive adequate initial intravenous pyridoxine because of inadequate hospital stocking, with resultant severe toxicity to one patient until antidote procurement.<sup>13</sup>

Antidotes specific to known chemical disaster scenarios are equally poorly accessible. Evaluations of a US city's preparedness in 1996 and 2000 determined that only 4.8% of local hospitals had sufficient atropine and pralidoxime to address a nerve agent incident, and none had sufficient cyanide antidotal capacity.<sup>31</sup> In a survey of Philadelphia hospitals in 2002, 87% of ED directors did not believe or did not know if adequate antidote stores for nerve agent and cyanide poisoning were available onsite.<sup>23</sup> This antidotal preparedness gap had not narrowed by 2013, when a report of US hospitals determined that only 16% of emergency care hospitals had sufficient cyanide antidote to treat just two 100-kg patients.<sup>21</sup>

The failure to adequately stock antidotes is also well described internationally. In a survey of Quebec hospital pharmacies, the number of adequately stocked antidotes ranged from 0 to 9 (of 13) and was correlated with *N*-acetylcysteine and naloxone utilization, annual ED visits, and weekend pharmacy coverage, suggesting that smaller hospitals were poorly positioned to adequately care for poisoned patients.<sup>12</sup> Ontario hospitals were no better; only 1 of 179 hospitals (0.6%) stocked adequate amounts of 10 basic antidotes, and more than half were stocked less than 50% of the time.<sup>29</sup> A 2003 study of British Columbia hospitals found zero hospitals with adequate stocking of 14 antidotes, with poor availability of DSFab, glucagon, pyridoxine, and antivenom.<sup>22</sup> In follow-up in 2005, only 51% to 70% had adequate folic acid, glucagon, methylene blue, atropine, pralidoxime, leucovorin, pyridoxine, and deferoxamine; fewer than 50% had adequate DSFab; and only 7 (8.9%) hospitals sufficiently stocked 21 essential antidotes.<sup>63</sup> Similar deficiencies in antidote stocking are reported in Greece,<sup>48</sup> Lebanon,<sup>34</sup> Malaysia,<sup>2</sup> Spain,<sup>45</sup> sub-Saharan Africa,<sup>52</sup> and Taiwan.<sup>46</sup> Hospitals in the United Kingdom generally had access to *N*-acetylcysteine, activated charcoal, dantrolene, desferrioxamine, naloxone, flumazenil, and vitamin K but lacked cyanide antidotes,

cyproheptadine, ethanol, fomepizole, pralidoxime, succimer, and viper antivenom.<sup>54</sup> Antidote stocking in New Zealand was generally robust, with only very rarely used antidotes being unavailable (eg, Prussian blue).<sup>1</sup>

## NATIONAL AVAILABILITY

National shortages can impede institutional attempts to obtain and sustain necessary antidotes. The underlying causes of antidote shortages are complex and include a constricted supplier and manufacturer pool, supply chain disruptions, manufacturing delays, demand issues, economic factors, legal decisions, and the unintended consequences of well-intentioned regulatory approaches (eg, regulatory inspections and the Food and Drug Administration {FDA} Unapproved Drugs Initiative).<sup>24,37,58</sup> Novel regulatory requirements present a particular threat to antidotes that are not specifically labeled for toxicologic use or are used at different dosages than the FDA-approved labeling. The 2011 American Hospital Association survey on drug shortages reported that 99.5% of hospitals reported experiencing one or more drug shortage in the previous 6 months, 82% of hospitals had to delay patient treatment as a result of a drug shortage, and hospitals rarely or never received advance notice of drug shortages and were not informed of the cause or the expected duration of the shortage.<sup>7</sup> To address this crisis, the 2012 Food and Drug Administration Safety and Innovation Act<sup>11</sup> required manufacturers to notify the Secretary of Health and Human Services of significant medication disruptions, required the development and implementation of a plan to prevent and mitigate drug shortages, and required the Comptroller General of the United States to conduct a study to examine the reasons for drug shortages and formulate recommendations on remediation.<sup>5</sup> Tragically, US national drug shortages continue to number in the hundreds of medications.<sup>10</sup> Certain shortages do challenge credulity. Salt, sugar, and baking soda do not suffer from a lack of raw materials or natural abundance, but 0.9% saline, dextrose, and sodium bicarbonate for parenteral administration are intermittently difficult to obtain.<sup>10</sup> Other specific antidote shortages have included atropine, benzodiazepines, black widow spider (*Latrodectus mactans*) antivenin, CaNa<sub>2</sub>EDTA, dexrazoxane, digoxin immune Fab, epinephrine, ethanol, lipid emulsion (20%), leucovorin, methylene blue, *N*-acetylcysteine, naloxone, North American coral snake (*Micrurus fulvius*) antivenin, octreotide, and vitamin K.<sup>5</sup> In one study, 141 of 1,751 (8.1%) drug shortages were products used to treat poisoned patients.<sup>37</sup> Associated medications for critical care such as inotropes, analgesics, induction agents and paralytics for intubation, and sedatives for mechanical ventilation have not been spared.<sup>10,36,62</sup> This pervasive systemic failure to provide basic medications undermines adequate “modern” health care. Internationally, entire countries have reported a substantial rise in hard endpoints such as mortality because of an inability to obtain antidotes. For example, death rates rose threefold when digoxin immune Fab stocks were exhausted in Sri Lanka.<sup>18</sup>

The use of substitute or atypical medications can engender side effects or toxicity that would require alternative antidotes. One study of directors of pharmacy found multiple adverse events associated with drug shortages, including omission, wrong dose dispensing and administration, wrong drug dispensing and administration, treatment delays, and requirements for increased patient monitoring.<sup>39</sup> Most patients want to be informed of drug shortages and the side effects of substitutes, and drug shortages lead to patient complaints.<sup>27,39</sup> Antidote shortages are particularly vexing because of a relatively narrow number of agents “in class,” or appropriate to the poisoning. In many situations, suitable alternatives either do not exist or create new benefit–side effect conundrums. For example, sodium acetate substitution for sodium bicarbonate is limited by ceilings in acute dosing

and the side effects of myocardial depression, hypotension, hypopnea, and hypoxemia.<sup>43,44</sup>

## COST

Cost can present a significant barrier to antidote acquisition, particularly for those that are infrequently used. The reasons for this are complex and include market exclusivity, generic availability, development costs, and “what the market will bear.”<sup>32</sup> However, even simple antidotes that are years since introduction are associated with massive cost increases. Without significant new research, the original cyanide antidote kit, containing amyl nitrite, sodium nitrite, and sodium thiosulfate, was rebranded and released as “new” Nithiodote without amyl nitrite, with subsequent market exclusivity and elimination of generic competition.<sup>19</sup> In one of the most egregious examples, Valeant Pharmaceuticals raised the price of CaNa<sub>2</sub>EDTA from \$950 to \$26,927 within a year.<sup>30</sup> Similar massive increases in the cost of vital drugs such as epinephrine and naloxone are described.<sup>20</sup> In a broader analysis, the average wholesale price of 15 of 33 antidotes had a greater than 50% price increase, and 8 of 33 had greater than \$1,000 increase from 2010 to 2015.<sup>25</sup> Similar marked cost increases are detailed in the position statements of toxicologic organizations.<sup>4</sup> Even in the hospital setting, where providers and patients are typically insulated from cost, massive price increases (sometimes upwards of 70 times) have led to medication abandonment and presumably alternative medication use.<sup>33</sup> Shortages themselves exacerbate cost pressures, as pharmacy directors reported a 300% to 500% markup on medications on shortage lists.<sup>14</sup> Although factors other than cost such as frequency of use, shelf life, and outdated product returns or recycling factor into decision making, hospital emphasis on cost alone might cause EDs to forgo the most appropriate antidote.<sup>51</sup> To address these costs and provide economies of scale, standardized, regional antidote collections with online administration guidelines have demonstrated success in providing antidote coverage.<sup>42</sup>

## RECOMMENDATIONS

Because the needs of each hospital are different, a hazard vulnerability assessment approach is recommended.<sup>16</sup> Conclusions on necessary antidotes could be similarly derived from a quality and safety framework provided by the analogous VA National Center for Patient Safety’s Safety Assessment Code (SAC) Matrix.<sup>61</sup> This would include evaluating which pharmaceutical products are used as therapeutics, hospital catchment area (ie, nearby industries, indigenous creatures and plants, agricultural operations, and military or government facilities), referral patterns and mutual aid agreements, local use history or experience, anticipated volume of use, and anticipated time to restocking or resupply of antidote.<sup>16</sup> This need to understand the local ecology extends to specific clinical practice areas as well. For example, oncologic centers should address their need for leucovorin, glucarpidase, and uridine triacetate. This review should also include addressing access to specialty antidotes for other oncologic conditions, such as extravasation, that are not typically included on antidote lists, for example, dexrazoxane and sodium thiosulfate for extravasation, amifostine for radiotherapy and cisplatin bladder toxicity, mesna for cyclophosphamide and ifosfamide bladder toxicity, and colony-stimulating and growth factors (eg, darbepoetin alfa, erythropoietin, granulocyte colony-stimulating factor, granulocyte-macrophage colony-stimulating factor, oprelvekin, and palifermin).

Table SC1–1 summarizes our recommendations for the availability and storage of necessary antidotes. To achieve these goals of adequate stockings, several strategies are provided in Table SC2–2.

TABLE SC1-1 Antidote Stocking: Indications, Availability, and Storage<sup>16,35,65</sup>

Antidote (Generic Name)	Indications	Recommended Stocking Level (24 h)	Storage Information	Immediately Available	Available <60 min
Acetylcysteine IV (N-Acetylcysteine)	APAP and other causes of hepatotoxicity	20% IV solution 6 × 30 mL	Store unopened vials at 20°C–25°C (68°F–77°F). Do not use previously opened vials.	N	Y
Acetylcysteine, oral	APAP toxicity	20% oral solution 7 × 30 mL + 7 × 10 mL	Use diluted preparation within 1 h.	N	Y
Activated charcoal	Xenobiotic adsorption	4 bottles, 50 g each 2 bottles, 25 g each	Store in closed container at room temperature away from heat, direct light, and moisture.	Y	Y
Antivenom ( <i>Centruroides</i> )	Scorpion envenomation	3 vials or local zoo access	Store at room temperature (up to 25°C [77°F]). Brief temperature excursions are permitted up to 40°C (104°F). DO NOT FREEZE.	N	Y
Antivenom ( <i>Crotalidae</i> )	Crotalinae snake envenomation	12–18 vials or zoo	Store at 2°C–8°C (36°F–46°F). Do not freeze. The product must be used within 4 h after reconstitution.	N	Y
Antivenom ( <i>Elapidae</i> )	Coral snake envenomation	Local zoo access		N	Y
Antivenom ( <i>Latrodectus mactans</i> )	Black widow spider envenomation	Local zoo access		N	N
Atropine	Bradycardias, cholinesterase inhibitor toxicity	165 mg (available in 0.4 mg/mL, 1 mg/mL solution for injection and a variety of concentrations as auto-injectors and prefilled syringes)	Protect from light and store in airtight containers.	Y	Y
Benzotropine	Acute dystonia	3 × 2 mL, 1 mg/mL	Store at room temperature away from moisture and heat.	Y	Y
Botulinum antitoxin	Botulism	CDC or Health Department		N	N
Calcium disodium EDTA	Lead	2 × 5 mL, 200 mg/mL	Store at 15°C–30°C (59°F–86°F).	N	N
Calcium chloride/gluconate	Oxalates, fluoride, hydrofluoric acid, ethylene glycol, calcium channel blockers, β-adrenergic antagonist, hypermagnesemia, hypocalcemia	Ca gluconate 4.65 mEq (1 g)/10 mL—30 vials (preferred) CaCl <sub>2</sub> 13.6 mEq (1 g)/10 mL—10 vials	Store at 15°C–30°C (59°F–86°F).	Y	Y
Calcium trisodium pentetate (calcium DTPA)	Internal contamination with radioactive plutonium, americium, curium	200 mg/mL 5 mL × 1	Store at 15°C–30°C (59°F–86°F).	N	N
Cyproheptadine	Serotonin toxicity	36 mg (4 mg tablets or 2 mg/5 mL syrup)	Store at 15°C–30°C (59°F–86°F) in a well-closed container.	N	N
Coagulation factor Xa (recombinant), inactivated-zhzo	Rivaroxaban or apixaban reversal	18 × 100 mg vials	Store at 2°C–8°C (36°F–46°F). Do not freeze.	Y	Y
Dantrolene	Malignant hyperthermia	50 × 20 mg vials or Ryanodex 4 × 250 mg vials	Avoid excessive heat over 40°C (104°F).	Y	Y
Deferoxamine mesylate	Iron	12 × 500 mg vials	Do not store above 25°C (77°F).	N	Y
Dextrose (D <sub>50</sub> W)	Hypoglycemia	10 × 50 mL (25 g)	Store at 15°C–30°C (59°F–86°F).	Y	Y
Digoxin-specific antibody fragments	Cardioactive steroids	15 vials	Refrigerate at 2°C–8°C (36°F–46°F). After reconstitution, store at 2°C–8°C (36°F–46°F) for up to 4 h.	Y	Y
Dimercaprol	Arsenic, lead, mercury	8 × 3 mL, 100 mg/mL	Store at 20°C–25°C (68°F–77°F).	N	Y
Diphenhydramine	Acute dystonia, histamine receptor blockade	10 × 1 mL, 50 mg/mL	Control room temperature at 15°C–30°C (59°F–86°F). Avoid freezing and light.	Y	Y
Ethanol, oral	Methanol, ethylene glycol, diethylene glycol	1 bottle of 40%/16 oz	Store at room temperature.	N	Y
Flumazenil	Benzodiazepines	6 × 10 mL, 0.1 mg/mL	Store at 15°C–30°C (59°F–86°F).	Y	Y

(Continued)

TABLE SC1-1 Antidote Stocking: Indications, Availability, and Storage<sup>16,35,65</sup> (Continued)

Antidote (Generic Name)	Indications	Recommended Stocking Level (24 h)	Storage Information	Immediately Available	Available <60 min
Fomepizole	Ethylene glycol, methanol, diethylene glycol	4 × 1.5 mL, 1 g/mL	Store at controlled room temperature, 20°C–25°C (68°F–77°F).	N	Y
Glucagon	β-Adrenergic antagonists, calcium channel blockers	100 × 1 mg	Store at 15°C–30°C (59°F–86°F). Use immediately after reconstituted. Discard extra.	Y	Y
Glucarpidase	Methotrexate	5 × 1,000 units/vial	Store at 36°F–46°F (2°C–°C). Do not freeze.	N	N
Hydroxocobalamin	Cyanide	2 × 5 g	Lyophilized form: Store at 15°F–30°F. Cyanokit may be exposed during short periods of temperature variations of usual transport. Reconstituted solution: Store up to 6 h at temperature not exceeding 104°F (40°C). Do not freeze. Discard any unused portion after 6 h.	Y	Y
Idarucizumab	Dabigatran	2 × 50 mL, 2.5 g/50 mL	Store in the refrigerator at 2°C–8°C (36°F–46°F). Do not freeze. Do not shake. Before use, the unopened vial may be kept at room temperature 25°C (77°F) for up to 48 h, if stored in the original package, to protect from light or up to 6 h when exposed to light.	Y	Y
Insulin, regular	Calcium channel blockers, β-adrenergic antagonists	20 × 10 mL 100 units/mL	Store unopened containers in refrigerator at 2°C–8°C (36°F–46°F). Do not freeze. Vial in use may be stored under refrigeration or at room temperature; store below 30°C (86°F) away from direct heat or light.	Y	Y
Leucovorin calcium/folinic acid	Methotrexate, methanol	2 × 50 mL, 10 mg/mL	Store at 2°C–8°C. Refrigerate; do not freeze. Protect from light.	N	Y
L-carnitine	Valproic acid	15 × 5 mL, 1 g/5 mL	Store vials at 25°C. Discard unused portion of an opened vial.	N	Y
Lipid emulsion	Local anesthetics	1 × 1,000 mL 20% + 1 × 250 mL 20%	Store below 25°C; do not freeze. Emulsions that have been frozen should be discarded.	Y	Y
Methylene blue	Methemoglobinemia	6 × 10 mL, 10 mg/mL	Store at 20°–25°C (68°–77°F).	Y	Y
Naloxone	Opioids	10 × 1 mL, 0.4 mg/mL 30 × 2 mL, 1 mg/mL	Store at 20°–25°C (68°–77°F); protect from light.	Y	Y
Octreotide	Sulfonylureas	5 × 1 mL, 50 mcg/mL	Store in refrigerator at 2°C–8°C for prolonged storage. Protect from light. At 20°C–30°C or 70°F–86°F, it is stable for 14 days if protected from light.	N	Y
Physostigmine	Anticholinergics	4 × 2 mL, 1 mg/mL	Store unopened vial at 15°C–30°C.	Y	Y
Phytonadione/vitamin K <sub>1</sub>	Warfarin, rodenticide toxicity	10 × 1 mL, 10 mg/mL; 20 × 5 mg tablets	Store in the tight, light-resistant, original container at 15°C–30°C. Protect from light.	Y	Y
Polyethylene glycol electrolyte lavage solution	Gastrointestinal decontamination	10 L	Store in sealed container at 59°–86°F. When reconstituted, keep solution refrigerated. Use within 48 h. Discard unused portion.	Y	Y
Potassium iodide	Radioactive iodine	1 × 30 mL, 65 mg/mL (use with accompanying dropper)	Store at 25°C (77°F). Excursions permitted to 15°C–30°C (59°–86°F). Keep container tightly closed. Keep in carton protected from light.	N	Y
Pralidoxime	Cholinesterase inhibitor (organic phosphorus compounds, carbamates)	18 × 1-g vials	Store at controlled room temperature 20°C–25°C (68°F–77°F).	N	Y

**TABLE SC1-1 Antidote Stocking: Indications, Availability, and Storage<sup>16,35,65</sup> (Continued)**

Antidote (Generic Name)	Indications	Recommended Stocking Level (24 h)	Storage Information	Immediately Available	Available <60 min
Protamine	Heparin	4 × 25 mL, 10 mg/mL 4 vials 50 mg/5 mL	Store at 15°C–30°C. Do not freeze.	Y	Y
Prothrombin complex concentrate (three-factor) Prothrombin complex concentrate (four-factor) and vitamin K <sub>1</sub>	Vitamin K antagonist–induced anticoagulation; coagulopathy from other direct oral anticoagulants	5 × 1,000 units	Store at 2–25°C (36–77°F) (this includes room temperature); not to exceed 25°C (77°F). Do not freeze.	Y	Y
Prussian blue	Thallium, cesium	18 g (36 caps)	Store in the dark at 25°C (77°F), excursions permitted to 15°C–30°C (59°F–86°F).	N	N
Pyridoxine	Ethylene glycol, isoniazid, <i>Gyromitrin</i> mushroom toxicity	15 g 150 × 1 mL, 100 mg/mL	Store at room temperature away from moisture and heat.	Y	Y
Sodium bicarbonate	Cyclic antidepressants, salicylates, metabolic acidosis	10 vials or syringes (~50 mEq/50 mL)	Store at 15°C–30°C; freezing should be avoided.	Y	Y
Sodium nitrite Sodium thiosulfate Hydroxocobalamin preferred	Cyanide	2 × 10 mL, 30 mg/mL 2 × 50 mL, 250 mg/mL	Protect from direct light. Do not freeze. Store at controlled room temperature between 20°C and 25°C (68°F–77°F); excursions permitted to 15°C–30°C (59°F–86°F).	Y	Y
Succimer	Arsenic, lead, mercury	30 × 100 mg capsules	Store between 15°C and 25°C and avoid excessive heat.	N	Y
Sugammadex	Reversal of neuromuscular blockade induced by rocuronium and vecuronium	4 × 5 mL, 100 mg/mL	Store at 25°C (77°F); excursions permitted to 15°C to 30°C (59°F to 86°F)	Y	Y
Thiamine	Thiamine deficiency, Wernicke-Korsakoff syndrome, ethylene glycol	8 × 2 mL, 100 mg/mL	Store in tight, light-resistant containers at a temperature <40°C, preferably between 15°C and 30°C.	Y	Y
Uridine triacetate	5-Fluorouracil, capecitabine	4 × 10-g packets	Store at USP-controlled room temperature, 25°C (77°F); excursions permitted to 15°C–30°C (59°–86°F).	N	N

APAP = acetaminophen; CDC = Centers for Disease Control and Prevention; DTPA = diethylenetriaminepentaacetic acid; EDTA = ethylenediaminetetraacetic acid; IV = intravenous; N = no; USP = United States Pharmacopeia; Y = yes.

**TABLE SC1-2 Strategies to Address Antidote Stocking and Administration**

Conduct a risk assessment (hazard vulnerability assessment or safety assessment) for antidotes.
Establish dedicated spaces within emergency departments, critical care areas, and the main pharmacy for antidote stocking.
Ensure close contact and communication with regional poison control centers that may be able to assist with antidote procurement (ie, Antivenom Index), guide appropriate antidote dosing and substitution, and assist in managing poisoned patients.
Establish a systematic mechanism for evaluating antidotal stocks, dating procedures, and resupply.
Establish surveillance mechanisms and written policies and procedures for potential antidote and medication shortages.
Establish local and regional strategies for antidote sharing and distribution.
Establish local and regional strategies for patient transfer to sites with toxicologic expertise.
Coordinate with prehospital and EMS providers antidote administration and transport guidelines (eg, atropine, hydroxocobalamin, naloxone, pralidoxime, sodium nitrite, sodium thiosulfate).
Coordinate, align, and integrate antidote stocking and policies with hospital, local, and regional disaster plans (eg, atropine, botulism antitoxin, calcium trisodium pentetate, hydroxocobalamin, potassium iodide, pralidoxime, Prussian blue, sodium nitrite, sodium thiosulfate).
Establish written policies and procedures for unfamiliar antidotes.
Establish written policies and procedures to anticipate emergent requests for formulary additions for antidotal substitutions.
Establish and implement an approved medication substitution protocol, to include staff communication and education.
Monitor the effects of medication substitution.

EMS = emergency medical services.

Recommendations are derived from references 3, 5, 30, 56.

## TECHNIQUES USED TO PREVENT GASTROINTESTINAL ABSORPTION

Lotte C. G. Hoegberg

Gastrointestinal (GI) decontamination is a highly controversial issue in medical toxicology. It can play an essential role in the initial phase of management of orally poisoned patients and frequently is the only treatment available other than routine supportive care. Unfortunately, as is true in most areas of medical toxicology, rigorous studies that demonstrate the effects of GI decontamination on clinically meaningful endpoints are difficult to find. The heterogeneity of poisoned patients demands that very large randomized studies be performed because patients who present to an emergency department (ED) typically have both unreliable histories and low-risk exposures (Chaps. 4 and 130). These factors, as well as other significant sources of bias, are often hidden in inclusion and exclusion criteria of even the best available studies. Numerous determinants contribute to the difficulties in designing and completing studies that provide sound evidence for or against a particular therapeutic option. Incontrovertible endpoints, such as complication-specific mortality, also demand exceptionally large studies because the overall morbidity and mortality of poisoned patients are quite low (Chap. 130). Whereas other endpoints, such as the length of stay in the hospital or intensive care unit (ICU), change in xenobiotic concentration, the rate of secondary complications, such as seizures or QT interval prolongation, and the need for specific treatments requiring expensive antidotes, must all be considered, these surrogate markers are not adequately rigorous and are inadequately precise measures of morbidity. In the science of decontamination investigators are also faced with the dilemma that randomizing half of a group of potentially ill patients to no decontamination is a significant ethical concern. Acetaminophen is often used both as the xenobiotic of choice in volunteer studies<sup>64,124,141,237,373</sup> and in the evaluation of actually poisoned patients.<sup>78</sup> However, despite its widespread use as a model, the applicability of the management approach for APAP poisoning to other ingestions is limited. It is our recommendation that decontamination should rarely be omitted unless a minimally toxic exposure has occurred.

As might be suspected, no available study provides adequate guidance for the management of a patient who has definitely ingested an unknown xenobiotic at an unknown time. Fortunately, in most cases, there is some component of the history or clinical presentation, such as vital signs, physical examination, or focused diagnostic studies such as an electrocardiogram (ECG) and anion gap, that offers insight into the nature of the ingested xenobiotic (Chap. 3).

For many, the ongoing controversy or debate on GI decontamination culminated in 1997 with the publication of the position statements on activated charcoal (AC), orogastric lavage, syrup of ipecac-induced emesis, and whole-bowel irrigation (WBI) from the American Academy of Clinical Toxicology (AACT) and the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT),<sup>66,186,331,351,352</sup> and evolved toward sequentially lesser aggressive approaches after subsequent revisions.<sup>33,67,186,332,334, 353</sup> Contrary to initial expectations of some, these excellent reviews failed to end the debate; they simply highlighted many shortcomings and ambiguities within the field. A 2000 study concluded that despite having the evidence reviewed and consensus recommendations made, poison specialists at North American poison control centers still offered a wide variety of recommendations for GI decontamination.<sup>173</sup> The study evaluated decontamination options for a theoretical patient with a serious potentially life-threatening overdose of enteric-coated aspirin. The recommendations made were often inconsistent with the published position statements and in some cases were dangerous. Even toxicologists who made substantial contributions to the development of these consensus statements disagreed

on certain aspects of the treatment but to a lesser extent. In a similar study, when an interactive questionnaire was sent to 11 European poison control centers, significant differences in the protocols for the recommended method of GI decontamination, timing, and intervention doses were found.<sup>122</sup> Subsequently published locally adjusted recommendations for specific xenobiotics such as APAP indicate a shift away from the position statements.<sup>61,151</sup> Although the revisions include some new evidence, these differences suggest that there is still inadequate evidence available to produce a proper evidence-based answer for many of the clinical decisions we face. In most of the clinical studies that provide evidence to form the basis for the consensus statements and subsequent works, the proportion of patients with life-threatening ingestions is very small, the exclusion criteria were too broad, or the health care delivery model was too limited to provide widespread applicability to currently poisoned patients. Similarly, there are few or no studies for most drugs with modified release kinetics or altered kinetics in overdose; for the never-ending flood of newly marketed pharmaceuticals; and for patients with mixed overdoses, extremes of age, or significant end-organ dysfunction. Thus, clinicians must often make decisions based on a theoretical approach emphasizing an understanding of basic principles rather than evidence with a substantial level of uncertainty.

The reported trends in the use of GI decontamination demonstrate a continued decline in the United States (Chap. 130). The frequency of AC use declined from 4.6% of all exposures in 2006 to 1.97% in 2015, and a similar decline was observed in the frequency of orogastric lavage (4.2% in 2006 to 0.08% in 2015) and WBI (0.11% in 2006 to 0.08% in 2015) (Chap. 130). The decline in the use of GI decontamination likely results from an epidemiologic shift in the developed countries away from overdoses of more difficult to treat or more lethal xenobiotics, such as salicylates, theophylline, barbiturates, and tricyclic antidepressants, toward benzodiazepines, prescription opioids, serotonergic reuptake inhibitors, and APAP, with a natural resultant decrease in morbidity and mortality or the availability of an excellent antidote. Although true for the developed countries, studies in developing countries indicate a different pattern of poisonings, with patients ingesting xenobiotics such as organic phosphorus compounds and other pesticides and herbicides with a more lethal toxicologic profile.<sup>46,92,93</sup>

Similar to the overall trend in decontamination, the use of orogastric lavage is continually declining (Chap. 130).<sup>196</sup> The frequency of orogastric lavage varies from lowest frequency (percent of lavage compared with total decontaminations using AC, orogastric lavage, and WBI) in North America (0.08%, US) (Chap. 130) and Scandinavia (7.9%–9%; Denmark and Norway),<sup>207,367</sup> in Mediterranean countries and Russia (30%–33%; Spain, Palestine, and Russia),<sup>14,184,197,304</sup> to the highest frequency in Asia and South American countries, India (34%–50%),<sup>35,159,203,240</sup> Nepal (43%),<sup>47</sup> and Bolivia (96%).<sup>105</sup> As noted earlier, the frequency tends to correlate with the type of xenobiotic ingested, with highest frequency of lavage in regions where insecticides such as organic phosphorus compounds and carbamates are more commonly ingested.<sup>35,47,105,159</sup> Additionally, the use of decontamination seems to correlate inversely with availability of costly antidotes and ICUs. Numbers available on cause of death in the different regions of the world are estimates at best because data gaps are common because of the limited functionality of existing death-registration systems.<sup>368</sup>

This chapter does not discuss details with regard to the risk assessment and general principles of managing acutely poisoned or overdosed patients;

these issues are discussed in Chap. 4. Rather, the focus is on when to do GI decontamination and what to do, that is, determining which decontamination technique or combination of techniques is preferred after an indication for GI decontamination is established. The literature published since the previous edition of this book is emphasized, existing evidence is summarized, and areas necessitating further investigation are identified. Detailed discussions of AC and WBI are found in the corresponding Antidotes in Depth sections, Activated Charcoal (Antidotes in Depth: A1) and Whole-Bowel Irrigation and Other Intestinal Evacuants (Antidotes in Depth: A2). In addition, when the ingested xenobiotic is known, readers should also refer to the decontamination sections found in Chap. 132 and Special Considerations SC2, which offer insight into xenobiotic-specific issues that may alter decontamination strategies.

The efficacy of techniques used to prevent absorption of xenobiotics from the GI tract depend on one simple concept: At the time of the intervention, there must be enough xenobiotic in the GI tract to alter the patient's outcome if absorbed. Although this is a very simple requirement, in reality, it is almost never known, but rather is inferred from the history, particular formulation of the xenobiotic, and clinical findings. Because the concept of time is so critical to an understanding of the role of GI decontamination, this will be discussed before the individual techniques are described.

## TIME

The most common route of exposure in poisoning in the United States continues to be ingestion (Chap. 130). Similar information on routes of exposure cannot be extracted from the data available from other parts of the world.<sup>104,368</sup> After ingestion, rates of absorption of pharmaceuticals are based on pharmacokinetic studies that are typically performed on fasting healthy human volunteers given a minimal number of pills with a small amount of liquid. In contrast, most overdose patients take large numbers of pills with some liquid or food. Gastric emptying time is prolonged by the presence of food or other solids compared with liquid.<sup>300</sup> Whereas gastric emptying of liquids begins instantly in an exponential fashion, for solids, a linear emptying phase begins after a lag phase.<sup>50,183</sup>

The short (1-hour) time frame when it is theoretically possible to obtain a clinical beneficial effect from GI decontamination that was initially recommended in the position statements<sup>33,67,353</sup> or clinical studies<sup>72</sup> is now being challenged,<sup>171,205,230,266,285</sup> and guidelines for certain xenobiotics such as APAP reinforce the acceptability of delayed GI decontamination especially in the setting of massive single dose ingestions (>30 g) or modified release preparation ingestions.<sup>61,62</sup>

Case reports and clinical practice demonstrate that poisoned patients still have xenobiotics in their stomachs as residuals or pharmacobezoars, from hours up to several days after ingestion and even on autopsy.<sup>88,101,180,205,267,285</sup> Details of a selection of these reports are summarized in [Table 5-1](#).

In a prospective study of 85 poisoned patients, markedly prolonged gastric emptying half-lives and gastric hypomotility were demonstrated using gastric scintigraphy ([Table 5-1](#)).<sup>1</sup> The authors speculated that stress in an overdosed patient might be part of the etiology of the hypomotility observed and that the management of patients should not be based on the assumption that GI motility is normal.

The most meaningful study was a systematic attempt to evaluate the residual contents of the stomach using upper GI endoscopy in 167 adult patients presenting to an ED after an oral drug overdose.<sup>230</sup> The results demonstrate that residual gastric contents were found in 60% of the patients presenting more than 1 hour after the tablet ingestion and was classified as either tablet or soluble.<sup>230</sup> In fact, many patients had significant material remaining in the stomach hours later ([Table 5-1](#)).

Finally, in a review of 1,038 autopsies, 92 (9%) showed tablet or capsule residues in the GI tract. Although the time from ingestion to death could not be determined, data showed several cases in which it was estimated that death occurred more than 1 hour after ingestion<sup>205</sup> ([Table 5-1](#)).

Collectively, these data challenge both the position statement recommendations<sup>33,67</sup> and the general practice because they evaluate the

patient's actual phase of gastric emptying before the initiation of GI decontamination rather than studying the retrieval efficiency. The results emphasize the impact of well-validated imaging studies attempting to confirm the presence of medication (tablets or capsules) or liquid contents in the stomach of overdosed patients that support existing case reports and case series.<sup>179,180,229,231,252,285,326,374</sup>

Although the ability of xenobiotics to be removed by orogastric lavage is variable and unknown, the ability to prevent absorption by adsorption of the xenobiotic to AC is likely also beneficial far later than the time frame that is widely promoted.<sup>230</sup> The time before maximum absorption is reached depends on several factors. These include but are not limited to, patient-specific variables such as gut perfusion, the nature of the xenobiotic (medication, plant, or mushroom materials, chemical, etc.) physical characteristic (physical state, formulation, solubility, ionization, etc.), ingested amount, and presence of other material or coingestants in the GI tract. Further special considerations should be taken into account regarding medications. The estimated time to maximum absorption depends on the pharmaceutical preparation (liquid or solid preparation, dissolution of solid preparations, immediate- versus extended-release tablets or capsules), the nature of the active pharmaceutical ingredient (leading to increased or reduced gastric emptying), and the volume or amount of ingested xenobiotics.

Absorption from solid preparations is generally slower than liquid preparations, as a disintegration step precedes the xenobiotic dissolution that is required to be ready for absorption. In addition, extended-release tablets and capsules are designed to disintegrate or release drug more slowly than their immediate-release counterparts. These effects cause both a delayed onset of symptoms and prolonged toxicity in overdoses compared with therapeutic use. Usual treatment nomograms calculated for immediate release formulations of some xenobiotics such as APAP, are not appropriate for controlled-release formulations because the absorption phase is prolonged, and the time to maximum plasma concentration is correspondingly prolonged.<sup>299</sup> Furthermore, the maximum blood concentrations obtained after the ingestion of a specific dose of an extended-release formulation will most probably not rise as high as for the same dose of an immediate-release preparation.

The formulation of the extended-release tablet is critical to the risk of development of a pharmacobezoar.<sup>285,286</sup> Many different extended-release drug delivery systems are available.<sup>250</sup> They include hydrophilic matrix systems, in which the polymeric coating swells in contact with an aqueous medium to form a gel layer on the surface of the tablet ([Fig. 5-1](#)), which tends to cause tablet adherence in aqueous acidic media ([Fig. 5-2](#)).<sup>286</sup> This adherence is also recognized in case reports associated with the formation of pharmacobezoars.<sup>24,285,312</sup> The active xenobiotic is ultimately released by dissolution, diffusion, or erosion.<sup>209,250</sup>

Extended-release preparations or xenobiotics known to slow gastric transit time were the predominantly retained xenobiotics in the retrospective review of autopsy reports.<sup>205</sup> Gastroscopy revealed pharmacobezoar formations in approximately 50% of the cases after ingestion of quetiapine extended-release tablets.<sup>285</sup> The formation of pharmacobezoars necessitates treatment recommendations based on nonexistent toxicologic data, and recommendations for the management of immediate-release pharmaceuticals are without utility.<sup>61,151,299</sup> The release of xenobiotic(s) retained within the pharmacobezoar is slower compared with the release from individual tablets because the surface-to-volume ratio is lower, thereby reducing the rate of dissolution.<sup>19,145,286</sup> The time to appearance of symptoms in the patient is expected to be both delayed and prolonged and the maximum serum concentration possibly lower, but as long as the xenobiotic(s) remains in the pharmacobezoar, continuous release will occur. There are no specific rules that adequately predict when pharmacobezoars form or in which patients they form, and after they have formed, pharmacobezoars are difficult to identify.<sup>320</sup> Evidence of continuing absorption should raise suspicion for pharmacobezoar formation. The most effective methods of GI dissolution of pharmacobezoars are yet to be explored.<sup>39,320</sup>

TABLE 5-1 Evidence to Suggest a Utility of Gastrointestinal Decontamination Beyond 1 Hour Postingestion

Author	Citation	Study Method	Outcome Measure	Main Result	Comments
<b>Volunteer Data</b>					
Christophersen et al. 2002	64	RCT, cross-over study ( $n = 12$ ); APAP 50 mg/kg, either given alone (control) or with AC 50 g at 1 or 2 h.	PK parameters for APAP: $AUC_{0-\infty}$ , $C_{max}$ , $t_{max}$ , and $t_{1/2}$ calculated to evaluate the effects of AC on APAP absorption.	AC at 1 h reduced APAP AUC by 66% at 1 h compared with control; AC at 2 h reduced APAP AUC by 22.7% compared with control.	AC was effective in reducing the systemic absorption of APAP when administered both 1 and 2 h after ingestion.
Green et al. 2001	124	RCT, crossover study ( $n = 10$ ); compared four groups given 4 g of APAP either alone (control) or with AC 50 g at 1, 2, or 3 h postdose.	PKs were calculated to evaluate the effects of AC on APAP absorption.	Only the 1-h group was significantly different from control, showing a 30.3% in AUC.	Benefits from AC administered 1 h after APAP; AC at 2 or 3 h had no significant effect.
Ollier et al. 2017	257	RCT, crossover study ( $n = 12$ ); compared 4 groups given 40 mg of rivaroxaban either administered alone (control) or with AC 50 g at 2, 5, or 8 h postdose.	PKs were calculated to evaluate if AC interfered with rivaroxaban absorption. Estimated PKs were further investigated at 14, 20, and 26 h by nonlinear mixed-effect PK modeling.	AC at 2, 5, and 8 h significantly reduced rivaroxaban AUC by 43%, 31%, and 29%, respectively. Modeling at 14, 20, and 26 h showed reductions in AUC of 23%, 16%, and 10%, respectively.	Benefits of AC up to 8 h and possibly beyond likely secondary to the prolonged absorption profile of rivaroxaban, incomplete initial dissolution, and possible enteroenteric recycling.
Sato et al. 2003	303	RCT ( $n = 46$ ); APAP 2 g in 13; 3 g in 33 volunteers. After 3 h, half of the participants received 75 g of AC.	Serum APAP concentrations at 4 and 7 h after the administration were compared.	APAP concentrations in the AC group were reduced by 23% at 4 h and by 62% at 7 h compared with control.	Benefits of AC administered 3 h after APAP.
Wang et al. 2014	366	RCT, crossover study ( $n = 18$ ); compared three groups given 20 mg of apixaban either alone (control) or with AC 50 g at 2 or 6 h postdose.	PKs were calculated to evaluate the effect of AC on apixaban absorption.	AC at 2 and 6 h significantly decreased apixaban AUC by 50% and 28%, respectively, and decreased elimination half-life to 5.3 h and 4.9 h, respectively, compared with control. There was no effect of AC on $C_{max}$ or $t_{max}$ .	Benefits of AC up to 6 h. The reduced exposure in apixaban from AC dosing appeared by a combination of decreased bioavailability and increased elimination in the GI tract by interruption of its enteroenteric recirculation.
Yeates et al. 2000	373	RCT, crossover study ( $n = 10$ ); compared four groups given 3 g of APAP either alone (control) or with AC 50 g at 1, 2, or 4 h postdose.	PKs were calculated to evaluate the effects of AC on APAP absorption.	AC at 1 and 2 h significantly reduced APAP AUC by 56% and 22%, respectively. At 4 h, the reduction of 8% was not significant.	Benefits of AC up to 2 h after APAP.
<b>Actual Overdose Data</b>					
Adams et al. 2004	1	Prospective cohort of poisoned patients who underwent gastric scintigraphy shortly after presentation and again at follow-up.	Gastric emptying half-time was compared in 104 patients at initial presentation and again in 85 at follow-up.	APAP, APAP–opioid combinations, CAs, and carbamazepine but not phenytoin had prolonged gastric emptying half-times that were significantly shorter on followup. For all patients combined, the mean gastric emptying half-time was 99.5 min on presentation vs 40 min at follow up ( $P < 0.0001$ ).	For many xenobiotics, the presence of an overdose itself decreases gastric motility and increases the likelihood of having material present in the stomach for a longer period of time. For the entire group, >50% of gastric contents present at presentation was still in the stomach 1.5 h later.
Chiew et al. 2017	62	Combined prospective observational study (two PCC) and retrospectively (three clinical toxicology unit databases) of APAP overdoses $\geq 40$ g ingested over $\leq 8$ h.	Acute liver injury, liver transplant, and death. APAP concentration at 4–16 h postingestion relative to 4-h standard nomogram line.	Of 200 cases, 14% developed hepatotoxicity, one liver transplant and one non-APAP–related death; AC was dosed to 25% at median of 2 h postingestion. AC within 4 h of ingestion reduced the APAP ratio and rates of hepatotoxicity compared with no AC. The APAP ratio was $\geq 2$ in 40%, and 22% received an increased dose of acetylcysteine (200 mg/kg/16 h) in the first 21 h, significantly reducing the risk of hepatotoxicity.	AC dosed within 4 h of APAP ingestion significantly reduced APAP concentrations and risk of hepatotoxicity.
Cooper et al. 2015	80	Population PK study of sertraline overdose using data collected prospectively from 28 patients overdosed with sertraline; median dose, 1,550 mg.	PK parameters, including $t_{1/2}$ , $C_{max}$ , $t_{max}$ , and AUC.	AC significantly increased sertraline clearance by an estimated factor of 1.9. AC significantly reduced $t_{1/2}$ and AUC of sertraline if dosed up to 4 h after drug ingestion.	PK benefits of AC up to 4 h after sertraline ingestion compared with no AC.

(Continued)

**TABLE 5-1** Evidence to Suggest a Utility of Gastrointestinal Decontamination Beyond 1 Hour Postingestion (*Continued*)

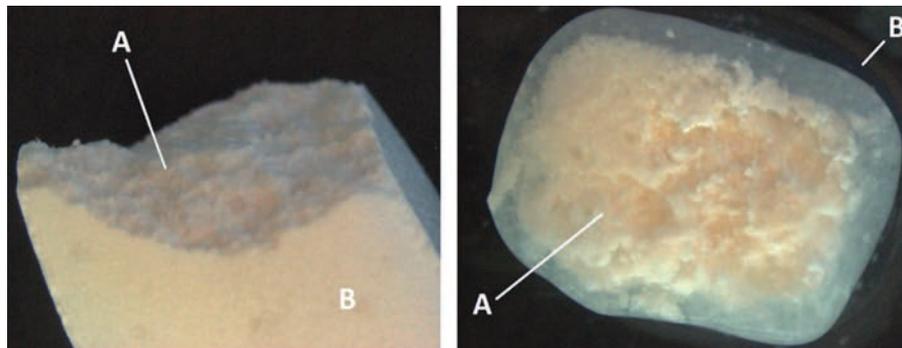

Author	Citation	Study Method	Outcome Measure	Main Result	Comments
Friberg et al. 2005	112	Population PK study of data from 63 citalopram overdose events in 53 patients; median dose, 270 mg. PK parameters were elicited from 14 studies on therapeutic citalopram dosing.	Comparison of AC given between 0.5 and 4 h overdose.	AC increased clearance by 72% and decreased bioavailability by 22%. In most patients, the AC was dosed more than 1 h after ingestion. Only 1 patient received AC within 1 h, 9 received AC within 1–2 h, and 7 patients received AC within 2–4 h.	Benefits of AC on clearance and relative fraction absorbed up to 4 h after citalopram ingestion.
Isbister et al. 2007	163	Prospective study describing quetiapine PK in overdose using Bayesian population PK analysis in 54 overdose events; median dose, 2,700 mg.	Comparison of AC given between 0.5 and 6 h.	PK estimated AC to reduce absorbed quetiapine fraction by 35%.	AC leads to a pronounced decrease in the relative fraction of quetiapine absorbed even when given after 1 h.
Livshits et al. 2015	205	Retrospective review of autopsy reports; cause of death was determined as <i>intoxication</i> or <i>overdose</i> . Decedents of all ages with solid drug ingestions.	Assessment of unabsorbed drug present in the GI tract and to analyze pharmacologic characteristics of retained drugs when present.	92 of 1038 autopsies had solid drug material in the GI tract; in 98%, the material was either modified-release preparations or drugs known to slow GI transit; most common were opioids and anticholinergics.	Unabsorbed drug can be found in the GI tract for a substantial time after oral drug ingestion of either modified-release preparations or substances known to slow GI tract motility.
Miyauchi et al. 2015	230	Cohort data from 167 overdoses prospectively collected. Endoscopy was performed on admission. Patients were classified into three groups; tablet/food phase, soluble/fluid phase, and reticular/empty phase.	The groups were compared with respect to time elapsed since ingestion and numbers and variety of orally overdosed drugs.	In the tablet/food group, 12 of 73 patients (16%) presented within 1 h, and 3 patients presented >12 h since ingestion. In the soluble/fluid phase group, 9 of 50 patients (18%) presented within 1 h, and 2 patients presented >12 h. In the reticular/empty phase group, 28 of 44 patients presented 1–6 h, 3 <1 h, and 13 >6 h since ingestion.	>60% of patients had substantial gastric contents >1 h after ingestion, and materials were found in 17% >4 h after ingestion.
Papazoglu et al. 2015	267	Case report in a 65-year-old patient.	Serum APAP concentration.	A combination of APAP–opioid ingestion a second APAP peak after completing 21 h of NAC. 9 h after finishing NAC, removal of the NG tube showed solid fragments in the tube lumen; continued absorption was confirmed by a serum APAP concentration.	Prolongation of NAC infusion beyond the standard protocol was necessary to prevent the development of hepatocellular damage.
Rauber-Lüthy et al. 2013	285	Case series of overdose patients undergoing gastroscopy ( $n = 9$ ). Ingested quetiapine doses were 6–24.4 g.	Gastroscopy findings in quetiapine extended-release tablet poisonings.	The time from ingestion to gastroscopy was known in 7 cases (2.25–13 h). In all patients, gastroscopic removal of a pharmacobezoar was performed.	Tablets present in the stomach many hours postingestion.

AC = activated charcoal; APAP = acetaminophen; AUC = area under the concentration vs time curve;  $C_{max}$  = maximal concentration; GI = gastrointestinal; inf = infinity; NAC = *N*-acetylcysteine; NG = nasogastric; PCC = Poison Control Center; PK = pharmacokinetics; RCT = randomized controlled trial;  $t_{1/2}$  = terminal elimination half-life;  $t_{max}$  = time to maximal concentration; TCA = tricyclic antidepressant.

## OROGASTRIC LAVAGE

The principal theory governing orogastric lavage for gastric emptying is very simple: if a portion of a xenobiotic with substantial toxic potential is removed before absorption, toxicity should be either prevented or

diminished. The relevant amount of xenobiotic that needs to be removed to obtain a beneficial treatment effect varies depending on the xenobiotic, the amount ingested, the overall health of the patient, and the shape of the dose–response curve for the individual xenobiotic. One group of authors defined

**FIGURE 5-1.** Acetaminophen 500-mg extended-release tablet microscopy. The tablet cut was in halves and showed as the dry tablet at the left and after incubation in 1 L of simulated gastric fluid for 4 hours at 37°C.<sup>286</sup> **A**, Tablet core. **B**, Hydrogel polymer coating material (*left*) forming the swelled gel-layer (*right*) surface of the tablet. the efficacy of orogastric lavage by the number of therapeutic doses recovered, with more than two or more than 10 therapeutic doses representing possible and definite clinical benefit, respectively. In 76 patients poisoned by sedative-hypnotics, they reported that 10 therapeutic doses were recovered in 6.6% of the patients lavaged, and two therapeutic doses were recovered in 15.8% of the cases.<sup>73</sup> This approach is emphasized to highlight the confusion, given that knowing the amount recovered fails to expand understanding without knowing either the dose ingested or the dose remaining.

Even though the benefit of orogastric lavage is questionable, many publications demonstrate that there is a continued frequent or routine use of orogastric lavage, without reflection on the clinical effect obtained or fragments or volume of the xenobiotic retrieved.<sup>3,15,39,56,68,102,119,132,133,154,160,175,187,204,211,228,236,238,280,283,296,315,318,327,370,374</sup> Only a few authors report that actual fragments or specific volumes were retrieved during the procedure.<sup>28,29,117,179,227,269,301,315,369</sup> This lack of precision supports the concept that routine use of orogastric lavage should be avoided.

More than a quarter of a century ago, several important clinical trials attempted to define the role of gastric emptying in poisoned patients.<sup>10,43,72,155,188,226,279,350</sup> (Table 5–2). Although all of these studies were limited because of the inclusion of a large number of low-risk patients, numerous restrictive exclusion criteria, and methodologic biases, they clearly demonstrated that many patients can be successfully managed without orogastric lavage. From 1995 until the present, few additional studies were published, and the series of updated position papers in 2004 and 2013 and reviews further emphasized the limited need for gastric emptying in poisoned patients.<sup>11,33,36,41,184,185,353,375</sup> No new clear evidence to support the clinical effectiveness of orogastric lavage is available,<sup>40,43,60,64,72,95,103,126,127,159,188,226,279,329,330,350</sup> and studies and reports describe a modest, varied, and unreliable effect.<sup>89,110,125,127,157,184,193,195,200,210,295,371</sup> The difficulties involved with attempting to evacuate ingested fragments were described in the 1970s, and a possible benefit from multiple orogastric lavage procedures was suggested.<sup>157,316</sup> Orogastric lavage using potassium permanganate lavage solutions or vegetable oils that were theoretically effective at protecting against the xenobiotic by change of oil–water equilibrium or chemical reaction were tried and abandoned because of variably poor efficacy.<sup>4,215,223</sup>

The ability to visualize fragments before determination of the need for GI decontamination has revitalized interest in selected use of orogastric lavage, and studies and case reports evaluate the amount of xenobiotic in the stomach before the initiation of orogastric lavage. Gastric tablet fragments are identified by endoscopy<sup>229–231</sup> using ultrathin esophagogastroduodenoscopy to confirm gastric presence of the ingested xenobiotic and thereby not only determine whether a potential benefit from orogastric lavage is present but also guide the actual orogastric lavage procedure. In two cases of potentially severe poisonings, direct visualization allowed observation of the effectiveness of orogastric lavage and aided clinicians in evacuating tobacco extract and the cyclic antidepressant amitriptyline.<sup>229,231,252</sup> Similarly, abdominal computed tomography was used to identify tablets, capsules, or liquid corresponding to the ingested xenobiotic up to 5 hours after the ingestion.<sup>2,179,180,374</sup> Unfortunately, transabdominal ultrasonography was neither able to determine the presence nor absence of tablets in simulated overdose studies, and both sensitivity and specificity were poor, leading the authors to conclude that ultrasonography is not a useful screening tool for the detection of gastric tablets and tablet residues.<sup>252,326</sup>

The clinical parameters listed in Table 5–3 help to identify individuals for whom orogastric lavage is usually not indicated based on a risk-to-benefit analysis. In contrast, for a small subset of patients (Table 5–3), gastric emptying is still recommended. A thorough understanding of this risk analysis is essential when deciding whether orogastric lavage is appropriate for a patient who has ingested a xenobiotic.

Time is an important consideration because for orogastric lavage to be beneficial, a consequential amount of xenobiotic must still be present in the stomach. Demographic studies have found that very few poisoned patients arrive at the ED within 1 to 2 hours after ingestion. In most studies, the average time from ingestion to presentation is approximately 3 to

4 hours, with significant variations.<sup>174,185,188,230,335</sup> This delay diminishes the likelihood of recovering a large percentage of the xenobiotic from the stomach to reduce a grave or possible lethal amount to a survivable amount except in those who have taken a massive amount. Many authors have adopted the consensus approach that orogastric lavage should not be considered unless a patient has ingested an amount of a xenobiotic with the potential to be severely harmful to organs or life threatening and when the procedure can be undertaken within 60 minutes of ingestion.<sup>89,289</sup> As discussed earlier and shown in Table 5–1, there is growing evidence to support the delayed persistence of significant amounts of drug in the stomach of selected overdose patients, thereby invalidating any concept of a hard stop occurring 60 minutes postingestion.

Assessment of whether or not orogastric lavage is appropriate for a patient must include an evaluation for potential contraindications (Table 5–4). Regardless of the severity of the ingestion and other contributing factors, such as time, there must be no contraindication to orogastric lavage procedures. Because the demonstrable benefit of orogastric lavage after ingestion of an unidentified xenobiotic is marginal at best, even relative contraindications usually dictate that the procedure should not be attempted. However, the clinical benefit could be significant if the ingested dose places the patient on the steep portion of the dose–response curve (Chap. 9). Under these circumstances, a small reduction in dose available for absorption would translate into a significant reduction in the potential for toxicity.

It is important to highlight the differences between volunteer studies using therapeutic doses of drugs and actual patients with clinically significant overdoses. The most important aspect of this comparison is a bias against gastric emptying and toward a benefit with AC. The drugs used in volunteer studies are typically well adsorbed by AC, and the doses of AC are significantly in excess of the AC–drug ratios that can be achieved in clinically significant overdoses. Larger overdoses, as might occur in patients with clinically important ingestions, are likely to saturate AC. An additional bias is introduced against gastric emptying in volunteer studies because the small amounts of any study xenobiotic used are unlikely to alter gastric motility, and thus the xenobiotics are more likely to pass through the pylorus before orogastric lavage is performed. A synthesis of available data can be used to develop indications for orogastric lavage (Table 5–4). Use of combination therapies with administration of AC after orogastric lavage was described by several,<sup>6,7,14,37,47,100,108,166,169,197,224,226,272,287,343,354</sup> but the procedure was not more effective than AC alone,<sup>41,64,193–195</sup> and it is unclear whether the outcome was due to orogastric lavage, other treatments, or their combination, and the procedure sometimes resulted in increased xenobiotic concentration and worsened clinical outcome.<sup>14</sup> In some cases, orogastric lavage delays AC administration further, and it is reasonable to eliminate orogastric lavage and only administer AC in cases when the benefits of orogastric lavage are estimated to be minimal to initiate the fastest decontamination procedure.

The procedure should always be performed by trained health care professionals and in health care settings. When deciding whether to actually perform orogastric lavage for a poisoned patient, these indications, contraindications, and potential adverse effects must be considered. Table 5–5 summarizes our recommended technique of orogastric lavage.

The tube size used for the procedure must be considered before initiation of the procedure if orogastric lavage is to be of value. Only gastric contents able to pass through the tube will be removed by the procedure (eg, liquid is able to pass through a small size tube, but a large tube might be necessary for tablets). If the ingested tablets are of known origin, it can be determined whether the tablets or capsules are able to pass through the tube at all in addition to difficulty of a pharmacobezoar that is unable to pass through any orogastric lavage tubes (Fig. 5–2).<sup>19,88,145,210,285,286,311,312</sup>

The volume of fluid used during orogastric lavage is not reported in most cases. Reported volumes vary from a few deciliters to 1 to 5 L<sup>51,194,216,219,364</sup> and up to 40 L,<sup>202</sup> or cycles of 250 mL until clear return fluid,<sup>188</sup> 200 to 400 mL cycles after aspiration of gastric content,<sup>73</sup> 400 to more than 1,000 mL each cycle,<sup>94</sup> or 8 mL/kg repeated five times.<sup>120</sup> Others are nonspecific, such as “one or more liters” or “lavage until the fluid was clear,” in both children<sup>44</sup> and

TABLE 5-2 Summary of Studies Evaluating the Effect of Gastric Lavage on the Absorption of Diverse Xenobiotics

Author	Citation	Study Method	Outcome Measure	Main Result	Comments
<b>Volunteer Studies</b>					
Christophersen et al. 2002	64	RCT; efficacy of AC and GL + AC 1 h compared with control (no AC) after a 50-mg/kg APAP dose ( $n = 12$ ).	PK parameters for APAP: $AUC_{0h-inf}$ , $C_{max}$ , $t_{max}$ , and $t_{1/2}$ .	AC reduced APAP absorption by 66%, GL + AC reduced by 48.2% with controls; no significant difference between AC and GL+AC.	Combination treatment with GL + AC is not better in reducing APAP absorption compared with AC alone.
Grierson et al. 2000	127	RCT; crossover; two sessions ( $n = 10$ ). Effect of GL to reduce absorption of liquids; 4 g of APAP, no GL vs GL (minimum $5 \times 200$ -mL cycles) after 1 h after ingestion.	PK parameters for APAP: $AUC_{0-8h}$ , $C_{max}$ , $C_{4h}$ , and $t_{max}$ .	No difference in $C_{max}$ or $t_{max}$ ; reduction after GL in $C_{4h}$ and AUC APAP absorption reduced by 20% (high SD).	Does not support of GL because clinical benefit was deemed unlikely, and other more effective treatments are available for APAP poisonings.
Lapatto-Reiniluoto et al. 2000	195	RCT; three sessions ( $n = 9$ ); 25 g of AC vs GL ( $10 \times 200$ mL) at 30 min after 150 mg of moclobemide, 10 mg of temazepam, and 80 mg of verapamil.	PK variables $AUC_{0-24h}$ , $C_{max}$ , $t_{max}$ , $t_{1/2}$ of moclobemide, temazepam, and verapamil compared with control.	AC – $AUC_{0-24h}$ reduction: moclobemide, 55%; temazepam, 45%; verapamil, NS. $C_{max}$ reduction: moclobemide, 40%; temazepam, 29%; verapamil, 16%. GL – $AUC_{0-24h}$ reduction: moclobemide, 44%; temazepam, NA; verapamil, NS. $C_{max}$ reduction: NS for all drugs.	GL was less effective in reducing absorption of moclobemide, temazepam, and verapamil.
<b>Actual Overdose Data: Case Reports (Examples), Case Series, Cohort, Retrospective</b>					
Comstock et al. 1981	73	Efficacy of GL (200- to 400-mL cycles) in 76 patients with sedative-hypnotic drug ingestions determined as recovered therapeutic doses. An efficacious lavage is suggested to be defined as recovery of at least either 2 or 10 therapeutic doses.	Drug concentrations in GL fluid and blood; time since ingestion when this could be determined.	Two or more therapeutic doses were recovered from 15.8% of the lavage samples, and 10 or more therapeutic doses were recovered from 6.6%. Poorest recoveries were obtained in patients lavaged more than 2 h after ingestion.	The majority of the patients did not benefit from GL.
Donkor et al. 2016	89	Retrospective review of 923 PCC records; Determine case type, location, and complications of GL cases.	Mortality, details of the xenobiotic ingestion (substance(s), time, dose), clinical effects, needs for care, decontamination method, GL outcome.	381 single and 540 multiple-xenobiotic ingestions: Non-TCA psychotropics, BZDs, and APAP were most common; 5 deaths; in 58% of cases GL was performed by PCC recommendation, in 42% without recommendation; complications reported in 20 cases; xenobiotic fragments were retrieved in 27%.	Inappropriate used of GL frequent; questionable effect beyond 1 h.
Leao et al. 2015	200	Retrospective data, 2012, carbamate or OP poisoning ( $n = 70$ ; 77% carbamates, 23% OPs).	Clinical characteristics and treatment patterns (atropine, GL, AC), length of stay.	OP poisonings were more severe, with 68.75% of patients presenting moderate to severe toxicity. Atropine and AC significantly reduced signs and symptoms; GL was not effective.	GL contraindicated in acute toxicity from carbamates or OPs.
Magdalan et al. 2013	210	Case report; 42-year-old patient; clomipramine extended-release tablets, unknown dose, 14 h before. Treatment included GL and then 50 g AC every 4 h.	CA level on admission, 1,955 ng/mL; postmortem blood clomipramine, 1,729 ng/mL and nor-clomipramine, 431 ng/mL, myocardium clomipramine, 14,420 ng/g, nor-clomipramine, 35,930 ng/g.	Died; prolonged toxicity related to a large gastric pharmacobezoar.	GL revealed no tablets in lavage fluids.
Woo et al. 2013	371	Case report; 57-year-old patient; dabigatran 11.25 g, alprazolam unknown dose, 1 h before. Treatment included GL and then AC.	Blood dabigatran, 970 ng/mL; thrombin clotting times measured above the testable limits ( $>120$ s) until 52 h postarrival.	Nontraditional intervention using GL in addition to AC in a coagulopathic patient.	The direct impact and efficacy of including GL was unclear.
<b>Controlled Studies in Patients</b>					
Bosse et al. 1995	43	RCT; prospective evaluation in 51 patients with TCA poisoning. Compared 50 g of AC, saline GL + 50 g AC, and 25 g AC + GL + 25 g AC. GL used 2 L or more as needed to produce a clear effluent.	Mortality; duration of hospital stay, ICU stay, mechanical ventilation, cardiotoxic symptoms and their duration (tachycardia, hypotension, wide QRS complex, ventricular dysrhythmias).	No deaths were reported. No statistically significant differences in clinical outcomes were shown between groups.	The clinical outcomes were similar using all three decontamination methods.

(Continued)

**TABLE 5-2** Summary of Studies Evaluating the Effect of Gastric Lavage on the Absorption of Diverse Xenobiotics (Continued)

Author	Citation	Study Method	Outcome Measure	Main Result	Comments
Comstock et al. 1982	72	Prospective evaluation in 339 patients with acute oral overdose of efficacy of AC after GL. All received GL, and 131 were randomly chosen also to receive AC.	Blood drug concentrations were continuously monitored to determine continued absorption after GI decontamination procedure.	The trend suggested that continued absorption was less frequent in the AC group. Ingestion time >1 h.	No clear additional benefit from AC.
Indira et al. 2013	159	Prospective evaluation in 176 patients with OP poisoning. Identified clinical profile of intermediate syndrome influencing the clinical course. All received GL and AC. Compared early (<1 h) vs late (>1 h) GL and single GL vs two GLs.	Mortality; vital signs; atropinization; pulse oximetry; cholinergic signs; specific treatment, including number of performed GL and antidote pralidoxime in OP poisonings.	Mortality rate was 28.4% ( $n = 50$ ), all secondary to respiratory failure. Mortality with single vs double GL was 23 vs 25 ( $P = 0.99$ ); 80 received single GL, 87 two GLs. Mortality with early vs late GL 12 vs 36 ( $P = 0.5$ ), 48 received GL <1 h, 119 >1 h; 9 patients did not receive GL; 31 had intermediate syndrome.	No significant protection by early GL. No difference between early vs late GL. More than one GL procedure was protective against intermediate syndrome but not final outcome. Intermediate syndrome: Strongly associated with mortality; lower in multiple GL group; no association with GL timing.
Krayeva et al. 2013	184	Prospective prehospital study on poisoning epidemiology, treatment, and complications from treatment ( $n = 2,536$ ).	Mortality, xenobiotic, clinical findings, treatment.	Overall mortality rate, 1.5%; mortality in +GL/+intubated 2.5%, in +GL/-intubation 2%, in -GL/-intubation 0%; Prehospital GL in 34% ( $n = 852$ ) (20% <1 h, 61% <2 h), all performed in the patients' homes.	High prevalence of GL differing from recommended treatment practice; GL performed by tradition after corrosive substance ingestions. Non-randomized, so outcome differences unclear.
Kulig et al. 1985	188	RCT; prospective evaluation in 592 overdose patients of the clinical outcome of AC (oral in alert patients or by NG tube in obtunded pts) compared with GL + AC.	Severity based on clinical course by symptoms (mild, moderate, severe) continuously the first 6 h.	GL within 1 h in obtunded pts improved clinical outcome; no difference between other groups.	Management without gastric emptying preferable in many patients; GE should not be standard care; benefit questionable effect of GL if initiated >1 h. Exclusion criteria biased against a benefit of GL.
Merigian et al. 1990	226	Prospective evaluation of GE (ipecac or GL) + AC or AC in the self-poisoned patient. AC was dosed in asymptomatic patients ( $n = 451$ ), GE + AC was dosed in symptomatic patients ( $n = 357$ ); 4-h observation. Sustained-release products and mushrooms were excluded because of potential late (>4 h) onset of symptoms.	Vital signs, supportive therapy, intubation, deterioration, duration of intubation, clinical disposition, disposition time, and total time in the ED.	No clinical deterioration occurred in the asymptomatic patients treated without GE. AC did not alter outcome measures in asymptomatic patients. GL was associated with a higher prevalence of ICU admissions and aspiration pneumonia. The data support the management of selected acute overdose patients without GE and failed to show a benefit from AC in asymptomatic overdose patients.	No additional benefits from GL. Increased prevalence of side effects and ICU care from GL. Large proportion of low-risk cases and extensive exclusion criteria biased against a benefit of GL and drove the negative outcome.
Pond et al. 1995	279	RCT; prospective evaluation in 876 overdose patients of the efficacy and safety of AC (oral or by NG tube in obtunded patients) compared with GL + AC.	Clinical course by symptoms (mild, moderate, severe) assessed every 1–2 h the first 6 h; length of hospital stay; complications.	Authors report no difference between groups after discounting positive cases.	No benefit of GL before AC. Exclusion criteria biased against a benefit of GL.
Saetta et al. 1991	295	RCT; prospective evaluation of gastric emptying procedures' (GL or ipecac) ability to force gastric contents into the small bowel using barium-impregnated polythene pellets ( $n = 60$ ).	Abdominal radiograph after pellet ingestion and GL ( $n = 20$ ) using 3.5–6 L of fluid.	51.8% pellets retained after GL of which 33.3% in the small intestine. Significantly fewer pellets (16.3%) had passed into the small intestine in the control group ( $n = 20$ ).	GL was inefficient and forced gastric content into the small intestine. Time from xenobiotic ingestion to pellet ingestion was unknown.
Underhill et al. 1990	350	RCT; prospective evaluation in 60 patients; APAP >5 g ingestion within 4 h; compared efficacy of GL and AC.	Percentage change between first and last APAP plasma concentrations.	Mean percentage falls in APAP concentrations were 39.3% for GL and 52.2% for AC.	AC was more effective in limiting APAP absorption compared with GL.

AC = activated charcoal; APAP = acetaminophen; AUC = area under the concentration vs time curve; BZD = benzodiazepine;  $C_{max}$  = maximal concentration; CA = cyclic antidepressant; GE = gastric emptying; GI = gastrointestinal; GL = orogastric lavage; h = hour; ICU = intensive care unit; NAC = *N*-acetylcysteine; NG = nasogastric; NS = not significant; OP = organic phosphorus compound; PCC = Poison Control Center; PK = pharmacokinetics; RCT = randomized controlled trial; SD = standard deviation;  $t_{1/2}$  = terminal elimination half-life;  $t_{max}$  = time to maximal concentration.

TABLE 5-3 Risk Assessment: When to Consider Orogastric Lavage

Orogastric Lavage Is Usually Not Indicated <sup>a</sup>	Orogastric Lavage Is Indicated <sup>b</sup>
The xenobiotic has limited toxicity at almost any dose.	The ingested xenobiotic is known to produce life-threatening toxicity or the patient has obvious signs or symptoms of life-threatening toxicity and
Although the xenobiotic ingested is potentially toxic, the dose ingested is likely less than that expected to produce significant illness.	■ There is reason to believe that, given the time of ingestion, a significant amount of the ingested xenobiotic is still present in the stomach or
The ingested xenobiotic is well adsorbed by AC, and the amount ingested is not expected to exceed the adsorptive capacity of AC.	■ The ingested xenobiotic is not adsorbed by AC or AC is unavailable or
Significant spontaneous emesis has already occurred.	■ Although the ingested xenobiotic is adsorbed by AC, the amount ingested exceeds the AC–xenobiotic ratio of 10:1 even when using a dose of AC that is twice the standard dose recommended and
The patient presents many hours postingestion and has minimal signs or symptoms of poisoning.	■ The patient has not had spontaneous emesis or
The ingested xenobiotic has a highly efficient antidote (eg, APAP and <i>N</i> -acetylcysteine).	■ No highly effective specific antidote exists or alternative therapies (eg, hemodialysis) pose a significant risk to the patient.
The procedure cannot be accomplished appropriately or safely (wrong tube size, lack of provider skill, anticipated extant esophageal or gastric injury, etc.)	

<sup>a</sup>Patients who fulfill some of these criteria can be decontaminated safely with activated charcoal alone or in many cases require no decontamination at all. <sup>b</sup>Patients who fulfill these criteria should undergo orogastric lavage if there are no contraindications or other compelling time-dependent interventions. For individuals who meet some of these criteria but who are judged not to be candidates for orogastric lavage, single- or multiple-dose activated charcoal or whole-bowel irrigation (or both) should be used. AC = activated charcoal; APAP = acetaminophen.

adults. Simple tube aspiration of gastric contents not followed by a formal lavage procedure is reported by some to be more effective.<sup>70,219,226</sup> No recent literature distinguishes aspiration and lavage as different procedures, and we consider the aspiration as an initial part of the full procedure. The specific fluid volume needed for the procedure to be optimal has not been formally studied, and severe adverse effects caused by the use of excessive volumes are described.<sup>94</sup> A review of controlled clinical trials of orogastric lavage in acute organic phosphorus compound poisoning concluded that excessive volumes of fluid or repetitive use of orogastric lavage were unlikely to increase the yield compared with that of a single aspiration while avoiding the risk of electrolyte disturbances.<sup>202</sup> Our general recommendation of volume is included in Table 5-5.

TABLE 5-4 Orogastric Lavage: Indications and Contraindications

Indications	Contraindications
The patient meets some of the criteria for orogastric lavage (Table 5-3).	The patient does not meet any of the criteria for orogastric lavage (Table 5-3).
The benefits of orogastric lavage outweigh the risks.	The patient has lost or will likely lose his or her airway protective reflexes without being intubated. (After intubation, orogastric lavage can be performed if otherwise indicated).
	Ingestion of a xenobiotic with a high aspiration potential (eg, a hydrocarbon) in the absence of endotracheal intubation.
	Ingestion of an alkaline caustic.
	Ingestion of a foreign body (eg, a drug packet).
	The patient is at risk of hemorrhage or gastrointestinal perforation because of underlying pathology, recent surgery, or another medical condition that could be further compromised by the use of orogastric lavage.
	Ingestion of a xenobiotic in a form known to be too large to fit into the lumen of the lavage tube (eg, many modified-release preparations).

TABLE 5-5 Technique for Performing Orogastric Lavage

Select the correct tube size
Adults and adolescents: 36–40 Fr
Children: 22–28 Fr
Procedure
1. If there is potential for airway compromise, endotracheal intubation should precede orogastric lavage.
2. The patient should be kept in the left lateral decubitus position if possible. Because the pylorus points upward in this orientation, this positioning theoretically helps prevent the xenobiotic from advancing through the pylorus during the procedure.
3. Before insertion, the proper length of tubing to be passed should be measured and marked on the tube. The length should allow the most proximal tube opening to be passed beyond the lower esophageal sphincter.
4. After the tube is inserted, it is essential to confirm that the distal end of the tube is in the stomach by withdrawal of material; injecting air; or if unable to clinically confirm placement, use radiographic confirmation.
5. Any material present in the stomach should be withdrawn.
6. In adults, 250-mL aliquots of a room temperature 0.9% saline lavage solution is instilled via a funnel or lavage syringe. In children, aliquots should be 10–15 mL/kg to a maximum of 250 mL.
7. Orogastric lavage should continue for at least several liters in an adult and for at least 0.5 to 1.0 L in a child or until a colorless particulate matter returns and the effluent lavage solution is clear.
8. After orogastric lavage, the same tube should be used to instill AC if indicated.
9. The tube should be withdrawn/removed.

Adverse effects of orogastric lavage include injury to the esophagus and stomach,<sup>22,51,83,128,172,188,216,219,248,265,364</sup> vomiting, bloody fluid return, and seizures,<sup>89</sup> as well as significant decreases in serum calcium,<sup>120</sup> ionized calcium,<sup>120</sup> and magnesium,<sup>120</sup> severe hyponatremia,<sup>232</sup> and leukocytosis.<sup>166</sup> Hyponatremia resulted from a lavage performed with 12 L of hypertonic saline.<sup>232</sup> An observational case series studying 14 consecutive orogastric lavages performed in a resource-poor location found three deaths directly related to the procedure, all of which seemed to result from inadequate airway protection.<sup>94</sup> These cases, as well as other well-known complications such as respiratory events, including the need for mechanical ventilation,<sup>167</sup> hypoxemia,<sup>167</sup> ECG changes,<sup>336</sup> respiratory failure,<sup>365</sup> and a higher frequency of aspiration pneumonia,<sup>33,44,167,219,226,323,352,353,365</sup> demonstrate that orogastric lavage is associated with risk and should only be performed based on the rigorous indications for gastric emptying listed in Tables 5-3 and 5-4.

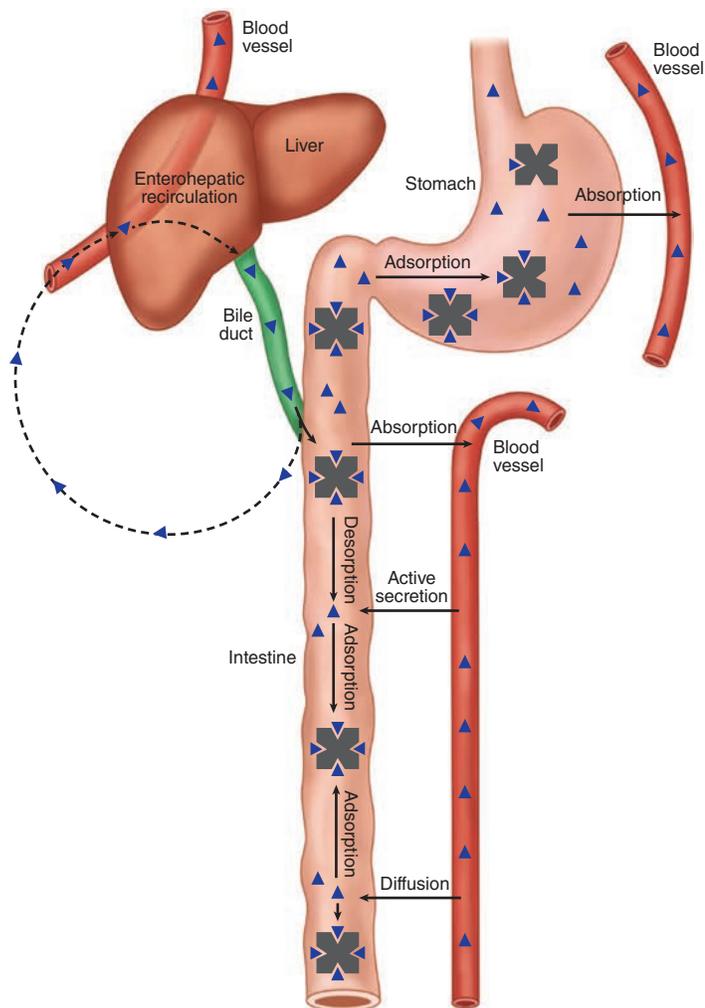

## ACTIVATED CHARCOAL

Activated charcoal is an effective method for reducing the absorption of many xenobiotics.<sup>5,11,21,27,115,129,165,176,244,257,259,366</sup> For certain xenobiotics, it also enhances elimination through interruption of either the enterohepatic or enteroenteric cycle.<sup>74,257,366</sup> Its superb adsorptive properties theoretically make it the single most useful management strategy for diverse patients with acute oral overdoses.<sup>16-18,41,64,74,75,118,142,152,273,274</sup>

### Mechanism

The entire effect of AC takes place in the GI tract. Oral AC is not absorbed through the wall of the GI tract but rather passes straight through the gut unchanged. To be adsorbed to AC, the xenobiotic must be dissolved in the GI liquid phase and be in physical contact with the AC. The possible sites of adsorption are demonstrated in Fig. 5-3. The surface (internal and external) of AC is specifically manufactured to chemically adsorb certain xenobiotics. Activated charcoal forms an equilibrium between free xenobiotic and xenobiotic that is adsorbed to it through relatively weak intermolecular forces.

**FIGURE 5-3.** Mechanism of xenobiotic (▼) removal by AC in the luminal space of the gastrointestinal tract. The position of systemic xenobiotic absorption depends on the physical chemical characteristics of the xenobiotic and takes place from stomach, intestine, or both. Xenobiotic reentry into the luminal space can take place by enterohepatic recirculation and enteroenteric recirculation by active secretion and passive diffusion. Excess and continued supply of activated charcoal facilitates adsorption of recycled xenobiotic and favors continued active and passive diffusion of xenobiotic to the luminal space and adsorption of xenobiotic.

Desorption of the adsorbed xenobiotic occurs, but if sufficient AC is present (see dosing listed later), the equilibrium will be shifted toward the xenobiotic-AC complex. The effect is a low free xenobiotic concentration in the GI liquid phase and reduced xenobiotic absorption.<sup>74,107</sup>

### Efficacy

However, as is true for the other methods of GI decontamination, there is a lack of sound evidence of its benefits as defined by clinically meaningful endpoints. This opinion is reflected both in the consensus statements and reviews and in the overall poison control center trend toward not performing decontamination (Chap. 130).<sup>11,67,165,225</sup> The consensus opinion concluded that *a single dose of activated charcoal should not be administered routinely in the management of poisoned patients and, based on volunteer studies, the effectiveness of activated charcoal decreased with time, providing the greatest benefit in severely poisoned patients if dosed within 1 hour of ingestion.* There was no evidence that the administration of a single dose of AC improved clinical outcome. These opinions are unfortunately biased by the fact that most “routinely” poisoned patients have low-risk exposures and do well with minimal interventions. Additionally, it is generally accepted that unless either airway protective reflexes are intact (and expected to remain so) or the patient’s

airway has been protected, the administration of AC is contraindicated.<sup>67</sup> Despite little scientific basis or support from clinical trials, less severely poisoned patients might theoretically benefit from AC in terms of reduced need for life support, monitoring, and antidotes,<sup>165</sup> and many reports of poisoned cases include AC as part of treatment to reduce the clinical effect of xenobiotics of various origin—medications,<sup>62,87,91,132,153,217,253,298,309,319,345</sup> plants,<sup>49,198,262,327,337</sup> mushrooms,<sup>113,123,182,260,359</sup> pesticides,<sup>187,200,235,282,369</sup> and other chemicals.<sup>135,377</sup>

Theoretically, early administration of AC to a patient presenting with a significant oral overdose of a potentially toxic xenobiotic would lower systemic exposure to that xenobiotic and thus be of benefit to the patient.<sup>80,257,366</sup> The precise definition of “early” is yet to be defined, as discussed in the section about time. Some studies failed to show benefit from the use of AC beyond a 1-hour limit.<sup>124,138,373</sup> Although these data do not support the administration of AC as a GI decontamination strategy more than 1 hour after an overdose, the applicability of these results to actual overdosed patients is not adequately evaluated.

However, a range of reports show significant effect if dosing is delayed up to 4 hours after the xenobiotic ingestion.<sup>91,112,161,162,165,171,237,322</sup> In fact, studies suggest efficacy up to 6 hours after ingestion for some xenobiotics.<sup>171,353</sup> A meta-analysis was performed to evaluate the effect of AC on xenobiotic absorption during the first 6 hours after ingestion. Data were obtained from 64 controlled studies in which AC was compared with placebo up to 6 hours after drug ingestion in volunteers. Activated charcoal was most effective when administered immediately after xenobiotic ingestion. However, even with a delay of 4 hours after ingestion, 25% of the participants achieved at least a 32% reduction in absorption.<sup>171</sup> The theoretical intuitive result has been difficult to demonstrate using clinically relevant endpoints in large unselected populations of poisoned patients, again most likely as a result of the inclusion of large numbers of minimally exposed low-risk individuals. Several randomized controlled trials failed to show a benefit of AC over either emesis or no therapy at all. Most suffer from inclusion of a large number of low-risk patients and selection biases from extensive exclusion criteria.<sup>79,96,290</sup> Data are summarized in Table 5-6. Furthermore, in an article on compliance related to AC nested within one randomized, controlled trial, it is stated that a large number of patients included in the trial had undergone gastric emptying in some form before being transferred from peripheral hospitals.<sup>233</sup>

Evaluations of the efficacy of AC are often performed by comparisons of pharmacokinetic parameters, such as area under the blood xenobiotic concentration-time curve (AUC), maximum blood concentration of the xenobiotic ( $C_{max}$ ), time to maximum blood concentration ( $T_{max}$ ), and elimination half-life ( $t_{1/2}$ ) (Chap. 9). More novel approaches include population pharmacokinetics.<sup>64,80,112,162,257,303,366,373</sup> Studies are summarized in Tables 5-1, 5-2, and 5-6.

Further increased effect of AC in reducing APAP absorption was observed in the presence of concomitant anticholinergic activity,<sup>125</sup> an observation relevant to consider in polydrug ingestions.

*Thus, it should be clear that the use of a 1-hour time frame should serve as a guideline rather than an absolute endpoint.* It is only logical that if an intervention is effective at 59 minutes, it will also be beneficial at 61 minutes. Although it is logical that efficacy decreases as time from ingestion increases, in certain cases, some benefit will be derived many hours after ingestion. Because after massive life-threatening ingestions, the absorption of xenobiotics is prolonged, there is no exact time limit for AC use.<sup>243</sup> As discussed earlier, good data from patients with actual ingestions demonstrate that a significant amount of xenobiotic is found in the stomach beyond this arbitrary 1-hour time frame. It is therefore recommended to administer AC to prevent absorption in poisoned patients even when they present late to medical care if there is a potential for clinically significant ongoing absorption. Additional benefits on enhanced elimination are discussed next.

### Prehospital Use

One of the first controlled trials of GI decontamination noted that many patients present hours after oral overdose, with children presenting earlier than adults (mean, 68 minutes versus 3.3 hours).<sup>188</sup> Over a 6-month

TABLE 5-6 Summary of Studies Evaluating the Effect of Activated Charcoal on the Absorption of Diverse Xenobiotics

Author	Citation	Study Method	Outcome Measure	Main Result	Comments
<b>Volunteer Data</b>					
Keranen et al. 2010	176	RCT; crossover; three sessions, ( $n = 12$ ) LTG 100 mg and OXC 600 mg were given orally, each to six subjects. Control = no AC vs either 50 g of AC once at 30 min or repeated 20 g AC doses 6–72 h after LTG and 12–48 h after OXC.	PK variables $AUC_{0-12h}$ , $AUC_{0-24h}$ , $C_{max}$ , $t_{max}$ , $t_{1/2}$ , $K_e$ of LTG, OXC, and the active metabolite of oxcarbazepine (MHD).	Single-dose AC dose decreased $AUC_{0-12h}$ of LTG, OXC, and MHD to 58%, 2.8%, and 4.2% of control, respectively. $T_{max}$ of OXC and MHD decreased to 4.4% and 8.1%, respectively. Repeated AC doses after LTG decreased its $AUC_{0-12h}$ to 39% and $t_{1/2}$ to 44%. Repeated AC doses after OXC decreased the $AUC_{12h-24h}$ and $t_{1/2}$ of MHD to 46% and 45% of control.	AC greatly reduced GI absorption of LTG and OXC, and it accelerated the elimination of LTG and MHD.
Mullins et al. 2009	237	RCT; crossover; four sessions ( $n = 9$ ). Effect of delayed AC on a simulated overdose of 5 g of APAP + 0.5 mg/kg of oxycodone. No AC vs 50 g of AC was dosed at 1, 2, or 3 h after ingestion.	PK parameters for APAP: $AUC_{0-8h}$ , $C_{max}$ , $t_{max}$ , and $t_{1/2}$ .	AC dosed at 1, 2, and 3 h lowered the AUC by 43%, 24%, and 8%, respectively. This was significant at 1 and 2 h. $C_{max}$ was lowered by 25% at 1 h but was similar to control at 2 and 3 h. $t_{1/2}$ was similar on all 4 study days.	AC was more beneficial if dosed early. Effect demonstrable up to 2 h.
<b>Actual Overdose Data: Case Reports, Case Series, and Cohort Studies</b>					
Isbister et al. 2004	161	Retrospective cohort of unselected population of overdose patients; characterization of aspiration pneumonitis frequency, outcomes, and factors that predispose to aspiration pneumonitis.	Poisoned patients with aspiration pneumonitis. Length of stay (in hours), GCS score (15 or <15), spontaneous emesis, treatment with AC, alcohol, and other coingestions.	71 of 4,562 poisoning cases with aspiration pneumonitis. Frequency was 1.0% in patients whose time from ingestion to hospital admission was <4 h; 1.9% in patients admitted 4–24 h after, and 4.4% in those admitted >24 h after the overdose. 62% of patients with aspiration pneumonitis had a GCS score of <15, compared with 23% without. Seizure was present in 16% compared with 2% without. TCA was coingested in 19% compared with 7% without. AC was dosed in 33% of both the aspiration and nonaspiration groups.	AC was not an independent risk factor for aspiration pneumonitis. Spontaneous vomiting, xenobiotic, and seizures are potential risk factors.
Isbister et al. 2009	162	Retrospective cohort of 176 patients on 286 occasions with quetiapine overdose; median dose was 2 g; evaluation of whether AC improves outcomes or shortens treatment requirement.	Measured intubation, duration of ventilation, and cardiac monitoring.	42 patients (15%) received AC, 4 patients (1%) received AC within 1 h but were excluded from analysis, 19 patients (7%) received AC within 2 h, and 36 patients (13%) received AC within 4 h. Single-dose AC within 2 h reduced the probability of intubation from 10% to 7% for 2-g ingestions only. AC between 2 and 4 h did not reduce the probability of intubation. The median duration of ventilation was not affected by AC. Abnormal QT intervals occurred in 8.4%, all with HR >100 beats/min.	Quetiapine dose and AC dosing (<2 h) influenced the probability of intubation. The effect of AC was small on only if given within 2 h.
Spiller et al. 2006	322	Nonrandomized prospective, multicenter, observational case series. Efficacy of AC in addition to standard NAC when AC given >4 h after APAP overdose. 145 patients included; 58 (40%) received NAC only, and 87 (60%) received NAC and AC.	Serum aminotransferase (ALT, AST).	23 patients had elevations of AST or ALT >1,000 IU/L, of which 21 patients received NAC only (38% of total NAC only group) and 2 patients received NAC and AC (2% of total NAC+AC group).	AC in addition to standard NAC was associated with a reduced incidence of liver injury from APAP.
<b>Controlled Studies</b>					
Cooper et al. 2005	79	RCT of overdosed patients presenting to one urban hospital. Excluding transfers, late presenters (>12 h), xenobiotics not adsorbed by AC, administration of AC contraindicated, and very serious ingestions. Patients were randomized to either AC or no decontamination. ( $n = 327$ adults).	Primary outcome: length of stay (the time of presentation until the patient was declared medically fit for discharge); secondary outcomes: need for ventilation, vomiting after admission, occurrence of aspiration, or death.	The study excluded seven severely poisoned patients who all arrived within 1 h of ingestion; the majority of the patients in the trial (nearly 60%) arrived within 2 h postingestion. No difference in clinical endpoints. The most common xenobiotics ingested were APAP, benzodiazepines, and newer antidepressants, all of which have low case-fatality rates.	There was no benefit of AC compared with no treatment in a general population with low risk ingestions after severely poisoned patients are excluded.

(Continued)

TABLE 5-6 Summary of Studies Evaluating the Effect of Activated Charcoal on the Absorption of Diverse Xenobiotics (Continued)

Author	Citation	Study Method	Outcome Measure	Main Result	Comments
de Silva et al. 2003	85	RCT ( $n = 401$ ); all with yellow oleander poisoning. All received one dose of AC and were then randomly assigned either 50 g of AC every 6 h for 3 days or sterile water.	Primary outcome: mortality; secondary outcomes: life-threatening cardiac dysrhythmias, dose of atropine used, need for cardiac pacing, admission to ICU, and length of stay. Analysis was by intention to treat.	201 patients received MDAC; 200 received water. Lower mortality rate reported in the MDAC group (5 {2.5%} vs 16 {8%}), and differences favored MDAC for all secondary endpoints, except length of stay.	MDAC reduced the number of deaths and life-threatening cardiac dysrhythmias after yellow oleander poisoning. This was a unique study in that all patients ingested life-threatening toxins. The number needed to treat to save a life was 18.
Duffull and Isbister, 2013	91	Prospectively collected APAP patients. Two groups: presenting early (4–7 h) and presenting late (7–16 h) ( $n = 1,303$ patients with 1,571 admissions).	Primary outcome: reported APAP dose predictive of the need for NAC; measures included time from APAP ingestion, timed APAP concentrations (4 and 16 h), ALT >1,000 U/L (hepatotoxicity), AC, and NAC.	Patients presenting late were more likely to have hepatotoxicity (5.5% vs. 0.4%; $P < 0.0001$ ), have a toxic APAP concentration (34% vs 18%; $P < 0.0001$ ), and receive NAC (48% vs 23%; $P < 0.0001$ ). The probability of requiring NAC if AC was not administered was 5% at 6–9 g of APAP, increasing to 90% at 48–50 g of APAP. AC reduced the probability of needing NAC, up to 14% at 28 g APAP and <10% at APAP doses <19 g or >37 g.	Benefits of AC if dosed up to 3 h postingestion.
Eddleston et al. 2008	96	RCT ( $n = 4,629$ acute self-poisoned patients) in a developing nation. Primary toxins were pesticides and yellow oleander seeds. Patients were randomized to no AC, single-dose AC, or MDAC.	Death.	No difference in mortality rates between groups. Many patients had GL before randomization; Audit of AC dosing shows limited compliance. Authors claim that logistic regression analysis found no influence of GL on their results.	MDAC did not reduce the number of deaths. The health care setting and xenobiotics were different from developed nations. The first 1,904 control patients received GL, as was the case for all patients presenting within 2 h of ingestion of substantial amounts of pesticides or potentially toxic xenobiotics.
Kulig et al. 1985	188	RCT, prospectively collected overdose patients ( $n = 592$ ); efficacy in altering clinical outcome of AC (oral in alert patients or by NG tube in obtunded pts) compared with GL + AC.	Severity based on clinical course by symptoms (mild, moderate, severe) continuously the first 6 h.	GL within 1 h in obtunded patients improved clinical outcome; there was no difference between other groups.	Management without gastric emptying is preferable in many patients; GE should not be standard care; benefit of GL in sickest subset with in the first hour; questionable effect of GL if initiated >1 h. Exclusion criteria were biased toward an AC effect.
Merigian and Blaho, 2002	225	RCT ( $n = 1,479$ adults); self-poisoning in a single hospital. Determine the effects of AC. Patients either received 50 g of AC or supportive care only.	Outcomes: clinical deterioration, length of stay in the ED or hospital, and complication rate.	The findings were no significant differences between groups when comparing the length of intubation time, length of hospital stay, and complication rates associated with the overdose. The AC group reported a higher incidence of vomiting and longer length of ED stay.	AC provided no additional benefit to supportive care alone and did not improve clinical outcome. AC was associated with a higher incidence of vomiting and a longer length of ED stay. Overall, most ingestions were benign and most serious xenobiotics as well as those not adsorbed to AC were excluded.
Roberts et al. 2006	290	RCT; acute self-poisoned patients (subgroup of Eddleston 2008 above who ingested yellow oleander seeds. ( $n = 104$ ).	Plasma clearance of the yellow oleander cardenolides.	Both AC and MDAC significantly increased the plasma clearance of cardenolides. There was no difference between groups in mortality, but given the absolute numbers of two to three deaths per group, this could be related to a lack of power in the study design.	A favorable influence of AC was shown on the PK profile of ingested yellow oleander cardenolides.

AC = activated charcoal; ALT = alanine transaminase; APAP = acetaminophen; AST = aspartate transaminase; AUC = area under the concentration versus time curve;  $C_{max}$  = maximal concentration; ED = emergency department; GCS = Glasgow Coma Scale; GL = gastric lavage; h = hours; HR = heart rate; inf = infinity;  $K_e$  = rate constant of elimination; LTG = lamotrigine; MDAC = multiple-dose activated charcoal; NAC = *N*-acetylcysteine; OXC = oxcarbazepine; PK = pharmacokinetics; RCT = randomized controlled trial;  $t_{1/2}$  = terminal elimination half-life;  $t_{max}$  = time to maximal concentration; TCA = tricyclic antidepressant.

period, another study of 63 patients who had taken potentially serious overdoses demonstrated a median time of arrival to a health care facility of 136 minutes after the overdose. Only 15 patients presented within 1 hour, and only 4 of 10 patients who qualified actually received AC within 1 hour. The results demonstrate not only the difficulty in clinically assessing patients before 1 hour but also the difficulty in adhering to the principle of treating patients with AC when they arrive within a few hours of ingestion unless AC could be safely administered to appropriate patients in the prehospital setting.<sup>174</sup> Enhanced communication between a poison control center and both emergency medical services and an ED was able to decrease the time to administration of AC.<sup>348,349</sup>

Prehospital use of AC has not gained wide acceptance because of unfounded concerns that it would not be administered properly by the untrained lay public and that many children would refuse to drink the charcoal slurry. In fact, an 18-month consecutive case series demonstrated that AC could be administered successfully in the home when given by the lay public. Home use of AC significantly reduced the time to AC administration after xenobiotic ingestion from a mean of  $73 \pm 18.1$  minutes for ED treatment to a mean of  $38 \pm 18.3$  minutes for home treatment.<sup>321</sup> Additionally, prehospital AC did not markedly delay transport or arrival of overdose patients into the ED and was generally safe in 441 cases collected retrospectively in which prehospital AC was given. The average elapsed time between xenobiotic ingestion and AC was 49.8 minutes (range, 7–199 minutes). Activated charcoal was administered more than 1 hour (22%) and more than 2 hours (3%) after the xenobiotic ingestion. Complications included emesis in 6.6% of the patients, as well as hypotension, hypoxia, and declining mental status, but authors attributed these events to the xenobiotic ingested rather than the AC itself.<sup>362</sup>

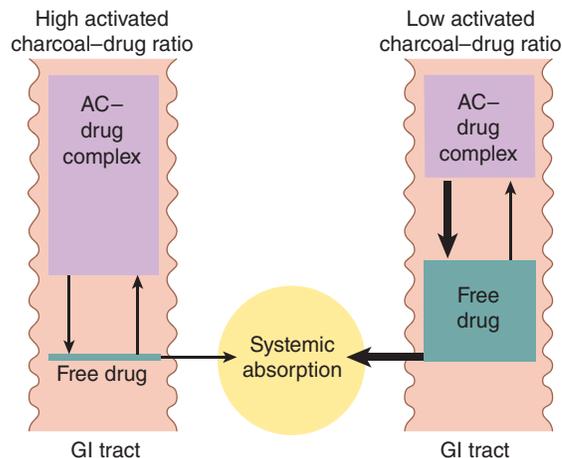

A prospective follow-up study evaluated adherence to a protocol of administering AC in the prehospital setting. Activated charcoal was indicated in 722 of 2,047 patients. Of these patients, 555 actually received AC at a mean of 88 minutes after ingestion; 72 patients refused to drink the AC, and no adverse effects were noted.<sup>9</sup>

However, many authorities recommend that AC should neither be a standard nor be administered at home and that administration should only be carried out by health professionals (Chap. 4).<sup>13,65,214,221,307,308</sup> However, we recommend that prehospital AC be used in rural and remote areas if the transport time to health care facilities exceeds the time frame of possible beneficial effect of AC, and its administration is expected to reduce the risk of appearance of life-threatening symptoms but only after consultation with a knowledgeable health care professional.

## Dosing

The optimal dose of oral AC has never been fully established. Since the initiation of its clinical use as a GI decontaminant, various factors are recommended for determining the optimal dose of AC. Two factors commonly discussed are the patient's weight and the quantity of the xenobiotic ingested. The problems in using the quantity of the xenobiotic as a basis for AC dosing are that the amount is usually unknown, and there is an implication that nothing else in the GI tract will occupy binding sites on AC. Additionally, the xenobiotic is often unknown, and xenobiotics vary enormously in their toxicities, rate of absorption, and the clinical effects they produce such as respiratory depression, convulsions, and effect on gastric emptying rate. Some xenobiotics are well adsorbed to AC, but others are not.<sup>74</sup> Because of variables such as the physical properties of the formulation ingested (liquid, solid, or sustained-release tablet), the volume and pH of gastric and intestinal fluids, and the presence of other xenobiotics adsorbed by AC,<sup>16-18,25,140,144,201,254,256</sup> the optimal dose cannot be known with certainty in any given patient.

Information concerning the maximum adsorptive capacity of AC for the particular xenobiotic ingested permits a theoretical calculation of an adequate dose,<sup>8,16,23,26,59,75,245,246,254,255,291,292,294,314,340,346</sup> assuming that the amount of xenobiotic ingested is known. However, clinicians must remain cognizant of the risk of approaching or exceeding the adsorptive capacity of the standard dose of approximately 1 g/kg of body weight of AC.<sup>8,26,53,144,156,242,294,358</sup>

**FIGURE 5-4.** The effect of high and low ratios of AC to xenobiotic in the gastrointestinal (GI) tract. The reduced systemic absorption achieved when the AC-xenobiotic ratio is high (*left*) is compared with the increased systemic absorption at a low activated charcoal-xenobiotic ratio (*right*).

Thus, the idea that a fixed ratio of AC to xenobiotic is appropriate for all xenobiotics is clearly inappropriate. It is possible, however, to develop a logical approach to dosing based on available data. The effect of the ratio of AC to xenobiotic is such that theoretically increasing the ratio enhances the completeness of adsorption corresponding to a higher percentage of adsorption and total amount of adsorbed xenobiotic (Fig. 5-4).<sup>243</sup> A meta-analysis demonstrated an increasing effect of AC with increasing AC-xenobiotic dose, up to a 40:1 ratio.<sup>171</sup> The optimal AC dose is theoretically the minimum dose that completely adsorbs the ingested xenobiotic and, if relevant, that maximizes enhanced elimination. The results of *in vitro* studies show that the ideal AC-xenobiotic ratio varies widely, but a common recommendation is to deliver an AC-xenobiotic ratio of 10:1, or 50 to 100 g of AC to adult patients, whichever is greater. From a theoretical perspective, this amount will adsorb 5 to 10 g of a xenobiotic, which should be adequate for most poisonings.<sup>16,17,67,74,255</sup> In human volunteers, the APAP clearance was increased with increasing doses of AC.<sup>130</sup> Fixed doses of 50, 25, or 5 g of AC were administered 1 hour after 50 mg/kg of APAP was given. The apparent half-life of APAP was significantly reduced from 2.5 hours for the 5-g AC dose to 1.9 hours and 1.6 hours for the 25- and 50-g doses, respectively.<sup>130</sup> The effect of larger doses of AC adsorbing larger amounts of xenobiotics was supported by the meta-analysis mentioned earlier.<sup>171</sup> Based on available data from *in vivo* and *in vitro* studies, we recommend the dosing regimen for activated charcoal is 50 to 100 g in adults (1 g/kg of body weight) and 0.5 to 1.0 g/kg of body weight in children.<sup>67,74</sup> These recommendations are generally based more on AC tolerance than on efficacy. When calculation of a 10:1 ratio exceeds these recommendations and the ingestion is potentially severely toxic, either orogastric lavage should be performed expeditiously before dosing of AC or multiple-dose AC (MDAC) therapy should be administered.

For example, consider a patient who intentionally overdosed by ingesting 30 (0.25-mg) digoxin tablets (total dose, 7.5 mg). Achieving a 10:1 ratio is quite easy, and a standard dose of 1 g/kg might exceed a 10,000:1 ratio. In comparison, consider a patient who intentionally ingests 30 (325-mg) aspirin tablets (total dose, 9.75 g). In this case, obtaining a 10:1 AC-xenobiotic ratio is more difficult and is even less likely if a patient ingests 60 or 100 of the aspirin tablets. Poisoning with a combination of xenobiotics sometimes approaches or exceeds the maximum adsorptive capacity for the standard dose of AC, and increasing the dose to reach a higher AC-xenobiotic ratio will be necessary in patients with severe poisonings from multiple xenobiotics.<sup>144</sup>

## Methods to Increase the Palatability of Activated Charcoal

Activated charcoal has a pronounced gritty texture, and it immediately sticks in the throat because it adheres to the mucosal surfaces and begins to cake.<sup>74</sup> In addition, the black appearance and insipid taste of AC make it less attractive.

There have been numerous attempts at making AC more appealing by providing flavors, including jam,<sup>84</sup> chocolate syrup,<sup>218,241</sup> cherry extract or syrup,<sup>131,263,372</sup> cookies,<sup>181</sup> juice,<sup>263</sup> sorbitol,<sup>76,81,220</sup> saccharin,<sup>76,77</sup> strawberry flavor,<sup>261</sup> orange or peppermint oil,<sup>74</sup> melted milk chocolate,<sup>97,98</sup> chocolate milk,<sup>58,131,263</sup> soda,<sup>58,131,263,284</sup> yogurt,<sup>143</sup> and ice cream.<sup>59,141,333</sup> The general recommendation, however, remains that AC should be mixed with water.<sup>13,170</sup> Because AC adsorbs the flavoring agents, the palatable taste from added flavors often disappears within minutes after mixing.<sup>74,76,77,84</sup> However, in cases in which the AC does not completely adsorb the flavoring agents, they provided a pleasant taste without significantly reducing the adsorptive properties of the AC.<sup>74,76,77,141,143</sup>

### Effect on Oral Therapeutics

The nonspecific nature and high adsorptive capacity of AC raise concerns about the simultaneous use of orally administered therapeutics. It would be expected that therapeutics administered shortly before or simultaneously with AC would be extensively adsorbed, greatly reducing therapeutic efficacy. Restored utility of a therapeutic would be complex and depend on all of the factors that influence the efficacy of AC. Additional concerns arise regarding the administration of oral maintenance medications. For example, AC will likely alter the kinetics of the new oral anticoagulants (dabigatran, apixaban, and rivaroxaban).<sup>257,310,366</sup> The issue is described to a limited extent and not in the context of poisoning.<sup>281,324</sup>

### Contraindications and Complications

Few clinically significant adverse effects are associated with the use of AC for poisoned patients.<sup>74,281</sup> Adverse GI effects are most commonly described, but the frequency varies,<sup>48,281,297</sup> and it might be difficult to differentiate from adverse effects resulting from the ingested xenobiotic.<sup>191,303</sup> In a study of 24 volunteers, mild adverse effects such as abdominal fullness or constipation (46%) and nausea (17%) were common.<sup>303</sup> In a randomized clinical trial, vomiting was not more frequent in patients treated with AC than those who did not receive AC.<sup>79</sup> Similarly, although vomiting was observed in 22% of patients in a randomized controlled trial of 1,103 patients with intentional poisoning; a nonsignificant difference in incidence was reported between patients who had or had not received GI emptying procedures.<sup>233</sup> A prospective cohort study estimating the incidence of vomiting subsequent to the therapeutic administration of AC in poisoned children younger than 18 years of age showed that one of five of these children vomited. Children with previous vomiting or nasogastric tube administration were at highest risk.<sup>264</sup> This incidence of vomiting appears to be greater when AC was administered with sorbitol<sup>351</sup> and after rapid ingestion of larger doses.<sup>243</sup> Although the coingestion of ethanol theoretically increases the risk of vomiting, ethanol does not interfere with the adsorptive capacity of AC in vivo.<sup>142</sup>

Pulmonary aspiration of gastric contents containing AC and inadvertent direct instillation of AC into the lungs from a misplaced nasogastric tube are rare but severe events<sup>79,86,111,121,136,313,360</sup> that might lead to airway obstruction, bronchospasm, hypoxemia, aspiration, permanent lung injury, and even death.<sup>249,259,360</sup> Administration of AC to intubated patients is associated with a low incidence of aspiration pneumonia.<sup>234</sup> In fact, pulmonary complications associated with AC aspiration appear to be primarily related to the aspiration of acidic gastric contents and not directly related to aspiration of AC.<sup>277,293</sup> A retrospective study found that only 1.6% of unselected overdose patients aspirated and that administration of AC was not an associated risk factor.<sup>161</sup> Pulmonary aspiration in overdose patients who have received AC is more easily recognized and thus documented because AC is a very identifiable marker.

Although relatively few reports of clinically significant emesis and pulmonary aspiration resulting from the administration of AC exist, the severity of these complications is clear. Consequently, it is important to evaluate whether AC therapy is likely to be beneficial based on the indications and contraindications listed in Table 5–7. This is especially true in small children, in whom the risks of nasogastric tube use often outweigh the benefits of AC.

**TABLE 5–7 Single-Dose Activated Charcoal Therapy: Indications and Contraindications**

Indications	Contraindications
The patient does not meet criteria for orogastric lavage (Table 5–1) or orogastric lavage is likely to be harmful.	Activated charcoal is known not to adsorb a clinically meaningful amount of the ingested xenobiotic.
The patient has ingested a potentially toxic amount of a xenobiotic that is well adsorbed by AC.	Airway protective reflexes are absent or expected to be lost, and the patient is not intubated.
The ingestion occurred within a time frame amenable to adsorption by AC or clinical factors are present that suggest that not all of the xenobiotic has already been systemically absorbed.	Gastrointestinal perforation is likely, as in cases of caustic ingestions.
Patients who have potentially life-threatening toxicity regardless of the time since ingestion as long as no absolute contraindications exist.	Therapy will likely increase the risk and severity of aspiration, such as in the presence of hydrocarbons with a high aspiration potential.
	Endoscopy will be an essential diagnostic modality (caustics).

### MULTIPLE-DOSE ACTIVATED CHARCOAL

Multiple-dose AC is defined as at least two sequential doses of AC.<sup>351</sup> In many cases, the actual number of doses administered is substantially greater. This technique serves two purposes: (1) to prevent ongoing absorption of a xenobiotic that persists in the GI tract (such as modified-release preparation) and (2) to enhance elimination in the postabsorptive phase by either disrupting enterohepatic recirculation or enteroenteric recirculation (“gut dialysis”).

The 1999 position statement of the AACT and the EAPCCT concluded that based on clinical studies, MDAC should be considered only if a patient has ingested a potentially life-threatening amount of carbamazepine, dapsone, phenobarbital, quinine, or theophylline. Although data have confirmed enhanced elimination of these drugs, no controlled studies have demonstrated clinical benefit after their ingestion. Volunteer studies demonstrate that MDAC increases the elimination of amitriptyline, dextropropoxyphene, digitoxin, digoxin, disopyramide, nadolol, phenylbutazone, phenytoin, piroxicam, and sotalol, but the position statement concluded that there are insufficient clinical data to support or exclude the use of MDAC in these patients.<sup>351</sup> A possibly beneficial effect of MDAC was shown in poisonings including *Amanita phalloides* and other *Amanita* spp.,<sup>57,118,168,276</sup> amiodarone,<sup>328</sup> carbamazepine,<sup>38,354</sup> digoxin,<sup>192,278</sup> dosulepin,<sup>222</sup> duloxetine,<sup>100</sup> diquat,<sup>344</sup> *Gymnopus penetrans*,<sup>239</sup> lamotrigine,<sup>100</sup> phenobarbital,<sup>69</sup> phenytoin,<sup>54</sup> quetiapine,<sup>38</sup> theophylline,<sup>55</sup> valproic acid,<sup>356</sup> verapamil,<sup>305</sup> and vinorelbine.<sup>376</sup> Furthermore, MDAC is recommended in severe poisonings, such as colchicine<sup>42</sup> and quinine.<sup>166</sup>

Although technically correct, the preceding statements suffer from a lack of high-quality evidence. Because the clinical studies used to formulate this opinion all lack sufficient numbers of significantly poisoned patients, they induce a bias against any benefit of MDAC. Additionally, none of the studies included a detailed analysis of sustained- or extended-release formulations, which are currently widely used. Finally, it is noteworthy that the definition of “life threatening” is highly subjective. Endpoints such as decreased morbidity or rigorously determined lengths of stay should be considered essential in any study design. Three studies with these clinical endpoints were previously discussed.<sup>130</sup> Unfortunately, their results were discordant, highlighting the difficulties within this field of study.<sup>45,85,96</sup> However one study is unique in that all 401 patients ingested life-threatening doses of yellow oleander seeds. The patients arrived within 24 hours of ingestion, all received 50 g of AC on arrival, and they were then randomly assigned either 50 g of AC every 6 hours (MDAC) for 3 days or sterile water. Death was the primary outcome, and secondary outcomes included life-threatening cardiac dysrhythmias, dose of atropine used, need for antidigoxin Fab fragments, need for cardiac pacing, admission to the ICU, and length of stay. Analysis was by intention to treat. A total of 201 patients received MDAC; 200 received water. The mortality rate was lower in

the MDAC group (5 {2.5%} versus 16 {8%}), and differences favored MDAC for all secondary outcomes, except length of stay. MDAC reduced the number of deaths and life-threatening cardiac dysrhythmias after yellow oleander poisoning. Furthermore, antidigoxin antibody Fab fragments was needed in seven patients in the placebo group, but none in the MDAC group needed the antidote.<sup>85</sup>

### Dosing

Various MDAC regimens were evaluated to optimize the efficacy of AC.<sup>158,176</sup> Reduced xenobiotic absorption and enhanced elimination were demonstrated compared with either single-dose AC or control without AC.<sup>176</sup> The effect of MDAC on elimination was studied in volunteers who were given lamotrigine and oxcarbazepine in therapeutic doses.<sup>176</sup> The MDAC dose regimen was 25 g of AC at 6, 12, 24, 36, 48, and 72 hours after a 100-mg lamotrigine dose or 20 g of AC at 12, 24, 36, and 48 hours after a 300-mg oxcarbazepine dose. Both AC regimens significantly reduced the total systemic xenobiotic load compared with control participants with reductions of 51% for lamotrigine and 41% for 10-hydroxy-carbazepine. The elimination half-life for both xenobiotics was significantly shortened with MDAC:  $11 \pm 3.5$  hours (MDAC) versus  $25 \pm 4.3$  hours (control) for lamotrigine and  $9.0 \pm 1.5$  (MDAC) versus  $20 \pm 12$  hours (control) for 10-hydroxy-carbazepine.<sup>176</sup>

Intravenous administration of a xenobiotic is an ideal method to evaluate the ability of different MDAC dose regimens to enhance elimination of a xenobiotic in the postabsorptive phase. A total dose of 150 g of oral AC, given as a loading dose of 50 g and the remaining 100 g divided in 12.5 g every hour, 25.0 g every 2 hours, or 50.0 g every 4 hours during a total time of 8 hours was equally effective in reducing the mean area under the concentration versus time curve (AUC) in volunteers receiving 8 mg/kg of aminophylline intravenously over a period of 60 minutes.<sup>158</sup> In a similar study, the AUC and  $t_{1/2}$  of aminophylline were reduced by 46% and 49%, respectively, by MDAC using a dosing regimen of 40-g loading dose and then five 20-g doses divided over 12 hours.<sup>34</sup>

### Contraindications and Complications

Similar to single-dose AC, MDAC can produce emesis, with subsequent pulmonary aspiration of gastric contents containing AC. It is intuitive that these risks are greater with MDAC than with single-dose therapy. One retrospective study attempted to determine the frequency of complications associated with the use of MDAC.<sup>90</sup> The authors identified nearly 900 patients who had received MDAC and found that only 0.6% of patients had clinically significant pulmonary aspiration. Although no patients developed GI obstruction, 9% had hypernatremia or hypermagnesemia without any clinical consequences noted. The authors did not specify whether the multiple-dose regimens administered included the use of cathartics, but the profile of the adverse reactions suggests that these electrolyte abnormalities were probably associated with cathartic use. Despite the obvious limitations, this study demonstrates a reasonably low rate of complications associated with MDAC.

Table 5-8 summarizes the indications and contraindications for MDAC therapy. Table 5-9 lists our recommended dosing regimens. Because the optimal doses and intervals for MDAC are not established, recommendations are based more on amounts that can be tolerated than on amounts that might be considered pharmacologically appropriate. Larger doses and shorter intervals should be used for patients with more severe toxicity. It is reasonable to base endpoints either on the patient's clinical condition or on xenobiotic concentrations when they are easily measured.

Further clinical and toxicokinetic studies concerning MDAC are needed to establish an optimal dosing regimen and to confirm an effect on relevant endpoints. From available data discussed earlier, the dosing and most appropriate dosing intervals should be evaluated in each individual overdose case including compliance and clinical challenges from complications (eg, emesis and vomiting). Readers are referred to Antidotes in Depth: A1 for a more detailed discussion of single-dose AC and MDAC therapy.

**TABLE 5-8 Multiple-Dose Activated Charcoal Therapy: Indications and Contraindications**

Indications	Contraindications
Ingestion of a life-threatening amount of <i>Amanita</i> spp., amiodarone, amitriptyline, carbamazepine, colchicine, dextropropoxyphene, digoxin, digoxin, disopyramide, dosulepin, duloxetine, diquat, <i>Gymnopilus penetrans</i> , lamotrigine, nadolol, phenobarbital, phenylbutazone, phenytoin, piroxicam, quetiapine, quinine, sotalol, theophylline, valproic acid, verapamil, or vinorelbine.	Any contraindication to single-dose activated charcoal.
Ingestion of a life-threatening amount of a xenobiotic that undergoes enterohepatic or enteroenteric recirculation and that is adsorbed to activated charcoal.	The presence of an ileus or other causes of diminished peristalsis.
Ingestion of a significant amount of any slowly released xenobiotic or of a xenobiotic known to form concretions or bezoars.	

### WHOLE-BOWEL IRRIGATION

Whole-bowel irrigation represents a method of purging the GI tract in an attempt to expeditiously achieve gut clearance and prevent further absorption of xenobiotics. This is achieved through the oral or nasogastric administration of large amounts of an osmotically balanced polyethylene glycol electrolyte lavage solution (PEG-ELS). WBI was subjected to a thorough literature review, which was published as a revised position statement in 2015.<sup>334</sup> No new evidence was available that required a major revision of the conclusions of the 2004 position statement.<sup>332</sup> The position statement was unable to establish a clear set of evidence-based indications for the use of WBI because no clinical outcome studies have ever been performed. When experimental, theoretical, and anecdotal human experience is considered, the use of WBI with PEG-ELS is reasonable for patients with potentially toxic ingestions of modified release pharmaceuticals and substantial amounts of metals. Other indications include the ingestion of large amounts of a xenobiotic with a slow absorptive phase in which morbidity is expected to be high, the ingested xenobiotic is not adsorbed by AC, and other methods of GI

**TABLE 5-9 Technique of Administering Multiple-Dose Activated Charcoal Therapy**

Initial dose orally or via orogastric or nasogastric tube:
Adults and children: 1 g/kg of body weight or a 10:1 ratio of activated charcoal to xenobiotic, whichever is greater. After massive ingestions, 2 g/kg of body weight is reasonable if such a large dose can be tolerated.
Repeat doses orally or via orogastric or nasogastric tube:
Adults and children: 0.5 g/kg of body weight every 4–6 h for 12–24 h in accordance with the dose and dosage form of xenobiotic ingested (larger doses or shorter dosing intervals are reasonable in high-risk cases).
<b>Procedure</b>
1. Add eight parts of water to the selected amount of powdered form. All formulations, including prepacked slurries, should be shaken well for at least 1 min to form a transiently stable suspension before the patient drinks or has it instilled via orogastric or nasogastric tube.
2. A cathartic can be added to AC for the first dose only when indicated. Cathartics should not be administered routinely and never be repeated with subsequent doses of activated charcoal.
3. If the patient vomits the dose of activated charcoal, it should be repeated. Smaller, more frequent doses or continuous nasogastric administration is better tolerated. Administration of an antiemetic is recommended.
4. If a nasogastric or orogastric tube is used for MDAC administration, time should be allowed for the last dose to pass through the stomach before the tube is removed. Suctioning the tube itself before removal will theoretically lessen the risk of subsequent activated charcoal aspiration.

MDAC = multiple-dose activated charcoal.

decontamination are unlikely to be either safe or beneficial.<sup>334</sup> The removal of packets of xenobiotics from body packers can be considered a unique indication for WBI (Special Considerations: SC5).<sup>31,341</sup>

Whole-bowel irrigation cannot be applied safely if the GI tract is not intact; there is an adynamic or obstructive ileus; in the presence of significant GI hemorrhage; or in patients with inadequate airway protection, uncontrolled vomiting, or hemodynamic instability that compromises GI function or integrity.<sup>82,332</sup> Compliance is often an issue because 1 to 2 L/h of PEG-ELS is required for rapid bowel cleansing in adults. These large volumes are facilitated when the solution is administered via a nasogastric tube.<sup>206</sup> Additionally, *in vitro*, the combination of WBI and AC decreases the adsorptive capacity of AC or increases the desorption of xenobiotic from AC,<sup>23,148,212</sup> especially when the WBI solution is premixed with AC.<sup>212,334</sup> When AC is necessary, it is reasonable to administer it immediately after the WBI procedure rather than simultaneously.

Results from volunteer studies often offer extreme variability in results,<sup>189,190,193,208</sup> and significant variations are noted when individual subjects are simultaneously given three different modified-release xenobiotics.<sup>193</sup> In one study, nine volunteers took sustained-release preparations of 200 mg of carbamazepine, 200 mg of theophylline, and 120 mg of verapamil, and 1 hour after ingestion, they were assigned to 25 g of AC followed by WBI, 1 L/h PEG-ELS, 25 g of AC, or water (200 mL). When the combination therapy was compared with AC alone, it was not more efficient at reducing pharmacokinetic parameters such as AUC (0–24 hours) and  $C_{max}$  for carbamazepine and theophylline, but for verapamil, the combination therapy was more effective than AC alone.<sup>193</sup> Similarly, in a volunteer study in which WBI was initiated 30 minutes after sustained-release APAP (75 mg/kg) ingestion, it did not significantly reduce the AUC compared with control.<sup>208</sup> In this study, a gelatin capsule containing 24 radiopaque polyvinyl chloride markers measuring 1 by 4.5 mm, which was given simultaneously with APAP, reached the colon more rapidly and in a “collected cluster” on the day of WBI administration compared with the control when the 24 markers were spread throughout the GI tract.

In both of these studies, therapeutic or nontoxic doses of pharmaceuticals were used as marker xenobiotics. In actual overdoses, the pharmacokinetic properties of pharmaceuticals and the effects of decontamination likely differ substantially. As mentioned earlier, study designs using AC and small doses of xenobiotics tend to bias the study toward a benefit of AC. In an overdose scenario, when the adsorptive capacity of AC is exceeded, it is intuitive that the benefits of other modalities would be more evident.

Pharmacokinetic and pharmacodynamic evaluation in venlafaxine-overdosed patients showed that compared with AC alone, combination therapy of WBI and AC decreased venlafaxine bioavailability (29% reduction), increased venlafaxine clearance (35% increase), lowered venlafaxine peak concentrations<sup>190</sup> and resulted in a decreased probability of venlafaxine induced seizures (odds ratio, 0.25 for the combination therapy versus 0.48 for AC alone).<sup>189</sup>

A small, retrospective, descriptive case series of 16 body packers treated with WBI supports the safety of WBI for body packers. Although the complication rate was reported as 12.5% (two of 16), these complications were not serious. One case of mild cocaine toxicity resulted from leakage, and one heroin body packer had to undergo surgery because of retained packages. There was no correlation between the dose of PEG-ELS, drug type, or packet quantity and length of hospital stay. Because there was no control group, it is not possible to evaluate whether WBI influenced any clinical outcome.<sup>106</sup> A variety of treatments were used to enhance GI clearance rates of cocaine packets in 61 verified body packers who were judged not to be able to clear the packets from their gut. In 33% of the procedures, PEG-ELS was used, and the dosage regimen of 1.5 L/h of PEG-ELS was continued until all packets had passed, with no limit on the total volume given.<sup>31</sup>

Whole-bowel irrigation is acceptable to treat overdoses in pregnant women and children. Two such cases involved iron overdoses in women during the second and third trimesters of pregnancy; both women were treated successfully without complications.<sup>347,355</sup> Pediatric case reports

**TABLE 5–10 Whole-Bowel Irrigation: Indications and Contraindications**

Indications	Contraindications
Potentially toxic ingestions of sustained-release and modified release drugs.	Airway protective reflexes are absent or expected to become so in a patient who is not intubated.
Ingestion of a toxic amount of a xenobiotic that is not adsorbed to AC when other methods of GI decontamination are not possible or not efficacious.	The GI tract is not intact. There are signs of ileus, obstruction, significant GI hemorrhage, or hemodynamic instability that might compromise GI motility.
Removal of illicit drug packets from body packers.	Persistent vomiting.
	Signs of leakage from cocaine packets (indication for surgical removal).

GI = gastrointestinal.

Reproduced with permission from Shargel L, Yu A: Applied Biopharmaceutics and Pharmacokinetics, 3rd ed. Norwalk, CT: Appleton & Lange; 1993.

describe combined WBI with succimer therapy<sup>71</sup> and eventually colonoscopic removal of ingested lead pellets.<sup>71,137</sup> Abdominal radiographs showed two small lead pellets, which WBI failed to remove, therefore requiring endoscopic removal.<sup>71</sup> Seven days of WBI, however, was ineffective in the removal of approximately 800 ingested lead pellets, which necessitated removal by colonoscopy.<sup>137</sup> Several reports support the use of WBI in children, including an intentional ingestion of mercury,<sup>302</sup> two pediatric body packers,<sup>342</sup> and a 16 month-old boy who had ingested a significant amount of iron.<sup>361</sup> In the latter case, despite WBI, the iron bezoar was not removed, treatment was eventually stopped, and the bezoar was expelled after a normal diet was resumed.<sup>361</sup>

The current evidence for the clinical efficacy of WBI is divergent, depending on the xenobiotic and its formulation. Additional case reports and series demonstrate the overall safety of WBI as well as some beneficial effects on secondary endpoints, but the benefits remain generally theoretical. The safety of using PEG-ELS was investigated with regard to its impact on the dissolution time of tablets. Although a hastened dissolution of immediate release APAP was shown in one study, no accelerated dissolution was observed from a variety of extended-release morphine formulations.<sup>139,251</sup>

The indications for WBI with PEG-ELS are patients with potentially toxic ingestions of modified-release pharmaceuticals, xenobiotic ingestions with slow absorptive phases when morbidity is expected to be high, and foreign body ingestions. The combination of WBI and AC is reasonable when adsorption of the ingested xenobiotic to AC is expected to be high. Other uses of WBI remain theoretical because the only support for the efficacy comes from surrogate markers and anecdotal experience. Table 5–10 summarizes the indications and contraindications for WBI.

## CATHARTICS

At present, there is no indication for the routine use of cathartics as a method of either limiting absorption or enhancing elimination. It is reasonable to administer a single dose as an adjunct to AC therapy when there are no contraindications and constipation or an increased GI transit time is expected. Multiple-dose cathartics should never be used, and magnesium- and phosphate-containing cathartics should be avoided in patients with kidney disease (Antidotes in Depth: A2).

## SURGERY AND ENDOSCOPY

Surgery and endoscopy are occasionally indicated for decontamination of poisoned patients. As might be expected, no controlled studies have been conducted, and potential indications are based largely on case reports and case series. A prospective, uncontrolled series of 50 patients with cocaine packet ingestion was published more than 30 years ago.<sup>52</sup> The patients were conservatively managed and only underwent surgery if there were signs of leakage or mechanical bowel obstruction. Bowel obstruction occurred in three patients, who promptly underwent successful emergency laparotomy; another six patients chose elective surgery. The authors concluded that body

packers should be treated conservatively and only operated on for xenobiotic leakage or bowel obstruction.<sup>52</sup> A similar study performed a 16-year retrospective analysis of all body packers treated in a single center.<sup>306</sup> Of the 2,880 body packers who were identified, 63 (2.2%) developed symptoms of severe cocaine toxicity after rupture of a package, 43 of the 63 symptomatic patients (68%) died before surgery could be initiated, and the 20 (32%) who underwent emergency laparotomy to remove the drug packets survived. Another report described two body packers who successfully underwent surgery to remove drug packets. In one case, the indications were rupture and signs of cocaine toxicity. In the other case, the indication for surgery was bowel obstruction.<sup>258</sup> Because most packages do not spontaneously rupture, mechanical obstruction is probably the most common reason for surgical removal of ingested drug packets.<sup>341</sup> Leakage from heroin-containing packages should be managed by naloxone infusion, but the lack of antidote when cocaine packages rupture necessitates surgery (Special Considerations: SC5).<sup>341</sup>

Over the years, case reports, presented mixed results for the endoscopic removal of drug packets, pharmacobezoars, or foreign material from the stomach.<sup>31,63,88,150,178,210,247,312,317,325,341</sup> At present, this method is not routinely recommended for the removal of drug packets because of the concern regarding packet rupture. The procedure is reasonable for removal of a compact pharmacobezoar containing a xenobiotic causing severe and continued poisoning.<sup>150,210,247,312</sup> Emergency GI endoscopy was performed in a patient with a case of Portland cement ingestion. Within 40 minutes of ingestion, the patient vomited grayish material. Gray material was found by endoscopy in the esophagus and gastric fundus, portions of which had become solid masses. Most materials were carefully washed out with suction, and the solid masses were removed with a retrieval net. Gastric lavage was deemed contraindicated because of the risk of esophageal perforation from caustic injury and tracheal aspiration of the stomach contents.<sup>178</sup>

A tablet conglomerate of 43 etilefrin hydrochloride 430-mg tablets in the stomach, which could neither be effectively treated with AC nor by orogastric lavage, was fragmented endoscopically. Removal of the tablet fragments led to the elimination of the residual tablets, and symptoms of toxicity resolved rapidly.<sup>312</sup> Under exceptional circumstances, there is certainly a precedent for attempting this procedure in a highly controlled setting such as an ICU or operating room.

In rare cases of massive iron overdoses when emesis, orogastric lavage, and gastroscopy failed or were estimated to result in an insufficient treatment outcome, gastrotomy was performed. The significant clinical improvement and postoperative recovery indicated that surgery in these particular cases was the correct approach.<sup>109,134,271</sup> In a case of zinc toxicity resulting from massive chronic coin ingestion, laparotomy and gastrotomy proved essential to remove the more than 270 coins ingested (Chap. 100).<sup>268</sup>

## OTHER ADJUNCTIVE METHODS USED FOR GASTROINTESTINAL DECONTAMINATION

Other xenobiotics, such as cholecystokinin, were studied as adjuncts to standard measures for GI decontamination.<sup>99,146</sup> Pharmaceuticals that either speed up GI passage or slow down gastric emptying were administered in an attempt to minimize the absorption of a xenobiotic. In all cases, the results were negligible, and the potential risks of administering additional pharmacologically active xenobiotics to an already poisoned patient seem to outweigh any benefit.<sup>12,363</sup> Interventions that reduce the absorption of xenobiotics from the GI tract other than AC were also studied, including sodium polystyrene sulfonate for lithium<sup>32,116,208,212,213,289,339</sup> or thallium overdose.<sup>149</sup> Human studies showed minimal decreased absorption and increased clearance of lithium when sodium polystyrene sulfonate was administered, and it is therefore not routinely recommended.<sup>116,289</sup> Similarly, case reports describe the use of the lipid-lowering resins cholestyramine and colestipol to interrupt the enterohepatic circulation of digoxin, digitoxin, and chlordanes to increase elimination.<sup>30,114,177,275</sup> With the increased use of AC and availability of digoxin-specific Fab fragments, indications for lipid-lowering resins for cardioactive steroid ingestions seem obsolete. Studies on clay products in

vitro have demonstrated a lower efficacy compared with AC and AC-kaolin products in the adsorption of *Nerium oleander* cardioactive steroids.<sup>338</sup>

## POST-BARIATRIC SURGERY PATIENTS

Patients who have undergone bariatric surgery represent a subgroup of patients who need special caution before GI decontamination procedures can be initiated. Bariatric surgery procedures differ, but they all alter the gastric anatomy and reduce the gastric volume significantly. Limited data are available in the literature, and a single report demonstrated that orogastric lavage was impossible because of resistance in the midesophagus. An 8-cm gastric pouch and a gastrojejunal anastomosis was shown on abdominal radiography, and instillation of AC-sorbitol via the gastric tube resulted in prompt oropharyngeal reflux.<sup>288</sup> Two retrospective case series discuss considerations in GI decontamination procedures in this subgroup of poisoned patients.<sup>199,270</sup> A retrospective poison control center study in 19 cases reported very poor results from orogastric lavage in four patients, with minor gastric bleeding caused by the procedure in one of the patients. No apparent complications were reported from AC dosing that was given in several instances (the specific number was not reported). Whole-bowel irrigation was used in two cases.<sup>270</sup> The use of GI decontamination procedures in a post-bariatric surgery population was retrospectively described in 527 cases. Activated charcoal was used in 14% of cases, MDAC in less than 1%, orogastric lavage in 2%, and WBI in less than 1%. Adverse effects for the procedures included nausea in 12%, vomiting in 9%, and hematemesis in less than 1%. Death unrelated to the toxic exposure was reported in 1%.<sup>199</sup>

Unfortunately, no studies investigated the optimal GI decontamination procedure in this subgroup of patients, and until studies are available, caution is required. Orogastric lavage is not indicated in a patient who has undergone bariatric surgery because the placement of a gastric tube possesses a risk of perforation injuries because of the altered gastric anatomy. The reduced gastric volume makes it impossible for the patient to hold more than an estimated volume of 100 mL of fluid at the time. Dosing of AC is possible but should be divided into smaller portions using a maximum volume of 100 mL. WBI is reasonable after ingestion of large amounts of slow-release formulations.

## GENERAL GUIDANCE

Only a few studies provide guidance based on meaningful clinical endpoints for GI decontamination. Pharmacokinetic and pharmacodynamic parameters were introduced and systematically evaluated in human overdoses,<sup>162-164,189,190,357</sup> of the increasingly popular pharmaceuticals known to cause central nervous system and cardiac toxicity: venlafaxine, citalopram, escitalopram, and quetiapine. Cohort studies<sup>162-164,189,190</sup> evaluated the effect of GI decontamination with the aim to predict cardiotoxicity and the effects of the GI decontamination method chosen in real-life situations that are often inconsistent with the recommendations of the position papers.<sup>33,66,185,332,334,351,353</sup> In a cohort of 436 venlafaxine overdoses, AC increased venlafaxine clearance and decreased the probability of seizures.<sup>189,190</sup> Similarly, 77 patients with escitalopram overdoses were used to develop a pharmacokinetic-pharmacodynamic model that predicted the probability of having abnormal QT interval as a surrogate for torsade de pointes.<sup>357</sup> In this model, AC decreased the bioavailability by 31% and reduced the relative risk reduction of prolonged QT interval by 35% after the ingestion of 200 mg of escitalopram or more.<sup>357</sup> The interruption of the enteroenteric recirculation of therapeutic doses of rivaroxaban and apixaban showed an effect of AC 6 hours after a therapeutic dose and pharmacokinetic modeling suggested effects from AC more than 8 hours after rivaroxaban dosing.<sup>257,366</sup>

The trends in GI decontamination have dramatically shifted toward less intervention over the years. In 2015, of the 2,168,371 human exposure reported to the American Association of Poison Control Centers (Chap. 130), it is remarkable that only 41,598 patients were given single-dose AC, 1,114 were given MDAC, 1,745 underwent lavage, and 1,683 received WBI. At the same time, the more serious exposures (major, moderate, and death)

increased and the less serious exposures (no effect, minor effect, not followed (nontoxic), decreased; Chap. 130). Similar trends in GI decontamination are reported elsewhere with no apparent worsening of outcome.<sup>20</sup> These trends in practice reflect the overall combined philosophy of the position statements, which are applicable to the vast majority of poisoned patients. They highlight the benign nature, in the developed world, of many exposures and the benefits of good supportive care in the typical patient for whom the interventions of GI decontamination represent more risk than benefit. In contrast, the survey mentioned at the beginning of this chapter regarding recommendations for a theoretical patient with a serious enteric-coated aspirin overdose reveals less consensus in that 36 different courses of action were proposed for the same patient—a situation in which nonintervention would likely be of greater risk to the patient than decontamination. Most of the poison control centers and toxicologists did, however, recommend at least one dose of AC.<sup>173</sup> This distinction serves as a reminder that the existing studies and consensus statements cannot be applied to all cases and that a lack of data produces significant uncertainty in choices for GI decontamination in either atypical or severely poisoned patients.<sup>147</sup>

It is essential to note that only one study has ever demonstrated a survival advantage for any form of GI decontamination of poisoned patients.<sup>85</sup> Its unique design, involving a cohort of patients with life-threatening toxicity, forces a reassessment of all previous and subsequent literature and confirms that the principles of decontamination are sound. It also suggests that the failure of most studies to demonstrate a benefit results not from a failure of the techniques used but from applying decontamination techniques to subsets of patients who were likely to have good outcomes regardless of intervention. By consulting experts within clinical and medical toxicology, treating clinicians will be assisted in the risk assessment and evaluation of poisoned patients, and guidelines for specific management can be provided, thereby initially obtaining correct and goal-directed treatment.

## SUMMARY

- The approach to GI decontamination must be individualized. No decontamination method is completely free of risks. The indications and contraindications for GI decontamination must be well defined for each patient, and the method of choice must depend largely on what was ingested, how much was ingested, who ingested it, and when it was ingested.
- Evidence points away from the routine GI decontamination of most patients presenting to an ED with an oral pharmaceutical drug overdose.
- A single dose of AC alone will be sufficient in moderate-risk patients, and only in a small subset of exceptionally high-risk patients will the benefit of orogastric lavage outweigh the risks.
- Orogastric lavage as a single intervention is reserved for cases in which the ingested xenobiotic is not adsorbed by AC and there is reason to believe that the ingested xenobiotic is both life threatening *and* remains in the stomach.
- Multiple-dose activated charcoal and WBI have narrowly defined indications, which will likely change as more investigators address poisoned patients.
- The absolute time frame for when GI decontamination is indicated depends on many factors, such as the rate of gastric emptying, the rate of release of the xenobiotic from modified-release pharmaceuticals, the rate of xenobiotic absorption, and the possibility of enterohepatic and enteroenteric recirculation. The commonly stated short time frame of up to 1 hour postingestion for intervention is an artificially constructed framework that limits the potential benefits of GI decontamination and places many seriously poisoned patients at substantial risk of unnecessary morbidity and mortality.

# DECONTAMINATION PRINCIPLES: PREVENTION OF DERMAL, OPHTHALMIC, AND INHALATIONAL ABSORPTION

Scott Lucyk

Decontamination is a term that describes limiting or minimizing the exposure of a patient to a xenobiotic. This involves removal of a xenobiotic by physical means or by chemical neutralization before it can be systemically absorbed. Despite limited controlled studies assessing its efficacy, decontamination remains the mainstay of initial treatment for a patient exposed to a potentially harmful xenobiotic. Decontamination strategies in toxicology often refer to gastrointestinal (GI) techniques to minimize absorption or enhance elimination in orally poisoned patients (Chaps. 5 and 6). These same principles apply to other exposure routes where local or systemic absorption and toxicity occur, including dermal, ophthalmic, and pulmonary routes. An important point to note is that as opposed to GI decontamination, in which initial patient assessment and management always comes first, in the case of dermal and pulmonary contamination, in which there is risk for contamination and harm to health care personnel, the use of appropriate personal protective equipment (PPE) is paramount before initiation of patient decontamination. The benefits of decontamination to remove or neutralize a xenobiotic are severalfold and include (1) prevention of further absorption and toxicity in exposed patients, (2) prevention of secondary contamination of other staff or equipment, and (3) prevention of contamination of the health care facility and other patients.

An organized approach to decontamination is required following the release of hazardous materials. Unintentional release of hazardous materials occurs at industrial sites, chemical manufacturing plants, pipelines, and waste sites.<sup>25</sup> Also, the threat of terrorist attack using hazardous materials mandates that the health care community be prepared to effectively manage these situations in a safe and efficient manner that optimally treats patients while at the same time maintains the safety of the health care providers.

This Special Consideration focuses on situations that require health care facility-based dermal, ophthalmic, and pulmonary decontamination. The approach to the decontamination process is discussed, but the acute medical management of specific local and systemic toxicities is covered in other chapters. Dealing with mass casualty events and the incident command system, as well as prehospital decontamination are covered in detail elsewhere (Chap. 132). In addition, approaches to patient triage, runoff control, and isolation requirements are not covered here.

## HAZARDOUS MATERIALS

Typically, decontamination efforts are initiated by first responders, including hazardous materials teams (HAZMAT), who respond to the site of initial xenobiotic release. However, in an instance when emergency medical services (EMS) is unable or uncertain how to decontaminate a patient or for patients who self-present to the hospital, it is prudent that health care providers are prepared to carry out effective decontamination. In fact, up to 80% of patients from a scene of xenobiotic release self-present to a hospital without undergoing any prior decontamination, mandating that hospital personnel have the appropriate knowledge and follow an organized approach to patient decontamination to ensure their personal safety and the safety of other health care providers and patients.<sup>5,39,40</sup> Close cooperation between the emergency department (ED) and prehospital providers, including HAZMAT teams responding to the initial site of exposure, help to

identify the xenobiotic involved and help to guide decontamination efforts. Appropriate communication with these teams before hospital arrival is paramount to ED preparations for a particular xenobiotic number of patients being brought by EMS, degree of prehospital decontamination, and associated injuries. Secondary contamination data from the Agency for Toxic Substances and Disease Registry (ATSDR) Hazardous Substances Emergency Events Surveillance system was studied. Between 1995 and 2001, six events involving 15 ED personnel, and from 2003 to 2006, 15 events involving at least 17 medical personnel were identified in which secondary contamination occurred.<sup>20,21</sup> After the Tokyo sarin subway attacks in 1995, many patients presented directly to a hospital as their first site of health care contact. Hospital-based decontamination attempts were not universal, with a limited number of patients receiving a change of clothes or shower, which resulted in approximately 23% of staff experiencing secondary contamination.<sup>41</sup>

A vast number of xenobiotics are involved in patient exposures, either from their deliberate use or from unintentional exposure. Identification of specific substances and their properties is helpful to determine specific toxic properties and the likelihood of systemic absorption. However, on initial hospital presentation, the exact xenobiotic or xenobiotics are often unknown, mandating that general safety and decontamination measures are promptly initiated to provide maximal safety to health care providers, with subsequent adjustments made as more product information becomes available.

In addition to concerns for toxicity related to hazardous materials, many of these exposures have nontoxicologic medical concerns that must be addressed simultaneously. Patients from industrial incidents often present with traumatic injuries or multiorgan dysfunction that require appropriate basic and advanced life support measures are instituted. Evaluation and support of patient airway, breathing, and circulation should ideally be done concomitantly with decontamination efforts, as long as health care providers are protected using appropriate PPE.

## PERSONAL PROTECTIVE EQUIPMENT

As noted earlier, the most important aspects of managing patients contaminated with hazardous materials are to protect health care providers and to prevent worsening the situation by creating additional exposed individuals. There are several levels of PPE, classified according to the Environmental Protection Agency from level A to D, that provide varied levels of protection against exposure to gases, vapors, aerosols, liquids, and solids. The type of exposure dictates the level of PPE that is required for appropriate (Chap. 132).

## DECONTAMINATION

### Dermal Exposures

The majority of decontamination for patients presenting after hazardous materials exposures will involve dermal decontamination. Patients exposed to liquids, aerosols, or solids require dermal decontamination. Patients who do not pose a risk of secondary contamination to health care workers include those who have undergone appropriate prehospital decontamination and those exposed only to vapors or gases with no signs of skin or eye irritation and who do not have gross deposition of the material on their clothing or skin. These patients should proceed directly to the treatment area without

further ED dermal decontamination.<sup>4,16,22,24</sup> However, gases or vapors condense on patient clothing, leading to secondary contamination from off-gassing if appropriate care is not taken in managing personal belongings (see later discussion). In addition, if a patient has ingested a chemical, vomitus poses a danger to health care providers through direct contact or off-gassing.<sup>4</sup> If able, patients should assist in their own decontamination efforts.

Methods of dermal decontamination include physical removal (clothing removal, removal of visible solid particles), adsorption (Fuller earth, activated charcoal, flour), dilution (flushing), or acts to neutralize the xenobiotic.<sup>30</sup>

### Physical Removal

Before initiation of dermal decontamination, the most important step is to remove contaminated clothing, which removes from 75% to 90% of the contaminants.<sup>13,22,26,39</sup> Clothing should be cut off rather than pulled off because pulling off clothing will worsen contaminant exposure to the patient and health care staff.<sup>22,39</sup> Clothing and personal belongings should be double bagged in sealed plastic bags with the patient's information written on it.<sup>3</sup> Appropriate sealing is required to prevent evaporation or aerosolization of the xenobiotic.<sup>4,30</sup> Dermal decontamination also includes physical removal of the xenobiotic with forceps or gentle removal with brushing or use of a towel on the skin. Another method is to gently scrape the xenobiotic from the skin using a flat edge such as a tongue depressor.<sup>24</sup> Care must be taken to gently remove xenobiotics, as abrasive cleansers increase systemic absorption. Flushing the skin with copious amounts of water is also effective at physically removing xenobiotics.

A method of dry decontamination using activated charcoal, flour, or Fuller Earth is suggested by some groups to adsorb certain nerve agents and sulfur mustard, after which the adsorbed compound is gently brushed or wiped off with a towel.<sup>22,24</sup> The US military also uses a compound called M-291, a carbon-based adsorbent–polystyrene polymeric–ion exchange resin, for local, dermal decontamination.<sup>22,24</sup> Although dry decontamination is effective for localized exposures, it is unlikely to be useful in the hospital setting and therefore is not recommended because a lack of familiarity will lead to delays in initiating more effective decontamination strategies.

### Dilution and Neutralization

Water only, soap and water, and 0.5% hypochlorite solutions are used to decontaminate skin after hazardous material exposures. The main factors determining usefulness of a hospital-based decontamination solution include safety (nontoxic and noncorrosive), availability, ease of use, affordability, and ease of disposal. The solution must also be nonirritating, rapid acting, and not produce toxic endproducts or enhance percutaneous absorption.<sup>11,24</sup> Regardless of the solution used to flush contaminated skin, the most important factor is that it must be done as soon as possible to minimize the inflammatory response and potential for local and systemic toxicity; after a xenobiotic is absorbed, topical decontamination is of limited utility.

Flushing contaminated skin with high volumes of low-pressure water will aid in physical removal and significant dilution of the xenobiotic. A military study showed that an oil-based xenobiotic was removed from 90% of subjects within 30 seconds and 100% of subjects at 90 seconds using a water only decontamination method.<sup>36</sup> Overall, showering with tepid water and liquid soap (mild, nonabrasive soap such as hand dishwashing soap) is the most effective, easiest, and most readily available method for removing hazardous materials from patients' hair and skin.<sup>6,39</sup> Use of alkaline soaps produces hydrolysis and neutralization of some xenobiotics; however, this contributes far less than the benefits of physical removal and dilution.<sup>24</sup> In addition, for patients exposed to non-water-soluble, oily, or adherent xenobiotics such as mustard or blister agents, addition of mild liquid soap and gentle scrubbing with a sponge or cloth helps to aid removal. Skin damage should be avoided to prevent further absorption of the xenobiotic. Patients should be scrubbed downward from head to toe with care taken to avoid contaminating unexposed areas.

Chemical alteration and deactivation, including hydrolysis and oxidative chlorination, were studied by the military in response to chemical weapons

and suggest some benefit. However, these approaches do not have any significant role in the hospital setting because they require prolonged contact time to be effective.<sup>22,32</sup> Hydrolysis through the addition of acidic solutions is prohibitively slow, and alkaline solutions require a pH that would damage skin or mucosa (ie, pH 10–11).<sup>24</sup> Oxidative chlorination with the addition of dilute (0.5%) hypochlorite solution, although still recommended by the military and effective for decontaminating oxidizing mustard agents and some organic phosphorus compounds, is not acceptable for use on ophthalmic or mucosal surfaces, in open wounds, or exposed nerve tissue.<sup>22,24</sup> Both the difficulty in obtaining 0.5% hypochlorite solution and its propensity to worsen certain tissue injuries make its use impractical in the hospital setting.

There are no controlled studies to assess the optimal duration of showering or skin rinsing and no current consensus exists. Recommendations for duration of water-based decontamination range from 3 to 30 minutes.<sup>4,7,12,39,48</sup> It is reasonable to wash exposed areas with tepid water and liquid soap for 5 to 15 minutes, with an additional 10 to 15 minutes for contaminated open wounds.<sup>7</sup> The US military has several processes to assess efficacy of decontamination (eg, M8 paper, M9 tape, chemical agent monitor); however, these are not readily available or realistic for use in the hospital setting.<sup>24</sup>

Certain exposures benefit from a different decontamination strategy, and in certain instances, use of water may actually worsen toxicity. Exceptions to the water-first approach are solid alkali metals, including sodium, potassium, and lithium because water causes these metals to form their corresponding bases (sodium, potassium, or lithium hydroxide) and liberate a substantial amount of heat.<sup>6</sup> In addition, alkyl metals such as alkyl of aluminum, zinc, magnesium, or lithium cause similar reactions.<sup>8</sup> Radioactive compounds (cesium and rubidium) also react on contact with water.<sup>27</sup> Specific dusts (pure magnesium, white phosphorus, sulfur, strontium, titanium, uranium, yttrium, zinc, and zirconium) spontaneously ignite on contact with air. If these compounds are suspected on patient skin or clothing, residual metal should be removed with forceps and stored in mineral oil.<sup>27</sup> As mentioned previously, the identification is often delayed, and because the time to removal is paramount, when uncertain exposures are encountered, exposed patients should be immediately washed with copious amounts of soap and water.

### Ophthalmic Exposures

There are more than 25,000 xenobiotics, including acids, bases, oxidizers, reducers, alkylators, chelators, and solvents, that cause chemical burns.<sup>44</sup> Acids and alkalis are the most commonly implicated xenobiotics in ophthalmic chemical exposures.<sup>33,44</sup> The severity of ophthalmic burns is determined by several factors, including solution concentration, pH, duration of exposure, extent of surface damaged, and degree of intraocular penetration.<sup>35,43</sup> Liquid xenobiotics are most commonly implicated, but gases (eg, chlorine, ammonia, nerve agents) dissolve on the surface of the eye and be absorbed into the lacrimal fluid or diffuse through the lacrimal fluid (eg, mustard gas). Solids or powders also lead to ophthalmic injury if not removed promptly.

### Decontamination

The single most important intervention after ophthalmic chemical injuries is immediate and copious irrigation because concentrated solutions penetrate the eye within seconds to minutes.<sup>9,44</sup> In one cohort of 101 patients with 131 burnt eyes, patients with delayed or no rinsing had a significant increase in number of operations required, worse visual outcomes, and increased length of stay in hospital compared with patients receiving immediate irrigation.<sup>28,45</sup> Contact lenses should be carefully removed to prevent any additional injury to the eye.<sup>4</sup> Often in industrial exposures, worksite safety precautions mandate that eyewash stations be readily available and that patients have initiated eye flushing before presentation to a health care facility. Some sites also have a portable eyewash station to be transported with the patient to hospital so that irrigation can be continued en route.

To adequately irrigate the eye and surrounding structures, the eye should be held open and continuously flushed. This process can be painful and irritating, so topical anesthetic should be applied before initiation. Solution can either be poured slowly into the eyes by gently pulling apart the patient's eyelids and tilting the head to the side or by using specially designed lenses that are placed beneath the eyelids to be in direct contact with the surface of the eye to enable direct flushing. The patient should be instructed to roll the eyeball to remove any particles retained beneath the eyelids.<sup>9</sup> The eyelids should be gently everted to assess for the presence of particulate debris that should be removed using a moist cotton tip. Irrigation should be continued for cycles of 10 to 15 minutes followed by pH rechecks (Chap. 24).<sup>1,45</sup> Ocular pH should be checked using litmus paper with a goal to continue irrigation until the pH is 7.5 to 8. Ophthalmic burns from strong or concentrated acids or alkalis require irrigation for at least 2 to 3 hours and immediate ophthalmologic consultation (Chap. 24).

Many different solutions and buffers were assessed in laboratory experiments while considering important ophthalmic properties, including osmolar regulation of tissues. Some experts caution that use of a low-osmolarity solution such as tap water will promote diffusion of the diluted xenobiotic into the deeper layers of the cornea and cause corneal edema.<sup>44,45</sup>

Overly complicated ocular decontamination protocols lead to physician uncertainty and delays in initiating treatment. Copious irrigation of the eye should be started promptly because time to irrigation is the most important factor. Any solution with a pH between 5 and 9 and temperature between 10° and 42°C is adequate for initial irrigation.<sup>44</sup> In residential exposures, prompt irrigation with any nontoxic liquid (eg, tap water) before and en route to a health care facility will significantly reduce injury. Although many different solutions and protocols have been studied, more evidence is required before these can be considered standard of care.

After appropriate irrigation has been effectively performed, a complete ophthalmologic assessment of consequential risk should be carried out, including visual acuity and intraocular pressure measurements for those with a toxic xenobiotic. Patients with ophthalmic exposure to chemicals should be assessed by an ophthalmologist because these patients are at risk for functional or anatomical loss of the eye, corneal ulceration, variations in ocular pressure, eyelid deformity and dysfunction, and tear abnormalities.<sup>9</sup> Decontamination attempts with copious flushing normalize the pH at the ophthalmic surface, however, the pH is not always reflective of the deeper structures of the globe, because xenobiotics will penetrate deeper into the eye.<sup>44</sup> Further treatments including cycloplegics, mydriatics, steroids, and topical antibiotics are beyond the scope of this chapter and should be discussed with an ophthalmologist (Chap. 24).

## Inhalational Exposures

Internal decontamination of the pulmonary system is rarely required, specifically when an individual is exposed to a xenobiotic in which continued damage is expected and the xenobiotic is not able to rapidly diffuse from the pulmonary system. Removal of xenobiotics from the pulmonary tree requires use of bronchoalveolar lavage. The rare instances when this is required include removal of carbonaceous material after smoke inhalation and after exposure to large amounts of insoluble radioisotopes such as the alpha emitter plutonium.<sup>47</sup> Health care providers performing bronchoalveolar lavage should use appropriate PPE, as determined by the hospital Radiation Safety Officer. All lavage fluid should be collected and disposed of according to hospital policies.

## SPECIFIC DECONTAMINATION EXAMPLES

### Corrosives

A review of controlled clinical studies concluded that water was the best decontaminating solution for dermal corrosive exposures and that time to decontamination was the most important factor in limiting morbidity and improving outcomes.<sup>6</sup> Only four controlled clinical studies were published comparing early extensive water decontamination with none or lesser dilutional treatments in patients with corrosive dermal injury. One controlled

cohort study of 35 patients compared those treated with "immediate" water irrigation (within 10 minutes and continued for at least 15 minutes) with those receiving water irrigation after they arrived at hospital. Despite having mean total burn surface area twice as large (12% versus 6%), the immediate water irrigation group had significantly fewer burns that progressed to full thickness (12.5% versus 63%) and shorter mean hospital stays (7.7 days versus 20.5 days).<sup>29</sup> A follow-up study by the same group published 10 years of experience and included 83 patients (including the 35 patients from the previous study) treated with copious water irrigation within 3 minutes of exposure. These patients were less likely to progress to full-thickness burns (13.5% versus 60.8%) and had fewer delayed complications (5.4% versus 30.4%) and shorter lengths of hospital stay (6.2 versus 22 days) than those not decontaminated with water early.<sup>38</sup>

Other solutions were investigated for the purpose of "active rinsing." They are postulated to not only provide the irrigation benefits of water but also act to neutralize the offending xenobiotic. One decontamination solution investigated for use in chemical exposures and burns is an emergency aqueous rinsing solution that contains unspecified amphoteric salts.<sup>18,33</sup> In vitro studies suggest the emergency rinsing solution can neutralize alkaline or acidic substances without significant release of exothermic energy.<sup>33</sup> Animal studies suggest that an emergency rinsing solution helps to minimize ocular burns and is associated with improved wound healing and pain alleviation after dermal burns.<sup>10,17</sup> Use of an amphoteric, emergency rinsing solution was studied after implementation at three alumina refineries and included 180 patients with dermal alkali exposures, predominantly sodium hydroxide.<sup>14,15</sup> An emergency rinsing solution-first compared with water-first decontamination approach was associated with a not statistically significant difference in signs of chemical burns (47.1% versus 78.6% although when burns were present, patients treated with emergency rinsing solution had fewer blisters or severe signs compared with those who had water treatment (7.9% versus 23.8%;  $P < 0.001$ ). A recent review of an emergency rinsing solution suggested it was a safe and effective method for improving healing time, healing sequelae, and pain management for chemical burns involving the skin and eyes of humans.<sup>31</sup> However, lack of treatment randomization, observer blinding, uncertain initial time to decontamination between the groups, and significant conflicts of interest limit the applicability of the studies. Further research and increased availability of amphoteric, emergency rinsing solutions are required before this can be recommended as a first-line therapy in preference to rapid and widely available water rinsing.

### Hydrofluoric Acid

Hydrofluoric acid is a weak acid ( $pK_a = 3.2$ ) that can cause severe burns and life-threatening electrolyte abnormalities. Standard decontamination includes immediate and prolonged water rinsing of exposed areas followed closely by administration of calcium gluconate by one of several routes (Chap. 104). Dermal or ophthalmic exposures to hydrofluoric acid to the skin or eyes should be flushed with plain water or 0.9% saline for at least 20 minutes.<sup>2</sup> Another use of emergency aqueous rinsing solution containing unspecified amphoteric salts was advanced for decontaminating hydrofluoric acid and fluoride ions in an acidic environment. Such solutions provide the flushing effect of water but also act to chelate fluoride ions and neutralize acidic ions without creating a significant exothermic reaction.<sup>33</sup> Several case series involving workplace decontamination with an emergency rinsing solution claim minimization or avoidance of burn severity and minimal lost work time.<sup>34,46</sup> However, a study in rats with hydrofluoric acid exposure showed no difference between skin cleansing with an emergency rinsing solution versus water only in causing electrolyte abnormalities.<sup>23</sup> In fact, there was a trend toward milder hypocalcemia and hyperkalemia in rats decontaminated with 500 mL of water followed by a single application of 2.5% calcium gluconate gel compared with the emergency rinsing solution. Prior studies using the same skin cleansing technique showed that those treated with water and calcium gluconate gel had less severe burns compared with the emergency rinsing solution group.<sup>19</sup> Further research with amphoteric blends of emergency rinsing solutions is required before it can be recommended for treatment of hydrofluoric acid exposures.

## Phenol

Phenol, also known as carboic acid, is a colorless compound used in the production of many products, including phenolic resins, industrial coatings, dyes, perfumes, fungicides, plastics, explosives, and fertilizers. Concentrated phenol solutions cause severe chemical burns. Phenol is also used for chemical face peeling and is occasionally used in medicine in specific topical and oropharyngeal analgesics and ointments.<sup>37</sup> After exposure to concentrated solutions, skin will turn white initially followed by yellow-brown discoloration. Because toxicity is often significant, adequate dermal decontamination is vital. As in the case of all caustics, both the skin surface area exposed and the product concentration determine local and systemic toxicity. A porcine model assessed the optimal dermal decontamination strategy to minimize local damage based on histologic assessment and systemic absorption.<sup>37</sup> Histologic injury compared 10 different decontamination strategies, including water washes ranging from 1 to 30 minutes, alternating soap and water washes, and 15 minutes of alternating 1-minute water and 1-minute treatment washes. The treatment washes compared included polyethylene glycol (PEG) 400, PEG 400–industrial methylated spirits (IMS), PEG 400–ethanol, polyvinylpyrrolidone (PVP)–isopropyl alcohol (IPA), and IPA. The PEG 400 and IPA washes were more effective than the other treatments at reducing morphologic changes, including papillary dermal edema, pyknotic basal cells, and collagen necrosis.<sup>37</sup> In vitro studies using isolated perfused porcine skin flaps were then assessed and found that all three decontamination strategies studied (15 minutes of alternating water and PEG 400 washes, alternating water and IPA washes, or water-only washes) statistically reduced the amount of systemically absorbed phenol compared with controls but did not show significant differences between each of the treatment arms.<sup>37</sup> A swine study of phenol exposure found that decontamination for 15 minutes with either PEG 300–IMS or water shower found no significant differences in amount of phenol absorbed, as judged by plasma phenol concentrations.<sup>42</sup>

Given the inconclusive findings in prior studies, decontamination using inexpensive, readily available tepid water should be performed. Further studies on the safety and efficacy of using IPA and PEG–IMS are required before their use should be applied systematically to patients with phenol burns presenting to hospital.

## Unknown Xenobiotics

Patients often present to health care facilities after exposure to an unknown xenobiotic. In these cases, patients should have clothing removed and affected areas washed with tepid water and liquid soap for 5 to 15 minutes, with an additional 10 to 15 minutes for contaminated open wounds. Ophthalmic exposures should have immediate water irrigation for cycles of 10 to 15 minutes followed by pH rechecks with goal pH of 7.5 to 8.

## SUMMARY

- An organized approach to patient decontamination after hazardous materials exposure is paramount to ensure best patient outcomes, prevention of secondary contamination of health care providers, and optimal functioning of the health care facility.
- As opposed to GI decontamination, dermal decontamination must be performed concurrently with the initial evaluation.
- Many different products were evaluated for dermal and ophthalmic decontamination. At this time, there is insufficient evidence and availability to recommend use of one product over another. Use of tepid water is the most reasonable option for most exposures.
- Regardless of the solution used, the most important aspect is time to decontamination; after health care providers have donned appropriate PPE, prompt initiation of decontamination is vital.
- Removal of clothing and showering with soap and water to clean the skin and hair is the easiest, most efficacious way to minimize primary and secondary contamination.
- Pulmonary decontamination is rarely required for exposures causing contamination of the pulmonary tree when continued exposure is expected, such as with insoluble radioisotopes.

## ACTIVATED CHARCOAL

Silas W. Smith and Mary Ann Howland

## INTRODUCTION

Activated charcoal (AC) is an excellent nonspecific adsorbent. Conclusions regarding the role of AC in poison management are achieved through the integration of pharmacologic data, controlled volunteer trials, studies in heterogeneous patients with overdose or poisoning, and clinical experience. Activated charcoal is provided to a patient after a risk-to-benefit assessment of the presumed ingested xenobiotic and patient-specific factors and circumstances. Benefits include preventing absorption or enhancing elimination by blocking enterohepatic or enteroenteric recirculation of a potentially toxic xenobiotic; risks include vomiting and subsequent aspiration pneumonitis. A detailed discussion of the merits of AC as a decontamination strategy is presented in Chap. 5.

## HISTORY

Charcoal a fine, black, odorless powder, has been recognized for more than two centuries as an effective adsorbent of many substances. Organic chemist Scheele first used charcoal to absorb gases in 1773 and was followed in 1791 by Lowitz's use of charcoal with colored liquids.<sup>6,89</sup> Bertrand attributed his survival in 1811 from separate mercuric chloride and arsenic trioxide ingestions to their antecedent admixture with charcoal.<sup>119</sup> In 1830, the French pharmacist Touery demonstrated the powerful adsorbent qualities of charcoal by ingesting several lethal doses of strychnine mixed with charcoal in front of colleagues, suffering no ill effects.<sup>6</sup> An American physician, Holt, first used charcoal to "save" a patient from mercury bichloride poisoning in 1834.<sup>6,89</sup> However, it was not until the 1940s that Andersen began to systematically investigate the adsorbency of charcoal and unquestionably demonstrate that charcoal is an excellent, broad-spectrum gastrointestinal (GI) adsorbent.<sup>6-8</sup>

## PHARMACOLOGY

## Chemistry and Preparation

Activated charcoal is produced in a two-step process, beginning with the pyrolysis of various carbonaceous materials such as wood, coconut, petroleum, or peat to produce charcoal. This processing is followed by treatment at high temperatures (600°–900°C) with a variety of oxidizing (activating) agents such as steam, carbon dioxide, or acids to increase adsorptive capacity through formation of an internal maze of pores.<sup>30,60,121</sup> Typical AC surface areas average 800 to 1,200 m<sup>2</sup>/g.<sup>117</sup>

## Mechanism of Action

The actual adsorption of a xenobiotic by AC relies on hydrogen bonding, ion-ion, dipole, and van der Waals forces, suggesting that most xenobiotics are best adsorbed by AC in their dissolved, nonionized form.<sup>30,63,117,151</sup>

## Pharmacokinetics

Activated charcoal is pharmacologically inert and unabsorbed. Its GI transit time is influenced by the type and quantity and ingested xenobiotic, fasting and hydration status, perfusion, and the use of associated cathartics or evacuants, among other factors. The transit of AC is superimposed on a wide range of interindividual variation in gastric emptying and small bowel transit times, even in healthy volunteers.<sup>62</sup> In six volunteers acting as their own controls, AC alone or administered with sodium chloride, sodium sulfate, magnesium sulfate, or a proprietary cathartic "salt" (36.7% anhydrous

citric acid, 17.65% magnesium sulfate, and 45.6% sodium bicarbonate), the GI transit times to fecal evacuation ranged from 29.3 ± 1.2 hours to 17.3 ± 1.9 hours.<sup>120</sup> In 59 overdose patients compared with 104 overdose historical control participants who ingested acetaminophen (APAP), carbamazepine, cyclic antidepressants, opioid-APAP combinations, and phenytoin, the addition of 70% sorbitol solution to 25 to 50 g of AC decreased the median half-lives for gastric emptying (from 100 to 82 minutes), small intestinal transit (from 209 to 180 minutes), and orocecal transit (from 270 to 210 minutes).<sup>1,2</sup>

## Pharmacodynamics

The adsorption rate to AC depends on external surface area, and the adsorptive capacity depends on the far larger internal surface area.<sup>30,31,110</sup> The adsorptive capacity is modified by altering the size of the pores. Current AC products have pore sizes that range from 10 to 1,000 angstroms (Å), with most of the internal surface area created by 10- to 20 Å-sized pores.<sup>30,32</sup> Most xenobiotics are of moderate molecular weight (100–800 Da) and adsorb well to pores in the range of 10 to 20 Å. Mesoporous charcoals with a pore size of 20 to 200 Å have a greater capacity to adsorb larger xenobiotics as well as those in their larger hydrated forms but are not available for clinical use.<sup>86</sup>

When the AC surface area is large, the adsorptive capacity is increased, but affinity is decreased because van der Waals forces and hydrophobic forces diminish.<sup>151</sup> According to the Henderson-Hasselbalch equation, weak bases are best adsorbed at basic pHs, and weak acids are best adsorbed at acidic pHs. For example, cocaine, a weak base, binds to AC with a maximum adsorptive capacity of 273 mg of cocaine per gram of AC at a pH of 7.0; this capacity is reduced to 212 mg of cocaine per gram of AC at a pH of 1.2.<sup>85</sup> Activated charcoal binds amitriptyline hydrochloride with adsorption capacities of 120 and 100 mg per gram of AC in simulated gastric and intestinal fluids, respectively.<sup>150</sup> The adsorption to AC of a weakly dissociated metallic salt such as mercuric chloride (HgCl<sub>2</sub>) decreases with decreasing pH because the number of complex ions of the type HgCl<sub>3</sub> and HgCl<sub>4</sub> increases, and the number of electroneutral molecules (HgCl<sub>2</sub>) is reduced.<sup>7</sup> Nonpolar, poorly water-soluble organic substances are more likely to be adsorbed from an aqueous solution than polar, water-soluble substances.<sup>30</sup> Among the organic molecules, aromatics are better adsorbed than aliphatics; molecules with branched chains are better adsorbed than those with straight chains; and molecules containing nitro groups are better adsorbed than those containing hydroxyl, amino, or sulfonic groups.<sup>30</sup>

Activated charcoal decreases the systemic absorption of most xenobiotics, including APAP, aspirin, barbiturates, cyclic antidepressants, phenytoin, theophylline, and other inorganic and organic materials.<sup>49,106,123</sup> Notable xenobiotics not amenable to AC are the alcohols, acids, alkalis, iron, lead, lithium, magnesium, potassium, and sodium salts.<sup>53</sup> Although the binding of AC to cyanide is less than 4%, the toxic dose is small, and 50 g of AC would theoretically be able to bind more than 10 lethal doses of potassium cyanide. Activated charcoal is capable of rapidly removing volatile anesthetic gases such as isoflurane, sevoflurane, and desflurane from anesthetic breathing circuits, which is potentially important in patients who are susceptible to or develop malignant hyperthermia.<sup>14</sup>

The efficacy of AC is directly related to the quantity administered. The effect of the AC to drug ratio on adsorption was demonstrated both in vitro and in vivo with para-aminosalicylate (PAS). In vitro, the fraction of

unadsorbed PAS decreased from 55% to 3% as the AC-to-PAS ratio increased from 1:1 to 10:1 at a pH of 1.2.<sup>114</sup> This study provides the best scientific basis for the 10:1 AC-to-drug ratio dose typically recommended. In human volunteers, as the AC-to-PAS ratio increased from 2.5:1 to 50:1, the total 48-hour urinary excretion decreased from 37% to 4%.<sup>114</sup> Presumably, this occurred because more of the PAS was adsorbed by AC in the lumen of the GI tract rather than being absorbed systemically. These same studies demonstrate AC saturation at low ratios of AC to drug and argue for a 10:1 ratio of AC to xenobiotic. A meta-analysis of 64 controlled volunteer studies demonstrated that the percentage of reduction in drug exposure provided by AC followed a sigmoidal dose–response curve.<sup>69</sup> Activated charcoal to drug ratios of 1:1, 5:1, 10:1, 20:1, 25:1, and 50:1 reduced drug exposures by 9.0%, 30.2%, 44.6%, 58.9%, 62.9%, and 73.0%, respectively.<sup>69</sup> In a subsequent study of volunteers ingesting 50 mg/kg of APAP, reducing a 1-hour postingestion 50 g AC dose to 25 or 5 g caused the APAP area under the concentration versus time curve (AUC) to increase by 23.6% and 59.0%, respectively.<sup>55</sup>

In vitro studies demonstrate that adsorption begins within about 1 minute of AC administration but does not achieve equilibrium for 10 to 25 minutes.<sup>31,106</sup> The clinical efficacy of AC to prevent absorption is inversely related to the time elapsed after ingestion and depends largely on the rate of absorption of the xenobiotic. According to a meta-analysis of volunteer studies, the median reductions of drug exposure when AC was administered at 0 to 5 minutes, 30 minutes, 60 minutes, 120 minutes, 180 minutes, 240 minutes, and 360 minutes after ingestion were 88.4%, 48.5%, 38.4%, 24.4%, 13.6%, 27.4%, and 11%, respectively.<sup>69</sup> Early AC administration is more important with rapidly absorbed xenobiotics, in which AC functions to prevent xenobiotic absorption by achieving rapid adsorption in the GI tract. After a xenobiotic is systemically absorbed or parenterally administered, AC can enhance elimination through enterohepatic and enteroenteric recirculation as opposed to affecting absorption.

Desorption (drug dissociation from AC) can occur, especially weak acids, as the AC–drug complex transits the stomach and intestine and as the pH changes from acidic to basic.<sup>50,113,147</sup> Whereas strongly ionized and dissociated salts, such as sodium chloride and potassium chloride, are poorly adsorbed, nonionized or weakly dissociated salts, such as iodine and mercuric chloride, respectively, are adsorbed. Binding of  $\gamma$ -hydroxybutyrate (800 mg) to AC (10 g) decreased from 84.3% to 23.3% when exchanging simulated gastric for intestinal fluid.<sup>105</sup> Diminished AC adsorptive capacity in the intestinal lumen can also occur because of the rapid adsorption by AC of intestinal fatty acids, which rapidly cover the surface of carbon granules.<sup>89</sup> Desorption can lead to ongoing systemic xenobiotic absorption over days. In this case, the apparent elimination half-life of the xenobiotic increases, but peak concentrations remain unaffected.<sup>111</sup> The clinical effects of desorption can be minimized by providing sufficient AC to overcome the decreased affinity of the xenobiotic secondary to pH change, such as by using multiple-dose AC (MDAC).<sup>73,96,109,124,140</sup> Although ethanol and other solvents such as polyethylene glycol (PEG) are minimally adsorbed by AC, they can decrease AC adsorptive capacity for a coingested xenobiotic by competing for AC binding.<sup>12,111,113,115</sup>

### Concomitant Administration of Activated Charcoal with Cathartics or Evacuants

Cathartics are often used with AC; however, evidence suggests that AC alone is comparably effective to AC plus a single dose of cathartic (sorbitol or magnesium citrate).<sup>3,73,90,92,96,104,110,122</sup> If a cathartic is used, it should be used only once. Repeated doses of magnesium-containing cathartics are associated with hypermagnesemia,<sup>99,142</sup> and repeated doses of any cathartic are associated with salt and water depletion, hypotension, and severe or fatal fluid and electrolyte derangements.<sup>48</sup> Activated charcoal with sorbitol is not recommended for children younger than 1 year of age.<sup>121</sup>

Whole-bowel irrigation (WBI) with PEG electrolyte lavage solution can significantly decrease the in vitro and in vivo adsorptive capacity of AC, depending on the individual xenobiotic, its formulation, and the GI location. For example, experiments demonstrate desorption of cocaine, fluoxetine,

salicylate, and theophylline from AC,<sup>10,76,85</sup> but chlorpromazine was not significantly affected by PEG at gastric pH.<sup>11</sup> A controlled crossover study compared the addition of a short course of WBI (1 L/h) with AC alone in nine healthy participants who were provided simultaneous carbamazepine (200 mg), theophylline (200 mg), and verapamil (120 mg).<sup>80</sup> Polyethylene glycol decreased AC's efficacy for carbamazepine and theophylline but was synergistic with AC for verapamil.<sup>80</sup> Whole-bowel irrigation did not improve upon AC's nonstatistically significant 11% decrease in absorption in volunteers ingesting 2.88 g of aspirin.<sup>91</sup> The most likely explanation is competition by PEG for the surface of the AC for solute adsorption. Activated charcoal and WBI interactions are further discussed in Antidotes in Depth: A2.

### Related Formulations

Porous carbon microsphere compounds (eg, AST-120) are clinically used to adsorb endogenous enteric uremic toxins to mitigate glomerular hypertrophy, interstitial fibrosis, and progression of chronic kidney disease.<sup>136,137,161</sup>

## ROLE OF ACTIVATED CHARCOAL IN GASTROINTESTINAL DECONTAMINATION

### Single-Dose Activated Charcoal

It is difficult to assess the efficacy of single-dose AC (SDAC) in a prospective study involving consecutive adults receiving 50 g of AC for self-poisonings because of the exclusions of multiple xenobiotic and sustained-release products and because SDAC was used in combination with other forms of GI decontamination in all symptomatic patients.<sup>97</sup> Not surprisingly, a beneficial effect of SDAC on outcome measures could not be demonstrated in asymptomatic patients. Similarly, a study of routine SDAC administration after oral overdose consisting primarily of benzodiazepines, APAP, and selective serotonin reuptake inhibitors could not demonstrate differences in mortality, length of stay, vomiting, or intensive care admissions.<sup>33</sup> A prospective trial of 876 patients comparing SDAC alone with SDAC plus gastric emptying was unable to demonstrate a difference in outcomes, with the exception of patients presenting within 1 hour of ingestion, although this difference was not sustained after being adjusted for severity.<sup>127</sup> Subsequent studies touting the lack of benefit of AC are of limited value because of similar design flaws such as including irrelevant exposures or those to which AC would not adsorb or conflating AC administration outcomes with orogastric lavage.<sup>118</sup> When evaluating SDAC alone, a meta-analysis of 64 controlled volunteer studies found significant reductions in ingested xenobiotic amounts when SDAC was provided in appropriate quantity (eg, a 10:1 AC: xenobiotic ratio) and within 240 minutes of exposure.<sup>69</sup>

Research subsequent to this meta-analysis has sustained primarily pharmacokinetic advantage of SDAC, although some improvements in clinically important endpoints were demonstrated. A healthy volunteer study in 12 patients in which SDAC was provided 15 minutes after supratherapeutic APAP ingestions (60 mg/kg) reduced APAP absorption by a mean of 41%.<sup>154</sup> In nine human volunteers ingesting 5 g of APAP and 0.5 mg/kg of oxycodone, 50 g of SDAC at 1, 2, or 3 hours reduced the APAP AUC by 43%, 22%, and 15%, respectively.<sup>103</sup> In six volunteers, concentrations of lamotrigine (100 mg); oxcarbazepine (600 mg); and oxcarbazepine's active metabolite, 10,11-dihydro-10-hydroxy-carbamazepine were reduced by 42%, 97.2%, and 95.8%, respectively, by 50 g of AC provided 30 minutes after ingestion.<sup>74</sup>

In a pharmacokinetics and pharmacodynamics evaluation of escitalopram overdosed patients, SDAC reduced the absorbed fraction by 31% and reduced the risk of QT prolongation by approximately 35% for escitalopram doses above 200 mg.<sup>152</sup> In 319 patients with 436 venlafaxine overdoses, SDAC or SDAC with WBI significantly decreased the odds of seizure to 0.48 and 0.25, respectively, compared with no decontamination.<sup>79</sup> In 176 patients presenting with 286 separate quetiapine overdoses, SDAC administration within 2 hours reduced the probability of intubation by 7% for a 2-g ingestion and by 17% for a 10-g ingestion, although time to extubation was unaffected.<sup>67</sup> In pharmacokinetic modeling study of sertraline overdose that was limited by uncertainty in ingestion time and dose, SDAC decreased the AUC and

decreased the maximum plasma concentration when administered between 1 and 4 hours after overdose.<sup>34</sup> Volunteer studies evaluated late AC administration in factor Xa inhibitor ingestions. Activated charcoal decreased ingested rivaroxaban AUCs by 43%, 31%, and 29% when administered 2 hours, 5 hours, and 8 hours postdose, respectively.<sup>116</sup> Similarly, for apixaban, which undergoes enteroenteric recirculation, AC decreased AUCs by 50% and 28%, when administered 2 hours and 6 hours postdose, respectively, as well as decreasing its apparent half-life from 13.4 hours to approximately 5 hours.<sup>155</sup> A retrospective observational study showed neither benefit nor harm of AC in organic phosphorus compounds or carbamate poisoning.<sup>101</sup> In light of further pharmacokinetic understanding and the potential for larger ingestions, more recent recommendations have relaxed the narrow AC administration “window” to support its utilization beyond 1 hour. This is true even in cases of ingestions for which an antidote exists, such as APAP.<sup>20,25,118</sup>

### Multiple-Dose Activated Charcoal

Multiple-dose AC functions both to prevent the absorption of xenobiotics that are slowly absorbed from the GI tract and to enhance the elimination of suitable xenobiotics that have already been absorbed. Multiple-dose AC decreases xenobiotic absorption when large amounts of xenobiotics are ingested and dissolution is delayed (eg, masses, bezoars), when xenobiotic formulations exhibit a delayed or prolonged release phase (eg, enteric coated, extended release), when GI motility is impaired because of coingestants, or when reabsorption can be prevented (eg, enterohepatic circulation of active xenobiotic, active metabolites, or conjugated xenobiotic hydrolyzed by gut bacteria to active xenobiotic).

The ability of MDAC to enhance elimination after absorption had already occurred was first reported in 1982.<sup>13</sup> This report concluded that orally administered MDAC enhanced the total body clearance (nonrenal clearance) of six healthy volunteers given 2.85 mg/kg of body weight of intravenous (IV) phenobarbital.<sup>13</sup> The serum half-life of phenobarbital decreased from  $110 \pm 8$  to  $45 \pm 6$  hours. An editorial suggested that MDAC enhanced the diffusion of phenobarbital from the blood into the GI tract and trapped it there for later fecal excretion. In this manner, AC was said to perform as an “infinite sink” allowing for “gastrointestinal dialysis” to occur.<sup>81</sup> These findings were confirmed by studies in dogs and rats using IV aminophylline and shown to be independent of theophylline enterohepatic circulation.<sup>39,78,94</sup> Subsequent studies using MDAC with IV aminophylline further extended these results to humans.<sup>64</sup> Using an isolated perfused rat small intestine, the concept of GI dialysis<sup>94</sup> was elegantly demonstrated because AC dramatically affected the pharmacokinetics of theophylline and produced a constant intestinal clearance that approximated intestinal blood flow.<sup>94</sup> In 114 hemodialysis patients who received a mean AC daily dose of  $3.19 \pm 0.81$  g/day in three divided doses, mean serum phosphate concentrations decreased by  $2.60 \pm 0.11$  mg/dL, further supporting the concept of “GI dialysis.”<sup>156</sup>

The toxicokinetic considerations underlying MDAC’s ability to enhance elimination are similar to those involved in deciding whether hemodialysis would be appropriate for a given xenobiotic. Successful MDAC requires the xenobiotic to be in the blood compartment (low volume of distribution), have limited protein binding, and have prolonged endogenous clearance. Experimental evidence suggests a role for MDAC in the absence of available Prussian blue (Antidotes in Depth: A31) to treat thallium poisoning.<sup>59</sup> Although MDAC increases to varying degrees the elimination of amitriptyline, cyclosporine,<sup>61</sup> carbamazepine,<sup>15,17,157</sup> dapsone,<sup>108</sup> digitoxin,<sup>35,126</sup> nadolol,<sup>43</sup> nortriptyline,<sup>36</sup> phenobarbital,<sup>128</sup> phenylbutazone,<sup>107</sup> propoxyphene,<sup>71</sup> quinine,<sup>28</sup> salicylate,<sup>58,75</sup> and theophylline,<sup>14,84,146</sup> its clinical utility remains to be defined.<sup>28,72,145</sup>

An analysis of 28 volunteer studies involving 17 xenobiotics was unable to correlate the physical chemical properties of a particular xenobiotic with MDAC’s ability to decrease the plasma half-life of that xenobiotic.<sup>22</sup> Although the half-life was not thought to be the best marker of enhanced elimination, it was the only parameter consistently evaluated in these exceptionally diverse studies. The xenobiotics with the longest intrinsic plasma half-lives seemed to demonstrate the largest percent reduction in plasma half-life

when MDAC was used. A subsequent animal model with therapeutic doses of four simultaneously administered IV xenobiotics (APAP, digoxin, theophylline, and valproic acid) clarified the role of pharmacokinetics on MDAC’s effectiveness.<sup>27</sup> Theophylline, APAP, and valproic acid all have small volumes of distribution. However, of the three, only valproic acid is highly protein bound at the doses used, which probably accounted for MDAC’s inability to increase its clearance while increasing clearance of the three other xenobiotics. However, volunteer studies do not accurately reflect the overdose situation<sup>95</sup> in which saturation of plasma protein binding, saturation of first-pass metabolism, and acid–base disturbances may make more free xenobiotic available for an enteroenteric effect and therefore more amenable to MDAC use. The most rapid and dramatic effect of MDAC was on theophylline clearance. Large volumes of distribution alone do not necessarily exclude MDAC’s benefit. Although digoxin has a large volume of distribution, it requires several hours to distribute from the blood to the tissues. Multiple-dose AC is beneficial as long as the digoxin remains in the blood compartment and distribution is incomplete.

In one case series of infants with aminophylline and theophylline overdoses, MDAC appeared to reduce theophylline half-lives (2–12 hours) compared with historical values.<sup>138</sup> Multiple-dose AC added as an adjunct to phototherapy in neonatal hyperbilirubinemia produced a significantly greater decline in bilirubin concentrations than in those receiving phototherapy alone.<sup>5</sup> In a randomized clinical study, patients with phenobarbital overdoses were given SDAC or MDAC.<sup>128</sup> Although the phenobarbital half-life was significantly decreased in the MDAC group (36 versus 93 hours), the length of intubation time required by each group did not differ from one another. This study was criticized for small size, unevenly matched groups, and focus on a single endpoint (extubation) potentially dependent on factors other than patient condition (eg, the time of day). In 15 adult patients with supratherapeutic phenytoin concentrations, MDAC reduced the time to phenytoin concentration less than 25 mg/L from 41.1 to 19.3 hours, although clinical endpoints were again unchanged.<sup>141</sup> Multiple-dose AC markedly decreased the apparent phenytoin half-lives in patients with prolonged half-lives because of CYP2C9 enzyme genetic polymorphisms.<sup>23</sup>

A compelling demonstration of MDAC’s benefits in the overdose setting comes from a study performed in Sri Lanka in patients with severe cardiac toxicity caused by intentional overdose with yellow oleander seeds.<sup>38</sup> An initial AC dose of 50 g was administered to all patients, who were then randomized to 50 g of AC every 6 hours for 3 days or placebo. There were statistically fewer deaths and fewer life-threatening dysrhythmias in the MDAC group. Subsequent randomized, controlled trials further evaluated no AC, SDAC, and MDAC in self-poisoned patients. In 104 patients ingesting yellow oleander seeds in Sri Lanka, despite erratic and prolonged absorption, SDAC and MDAC significantly and equivalently reduced cardiac glycoside 24-hour mean residence time (which quantifies the time course of a xenobiotic through the body) from  $11.21 \pm 1.55$  hours (no AC) to  $10.36 \pm 1.14$  hours (SDAC) and  $10.20 \pm 0.99$  hours (MDAC), respectively, and apparent terminal half-life from 62.9 hours (no AC) to 33.9 hours (SDAC) and 32.3 hours (MDAC), respectively.<sup>131</sup> Despite this, neither SDAC nor MDAC reduced the mortality rate among 4,629 randomized, poisoned patients.<sup>44</sup> However, in this study, about one-third of the patients had ingested yellow oleander seeds, slightly less than one-third ingested pesticides, and mechanical forced emesis or gastric lavage occurred in 54.0% and 7.5% of patients prandomization.<sup>44</sup> It is unclear how these trials apply to management in developed countries, where the use of antidotes such as digoxin-specific antibody fragments for cardioactive steroid poisoning and atropine and pralidoxime for organic phosphorus pesticide poisoning routinely complement GI decontamination and the absorption kinetics of most prescription medications differ from the substances ingested in the trial.<sup>68</sup> A systematic review concluded that MDAC could enhance phenobarbital or primidone elimination in severe poisonings, although supportive care is the relevant clinical intervention.<sup>130</sup>

Ultimately, the decision to administer SDAC or MDAC should involve a patient-tailored, risk-to-benefit analysis. Potential adverse effects are weighed against the particular ingested xenobiotic, its quantity, and

formulation; dose–response curve of the xenobiotic; the impact of SDAC or MDAC on this curve; the time since ingestion; coingestants; gastric motility and contents; available antidotes, therapies, and medical support; the severity of presentation; anticipated sequelae; patient cooperativity; and other patient-specific factors and comorbidities.<sup>68,117,121,143</sup>

## ADVERSE EFFECTS AND SAFETY ISSUES

Contraindications to AC include presumed GI perforation or discontinuity or the need for endoscopic visualization (eg, in caustic ingestions). To prevent aspiration pneumonitis from oral AC administration, an airway assessment must occur, and potential airway compromise should be excluded. Subsequently, a risk-to-benefit assessment with regard to the need for airway protection and the need for AC should be made. Other considerations include a determination of adequate GI motility (appropriate bowel sounds to ensure peristalsis) and normal abdominal examination findings and absent distension or signs of an acute abdomen. With compromised bowel function, AC should be withheld or delayed until the stomach can be decompressed to decrease the risk of subsequent vomiting and aspiration.

Although the use of AC is relatively safe, emesis, which typically occurs after rapid administration; constipation; and diarrhea are frequently reported after AC administration.<sup>110</sup> Constipation and diarrhea are more likely to result from the ingestion itself than from the AC. However, black stools that are negative for occult blood, black tongues, and darkened mucous membranes are frequently observed. Serious adverse effects of AC include pulmonary aspiration of AC with or without gastric contents, leading to airway obstruction (potentially of rapid onset), acute respiratory distress syndrome, bronchiolitis obliterans, and death;<sup>9,40,47,52,57,70,117,121,125,139</sup> peritonitis from spillage of enteric contents, including AC, into the peritoneum after GI perforation;<sup>88</sup> and intestinal obstruction and pseudo-obstruction, especially after repeated AC doses in the presence of either dehydration or prior bowel adhesions.<sup>19,54,83,98,158</sup> Although a significant number of patients aspirate gastric contents before endotracheal intubation and AC administration,<sup>100,132</sup> the incidence of AC aspiration after endotracheal intubation varies from 4% to 25%, depending on the nature of the study. Another retrospective investigation demonstrated a 1.6% incidence of aspiration pneumonitis in unselected overdosed patients. Altered mental status, spontaneous emesis, and cyclic antidepressant overdose were associated risk factors; AC was not in itself a risk factor.<sup>66</sup> Because sorbitol is hepatically metabolized to fructose, the package insert warns against administration of AC with sorbitol to patients with a genetic intolerance to fructose.<sup>121</sup>

## Adverse Effects of Multiple-Dose Activated Charcoal

Complications observed with SDAC increase with MDAC. Other adverse effects of MDAC include diarrhea when multiple sorbitol-containing AC preparations are used, constipation, vomiting with a subsequent risk of aspiration, intestinal ileus and obstruction, and a reduction of serum concentrations of therapeutically used xenobiotics.<sup>42,98,117,125</sup> One retrospective review of 834 poisoned patients uncontrolled for type of ingestion found that MDAC was associated with clinically significant pulmonary aspiration in 0.6%, GI obstruction in 0%, hypernatremia in 6.0%, and hypermagnesemia in 3.1%.<sup>42</sup> Administration of multiple sorbitol-containing AC preparations infrequently produces salt and water depletion, hypotension, and potentially fatal electrolyte derangements, especially in children.<sup>48,102</sup>

## PREGNANCY AND LACTATION

The safety in pregnancy category for AC is undetermined. The benefit of preventing absorption with AC should outweigh the risk of administration to the pregnant patient. The underlying elevated prevalence of nausea and vomiting in pregnancy<sup>77</sup> might predispose pregnant patients to a potentially higher rate of vomiting, although this is speculative. Single-dose AC and MDAC have been safely administered to pregnant patients as part of poisoning management.<sup>18,26,37,93,133</sup> Murine and lapine studies have not demonstrated any teratogenic risk.<sup>121</sup> The lack of absorption of AC would not predispose it to breast milk excretion, although definitive safety in lactation has not been established.<sup>121</sup>

## DOSING AND ADMINISTRATION

Single-dose AC should be administered when a xenobiotic is still expected to be available for adsorption in the GI tract and the benefit of preventing absorption outweighs the risk. The optimal SDAC dose is unknown.<sup>28</sup> However, most authorities recommend a minimum AC dose of 1 g/kg of body weight or a 10:1 ratio of AC to xenobiotic, up to an amount that can be tolerated by the patient and safely administered, which usually represents 50 to 100 g in adults. For some ingestions (eg, salicylate or APAP), a 10:1 ratio would be impracticable to achieve, although the 1-g/kg dose appears to be efficacious. This is supported by volunteer studies of supratherapeutic ingestions.<sup>55,69</sup> Activated charcoal that is not premixed is best administered as a slurry in a 1:8 ratio of AC to suitable liquid, such as water or cola.

## Prehospital Administration

Prehospital AC administration by emergency medical personnel expedites the administration after overdose.<sup>4,159</sup> However, the implementation costs and potential adverse effects have to be weighed against the small number of patients who would actually benefit.<sup>65</sup> In a study simulating home administration in 50 young children, 86% readily drank the AC–water slurry, and 76% of them consumed 95% to 100% of the total dose.<sup>21</sup> Of seven children in a simulated home environment administered AC in regular cola, three drank 1 g/kg, two drank about half of this therapeutic dose, and the other two drank very little.<sup>134</sup> A prospective poison control center case series demonstrated successful home AC administration. In this series, the median age of the patients was 3 years, and the median AC dose ingested was 12 g.<sup>144</sup> However, other attempts at getting children to ingest AC were not as successful. Difficulty was noted in 70% of attempts to administer a standard AC dose to children in the home setting.<sup>41</sup> A review of AC in the home suggested variable success depending on the parent and child.<sup>46</sup> A retrospective review of poisoned children concluded that those who were preannounced to an emergency department by the poison control center received AC earlier (59 ± 34 minutes) than patients without a referral (71 ± 43 minutes).<sup>148</sup> One additional retrospective review determined that prehospital paramedic-administered AC did not increase EMS encounter duration.<sup>153</sup>

## Hospital Administration

Administration in children is facilitated by offering an opaque, decorated, covered cup and a straw.<sup>160</sup> The black color and gritty nature of AC have led to the development of many formulations to improve palatability and patient acceptance. Bentonite, carboxymethyl cellulose, and starch<sup>56,104,135</sup> are used as thickening agents, and cherry syrup, chocolate syrup, sorbitol, sucrose, saccharin, and ice cream have been used as flavoring agents.<sup>31,82,87,162</sup> Most additives do not decrease the adsorptive capacity; however, improvements in palatability and acceptance have been minimal or nonexistent with all of these formulations.<sup>30</sup> Although a milk chocolate AC formulation evaluated by children was rated superior in palatability to standard AC preparations,<sup>45</sup> it was never marketed in the United States. A marketed cherry-flavored AC product was rated by adult volunteers as preferable over plain AC, and a statistically significant larger quantity of the flavored AC was ingested.<sup>29</sup> This difference was not maintained in adult overdosed patients; most patients consumed the entire bottle of AC independent of cherry flavoring. Cold cola was used to enhance palatability in volunteer children and adults. Children preferred regular cola over diet cola. Teenagers preferred the palatability of AC mixed with chocolate milk or cola over AC mixed with water, but this did not significantly improve ease of swallowing.<sup>24</sup> Adults rated cola–AC preferable to plain AC.<sup>129,134</sup> Other studies in adult overdosed patients compared different AC brands without additives or flavoring to determine the AC quantity typically ingested.<sup>16,51</sup> In one study, approximately half of the 50 g of AC offered was ingested, and 7% of the patients vomited.<sup>16</sup> In the other study, 60 g of AC as Liqui-Char (standard AC) or CharcoAid G (superactivated granulated AC) was offered, and approximately 95% of each formulation was consumed in 20 minutes. There was no difference in the amount consumed even though the palatability of the granular form of AC (CharcoAid G) was rated higher.<sup>51</sup>

## Multiple-Dose Activated Charcoal Administration

An initial AC loading dose should be administered to adults and children in an attempt to achieve a AC-to-xenobiotic ratio of 10:1 or 1 g/kg of body weight (if the xenobiotic exposure amount is unknown). The correct AC dose and interval for multiple dosing, when it is indicated, is best tailored to the amount and dosage form of the xenobiotic ingested, the severity of the overdose, the potential lethality of the xenobiotic, and the patient's ability to tolerate AC. Benefit should always be weighed against risk. Doses of AC for multiple dosing have varied considerably in the past, ranging from 0.25 to 0.5 g/kg of body weight every 1 to 6 hours to 20 to 60 g for adults every 1, 2, 4, or 6 hours. Some evidence suggests that the total dose administered may be more important than the frequency of administration.<sup>64,149</sup> Continuous nasogastric administration of AC is reported, especially when vomiting is a problem, although the risk-to-benefit assessment would require consideration.<sup>50,112,149</sup> After the initial AC loading dose of 1 g/kg, subsequent doses of 0.5 g/kg (~25–50 g in adults) every 4 to 6 hours for up to 12 to 24 hours is reasonable in most circumstances.

## FORMULATION AND ACQUISITION

Activated charcoal is supplied in bottles or tubes as a ready-to-use aqueous suspension in multiple doses formulations (eg, suspensions of 15 g, 25 g, and 50 g of AC in 72 mL, 120 mL, and 240 mL at a fixed concentration of 208 mg/mL AC).<sup>121</sup> Some AC suspensions are also premixed with sorbitol (eg, 25 and 50 g AC with 48 or 96 g of sorbitol to yield 208 mg/mL of AC and 400 mg/mL of sorbitol).<sup>121</sup> When not premixed, it is recommended to create a slurry of AC in a 1:8 ratio of AC to suitable liquid (eg, water, cola).

## SUMMARY

- Activated charcoal is an effective, nonspecific adsorbent.
- Absent contraindications, AC should be of benefit to a patient with a potentially life-threatening ingestion of a xenobiotic that is adsorbed by AC and is expected to be present in the GI tract at the time of administration. Activated charcoal does not adsorb alcohols, acids, alkalis, iron, lead, lithium, magnesium, potassium, or sodium salts.
- Multiple-dose AC is useful to prevent systemic absorption of xenobiotics with prolonged absorptive phases such as extended-release formulations or enteroenteric recirculation.
- In the postabsorptive phase, MDAC decreases the elimination half-lives of certain xenobiotics.
- Care must be taken to avoid pulmonary aspiration and intestinal obstruction when administering AC and MDAC.
- Home availability of AC should be encouraged in remote locations where prehospital care is not immediately available.

# WHOLE-BOWEL IRRIGATION AND OTHER INTESTINAL EVACUANTS

Silas W. Smith and Mary Ann Howland

## INTRODUCTION

One approach to altering the pharmacokinetics of a xenobiotic is to administer a gastrointestinal (GI) evacuant. Selected patients benefit from minimizing systemic exposure by decreasing GI transit time and increasing rectal evacuation. The most effective process of evacuating the GI tract in poisoned patients is referred to as whole-bowel irrigation (WBI). Whole-bowel irrigation is typically accomplished using polyethylene glycol with a balanced electrolyte lavage solution (PEG-ELS). Unless stated otherwise, WBI will mean WBI with PEG-ELS. A detailed discussion of the merits of WBI in the context of various decontamination strategies is provided in Chap. 5.

## HISTORY

In 1625 while endeavoring to recover from the febrile “Hungarian disease,” Johann Glauber drank from a well from which he later isolated *sal mirabile*, now known as sodium sulfate,  $\text{Na}_2\text{SO}_4$ .<sup>54</sup> He advocated its use as a purgative and determined a synthetic production method.<sup>54</sup> In 1675, Nehemiah Grew first observed the presence of the eponymous purgative salt in the springs at Epsom, later determined to be magnesium sulfate.<sup>125</sup> Phosphate of soda, called “tasteless purging salt,” was found in the urine by Hellot in 1737 and introduced into clinical practice as a purgative by George Pearson some 50 years later.<sup>119</sup> In 1882 and 1883, Hay reported a series of experiments that provided the foundational understanding of the mechanism of action of the saline cathartics. He identified the viscus as the main source of bowel fluid, which was secretory in nature, and established the dose–response principle of decreased time to stool as salt concentrations were increased.<sup>50,51</sup> Polyethylene glycol was initially introduced in 1957 as a nonabsorbable marker for the study of human fat, carbohydrate, and protein absorption.<sup>20</sup> Experimental studies of intestinal lavage in normal human subjects appeared in 1968.<sup>89</sup> In 1973, Hewitt and colleagues reported on WBI in clinical practice using their method of “whole-gut irrigation” with a solution of sodium chloride, potassium chloride, and sodium bicarbonate in distilled water to prepare the large bowel for surgery.<sup>53</sup> In 1976, WBI was used therapeutically for poisoning in a patient ingesting 300 lead air-gun pellets who was unresponsive to oral magnesium sulfate purgation.<sup>159</sup>

## PHARMACOLOGY

### Nomenclature

Xenobiotics that promote intestinal evacuation are referred to as laxatives, cathartics, purgatives, promotility agents, and evacuants. Depending on the dose, the same xenobiotic might accomplish some or all of these tasks, with differing side effect profiles. Laxatives promote a soft-formed or semifluid stool within 6 hours to 3 days. Cathartics promote a rapid, watery evacuation within 1 to 3 hours.<sup>131</sup> The term *purgative* relates the force associated with bowel evacuation. Evacuants are commonly used for preprocedural bowel cleansing, with an onset of action of as little as 30 to 60 minutes, but typically require 4 hours for a more complete effect. Promotility xenobiotics stimulate GI motor function via the enteric nervous system through a variety of acetylcholine, dopamine, guanylate cyclase-C, motilin, opioid, and serotonin receptor and intestinal chloride channel interactions.

Laxatives are further classified into categories of bulk-forming, softener or emollient, lubricant, stimulant or irritant, saline, hyperosmotic, and evacuant. Bulk-forming laxatives include high-fiber products such as

methylcellulose, polycarbophil, and psyllium; softeners or emollients include docusate calcium. Mineral oil is the sole lubricant. These cathartics are not used therapeutically in medical toxicology because their onset of action is delayed. Stimulant or irritant laxatives include anthraquinones (sennosides, aloe, and casanthranol), diphenylmethane (bisacodyl), and castor oil. Saline (meaning salt) cathartics, which include magnesium citrate, magnesium hydroxide, magnesium sulfate, sodium phosphate, and sodium sulfate, are used infrequently. Hyperosmotic xenobiotics, generally nonabsorbable sugars and alcohols, including sorbitol and lactulose, are occasionally used in poisoned patients. The most common process of evacuating the intestinal tract in poisoned patients is WBI.

## Chemistry and Preparation

Magnesium citrate and magnesium sulfate (“Epsom salt”) are water-soluble salts of magnesium; magnesium hydroxide (“milk of magnesia”) is insoluble.<sup>64</sup> Sodium sulfate is prepared either through purification of naturally occurring brine deposits or other manufacturing processes. Sodium phosphate is supplied as a combination of the monobasic monohydrate and dibasic anhydrous forms. D-Sorbitol, an isomer of mannitol, is a hexitol naturally occurring in many fruits and is produced commercially by the reduction of glucose. Lactulose is a water-soluble, synthetic disaccharide, 4-O-β-D-galactopyranosyl-D-fructofuranose. Sodium picosulfate is a monohydrate, disodium salt prodrug.

The addition reaction of ethylene oxide to an ethylene glycol equivalent polymerizes ethylene oxide into PEG. The “n” in the molecular structure of PEG,  $\text{H}-(\text{OCH}_2\text{CH}_2)_n-\text{OH}$  refers to the average number of repeating oxyethylene groups.<sup>69</sup> The number after PEG represents its average molecular weight (MW). Also known as macrogol, PEG has numerous medicinal applications. It can be conjugated to pharmaceuticals to delay vascular clearance or preclude blood–brain barrier transit (“PEGylation”), serve as a solvent in oral liquids and soft capsules, function as a nonalcohol solubilizer and diluent for liquid oral-dose medications, provide a base for medical ointment and cosmetics, and act as a base liquid for producing vapor in electronic cigarettes.<sup>1</sup> Low-molecular-weight PEG (eg, 300 or 400 Da), because of its advantageous solvent properties, is used to decontaminate phenol burns, although animal studies demonstrated the equal efficacy of copious (ie, deluge) quantities of water.<sup>59</sup> Higher-molecular-weight variants are used to promote laxation. Although PEG’s physical properties (eg, water solubility, hygroscopicity, vapor pressure, melting or freezing range, and viscosity) vary with MW and blending because of chain-length effects, the chemical properties are similar.<sup>145</sup> Polyethylene glycol 3350 used in pharmaceutical, personal care, and food applications is water soluble. It has a MW range of 3,015 to 3,685 Da, an average number of 75.7 repeating oxyethylene units, a pH of a 5% aqueous solution of 4.5 to 7.5 at 25°C, a density of 1.09 g/cm<sup>3</sup> at 60°C, a melting or freezing range between 53° and 57°C, a water solubility of 67% by weight at 20°C, and a viscosity of 90.8 centistokes at 100°C.<sup>144</sup> Polyethylene glycol 3350 without electrolytes is sold for nonprescription use for short-term treatment of constipation. Whole-bowel irrigation used in poison management is typically accomplished using PEG 3350 added to a balanced electrolyte lavage solution (PEG-ELS), which contains an isotonic mixture of sodium sulfate, sodium bicarbonate, sodium chloride, and potassium chloride.<sup>131</sup>

## Mechanisms of Action

The effects of saline cathartics are largely attributed to their relatively non-absorbable ions that establish an osmotic gradient and draw water into the gut.<sup>116</sup> The increased water leads to increased intestinal pressure and a subsequent increase in intestinal motility. Magnesium ions also lead to the release of cholecystokinin from the duodenal mucosa, which stimulates intestinal motor activity and alters fluid movement, contributing to catharsis.<sup>19,131,138</sup> A lack of endogenous hydrolytic enzymes allows sorbitol, lactulose, and sodium picosulfate to reach the colon unchanged. Colonic bacteria metabolize sorbitol into acetic and short-chain fatty acids and lactulose into lactic acid and small amounts of formic and acetic acids. This results in a slight acidification of colonic contents, an increase in osmotic pressure that draws water into the lumen, and stimulation of colonic propulsive motility.<sup>131</sup> Colonic bacteria hydrolyze sodium picosulfate, marketed in the United States for bowel preparation in combination with magnesium oxide and citric acid, which create magnesium citrate in solution, to active 4,4'-dihydroxydiphenyl-(2-pyridyl) methane, a stimulant laxative.<sup>4,72</sup>

Long-chain PEGs (eg, MW ~3,350 Da) are nonabsorbable, isoosmotic, indigestible molecules that remain in the colon together with the water diluent, resulting in WBI primarily by the mechanical effect of large-volume lavage. As assessed in controlled clinical trials in patients undergoing colonoscopy, the added balanced electrolyte solution practically eliminates electrolyte abnormalities and helps preclude fluid shifts across the GI mucosa.<sup>16,83</sup> Sodium sulfate in many preparations reduces sodium absorption in the small intestine because of the absence of chloride, which is the accompanying anion necessary for active absorption against the electrochemical gradient.<sup>94</sup>

Promotility xenobiotics such as metoclopramide and erythromycin stimulate gut motor function. Metoclopramide mediates GI 5-hydroxy tryptamine (5HT<sub>4</sub>) receptor agonist and dopamine (D<sub>2</sub>) receptor antagonist activity, which both result in increased acetylcholine release and GI motility. Erythromycin stimulates gut motor function via direct stimulation of GI motilin receptors.<sup>151</sup> Prucalopride (approved outside of the United States) and tegaserod (withdrawn from the US market because of adverse cardiovascular effects but supplied in emergency situations) are selective, 5-HT<sub>4</sub> receptor agonists. Tegaserod and WBI were combined together in an attempt to improve colonoscopy preparations but not in poisoned patients.<sup>3</sup> Lubiprostone activates chloride channel protein 2 to induce chloride secretion and to enhance the contraction of gastric and colonic musculature.<sup>70</sup> Lubiprostone is sometimes used with WBI to treat constipation but not in poisoned patients. Linaclotide and plecanatide are guanylate cyclase-C agonists that increase intracellular and extracellular cGMP concentrations to stimulate secretion of chloride and bicarbonate and water into the intestinal lumen primarily through activation of the cystic fibrosis transmembrane conductance regulator ion channel.<sup>140</sup> Use in poisoning is unstudied. Nonselective  $\mu$ -opioid antagonists (naloxone and naltrexone), although primarily used to reverse central nervous system-associated effects, also mitigate acute and chronic opioid-associated constipation; they are used in combination with WBI in certain opioid poisonings (eg, enteral concealment of drug packets and transdermal fentanyl patch ingestion).<sup>43,147</sup> Use of peripherally acting  $\mu$ -opioid antagonists (methylnaltrexone, naloxegol, and alvimopan) in poisoning is not yet reported.

## Pharmacokinetics

Absorption of magnesium, phosphate, and other electrolytes contained in hypertonic products is well described.<sup>34,110,116</sup> In one prospective, nonrandomized study, 9 of 14 patients developed elevated magnesium concentrations (2.2–5.0 mEq/L) after multiple doses of magnesium-containing cathartics were administered for suspected drug overdose despite normal blood urea nitrogen and creatinine concentrations.<sup>135</sup> During the 24 hours after administration of oral sodium phosphate solution in seven healthy volunteers, serum phosphorus reached a mean peak concentration of 7.6 mg/dL (range, 3.6–12.4 mg/dL), and ionized calcium reached a mean nadir concentration of 4.6 mg/dL (range, 4.4–5.2 mg/dL).<sup>34</sup>

By virtue of its high osmotic nature, long-chain PEG is poorly absorbed, is retained in the lumen, and does not distribute. Polyethylene glycol is

therefore eliminated unmetabolized in rectal effluent. A lack of absorption presents sorbitol, lactulose, and sodium picosulfate to endogenous bacteria for metabolism within the gut lumen.

## Pharmacodynamics

Patients who ingested 45 mL of an aqueous sodium phosphate preparation taken the evening before and the morning of a procedure had stool production within 1.7 hours of the first dose and within 0.7 hours of the second dose, with a mean duration of activity of 4.6 and 2.9 hours, respectively, and termination of increased stool production within 4 to 5 hours.<sup>85</sup> In six volunteers, saline cathartics decreased activated charcoal (AC) mean GI transit time from 29.3  $\pm$  1.2 hours to 24.4  $\pm$  1.2 hours, 15.4  $\pm$  3.0 hours, 17.3  $\pm$  1.9 hours, and 17.5  $\pm$  2.3 hours with sodium chloride, sodium sulfate, magnesium sulfate, and a proprietary cathartic “salt” (36.7% anhydrous citric acid, 17.65% magnesium sulfate, and 45.6% sodium bicarbonate), respectively.<sup>117</sup> When different cathartics were compared with respect to time to first stool and number of stools,<sup>62,78,108,109,139</sup> sorbitol produced 10 to 15 watery stools and the most abdominal cramping before catharsis. Sorbitol produced stools in the shortest amount of time, which also was associated with the highest incidence of nausea, vomiting, generated gas, and flatus.<sup>71,74,111</sup> In one systematic review, the mean transit times after administration of sorbitol, magnesium citrate, magnesium sulfate, and sodium sulfate were 0.9 to 8.5 hours, 3 to 14 hours, 9.3 hours, and 4.2 to 15.4 hours, respectively.<sup>9</sup> In comparison, the first bowel movement typically occurs relatively quickly after the initiation of WBI. Patients ingesting PEG-ELS (1.2–1.8 L/h until the rectal effluent was clear) completed their colonic preparation goals within 1.5 to 3 hours after averaging a total of 5.5 L per patient (range, 3–8 L).<sup>46</sup> As assessed by magnetic resonance imaging in 24 healthy volunteers, ingesting either a split dose (1 L the evening before and 1 L on the study day) or single dose (2 L) of WBI rapidly increased small bowel water content by fourfold over baseline, increased total colonic volume by 35  $\pm$  8% (split dose) and 102  $\pm$  27% (single dose), and dramatically increased the ascending colon motility index.<sup>97</sup>

## ROLE OF GASTROINTESTINAL EVACUATION IN POISONING MANAGEMENT

Cathartics should not be used in the routine management of overdosed patients.<sup>9</sup> Intuitively, the advantages of cathartics appear to result from their ability to decrease the potential for constipation or obstruction from AC and hasten the delivery of AC to the small intestine. However, these theoretical advantages were never demonstrated clinically.

Studies demonstrate that when administered alone, cathartics such as sorbitol or sodium sulfate decrease peak or total absorption of some xenobiotics, but no study of cathartics alone has achieved pharmacokinetic results comparable to that of AC alone.<sup>6,30,100,120,153</sup> When comparing the efficacy of a single dose of AC alone with that of AC plus a single dose of cathartic, studies suggest the combination to be equal to,<sup>6,105,114,134</sup> slightly better than,<sup>30,71</sup> or even slightly worse than AC alone.<sup>100,153</sup> We currently advocate WBI to hasten the elimination of poorly absorbed xenobiotics or sustained-release medications before they can be absorbed. This approach is theoretically sound and does not produce the fluid and electrolyte complications associated with cathartics. Unfortunately, evidence of efficacy is limited to anecdotal case reports and volunteer studies.

Many studies of WBI demonstrate patient acceptance, effectiveness, and safety when used for bowel preparation, its labeled indication.<sup>8,17,21,22,35,38,39,121,146,149</sup> Animal models suggest that WBI enhances systemic clearance via GI dialysis, similar to multiple-dose AC (MDAC).<sup>84</sup> In actuality, low flow rates, the typical delay in administering WBI in actual clinical situations, and the inconvenience of this procedure make it highly unlikely that enhanced systemic clearance can be achieved in humans. In human volunteer studies, WBI was more effective than AC with sorbitol for enteric-coated acetylsalicylic acid (ASA) when administered 4 hours after ingestion,<sup>74</sup> decreased peak lithium concentrations, and lithium area under the plasma drug concentration versus time curve (AUC) compared with control participants;<sup>136</sup> decreased the bioavailability of two sustained-release

medications;<sup>26,81</sup> and propelled radiopaque markers through the gut more efficiently than control participants.<sup>91</sup> In a retrospective analysis of 59 acute-on-chronic lithium overdoses, those decontaminated at an early stage with sodium polystyrene sulfonate, WBI, or both achieved statistically significant and clinically relevant decreases in peak serum lithium concentrations compared with those with delayed (>12 hours) or no decontamination (2.39 versus 4.08 mEq/L).<sup>23</sup> A retrospective chart review of 176 pediatric cases documented WBI use in 72 cases involving sustained- and delayed-release medications, such as nifedipine, bupropion, verapamil, diltiazem, and felodipine.<sup>86</sup> Abdominal radiographs were performed in 36 patients, of whom 16 had demonstrable radiopaque pills. Four of these individuals had repeat abdominal radiographs, all of which demonstrated a decrease in opacities.

As expected, WBI was inferior to AC with regard to prevention of absorption when administered after 650 mg of immediate-release aspirin.<sup>124</sup> Additionally, after the aspirin was absorbed, WBI was unable to enhance systemic clearance.<sup>99</sup> Likewise, only a small, statistically insignificant effect of WBI could be demonstrated on the absorption of extended-release acetaminophen (APAP) in a human volunteer study.<sup>91</sup> These findings highlight the limited utility of WBI to assist in the prevention of absorption of relatively rapidly absorbed xenobiotics. Reports suggest successful WBI use in the management of overdoses of iron,<sup>40,68,96,141,142</sup> sustained-release theophylline,<sup>63</sup> sustained-release verapamil,<sup>24</sup> modified-release fenfluramine,<sup>107</sup> zinc sulfate,<sup>25</sup> lead,<sup>104,106,128,159</sup> arsenic trioxide,<sup>61</sup> arsenic-containing herbicide,<sup>82</sup> mercuric oxide powder,<sup>92</sup> strontium,<sup>73</sup> potassium chloride capsules,<sup>49,58</sup> clonidine and fentanyl transdermal patches,<sup>43,60</sup> and in body packers.<sup>57,147</sup> Whole-bowel irrigation for 5 hours after ingestion of 10 fluorescent coffee beans by each of seven volunteers removed an average of only four beans (range, 1–8).<sup>126</sup> Similar failures are reported with jequirity beans (*Abrus precatorium*),<sup>25</sup> iron,<sup>29,154</sup> and button batteries.<sup>141</sup> It can be argued that because of physical characteristics (eg, density, solubility, size, or pharmacobezoar formation), these cases might not be representative of xenobiotics amenable to WBI. The American Academy of Clinical Toxicology/European Association of Poisons Centres and Clinical Toxicologists (AACT/EAPCC) 2015 WBI position paper recapitulates the 2004 guidelines that WBI “can be considered for potentially toxic ingestions of sustained-release or enteric-coated drugs, drugs not adsorbed by activated charcoal (eg, lithium, potassium, and iron) and for removal of illicit drugs in body ‘packers’ or ‘stuffers,’” but there was no evidence to demonstrate improved outcomes.<sup>143</sup> Whole-bowel irrigation is recommended for evacuation of highly toxic xenobiotics with a slow absorption phase and not adsorbed to AC (eg iron, lead, lithium, potassium). When AC is expected to be of benefit, it is recommended that it be administered prior to WBI to achieve its greatest effect.

### Internal Drug Concealment

The approach to patients with internal concealment and enteral transport of illicit substances (eg, cocaine, heroin, amphetamines, and hashish) is comprehensively reviewed in Special Considerations: SC5. In uncontrolled poison control center studies, these patients, along with incarcerated patients, had a higher utilization of WBI and presented a high risk for major adverse events, including death.<sup>27</sup> Close coordination with surgical services is advised because of the risks of obstruction, intestinal retention, or rupture. Because mineral oil rapidly degrades latex condoms,<sup>156</sup> its use in evacuating drug packets, which can be constructed in this fashion, risks fatal rupture<sup>155</sup> and is therefore contraindicated. In a retrospective descriptive case series of 16 body packers, management with WBI was successful in 14; a ruptured cocaine packet produced mild toxicity in 1 patient, and packets were retained in 1 heroin body packer.<sup>42</sup> In another retrospective analysis of 34 cocaine body stuffers who were asymptomatic on presentation, 14 received AC (2 left against medical advice before 24 hours), 1 received WBI alone, and 19 received AC plus WBI and remained asymptomatic and were discharged after 24 hours.<sup>66</sup> A review of 1,250 confirmed body packers found the success rate of WBI to be 98%.<sup>95</sup> All WBI-managed patients passed all of their packets within 5 days. WBI occasionally fails to evacuate all of the drug packets because of inadequate dosing, partial obstruction, or the nature of the procedure. In one case, prolonged WBI failed to clear packets from

a methamphetamine body stuffer who engaged in “parachuting (swallowing powdered or crushed drugs by rolling or folding in toilet paper or other paper).”<sup>752</sup> As a result of these failures, promotility xenobiotics were added to WBI and presumably successfully enhanced bowel evacuation in two body packers suspected of having ingested well-constructed drug packets.<sup>148</sup>

### ADVERSE EFFECTS AND SAFETY ISSUES

Potential adverse effects associated with various cathartics and promotility xenobiotics include salt and water depletion, hypernatremia, hypermagnesemia, hyperphosphatemia, hypokalemia, and metabolic (contraction) alkalosis, absorption of magnesium or other absorbable electrolytes, activation of the renin–angiotensin–aldosterone system, phosphate-induced nephropathy, and colonic fermentation of digestible sugars.<sup>28,44,133</sup> Cathartic-induced rectal prolapse is reported in geriatric patients.<sup>76</sup> The use of repetitive doses of cathartics, either by design or unintentionally, has led to hypermagnesemia, altered mental status, and death.<sup>65,110,135,158</sup> Hypocalcemia, hyperphosphatemia, and hypokalemia have accompanied the use of hypertonic phosphate enemas and oral sodium phosphate despite adherence to recommended dosing.<sup>36,44,48,88,98,122,137</sup> Frail elderly patients, children, and those with decreased kidney function are most susceptible to adverse effects.<sup>15,18</sup> On January 8, 2014, the US Food and Drug Administration issued a safety warning that using more than one dose of nonprescription sodium phosphate-containing drugs in 24 hours to treat constipation risked rare but serious severe salt and water depletion, electrolyte abnormalities, acute kidney injury, dysrhythmias, and death.<sup>5</sup>

Softeners increase intestinal permeability and therefore increase the absorption of some xenobiotics.<sup>13,131</sup> Stimulant and irritant laxatives are rarely used today in medical toxicology because of their significant GI side effects, including abdominal discomfort, cramping, and tenesmus and with chronic administration, bowel habituation, and intestinal tissue damage.

Contraindications to WBI include prior, current, or anticipated diarrhea; salt and water depletion; significant GI anatomical or functional compromise such as colitis, hemorrhage, ileus, obstruction, perforation, or toxic megacolon; an unprotected or compromised airway; and hemodynamic instability.<sup>10,141</sup>

Multiple-dose AC regimens containing 70% sorbitol used to enhance elimination cause severe cathartic-related adverse effects (salt and water depletion)<sup>7,41,87,101</sup> The potential for sorbitol-related adverse events from the unintentional use of repetitive AC dosing was emphasized by a survey revealing that 16% of hospitals surveyed only stocked AC premixed with sorbitol.<sup>157</sup> The retention of sorbitol after repetitive doses in an aperistaltic gut can lead to significant morbidity from gas formation and abdominal distension as a result of the digestive action of gut bacteria.<sup>87</sup>

Adverse effects resulting from the use of WBI include vomiting, particularly after rapid administration, abdominal bloating, fullness, cramping, flatulence, and pruritus ani. In 176 pediatric cases detailed in the California Poison Control System electronic database, 16 vomited, and 1 experienced abdominal pain.<sup>86</sup> In an alternative administration strategy in which 46 children were provided 238 g of PEG 3350 mixed with 1.9 L of Gatorade, rates of nausea and vomiting, abdominal pain and cramping, and fatigue and weakness were 60%, 44%, and 40%, respectively.<sup>2</sup> Typically, patients need to remain near a commode for 4 to 6 hours to complete WBI therapy. Slow or low-volume administration of WBI results in sodium absorption. If a total of 500 mL of WBI was used instead of multiple liters, potentially 1.5 g of sodium can be absorbed.<sup>37</sup> This adverse effect is suggested to have resulted in the exacerbation of congestive heart failure in an unstable patient with cardiac and renal dysfunction.<sup>47</sup> An unusual complication of WBI is colonic perforation, which occurred in a patient with acute diverticulitis.<sup>80</sup> Other adverse effects noted by the manufacturer include isolated reports of upper GI bleeding from a Mallory-Weiss tear, esophageal perforation, aspiration pneumonitis after vomiting, and acute respiratory distress syndrome (ARDS). Rare cases of both hypotension and hypernatremia, leading to altered consciousness, seizures, cerebral edema, and death, are reported with PEG, alone or in combination with ELS.<sup>14,112,127</sup>

Unintentional administration of WBI by other than the enteral route has occurred. A 4-year-old child inadvertently received 390 mL of WBI

intravenously with no obvious adverse result.<sup>123</sup> In contrast, ARDS developed in an 11-year-old child administered WBI through a nasogastric tube inadvertently inserted in the trachea.<sup>113</sup> In a similar case, an inappropriately used nasogastric tube was responsible for WBI aspiration in a 3-year-old boy, with resultant hypoxia and hemodynamic instability requiring endotracheal intubation.<sup>45</sup> An 8-year-old girl who developed emesis during nasogastric infusion of 1 L of WBI experienced gagging, coughing, emesis, and respiratory distress 2 hours after infusion; she progressed to ARDS and required intubation and ventilatory support for 2 days.<sup>118</sup> A report of 2 cases suggests that vomiting and aspiration are more frequent than previously recognized in hemodynamically unstable patients.<sup>33</sup> Presumably, a patient's hypotension results in GI hypoperfusion and ileus, which, with the continued administration of WBI in the presence of decreased GI motility, produces abdominal distension and vomiting.

For MiraLAX (electrolyte-free PEG 3350 powder) to be useful in WBI, it would need to be administered at a dose of 2 L/h (8 heaping teaspoons in 2 L of water/h) in adults. This is not recommended for WBI because it does not contain any added electrolytes and could result in an electrolyte imbalance and shifts. Use of sodium picosulfate with magnesium citrate was associated with a 65.2% adverse event rate (vomiting, abdominal pain, paresthesias, nausea, bloating, and thirst) in a study of 153 patients undergoing routine bowel preparation.<sup>72</sup>

### XENOBIOTIC, ACTIVATED CHARCOAL, AND WHOLE-BOWEL IRRIGATION INTERACTIONS

Theoretically, WBI might worsen drug toxicity by facilitating drug dissolution because of the addition of the large volume of WBI, increasing drug solubility (lower molecular weight PEGs are used as pharmaceutical excipients and solvents), or through compromise of the adsorbent benefits of coadministered AC. In a simulated gastric fluid model containing 5 g of APAP, 0.5 L of WBI increased APAP concentrations at all time points and increased the AUC<sub>0-90 min</sub> from 315 mg-min/L to 6233 mg-min/L compared with 0.9% sodium chloride control.<sup>115</sup> Whole-bowel irrigation did not accelerate the release of extended-release morphine in a separate simulated gastric fluid model maintained in an acid pH.<sup>55</sup> In a prospective, randomized, crossover study of 10 volunteers administered 75 mg/kg of a bilayer, delayed-release APAP preparation, WBI initiated 30 minutes after ingestion resulted in a statistically insignificant decrease in the APAP AUC.<sup>91</sup>

Several *in vitro* studies with cocaine, chlorpromazine, fluoxetine, salicylate, and theophylline demonstrate that the addition of WBI to AC significantly decreases the adsorptive capacity of AC.<sup>11,12,56,75,93</sup> Some interactions were affected by pH and magnified by high ratios of WBI to AC.<sup>12,75,93</sup> The most likely explanation is competition with the AC surface for solute adsorption. Additionally, in an animal model, WBI appeared to have an adverse effect by washing the AC away from the sustained-release theophylline.<sup>26</sup> One controlled study evaluated the effect of WBI added to 25 g of AC in nine healthy human volunteers simultaneously ingesting 200 mg of carbamazepine, 200 mg of theophylline, and 120 mg of verapamil.<sup>81</sup> Compared with AC alone, WBI and AC significantly decreased verapamil peak concentration (C<sub>max</sub>) and AUC but significantly increased carbamazepine C<sub>max</sub> and AUC and nonsignificantly increased theophylline C<sub>max</sub> and AUC. One case report documents rapid increases in carbamazepine concentrations temporally related to the initiation of WBI.<sup>90</sup> Although the patient received MDAC and hemoperfusion, xenobiotic concentrations were increasing 58 hours after ingestion. It is possible that WBI competed for carbamazepine binding to AC, displacing some drug and making it available for absorption. A similar rapidly increasing drug concentration occurred after the initiation of WBI in a patient with a reported 10-g phenytoin overdose.<sup>32</sup> In this case, AC was not given before the initiation of WBI. One possible explanation is that the massive dose of phenytoin prevented its own absorption by exceeding its solubility, but the administration of WBI provided sufficient diluent to allow phenytoin dissolution before GI emptying with subsequent absorption. One human study evaluated the influence of various decontamination strategies on the probability of seizures in 319 patients who overdosed on venlafaxine on 436 occasions.<sup>79</sup>

Whole-bowel irrigation added to AC alone in a mean ingestion of 2100 mg further reduced the odds ratio (OR) of a seizure to 0.25 (0.08–0.62) compared with an OR of 0.48 (0.25–0.89) with AC alone. Most of these patients ingested extended-release venlafaxine. These results demonstrate that combining AC and WBI provided a greater benefit than the sum of the independent effects of single-dose AC and WBI, and argued against adverse clinical effects caused by desorption in venlafaxine ingestion.<sup>79</sup> Problems with this study include assumptions on dose, weight, and time of ingestion, as well as all the limitations associated with nonrandomization of decontamination procedures.

### PREGNANCY AND LACTATION

Commercial preparations of WBI are pregnancy category C.<sup>21,22,129,130</sup> Animal reproduction studies have not been conducted with Colyte, GoLYTELY, NuLYTELY, or TriLyte.<sup>21,22,129,130</sup> The underlying elevated prevalence of nausea and vomiting in pregnancy<sup>77</sup> might predispose pregnant patients to vomit more frequently, although this is speculative. Whole-bowel irrigation with large volumes of fluid was used successfully in pregnant women at 26 and 38 weeks of gestation.<sup>150,152</sup> The lack of absorption of WBI would not predispose it to excretion in breast milk, although definitive safety in lactation is not established.

### DOSING AND ADMINISTRATION

The usual nonprescription daily dose for the short-term treatment (2 weeks) of occasional constipation is 17 g of PEG 3350 without electrolytes powder in 8 oz (240 mL) of water. The recommended dose of WBI is considerably larger: 0.5 L/h or 25 mL/kg/h for small children and 1.5 to 2.0 L/h or 20 to 30 mL/min for adolescents and adults. Whole-bowel irrigation solution is administered orally or through a nasogastric tube for 4 to 6 hours or until the rectal effluent becomes clear. If the xenobiotic being removed is radiopaque, a diagnostic imaging technique demonstrating the absence of the xenobiotic is a reasonable clinical endpoint (Special Considerations: SC5). An antiemetic such as metoclopramide or a 5-HT<sub>3</sub> serotonin antagonist is recommended for the treatment of nausea or vomiting. In carefully select patients, promotility agents serve as useful adjuncts.<sup>148</sup>

### FORMULATION AND ACQUISITION

The original WBI solution was GoLYTELY manufactured by Braintree. This solution contained PEG with electrolytes and sodium sulfate as an added laxative. Colyte is manufactured by Schwartz Pharma and is similar to GoLYTELY. Braintree later introduced NuLYTELY, a PEG formulation with 52% less total salt than GoLYTELY without added sodium sulfate. These changes decreased the salty taste and the risk of fluid- or electrolyte-related complications.<sup>102</sup> Many products are available with flavors. The available WBI products are prepared by filling the container to the 4-L (or 1-gal) mark with water and shaking vigorously several times to ensure dissolution. Lukewarm water facilitates dissolution, but subsequent chilling improves palatability. Chilled solutions are not recommended for infants because of hypothermia risk. Products are stable with refrigeration for 48 hours after reconstitution. Available WBI products (eg, GoLYTELY, Colyte, NuLYTELY, TriLyte) differ slightly in their composition. All contain PEG 3350 with varying amounts of sodium chloride, potassium chloride, sodium sulfate, and sodium bicarbonate, which upon reconstitution yield the following concentrations: sodium, 65 to 125 mEq/L; potassium, 5 to 10 mEq/L; chloride, 35 to 53 mEq/L; bicarbonate, 17 to 20 mEq/L; and sulfate, 0 to 80 mEq/L.<sup>21,22,129,130</sup>

MiraLAX contains electrolyte-free PEG 3350 powder meant for oral administration after dissolution in water, juice, or soda. It is indicated for occasional constipation and not for poisoning management, with a recommended dose of 1 heaping teaspoon (17 g) in 8 oz (240 mL) of liquid per day. However, alternative WBI formulations using electrolyte-free PEG 3350 with Gatorade have been used clinically. One study of 139 patients comparing 4 L of PEG-ELS with electrolyte-free PEG combined with 1.9 L of Gatorade and found no differences in colonoscopy preparation scores, higher overall patient satisfaction scores with the Gatorade mixture, and fewer adverse effects (bloating and nausea).<sup>103</sup> In 46 children provided PEG 3350 mixed with 1.9 L of Gatorade over a few hours, 93.5% completed the regimen, and 77%

achieved effective colonic visualization.<sup>2</sup> In a retrospective evaluation of an endoscopic database analysis, patients undergoing bowel preparation using PEG 3350 without electrolytes (238 g of MiraLAX in 64 oz of Gatorade) and four 5-mg bisacodyl tablets were more likely to achieve an excellent or good bowel cleansing compared with patients receiving a GoLYTELY preparation (93.3% versus 89.3%), without any adverse events.<sup>132</sup> Coffee added to 1.5 L of PEG for bowel preparation improved perceived ease of drinking, taste, and preference.<sup>67</sup> Similarly, in a trial of 107 patients, admixing 2 L of PEG–ascorbic acid with orange juice significantly improved palatability and diminished nausea from 59.3% to 26.4%.<sup>31</sup>

## SUMMARY

- Cathartics are not considered part of routine management of poisoning and overdose in children or adults and should not be used as an AC substitute when xenobiotics known to be adsorbed to AC are involved.
- When MDAC is administered, if a cathartic is used, it should be provided only with the first dose of AC. Sufficient oral fluids should always accompany cathartic administration to avoid salt and water depletion and inspissation.
- Activated charcoal should be given first to patients for whom it is indicated, and if WBI is being performed in conjunction, a comparable dose of AC should be given after WBI to prevent or overcome the potential desorption and possible further systemic absorption of the xenobiotic.
- Unless contraindicated, WBI is recommended over repetitive-dose cathartics for evacuation of modified release or poorly soluble xenobiotics not adsorbed to AC.
- The precise role of WBI and the interactions between PEG-ELS and AC in overdosed patients remain incompletely defined. Absent controlled clinical studies to assess outcome, WBI is recommended for ingestions of xenobiotics not adsorbed by AC (eg, iron, lead, lithium); and foreign body ingestions, specifically drug packets in body packers, and xenobiotic ingestions with a slow absorptive phase and a high expectation of morbidity.

# PRINCIPLES AND TECHNIQUES APPLIED TO ENHANCE ELIMINATION

David S. Goldfarb and Marc Ghannoum

Enhancing the elimination of a xenobiotic from a poisoned patient is a logical step after initial stabilization of the airway, breathing, and circulation; supportive measures; and techniques to inhibit absorption. **Table 6–1** lists methods that might be used to enhance elimination. In this chapter, hemodialysis, hemoperfusion, and hemofiltration are considered *extracorporeal treatments* (ECTRs) because xenobiotic removal occurs in a blood circuit outside the body. Extracorporeal treatments are used infrequently because most poisonings are not amenable to removal by these methods. In addition, because these elimination techniques have associated adverse effects, costs, and complications, the risk-to-benefit analysis suggests they are only indicated in a relatively small proportion of patients and situations.

## EPIDEMIOLOGY

Although undoubtedly an underestimate of true use, enhanced elimination techniques were performed relatively infrequently in the cohorts of millions of patients reported by the American Association of Poison Control Centers (AAPCC) National Poison Data System (NPDS) (Chap. 130). Alkalinization of the urine was reportedly used 11,651 times, multiple-dose activated charcoal (MDAC) 1,104 times, hemodialysis 2,663 times, and hemoperfusion 49 times. As in the past, there continue to be many instances of inappropriate use of ECTRs, such as in the treatment of overdoses of cyclic antidepressants (CAs).<sup>35</sup>

The AAPCC data reveal that there is a continued increase in the reported use of hemodialysis, paralleling a decline in reports of charcoal hemoperfusion (Chap. 130) (**Table 6–2**). Lithium and ethylene glycol were the most common xenobiotics for which hemodialysis was used between 1985 and 2014 (**Fig. 6–1**).<sup>18</sup> Possible reasons for the decline in use of charcoal and resin hemoperfusion are described in the section on hemoperfusion in this chapter. Peritoneal dialysis (PD), a slower modality that should have little or no role in any poisoning, is no longer reported separately. “Other extracorporeal procedures” in past AAPCC reports include continuous modalities (discussed later in the section Continuous Hemofiltration and Hemodiafiltration), plasmapheresis, and PD.

Very few prospective, randomized, controlled clinical trials have been conducted to determine which groups of patients actually benefit from enhanced elimination of various xenobiotics and which modalities are most efficacious. For most poisonings, it is unlikely that such studies will ever be performed, given the relative scarcity of appropriate cases of sufficient severity and because of the many variables that would hinder controlled comparisons. Thus, limited evidence deemed of high quality exists. We must therefore rely on an understanding of the principles of these methods to identify the individual patients for whom enhanced elimination is indicated. In particular, isolated case reports in which the kinetics are well described, including half-lives with and without enhanced elimination, clearance, and

quantification of removal are very useful in establishing the efficacy of a method. Fortunately, in the absence of robust evidence, consensus-based recommendations have now been published and are being developed to guide clinical decisions. The American Academy of Clinical Toxicology (AACT) and the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT) published joint position papers on urine alkalinization<sup>50</sup> and MDAC.<sup>56</sup> The Extracorporeal Treatments in Poisoning (EXTRIP) work group, a collaboration of experts from diverse specialties (clinical toxicology, nephrology, pharmacology, critical care, emergency medicine) representing more than 30 international societies, has published several recommendations regarding the indications for dialysis and other ECTRs for overdose<sup>3,9,17,20,23,24,26,29,39,43,52,58</sup> (see also <http://extrip-workgroup.org>).

## GENERAL INDICATIONS FOR ENHANCED ELIMINATION

Enhanced elimination is generally indicated for several types of patients, with the preexisting condition that the responsible xenobiotic is removable.<sup>22</sup>

- *Patients who fail to respond adequately to comprehensive supportive care.* Such patients have evidence of poor prognostic factors such as intractable hypotension, heart failure, seizures, metabolic acidosis, or dysrhythmias. Hemodialysis is much better tolerated than in the past and offers potentially life-saving opportunities for patients with toxicity caused by theophylline, lithium, salicylates, or toxic alcohols, among others.
- *Patients in whom the normal route of elimination of the xenobiotic is impaired.* Such patients have kidney or hepatic dysfunction, either preexisting or caused by the overdose. For example, a patient with impaired kidney function is more likely to develop toxicity from a large lithium ingestion and require hemodialysis as treatment.
- *Patients in whom the amount of xenobiotic absorbed or its high concentration in serum indicates that serious morbidity or mortality is likely.* Such patients do not necessarily appear acutely ill on initial evaluation. Xenobiotics in this group include ethylene glycol, lithium, methanol, paraquat, salicylates, and theophylline.
- *Patients with concurrent disease or in an age group (very young or old) associated with increased risk of morbidity or mortality from the overdose.* Such patients are intolerant of prolonged coma, immobility, and hemodynamic instability. An example is a patient with both severe underlying respiratory disease and chronic salicylate poisoning.
- *Patients with concomitant electrolyte disorders that could be corrected with hemodialysis.* An example is the metabolic acidosis with elevated lactate associated with metformin toxicity discussed in the hemodialysis section of this chapter.

**TABLE 6–2** Changes in AAPCC Annual Reported Use of Extracorporeal Therapies<sup>a</sup>

	1986	1990	2001	2004	2007	2011	2015
Hemodialysis	297	584	1,280	1,726	2,106	2,323	2,663
Charcoal hemoperfusion	99	111	45	20	16	14	49
Resin	23	37	—	—	—	—	—
Peritoneal dialysis	62	27	—	—	—	—	—
Other extracorporeal: Such as CVVH and CVVHD	—	—	26	33	24	26	51

CVVH, continuous venovenous hemofiltration; CVVHD, continuous venovenous hemodialysis.

<sup>a</sup>Data from American Association of Poison Control Centers annual reports.

**TABLE 6–1** Potential Methods of Enhancing Elimination of Xenobiotics

Occurring Inside the Body	Occurring Outside the Body (Extracorporeal)
Cerebrospinal fluid replacement	Exchange transfusion
Forced diuresis	Hemodialysis
Manipulation of urine pH	Hemofiltration and hemodiafiltration
Metal chelators	Hemoperfusion (charcoal, resin)
Multiple-dose activated charcoal	Liver support devices
Peritoneal dialysis	Plasmapheresis
Resins (Prussian blue, sodium polystyrene sulfonate, cholestyramine, colestipol)	

**FIGURE 6-1.** Xenobiotics that were most commonly reported by the AAPCC as treated with extracorporeal therapies per 5 year intervals. ECTR = extracorporeal treatment.

Ideally, these techniques are applied to poisonings for which studies suggest an improvement in outcome in treated patients compared with patients not treated with extracorporeal removal. As previously mentioned, these data are rarely available.<sup>21</sup>

The need for extracorporeal elimination is less clear for patients who are poisoned with xenobiotics that are known to be removed by an ECTR but that cause limited morbidity if supportive care is provided. Relatively high rates of endogenous clearance would also make extracorporeal elimination redundant. Examples of such xenobiotics include ethanol and some barbiturates; both are subject to substantial rates of hepatic metabolism, and neither would be expected to lead to significant morbidity after the affected patient has had endotracheal intubation and is mechanically ventilated. There may be instances of severe toxicity from these two xenobiotics for which enhanced elimination will reduce the length of intensive care unit (ICU) stays and the associated nosocomial risks; extracorporeal elimination would then be a reasonable option. Dialysis should be avoided if other more effective and less invasive modalities are available. For example, a patient with an acetaminophen (APAP) overdose should be initially treated with *N*-acetylcysteine instead of hemodialysis unless evidence of mitochondrial injury is apparent.<sup>26</sup>

### CHARACTERISTICS OF XENOBIOTICS APPROPRIATE FOR EXTRACORPOREAL THERAPY

The appropriateness of any modality for increasing the elimination of a given xenobiotic depends on various properties of the molecules in question. Effective removal by the ECTR and other methods listed in Table 6-1 is limited by a number of factors, including a large volume of distribution ( $V_d$ ), molecular and compartmental factors. The  $V_d$  relates to the concentration of the xenobiotic in the blood or serum as a proportion of the total body burden. The  $V_d$  can be envisioned as the apparent volume in which a known total dose of drug is distributed before metabolism and excretion occur:

$$V_d \text{ (L/kg)} \times \text{Patient weight (kg)} = \text{Dose (mg)} / \text{Concentration (mg/L)}$$

The larger the  $V_d$ , the less the xenobiotic is present in the blood compartment for elimination. A xenobiotic with a  $V_d$  below 1 L/kg is usually considered amenable to extracorporeal elimination. Methanol is an example of a xenobiotic with a small  $V_d$ , approximately equal to total body water (0.6 L/kg). A substantial fraction of a dose of methanol can be removed by hemodialysis. In addition to the alcohols, other xenobiotics with a relatively low  $V_d$  include phenobarbital, lithium, salicylates, valproic acid, bromide and fluoride ions, and theophylline. In contrast, lipid-soluble xenobiotics have large volumes of distribution ( $\geq 1$  L/kg of body weight); an insignificant fraction of digoxin with a large  $V_d$  (5–12 L/kg of body weight) would be removed by hemodialysis. Other high  $V_d$  xenobiotics include many  $\beta$ -adrenergic antagonists (with the possible exception of atenolol), diazepam, organic phosphorus compounds, antipsychotics, quinidine, and the CAs.

Pharmacokinetics also influences the ability to enhance elimination of a xenobiotic. Kinetic parameters after an overdose often differ from those after therapeutic or experimental doses. For instance, carrier- or enzyme-mediated elimination processes may be overwhelmed by higher concentrations of the xenobiotic in question, making extracorporeal removal potentially more useful. Similarly, plasma protein- and tissue-binding sites may all be saturated at higher concentrations, making extracorporeal removal feasible in instances in which it would have no role in less significant overdoses. Examples include salicylates and valproic acid, which are poorly dialyzed at nontoxic concentrations because of high protein binding. However, at higher concentrations, protein-binding sites become saturated and lead to a higher proportion of the drug free in the serum, amenable to removal by hemodialysis at a clinically relevant rate. Estimated endogenous elimination rates of a xenobiotic should be derived by proper toxicokinetic models and not by pharmacokinetic data after therapeutic doses.

When assessing the efficacy of any technique of enhanced elimination, a generally accepted principle is that the intervention is worthwhile only if a large portion of total body drug burden can be eliminated or if total body clearance of the xenobiotic is increased by a factor of at least 2.<sup>36</sup>

This substantial increase is easier to achieve when the xenobiotic has a low endogenous clearance. Examples of xenobiotics with low endogenous clearances ( $<4$  mL/min/kg) include valproic acid, lithium, paraquat, phenytoin, salicylate, and theophylline. Xenobiotics with high endogenous clearances include many  $\beta$ -adrenergic antagonists, lidocaine, opioids, nicotine, and CAs. Enhancement of elimination is expected to contribute more to overall clearance of the former group than to the latter.

There are many caveats in interpreting the toxicokinetic efficacy of any technique of elimination.<sup>37</sup> Several publications only report the blood or serum concentrations of the xenobiotic at the beginning and the end of the procedure; these data are somewhat informative for one-compartment xenobiotics that are limited to the extracellular space, such as theophylline. The difference between the theophylline concentration before the procedure and the concentration at the end of the procedure, divided by the concentration at the beginning, is the fraction of the body burden of the xenobiotic that is eliminated. However, this calculation does not account for endogenous clearance and would not be appropriate to estimate the effect of treatment on the total body burden of a xenobiotic that distributes in a larger  $V_d$  or with multicompartment kinetics. Furthermore, the serum concentration of a xenobiotic seldom reflects its concentration in the toxic compartment.

Certain xenobiotics, such as lithium, distribute in part to the intracellular compartment, and equilibrium is established between the intracellular and extracellular compartments. The latter compartment includes the blood from which xenobiotic elimination occurs and the interstitium. An increase in the elimination rate from the extracellular compartment, such as by hemodialysis, alters this equilibrium. The rate of redistribution of the xenobiotic from the intracellular compartment into the now dialyzed intravascular compartment is often slower than the rate of clearance across the dialysis membrane. In that case, the serum concentration becomes relatively low despite a substantial intracellular burden. This low serum concentration reduces the concentration gradient for diffusion from serum to dialysate so that dialysance (the dialysis clearance) is reduced. Thus, although serum concentrations decrease precipitously during the procedure, the total-body burden of the xenobiotic is not affected significantly if it does not move from cells to the dialyzable intravascular compartment. To fully appreciate the limitation of only observing serum concentration, the following example can be illustrated: a 60-kg patient ingests 100 (25-mg) amitriptyline tablets, a CA.<sup>14</sup> Because of significant lipophilicity, this class of xenobiotics has a high  $V_d$ . Assuming that the drug is fully absorbed, the 2,500 mg of amitriptyline distributes in an apparent volume of 40 L/kg of body weight to achieve a serum concentration of 1,000 ng/mL, a potentially toxic concentration. One might consider dialysis useful if the serum concentration of amitriptyline decreases from 1,000 ng/mL to 400 ng/mL during a 4-hour dialysis. If dialysis is performed with a blood flow rate of 350 mL/min (plasma flow rate of 200 mL/min, assuming a hematocrit of  $\sim 43\%$ ) and the extraction ratio is 100%, the clearance of drug is 200 mL/min or 200 mcg/min. In 4 hours (240 minutes) of treatment, only 48 mg (48,000 mcg), or less than 2% of the amount ingested, would be removed. The treatment would not affect toxicity despite decreasing serum concentrations.

When assessing overall efficacy, the evidence of enhanced elimination must be considered in the context of the clinical response. In some instances, observed improvement is not predicted by the kinetics of the parent xenobiotic and may not result from the intervention. For example, in severe cases of CA poisoning, unexpected improvement during hemoperfusion could be fortuitous because the toxicity is manifested early and ameliorates rapidly during the initial distribution phase.

Beginning a procedure during the initial distribution phase will likely increase the fraction of the drug burden that can be removed. Later, after the xenobiotic has distributed into fat, moved intracellularly, or has been bound by plasma or tissue proteins, administration of ECTR will have much lower clearance rates and benefits. Examples of xenobiotics that might be better removed soon after ingestion include paraquat and thallium.

The extent of xenobiotic removal by enhanced elimination is not necessarily correlated to clinical improvement. For example, no difference was

observed between patients with lithium poisoning for whom hemodialysis was done and those for whom it was recommended by a poison control center but not done.<sup>4</sup> Unfortunately, this study was underpowered and limited by confounding by indication. Furthermore, although paraquat exhibits all the chemical characteristics necessary for high extracorporeal removal, the outcome of patients presenting late after paraquat ingestion remains dismal despite active elimination procedures.

Occasionally, there will be unanticipated evidence of improvement despite removal of marginal amounts of the xenobiotic and active metabolites. Some authors have attributed this surprising finding to removal of a critical amount of xenobiotic from a shallow “toxic effect” compartment. This theory has been advanced to explain the response to hemodialysis of patients overdosed with the CAs and the antipsychotic chlorprothixene. Such effects may lead to transient improvements that are not sustained as drug redistributes from one pool to another, leading to early benefit but eventual recurrence of symptoms. Much of the relevant literature fails to provide long-term follow-up to demonstrate prolongation of benefits after the ECTR is completed and xenobiotics have redistributed.

### Improving the Literature

These many limitations in the available medical literature regarding the appropriate indications and utilization of ECTRs in the treatment of poisonings led EXTRIP to promote improvements in case reporting.<sup>37</sup> The paper makes suggestions for the data that should be obtained when the ECTR is applied. We recommend that this paper be reviewed when possible before instituting therapy so that the requisite and comprehensive data will be obtained. The result of this consideration will be more thorough case reporting and the ensuing publication of more thorough and useful medical literature.

### TECHNIQUES TO ENHANCE REMOVAL OF XENOBIOTICS

Although the efficacy of, or need for, removal of many xenobiotics remains controversial, consensus regarding the indications for these procedures has developed. This consensus has led to consistent application of several techniques of enhanced elimination for some toxic exposures that occur relatively more frequently.

#### Multiple-Dose Activated Charcoal: “Gastrointestinal Dialysis”

Oral administration of multiple doses of activated charcoal increases elimination of some xenobiotics present in the blood. This modality is discussed in more detail in Antidotes in Depth: A1 and will not be discussed here.

#### Resins

Resins are sometimes used in poisoning management. They can reduce the bioavailability of ingested drugs and act as decontaminants, similarly to activated charcoal. In addition, however, they can promote elimination of certain xenobiotics by enhancing their back-diffusion from plasma to gut (gastrointestinal dialysis) and interrupt enterohepatic recirculation.

The most commonly used resins are sodium polystyrene sulfonate (Kayexalate), cholestyramine, and Prussian blue. Sodium polystyrene sulfonate is an ion exchanger that is used regularly for hyperkalemia in patients with chronic kidney disease. Limited data now exist on its potential use in lithium poisoning, although treatment results in hypokalemia.<sup>19</sup> Prussian blue is also an ion exchanger used for treatment of poisoning by cesium or thallium (Antidotes in Depth: A31). Cholestyramine, a bile acid sequestrant, binds several xenobiotics, including digoxin, ibuprofen, and mycophenolate mofetil, although its application in poisoning is doubtful (Chap. 62).

#### Forced Diuresis

Forced diuresis by volume expansion with isotonic sodium-containing solutions, such as 0.9% sodium chloride and Ringer's lactate (RL) solution with or without the addition of a diuretic, does increase renal clearance of some molecules. This therapy would theoretically be most useful for xenobiotics such as lithium for which the glomerular filtration rate (GFR), representing the volume of plasma filtered across the glomerular basement membrane

per minute, is an important determinant of excretion. In people with normal extracellular fluid (ECF) volume, the increase in GFR and increase in xenobiotic renal elimination expected with plasma volume expansion is variable and unpredictable and not likely to be clinically significant. The effect is potentially more important in patients who have contraction of the ECF volume; loss of extracellular volume leads to a reduction of GFR partly as a result of decreased cardiac preload and cardiac output, which, in turn, reduces renal plasma flow. This circumstance is also accompanied by activation of angiotensin II, a small peptide that acts as a pressor and stimulates sodium reabsorption in the proximal tubule. Because small molecules such as lithium are both filtered at the glomerulus and reabsorbed by the proximal tubule, especially when volume depletion has occurred and angiotensin II has been activated, repletion of ECF volume with 0.9% sodium chloride will increase GFR and suppress proximal tubular sodium reabsorption. The result is an increase in excretion of low-molecular-weight xenobiotics such as lithium. After the ECF volume is restored, the continued infusion of 0.9% sodium chloride or RL will not enhance elimination of lithium to any major extent.

The major risk of excessive volume repletion is ECF volume overload, manifested by pulmonary and cerebral edema. This complication is particularly likely in patients with baseline chronic kidney disease such as is associated with long-standing lithium use. Other patients with acute kidney injury (AKI) not mediated by ECF volume depletion are also at risk. Knowing the result of past serum creatinine concentrations permits distinction between acute from chronic kidney disease in such cases. Administration of diuretics such as furosemide along with saline diminishes the risk of ECF volume overload but complicates the therapy, confuses the assessment of ECF volume, and increases the risk of metabolic alkalosis and hypokalemia. The unproven efficacy of enhanced diuresis in the management of *any* overdose has led most experts to abandon its use. On the other hand, the repletion of ECF volume when volume contraction is present, as determined by the history and physical examination, is, of course, appropriate. Saline diuresis may be used to treat toxin-induced hypercalcemia, which can result from excessive ingestion of calcium supplements or vitamin D ingestion.

### Manipulations of Urinary pH

Many xenobiotics are weak acids or bases that are ionized in aqueous solution to an extent that depends on the  $pK_a$  of the xenobiotic and the pH of the solution. Knowing these variables, the Henderson-Hasselbalch equation (Chaps. 9 and 10) can be used to determine the relative proportions of the acids, bases, and buffer pairs. Whereas cell membranes are relatively impermeable to ionized, or polar molecules (eg, an unprotonated salicylate anion), nonionized, nonpolar forms (eg, the protonated, noncharged salicylic acid) cross more easily. As xenobiotics pass through the kidney, they may be filtered, secreted, and reabsorbed. If the urinary pH is manipulated to favor the formation of the ionized form in the tubular lumen, the xenobiotic is trapped in the tubular fluid and is not passively reabsorbed into the bloodstream. This is referred to as ion trapping. Hence, the rate and extent of its elimination can be increased. To make manipulation of urinary pH worthwhile, the renal excretion of the xenobiotic must be a major route of elimination. The 2004 position paper of the AACT and EAPCCT emphasizes that, as discussed earlier for extracorporeal therapies, enhanced removal does not necessarily translate into a clinical benefit with improved outcomes.<sup>50</sup>

Alkalinization of the urine to enhance elimination of weak acids has a role for salicylates, phenobarbital, chlorpropamide, formate, diflunisal, fluoride, methotrexate, and the herbicide 2,4-dichlorophenoxyacetic acid (2,4-D). These weak acids are ionized at alkaline urine pH, and tubular reabsorption is thereby greatly reduced. Alkalinization is achieved by the intravenous administration of sodium bicarbonate (1–2 mEq/kg rapid initial infusion with additional dosing) to increase urinary pH to 7 to 8. This degree of alkalinization will be difficult, if not impossible, if metabolic acidosis and acidemia are present, as often is the case in patients with salicylate poisoning. In this situation, bicarbonate (administered as the sodium salt, sodium bicarbonate) is consumed by titration of plasma protons before it

can appear in the urine. On the other hand, salicylate poisoning often causes respiratory alkalosis as well. In that case, when the  $PCO_2$  is low, raising serum bicarbonate, equivalent to the induction of metabolic alkalosis, may lead to profound, life-threatening alkalemia. Finally, as for the case of 0.9% sodium chloride or RL, there is a risk of ECF volume overload with sodium bicarbonate administration. Modest reductions in GFR also reduce the likelihood of successful urinary alkalization and increase the risk of pulmonary edema. Hypernatremia may also occur, especially if sodium bicarbonate is given as a hypertonic solution. Bicarbonaturia is also associated with urinary potassium losses, so the patient's serum potassium concentration should be monitored frequently and the appropriate dose of potassium administered as long as GFR is not impaired. A further complication of alkalemia is a decrease of ionized calcium, which becomes bound by albumin as protons are titrated off serum proteins; in this event, tetany, prolonged QT interval, and cardiac dysrhythmias are risks. If these complications can be identified and dealt with judiciously and safely, the renal clearance of salicylate increases fourfold as urine pH increases from 6.5 to 7.5 with alkalization.<sup>49</sup> Increasing urine pH by decreasing proximal tubular bicarbonate reabsorption via administration of carbonic anhydrase inhibitors such as acetazolamide is not recommended. Although an alkaline urine pH will result and elimination of a xenobiotic enhanced, this is achieved at the expense of inducing a metabolic acidosis. In the case of salicylates, acidemia increases distribution into the central nervous system. The role of urinary alkalization in the management of patients with salicylate poisoning is discussed further in Chap. 37.

Alkalinization is also used to increase the solubility of methotrexate and its metabolites and thereby prevents their precipitation in tubules when patients are given high-dose methotrexate.<sup>8</sup> Precipitation of sulfonamide antibiotics, resulting in crystalluria, kidney stones, or kidney failure, can be prevented by alkalization. Administration of sodium bicarbonate, sodium chloride, or RL also protects the kidneys from the toxic effects of myoglobinuria in patients with extensive rhabdomyolysis. Acidification of the urine by systemic administration of HCl or  $NH_4Cl$  to enhance elimination of weak bases, such as phencyclidine or the amphetamines, is not useful and is potentially dangerous. The technique was abandoned because it does not significantly enhance removal of xenobiotics and is complicated by acidemia.

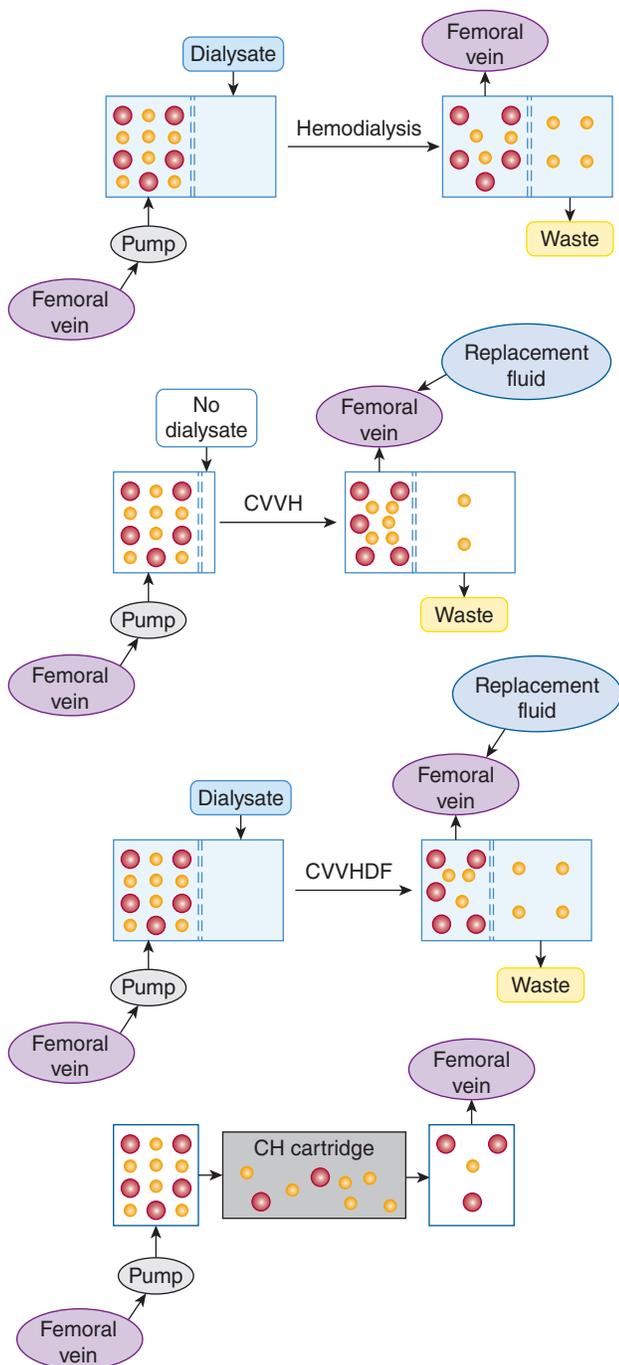

### Peritoneal Dialysis

Peritoneal dialysis is a technique in which a solution is introduced into the abdomen via a catheter so that the patient's peritoneum can act as a membrane across which water, solutes, and xenobiotics are exchanged with the blood. Theoretically, PD enhances the elimination of water-soluble, low-molecular-weight, non-protein-bound xenobiotics with a low  $V_d$ . Clearance of xenobiotics by PD is related to the number of exchanges, the dwell time of dialysate, the surface area of the peritoneum, and the molecular weight of the compound. The highest clearances are achieved for xenobiotics with molecular weights below 500 Da. The efficacy of PD is markedly decreased when the patient is hypotensive.

Although PD is a relatively simple method to enhance xenobiotic elimination, it is too slow to be clinically useful.<sup>46</sup> Consequently, PD is not the ECTR of choice unless other more efficient techniques are unavailable. Besides exchange transfusion, it may be the only practical option in small children when experience with extracorporeal techniques in younger age groups is lacking or until a child can be transported to an appropriate center where hemodialysis can be performed.

### Hemodialysis

Hemodialysis has been used for 100 years, ever since the discovery by John J. Abel and coworkers that dialysis could remove substantial amounts of salicylates from animals.<sup>1</sup> During conventional hemodialysis, blood and counter-current dialysate are separated by a semipermeable membrane (*dialyzer*). Xenobiotics then diffuse across the membrane from blood into the dialysate down the concentration gradients (Fig. 6–2). Blood is pumped through one lumen of a temporary dialysis catheter, passed through the machine, and returned to the venous circulation through the second lumen.

**FIGURE 6-2.** Comparative schematic layouts of hemodialysis (HD), continuous venovenous hemofiltration (CVVHDF), continuous venovenous hemofiltration with dialysis (CVVHD), and hemoperfusion (HP). Red circles are high molecular-weight (MW) xenobiotics, such as methotrexate, whose high MW makes them too large to be removed by HD. Yellow circles are low MW diffusible solutes such as urea or methanol. In dialysis, solute moves across a semipermeable membrane (dashed lines) from a solution in which it is present in a high concentration (blood) to one in which it is at a low concentration (dialysate). In CVVH and CVVHDF, plasma moves across a similar membrane in response to hydrostatic pressures; replacement fluid must be provided. The latter also uses a dialysate to augment clearance. The availability of blood pumps has made arteriovenous modalities nearly obsolete. Charcoal hemoperfusion (CH) requires movement of blood through a sorbent-containing cartridge and does not include dialysis or hemofiltration.

The utility of hemodialysis for the treatment of patients with toxicity caused by lithium, toxic alcohols, salicylates, or theophylline is unquestionable and is not dealt with here; each of these xenobiotics is described in detail in separate chapters that also review their toxicity and indications for

extracorporeal therapies. This section describes the hemodialysis procedure and its application in general.

Prompt consultation with a nephrologist is always indicated in the case of poisoning with a xenobiotic that might benefit from extracorporeal removal. Annual AAPCC data consistently suggest that some salicylate-related deaths, for example, could have been prevented if hemodialysis had been instituted earlier (Chap. 130).<sup>12</sup> To perform hemodialysis, a nephrologist must be available along with a nurse. The dialysis machine requires preparation, and a vascular access catheter must be inserted. A delay, ranging from one to several hours before hemodialysis can be instituted should be anticipated, particularly during hours when the hospital's dialysis unit, if there is one, is closed. If indicated, modalities of treatment such as fomepizole or ethanol for poisoning with toxic alcohols should be administered, and other modalities to enhance elimination, such as urinary alkalization or oral MDAC, should be used when appropriate.

The technical details of performing hemodialysis for treatment of patients with poisonings do not differ markedly from those used in the treatment of patients with acute kidney failure. Several technologic advances have enabled improved xenobiotic clearance while limiting side effects and enabling better tolerance of dialysis.

Vascular access is obtained via a double-lumen catheter that is made of silicon, polyethylene, polyurethane, or polytetrafluoroethylene (Teflon). The catheter is usually inserted via the femoral, subclavian, or jugular vein. Whereas the subclavian and internal jugular veins have the added risk of pneumothorax and necessitate radiographic confirmation of catheter position, femoral catheters have increased blood recirculation (ie, lower efficacy of ~10%–15%).<sup>38</sup> Hemostasis after catheter removal is also more easily achieved at the femoral site. Bleeding or thrombosis at the site used for vascular access occur in approximately 5% to 10% of cases but can be minimized by ultrasonographic placement of the catheter and addressed by adequate postprocedure tamponade of the catheter site. Larger catheters now permit blood flow rates that can be as high as 450 to 500 mL/min, although 350 mL/min is sometimes the maximum rate achievable. Nosocomial bacteremia occurs when central catheters are indwelling but are exceedingly rare if they are in place for less than 3 days. This complication is therefore unusual in poisoning in which ECTRs are necessary for relatively short periods of time. Femoral venous lines should always be removed in patients who are mobile and out of bed.

Because modern dialysis membranes also have higher water permeability, computerized ultrafiltration control is necessary. These membranes, composed of polysulfone, polyamide, polyacrylonitrile, and other synthetic polymers, have better biocompatibility than older, cellulose-derived membranes. Better biocompatibility translates into lesser activation of inflammatory mediators and better dialytic tolerance. It is unlikely that better biocompatibility will affect outcomes for dialysis of poisoned patients who require only one or two treatments.

Dialysis membrane composition has also continually evolved. The hollow-fiber dialyzer, almost universally used today, is composed of thousands of blood-filled capillary tubes held together in a bundle and bathed in the machine-generated dialysate. Hemodialysis efficacy for poisonings with low-molecular-weight xenobiotics should improve with the use of larger membranes with larger clearances. "High-flux," synthetic dialyzers have larger pores and increased surface area that allow greater clearance of larger molecules. With the use of high-flux and high-efficiency dialyzers, small molecule clearance has more than doubled, but clearance of larger molecules, such as  $\beta_2$ -microglobulin (molecular weight, 11,800 Da) has increased by a factor of five compared with cellulose-based dialyzers. There are some instances in which high-flux dialyzers might be important in promoting clearance of larger molecules, such as vancomycin (molecular weight, 1,449 Da), which were not readily removed by conventional low-flux membranes.<sup>10</sup> However, the indications for performing hemodialysis to enhance removal of vancomycin and other xenobiotics with higher molecular weights have not been delineated. Nonetheless, a sound pharmacologic basis for the efficacy of dialysis must still be present; no amount of increased clearance will eliminate a

xenobiotic with a large  $V_d$  or significant protein or tissue binding. However, it is important to consider that clearance rates for many xenobiotics reported in the literature of the 1970s and 1980s significantly underestimate currently achievable clearance rates.

To limit the risk of hemodynamic instability during hemodialysis, the blood lines and artificial kidney (the dialysis membrane) should be primed with an appropriate volume of fluid at the onset of the procedure. Furthermore, for many years, the source of base in dialysate has been sodium bicarbonate rather than sodium acetate; the latter caused hypotension and decreased cardiac output. Computerized machines allow fine control of ultrafiltration rates to limit volume losses; in the past, imprecise calculations and manipulations led to frequent episodes of hypotension. As a result of such innovations, treatment can be delivered in more instances than was previously possible. Hypotension still occurs in some in critically ill patients but can often be corrected with 0.9% sodium chloride, colloid, vasopressors, or inotropes.

Full anticoagulation with heparin is usually required to avoid clotting of the circuit. A typical adult heparin dose is 1,000 to 5,000 units as a bolus followed by 500 to 1,000 units hourly, but lower doses can also be given. Alternatively, in patients at high risk of bleeding (eg, methanol), periodic 0.9% sodium chloride flushes of the dialysis membrane often suffice.

In poisoned patients, hemodialysis is usually performed for 4 to 8 hours but needs to be prolonged in some cases if there is a large poison body burden, as is sometimes necessary for toxic alcohols. Some precautions are needed for the prescription of the dialysis parameters because poisoned patients have different characteristics than chronic kidney disease patients. In particular, serum potassium, phosphorus, and pH can be markedly different. Assuming that the patient's serum potassium concentration is normal, a standard bicarbonate-based dialysate with a potassium concentration of 3 or 4 mEq/L and a calcium concentration of 3 mEq/L, flowing at 600 to 800 mL/min, is indicated. If dialysis is performed in a dialysis unit, the dialysate is a mix of a concentrate with sodium bicarbonate and highly purified water, usually derived by reverse osmosis or deionization. Phosphate can be added to the dialysate bath if needed or administered intravenously if needed. Ultrafiltration is rarely required unless oliguric AKI associated with volume expansion is present. In rare circumstances, when the toxic burden of a xenobiotic is overwhelming, there have been reports of using two dialysis catheters and two independent dialysis circuits to provide maximal xenobiotic clearance.<sup>13</sup> Complications specifically related to the dialysis procedure are rare. Furthermore, centers administering dialysis treatments are increasingly common today, and costs of the procedure are on the decline. For these reasons, if dialysis appears required for survival of a poisoned patient, it should usually be attempted.

Table 6-3 lists the characteristics of xenobiotics that make them amenable to hemodialysis. These requirements greatly reduce the number of xenobiotics that can be expected to be cleared by dialysis. During hemodialysis, clearance of a xenobiotic ( $Cl_x$ ) can be calculated by:

$$Cl_x = Q_p \times ER$$

where  $Q_p$  is the plasma flow rate and ER is the extraction ratio.

$$Q_p = Q_b \times (1 - Hct)$$

where  $Q_b$  is blood flow rate and Hct is hematocrit. The ER is a measure of the percentage of xenobiotic passing through the artificial kidney or charcoal hemoperfusion cartridge. This can be calculated as:

$$ER = \frac{C_{in} - C_{out}}{C_{in}} \times 100$$

where  $C_{in}$  is the concentration of the xenobiotic in blood entering the system and  $C_{out}$  is the concentration in blood leaving the system.

Thus:

$$Cl_x = [Q_p(C_{in} - C_{out})]/C_{in}$$

TABLE 6-3 Characteristics of Xenobiotics That Allow Clearance by Hemodialysis, Hemoperfusion, and Hemofiltration			
For All Three Techniques	For Hemodialysis	For Hemoperfusion	For Hemofiltration
Low $V_d$ (<1 L/kg)	MW <5,000 Da	MW <50,000 Da	MW <40,000 Da
Single-compartment first-order kinetics	Low protein binding	Adsorption by activated charcoal	Low protein binding
Low endogenous clearance (<4 mL/min/kg)			

MW = molecular weight;  $V_d$  = volume of distribution.

With the current routine use of high flux membranes, hemodialysis appears, in some cases, as efficient as hemoperfusion to remove certain xenobiotics. Because valproic acid is increasingly prescribed for nonseizure disorders, the incidence of both intentional and unintentional overdoses of this drug will also increase. As discussed previously, valproic acid is largely protein bound at therapeutic serum concentrations. Toxic concentrations saturate protein-binding sites, leading to a higher proportion of unbound drug in the serum and a lower apparent  $V_d$ , thereby making the drug more dialyzable. Indeed, several case reports have demonstrated that the clearance of valproic acid with high-flux hemodialysis is at least equivalent to, if not greater than, that of charcoal hemoperfusion.<sup>27,32</sup> Although carbamazepine has a low molecular weight and a  $V_d$  that would allow for clearance by hemodialysis, its high protein binding and lack of water solubility are expected to impede the efficacy of hemodialysis. Nonetheless, current evidence shows that high-flux hemodialysis has comparable efficacy to charcoal hemoperfusion for carbamazepine toxicity.<sup>47</sup> Because of its potential efficacy and availability, lower cost, and preferable adverse event profile, high-flux hemodialysis should probably replace charcoal hemoperfusion as the treatment modality of choice when extracorporeal elimination is to be performed. As stated earlier, however, effective clearance is not necessarily a surrogate for improved outcomes.

In addition to removing xenobiotics, hemodialysis can correct acid-base and electrolyte abnormalities such as metabolic acidosis or alkalosis, hyperkalemia, and ECF volume overload. Consequently, hemodialysis is preferred, if not essential, for poisonings characterized by these disorders, especially when clearance rates resulting from hemoperfusion and hemodialysis are relatively similar. Examples include salicylate and toxic alcohol poisoning, which is often associated with metabolic acidosis. Valproic acid toxicity causes hyperammonemia, which is reduced by hemodialysis, possibly contributing to the benefit of the procedure.

A more controversial question is the role of dialysis in the treatment of metformin-associated lactic acidosis. Although debated, present evidence now suggests that metformin intoxication itself induces metabolic acidosis with elevated lactate concentration. Here, the small molecular weight and negligible plasma protein binding of metformin allow for adequate drug removal despite a relatively large  $V_d$ .<sup>7</sup> Endogenous renal elimination of metformin is quite high, and dialysis has therefore less impact on total metformin clearance in patients with intact kidney function. In addition, hemodialysis would rapidly correct acidosis via administration of sodium bicarbonate without the complication of volume overload. Clinical improvement with hemodialysis results as much or more from rapid correction of the acidosis as from removal of the drug.

An important unwanted effect of hemodialysis is the removal of therapeutic drugs and antidotes. Doses of these xenobiotics need to be increased during dialysis or administered immediately afterward. Examples include ethanol, fomepizole,<sup>44</sup> N-acetylcysteine,<sup>16</sup> many antibiotics, and water-soluble vitamins.

### Hemoperfusion

During hemoperfusion, blood is pumped via a catheter through a cartridge containing a very large surface area of sorbent, either activated charcoal or

a resin, on to which the xenobiotic can be directly adsorbed (Fig. 6-2). The activated charcoal sorbent is coated with a very thin layer of polymer membrane such as cellulose acetate (Adsorba; Gambro, Lakewood, CO), heparin-hydrogel, or polyHEMA.<sup>15</sup> The membrane prevents direct contact between blood and sorbent, improves biocompatibility, and helps prevent activated charcoal embolization.

Other adsorptive resins were used for hemoperfusion in the past, such as the synthetic Amberlite XAD-2 and XAD-4 and anion exchange resins such as Dow IX-2. None of these columns is currently approved or available for use in the United States, but they remain available in other countries. The literature regarding their efficacy is scant and relatively anecdotal. Although in vitro evidence suggests that these resins may have greater adsorptive capacities than activated charcoal, there are few, if any, meaningful comparisons in a clinical setting.

The adsorptive capacity of the cartridge is reduced with use because of deposition of cellular debris and blood proteins and saturation of active sites by the xenobiotic in question. Hemoperfusion is usually performed for 4 to 6 hours at flow rates that can usually not exceed 350 mL/min because of the risk of hemolysis.<sup>51</sup> The technique can be used in adults or children.

The characteristics of xenobiotics that make them amenable to hemoperfusion (Table 6-3) differ slightly from those for hemodialysis in that hemoperfusion is not as limited by plasma protein binding, although this is less true with the advent of new dialysis membranes, which now permit removal of significant amounts of highly bound xenobiotics. Some xenobiotics are poorly adsorbed by activated charcoal, including the alcohols, lithium, and many metals (Antidotes in Depth: A1), making hemoperfusion inappropriate in their management.<sup>15</sup> Hemodialysis and hemoperfusion are sometimes combined to optimize clearance (Fig. 6-3), with greater removal rates than with either procedure alone, although it is unclear if this marginal benefit outweighs the cost and added complication rates of this combination.

Added to the questionable benefits of hemoperfusion, multiple limitations make their use less attractive compared with hemodialysis. A practical problem limiting the use of charcoal hemoperfusion is the availability of the cartridges. In a survey of New York City hospital dialysis units taking

911 calls, only 10 of 34 units had cartridges.<sup>54</sup> Saturation of the cartridge is apparent within 1 hour of use and markedly decreases absorptive capacity at 2 hours, but no such decreased performance is apparent with hemodialyzers. Compared with hemodialysis, patients must be anticoagulated with greater amounts of heparin. The cartridges are expensive (~\$600 compared with the maximal cost for a high-flux dialysis membrane at less than \$40), especially if cartridges are replaced regularly. Some have expiration dates, limiting their shelf life. Others have an indefinite shelf life but must be autoclaved before use, which will likely delay their use in an emergency. Complications of hemoperfusion are more common than with hemodialysis: thrombocytopenia, leukopenia, and hypocalcemia.<sup>55</sup> Finally, hemoperfusion cannot correct acid-base or electrolyte abnormalities and cannot provide ultrafiltration if volume overload occurs.

Although hemoperfusion has historically been considered the preferred method to enhance the elimination of carbamazepine, phenobarbital, phenytoin, and theophylline (Table 6-4), older comparisons of hemodialysis and hemoperfusion clearance rates are now obsolete. The most frequent indication for charcoal hemoperfusion in the past was theophylline toxicity, and theophylline is rarely used today in the treatment of obstructive lung disease and asthma and is consequently less often implicated in acute and chronic poisoning. In a review of the AAPCC annual data, theophylline was the most common xenobiotic for which hemoperfusion was reported from 1985 to 2000, but carbamazepine became the most frequent xenobiotic removed by hemoperfusion after 2001.<sup>18,28</sup> As in the case of hemodialysis, doses of drugs used therapeutically will need to be increased if they are removed by hemoperfusion.

### Liver Support Devices

A newer concept for poisonings is that of liver support devices or liver dialysis. These procedures are currently available in the United States, mostly for the treatment of liver failure. Several techniques have been developed; the following three are the most common. (1) Single-pass albumin dialysis (SPAD) is similar to hemodialysis but has albumin added to the dialysate in counter-directional flow, which is then discarded after passing through a filter. (2) The Molecular Adsorbents Recirculation System (MARS) is identical to SPAD, but the albumin-enhanced dialysate (with the adsorbed xenobiotics) is itself recycled after going through another dialysis circuit and through both resin and activated charcoal cartridges. (3) The Prometheus system is a device that combines albumin adsorption with high-flux hemodialysis after selective filtration of the albumin fraction through a polysulfone filter. In all of these techniques, the dialysate bathing the fibers contains human serum albumin that binds the xenobiotic of interest. A steep concentration gradient from blood to dialysate is established so that even highly protein-bound xenobiotics can be removed from the plasma. The membrane is impermeable to albumin, which remains in the dialysate.

These extracorporeal devices are all able to remove protein-bound xenobiotics, but their use in poisoning remains limited to rare case reports. These devices are mostly used in patients with hepatic encephalopathy and liver failure and as a bridge to hepatic transplantation.<sup>42</sup> In toxicology, their use is mostly described in hepatic failure following toxicity of APAP or *Amanita* toxin exposure (Chap. 117). The reasons why the procedure might offer significant benefits are not completely understood, although it does remove both water-soluble and protein-bound compounds, such as bile salts and aromatic amino acids, to account for the therapeutic advantage in hepatic failure. Specific uses for liver support devices for elimination enhancement has been described in poisoning with phenytoin,<sup>53</sup> theophylline,<sup>33</sup> valproic acid,<sup>11</sup> and *Amanita* mushrooms.<sup>31</sup> Whether these relatively expensive (in excess of \$10,000 per treatment), complicated, and nonspecific procedures would offer benefit in a handful of instances in which protein binding limits removal of xenobiotics is not known.

### Hemofiltration

Hemofiltration is the movement of plasma across a semipermeable membrane in response to an active hydrostatic pressure by convection. In pure

**FIGURE 6-3.** Example of a hemodialyzer (orange circle) used in series with a charcoal cartridge (green circle) for a paraquat poisoning.

TABLE 6-4 Properties of Xenobiotics Grouped by Benefit of Extracorporeal Techniques for Elimination

Xenobiotic	MW (Da)	Water Soluble	V <sub>d</sub> (L/Kg)	Protein Binding (%)	Endogenous Clearance (mL/min/kg)	Comments
<b>Clinically Beneficial</b>						
Bromide	35	Yes	0.7	0	0.1	Falsely elevated chloride measurement
Caffeine	194	Yes	0.6	36	1.3	Hyperglycemia, hypokalemia, metabolic acidosis
Ethylene glycol	62	Yes	0.6	0	2.0	Oxaluria, kidney failure
Diethylene glycol	106	Yes	0.5	0	NA	Kidney failure
Isopropanol	60	Yes	0.6	0	1.2	No acidosis, ketosis and ketonuria
Lithium	7	Yes	0.8	0	0.4	Low anion gap, low Cl in kidney failure
Metformin	129	Yes	3–5	0	8	Very low Cl in kidney failure
Methanol	32	Yes	0.6	0	0.7	Risk of CNS hemorrhage
Propylene glycol	76	Yes	0.6	0	1.7	Lactic acidosis
Salicylate	138	Yes	0.2	50 (saturable)	0.9	Cl and protein binding ↓, with ↑ dose; HD also corrects electrolytes and acid–base disturbance
Theophylline	180	Yes	0.5	56	0.7	HP and HD can also be combined
Valproic acid	144	Yes	0.2	90 (saturable)	0.1	↑ Concentrations associated with ↓ % protein binding, HD also clears ammonia when elevated
<b>Possibly Clinically Beneficial</b>						
Acetaminophen	151	Yes	0.9	30	2.0	For coma and mitochondrial injury
Amatoxins	373–990	Yes	0.3	0	2.7–6.2	Possibly effective if performed within the first 24 h of exposure
Aminoglycosides	>500	Yes	0.3	1.5	<10	Cl ↓ with kidney failure
Atenolol	255	Yes	1.0	2.5	<5	Useful if Cl ↓ caused by kidney failure
Carbamazepine	236	No	1.4	74	1.3	Cl ↑ in patients on long-term therapy
Disopyramide	340	No	0.6	1.2	1.6	Protein binding ↓ as concentration ↑
Fluoride	19	Yes	0.3	50	2.5	Hypocalcemia may be improved by HD
Methotrexate	454	Yes	0.6	50	1.5	Urine alkalinization is indicated, good antidote
Paraquat	186	Yes	1.0	6	24.0	Tight tissue binding precludes efficacy unless initiated early
Phenobarbital	232	No	0.5	24	0.1	Only for prolonged coma
Phenytoin	252	No	0.6	90	0.3	Cl ↓ as dose ↑; HD efficient

CL = clearance; CNS = central nervous system; HD = hemodialysis; HF = hemofiltration; HP = hemoperfusion; MW = molecular weight; NA = not available; V<sub>d</sub> = volume of distribution.

hemofiltration, there is no dialysate solution on the other side of the dialysis membrane (Fig. 6-2). Molecules are transported across the membrane with plasma water, a mechanism known as *convective transport* or *bulk flow*. The ECF volume status of the patient determines whether replacement of all or some of the filtered plasma with physiologic electrolyte solution (RL or other commercially available preparations) is indicated. Although this technique can be done intermittently using a hemodialysis machine, it has been adapted for use in ICUs as a continuous form of treatment, particularly when removal of ECF is indicated. Hemofiltration is classically administered continuously for patients with AKI, although there is growing interest of this technique as a chronic treatment for patients with end-stage kidney disease. Compared with hemodialysis (diffusion), hemofiltration favors the elimination of larger xenobiotics (eg, myoglobin, molecular weight = 17,000 Da) but is slightly less performant for the removal of smaller molecules.<sup>6</sup> Because most xenobiotics of interest in toxicology are smaller than 1,000 Da, it is unclear if hemofiltration has any advantage over pure hemodialysis. Solute clearance

can be significantly enhanced by combining both diffusion and convection, a technique known as *hemodiafiltration*. Table 6-3 summarizes the properties of xenobiotics that make them amenable to hemofiltration.

### Continuous Techniques

Continuous techniques are referred to collectively as modalities of *continuous renal replacement therapy* (CRRT). The blood flow and effluent flow are lower than those administered during intermittent techniques, so the achievable xenobiotic clearance is lower. However, what they lack in removal rates is compensated by longer administration (they can be performed without interruption for several days).

For all of these procedures, the patient usually must be fully anticoagulated, with either heparin or with citrate. Continuous techniques include *continuous venovenous hemofiltration* (CVVH), *continuous venovenous hemodialysis* (CVVHD), and *continuous venovenous hemodiafiltration* (CVVHDF) (Fig. 6-2). These have largely replaced arteriovenous techniques, which did

not require a blood pump but presented a high incidence of thrombotic and bleeding complications at the catheter site.

There are several possible advantages of continuous modalities; the major benefits are a slower fluid removal rate and solute flux, which are pertinent for acutely ill patients who are hemodynamically unstable, fluid overloaded, and oliguric. Another practical advantage of CRRT is that the procedure is usually done in ICUs by ICU nurses, and when available in such units, it might not require dialysis personnel. Familiarity of ICU staff with the procedure is critical to its availability when needed; it is most likely to be used effectively in hospitals with higher incidence rates of AKI. In clinical toxicology, CRRT is sometimes used after hemodialysis or hemoperfusion to further remove a xenobiotic, especially those that distribute slowly from tissue-binding sites or from the intracellular compartment.<sup>41</sup>

However, the rate of removal with this form of therapy is considerably inferior to that achieved by intermittent hemodialysis or hemoperfusion and so is not ideal for severely poisoned patients.<sup>46</sup> Patients who can tolerate slower clearance rates may not require this enhanced elimination therapy at all. It is true that a prolonged slower treatment can prevent a rebound of the xenobiotic's serum concentrations that commonly occurs after high-efficiency techniques. However, rebound occurs at the expense of diminishing xenobiotic concentration in the deeper and potentially toxic compartments, as has been shown nearly 50 years ago for lithium.<sup>2</sup> Rebound may therefore not be worrisome and may in fact be desirable while providing for an additional opportunity to remove more xenobiotic with hemodialysis. Rebound should be distinguished from increasing plasma values caused by ongoing intestinal absorption of the xenobiotic because these two entities do not carry the same prognostic relevance.

For these reasons, intermittent hemodialysis is preferable over CRRT for removal of xenobiotics.<sup>25</sup> Continuous modalities are best suited for hemodynamically unstable patients who require net ultrafiltration, although this situation is infrequent unless oliguric AKI is present. Of the guidelines published by EXTRIP to date, none has yet considered any CRRT technique superior to hemodialysis or the first choice of therapy when hemodialysis is available.

### Plasmapheresis and Exchange Transfusion

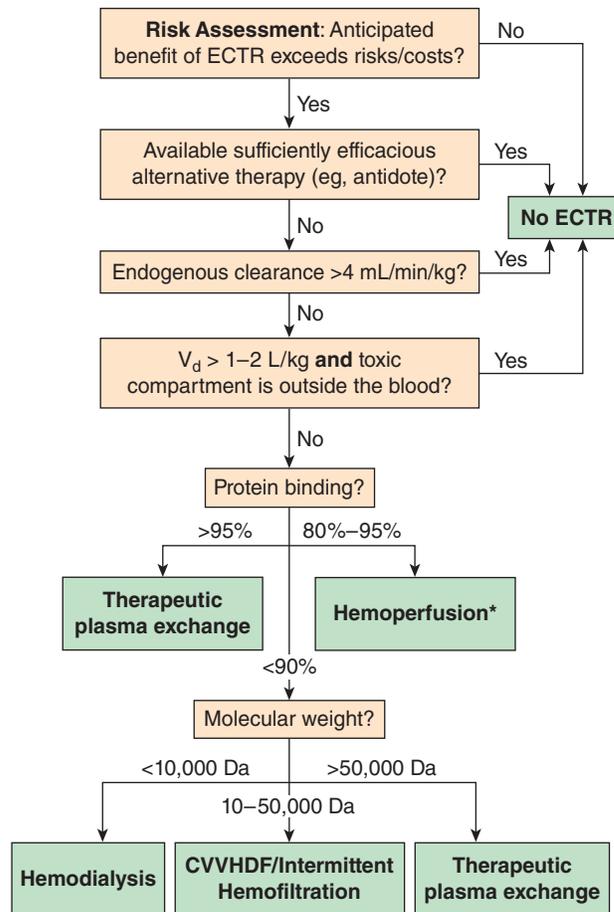

Plasmapheresis and exchange transfusion are intended to eliminate xenobiotics that are either extremely large (>100,000 Da, typified by immunoglobulins) or extensively protein bound. The xenobiotic to be eliminated should also have limited endogenous metabolism to make pheresis or exchange worthwhile.<sup>30</sup> By removing plasma proteins, both techniques offer the consequent potential benefit of removal of protein-bound xenobiotics such as *Amanita* toxins, thyroxine, vincristine, monoclonal antibodies, or complexes of digoxin and antidigoxin antibodies. However, there is little evidence that either technique affects the clinical course and prognosis of a patient poisoned by any of these or other xenobiotics.

Pheresis is particularly expensive, and both pheresis and exchange transfusion expose the patient to the risks of infection with plasma- or blood-borne diseases. Replacement of the removed plasma during plasmapheresis can be accomplished with fresh-frozen plasma, albumin, or combinations of both. The former is associated with hypersensitivity reactions, such as fever, urticaria, wheezing, and hypotension.

A different setting in which exchange transfusion may be an appropriate technique is in the management of small infants or neonates in whom dialysis or hemoperfusion is often technically difficult or impossible, such as in the neonatal population. In premature neonates, a single volume exchange appeared to alleviate manifestations of aminophylline toxicity.<sup>45</sup> The therapy has been successfully used to treat other pediatric patients with poisonings, including severe salicylism.<sup>40</sup>

### OTHER TECHNIQUES TO ENHANCE ELIMINATION

Further discussions of some of the techniques to enhance elimination that are not discussed here may be found in Special Considerations: SC7 (cerebrospinal fluid drainage and replacement), Antidotes in Depth: A22 (toxin-specific antibodies), and Chap. 93 (chelation). All of these techniques have

**FIGURE 6-4.** Clinical approach to consideration of using an extracorporeal treatment (ECTR) in poisoning situation. This assessment requires analysis of the patient's condition, the specific xenobiotic, alternative treatments, molecular and toxicokinetic characteristics, and available modalities. \* If the xenobiotic is adsorbed to activated charcoal, hemoperfusion is preferred, it not then evaluate based on molecular weight.

limited and very specific indications. A summarized approach to the use of ECTRs is shown in Fig. 6-4.

### TOXICOLOGY OF HEMODIALYSIS

Unlike patients who receive acute hemodialysis once or twice in the management of poisoning, patients with chronic kidney failure are repeatedly exposed to large volumes of water derived from municipal reservoirs during the course of their hemodialysis treatments. If an "average" regimen consists of three treatments of 4 hours each week, with dialysate flows of 800 mL/min, patients will be exposed to nearly 600 L of water separated from them only by a semipermeable membrane designed to allow solute passage in either direction. Problems with dialysate generation therefore have the potential to be lethal to this population by exposing them to significant quantities of toxins. There are two potential sources of dialysate contamination: the municipal reservoirs and water treatment plants and the dialysis unit.<sup>48</sup>

Contamination of dialysate from the municipal water supply may occur as a result of xenobiotic runoff into reservoirs or as a result of inadvertent or intentional addition of a chemical by the municipality. Chlorine and chloramine are frequently added to municipal water supplies to control bacterial populations. However, chlorine may combine with nitrogenous compounds and form chloramine, which causes nausea, vomiting, methemoglobinemia, and hemolytic anemia.<sup>57</sup> Chloramine has been blamed for decreased bone marrow sensitivity to erythropoietin. Aluminum is present in some municipal water supplies, and before it was recognized as a problem, aluminum led to encephalopathy characterized by seizures, myoclonus, and dementia, as well as osteomalacia and microcytic anemia.

Water from the municipal supply may be treated with a variety of ways. It firsts enter the dialysis unit and is treated with a water softener to remove calcium and magnesium. It is then run through an activated charcoal bed to adsorb chloramine. The potential toxicity (hemolysis and death) from this compound has caused the Association for the Advancement of Medical Instrumentation (AAMI), which sets the standards for performance of dialysis, to mandate a redundancy in the carbon beds; when the active sites in one carbon bed are exhausted, a second will ensure that no toxicity will occur. Most commonly, water for dialysate is then generated by reverse osmosis, a process that requires that water, in response to applied hydrostatic pressure (and against the osmotic gradient), cross a membrane that is relatively impermeable to solutes, leaving them behind. Alternatively, but less commonly, water can also be purified using deionization, a technique that runs water over an exchange resin, releasing hydroxyl ions in exchange for charged species in the water.

Current requirements are that water be highly purified but not sterile, because bacteria cannot cross from the dialysate into the blood. However, small quantities of endotoxin (molecular weight, 5–15,000 Da) can cross, particularly in situations that include the use of high-flux membranes. Endotoxin is suspected of contributing to activation of circulating cytokines, malnutrition, fever, and other syndromes such as carpal tunnel syndrome, which are associated with chronic inflammation. Recommendations for the frequency of testing for endotoxin and the maximum amounts of endotoxin tolerated are established by the AAMI and are continually debated and continue to become more stringent. Water contamination should especially be suspected when multiple dialysis patients experience similar symptoms nearly simultaneously. General water chemistry and microbiology testing is mandated at regular intervals. Defects in any aspect of the hemodialysis apparatus with insufficient control and monitoring may lead to catastrophic outbreaks in dialysis units.<sup>5</sup> Similarly, nationwide aluminum contamination of dialysates for PD has been reported.<sup>34</sup>

## SUMMARY

- Urinary alkalinization and many of the other techniques listed in Table 6–1 can be instituted quickly in the emergency department.
- The extracorporeal methods of xenobiotic removal, including hemodialysis, hemoperfusion, and continuous renal replacement therapies, all require consultation with a nephrologist, intensivist, or both.
- Timely use of these techniques requires mobilization of a competent team and preparation of the requisite equipment.
- Rapid identification of a toxic exposure for which these techniques are appropriate and the presence of more ominous prognostic features should lead to prompt notification of the appropriate consult services so that application of these techniques can proceed in an expeditious manner.
- The applicability of these techniques to new xenobiotics should be considered based on the principles discussed so that these and newer treatment modalities are not used indiscriminately.
- The literature regarding these techniques in general, and for the treatment of specific xenobiotic exposures in particular, should be read critically and with appropriate skepticism.

# LABORATORY PRINCIPLES

Ami M. Grunbaum and Petrie M. Rainey

Clinical toxicology addresses the harm caused by acute and chronic exposures to excessive amounts of a xenobiotic. Detecting the presence or measuring the concentration of toxic xenobiotics is the primary activity of the analytical toxicology laboratory. Such testing is closely intertwined with therapeutic drug monitoring (TDM), in which drug concentrations are measured as an aid to optimizing drug dosing regimens. Another offshoot of laboratory toxicology that has become increasingly requested is testing for drugs of abuse.

The goal of the hospital toxicology laboratory is to provide clinically relevant test results to support the management of poisoned or intoxicated patients.

To be of optimal clinical value, the laboratory service requires both an appropriate test menu that meets quality criteria, as well as the ability to provide results within a clinically relevant time frame.

## RECOMMENDATIONS FOR ROUTINELY AVAILABLE TOXICOLOGY TESTS

Despite a common focus, there is remarkable variability in the range of tests offered by clinical toxicologic laboratories. Test menus range from batched testing for routinely monitored drugs and common drugs of abuse to around-the-clock availability of a broad arsenal of assays with the potential to identify thousands of compounds. For most laboratories, it would be entirely impractical and inefficient to attempt to provide a full range of analyses in real-time because of cost constraints, staffing issues, and the required technical expertise.

Decisions on the test menu and turn-around times (TATs) to be offered should be made by the laboratory director in consultation with the medical toxicologists and other clinicians who will use the service. They should take into account regional patterns of the use of both licit and illicit xenobiotics and exposure to environmental xenobiotics as well as the available resources and competing priorities.

The essential questions that need to be addressed include:

1. Which tests should be available?
2. Do the assays require qualitative or quantitative results?
3. What specimen matrices will be tested (eg, blood, urine, other body fluid)?
4. When and how should the specimen be obtained?
5. What is the acceptable TAT?

From a consensus process that involved clinical biochemists, medical toxicologists, forensic toxicologists, and emergency physicians, the National Academy of Clinical Biochemists (NACB) recommended that hospital laboratories provide a two-tiered approach to toxicology testing.<sup>27</sup> In the United Kingdom, the National Poisons Information Service and the Association of Clinical Biochemists recommend a nearly identical list of tests, omitting the anticonvulsants.<sup>21</sup>

Tier 1 (Table 7-1) includes basic tests that should be offered locally because of their clinical relevance and the technical feasibility of rapid TATs. As with all laboratory tests, they should be selectively ordered based on the history, clinical presentation, and other relevant factors and not simply ordered as a general screening panel for all suspected cases of poisoning. The recommended TATs for most of the tests listed was 1 hour or less.

Unfortunately, on-site testing for the toxic alcohols is often difficult because of the complexity of their chromatography-based methodologies. As a compromise, a TAT of 2 to 4 hours was deemed acceptable. Another option is to calculate the serum osmolar gap (see later), which provides some important clinical information regarding the toxic alcohols.

TABLE 7-1 Tier-1 (Basic) Toxicology Assays

Quantitative Serum Assays	Qualitative Urine Assays
Acetaminophen	Amphetamines
Alcohols (ethanol, methanol, ethylene glycol)	Barbiturates
Carbamazepine	Cocaine
Cooximetry (carboxyhemoglobin, methemoglobin, oxygen saturation)	Opiates
Digoxin	Phencyclidine
Iron (plus transferrin or iron-binding capacity)	Tricyclic antidepressants
Lithium	
Phenobarbital (if urine barbiturates positive)	
Phenytoin	
Salicylates	
Theophylline	
Valproic acid	

Data from Wu AH, McKay C, Broussard LA, et al: National academy of clinical biochemistry laboratory medicine practice guidelines: recommendations for the use of laboratory tests to support poisoned patients who present to the emergency department. *Clin Chem*. 2003 Mar;49(3):357-379.

Although the consensus for the menu of serum assays was generally excellent, there was less agreement as to the need for qualitative urine assays. This was largely a result of issues of poor sensitivity and specificity, poor correlation with clinical effects, and infrequent alteration of patient management. Although these were potential issues for all of the urine drug tests, they led to explicit omission of tests for tetrahydrocannabinol (THC) and benzodiazepines from the recommended list despite their widespread use. The results for THC have little value in managing patients with acute clinical concerns, and tests for benzodiazepines have an inadequate spectrum of detection. Testing for amphetamines, propoxyphene, and phencyclidine (PCP) is only recommended in areas where use is prevalent. It is also suggested that the diagnosis of tricyclic antidepressant (TCA) toxicity not be based solely on the results of a urine screening immunoassay because a number of other drugs cross-react. The significance of TCA results should always be correlated with electrocardiographic and clinical findings. The only urine test included in the United Kingdom guidelines was a spot test for paraquat.<sup>21</sup> Paraquat testing was omitted in the NACB guidelines because of a very low incidence of paraquat exposure in North America.<sup>27</sup>

The NACB guidelines also recommend additional tier 2 testing in selected patients whose clinical presentations are compatible with poisoning but remain undiagnosed and are not improving. In general, such testing should not be ordered until the patient is stabilized and input is obtained from a medical toxicologist or poison control center. This second level of testing may be provided directly by referral to a reference laboratory or a regional toxicology center. Such a system has the advantages of avoiding costly duplication of services and providing a pooled workload to enable the development of technical expertise for complex, low-volume methodologies.

Many physicians order a broad-spectrum toxicology panel, or a “tox screen” for a poisoned or overdosed patient if one is readily available, but only 7 % of clinical laboratories provide relatively comprehensive urine toxicology testing (as estimated from proficiency testing data).<sup>6</sup> Although broad-spectrum toxicology screens can identify many xenobiotics present in poisoned or overdosed patients, the results of broad-spectrum screens infrequently have altered management or outcomes.<sup>4,14,15</sup>

The extent to which the NACB recommendations are being followed may be estimated from the numbers of laboratories participating in various types of proficiency testing. Result summaries from the 2017 series of proficiency surveys administered by the College of American Pathologists suggest that among laboratories that offer routine clinical testing, only about 40% offer quantitative assays for lithium, phenobarbital and theophylline; 50% to 60% offer assays for acetaminophen (APAP), carbamazepine, carboxyhemoglobin, methemoglobin, ethanol, salicylates, and valproic acid; 60% to 70% offer digoxin, iron, and transferrin or iron-binding capacity; and 70% to 80% offer screening tests for drugs of abuse in urine.<sup>6</sup>

About 7% of laboratories participated in proficiency testing for a full range of toxicology services. These full-service laboratories typically offer quantitative assays for additional therapeutic drugs, particularly TCAs, as well as assays that are designated as broad-spectrum or comprehensive toxicology screens. About 7% of laboratories participated in proficiency testing for a full range of toxicology services. These full-service laboratories typically offer quantitative assays for additional therapeutic drugs, particularly TCAs, as well as assays that are designated as broad-spectrum or comprehensive toxicology screens. Only about 2% of laboratories offer testing for volatile alcohols other than ethanol; most of these also offer testing for ethylene glycol.<sup>6</sup>

Although relatively few laboratories offer a wide range of in-house testing, most laboratories offer a limited toxicology panel and send out specimens to reference laboratories that offer large toxicology menus. The TAT for such “send-out” tests ranges from a few hours to several days, depending on the proximity of the reference laboratory and the type of test requested.

Even in full-service toxicology laboratories, the test menus vary substantially from institution to institution. Larger laboratories typically offer one or more broad-spectrum test panels, often referred to as “tox screens.” There is as much variety in the range of xenobiotics detected by various toxicologic screens as there is in the total menu of toxicologic tests. Routinely available tests are usually listed in a printed or online laboratory manual. Some laboratories with comprehensive services offer locally developed chromatographic assays for additional xenobiotics that are not listed. Testing that is sent to a reference laboratory is often not listed in the laboratory manual. The best way to determine if a particular xenobiotic can be detected or quantitated is to ask the director or supervisor of the toxicology or clinical chemistry section because laboratory clerical staff are likely only to be aware of tests listed in the manual.

## USING THE TOXICOLOGY LABORATORY

There are many reasons for toxicologic testing. The most common function is to confirm or exclude suspected toxic exposures. A laboratory result provides a level of confidence not readily obtained otherwise and may avert other unproductive diagnostic investigations driven by the desire for completeness and medical certainty. Testing increased diagnostic certainty in more than half of cases,<sup>1,15</sup> and in some instances, a diagnosis is based primarily on the results of testing. This can be particularly important in poisonings or overdoses with xenobiotics having a delayed onset of clinical toxicity, such as APAP, or in patients exposed to multiple xenobiotics. In these instances, characteristic clinical findings typically have not developed at the time of presentation or are obscured or altered by the effects of coingestants.

Testing provides two key parameters that will have a major impact on the clinical course, namely, the xenobiotic involved and the intensity of the exposure. This information can assist in triage decisions and can facilitate management decisions, such as the use of specific antidotes or interventions to hasten elimination. Well-defined exposure information can also facilitate provision of optimum advice by poison control centers. Finally, positive findings for ethanol or drugs of abuse in trauma patients should serve as an indication for substance use intervention as well as a risk marker for the likelihood of future trauma.<sup>15</sup>

Laboratory support of a clinical diagnosis of poisoning provides important feedback, enabling the clinical team to confirm a suspected diagnosis. Another important benefit is reassurance that an unintentional ingestion did not result in absorption of a toxic amount of xenobiotic. This reassurance

allows physicians to avoid spending excessive time with patients who are relatively stable. It also allows admissions and discharges to be made and interventions to be undertaken more confidently and efficiently than would be likely based solely on a clinical diagnosis. Testing is also indicated for medicolegal reasons to establish a diagnosis “beyond a reasonable doubt.”

Unfortunately, clinicians are often unaware of the capabilities and limitations of their laboratory. A survey of emergency physicians found that more than 75% were not fully aware of the range of drugs detected and not detected by the toxicology screen of their laboratory. The majority believed that the screen was more comprehensive than it actually was.<sup>12</sup>

The key to optimal use of the toxicology laboratory is communication. This begins with learning the capabilities of the laboratory, including the xenobiotics on its menus, which can be quantitated and which merely detected, and the anticipated TATs. For screening assays, one should know which xenobiotics are routinely detected, which ones can be detected if specifically requested, and which ones cannot be detected even when present at concentrations that typically result in toxicity.

One should know the specimen type that is appropriate for the test requested. A general rule is that quantitative tests require serum (red stopper) or heparinized plasma (green stopper) but not ethylenediamine tetraacetic acid (EDTA) plasma (lavender stopper) or citrate plasma (light-blue stopper). Both EDTA and citrate bind divalent cations that serve as cofactors for enzymes used as reagents or labels in various assays. Additionally, liquid EDTA and citrate anticoagulants dilute the specimen. Serum or plasma separator tubes (gold or green stoppers with a separator gel at the bottom of the tube) are also acceptable, provided that prolonged gel contact before testing is avoided. Some hydrophobic drugs diffuse slowly into the gel, leading to falsely low results after several hours. A random, clean urine specimen is generally preferred for toxicology screens because the higher drug concentrations usually found in urine can compensate for the lower sensitivity of the broadly focused screening techniques. However, it should be emphasized that urine testing typically provides qualitative information and generally does not indicate the degree of clinical toxicity. The concentrations of xenobiotics and their metabolites are dramatically affected by the hydration status and underlying kidney function of the patient. A urine specimen of 20 mL is usually optimal. Requirements for all specimens vary from laboratory to laboratory.

When requesting a screening test, an important—and often overlooked—item of communication is specifying any xenobiotics of particular concern. This often enables faster results and a greater likelihood of detection. It is also important to provide sufficient clinical information, including the times and dates of suspected exposure and of specimen collection.

Most full-service toxicology laboratories welcome consultation on difficult cases or results that appear inconsistent with the clinical presentation. The laboratory will be familiar with the capabilities and limitations of their testing methods, as well as common sources of discrepant results. For example, they are aware of coadministered drugs or xenobiotics that interfere either positively or negatively with laboratory measurements.

## METHODS USED IN THE TOXICOLOGY LABORATORY

Most tests in the toxicology laboratory are directed toward the identification or quantitation of xenobiotics. The primary techniques used include spot tests, spectrochemical tests, immunoassays, and chromatographic techniques. Mass spectrometry (MS) is also used, usually in conjunction with gas chromatography (GS) or liquid chromatography (LC). [Table 7–2](#) compares the basic features of these methodologies. Other methodologies include ion-selective electrode measurements of lithium, atomic absorption spectroscopy or inductively coupled plasma mass spectroscopy for lithium and heavy metals, and anodic stripping methods for heavy metals. Many adjunctive tests, including glucose, creatinine, electrolytes, osmolality, metabolic products, and enzyme activities, are also useful in the management of poisoned or overdosed patients. The focus here is on the major methods used for directly measuring xenobiotics.

TABLE 7-2 Relative Comparison of Toxicology Methods

Method	Sensitivity	Specificity	Quantitation	Analyte Range	Speed	Cost
Spot test	+	±	No	Few	Fast	\$
Spectrochemical	+	+	Yes	Few	Medium	\$
Immunoassay	++	++	Yes	Moderate	Variable	\$\$
TLC	+	++	No	Broad	Slow	\$\$
HPLC	++	++	Yes	Broad	Medium	\$\$
GC	++	++	Yes	Broad	Medium	\$\$
GC/MS	+++	+++	Yes	Broad	Slow	\$\$\$
LC/MS/MS	+++	+++	Yes	Broad	Medium	\$\$\$\$

\$ = very low cost; \$\$\$\$ = very high cost; GC = gas chromatography; GC/MS = gas chromatography/mass spectroscopy; HPLC = high-performance liquid chromatography; LC/MS/MS = liquid chromatography/tandem mass spectroscopy; TLC = thin-layer chromatography. Sensitivity and specificity - High (+++); Low (+)

### Spot Tests

These are simple, noninstrumental, qualitative assays that rely on a rapid reaction between a xenobiotic and a chemical reagent to form a colored product. A classic example is the Trinder test for salicylates, in which salicylate is complexed with ferric ions to produce a violet-colored product.<sup>2</sup> Although once a mainstay of toxicologic testing, spot tests are rarely used today because of the significant variability in visual interpretation. However, the fundamental chemical reactions used in the tests are often used in modern quantitative methods.

### Optical (Spectrophotometric) Tests

Spectrophotometry involves the measurement of light intensity at selected wavelengths. The method depends on the light-absorbing properties of a substance in solution. The intensity of transmitted light passing through the solution decreases in proportion to the concentration of the substance. The transmitted light is then measured and related to the concentration of the analyte.

Analytes that are intrinsically light absorbing are measured by *direct spectrometry*. An example of this is cooximetry for the measurement of hemoglobin and its variants in a whole blood sample. Because the absorbance of hemoglobin is altered by its oxidative state, measurements at multiple wavelengths are used to individually quantify the amounts of deoxyhemoglobin, oxyhemoglobin, carboxyhemoglobin, and methemoglobin. Classic pulse oximetry, which uses only two wavelengths, yields spurious results in the presence of significant amounts of methemoglobin or carboxyhemoglobin. Cooximetry is relatively free of interferences because the concentrations of the hemoglobins are so much higher than other substances in the blood. However, the presence of intensely colored substances such as methylene blue, hydroxocobalamin or unexpected hemoglobin species such as sulfhemoglobin cause spurious results or error flags.

Most analytes in physiologically relevant concentrations do not absorb enough light at a distinct wavelength or are not present at high enough concentrations to be measured by direct spectrometry. *Spectrochemical* methods use chemical reactions to produce intensely colored compounds that absorb light at specific wavelengths. The Trinder test described earlier is one early example. The difference between the spot test and the more advanced spectrochemical test versions is the degree of automation involved, and the spectrophotometer detector used to quantify the concentration of the colored product. The ultimate limitation of the Trinder test is its lack of specificity; a variety of both endogenous and exogenous compounds cross-react with the ferric reagents, yielding a large number of false positives.

*Indirect spectrochemistry* improves on the selectivity of the spectrochemical assays by increasing the selectivity of the reaction that generates the light-absorbing product. Enzymes that catalyze highly selective reactions are often used for this purpose. For example, many ethanol assays are based

on an indirect spectrochemical method that uses alcohol dehydrogenase to specifically catalyze the oxidation of ethanol to acetaldehyde with the concomitant reduction of the cofactor NAD<sup>+</sup> (oxidized nicotinamide adenine dinucleotide) into reduced NADH. The generation of NADH is spectrophotometrically monitored by the increase in absorbance at 340 nm. Reactions leading to the conversion of NAD<sup>+</sup> to NADH or vice versa are very common in the clinical laboratory.

In spectrochemical assays, light absorbance is measured after the completion of the reaction (endpoint method) or by making multiple measurements during the reaction to determine the rate of reaction (kinetic method). The initial rate of reaction is constant and proportional to the concentration of the analyte. Kinetic methods are typically faster and less sensitive to interference from other light-absorbing substances because their absorbance is constant and does not affect the measured rate. Kinetic methods are more complex and require precise timing.

Although enzymatic methods are more specific, they are not free of interferences from cross-reacting substrates. For example, some lactate assays use the enzyme lactate oxidase, which also accepts glycolic acid as a substrate. Consequently, patients who have high glycolate concentrations from metabolism of ingested ethylene glycol may have falsely elevated lactate measurements. Likewise, because endogenous lactate dehydrogenase can oxidize lactate to pyruvate with concomitant reduction of NAD<sup>+</sup> to NADH, patients with high serum lactate concentrations can convert NAD<sup>+</sup> to NADH via this pathway, leading to falsely increased results in assays based on NADH production.

### Determination of Volatiles by Serum Osmol Gap

As mentioned earlier, because of their significant toxicity and the availability of an effective antidote such as fomepizole for methanol and ethylene glycol poisonings, their measurements are considered to be tier 1 tests. However, on-site availability is often limited. One possible alternative measure in such overdoses of toxic alcohols is the serum osmol gap, derived from the measured serum osmolality and calculated serum osmolality:

$$\text{Osmol gap (mOsm/kg)} = \text{Measured serum osmolality} - \text{Calculated serum osmolality}$$

where

$$\text{Calculated serum osmolality} = 2 \times \text{Na (mmol/L)} + \text{Glucose (mg/dL)}/18 + \text{BUN (mg/dL)}/2.8$$

$$\text{or} = 2 \times \text{Na (mmol/L)} + \text{Glucose (mmol/L)} + \text{BUN (mmol/L)}$$

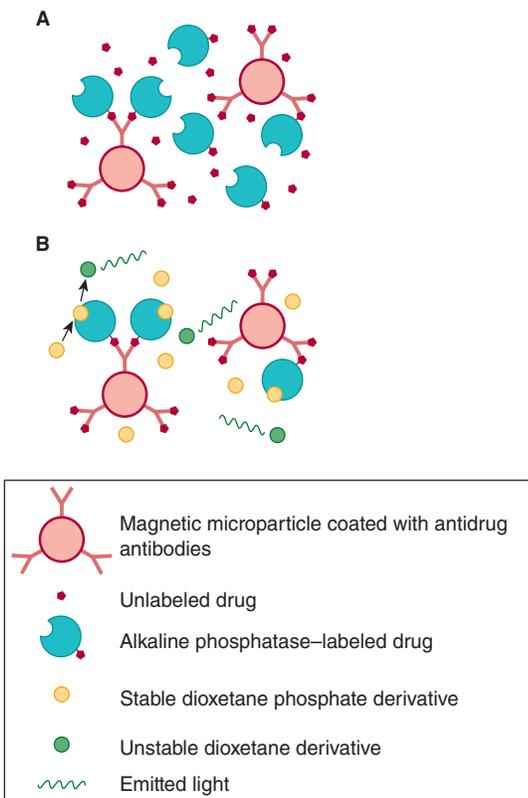

Normally, the osmol gap is less than  $-2 \pm 6$ . Alcohols and acetone, when present at significant concentrations, increase the measured osmolality and would increase the osmol gap. An important caveat is that both measured osmolality and calculated osmolality should be obtained from the same

serum sample, and because of the volatile nature of these substances, the serum osmolality should be analyzed expeditiously by a freezing point depression osmometer. Furthermore, other substances that may be administered (eg, mannitol for osmotic diuresis or propylene glycol as a solvent for diazepam or phenytoin) also increase serum osmolality (Chap. 12).<sup>2</sup>

### Immunoassays

The need to measure very low concentrations of an analyte with a high degree of specificity led to the development of immunoassays. The combination of high affinity and high selectivity makes antibodies excellent assay reagents. There are two common types of immunoassays: noncompetitive and competitive. In noncompetitive immunoassays, the analyte is sandwiched between two antibodies, each of which recognizes a different epitope on the analyte. In competitive immunoassays, analyte from the patient's specimen competes for a limited number of antibody binding sites with a known amount of a labeled version of the analyte provided in the reaction mixture. Because most xenobiotics are too small to have two distinct antibody binding sites, drug immunoassays are usually competitive.

Competitive immunoassays can either be heterogeneous or homogenous. An early example of the heterogeneous immunoassay was the radioimmunoassay (RIA). In this technique, the patient sample and radiolabeled antigen are added to a solution containing antibody fixed to a surface, such as the wall of a tube or beads, and compete for binding. A subsequent wash step removes any unbound radiolabel before the tube or beads are placed in a counter to measure the remaining radioactivity, which is inversely proportional to the amount of xenobiotic in the patient sample. Modern heterogeneous assays (Fig. 7-1) have largely replaced radioactive labels

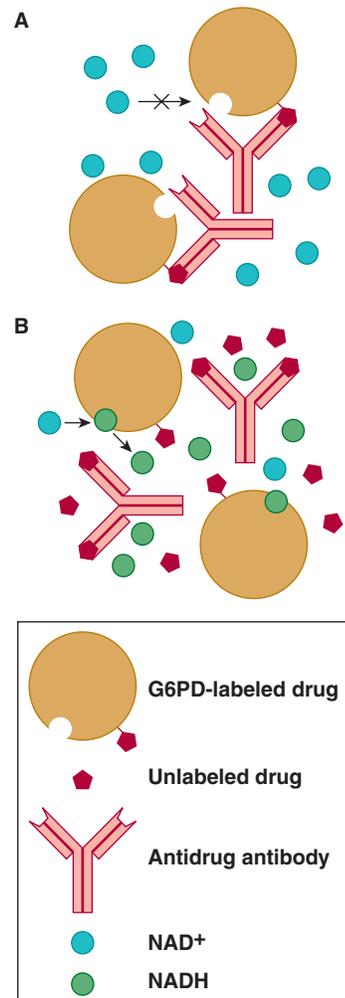

**FIGURE 7-1.** Magnetic microparticle chemiluminescent competitive immunoassay. **(A)** Unlabeled drug from the specimen competes with alkaline phosphatase-labeled drug for binding to antibody-coated magnetic microparticles. The microparticles are then held by a magnetic field while unbound material is washed away. **(B)** A dioxetane phosphate derivative is added and is dephosphorylated by microparticle-bound alkaline phosphatase to give an unstable dioxetane product that spontaneously decomposes with emission of light. The rate of light production is directly proportional to the amount of alkaline phosphatase bound to the microparticles and inversely proportional to the concentration of competing unlabeled drug from the specimen.

with fluorescent or luminescent moieties, often activated by an enzymatic reaction. The fixed surfaces have also been updated to microbeads with very large surface areas. These improvements have enabled methods with faster assay times than previously and higher sensitivities than attainable by homogenous assays.

Homogenous immunoassays are among the most widely used methods. In these techniques, the signal generated by the labeled moiety is modified by binding to the assay antibody. This negates the need to physically separate or wash out the unbound labels. Avoiding the separation step simplifies the methodology and facilitates automation. Commonly used homogenous techniques include the enzyme multiplied immunoassay technique (EMIT) and the cloned enzyme donor immunoassay (CEDIA).<sup>2</sup>

In the EMIT technique (Fig. 7-2), an enzyme-analyte conjugate is used as the label and competes with unlabeled substrate from the patient sample. If antibody binds to the labeled analyte, it blocks the active site and reduces the activity of the enzyme. Unlabeled substrate from the patient's specimen will displace the enzyme from the antibody and increase its activity in proportion to its concentration.

In the CEDIA technique, two complementary yet inactive fragments of a reporting enzyme are genetically engineered, in which one fragment is linked

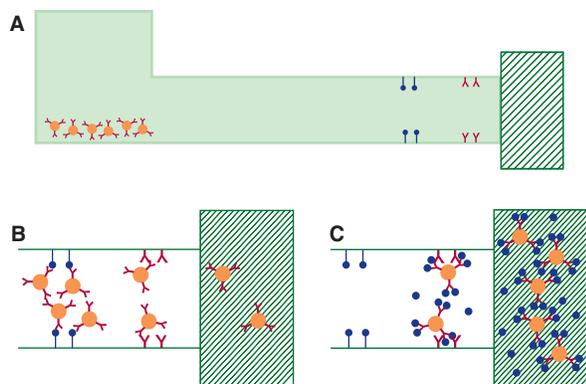

**FIGURE 7-2.** Enzyme multiplied immunoassay technique. The drug to be measured is labeled by being attached to the enzyme glucose-6-phosphate dehydrogenase (G6PD) near the active site. **(A)** Binding of the enzyme-labeled drug to the assay antibody blocks the active site, inhibiting conversion of NAD<sup>+</sup> (oxidized form of nicotinamide adenine dinucleotide) to NADH (reduced form of nicotinamide adenine dinucleotide). **(B)** Unlabeled drug from the specimen can displace the drug-enzyme conjugate from the antibody, thereby unblocking the active site and increasing the rate of reaction.

to the target drug. These two fragments spontaneously reassemble into the active enzyme in solution. However, in the absence of substrate from patient's specimen, assay antibody will prevent formation of the active enzyme.

Both EMIT and CEDIA assays are used for quantitative TDM in blood and for qualitative screening of drugs of abuse in urine. Microparticle capture assays are a type of qualitative competitive immunoassay that have become very popular, especially for urine drug screening tests. The use of either colored latex or colloidal gold microparticles enables the result to be read visually as the presence or absence of a colored band, with no special instrumentation required. Competitive binding occurs as the assay mixture is drawn by capillary action through a porous membrane. This design feature is responsible for the alternate names of the technique: lateral flow immunoassay or immunochromatography.

The simplest microparticle capture design uses an antidrug antibody bound to colored microparticles and a capture zone consisting of immobilized drug (Fig. 7-3). If the specimen is xenobiotic free, the beads will bind to the immobilized analyte, forming a colored band. When the amount of xenobiotic in the patient specimen exceeds the detection limit, all of the antibody sites will be occupied by xenobiotic from the specimen, and no labeled antibody will be retained in the capture zone. The use of multiple antibodies and discrete capture zones with different immobilized analytes can allow several xenobiotics to be detected with a single device.

Although immunoassays have a high degree of sensitivity and selectivity, they are also subject to interferences and problems with cross-reactivity. Cross-reactivity refers to the ability of the assay antibody to bind to xenobiotics other than the target analyte. Xenobiotics with similar chemical structures may be efficiently bound, which can lead to falsely elevated results. In some situations, cross-reactivity can be beneficially exploited. For example, some immunoassays effectively detect classes of xenobiotics rather than one specific xenobiotic. Immunoassays for opioids use antibodies to morphine that cross-react to varying degrees with structurally related substances, including codeine, hydrocodone, and hydromorphone. Oxycodone typically has low cross-reactivity, and higher concentrations are required to give a positive result. The cross-reactivity of nonmorphine opiates varies with manufacturer. It is recommended that clinicians consult directly with their

**FIGURE 7-3.** Microparticle capture immunoassay. (A) Diagram of a device before specimen addition. Colored microbeads (about the size of red blood cells) coated with antidrug antibodies (Y) are in the specimen well. At the far end of a porous strip are capture zones with immobilized drug molecules (•) and a control zone with antibodies recognizing the antibodies that coat the microbeads. (B) Adding the urine specimen suspends the microbeads, which are drawn by capillary action through the porous strip and into an absorbent reservoir (hatched area) at the far end of the strip. In the absence of drug in the urine, the antibodies will bind the beads to the capture zone containing the immobilized drug and form a colored band. Excess beads will be bound by antibody-antibody interactions in the control zone, forming a second colored band that verifies the integrity of the antibodies in the device. (C) If the urine contains the drug (•) in concentrations exceeding the detection limit, all of the antibodies on the microbeads will be occupied by drug from the specimen, and the microbeads will not be retained by the immobilized drug in the capture zone. No colored band will form. However, the beads will be bound and form a band in the control zone.

laboratory for the relative sensitivities of the immunoassay used. Structurally unrelated synthetic opioids, such as meperidine and methadone, have little or no cross-reactivity and are not detected by opiate immunoassays. Immunoassays for the benzodiazepine class react with a wide variety of benzodiazepines but with varying degrees of sensitivity.<sup>14,16</sup> Because of the highly variable response of immunoassays to the various opiates and benzodiazepines, methods based on MS should be used for definitive results.

Cross-reactivity also leads to interferences between xenobiotics of similar structure. Assays for the TCA family have similar reactivity with amitriptyline, nortriptyline, imipramine, and desipramine and can be used to provide an estimate of the total concentration of any combination of these xenobiotics. However, a large number of other xenobiotics with tricyclic structures, including carbamazepine, many phenothiazines, and diphenhydramine, also cross-react and generate a signal, particularly at concentrations found in patients who are poisoned or overdosed.

Even when an antibody is selected to be specific to a single xenobiotic, it is common that metabolites of the target xenobiotic show some cross-reactivity. This cross-reactivity can lead to difficulties in interpretation because both active and inactive metabolites are measured, and not necessarily with similar sensitivities as the target xenobiotic.

Immunoassays are also subject to interference by xenobiotics that impair detection of the label. Elevated lactate concentrations often lead to spuriously increased xenobiotic concentrations in specimens tested by EMIT, as described earlier. Immunoassays that rely on enzyme labels are particularly sensitive to nonspecific interference because enzyme activity is highly dependent on reaction conditions. A number of substances that can inhibit the enzyme reaction in EMIT assays are used to adulterate urine submitted for drug abuse testing with the intent of producing false-negative results (see the later discussion of screening for drugs of abuse).

## Chromatography

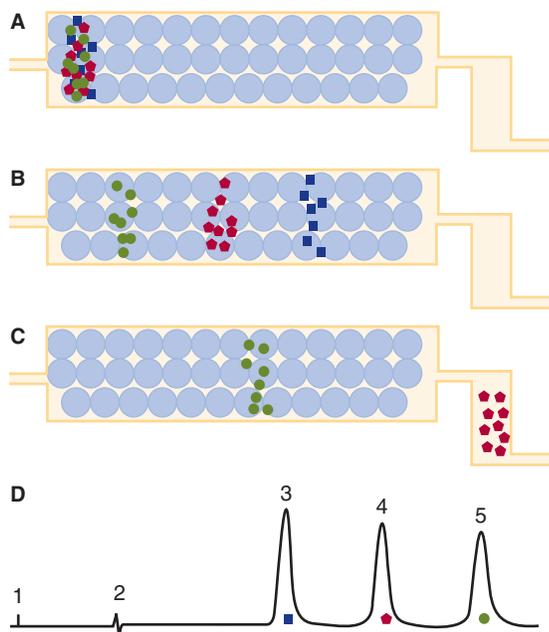

Essentially, chromatography is a separation method by which a complex mixture (eg, a biological fluid) is physically separated into its individual components. The fundamental principle of the methodology is the differential partitioning of a mixture between stationary and mobile phases. During the process, the mobile phase carries the mixture (sample) through a stationary phase. The different components of the sample will have differing affinities for the two phases and will spend more or less time interacting with the stationary phase and will elute at different rates. Under controlled separation conditions, the velocities of the different components in the sample are highly reproducible. A tremendous variety of xenobiotics can be identified based on their characteristic velocities, as measured by the time required to elute from the stationary phase (retention time,  $t_R$ ).

To make clinical specimens compatible with the chromatographic separation requirements, the samples usually undergo an initial "clean-up" process to reduce their salt and protein content and to concentrate the analytes being measured for increased sensitivity. This process also enables an increased resolution of xenobiotics that would have otherwise migrated at similar rates and not been separately identifiable thereby increasing specificity.

Two common methods of clean-up or extraction include liquid-liquid extraction and solid-phase extraction (SPE).<sup>2</sup> The latter has become increasingly popular because it can be commercially prepared and purchased as single-use cartridges or multi-well plates, simplifying sample preparation and assisting automation. Solid-phase extraction is itself a modified chromatographic procedure in which a urine or serum patient specimen passes through a stationary phase that retains the analytes of interest. The retained xenobiotics are then selectively eluted with an organic solvent such as methanol.

Many analytes need to be chemically derivatized either before or after chromatographic separation to increase their ability to be detected. For example, to be detectable by a fluoroscopic detector, primary amines can be labeled with a fluorescamine tag.

There exist many different chromatographic modalities, including simple and inexpensive paper and thin-layer chromatography that are limited to

**FIGURE 7-4.** High-performance liquid chromatography (HPLC). HPLC is schematically shown. (A) A mixture of three compounds (■) (●) (●) is injected into a column filled with a spherical reversed-phase packing. (B) The compounds move through the column at characteristic speeds. The most hydrophilic compound (■) moves most quickly, and the most hydrophobic compound (●) moves most slowly. (C) The compound of intermediate polarity (●) has reached the detection cell, where it absorbs light directed through the cell and generates a signal proportional to its concentration. (D) Illustration of the HPLC tracing that might result: 1 indicates the time of injection. The artifact at 2 results when the injection solvent reaches the detector and indicates the retention time of a completely unretained compound. The peaks at 3, 4, and 5 correspond to the separated compounds. For example, peak 4 might be amitriptyline, peak 3 might be the more polar metabolite, nortriptyline, and peak 5 could be the more hydrophobic internal standard *N*-ethylnortriptyline. Later-emerging peaks are typically wider and shorter because of more time for diffusive forces to spread out the molecules.

qualitative measures of analytes present in high concentrations. Liquid chromatography and GC are columnar techniques that require more technical expertise but permit identification and quantification of a large variety of xenobiotics with low limits of detection.

In **high-performance liquid chromatography (HPLC)**, a column is packed with solid particles that support a thin, liquid stationary phase. The mobile phase containing the specimen is pumped through under high pressure, and separation occurs between the two phases (Fig. 7-4). Smaller particles can be packed more densely, increasing the surface area of separation with improved column efficiency and resolution but at the expense of increased resistance to flow, requiring higher pumping pressures. Using high pressures with small particles, good separations can be achieved with relatively short assay times. Several different separation modalities are used in HPLC, including size exclusion, affinity, ion exchange, and partition separation. Xenobiotic assays most commonly use reverse-phase partitioning, in which separation occurs between a stationary nonpolar phase and a relatively polar mobile phase. Hydrophobic compounds are more strongly adsorbed by the stationary phase, and hydrophilic compounds tend to remain in the polar mobile phase. This results in the most hydrophilic xenobiotics eluting first followed by the progressively more hydrophobic xenobiotics. The most common reverse-phase columns use particles coated with octadecyl hydrocarbon chains and are referred to as C-18 columns.

In HPLC, the xenobiotics are detected after they exit the chromatographic column. The detector output is typically plotted as signal intensity versus time (Fig. 7-4D). Identification of the xenobiotics is made by their characteristic retention times and quantification is based on the area under the curve of the corresponding peak. To objectively validate the identity and

quantification of the xenobiotic, a structurally related calibrant (an “internal standard,” shown as peak 5 in Fig. 7-4D) is added to the specimen in known concentrations.

The advantages of HPLC include the ability to separately identify and quantify multiple related xenobiotics and their metabolites (eg, opiates or benzodiazepines) in a single run of the same sample. By comparison, an immunoassay method would provide a single measurement that would either be unable to discriminate between related xenobiotics (lack of specificity) or be unable to identify them altogether (lack of sensitivity).

Disadvantages include relatively expensive instrumentation with complex specimen preparation that requires specialized expertise to design and execute.

**Gas chromatography** is similar in principle to HPLC but uses an inert carrier gas such as helium or nitrogen as the mobile phase pumped through a heated column to which the stationary phase is chemically bonded. The sample is heat vaporized and pumped through the column, and the xenobiotics are detected in the gas stream as they exit the column. The low flow resistance of gas allows very high flow rates and very long columns, enabling extremely high resolution in a short time. Analytes partition between the mobile gas phase and stationary phase based on their intrinsic volatility, which depends on temperature. Volatility can be optimized by adjusting the temperature of the system so that xenobiotics with a wide range of volatility can be analyzed in a single run.

Although the temperature-dependent partitioning and high flow rates of GC systems enable fast measurements and high resolution of multiple xenobiotics, the methodology is limited to analytes such as alcohols that are reasonably volatile at temperatures below 572°F (300°C) above which the stationary phase begins to break down. Another limitation is the limited column capacity, so that highly sensitive detectors are required to measure the small quantities that can be chromatographed.

By itself, chromatography is simply a separation method. It must be combined with a detection method to allow identification and, if desired, quantification of the separated substances. There exist a variety of different detectors, ranging from the extremely simple yet low sensitivity (visual) to the relatively complex with extremely low detection limits (mass spectrometers).

The most common detector used in HPLC assays remains the spectrophotometer. Essentially, spectrophotometry is a measure of intensity of a light beam as a function of its wavelength, the “color.” As concentrations increase, the intensity of transmitted light decreases. The ultraviolet (UV) range is often used for measurements because most organic compounds tend to absorb light at these wavelengths. Whereas fixed-wavelength photometers generate light of a specific wavelength, variable-wavelength photometers can be tuned to operate at the optimal absorbance for a selected analyte. Alternatively, diode arrays can detect multiple wavelengths simultaneously, providing additional spectral information and specificity.

Other detectors that are used in HPLC include fluorometers, electrochemical detectors, and mass spectrometers. Fluorescence occurs when a molecule absorbs light at one wavelength and reemits light at a longer wavelength. Fluorometers use this property to excite and detect fluorescing xenobiotics. Analytes can either be naturally fluorescent or be derivatized with a fluorescent tag. Electrochemical detectors measure the electrical current produced by an electroactive analyte as it undergoes either reduction or oxidation at an electrode surface. These techniques (and MS, which is described later) are extremely sensitive and can detect picogram amounts of analytes.

The most common GC detector is the flame ionization detector (FID). As organic molecules emerge from the GC column, they are mixed with hydrogen and air and are burned by a flame. This creates charged combustion intermediates that can be measured as current. The amount of generated current is proportional to the mass of carbon burnt so that the FID is most sensitive to hydrocarbons, such as alcohols and other xenobiotics that are highly combustible. Nitrogen–phosphorus detectors are also widely used in xenobiotic analysis. In this modification of an FID, an alkali bead is heated above the flame. The presence of alkali atoms in the combusted xenobiotic generates enhanced electron emissions.

## Mass Spectrometry

The chromatographic devices described earlier can detect broad ranges of xenobiotics but do not specifically identify them. The identity of the compounds detected must be inferred from the retention time. The mass spectrometer serves as a highly sensitive detector when paired with a chromatographic system and has the additional advantage of being able to definitively identify compounds by mass analysis. It is considered to be a “universal detector” because all compounds have mass and can, in theory, be detected.

Mass spectrometers determine the molecular weight of ions in vacuum. The basic design of the apparatus can be simplified into three components—the ion source in which the sample molecules are ionized; the mass analyzer in which the ions are separated according to their mass-to-charge ( $m/z$ ) ratio; and the detector, which registers the signals. Important secondary components include a vacuum generator to avoid collisions between the ions generated and ambient air molecules and a computer for data analysis and recording.

### Ion Source

A number of ionization techniques have been developed for MS. The most commonly used techniques for xenobiotic measurements include electron impact (EI) ionization in GC-coupled systems and electrospray ionization (ESI) in HPLC systems.

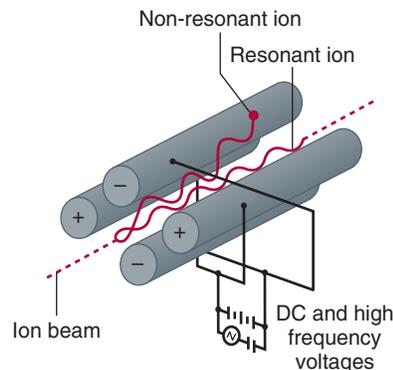

In EI, the gas phase analyte is introduced into the ionization chamber, where it is bombarded by a stream of electrons. Electron impact can dislodge an electron from the analyte, creating a positively charged ion and frequently imparting sufficient energy to the ion to break it into pieces. The ion fragments into which a molecule can break are characteristic properties of the xenobiotic, permitting its identification.

In ESI, an electrical charge is applied to the HPLC effluent entering the ionization chamber, producing a fine mist of charged droplets. As the solvent evaporates and the droplet size decreases, the surface charge increases. The repulsive force of like-charged particles causes further splitting into smaller droplets and eventual release of desolvated ions.<sup>18</sup>

A third MS ionization modality that has a limited role in toxicology is inductively coupled plasma (ICP). Whereas the EI and ESI are “soft” techniques, producing little fragmentation, ICP is the ultimate in “hard” ionization, in which samples are virtually completely atomized during ionization. Consequently, its primary use is for elemental analysis, as in the detection and measurement of trace metals and heavy metals in tissues and body fluids. It is an extremely sensitive technique, able to detect particles on the order of parts per trillion or lower. In ICP, a nebulized liquid sample is introduced into the ionization chamber, where it is injected into a hot argon plasma created by inductively coupling power into the plasma using a high-powered radiofrequency generator, reaching temperatures of approximately 10,000° K.

### Mass Analyzer

Ionic species can be separated according to their  $m/z$  ratios by a variety of techniques, including ion traps, time-of flight instruments, and magnetic sector fields. Quadrupole mass spectrometers are the most common MS instruments found in clinical laboratories (Fig. 7-5).<sup>18</sup> This instrument consists of four parallel electrically conductive rods, which essentially function as a mass filter. Applying direct current (DC) and alternating current (AC) in specific patterns creates an electromagnetic field through which only ions of a very narrow  $m/z$  range can pass to reach the detector. By rapidly and repeatedly scanning through many voltage settings, a range of  $m/z$  ions are sequentially allowed to reach the detector, generating a mass spectrum. The mass spectrum records the  $m/z$  ratios of the pieces produced by the ionic fragmentation of the parent ion, as well as their relative abundance. Fig. 7-6 shows the spectrum obtained from a gas chromatograph (GC-MS) at a time when the TMS derivative of the cocaine metabolite benzoylecgonine (TMS-BE) was emerging from the column. Because benzoylecgonine cannot be volatilized, it must be derivatized to be compatible with GC. The concentration of TMS-BE in the specimen is determined from the ratio of the peak height at  $m/z$  240 to the height of a

**FIGURE 7-5.** Principle of quadrupole analyzer. Four electrically conductive rods are arranged in parallel forming a channel through which the ion beam passes. By applying direct (DC) and alternating (AC) currents, an electromagnetic field is generated that permits only ions of a defined mass-to-charge ( $m/z$ ) range to pass through to reach the mass detector while nonresonant ions are ejected radially. Modified after Manz A, Lossfidis D, Pamme N: Bioanalytical Chemistry. London: Imperial College Press; 2004. Chapter 4 Mass Spectrometry.

peak at  $m/z$  243 that results from a corresponding fragment of the internal standard, TMS-BE labeled with three deuterium atoms (d3-TMS-BE). The specificity of the identification is verified by finding peaks at  $m/z$  256 and  $m/z$  361, with peak height ratios to the peak at  $m/z$  240 comparable to the ratios seen with authentic TMS-BE. The detection at the correct retention time of a xenobiotic producing all three peaks in the correct ratios produces an extremely specific identification.

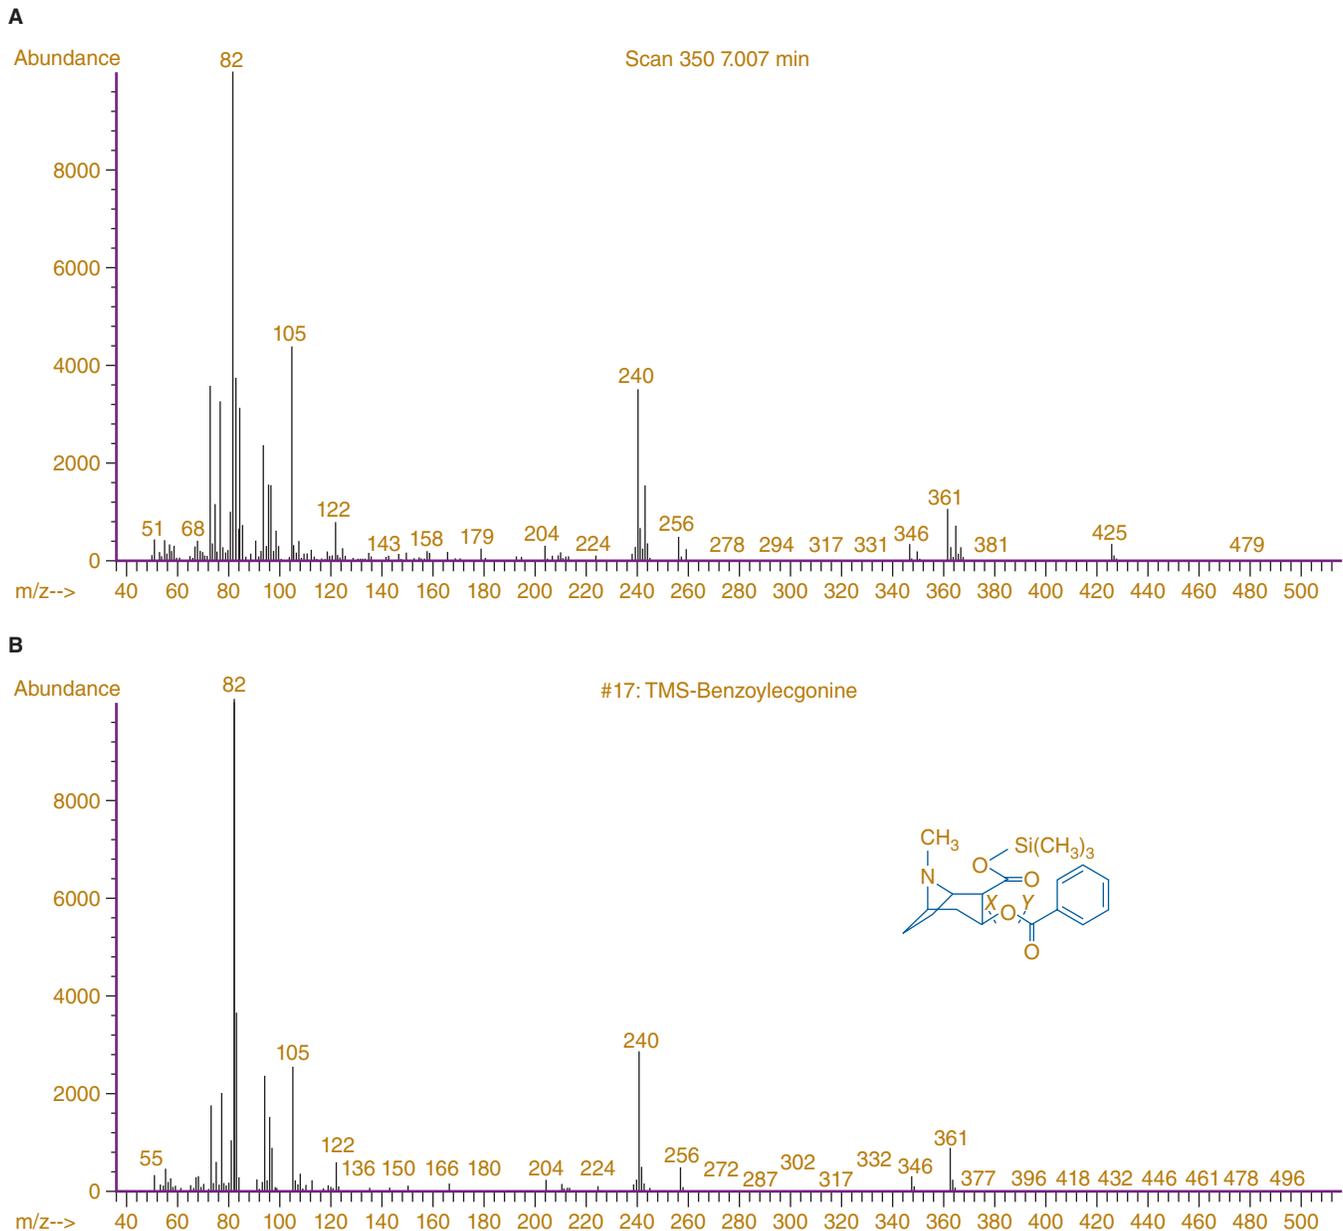

This *scanning mode* can be used for toxicologic screening because its permits identification of many different analytes in a single run. However, because a wide range of  $m/z$  need to be observed, the time spent on any specific value is limited, decreasing analytical sensitivity. Alternatively, when measuring for specific analytes, the analyzer can be set up in *selected ion monitoring (SIM) mode*. In this mode, the quadrupole mass filter is set to filter and detect only a few selected  $m/z$ . In the illustrated example of TMS-BE, the characteristic peaks at  $m/z$  240, 256, and 361 are used, along with one or more of the corresponding peaks from the internal standard.

### Tandem Mass Spectrometry

The high sensitivity and specificity afforded by chromatography/MS is being further improved by the related hybrid technique of liquid chromatography/tandem mass spectrometry (LC/MS/MS) (Fig. 7-7).<sup>19</sup> This technique is used in an increasing number of clinical toxicology laboratories for identification and quantification of suspected xenobiotics. In this setup, the effluent from a LC apparatus enters a soft ionization chamber (eg, ESI) that generates large, singly-charged ionic fragments that are directed into a series of three MS quadrupoles. The first quadrupole (Q1) selectively filters ions of specific  $m/z$ , called the “parent ion.” The second quadrupole (Q2) is filled with inert gas and acts as a collision cell. As the filtered parent ions enter Q2 at high velocity, they collide with the gas molecules and are fragmented into smaller “daughter ions.” These fragments are then introduced into the third quadrupole (Q3) for mass analysis. Characterizing the compounds by three physical properties (the parent and daughter ions masses, along with the chromatographic retention time) affords a high selectivity that dramatically reduces potential interferences.

### Ion Detector

Because relatively few ions make it all the way through the mass spectrometer, the signals must be amplified in order to be measurable. Most MS detectors use electron multipliers for ion amplification and detection, in which ions impact a dynode, generating an electronic current that is amplified through a series of impacts on sequential dynodes before reaching the measuring anode.

**FIGURE 7-6.** Mass spectrum of the trimethylsilyl derivative of benzoyllecgonine (TMS-BE). **(A)** Mass spectrum of effluent from a gas chromatography (GC) column at the retention time of TMS-BE. The unfragmented parent ion of TMS-BE is at a mass-to-charge ( $m/z$ ) ratio of 361. The two fragment peaks at  $m/z$  243 and 259 result from fracture of the bonds at X and Y, respectively, in structure of TMS-BE (inset in **B**). Additional peaks at  $m/z$  243, 259, and 361 are derived from trideuterated TMS-BZE (d3-TMS-BE) added as an internal standard. The mass spectrometer can identify and quantify TMS-BE and d3-TMS-BE independently of one another by measuring the heights of the peaks unique for each compound. The peak at  $m/z$  425 is from a coeluting contaminant. **(B)** Mass spectrum of pure TMS-BE.

## LABORATORY ERRORS

Laboratory testing is a complex process and, consequently, is prone to errors. But what are the sources of these errors? A more informative approach would be to break down the testing process into the preanalytical, analytical, and postanalytical phases. The preanalytical phase can be thought of as the test processing that takes place before the sample is placed on the analyzer, and the postanalytical phase involves the recording and transmission of test results.

Preanalytical errors include sample misidentification, inadequate tube filling, inappropriate containers, hemolysis, and delays in transport. A commonly cited source of analytical error is cross-reactivity with other compounds. Examples of postanalytical errors include erroneous transcription of test results and word misidentification.

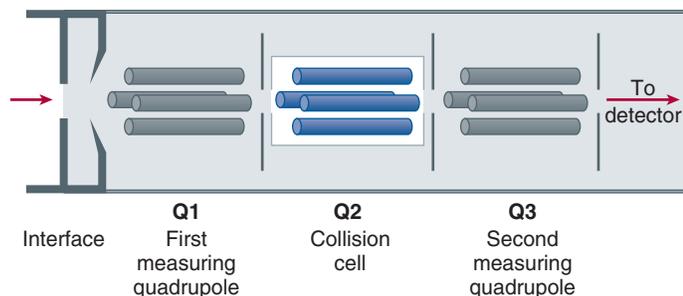

With the advent of automation and test standardization, error rates decreased dramatically from approximately 160,000 errors per million tests in 1947 to 450 per million in 1997.<sup>22</sup> The majority (60%–70%) of modern

laboratory errors occur in the preanalytical phase; approximately 10% to 15% of errors occur during the analytical phase and 15% to 20% in postanalysis.<sup>22</sup>

Errors, especially in the less automated preanalytical phase, can be minimized with appropriate procedures and training and good communication between the clinical and laboratory services. Analytical errors caused by cross-reactivity are typically methodology and test dependent and are described elsewhere in this chapter. A more detailed discussion of these sorts of errors is beyond the scope of this chapter. A good practical resource is the medical director of your local laboratory.

## THERAPEUTIC DRUG MONITORING AND QUANTITATIVE DRUG MEASUREMENTS

Therapeutic drug monitoring (TDM) involves the quantification of drug concentrations in biological fluids (typically serum, plasma, or whole blood) to assess therapeutic compliance or efficacy or to elucidate the cause of

**FIGURE 7-7.** Schematic of a tandem mass spectrometer. Effluent from an interfaced liquid chromatography (LC) system enters the ionization chamber where ion fragments are generated and directed into three successive quadrupoles (Q1, Q2, Q3). Q1 selectively filters ions of a specific mass-to-charge ( $m/z$ ) (ie, “parent ions”). Q2 functions as a collision cell generating further ionic fragmentation. Q3 performs a second round of ion filtration before mass detection. By using a second round of ion fragmentation and filtering, higher selectivity and reduced interference are achieved. (Data from Manz A, Lössfödis D, Pamme N: *Bioanalytical Chemistry*. London: Imperial College Press; 2004.)

drug-induced toxicity. Therapeutic drug monitoring describes a patient’s pharmacokinetic status at the moment of specimen collection. Pharmacokinetics is the relationship between the drug dose and the time course of drug absorption, distribution, metabolism, and elimination, which represent the effects of the body on the drug. Pharmacodynamics describes the effects of the drug on the body.

Drugs that are candidates for TDM share several characteristics:

1. Narrow therapeutic ranges.
2. Therapeutic effects and dose adjustments not readily assessed by clinical observation.
3. Unpredictable relationships between dose and clinical outcome. This is especially true during periods of physiological flux (eg, initiation of therapy acute illness, disease, puberty, pregnancy, aging, and polypharmacy).
4. Correlation between drug concentrations and their efficacy and toxicity
5. Drug toxicity leads to significant morbidity such as hospitalization, irreversible organ damage, and death.
6. Availability of appropriate analytic techniques.

When properly used to guide dosing adjustments, xenobiotic concentration measurements improve medical outcomes.<sup>11</sup> However, many therapeutic drug measurements are drawn at inappropriate times or are made without an appropriate therapeutic question in mind. An essential requirement for interpretation of xenobiotic concentrations is that the relationship between concentrations and effects must be known. Such knowledge is available for routinely monitored xenobiotics and is often encapsulated in published ranges of therapeutic and toxic concentrations. Concentrations designated as “toxic” are usually higher than the upper end of the therapeutic range and typically represent concentrations at which toxicity is acute and potentially serious (see back cover).

For most xenobiotics, the relationships between toxic concentrations and effects cannot be systematically studied in humans and consequently are often incompletely defined. These relationships are largely inferred from data provided in overdose case reports and case series. The measurement of xenobiotic concentrations in patients with poisonings or overdose cases in which concentration–effect relationships are not well defined contribute more to the management of future overdosed patients than to the management of the patient in whom the measurements were made.

For toxicologists, xenobiotic concentrations are especially useful in two ways. For xenobiotics, when toxicity is delayed or is clinically unapparent during the early phases of an overdose or poisoning, concentrations have substantial prognostic value and facilitate anticipatory management. These concentrations are also used to make decisions regarding the

use of antidotes or of interventions to hasten drug elimination, such as hemodialysis.

Quantitative xenobiotic measurements are subject to various interferences, but these are less problematic than in qualitative assays. Signals generated by cross-reacting substances are generally weaker than those from the target analyte and are relatively unlikely to lead to a false diagnosis of toxicity, particularly if the target analyte is absent. Such cross-reactivity can be exploited in some instances to provide confirmatory evidence of a poison for which no specific assay is immediately available. For example, the immunoassay finding of apparent nontoxic concentrations of TCAs can help confirm a diphenhydramine overdose, and the finding of a measurable digoxin concentration in an unexposed patient suggests poisoning with other cardioactive steroids of plant or animal origin or endogenous production. Negative interferences are much less frequent. Interferences in chromatographic methods usually result from the presence of other compounds with migration rates similar to the target analyte. Because the migration rates are rarely exactly the same, the laboratory can often recognize the presence of the interference as an overlapping peak when both compounds are present. In such instances, the interference may impair accurate measurement of the xenobiotic concentration. When no target xenobiotic is present, misidentification of the interfering peak as the target becomes much more likely because a single peak is seen at approximately the expected position. Because interferences in chromatographic methods are generally unique to a specific method, information about these interferences should be obtained by asking the laboratory.

Xenobiotic measurements are unlike most other laboratory measurements in that the concentrations are highly dependent on the timing of the measurement. Knowledge of the pharmacokinetics of a xenobiotic can substantially enhance the ability to draw meaningful conclusions from a measured concentration. Some xenobiotics alter their pharmacokinetic behavior at very high concentrations. These changes in pharmacokinetics (called toxicokinetics) are often predictable from the mechanisms of drug clearance and the extent of binding to plasma proteins and to tissues (Chap. 9).

Knowledge of the relationship between xenobiotic concentrations and effects, or pharmacodynamics, is also important. Effects depend on local concentrations at the site of action, typically at cell membrane receptors, intracellular locations, or within deeper tissue compartments such as across the blood–brain barrier within the central nervous system. Serum or plasma concentrations can be correlated with effects only when these concentrations are in equilibrium with concentrations at the site of action. During the absorption and distribution phases, the concentration ratio will be higher than its equilibrium value, yet often the only xenobiotic concentration measured after an acute overdose is one obtained while absorption and distribution are still ongoing. This effect explains some observations of apparent poor correlation between measured concentrations and toxic effects.

### Free Drug Monitoring

Drugs bind to serum proteins to various degrees. For example, whereas lithium is 0% protein bound, valproate and phenytoin are more than 90% protein bound at therapeutic concentrations. The major drug-binding proteins are albumin,  $\alpha$ -1 acid glycoprotein, and the various lipoproteins.

For xenobiotics that bind significantly to plasma proteins, the concentration of xenobiotic that is not bound to proteins (the free-xenobiotic concentration) is in equilibrium with concentrations at the site of action. For most drugs at therapeutic concentrations, the free-drug concentration is an approximately constant percentage of the total drug concentration. The total concentration is what is usually measured in the laboratory. Under these conditions, the ratio of total concentration to active site concentration is approximately constant, and a reasonable correlation between total concentration and effects can be expected.

Although free-drug concentration can be estimated from total concentration in most cases, under certain pathological conditions, free-drug concentration may be significantly elevated even if the concentration of the total drug is within therapeutic range.

**TABLE 7-3** Protein Binding Characteristics of Some Commonly Monitored Therapeutic Drugs<sup>9</sup>

Drug	Percent Protein Bound	Free-Drug Monitoring Candidate
Ethosuximide	0	No
Lithium	0	No
Procainamide	10–15	No
Digoxin	25	Yes
Theophylline	40	No
Phenobarbital	40	No
Lidocaine	60–80	Yes
Carbamazepine	80	Yes
Quinidine	80	Yes
Phenytoin	90	Yes
Valproate	90–95	Yes
Mycophenolate	92–98	Yes
Tacrolimus	97	Yes
Cyclosporine	98	Yes

These pathological conditions can include:

1. Uremia
2. Liver disease
3. Hypoalbuminemia
4. Polypharmacy, in which one strongly bound drug such salicylates can displace another phenytoin

In general, candidates for free drug monitoring are drugs that are greater than 80% protein bound. An exception is digoxin; although it is only 25% bound, after treatment with digoxin-specific antibody fragments, the free fraction is less than 1% of the total concentration.

The protein-binding characteristics of some commonly monitored therapeutic drugs are summarized in [Table 7-3](#). In current clinical practice, free drug monitoring is best described for the classical anticonvulsants phenytoin, carbamazepine, and valproate.

The analytical considerations and limitations make the routine use of free drug monitoring prohibitive. To be able to quantify free drug, the analytical technique must first be able to isolate the unbound drug and then be sensitive enough to be able to measure the relatively low concentrations. The two most common separation techniques require either a prolonged separation time such as equilibrium dialysis or a series of manual steps that are difficult to automate in the modern clinical laboratory such as offline filtration and high-speed centrifugation. Because the concentrations of the free drugs are dramatically lower than the total drug, the analytical ranges and sensitivities of the measuring instruments are by necessity very different. It is recommended that clinicians contact their local clinical laboratory to find the specific tests (and TATs) that are available.

## SCREENING FOR DRUGS OF ABUSE

Testing for drugs of abuse is a significant component of medical toxicology testing. These tests are widely used in the evaluation of potential poisonings and are assuming an increasing role in ensuring the appropriate use of analgesics.<sup>8</sup> Initial testing is usually done with a screening immunoassay. Although drug-screening immunoassays were initially developed for use in workplace drug-screening programs and are not always optimal for medical purposes, their wide availability, low cost, and ease of use led to their nearly

universal adoption in clinical laboratories. Drug abuse testing for nonmedical reasons is generally considered to be forensic testing, and confirmation of immunoassay results is considered mandatory in such circumstances. Confirmatory testing compensates for some immunoassay shortcomings but is frequently not done when screening tests are used for medical purposes. Despite the widespread use of drug-screening immunoassays in medical practice, studies suggest that many physicians do not fully understand the capabilities and limitations of these tests.<sup>23</sup>

The most commonly tested-for xenobiotics are amphetamines, cannabinoids, cocaine, opioids, and PCP. These are often referred to as “the NIDA five” because they are the five drugs that were recommended in 1988 by the National Institute on Drug Abuse (NIDA) for drug screening of federal employees. The responsibility for recommendations for federal drug testing now lies with the Substance Abuse and Mental Health Services Administration (SAMHSA). Drug-screening immunoassays are also frequently done for oxycodone, methadone and benzodiazepines and less frequently for hydrocodone. [Table 7-4](#) lists some of the general characteristics of these tests. Commercial urine immunoassays are also available for buprenorphine, lysergic acid diethylamide, methaqualone, methylenedioxymethamphetamine (MDMA), and hydrocodone. These screening immunoassays are available in a number of formats, which differ in performance. Almost all of them are designed to be used with urine specimens because these can be obtained noninvasively and generally have higher concentrations than serum, enhancing the sensitivity of the test.

The screening tests for cannabinoids and cocaine are directed toward metabolites rather than the parent compound. The parent xenobiotics, cocaine and THC, are both short lived and persist for no more than a few hours after use. The metabolites remain present for substantially longer periods of time. Detection of the metabolites increases the ability to detect any recent xenobiotic use. However, this limits the utility of the assays for determining whether a patient is currently under the influence of the drug. Because the metabolites are rapidly formed, a negative test result generally excludes toxicity, but a positive test result indicates only use in the recent past, not current toxicity.

The use of specific cutoff concentrations is nearly universal. Test results are considered positive only when the concentration of the xenobiotic in the specimen exceeds a predetermined threshold. This threshold should be set sufficiently high that false-positive results as a consequence of analytic variability or cross-reactivity are extremely infrequent. They should also be low enough to give consistent positive results in persons who are regularly using xenobiotics. Cutoff concentrations used vary with the xenobiotic or xenobiotic class under investigation. In some screening immunoassays, the laboratory has the option of selecting from several cutoff values.

The use of cutoff values sometimes creates confusion when a patient who is known to have recently used a xenobiotic has a negative result reported on a xenobiotic screen. In such instances, the drug is usually present but at a concentration below the cutoff value. A quantitative confirmatory test (see later) is usually able to demonstrate the presence of the drug or its metabolites under such circumstances. Another potential problem occurs when a patient’s drug-screening test result is positive after previously having become negative. This is usually interpreted as indicating renewed drug use, but it may actually be due to variations in urine production. The rate of the urine flow may vary up to 100-fold, with a reflected change in the urine drug concentration. This effect is often exploited by individuals who drink large quantities of water before taking a urine drug test to increase urine flow and decrease urine drug concentrations. In contrast, a decrease in the rate of urine production could result in a positive test result after a negative one despite no new drug exposure. A similar effect is produced by changes in urine pH. Drugs containing a basic nitrogen (eg, amphetamine) demonstrate ionic trapping, with increasing concentrations as urine pH decreases. Similarly, excretion of an anionic drug such as salicylate increases with increasing urine pH.

Another widely used practice is the confirmation of positive screening results using an analytical methodology different from that used in the screen. The most common confirmatory methods are gas chromatography/mass

**TABLE 7-4** Performance Characteristics of Common Urine Drug Screening Immunoassays<sup>a</sup>

Drug/Class	Detection Limits (ng/mL) <sup>b</sup>	Confirmation Limits (ng/mL) <sup>b</sup>	Detection Interval <sup>c</sup>	Comments
Amphetamine/methamphetamine	500	500	1–2 days (2–4 days)	Decongestants, ephedrine, L-methamphetamine, selegiline, and bupropion metabolites are reported to give false-positive test results with some assays; MDA, MDEA, and MDMA are variably detected.
Barbiturates	200		2–4 days	Phenobarbital detection interval is up to 4 weeks.
Benzodiazepines	100–300		1–30 days	Benzodiazepines vary in reactivity and potency. Hydrolysis of glucuronides increases sensitivity. False-positive test results are reported with oxaprozin.
Cannabinoids	50	15	1–3 days (1 month)	Screening assays detect inactive and active cannabinoids; confirmatory assay detects inactive metabolite THCA. Duration of positivity is highly dependent on screening assay detection limits.
Cocaine	150	100	2 days (1 wk)	Screening and confirmatory assays detect inactive metabolite BE. False-positive test results caused by cross-reactive compounds are unlikely.
Opiates			1–2 days (1 week)	Semisynthetic opioids derived from morphine show variable cross-reactivity. Fully synthetic opioids (eg, fentanyl, meperidine, methadone, tramadol) have minimal cross-reactivity. Quinolones are known to cross-react with some assays.
Codeine/morphine	2,000	2,000		
Hydrocodone/hydromorphone	300	100		
Oxycodone/oxymorphone	100	50		
6-Acetylmorphine	10	10		
Methadone	300		1–4 days	Doxylamine is reported to cross-react with some assays.
Phencyclidine	25	25	4–7 days (1 month)	Dextromethorphan, diphenhydramine, ketamine, and venlafaxine is reported to cross-react with some assays.

<sup>a</sup>Performance characteristics vary with manufacturer and may change over time. For the most accurate information, consult the package insert of the current lot or contact the manufacturer. <sup>b</sup>Substance Abuse and Mental Health Services Administration recommendations<sup>10</sup> are shown for amphetamines/methamphetamines, cannabinoids, cocaine, opiates, and phencyclidine immunoassays. Other commercial immunoassay cutoffs are also listed. Other cutoffs may be set by individual laboratories. <sup>c</sup>Values are after typical use; values in parentheses are after heavy or prolonged use.

BE = benzoylecgonine; MDA = methylenedioxyamphetamine; MDEA = methylenedioxyethylamphetamine; MDMA = methylenedioxyamphetamine; THCA = tetrahydrocannabinolic acid.

spectrometry (GS/MS) and liquid chromatography/mass spectrometry (LC/MS). The high specificity afforded by the combination of the retention time and the mass spectrum makes false-positive results extremely unlikely. Chromatographic/MS methods also have greater sensitivity than the screening immunoassays, minimizing failed confirmations because of a drug concentration below the sensitivity of the confirmatory assay.

Immunoassay results are generally obtainable within 1 hour. Confirmatory testing usually requires at least several hours or longer for low-volume tests that are often batched and frequently have to be sent out to offsite laboratories. This creates a problem when confirmation of initial immunoassay results is required. Most laboratories provide a verbal report of a presumptive positive result to facilitate medical management but will not enter the result into a permanent record, such as the laboratory computer, until after confirmation is completed.

Confirmatory testing is less critical in an emergency department setting because a positive finding infrequently has consequences that extend beyond the medical management of the patient. An exception occurs when results of testing performed on motor vehicle crash victims are subsequently subpoenaed as evidence in legal proceedings. Confirmatory testing also becomes more important in drug abuse testing associated with chronic pain management programs, in which unexpected findings (whether positive or negative) may result in termination of care.

One workplace drug-screening practice that is not widely followed in medical toxicology is maintenance of a chain of custody. Employers generally insist on chain of custody for workplace testing because actions taken in response to a positive result are often contested in court. A chain of custody provides results that are readily defended in court. Laboratories providing testing for medical purposes rarely keep a chain of custody because it is quite expensive and does not benefit the patient. Additionally, the medical personnel responsible for obtaining the specimens are rarely trained in collection requirements for a chain of custody.

Another practice common in workplace testing but rare in medical laboratories is testing for specimen validity. It is common for individuals to try to “beat” obscure or falsify a workplace drug test through a variety of means, including diluting the specimen (either physiologically by water ingestion or by direct addition of water to the specimen), substituting “clean” urine obtained from another individual, or adding various substances that will either destroy drugs in the specimen or inactivate the enzymes or antibodies used in the screening immunoassays. Such substances include acids, bases, oxidizing agents (bleach, nitrite, peroxide, peroxidase, iodine, chromate), glutaraldehyde, pyridine, niacin, detergents, and soap. SAMHSA requires validity testing for all specimens in federal workplace testing, including measurement of urinary pH, specific gravity, and creatinine concentration, as well as tests for the presence of adulterants.<sup>10</sup> Dipsticks are available that detect the most common adulterants. However, manipulation or adulteration is rarely a problem in specimens obtained for emergency medical care, and most clinical laboratories do not provide validity testing.

A rapidly expanding epidemic of misuse of opioid analgesics and accompanying deaths caused by unintentional overdoses has led to the issuance of extensive recommendations, and often regulations, for managing chronic opioid therapy for noncancer pain. The use of periodic urine drug tests to monitor compliance with prescribed medications, as well as to detect use of illicit or unprescribed xenobiotics, is consistently a feature of such recommendations, although there is currently very little evidence that this practice reduces misuse or diversion of prescribed drugs or improves outcomes for patients.<sup>5</sup> There is evidence that the results of urine drug monitoring are inconsistent with the agreed-upon pain management plan in a very substantial fraction of patients so tested.<sup>5</sup>

The objectives of urine drug testing in chronic pain patients and abuse clinics are more complex in that negative results could signal misuse or diversion of a prescribed opioid, but positive results also indicate illicit xenobiotic use. In questionable cases, confirmatory testing by assays capable of

distinguishing and quantitating prescription opiates and opioids, as well as key metabolites should be obtained. This done on specimens with a positive screening result to ensure that it is positive for the right reasons and for an unexpected negative result to address the possibility that the expected opioid or its metabolites are actually present but at concentrations too low to give a signal exceeding the cutoff value.

## PERFORMANCE CHARACTERISTICS OF COMMON (URINE) DRUG SCREENING ASSAYS

There are problems with the performance characteristic summaries of all urine drug immunoassays (Table 7–4). Much of this confusion arises because there are multiple manufacturers of urine drug immunoassays. Each uses proprietary antibodies in a proprietary design and thus has unique performance characteristics, including differing reactivity with target drugs and cross-reactivity with interfering substances creating different false positives and false negatives. Reformulation of assays can remedy problems that previously existed, but this does not prevent older reports of false-positive results that are no longer valid from being cited repetitively in the current literature. For example, the interference of ibuprofen in a widely used assay for cannabinoids was corrected more than 20 years ago but continues to be cited in contemporary literature.<sup>24</sup> The best source of current information is the laboratory that is performing the testing or the assay manufacturer.

Immunoassays for opiates are directed toward morphine but have good cross-reactivity with many (but not all) structurally similar natural and semi-synthetic opioids. The extent of cross-reactivity varies among manufacturers. For example, oxycodone exhibits approximately 30% cross-reactivity relative to morphine in a fluorescence polarization immunoassay but less than 5% cross-reactivity in a number of other screening assays.<sup>16,26</sup> A failure to appreciate the poor detection of oxycodone can create problems when opiate-screening immunoassays are used to confirm that patients receiving prescription oxycodone for chronic pain are indeed taking it rather than diverting it for illicit sale. If a low cross-reactivity assay is used, a patient taking oxycodone as prescribed might have a negative result, but another patient who is selling oxycodone and using the proceeds to buy heroin would have a positive result. To address this problem, assays specific for oxycodone were introduced. These assays are sensitive to therapeutic amounts of oxycodone but relatively insensitive to other opiates.

Synthetic opioids, such as dextromethorphan, fentanyl, meperidine, methadone, propoxyphene, and tramadol, have limited cross-reactivity with opiate immunoassays. Urine immunoassays specific for many of these compounds are available. Given the increasing importance of buprenorphine as maintenance therapy for opioid dependency, it is worth noting that the combination of high potency and low cross-reactivity means that buprenorphine will generally not be detected by opiate immunoassays. It was for this reason that immunoassays for specific detection of buprenorphine were developed.

A positive immunoassay result may reflect multiple contributions from various opiates and opiate metabolites. Concentrations of morphine glucuronide in the urine can up to 10-fold higher than the concentrations of unchanged morphine and can contribute substantially to positive results. A positive opiate result after the use of heroin (diacetylmorphine) is primarily a result of the morphine and morphine glucuronide that result from heroin metabolism. Distinguishing heroin from other opioids requires detection of 6-monoacetylmorphine, the heroin-specific metabolite.

The duration of positivity of an opiate immunoassay after last use depends on the identity and amount of the opiate used, the specific immunoassay, the cutoff value, and the pharmacokinetics of the individual. Currently, SAMHSA recommends a cutoff equivalent to 2,000 ng/mL of morphine for workplace screening because poppy seeds rarely produce transient positive results with the previously recommended cutoff of 300 ng/mL. However, most toxicology laboratories continue to use a 300-ng/mL cutoff.

Drug-screening assays for cocaine are actually assays for the cocaine metabolite benzoylecgonine, which is eliminated more slowly than cocaine. This extends the duration of positivity after last use from a few hours to 2 days and sometimes to 1 week or longer after significant or prolonged use.

Because the assay is directed toward a metabolite, positive results do not equate with toxicity but merely indicate recent exposure. The assay is highly specific for benzoylecgonine, and false-positive results due to an interfering substance are extremely uncommon.

Immunoassays for cannabinoids are also directed toward a metabolite, in this case tetrahydrocannabinolic acid (THC-COOH). These immunoassays exhibit cross-reactivity with other cannabinoids but little else. Because cannabinoids are structurally unique and occur only in plants of the genus *Cannabis*, false-positive results are uncommon. It is unusual, although possible, to become exposed to sufficient “secondhand” or sidestream marijuana smoke to develop a positive urine test result.<sup>7</sup> Legal hemp products include fiber, oil, and seedcake derived from *Cannabis* varieties with low concentrations of cannabinoids. Hemp food products contain insufficient amounts of THC to produce psychoactive effects and usually will not increase urinary cannabinoid concentrations above a 50-ng/mL screening threshold.<sup>14,23</sup>

Interpretation of a positive result for cannabinoids can be problematic. Urine is typically positive for up to 3 days after occasional recreational use. However, with significant or prolonged use, there is significant accumulation of cannabinoids in adipose tissue. These stored cannabinoids are slowly released into the bloodstream and produce positive findings for 1 month or more. Consequently, little can be concluded from a positive finding in terms of current clinical findings. Because positive results in the absence of toxicity are very common and because THC is rarely responsible for serious acute clinical manifestations, NACB guidelines recommend against its routine inclusion in drug screening for patients with acute symptoms.<sup>27</sup> Synthetic cannabinoids (found in products sold as “spice,” “K2,” and a variety of changing names) are generally not detected by cannabinoid assays, presumably because of a combination of very low concentrations in urine and limited cross-reactivity.

Amphetamine screening tests have the greatest problems with false-positive results. A number of structurally related xenobiotics have significant cross-reactivity, including bupropion metabolites<sup>3</sup> and nonprescription decongestants such as pseudoephedrine, as well as L-ephedrine, which is found in a variety of herbal preparations. Some nonprescription nasal inhalers contain L-methamphetamine, the less potent levorotary isomer of D-methamphetamine. It is particularly problematic because it not only cross-reacts in immunoassays but also cannot be distinguished from the D-isomer by MS.<sup>13</sup> This cross-reactivity is beneficial from the point of view of the medical toxicologist because all of these compounds similar produce toxicity. But it is problematic in drug abuse screening because of the widespread legitimate use of cold medications. Assays with greater selectivity for amphetamine or methamphetamine exist. Although these assays produce fewer false-positive results caused by decongestant cross-reactivity, they are also less sensitive for the detection of other abused amphetaminelike compounds, including methylenedioxyamphetamine (MDA), MDMA, and phentermine. Cross-reactivity patterns vary from assay to assay.<sup>16</sup> Literature produced by the manufacturer should be consulted for specific details. A number of designer phenethylamine derivatives (eg, those found in “bath salts”) might be expected to cross-react in amphetamine assays because of structural similarity. However, they are typically much more potent than amphetamine or methamphetamine and do not achieve high enough concentrations to give a signal exceeding the cutoff.

Testing for benzodiazepines is complicated by the wide array of benzodiazepines that differ substantially in their potency, cross-reactivity, and half-lives. There are also substantial differences in the detection patterns of the various immunoassays.<sup>14,16</sup> This heterogeneity complicates the interpretation of benzodiazepine-screening assays. Screening results are typically positive in persons using low therapeutic doses of diazepam but negative after an overdose of a highly potent benzodiazepine such as clonazepam. To improve the scope of detection, some assays use antibodies to oxazepam, which is a metabolite of a number of different benzodiazepines. These assays have poor sensitivity to benzodiazepines that are not metabolized to oxazepam. False-negative results occur for benzodiazepines that are excreted in the urine almost entirely as glucuronides that have poor cross-reactivity with

antibodies directed toward an unmodified benzodiazepine. This is one reason for the poor detectability of lorazepam in some screening assays. The latter situation has led to the recommendation that specimens be treated with  $\beta$ -glucuronidase before analysis.<sup>20</sup> Some assays now include  $\beta$ -glucuronidase in the reagent mixture or use antibodies directed toward glucuronidated metabolites. The frequency of false-negative results and the fact that benzodiazepines are relatively benign in overdose have led the NACB guidelines to withhold recommendation for routine screening of urine for benzodiazepines until these problems with the immunoassays are addressed.<sup>27</sup>

Barbiturates are comparable to benzodiazepines in their heterogeneity of potency, cross-reactivity, and half-lives, although the differences are less substantial. Specific assays for serum phenobarbital can often help to clarify the significance of a positive barbiturate screen.

Some PCP screening assays give positive results with dextromethorphan, ketamine, or diphenhydramine but only when these are used in amounts above usual therapeutic quantities. A positive result may serve as a clue to a possible overdose with any of these substances. Furthermore, much of the illicit PCP actually consists of a mixture of various congeners and byproducts of synthesis. The cross-reactivity of these xenobiotics with the assay varies significantly and may result in false-negative assay results in patients who use PCP.

## SUMMARY

- Most hospital laboratories offer basic, clinically relevant tests that are needed on an urgent basis locally (tier 1 testing). Additional (tier 2) testing in selected patients who are not improving in whom unconfirmed poisoning is still suspected is typically referred out to reference toxicology laboratories.
- Although broad-spectrum toxicology screens can identify many drugs present in overdosed patients, the results of broad-spectrum screens infrequently have altered management outcomes.
- When requesting a screening test, an important and often overlooked item of communication is specifying any xenobiotics of particular concern.
- Xenobiotic concentrations are often useful to make decisions regarding the use of antidotes or if interventions to hasten drug elimination, such as hemodialysis, are indicated.
- Test errors can originate from the preanalytical, analytical, or postanalytical testing phases, with most occurring preanalytically. Adherence to procedure protocols and effective communication between personnel and services is key in reducing these errors.
- The predictive power of the result of a toxicology screen depends on a number of factors, including the likelihood of poisoning before receiving the test results (the prior probability or the prevalence), the range of xenobiotics effectively detected, and the frequency of false-positive test results.

## FOR MORE INFORMATION

Additional information about clinical toxicology laboratories, including topics not covered in this chapter, may be found in contemporary textbooks.<sup>2,17,25</sup>

# PRINCIPLES OF DIAGNOSTIC IMAGING

David T. Schwartz

Diagnostic imaging plays a significant role in the management of many patients with toxicologic emergencies. Radiography can confirm a diagnosis (eg, by visualizing the xenobiotic), assist in therapeutic interventions such as monitoring gastrointestinal (GI) decontamination, and detect complications of the xenobiotic exposure (Table 8-1).<sup>219</sup>

Conventional radiography is readily available in the emergency department (ED) and is the imaging modality most frequently used in acute patient management. Other imaging modalities are used in certain toxicologic emergencies, including computed tomography (CT); enteric and intravascular contrast studies; ultrasonography; transesophageal echocardiography (TEE); magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA); and nuclear scintigraphy, including positron emission tomography (PET) and single-photon emission tomography (SPECT).

## VISUALIZING THE XENOBIOTIC

A number of xenobiotics are radiopaque and can potentially be detected by conventional radiography. Radiography is most useful when a substance that is known to be radiopaque is ingested or injected. When the identity of the xenobiotic is unknown, the usefulness of radiography is very limited. When ingested, a radiopaque xenobiotic is often seen on an abdominal radiograph as described in detail in this chapter. Injected radiopaque xenobiotics are also visualized by radiography. If the toxic material itself is available for examination, it can be radiographed outside of the body to detect its radiopacity or any radiopaque contents (Fig. 102-2).<sup>92</sup>

## RADIOACITY

The radiopacity of a xenobiotic is determined by several factors. First, the intrinsic radiopacity of a substance depends on its physical density ( $\text{g}/\text{cm}^3$ ) and the atomic numbers of its constituent atoms. Biologic tissues are composed mostly of carbon, hydrogen, and oxygen and have an average atomic number of approximately 6. Substances that are more radiopaque than soft tissues include bone, which contains calcium (atomic number 20), radiocontrast agents containing iodine (atomic number 53) and barium (atomic number 56), iron (atomic number 26), and lead (atomic number 82). Some xenobiotics have constituent atoms of high atomic number, such as chlorine (atomic number 17), potassium (atomic number 19), and sulfur (atomic number 16) that contribute to their radiopacity.

The thickness of an object also affects its radiopacity. Small particles of a moderately radiopaque xenobiotic are often not visible on a radiograph. Finally, the radiographic appearance of the surrounding area also affects the detectability of an object. A moderately radiopaque tablet is easily seen against a uniform background, but in a patient, overlying bone or bowel gas often obscures the tablet.

## ULTRASONOGRAPHY

Compared with conventional radiography, ultrasonography theoretically is a useful tool for detecting ingested xenobiotics because it depends on echogenicity rather than radiopacity for visualization.<sup>40</sup> Solid pills within the fluid-filled stomach infrequently have an appearance similar to gallstones within the gallbladder. In one *in vitro* study using a water-bath model, virtually all intact pills could be visualized.<sup>8</sup> The authors were also successful at detecting pills within the stomachs of human volunteers who ingested pills. Nonetheless, reliably finding pills scattered throughout the GI tract, which often contains air and feces that block the ultrasound beam, is a formidable task. In a well-controlled trial comparing participants who ingested 50 enteric-coated placebo tablets with control participants, ultrasonography of

the stomach had a sensitivity of only 62.5% at the time of ingestion and 20.8% after 1 hour and a specificity of 58.3% and 79%, respectively.<sup>234</sup> Ultrasonography, therefore, has limited clinical practicality and is therefore not routinely recommended.

## INGESTION OF AN UNKNOWN XENOBIOTIC

Although a clinical policy issued by the American College of Emergency Physicians in 1995 suggested that an abdominal radiograph should be obtained in unresponsive overdosed patients in an attempt to identify the involved xenobiotic, the role of abdominal radiography in screening a patient who has ingested an unknown xenobiotic is questionable.<sup>7</sup> The number of potentially ingested xenobiotics that are radiopaque is limited. In addition, the radiographic appearance of an ingested xenobiotic is not sufficiently distinctive to determine its identity (Fig. 8-1).<sup>1,248,266</sup> However, when ingestion of a radiopaque xenobiotic such as ferrous sulfate tablets or another metal with a high atomic number is suspected, abdominal radiographs are helpful.<sup>6</sup> In addition, knowledge of potentially radiopaque xenobiotics is useful in suggesting diagnostic possibilities when a radiopaque xenobiotic is discovered on an abdominal radiograph that was obtained for reasons other than suspected xenobiotic ingestion, such as in a patient with abdominal pain (Fig. 8-2).<sup>214,225</sup>

Several investigators evaluated the radiopacity of various medications.<sup>61,70,97,103,114,173,211,228,238</sup> These investigators used an *in vitro* water-bath model to simulate the radiopacity of abdominal soft tissues.<sup>211</sup> The studies found that only a small number of medications exhibit some degree of radiopacity. A short list of the more consistently radiopaque xenobiotics is summarized in the mnemonic CHIPES—chloral hydrate, “heavy metals,” iron, phenothiazines, and enteric-coated and sustained-release preparations.

The CHIPES mnemonic has several limitations.<sup>211</sup> It does not include all of the pills that are radiopaque *in vitro* such as acetazolamide and busulfan. Most radiopaque medications are only moderately radiopaque, and when ingested, they dissolve rapidly, becoming difficult or impossible to detect. “Psychotropic medications” include a wide variety of compounds of varying radiopacity.<sup>173,211</sup> For example, whereas trifluoperazine (containing fluorine; atomic number 9) is radiopaque *in vitro*, chlorpromazine (containing chlorine; atomic number 17) is not.<sup>211</sup> Sustained-release preparations and those with enteric coatings have variable composition and radiopacity. Pill formulations of fillers, binders, and coatings vary among manufacturers, and even a specific product can change depending on the date of manufacture. Furthermore, the insoluble matrix of some sustained-release preparations is radiopaque and when seen on a radiograph, these tablets once opened no longer contain active medication. Some sustained-release cardiac medications such as verapamil and nifedipine have inconsistent radiopacity.<sup>140,227,240</sup> Finally, this was a very old study, and many pills currently on the market have never been tested.

## EXPOSURE TO A KNOWN XENOBIOTIC

When a xenobiotic that is known to be radiopaque is involved in an exposure, radiography plays an important role in patient care.<sup>6</sup> Radiography can confirm the diagnosis of a radiopaque xenobiotic exposure, quantify the approximate amount of xenobiotic involved, and monitor its removal from the body. Examples include ferrous sulfate, sustained-release potassium chloride,<sup>123,232</sup> and heavy metals.

### Iron Tablet Ingestion

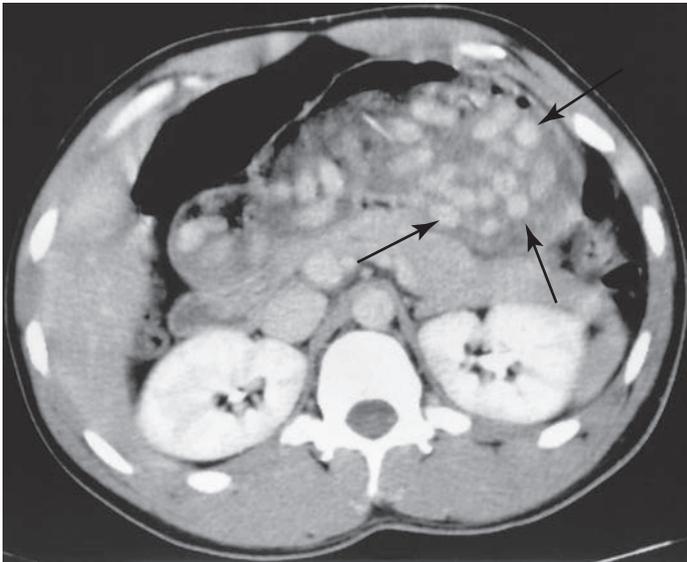

Adult-strength ferrous sulfate tablets are readily detected radiographically because they are highly radiopaque and disintegrate slowly when ingested.

**TABLE 8-1** Xenobiotics with Diagnostic Imaging Findings

<i>Xenobiotic</i>	<i>Imaging Study<sup>a</sup></i>	<i>Findings</i>
Amiodarone	Chest	Phospholipidosis (interstitial and alveolar filling), pulmonary fibrosis
Asbestos	Chest	Interstitial fibrosis (asbestosis), calcified pleural plaques, mesothelioma
Beryllium	Chest	Acute: airspace filling; chronic: hilar adenopathy
Body packer	Abdominal Enteric contrast or abdominal CT Ultrasonography	Ingested packets, ileus, bowel obstruction Retained packets, bowel obstruction or perforation Ingested packets
Carbon monoxide	Head CT, MRI SPECT, PET	Bilateral basal ganglion lucencies, white matter demyelination Cerebral dysfunction
Caustic ingestion	Enteric contrast CT	Esophageal perforation or stricture
Chemotherapeutics (busulfan, bleomycin)	Chest	Interstitial pneumonitis
Cholinergics	Chest	Diffuse airspace filling (bronchorrhea)
Cocaine	Chest, abdominal Noncontrast, head CT, MRI, TEE SPECT, PET	Diffuse airspace filling, pneumomediastinum, pneumothorax, aortic dissection, perforation SAH, intracerebral hemorrhage, infarction Cerebral dysfunction, dopamine receptor downregulation
Corticosteroids	Skeletal	Avascular necrosis (femoral head), osteoporosis
Ethanol	Chest Head CT, MRI SPECT, PET	Dilated cardiomyopathy, aspiration pneumonitis, rib fractures Cortical atrophy, cerebellar atrophy, SDH (head trauma) Cerebellar and cortical dysfunction
Fluorosis	Skeletal	Osteosclerosis, osteophytosis, ligament calcification
Hydrocarbons (low viscosity)	Chest	Aspiration pneumonitis
Inhaled allergens	Chest	Hypersensitivity pneumonitis
IDU injection drug use	Chest, skeletal, cranial CT	Septic emboli, pneumothorax, osteomyelitis (axial skeleton), AIDS-related infections
Iron	Abdominal	Radiopaque tablets
Irritant gases	Chest	Diffuse airspace filling thorax
Lead	Skeletal Abdominal	Metaphyseal bands in children (proximal tibia, distal radius), bullets (dissolution near joints) Ingested leaded paint chips or other leaded compounds
Manganese	MRI brain	Basal ganglia and midbrain hyperintensity
Mercury (elemental)	Abdominal, skeletal, or chest	Ingested, injected, or embolic deposits
Metals (Pb, Hg, Tl, As)	Abdominal	Ingested xenobiotic
Nitrofurantoin	Chest	Hypersensitivity pneumonitis
Opioids	Chest Abdominal	ARDS Ileus
Phenytoin	Chest, CT	Hilar lymphadenopathy, pseudolymphoma
Procainamide, isoniazid, hydralazine	Chest Echocardiogram	Pleural and pericardial effusions (xenobiotic-induced lupus syndrome) Pericardial effusion
Salicylates	Chest	ARDS
Silica, coal dust	Chest	Interstitial fibrosis, hilar adenopathy (egg-shell calcification)
Thorium dioxide	Abdominal	Hepatic and splenic deposition

<sup>a</sup>Conventional radiography unless otherwise stated.

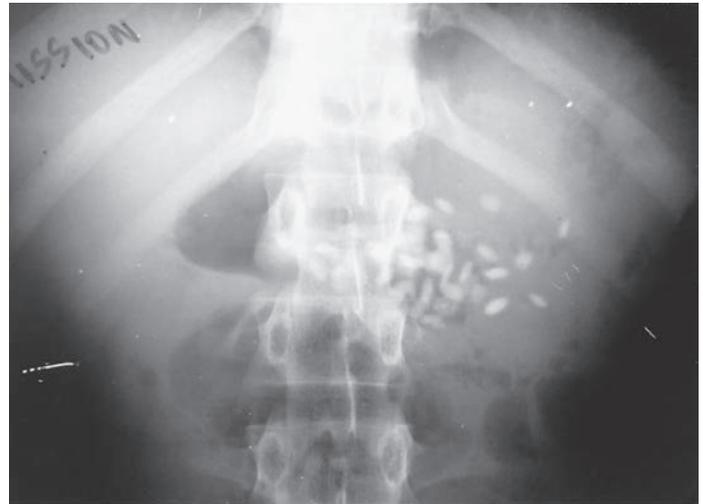

AIDS = acquired immune deficiency syndrome; ARDS = acute respiratory distress syndrome; CT = computed tomography; MRI = magnetic resonance imaging; PET = positron emission tomography; SAH = subarachnoid hemorrhage; SDH = subdural hematoma; SPECT = single-photon emission tomography; TEE = transesophageal echocardiography.

**FIGURE 8-1.** Ingestion of an unknown substance. A 46-year-old man presented to the emergency department with a depressed level of consciousness. Because he also complained of abdominal pain and mild diffuse abdominal tenderness, a computed tomography (CT) scan of the abdomen was obtained. The CT scan revealed innumerable tablet-shaped densities within the stomach (*arrows*). The CT finding was suspicious for an overdose of an unknown xenobiotic. Orogastric lavage was attempted, and the patient vomited a large amount of whole navy beans. Computed tomography is able to detect small, nearly isodense structures such as these that cannot be seen using conventional radiography. (Used with permission from Dr. Earl J. Reisdorff, MD, Michigan State University, Lansing, MI.)

**FIGURE 8-2.** Detection of a radiopaque xenobiotic on an abdominal radiograph. An abdominal radiograph obtained on a patient with upper abdominal pain revealed radiopaque material throughout the intestinal tract (*arrows*). Further questioning of the patient revealed that he consumed bismuth subsalicylate (Pepto-Bismol) tablets to treat his peptic ulcer (bismuth; atomic number 83). The identification of radiopaque material does not allow determination of the nature of the substance.

A

B

**FIGURE 8-3.** Iron tablet overdose. (A) Identification of the large amount of radiopaque tablets confirms the diagnosis in a patient with a suspected iron overdose and permits rough quantification of the amount ingested. (B) After emesis and whole-bowel irrigation, a second radiograph revealed some remaining tablets and indicated the need for further intestinal decontamination. (Used with permission from the Fellowship in Medical Toxicology, NYU School of Medicine, New York City Poison Control Center.)

Aside from confirming an iron tablet ingestion and quantifying the amount ingested, radiographs repeated after whole-bowel irrigation help to determine whether further GI decontamination is needed (Fig. 8-3).<sup>60,74,118,123,172,178,181</sup> Nonetheless, caution must be exercised in using radiography to exclude an iron ingestion. Some iron preparations are not radiographically detectable. Liquid, chewable, or encapsulated (Chap. 45) (“Spansule”) iron preparations rapidly fragment and disperse after ingestion. Even when intact, these preparations are less radiopaque than ferrous sulfate tablets.<sup>61</sup>

### Metals

Metals, such as arsenic, cesium, lead, manganese, mercury, potassium, and thallium, are often detected radiographically. Examples of metal exposure include leaded ceramic glaze (Fig. 8-4),<sup>199</sup> paint chips containing lead (Fig. 93-7),<sup>131,158</sup> mercuric oxide and elemental mercury (Fig. 95-1),<sup>143</sup> thallium salts (atomic number 81),<sup>53,159</sup> and zinc (atomic number 30).<sup>28</sup> Arsenic (Fig. 8-5) with a lower atomic number (atomic number 33) is also radiopaque.<sup>93,136,246</sup>

**FIGURE 8-4.** An abdominal radiograph of a patient who intentionally ingested ceramic glaze containing 40% lead. (Used with permission from the Fellowship in Medical Toxicology, NYU School of Medicine, New York City Poison Control Center.)

**FIGURE 8-5.** An abdominal radiograph in an elderly woman incidentally revealed radiopaque material in the pelvic region (arrowhead). This was residual from gluteal injection of antisyphilis therapy she had received 35 to 40 years earlier. The injections may have contained an arsenical. (Used with permission from Dr. Emil J. Balthazar, Department of Radiology, Bellevue Hospital Center.)

### Mercury

Unintentional ingestion of elemental mercury used to occur when a glass thermometer or a long intestinal tube with a mercury-containing balloon broke. Liquid elemental mercury is injected subcutaneously or intravenously. Radiographic studies assist débridement by detecting mercury that remains after the initial excision. Elemental mercury that is injected intravenously produces a dramatic radiographic picture of pulmonary embolization (Fig. 8-6).<sup>32,47,148,169</sup>

### Lead

Ingested lead is detected only by abdominal radiography, such as in a child with lead poisoning who has ingested paint chips (Fig. 93-7). Metallic lead (eg, a bullet) that is embedded in soft tissues is not usually systemically absorbed. However, when the bullet is in contact with an acidic environment such as synovial fluid or cerebrospinal fluid (CSF), there significant absorption often occurs. Over many years, mechanical and chemical action within the joint causes the bullet to fragment and gradually dissolve.<sup>52,54,62,231,236</sup> Radiography confirms the source of lead poisoning by revealing metallic material in the joint or CSF (Fig. 8-7).

### Xenobiotics in Containers

In some circumstances, ingested xenobiotics are seen even though they are of similar radiopacity to surrounding soft tissues. If a xenobiotic is ingested in a container, the container itself will be visible (Special Considerations: SC5).

### Body Packers

“Bodypackers” are individuals who smuggle large quantities of illicit drugs across international borders in securely sealed packets.<sup>4,18,20,31,43,65,69,111,129,146,157,184,220,223,243</sup> The uniformly shaped, oblong packets are seen on abdominal radiographs either because there is a thin layer of air or metallic foil within the container wall or because the packets are outlined by bowel gas (Fig. 8-8). In some cases, a “rosette” representing the knot at the end of the packet is seen. Intraabdominal calcifications (pancreatic calcifications and bladder stones) have occasionally been misinterpreted as drug-containing packets.<sup>244,261</sup>

The sensitivity of abdominal radiography for such packets is high, in the range of 85% to 90%. The major role of radiography is as a rapid screening test to confirm the diagnosis in individuals suspected of smuggling drugs, such as persons being held by airport customs agents. However, because packets are occasionally not visualized and the rupture of even a single packet can be fatal, abdominal radiography should not be relied on to exclude the diagnosis of body packing.<sup>204</sup> Ultrasonography is used to rapidly detect packets, although it also should not be relied on to exclude such a life-threatening ingestion.<sup>39,94,161</sup> Computed tomography without oral contrast is more sensitive than radiography and ultrasonography (Figs. SC5-1 and SC5-2).<sup>15,16,27,33,69,147,185,218,220</sup> After intestinal decontamination, an upper GI series with oral contrast or CT without enteric contrast usually reveals any remaining packets (Fig. SC5-1).<sup>96,107,152,174</sup>

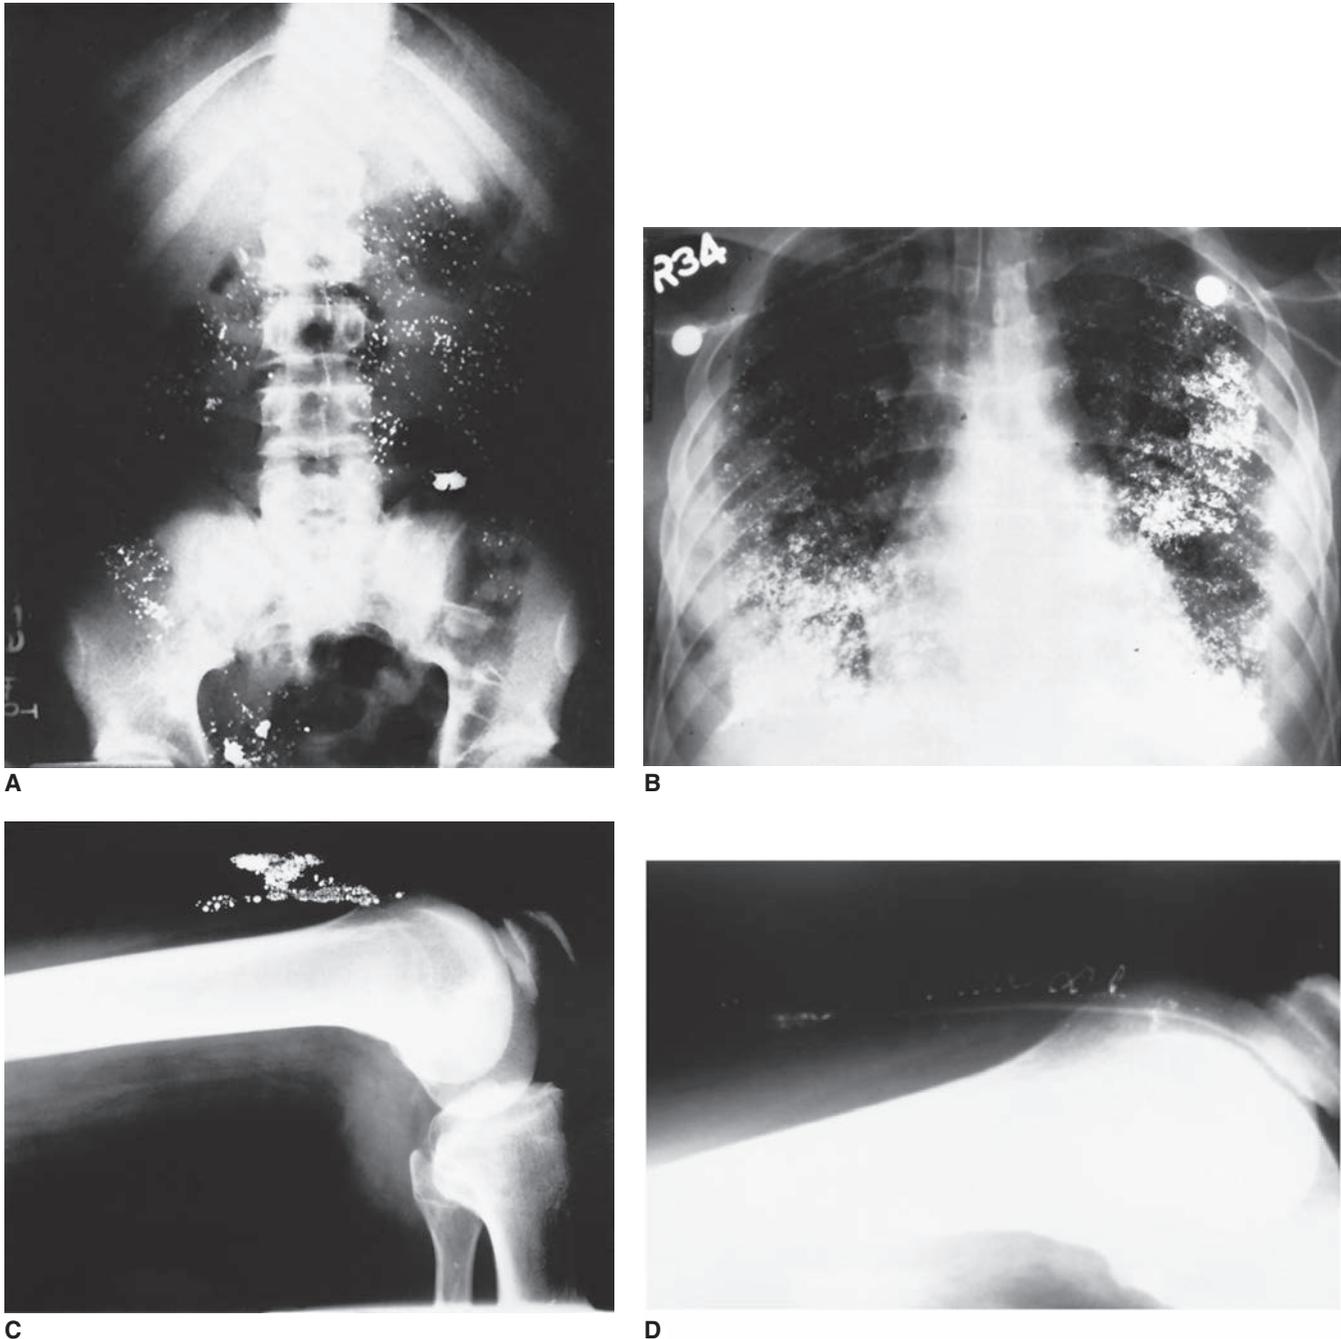

### Body Stuffers

A “body stuffer” is an individual who, in an attempt to avoid imminent arrest, hurriedly ingests contraband in insecure packaging.<sup>201</sup> The risk of leakage from such haphazardly constructed containers is high. Unfortunately, radiographic studies cannot reliably confirm or exclude such ingestions.<sup>226</sup>

Occasionally, a radiograph will demonstrate the ingested container (Fig. 8-9). If the drug is in a glass or in a hard-plastic crack vial, the container is frequently seen.<sup>106</sup> If the body stuffer swallows soft plastic bags containing the drug, the containers are not usually visible. However, in three reported cases, “baggies” were visualized by abdominal CT.<sup>44,57,99,101,125,186</sup>

### Halogenated Hydrocarbons

Some halogenated hydrocarbons are visualized radiographically.<sup>38,45</sup> Radiopacity is proportionate to the number of chlorine atoms. Both carbon tetrachloride (CCl<sub>4</sub>) and chloroform (CHCl<sub>3</sub>) are radiopaque. Because these liquids are immiscible in water, a triple layer is seen within the stomach on an upright abdominal radiograph—an uppermost air bubble, a middle

**FIGURE 8-6.** Elemental mercury exposures. (A) Unintentional rupture of a Cantor intestinal tube distributed mercury throughout the bowel. (B) The chest radiograph in a patient after intravenous injection of elemental mercury showing a metallic pulmonary embolism. The patient developed respiratory failure, pleural effusions, and uremia and died despite aggressive therapeutic interventions. (C) Subcutaneous injection of elemental mercury is readily detected radiographically. Because mercury is systemically absorbed from subcutaneous tissues, it must be removed by surgical excision. (D) A radiograph after surgical débridement reveals nearly complete removal of the mercury deposit. Surgical staples and a radiopaque drain are visible. (Image A used with permission from Dr. Richard Lefleur, Department of Radiology, Bellevue Hospital Center; image B used with permission from Dr. N. John Stewart, Department of Emergency Medicine, Palmetto Health, University of South Carolina School of Medicine; and images C and D used with permission from the Fellowship in Medical Toxicology, NYU School of Medicine, New York City Poison Control Center.)

radiopaque chlorinated hydrocarbon layer, and a lower gastric fluid layer. However, these ingestions are rare, and the quantity ingested is usually too small to show this effect. Other halogenated hydrocarbons such as methylene iodide are highly radiopaque.<sup>259</sup>

### Moth Repellants

Some types of moth repellants (mothballs) can be visualized by radiography. Whereas relatively common and nontoxic paradichlorobenzene moth repellants (containing chlorine; atomic number 17) are moderately radiopaque, more toxic naphthalene moth repellants are faintly radiopaque.<sup>233</sup> If the

patient is known to have ingested a moth repellant but the nature of the moth repellant is unknown, the difference in radiopacity helps determine the type. Radiographs of the moth repellant outside of the patient can distinguish these two types (Fig. 102-2).

### Radiolucent Xenobiotics

A radiolucent xenobiotic is often visible because it is less radiopaque than surrounding soft tissues. Hydrocarbons such as gasoline are relatively radiolucent when embedded in soft tissues. The radiographic appearance resembles subcutaneous gas as seen in a necrotizing soft tissue infection (Fig. 8-10).<sup>176</sup>

**FIGURE 8-7.** A “lead arthrogram” discovered many years after a bullet wound to the shoulder. At the time of the initial injury, the bullet was embedded in the articular surface of the humeral head (*arrow*). The portion of the bullet that protruded into the joint space was surgically removed, leaving a portion of the bullet exposed to the synovial space. A second bullet was embedded in the muscles of the scapula. Eight years after the injury, the patient presented with weakness and anemia. Extensive lead deposition throughout the synovium is seen. The blood lead concentration was 91 mcg/dL. (Used with permission from the Fellowship in Medical Toxicology, NYU School of Medicine, New York City Poison Control Center.)

### EXTRAVASATION OF INTRAVENOUS CONTRAST MATERIAL

Extravasation of intravenous (IV) radiographic contrast material is a common occurrence. In most cases, the volume extravasated is small, and there are no clinical sequelae.<sup>21,42,63,200</sup> Rarely, a patient has an extravasation large enough to cause cutaneous necrosis and ulceration.

Recently, the incidence of sizable extravasations has increased because of the use of rapid-bolus automated power injectors for CT studies.<sup>251</sup> Fortunately, nonionic low-osmolality contrast solutions are currently nearly always used for these studies. These solutions are far less toxic to soft tissues than older ionic high-osmolality contrast materials.

The treatment of contrast extravasation has not been studied in a large series of human participants and is therefore controversial. Various strategies are proposed. The affected extremity should be elevated to promote drainage. Although topical application of heat causes vasodilation and could theoretically promote absorption of extravasated contrast material, the intermittent application of ice packs is recommended to lower the incidence of ulceration. Rarely, an extremely large volume of liquid is injected into the soft tissues, which requires surgical decompression when there are signs of a compartment syndrome. A radiograph of the extremity will demonstrate the extent of extravasation (Fig. 8-11).<sup>42</sup>

Precautions should be taken to prevent extravasation. A recently placed, well-running IV catheter should be used. The distal portions of the extremities (hands, wrist, and feet) should not be used as IV sites for injecting contrast. Patients who are more vulnerable to complications and those whose veins are more fragile, such as infants, debilitated patients, and those with an impaired ability to communicate, must be closely monitored to prevent or determine if extravasation occurs.

### Summary

Obtaining an abdominal radiograph in an attempt to identify pills or other xenobiotics in a patient with an unknown ingestion is unlikely to be helpful and is, in general, not warranted. Radiography is most useful when the suspected xenobiotic is known to be radiopaque, as is the case with iron tablets and heavy metals. Radiography will demonstrate xenobiotic within the patient’s abdomen; elsewhere in the patient’s body; or, if the material is available, outside of the patient.

### VISUALIZING THE EFFECTS OF A XENOBIOTIC ON THE BODY

The lungs, central nervous system (CNS), GI tract, and skeleton are the organ systems that are most amenable to diagnostic imaging. Disorders of the lungs and skeletal system are seen by plain radiography. For abdominal pathology, contrast studies and CT are more useful, although plain radiographs can diagnose intestinal obstruction, perforation, and radiopaque foreign bodies. Imaging of the CNS uses CT, MRI, and nuclear scintigraphy (PET and SPECT).<sup>95</sup>

### Skeletal Changes Caused by Xenobiotics

A number of xenobiotics affect bone mineralization. Toxicologic effects on bone result in either increased or decreased density (Table 8-2). Some xenobiotics produce characteristic radiographic images, although exact diagnoses usually depend on correlation with the clinical scenario.<sup>11,171</sup> Furthermore, alterations in skeletal structure develop gradually and are usually not visible unless the exposure continues for at least 2 weeks.

#### Increase in Bone Density

**Lead Poisoning.** Skeletal radiography suggests the diagnosis of chronic lead poisoning in children even before the blood lead concentration is obtained. With lead poisoning, the metaphyseal regions of rapidly growing long bones develop transverse bands of increased density along the growth plate (Fig. 8-12).<sup>25,189,191,209</sup> Characteristic locations are the distal femur and proximal tibia. Flaring of the distal metaphysis also occurs. Such lead lines are also seen in the vertebral bodies and iliac crest. Detected in approximately 80% of children with a mean lead concentration of  $49 \pm 17$  mcg/dL, lead lines usually occur in children between the ages of 2 and 9 years.<sup>25</sup> In most children, it takes several weeks for lead lines to appear, although in very young infants (2–4 months old), lead lines develop within days of exposure.<sup>265</sup> After exposure ceases, lead lines diminish and eventually disappear in some children.

Lead lines are caused by the toxic effect of lead on bone growth and do not represent deposition of lead in bone. Lead impedes resorption of calcified cartilage in the zone of provisional calcification adjacent to the growth plate. This is termed *chondrosclerosis*.<sup>25,56</sup> Other xenobiotics that cause metaphyseal bands are yellow phosphorus (Chap. 112), bismuth (Chap. 87), and vitamin D (Chap. 44).

**Fluorosis.** Fluoride poisoning causes a diffuse increase in bone mineralization. Endemic fluorosis occurs where drinking water contains very high concentrations of fluoride ( $\geq 2$  or more parts per million), as an occupational exposure among aluminum workers handling cryolite (sodium–aluminum fluoride), or with excessive tea drinking. The skeletal changes associated with fluorosis are osteosclerosis (hyperostosis deformans), osteophytosis, and ligament calcification (Fig. 8-13). Fluorosis primarily affects the axial skeleton, especially the vertebral column and pelvis. Thickening of the vertebral column causes compression of the spinal cord and nerve roots. Without a history of fluoride exposure, the clinical and radiographic findings are mistaken for osteoblastic skeletal metastases. The diagnosis of fluorosis is confirmed by histologic examination of the bone and measurement of fluoride concentrations in the bone and urine (Figs. 81-1 and 81-2).<sup>26,120,253</sup>

**Bisphosphonates.** Bisphosphonates such as alendronate are commonly used to treat osteoporosis. They increase bone density by inhibiting osteoclast activity and decreasing bone resorption. However, by suppressing bone turnover and fracture healing, bisphosphonates are associated with accumulated microdamage to bone and skeletal weakening, which makes the bone vulnerable to fractures. Radiographically, there is thickening of the cortex of diaphyseal bone, typically the proximal femoral shaft. Such bone is associated with atypical proximal femoral shaft and subtrochanteric fractures after low-energy injuries such as a fall from standing. The fractures are transverse and have a characteristic “beaked” appearance caused by the cortical thickening (Fig. 8-14).<sup>89,137,215-217,260</sup>

#### Focal Loss of Bone Density

Skeletal disorders associated with focal diminished bone density (or mixed rarefaction and sclerosis) include osteonecrosis, osteomyelitis, and

**FIGURE 8-8.** Three “body packers” showing the various appearances of drug packets. Drug smuggling is accomplished by packing the gastrointestinal tract with large numbers of manufactured, well-sealed containers. (A) Multiple oblong packages of uniform size and shape are seen throughout the bowel. (B) The packets are visible in this patient because they are surrounded by a thin layer of air within the wall of the packet. (C and D) Small bowel obstruction caused by drug packets in a man who developed abdominal pain and vomiting 1 day after arriving on a plane flight from Colombia. Computed tomography confirmed bowel obstruction, and the patient underwent laparotomy and removal of 15 packets through an enterotomy. (Images A and B used with permission from Dr. Emil J. Balthazar, Department of Radiology, Bellevue Hospital Center. Images C and D used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

**FIGURE 8-9.** Two “body stuffers.” Radiography infrequently helps with the diagnosis. **(A)** An ingested glass crack vial is seen in the distal bowel (*arrow*). The patient had ingested his contraband several hours earlier at the time of a police raid. Only the tubular-shaped container, and not the xenobiotic, is visible radiographically. The patient did not develop signs of cocaine toxicity during 24 hours of observation. **(B)** Another patient in police custody was brought to the emergency department for allegedly ingesting his drugs. The patient repeatedly denied this. The radiographs revealed “nonsurgical” staples in his abdomen (*arrows*). When questioned again, the patient admitted that he had swallowed several plastic bags that were stapled closed. (Used with permission from the Fellowship in Medical Toxicology, NYU School of Medicine, New York City Poison Control Center.)

**FIGURE 8-10.** Subcutaneous injection of gasoline into the antecubital fossa. The radiolucent hydrocarbon mimics gas in the soft tissues that is seen with a necrotizing soft tissue infection such as necrotizing fasciitis or gas gangrene (*arrows*). (Used with permission from the Fellowship in Medical Toxicology, NYU School of Medicine, New York City Poison Control Center.)

**FIGURE 8-11.** Extravasation of intravenous contrast into the soft tissues of the upper extremity that occurred during a computed tomography contrast bolus administered by a power injector. Despite the extensive extravasation, the patient was successfully managed with limb elevation and cool compresses. (Used with permission from Mark Bernstein, MD, Department of Radiology, New York University School of Medicine.)

TABLE 8-2 Xenobiotic Causes of Skeletal Abnormalities

Increased Bone Density	Diminished Bone Density (Either Diffuse Osteoporosis or Focal Lesions)
<p><i>Metaphyseal bands (children)</i> Lead, bismuth, phosphorus: chondrosclerosis caused by toxic effect on bone growth.</p>	<p>Corticosteroids: Osteoporosis: diffuse Osteonecrosis: focal avascular necrosis of the femoral head; loss of volume with both increased and decreased bone density Also occurs in alcoholism, bismuth arthropathy, Caisson disease (dysbarism), trauma</p>
<p><i>Diffuse increased bone density</i> Fluorosis: osteosclerosis (hyperostosis deformans), osteophytosis, ligament calcification; usually involves the axial skeleton (vertebrae and pelvis) and can cause compression of the spinal cord and nerve roots Hypervitaminosis A (pediatric): cortical hyperostosis and subperiosteal new bone formation; diaphyses of long bones have an undulating appearance Hypervitaminosis D (pediatric): generalized osteosclerosis, cortical thickening, and metaphyseal bands</p>	<p>Hypervitaminosis D (adult): focal or generalized osteoporosis Injection drug use: osteomyelitis (focal lytic lesions) caused by septic emboli; usually affects vertebral bodies and sternomanubrial joint Vinyl chloride monomer: acroosteolysis (distal phalanges)</p>

osteolysis. Osteonecrosis, also known as avascular necrosis, most often affects the femoral head, humeral head, and proximal tibia.<sup>149</sup> There are many causes of osteonecrosis. Xenobiotic causes include long-term corticosteroid use and alcoholism. Radiographically, focal skeletal lucencies and sclerosis are seen, ultimately with loss of bone volume and collapse (Fig. 8-15A).

**Acroosteolysis.** Acroosteolysis is bone resorption of the distal phalanges and is associated with occupational exposure to vinyl chloride monomer. Protective measures have reduced its incidence since it was first described in the early 1960s.<sup>192</sup>

**Osteomyelitis.** Osteomyelitis is a serious complication of injection drug use. It usually affects the axial skeleton, especially the vertebral bodies, as well as the sternomanubrial and sternoclavicular joints (Figs. 8-15B and C).<sup>90,95</sup> Back pain or neck pain in injection drug users warrants careful consideration. Spinal epidural abscesses causing spinal cord compression accompany vertebral osteomyelitis. Radiographic findings are negative early in the disease course before skeletal changes are visible, and the diagnosis is confirmed by MRI or CT (Fig. 8-15D).

### Soft Tissue Changes

Certain abnormalities in soft tissues, that occur predominantly as a consequence of infectious complications of injection drug use, are amenable to radiographic diagnosis.<sup>90,95,116,239</sup> In an injection drug user who presents with signs of local soft tissue infections, radiography is indicated to detect a retained metallic foreign body, such as a needle fragment, or subcutaneous gas, as is recognized in a necrotizing soft tissue infection such as necrotizing fasciitis. Computed tomography is more sensitive at detecting soft tissue gas than is conventional radiography. Computed tomography and ultrasonography also detect subcutaneous or deeper abscesses that require surgical or percutaneous drainage.

### Pulmonary and Other Thoracic Problems

Many xenobiotics that affect intrathoracic organs produce pathologic changes that will be detected on chest radiographs.<sup>10,30,58,76,105,144,165,195,203,230,262,263</sup> The lungs are most often affected, resulting in dyspnea or cough, but the pleura, hila, heart, and great vessels are also involved. Patients with chest pain need to be evaluated for pneumothorax, pneumomediastinum, or aortic dissection. Patients with fever, with or without respiratory symptoms, can have focal infiltrates, pleural effusions, or hilar lymphadenopathy.

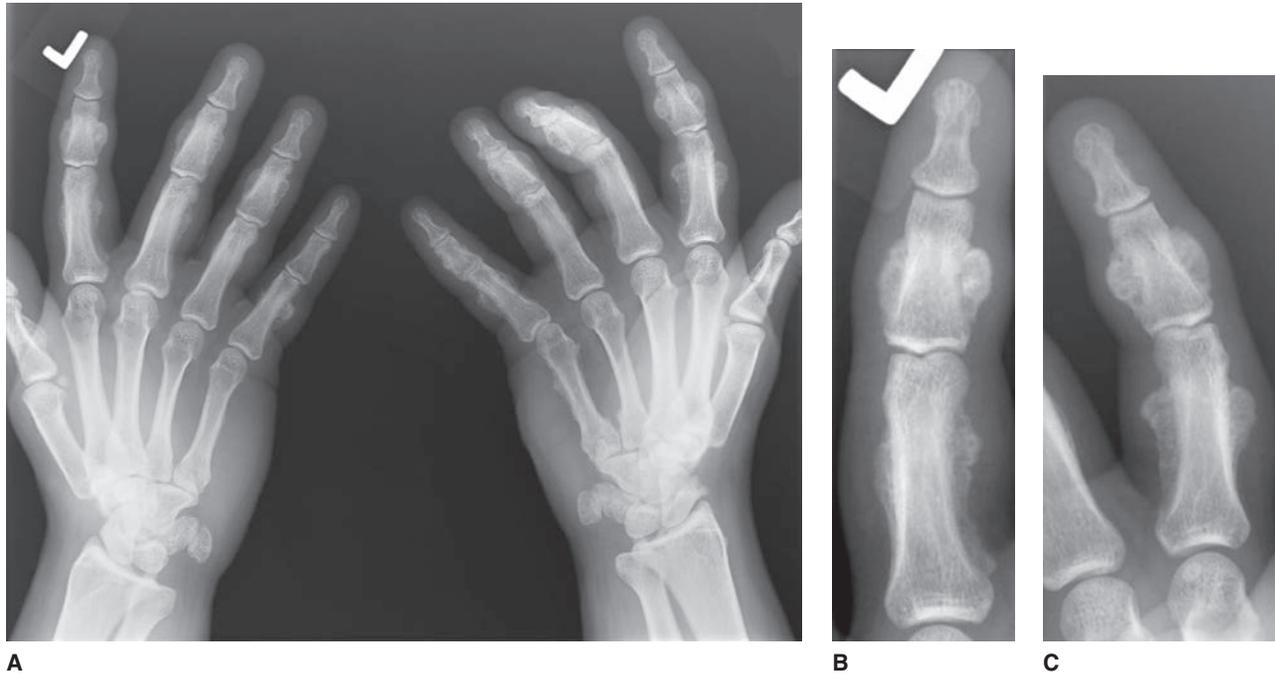

A

B

**FIGURE 8-12.** (A) A radiograph of the knees of a child with lead poisoning. The metaphyseal regions of the distal femur and proximal tibia have developed transverse bands representing bone growth abnormalities caused by lead toxicity. The multiplicity of lines implies repeated exposures to lead. (B) The abdominal radiograph of the child shows many radiopaque flakes of ingested leaded paint chips. Lead poisoning also caused abnormally increased cortical mineralization of the vertebral bodies, which gives them a boxlike appearance. (Used with permission from Dr. Nancy Genieser, Department of Radiology, Bellevue Hospital Center.)

Chest radiographic findings suggest certain diseases, although the diagnosis ultimately depends on a thorough clinical history. When a specific xenobiotic exposure is known or suspected, the chest radiograph can confirm the diagnosis and help in assessment. If a history of xenobiotic exposure is not obtained, a patient with an abnormal chest radiograph can initially be misdiagnosed as having pneumonia or another disorder that is more

**FIGURE 8-13.** Skeletal fluorosis. A 28-year-old man developed progressive muscle and joint pain over 3 to 4 weeks particularly involving his hands with thickening of his fingers. The results of an evaluation for inflammatory rheumatologic disorders were negative. Radiographs of his hands showed exuberant periosteal new bone formation known as “periostitis deformans,” which is characteristic of skeletal fluorosis. Further questioning revealed that the patient had been “huffing” the propellant of “Dust Off”; 225 cans were found at his residence. The propellant is difluoroethane (Freon 152a). The hydrocarbon is dehalogenated in the liver, and chronic exposure results in fluoride toxicity. (Used with permission from Dr. Eric Lavonas, Rocky Mountain Poison and Drug Center, Denver Health and Hospital Authority, Denver, CO, and Dr. Shawn M. Varney, Department of Emergency Medicine, San Antonio Military Medical Center, TX.)

**FIGURE 8-14.** Bisphosphonate- (alendronate-) associated proximal femoral shaft fracture. A 61-year-old woman tripped on the sidewalk, falling on to her right side. She had been taking alendronate for 3 years for osteoporosis. There are diffuse cortical thickening of the femoral shaft and a transverse fracture in the subtrochanteric region with “beaking” of the fractured cortex on the medial side of the fracture. (Used with permission from the Fellowship in Medical Toxicology, NYU School of Medicine, New York City Poison Control Center.)

common than xenobiotic-mediated lung disease. Therefore, patients with chest radiographic abnormalities should be carefully questioned regarding possible xenobiotic exposures at work or at home, as well as the use of medications or other drugs.

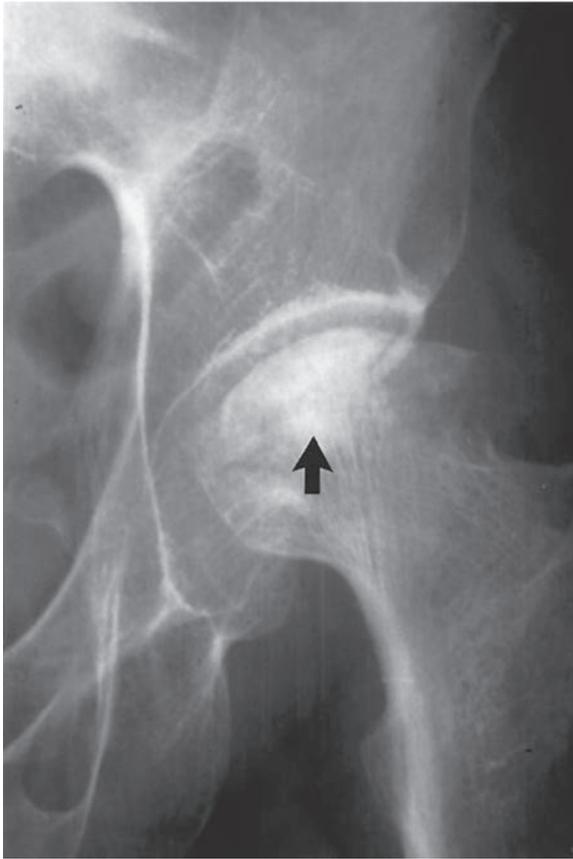

Many pulmonary disorders are radiographically detectable because they result in fluid accumulation within the normally air-filled lung. Fluid accumulates within the alveolar spaces or interstitial tissues of the lung, producing the two major radiographic patterns of pulmonary disease, airspace filling and interstitial lung disease (Table 8-3). Most xenobiotics are widely distributed throughout the lungs and produce diffuse rather than focal radiographic abnormalities.

#### Diffuse Airspace Filling

Overdose with various xenobiotics, including salicylates, opioids, and paracetamol, cause acute respiratory distress syndrome (ARDS) (formerly known as noncardiogenic pulmonary edema or acute lung injury) with or without diffuse alveolar damage and characterized by leaky capillaries (Fig. 8-16). There are, of course, many other causes of ARDS, including sepsis, anaphylaxis, and major trauma.<sup>256</sup> Other xenobiotic exposures that result in diffuse airspace filling include inhalation of irritant gases that are of low water solubility such as phosgene ( $\text{COCl}_2$ ), nitrogen dioxide (silo filler’s disease), chlorine, hydrogen sulfide, and sulfur dioxide (Chaps. 121 and 123).<sup>122</sup> Organic phosphorus compound poisoning causes cholinergic hyperstimulation, resulting in bronchorrhea (Chap. 110). Smoking “crack” cocaine is associated with diffuse alveolar hemorrhage (Chap. 75).<sup>46,72,193</sup>

#### Focal Airspace Filling

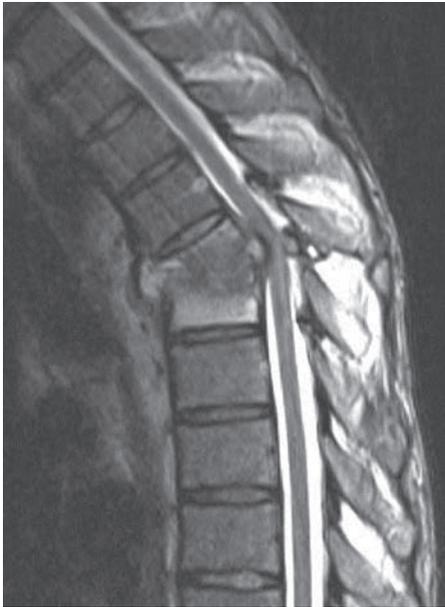

Focal infiltrates are usually caused by bacterial pneumonia, although aspiration of gastric contents also causes localized airspace disease.<sup>235</sup> Aspiration occurs during sedative-hypnotic or alcohol intoxication or during a seizure. During ingestion, low-viscosity hydrocarbons often enter the lungs while they are being swallowed (Figs. 8-17 and 105-1).<sup>164</sup> There is a typical delay in the development of radiographic abnormalities, and the chest radiograph abnormalities appear over the first 6 hours after the ingestion.<sup>9</sup> During

**FIGURE 8-15.** Focal loss of bone density and collapse: **(A)** Avascular necrosis causing collapse of the femoral head in a patient with long-standing steroid-dependent asthma (*arrow*). **(B and C)** Vertebral osteomyelitis in an injection drug user who presented with posterior thoracic pain for 2 weeks and then lower extremity weakness. As seen on computed tomography (CT), the infection begins in the intervertebral disk and then spreads to the adjacent vertebral bodies. Magnetic resonance image shows extension into the spinal canal causing spinal cord compression. **(D)** An injection drug user with thoracic back pain, leg weakness, and low-grade fever. Radiographic and CT findings of the spine were negative. Magnetic resonance image showing an epidural abscess (*arrow*) compressing the spinal cord. The cerebrospinal fluid in the compressed thecal sac is bright on this T2-weighted image. (Reproduced with permission from Schwartz DT, Reisdorff EJ: *Emergency Radiology*. New York, NY: McGraw-Hill; 2000.)

**TABLE 8-3** Chest Radiographic Findings in Toxicologic Emergencies

Radiographic Finding	Responsible Xenobiotic	Disease Processes
Diffuse airspace filling	Opioids	ARDS
	Paraquat	
	Salicylates	
	Irritant gases: NO <sub>2</sub> (silo filler's disease), phosgene (COCl <sub>2</sub> ), Cl <sub>2</sub> , H <sub>2</sub> S	
	Organic phosphorus compounds, carbamates	Cholinergic stimulation (bronchorrhea)
	Alcoholic cardiomyopathy, cocaine, doxorubicin, cobalt	Congestive heart failure
Focal airspace filling	Low-viscosity hydrocarbons	Aspiration pneumonitis
	Gastric contents aspiration: CNS depressants, alcohol, seizures	
Multifocal airspace filling	Injection drug user	Septic emboli
Interstitial patterns	Inhaled organic allergens: farmer's lung, pigeon-breeder's lung	Hypersensitivity pneumonitis
Fine or coarse reticular or reticulonodular pattern	Nitrofurantoin, penicillamine	
Patchy airspace filling seen in some cases	Chemotherapeutics: bleomycin, busulfan, carmustine, cyclophosphamide, methotrexate	Cytotoxic lung damage
	Amiodarone	Phospholipidosis
	Talcosis (illicit drug contaminant)	Injected particulates
	Pneumoconiosis: asbestosis, berylliosis (chronic), coal dust, silicosis	Inhaled inorganic particulates

ARDS = acute respiratory distress syndrome; CNS = central nervous system.

**FIGURE 8-16.** Diffuse airspace filling. The chest radiograph of a patient who had recently injected heroin intravenously presented with respiratory distress and acute respiratory distress syndrome. The heart size is normal.

**FIGURE 8-17.** Focal airspace filling as a result of hydrocarbon aspiration. A 34-year-old man aspirated gasoline. The chest radiograph shows bilateral lower lobe infiltrates. (Used with permission from the Fellowship in Medical Toxicology, NYU School of Medicine, New York City Poison Control Center.)

aspiration, the most dependent portions of the lung are affected. When the patient is upright at the time of aspiration, the lower lung segments are involved. When the patient is supine, the posterior segments of the upper and lower lobes are affected.<sup>75</sup>

### Multifocal Airspace Filling

Multifocal airspace filling occurs with septic pulmonary emboli, which is a complication of injection drug use and right-sided bacterial endocarditis. The foci of pulmonary infection often undergo necrosis and cavitation (Fig. 8-18).<sup>91,95</sup>

### Interstitial Lung Diseases

Toxicologic causes of interstitial lung disease include hypersensitivity pneumonitis, use of medications with direct pulmonary toxicity, and inhalation or injection of inorganic particulates.<sup>91</sup> Interstitial lung diseases have acute, subacute, or chronic courses. On the chest radiograph, acute and subacute disorders cause a fine reticular or reticulonodular pattern (Fig. 8-19). Chronic interstitial disorders cause a coarse reticular “honeycomb” pattern.

### Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis is a delayed-type hypersensitivity reaction to an inhaled or ingested allergen.<sup>49,113,195</sup> Inhaled organic allergens such as those in moldy hay (farmer’s lung) and bird droppings (pigeon breeder’s lung) cause hypersensitivity pneumonitis in sensitized individuals. There are two clinical syndromes: an acute, recurrent illness and a chronic, progressive illness. The acute illness presents with fever and dyspnea. In these cases, the chest radiograph findings are normal or show fine interstitial or alveolar infiltrates. Chronic hypersensitivity pneumonitis causes progressive dyspnea, and the radiograph shows interstitial fibrosis.

The most common medication causing hypersensitivity pneumonitis is nitrofurantoin. Respiratory symptoms occur after taking the medication for

**FIGURE 8-18.** Multifocal airspace filling. The chest radiograph in an injection drug user who presented with high fever but without pulmonary symptoms. Multiple ill-defined pulmonary opacities are seen throughout both lungs, which are characteristic of septic pulmonary emboli. His blood cultures grew *Staphylococcus aureus*. (Used with permission from the Fellowship in Medical Toxicology, NYU School of Medicine, New York City Poison Control Center.)

**FIGURE 8-19.** Reticular interstitial pattern. The chest radiograph of a patient with cardiac disease who presented to the emergency department with progressive dyspnea. The initial diagnostic impression was interstitial pulmonary edema. The patient was taking amiodarone for malignant ventricular dysrhythmias (note the implanted automatic defibrillator). The lack of response to diuretics and the high-resolution computed tomography pattern suggested that this was toxicity to amiodarone. The medication was stopped, and there was partial clearing over several weeks. (Used with permission from Dr. Georgeann McGuinness, Department of Radiology, New York University.)

1 to 2 weeks. Other medications that may cause hypersensitivity pneumonitis include sulfonamides and penicillins.

### Chemotherapeutics

Various chemotherapeutics, such as bleomycin, busulfan, cyclophosphamide, and methotrexate, cause pulmonary injury by their direct cytotoxic effect on alveolar cells.<sup>48,79</sup> The radiographic pattern is usually interstitial (reticular or nodular) but also includes airspace filling or mixed patterns. The patient presents with dyspnea, fever, and pulmonary infiltrates that begin after several weeks of therapy. Other causes of these clinical and radiographic findings must be evaluated, including opportunistic infection, pulmonary carcinomatosis, pulmonary edema, and intraparenchymal hemorrhage. Symptoms usually resolve with discontinuation of the offending medication.

### Amiodarone

Amiodarone toxicity causes phospholipid accumulation within alveolar cells and results in pulmonary fibrosis. An interstitial radiographic pattern is seen, although airspace filling also occur (Fig. 8-19) (Chap. 57).

### Particulates

Inhaled inorganic particulates, such as asbestos, silica, and coal dust, cause pneumoconiosis. This is a chronic interstitial lung disease characterized by interstitial fibrosis and loss of lung volume.<sup>2,198,258</sup> Intravenous injection of illicit xenobiotics that have particulate contaminants, such as talc, causes a chronic interstitial lung disease known as talcosis.<sup>2,64,255</sup>

### Pleural Disorders

Asbestos-related calcified pleural plaques develop many years after asbestos exposure (Fig. 8-20). These lesions do not cause clinical symptoms and have only a minor association with malignancy and interstitial lung disease. Asbestos-related pleural plaques should not be called *asbestosis* because that term refers specifically to the interstitial lung disease caused by asbestos. Pleural plaques must be distinguished from mesotheliomas, which are not calcified, enlarge at a rapid rate, and erode into nearby structures such as the ribs.

Pleural effusions occur with drug-induced systemic lupus erythematosus (SLE).<sup>165</sup> The medications most frequently implicated are procainamide, hydralazine, isoniazid, and methyldopa. The patient presents with fever as well as other symptoms of SLE.

Pneumothorax and pneumomediastinum are associated with illicit drug use. These complications are related to the route of administration rather than to the particular drug. Barotrauma associated with the Valsalva maneuver or intense inhalation with breath holding during the smoking of “crack” cocaine or marijuana results in pneumomediastinum (Fig. 8-21A).<sup>24,59,91,177</sup> Pneumomediastinum is one cause of cocaine-related chest pain that can be diagnosed by chest radiography. Forceful vomiting after ingestion of syrup of ipecac or alcohol produces a Mallory-Weiss syndrome, pneumomediastinum, and mediastinitis (Boerhaave syndrome).<sup>264</sup> Intravenous drug users who attempt to inject into the subclavian and internal jugular veins cause pneumothoraces.<sup>55</sup>

### Lymphadenopathy

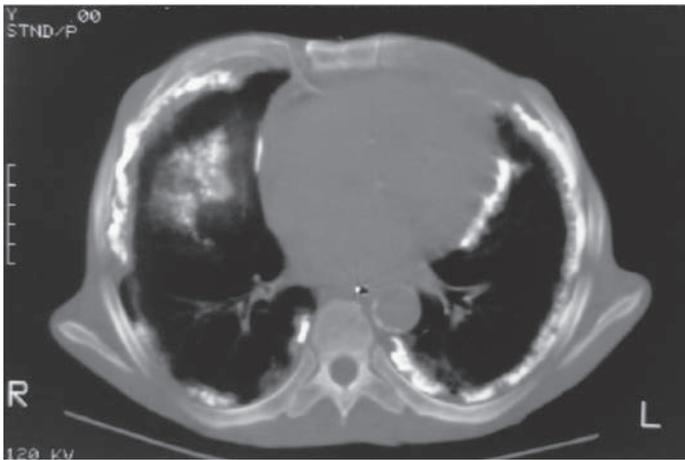

Phenytoin causes drug-induced lymphoid hyperplasia with hilar lymphadenopathy.<sup>165</sup> Chronic beryllium exposure results in hilar lymphadenopathy that mimics sarcoidosis, with granulomatous changes in the lung parenchyma. Silicosis is associated with “eggshell” calcification of hilar lymph nodes.

### Cardiovascular Abnormalities

Dilated cardiomyopathy occurs in chronic alcoholism and exposure to cardiotoxic medications such as doxorubicin. Enlargement of the cardiac silhouette is also caused by a pericardial effusion, which accompanies drug-induced SLE. Aortic dissection is associated with use of cocaine and amphetamines.<sup>80,91,134,180,190,194,221</sup> The chest radiograph shows an enlarged or indistinct aortic knob and an enlarged ascending or descending aorta (Figs. 8-21B to D).

A

B

**FIGURE 8-20.** (A) Calcified plaques typical of asbestos exposure are seen on the pleural surfaces of the lungs, diaphragm, and heart. The patient was asymptomatic; this was an incidental radiographic finding. (B) The computed tomography (CT) scan demonstrates that the opacities seen on the chest radiograph do not involve the lung itself. A lower thoracic image shows calcified pleural plaques (the diaphragmatic plaque is seen on the right). The CT scan confirms that there is no interstitial lung disease (“asbestosis”). (Used with permission from the Fellowship in Medical Toxicology, NYU School of Medicine, New York City Poison Control Center.)

## Abdominal Problems

Abdominal imaging modalities include conventional radiography, CT, GI contrast studies, and angiography.<sup>82,222</sup> Conventional radiography is limited in its ability to detect most intraabdominal pathology because most pathologic processes involve soft tissue structures that are not well seen. Plain radiography readily visualizes gas in the abdomen and is therefore useful to diagnose pneumoperitoneum (free intraperitoneal air) and bowel distension caused by mechanical obstruction or diminished gut motility (adynamic ileus). Other abnormal gas collections, such as intramural gas associated with intestinal infarction, are seen infrequently (Table 8-4).<sup>88,141,151,162,225</sup>

### Pneumoperitoneum

Gastrointestinal perforation is diagnosed by the visualization of free intraperitoneal air under the diaphragm on an upright chest radiograph. Peptic ulcer perforation is associated with crack cocaine use.<sup>3,36,127</sup> Esophageal or gastric perforation (or tear) is a well reported complication of forceful emesis induced by syrup of ipecac or alcohol intoxication or attempted placement of a large-bore orogastric tube (Fig. 8-22).<sup>264</sup> Esophageal and gastric perforation

also occur after the ingestion of caustics such as iron, alkali, or acid.<sup>121</sup> Esophageal perforation causes pneumomediastinum and mediastinitis.

### Obstruction and Ileus

Both mechanical bowel obstruction and adynamic ileus (diminished gut motility) cause bowel distension. With mechanical obstruction, there are a greater amount of intestinal distension proximal to the obstruction and a relative paucity of gas and intestinal collapse distal to the obstruction. In adynamic ileus, the bowel distension is relatively uniform throughout the entire intestinal tract. On the upright abdominal radiograph, both mechanical obstruction and adynamic ileus show air-fluid levels. In mechanical obstruction, air-fluid levels are seen at different heights and produce a “stepladder” appearance.

Mechanical bowel obstruction is caused by large intraluminal foreign bodies such as a body packer’s packets or a medication bezoar.<sup>77,238</sup> Adynamic ileus results from the use of opioids, anticholinergics, and tricyclic antidepressants (Fig. 8-23).<sup>18,82</sup> Because adynamic ileus occurs in many diseases, the radiographic finding of an ileus is not helpful diagnostically. When the distinction between obstruction and adynamic ileus cannot be made based on the abdominal radiographs, abdominal CT can clarify the diagnosis.<sup>160</sup>

### Mesenteric Ischemia

In most patients with intestinal ischemia, plain abdominal radiographs show only a nonspecific or adynamic ileus pattern. In a small proportion of patients with ischemic bowel (5%), intramural gas is seen.<sup>18</sup> Rarely, gas is also seen in the hepatic portal venous system. Computed tomography is better able to detect signs of mesenteric ischemia particularly bowel wall thickening (Fig. 8-24).<sup>17</sup>

Intestinal ischemia and infarction infrequently are caused by the use of cocaine; other sympathomimetics; and the ergot alkaloids, all of which induce mesenteric vasoconstriction.<sup>95,130,154</sup> Calcium channel blocker overdoses cause splanchnic vasodilation and hypotension that results in intestinal ischemia. Superior mesenteric vein thrombosis is caused by hypercoagulability associated with chronic oral contraceptive use.

### Gastrointestinal Hemorrhage and Hepatotoxicity

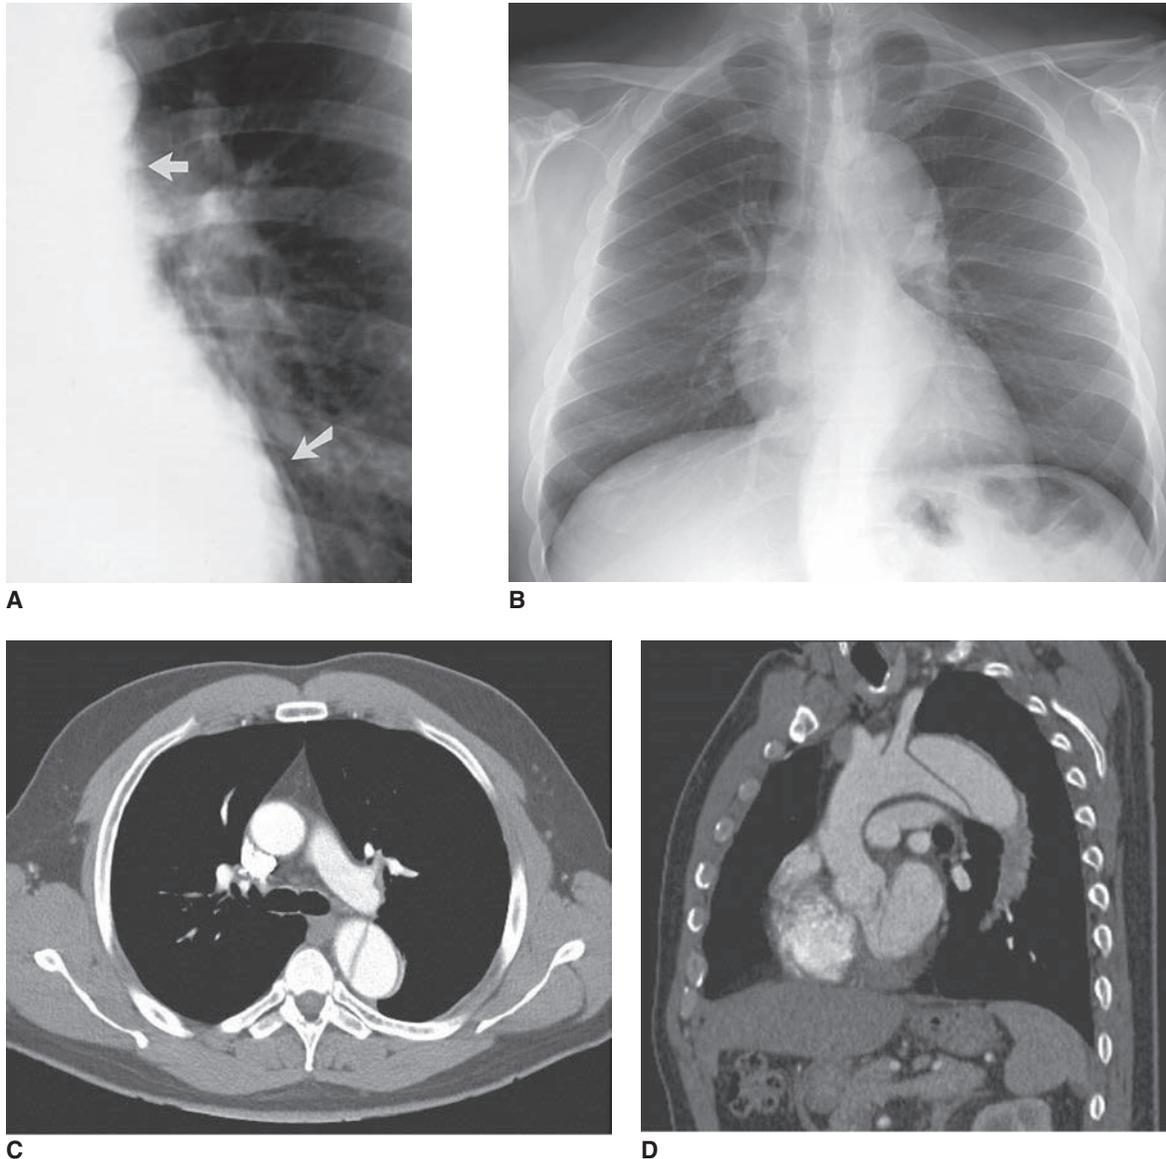

Radiography is not usually helpful in the diagnosis of such common abdominal complications as GI hemorrhage and hepatotoxicity unless the bleeding is due to ingestion of ferrous sulfate tablets.

The now obsolete radiocontrast thorium dioxide (Thorotrast; thorium, atomic number 90) provides a unique example of pharmaceutical-induced hepatotoxicity. It was used as angiographic contrast until 1947, when it was found to cause hepatic malignancies. The radioactive isotope of thorium has a half-life of 400 years. It accumulates within the reticuloendothelial system and remains there for the life of the patient. It had a characteristic radiographic appearance, with multiple punctate opacities in the liver, spleen, and lymph nodes (Fig. 8-25). Patients who received thorium before its removal from the market still rarely present with hepatic malignancies.<sup>22,247</sup>

### Contrast Esophagram and Upper Gastrointestinal Series

Ingestion of a caustic causes severe damage to the mucosal lining of the esophagus. This can be demonstrated by a contrast esophagram. However, in the acute setting, upper endoscopy should be performed rather than an esophagram because it provides more information about the extent of injury and prognosis. In addition, administration of barium will coat the mucosa, making endoscopy difficult. Computed tomography has been proposed as a noninvasive means to assess degree of esophageal injury and estimate the risk of later developing an esophageal stricture.<sup>207</sup> For later evaluation, a contrast esophagram identifies mucosal defects, scarring, and stricture formation (Figs. 8-26 and 103-4).<sup>153,207</sup>

The choice of radiographic contrast material (barium or water-soluble material) depends on the clinical situation. If the esophagus is severely strictured and there is a risk of aspiration, barium should be used because water-soluble contrast material is damaging to the pulmonary parenchyma. If, on the other hand, esophageal or gastric perforation is suspected, water-soluble

**FIGURE 8-21.** Two patients with chest pain after cocaine use. (A) Pneumomediastinum after forceful inhalation while smoking “crack” cocaine. A fine white line representing the pleura elevated from the mediastinal structures is seen (arrows). The patient’s chest pain resolved during a 24-hour period of observation. (B to D) Thoracic aortic dissection after cocaine use. The patient presented with chest pain radiating to the back. He had a history of hypertension and was noncompliant with medications. Chest radiography shows an enlarged aorta caused by aortic wall weakening secondary to his long-standing hypertension. Computed tomography angiography shows the intraluminal dissection flap originating at the left subclavian artery and extending into the descending aorta. (Used with permission from the Fellowship in Medical Toxicology, NYU School of Medicine, New York City Poison Control Center.)

contrast is safer because extravasated barium is highly irritating to mediastinal and peritoneal tissues, but extravasated water-soluble contrast is gradually absorbed into the circulation.

Ingested foreign bodies cause esophageal and gastric outlet obstruction. Esophageal obstruction caused by a drug packet can be demonstrated by a contrast esophagram. Bezoars and concretions of ingested material in the stomach may cause gastric outlet obstruction. This is reported with potassium chloride tablets and enteric-coated aspirin.<sup>12,224</sup>

### Abdominal Computed Tomography

CT provides great anatomic definition of intraabdominal organs and plays an important role in the diagnosis of a wide variety of abdominal disorders. In most cases, both oral and IV contrast are administered. Oral contrast delineates the intestinal lumen. Intravenous contrast is needed to reliably detect lesions in hepatic and splenic parenchyma, the kidneys, and the bowel wall.

Certain abdominal complications of poisonings are amenable to CT diagnosis. Intestinal ischemia causes bowel wall thickening; intramural

hemorrhage; and at a later stage, intramural gas and hepatic portal venous gas (Fig. 8-24).<sup>17</sup> Hepatic portal venous gas is also seen after ingestion of high-concentration hydrogen peroxide (Fig. 8-27).<sup>29,71,78,84,150,167,179,196</sup> Splenic infarction and splenic and psoas abscesses are complications of IV drug use that are diagnosed on CT.<sup>18</sup> Radiopaque foreign substances such as intravenously injected elemental mercury may be detected and accurately localized by CT.<sup>148</sup> Ingested foreign bodies, such as a body packer’s packets, are detected on noncontrast CT (Fig. 8-8D and Special Considerations: SC5-2 and 5-3).<sup>16,99,101,147</sup>

### Vascular Lesions

Angiography detects such complications of injection drug use as venous thrombosis and arterial laceration causing pseudoaneurysm formation (Figs. 8-28 and 8-29). Intravenous injection of amphetamine, cocaine, or ergotamine causes necrotizing angitis that is associated with microaneurysms, segmental stenosis, and arterial thrombosis. These lesions are seen in the kidneys, small bowel, liver, pancreas, and cerebral circulation (Fig. 8-30).<sup>41,95</sup>

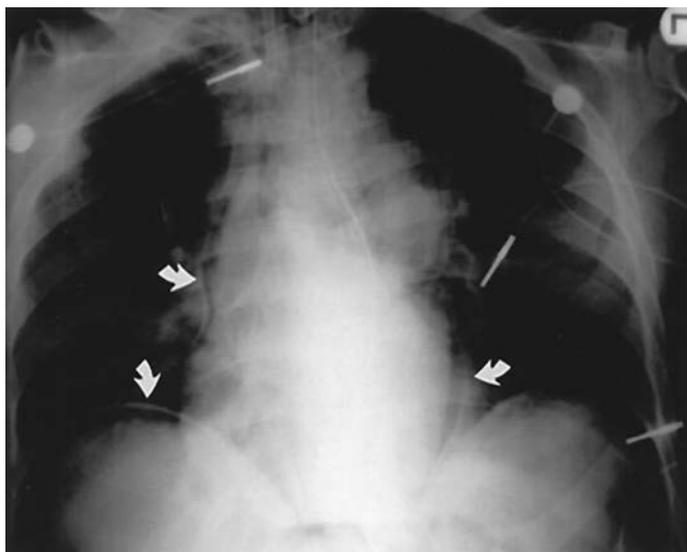

**TABLE 8-4 Plain Abdominal Radiography in Toxicologic Emergencies**

Radiographic Finding	Xenobiotic
Pneumoperitoneum (hollow viscus perforation)	Caustics: iron, alkali, acids Cocaine GI decontamination (ipecac, lavage tube)
Mechanical obstruction (intraluminal foreign body)	Foreign-body ingestion Body packer Enteric-coated pills Bezoar
Intestinal Gastric outlet } Upper GI series Esophageal }	
Ileus (diminished gut motility)	Antimuscarinics Cyclic antidepressants Mesenteric ischemia caused by cocaine, oral contraceptives, cardioactive steroids Hypokalemia Hypomagnesemia Opioids
Intramural gas (intestinal infarction)	Calcium channel blockers Cocaine
Bowel wall thickening	Cocaine
Hepatic portal venous gas (CT is more sensitive)	Ergot alkaloids Oral contraceptives
Foreign-body ingestion	Bismuth subsalicylate Body packers and stuffers Calcium carbonate Enteric-coated and sustained-release tablets Iron pills Metals (As, Cs, Hg, K, Pb, Tl) Pica (calcareous clay)
Nephrocalcinosis	Calcium Vitamin D

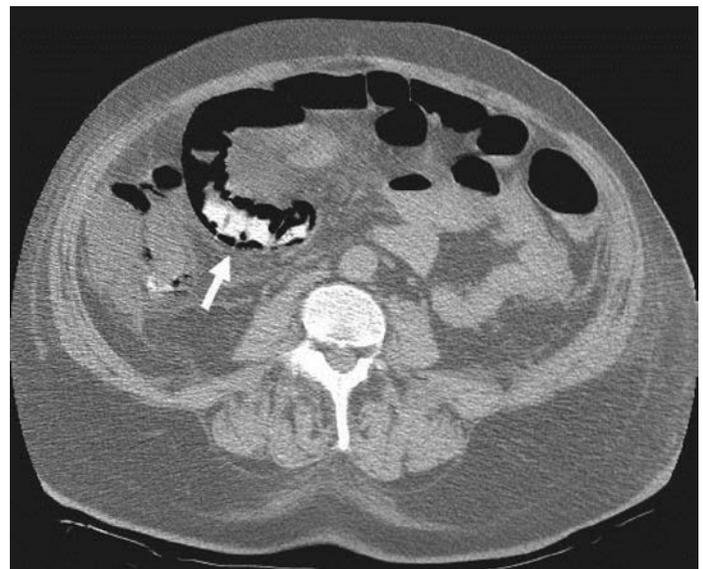

CT = computed tomography; GI = gastrointestinal.

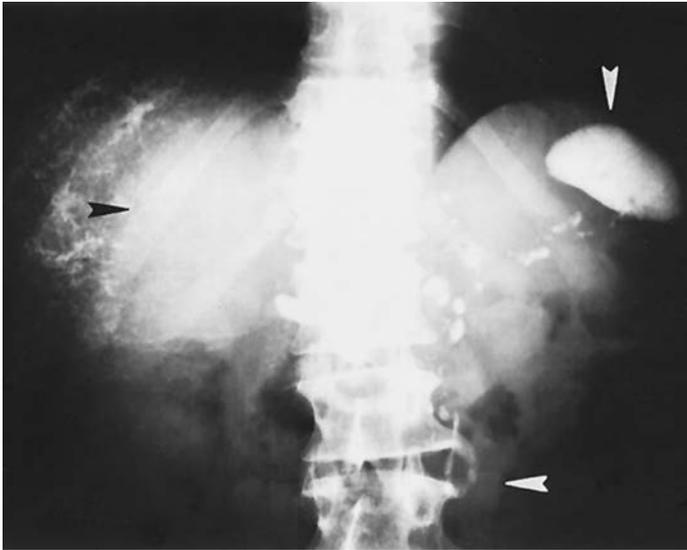

**FIGURE 8-23.** Methadone maintenance therapy causing marked abdominal distension. The radiograph reveals striking large bowel dilatation, termed *colonic ileus*, caused by chronic opioid use. A similar radiographic picture is seen with anticholinergic poisoning. A contrast enema can clarify the diagnosis. (Used with permission from Dr. Emil J. Balthazar, Department of Radiology, Bellevue Hospital Center.)

**FIGURE 8-22.** Gastrointestinal perforation after gastric lavage with a large-bore orogastric tube. The upright chest radiograph shows air under the right hemidiaphragm and pneumomediastinum (arrows). An esophagram with water-soluble contrast did not demonstrate the perforation. Laparotomy revealed perforation of the anterior wall of the stomach. (Used with permission from the Fellowship in Medical Toxicology, NYU School of Medicine, New York City Poison Control Center.)

**FIGURE 8-24.** Bowel infarction in a 50-year-old man with an aspirin overdose. He presented with kidney failure, hypotension, and altered mental status. The next day after hemodialysis and hemofiltration, he developed abdominal distension and fever. Abdominal computed tomography showed extensive intramural gas (arrow) caused by bowel infarction, and the patient underwent surgical bowel resection. (Used with permission from the Fellowship in Medical Toxicology, NYU School of Medicine, New York City Poison Control Center.)

**FIGURE 8-25.** An abdominal radiograph of a patient who had received thorium dioxide (Thorotrast) for a radiocontrast study many years previously. The spleen (vertical white arrowhead), liver (horizontal black arrowhead), and lymph nodes (horizontal white arrowhead) are demarcated by thorium retained in the reticuloendothelial system. (Used with permission from Dr. Emil J. Balthazar, Department of Radiology, Bellevue Hospital Center.)

Complications include aneurysm rupture and visceral infarction. Renal lesions cause severe hypertension and acute kidney injury.<sup>210</sup>

### Neurologic Problems

Diagnostic imaging studies have revolutionized the management of CNS disorders.<sup>67,86</sup> Both acute brain lesions and chronic degenerative changes are detected (Table 8-5).<sup>139,237</sup> Some xenobiotics have a direct toxic effect on the

CNS; others indirectly cause neurologic injury by causing hypoxia, hypotension, hypertension, cerebral vasoconstriction, head trauma, or infection.

### Imaging Modalities

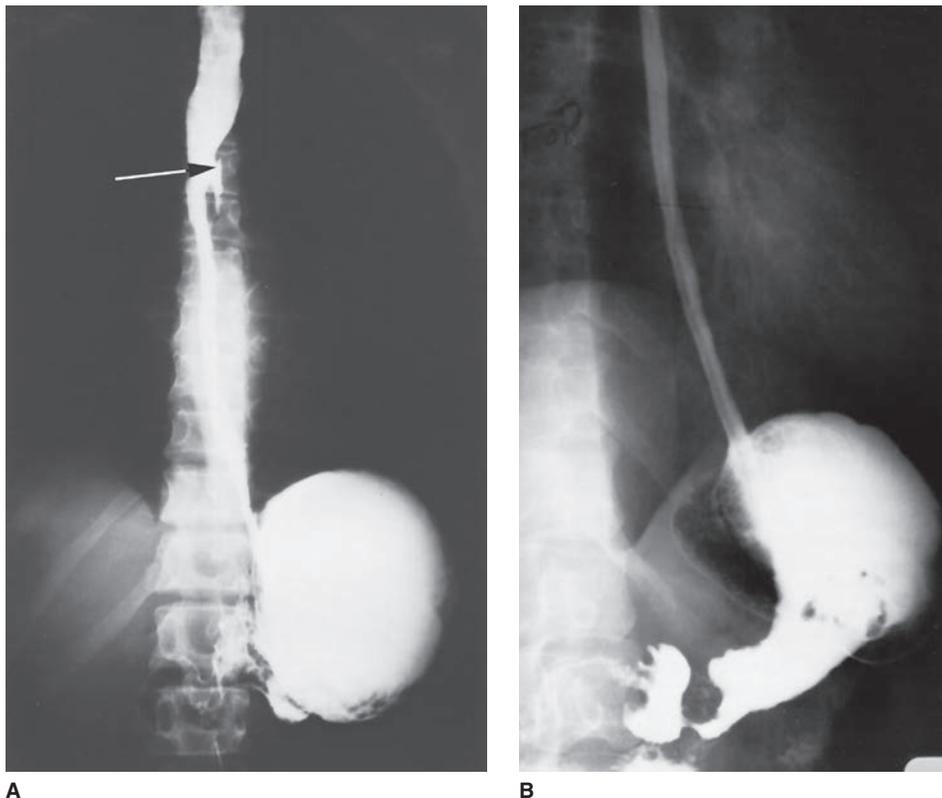

Computed tomography can directly visualize brain tissue and many intracranial lesions.<sup>85</sup> Computed tomography is the imaging study of choice in the emergency setting because it readily detects acute intracranial hemorrhage as well as parenchymal lesions that are causing mass effect. Computed tomography is fast, is widely available on an emergency basis, and can accommodate critical patient support and monitoring devices. Infusion of IV contrast further delineates intracerebral mass lesions such as tumors and abscesses.

*Magnetic resonance imaging* (MRI) has largely supplanted CT in nonemergency neurodiagnosis. It offers better anatomic discrimination of brain tissues and areas of cerebral edema and demyelination. However, MRI is no better than CT in detecting acute blood collections or mass lesions. In the emergency setting, the disadvantages of MRI outweigh its strengths. Magnetic resonance imaging is often readily available on an emergency basis, but image acquisition time is long, and critical care supportive and monitoring devices are often incompatible with MR scanning machines.<sup>142</sup>

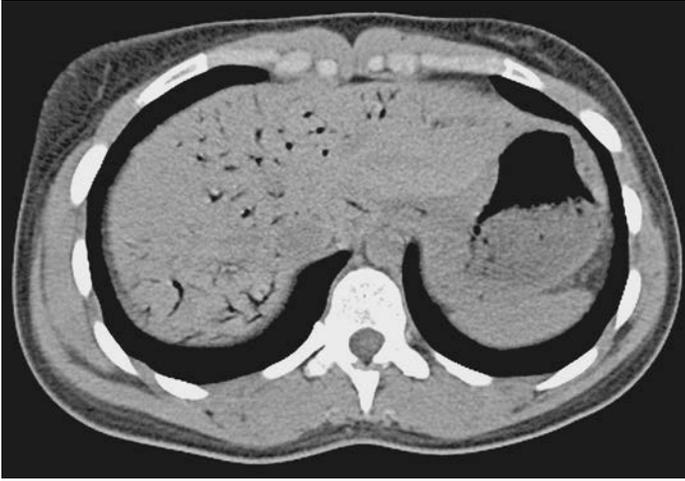

*Nuclear scintigraphy* that uses CT technology (SPECT and PET) is being used as a tool to elucidate functional characteristics of the CNS. Examples include both immediate and long-term effects of various xenobiotics on regional brain metabolism, blood flow, and neurotransmitter function.<sup>73,135,182,250</sup>

### Emergency Cranial Computed Tomography Scanning

An emergency noncontrast CT scan is obtained to detect acute intracranial hemorrhage and focal brain lesions causing cerebral edema and mass effect. Patients with these lesions present with focal neurologic deficits, seizures, headache, or altered mental status. Toxicologic causes of intraparenchymal and subarachnoid hemorrhage include cocaine and other sympathomimetics (Fig. 8-31).<sup>133,138</sup> Cocaine-induced vasospasm causes ischemic infarction, although this is not well seen by CT until 6 to 24 or more hours after onset of

**FIGURE 8-26.** (A) A barium swallow performed several days after ingestion of liquid lye shows intramural dissection and extravasation of barium with early stricture formation. (B) At 3 weeks after ingestion, there are an absence of peristalsis, diffuse narrowing of the esophagus, and reduction in size of the fundus and antrum of the stomach as a result of scarring. (Used with permission from Dr. Emil J. Balthazar, Department of Radiology, Bellevue Hospital Center.)

**FIGURE 8-27.** Abdominal computed tomography showing extensive hepatic portal venous gas in a woman who inadvertently ingested a small quantity of commercial concentration (35%) hydrogen peroxide. She also had gastric and esophageal erosions on endoscopy and was treated successfully with antacids and hyperbaric oxygen. (Used with permission from the Fellowship in Medical Toxicology, NYU School of Medicine, New York City Poison Control Center.)

the neurologic deficit (Fig. 8-32). Drug-induced CNS depression, most commonly ethanol intoxication, predisposes the patient to head trauma, which may result in a subdural hematoma or cerebral contusion (Fig. 8-33). Toxicologic causes of intracerebral mass lesions include septic emboli complicating injection drug use and HIV-associated CNS toxoplasmosis and lymphoma (Fig. 8-34).<sup>23,90,95,175</sup> On a contrast CT, such tumors and focal infections exhibit a pattern of “ring enhancement.”

### Xenobiotic-Mediated Neurodegenerative Disorders

A number of xenobiotics directly damage brain tissue, producing morphologic changes that may be detectable using CT and especially MRI. Such changes include generalized atrophy, focal areas of neuronal loss, demyelination, and cerebral edema. Imaging abnormalities help establish a diagnosis or predict prognosis in a patient with neurologic dysfunction after a xenobiotic exposure. In some cases, the imaging abnormality will suggest a

toxicologic diagnosis in a patient with a neurologic disorder in whom a xenobiotic exposure was not suspected clinically.<sup>5,14, 67,117,124,183,237,257</sup>

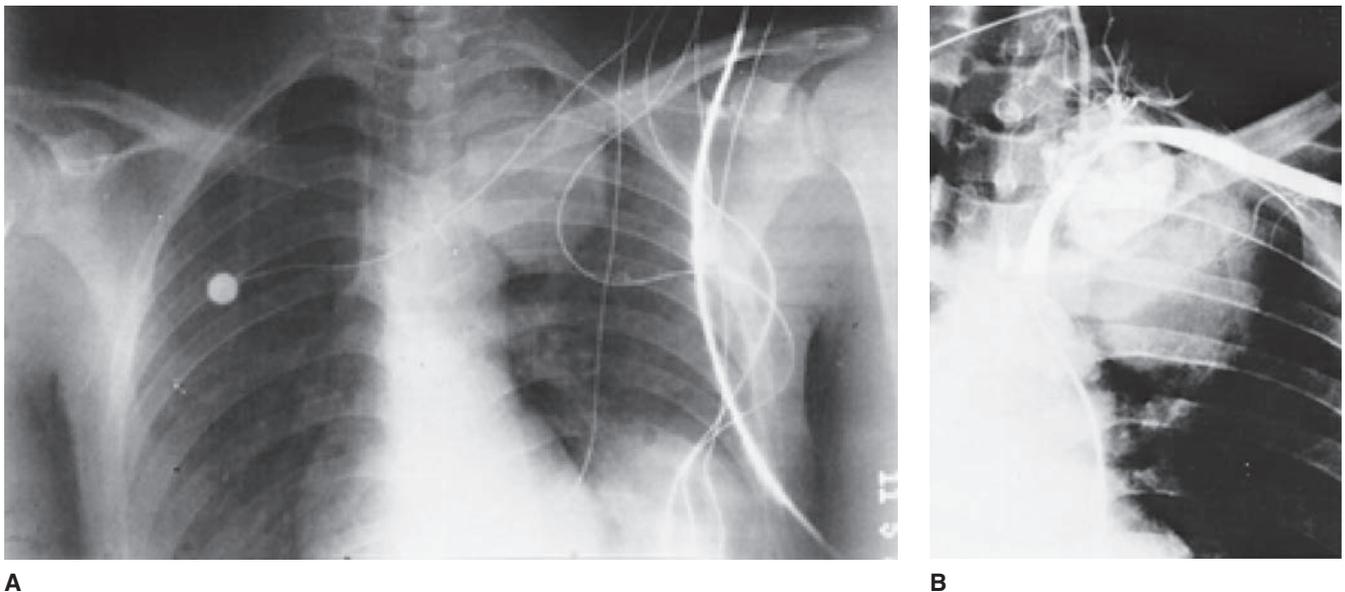

**Atrophy.** Ethanol is the most widely used neurotoxin. With long-term ethanol use, there is a widespread loss of neurons and resultant atrophy. In some individuals with alcoholism, the loss of brain tissue is especially prominent in the cerebellum. However, the amount of cerebral or cerebellar atrophy does not always correlate with the extent of cognitive impairment or gait disturbance.<sup>51,81,100,102,126,252,254</sup> Chronic solvent exposure, such as toluene (occupational and illicit use), also causes diffuse cerebral atrophy.<sup>109,202</sup>

**Focal Lesions.** Carbon monoxide poisoning produces focal degenerative lesions in the brain. In about half of patients with severe neurologic dysfunction after carbon monoxide poisoning, CT scans show bilateral symmetric lucencies in the basal ganglia, particularly the globus pallidus (Figs. 8-35 and 122-1).<sup>35,110,117,155,166,183,187,188,212,213,241,249</sup> The basal ganglia are especially sensitive to hypoxic damage because of their limited blood supply and high metabolic requirements. Subcortical white matter lesions also occur after carbon monoxide poisoning. Although less frequent than lesions of the basal ganglia, white matter lesions are more clearly associated with a poor neurologic outcome. Magnetic resonance imaging is more sensitive than CT at detecting these white matter abnormalities.<sup>35,67,119,188,241</sup>

Basal ganglion lucencies, white matter lesions, and atrophy are caused by other xenobiotics such as methanol,<sup>13,50,83,98,168,205</sup> ethylene glycol, cyanide,<sup>68,163</sup> hydrogen sulfide, inorganic and organic mercury,<sup>156,212</sup> manganese,<sup>14,229</sup> heroin,<sup>124,128</sup> barbiturates, chemotherapeutics, solvents such as toluene,<sup>67,109,202</sup> and podophyllin.<sup>34,170</sup> Nontoxicologic disorders cause similar imaging abnormalities, including hypoxia, hypoglycemia, and infectious encephalitis.<sup>98,104</sup>

Focal lesions in the spinal cord are also caused by xenobiotic exposure, such as habitual use of nitrous oxide, and cause myelopathic symptoms. These lesions are visualized by MRI (Fig. 65-3).

**Posterior Reversible Encephalopathy Syndrome.** A wide range of medical conditions and medications cause symmetrical cortical and subcortical white matter changes that are reversible when the condition or xenobiotic is removed. This was formerly termed *reversible leukoencephalopathy syndrome*, but because the changes are not limited to the white matter and often involve the occipital lobes, it is now more commonly known as *posterior reversible encephalopathy syndrome*. However, this term too has been questioned because the changes are often more diffuse. These changes are most

**FIGURE 8-28.** (A) Chest radiograph of a young drug user who used the supraclavicular approach for heroin injection. The large mass in the left chest was suspicious for a pseudoaneurysm. (B) An arch aortogram performed on the patient revealed a large pseudoaneurysm and hematoma subsequent to an arterial tear during attempted injection. Surgical repair was performed. (Used with permission from Dr. Richard Lefleur, Department of Radiology, Bellevue Hospital.)

**FIGURE 8-29.** Venogram of a 50-year-old patient who routinely injected heroin into his groin. Occlusion of the femoral vein (*black arrowhead*) with diffuse aneurysmal dilatation (*small arrowhead*) and extensive collaterals (*double arrowheads*) are shown. Incidental radiopaque materials are noted in the right buttock (*double arrowheads*). By history, this represents either bismuth or arsenicals he received as antisyphilitic therapy. (Used with permission from Dr. Richard Lefleur, Department of Radiology, Bellevue Hospital.)

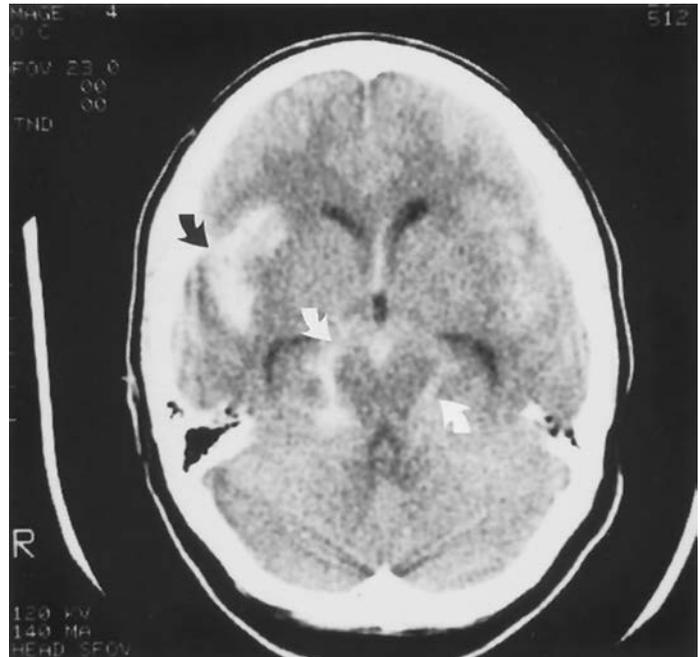

**FIGURE 8-30.** A selective renal angiogram in an injection methamphetamine user demonstrating multiple small and large aneurysms (*arrowheads*). (Used with permission from Dr. Richard Lefleur, Department of Radiology, Bellevue Hospital.)

**TABLE 8-5** Cranial Computed Tomography (Noncontrast) in Toxicologic Emergencies

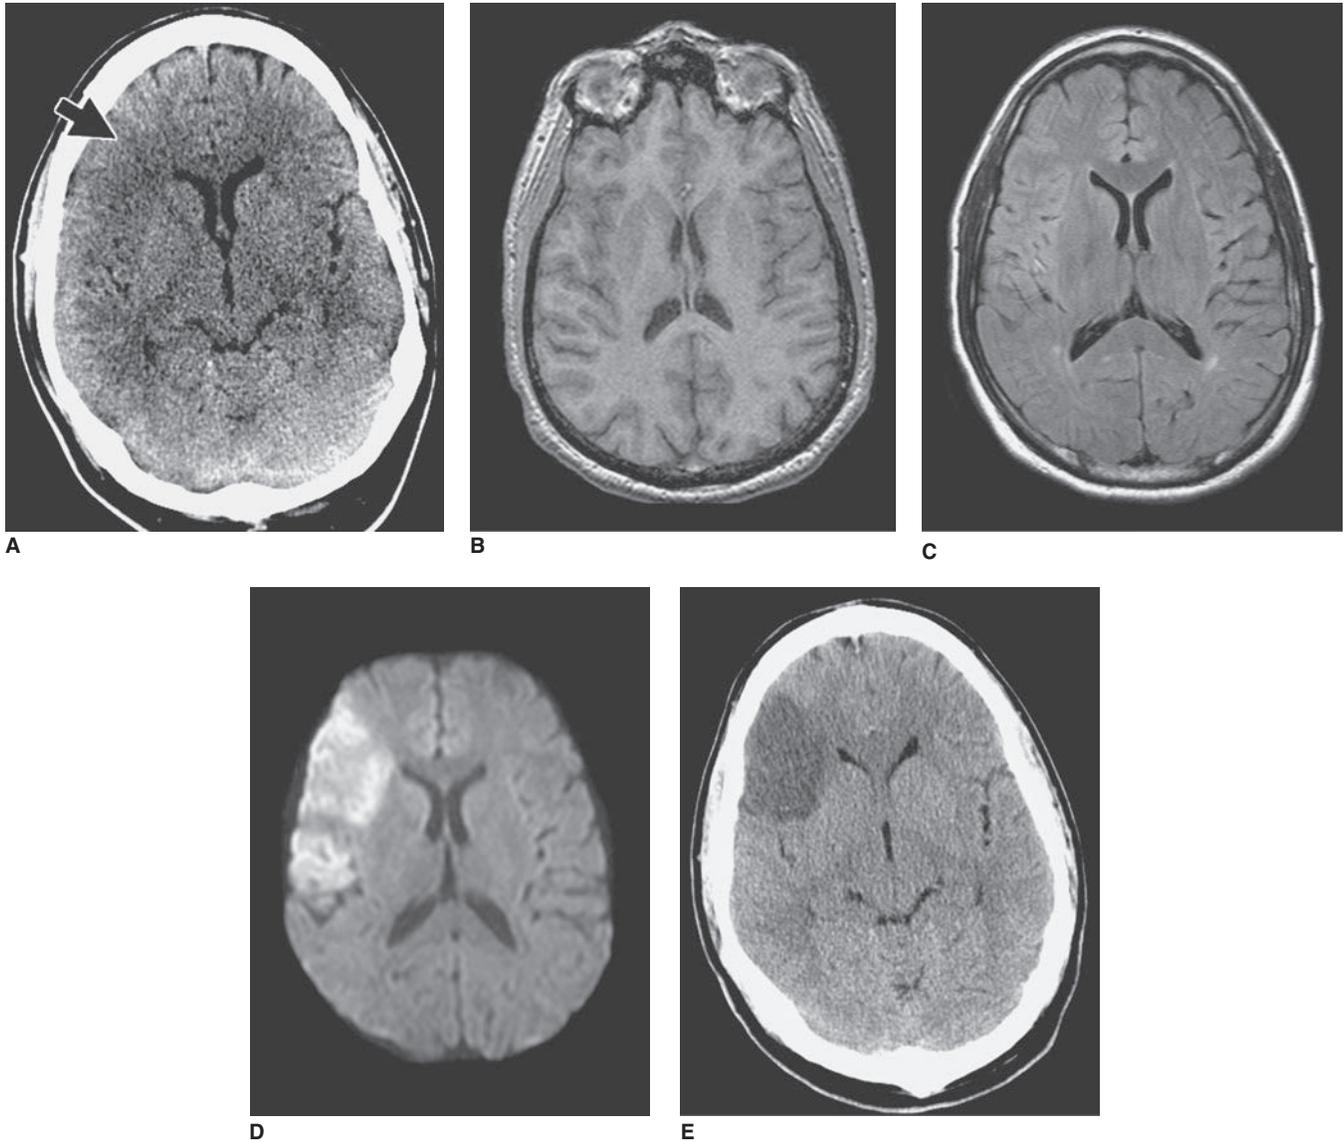

Computed Tomography Finding	Brain Lesion	Xenobiotic Etiology
Hemorrhage	Intraparenchymal hemorrhage	Sympathomimetics: cocaine (“crack”), amphetamine, phenylpropanolamine, phencyclidine, ephedrine, pseudoephedrine
	Subarachnoid hemorrhage	Mycotic aneurysm rupture (IDU)
	Subdural hematoma	Trauma secondary to ethanol, sedative-hypnotics, seizures Anticoagulants, NSAIDs, ASA
Brain lucencies	Basal ganglia focal necrosis (also subcortical white matter lucencies)	Carbon monoxide, cyanide, hydrogen sulfide, methanol, manganese
	Stroke: vasoconstriction	Sympathomimetics: cocaine (“crack”), amphetamine, phenylpropanolamine, phencyclidine; ephedrine, pseudoephedrine; ergotamine
	Mass lesion: tumor, abscess	Septic emboli, AIDS-related CNS toxoplasmosis or lymphoma
Loss of brain tissue	Atrophy: cerebral, cerebellar	Alcoholism, toluene

CNS = central nervous system; IDU = injection drug use; NSAIDs = nonsteroidal antiinflammatory drugs; ASA = Aspirin.

apparent on cranial MRI. The syndrome was initially described in association with hypertensive encephalopathy (malignant hypertension) and eclampsia, but it is associated with a variety of immunosuppressants and chemotherapeutics (cyclophosphamide, tacrolimus cisplatin, vincristine), as well as therapeutic monoclonal antibodies (bevacizumab, rituximab, adalimumab).

**FIGURE 8-31.** Subarachnoid hemorrhage after intravenous cocaine use. The patient had sudden severe headache followed by a generalized seizure. Extensive hemorrhage is seen surrounding the midbrain (*white arrows*) and in the right Sylvian fissure (*black arrow*). Angiography revealed an aneurysm at the origin of the right middle cerebral artery. (Used with permission from The Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

**FIGURE 8-32.** Acute stroke confirmed by diffusion-weighted magnetic resonance image (MRI). A 39-year-old man presented with left facial weakness that began 3 hours earlier after smoking crack cocaine. He also complained of left arm “tingling” but had normal examination findings. An emergency noncontrast computed tomography (CT) scan was obtained that was interpreted as normal (A), although in retrospect, there was subtle loss of the normal gray–white differentiation (arrow). Magnetic resonance imaging was obtained to confirm that the facial palsy was a stroke and not a peripheral seventh cranial nerve palsy. Standard MRI sequence (T1-weighted, T2-weighted, and fluid-attenuated inversion recovery) were normal in this early ischemic lesion (B and C). Diffusion-weighted imaging is able to show such early ischemic change—cytotoxic (intracellular) edema (D). The patient’s facial paresis improved but did not entirely resolve. A repeat CT scan 2 days later showed an evolving (subacute) infarction with vasogenic edema (E). Infarction was presumably caused by vasospasm because no carotid artery lesion or cardiac source of embolism was found. (Reproduced with permission from Schwartz DT: *Emergency Radiology: Case Studies*. New York, NY: McGraw-Hill; 2008.)

The clinical manifestations include headache, visual disturbance, altered mental status, and seizures (Fig. 8-36).<sup>19,112,132,206</sup> These reversible cerebral disorders are distinct from irreversible white matter disease termed *toxic leukoencephalopathy*. This is associated with various cancer chemotherapeutics, carbon monoxide, toluene, methanol, and heroin inhalation (“chasing the dragon”).<sup>66,197,242</sup>

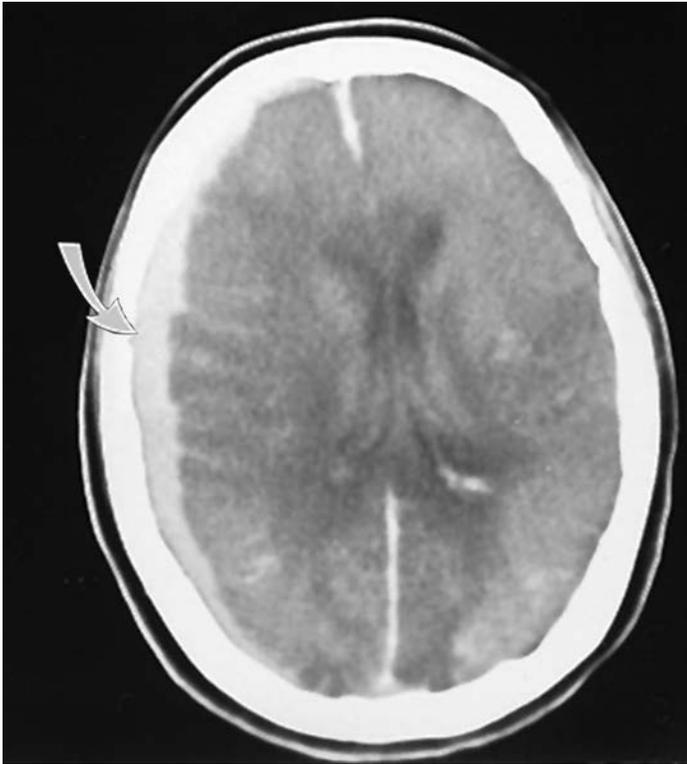

### Nuclear Scintigraphy

Whereas both CT and MRI display cerebral anatomy, nuclear medicine studies provide functional information about the brain. Nuclear scintigraphy uses radioactive isotopes that are bound to carrier molecules (ligands). The choice of ligand depends on the biologic function being studied. Brain cells take up the radiolabeled ligand in proportion to their physiologic activity or the regional blood flow. The radioactive emission from the isotope is detected by a scintigraphic camera, which produces an image showing the quantity and distribution of tracer. Better anatomic detail is provided by using CT

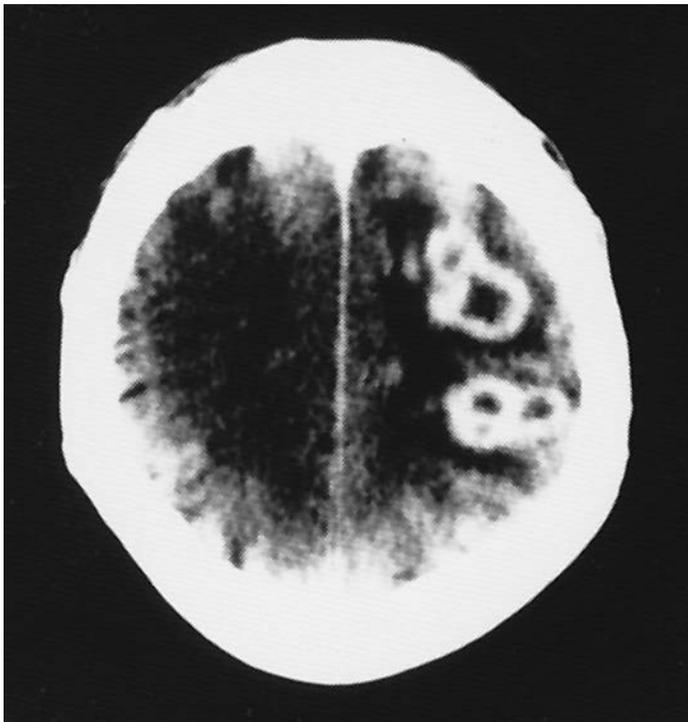

techniques to generate cross-sectional images. There are two such technologies: SPECT and PET. These imaging modalities are used in the research and clinical settings to study the neurologic effects of particular xenobiotics and the mechanisms of xenobiotic-induced neurologic dysfunction.

Single-photon emission computed tomography (SPECT) uses conventional isotopes such as technetium-99m and iodine-123.<sup>135</sup> These isotopes are bound to ligands that are taken up in the brain in proportion to regional blood flow, reflecting the local metabolic rate.

Position emission tomography (PET) uses radioactive isotopes of biologic elements such as carbon-11, oxygen-15, nitrogen-13, and fluoride-18 (a substitute for hydrogen).<sup>182</sup> These radioisotopes have very short half-lives so that PET scanning requires an onsite cyclotron to produce the isotope. The isotopes are incorporated into molecules such as glucose, oxygen, water, various neurotransmitters, and xenobiotics. Labeled glucose is taken up in proportion to the local metabolic rate for glucose. Uptake of labeled oxygen demonstrates the local metabolic rate for oxygen. Labeled neurotransmitters

**FIGURE 8-33.** An acute subdural hematoma in a patient with alcoholism after an alcohol binge. A crescent-shaped blood collection is seen between the right cerebral convexity and the inner table of the skull (arrow). (Used with permission from the Fellowship in Medical Toxicology, NYU School of Medicine, New York City Poison Control Center.)

**FIGURE 8-34.** An injection drug user with ring-enhancing intracerebral lesions. The patient presented with fever and altered mental status. In this patient, the lesions represent multiple septic emboli complicating acute *Staphylococcus aureus* bacterial endocarditis. A similar ring-enhancing appearance is seen with lesions caused by toxoplasmosis or primary central nervous system lymphoma in patients with AIDS. This patient was HIV negative. (Used with permission from the Fellowship in Medical Toxicology, NYU School of Medicine, New York City Poison Control Center.)

**FIGURE 8-35.** A head computed tomography scan of a patient with mental status changes after carbon monoxide poisoning. The scan shows characteristic bilateral symmetrical lucencies of the globus pallidus (arrows). (Used with permission from Dr. Paul Blackburn, Maricopa Medical Center, Arizona.)

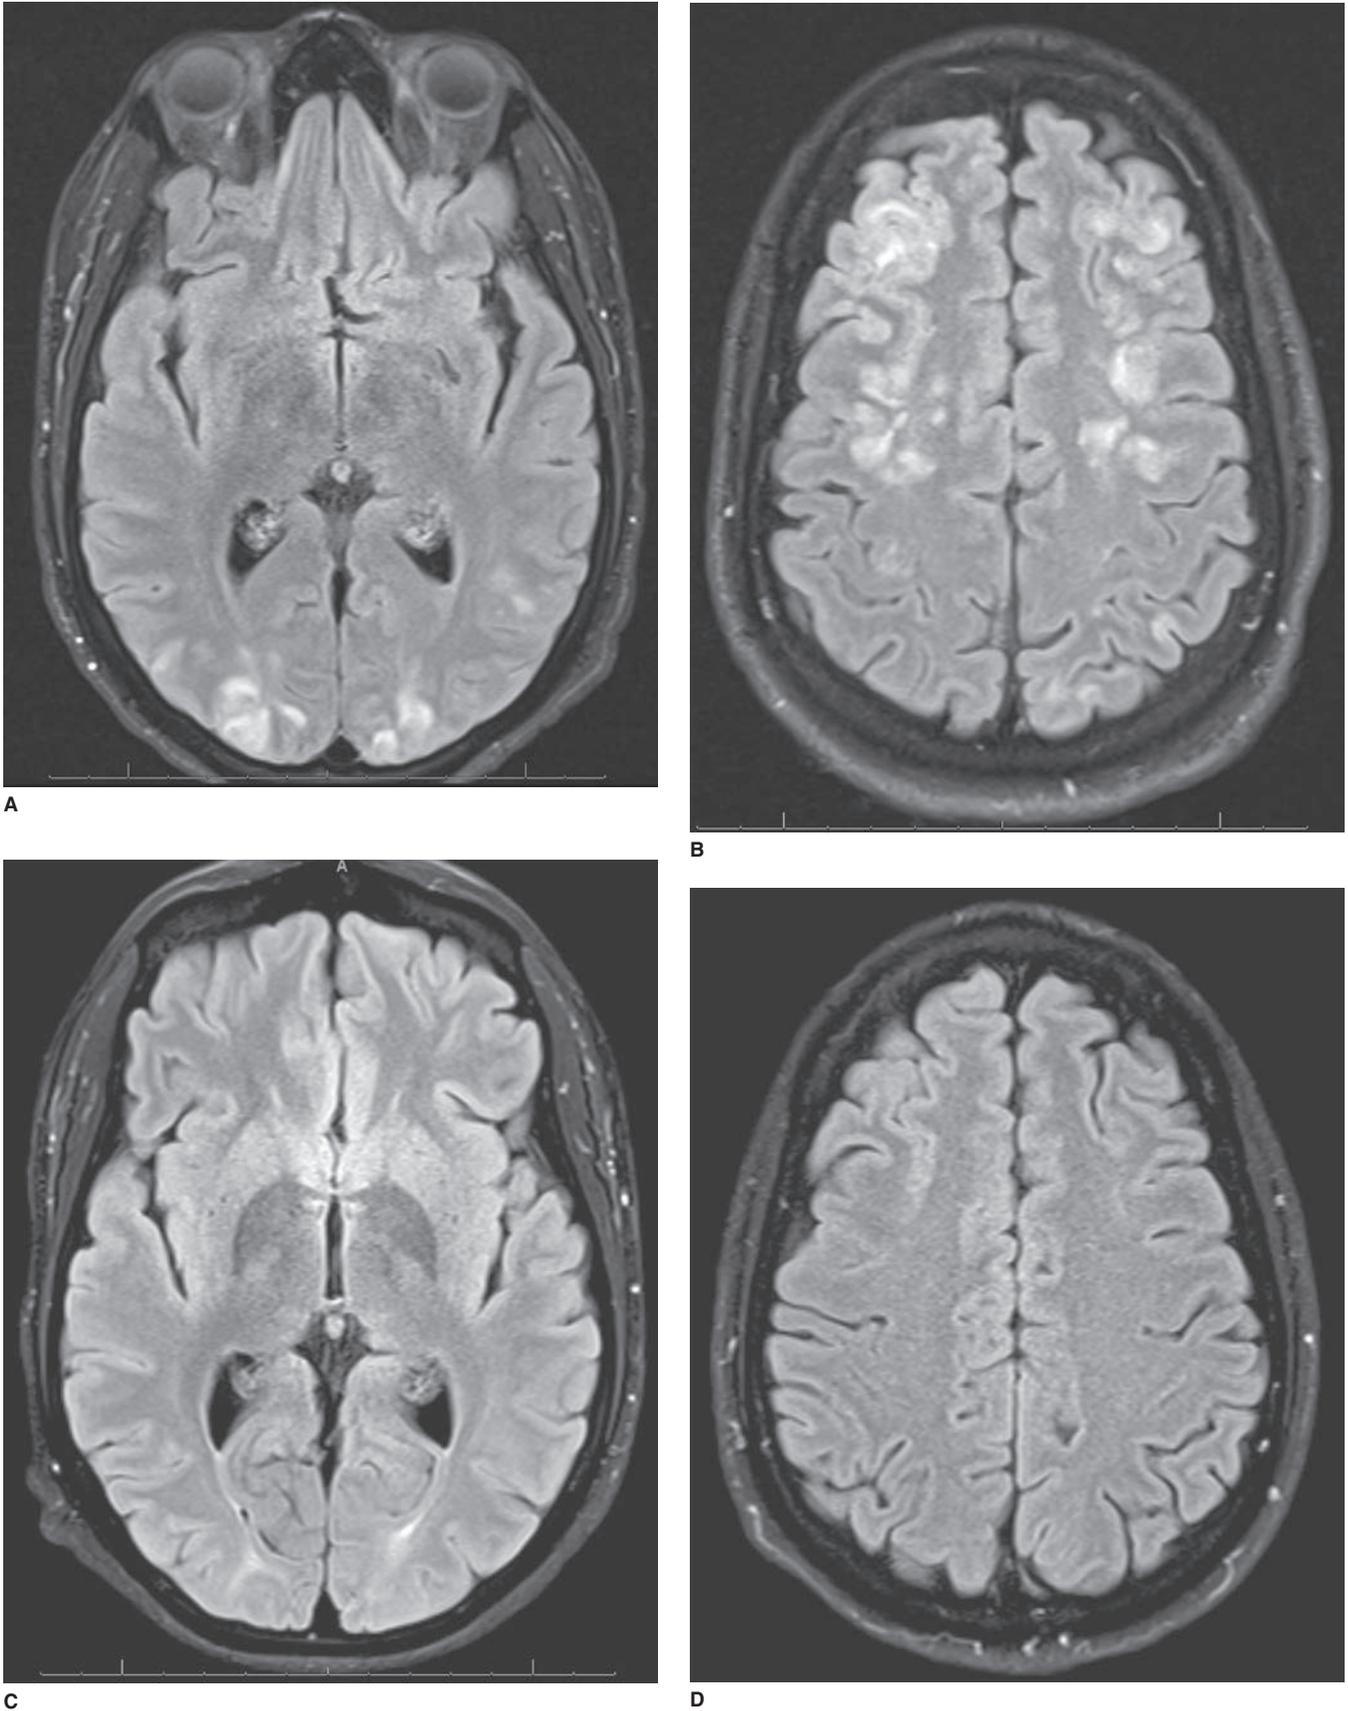

generate images reflecting their concentration and distribution within the brain.

Both PET and SPECT are used to study the effects of various xenobiotics on cerebral function. For example, although both CT and MRI can detect cerebellar atrophy in individuals with chronic alcoholism, there is a poor correlation between the magnitude of cerebellar atrophy and the clinical signs of cerebellar dysfunction. Position emission tomography scans demonstrate diminished cerebellar metabolic rate for glucose, which correlates more accurately with the patient's clinical status.<sup>87,252</sup>

In patients with severe neurologic dysfunction after carbon monoxide poisoning, SPECT regional blood flow measurements show diffuse hypometabolism in the frontal cortex.<sup>37</sup> In one patient, severe perfusion abnormalities improved slightly over several months in proportion to the patient's gradual clinical improvement.<sup>115,220</sup> In another patient treated with hyperbaric oxygen, a SPECT scan revealed increased blood flow in the frontal lobes, although the blood flow still remained significantly diminished.<sup>145</sup>

In patients who chronically use cocaine, SPECT blood flow scintigraphy demonstrates focal cortical perfusion defects. The extent of these perfusion deficits correlates with the frequency of drug use. Focal perfusion defects probably represent local vasculitis or small areas of infarction.<sup>108,245</sup> Position emission tomography scanning has been used to demonstrate the effects of cocaine on cerebral blood flow and regional glucose metabolism. Position emission tomography neurotransmitter studies show promise in elucidating potential mechanisms of action of cocaine. Using radiolabeled dopamine analogs, downregulation of dopamine ( $D_2$ ) receptors is noted after a cocaine binge. This finding is possibly associated with cocaine craving that occurs during cocaine withdrawal. Using  $^{11}C$ -labeled cocaine, uptake of cocaine is demonstrated in the basal ganglia, a region rich in dopamine receptors.<sup>250</sup>

There are many advances in the use of these imaging modalities, and initial applications are being applied to patient care. These imaging modalities are capable of demonstrating abnormalities in many patients with xenobiotic exposures, although other patients with significant cerebral dysfunction have normal study findings.

**FIGURE 8-36.** Posterior reversible encephalopathy syndrome (PRES) caused by cyclosporine. A 29-year-old man with severe aplastic anemia was treated with stem cell transplantation and cyclosporine to prevent subsequent graft versus host disease. The next day, he developed headache followed by a generalized tonic-clonic seizure with a prolonged postictal period. The head computed tomography scan was normal, and magnetic resonance imaging (MRI) revealed symmetric areas of fluid-attenuated inversion recovery hyperintensity involving the cortex and subcortical white matter of the occipital, frontal, and parietal lobes (A and B). Cyclosporine was stopped. The next day, he returned to his normal mental status. Follow-up MRI 1 week later revealed near-complete resolution (C and D). (Used with permission from Dr. Alexander Baxter, Department of Radiology, New York University School of Medicine.)

## SUMMARY

This chapter has highlighted a variety of situations in which diagnostic imaging studies are useful in toxicologic emergencies.

- Imaging is an important tool in establishing a diagnosis, assisting in the treatment of patients, and detecting complications of a toxicologic emergency.
- The imaging modalities include plain radiography, CT, enteric and intravascular contrast studies, nuclear scintigraphy, and ultrasonography.
- Effective use of a diagnostic test requires a precise understanding of the clinical situations in which each test can be useful, knowledge of the capabilities and limitations of the tests, and how the results should be applied to the care of an individual patient.

# PHARMACOKINETIC AND TOXICOKINETIC PRINCIPLES

Mary Ann Howland

*Pharmacokinetics* is the study of the absorption, distribution, metabolism, and excretion of xenobiotics. Xenobiotics are substances that are foreign to the body and include natural or synthetic chemicals, drugs, pesticides, environmental agents, and industrial agents.<sup>56</sup> Mathematical models and equations are used to describe and to predict these phenomena. *Pharmacodynamics* is the term used to describe an investigation of the relationship of therapeutic xenobiotic concentration to its clinical effects. *Toxicokinetics*, which is analogous to pharmacokinetics, is the study of the absorption, distribution, metabolism, and excretion of a xenobiotic under circumstances that produce toxicity. *Toxicodynamics*, which is analogous to pharmacodynamics, is the study of the relationship of toxic xenobiotic concentrations to their clinical effects.

Overdoses challenge the mathematical precision of toxicokinetics and toxicodynamics because many of the variables, such as dose host variables, time of ingestion, and presence of vomiting, or diarrhea, that affect the result are often unknown. In contrast to the therapeutic setting, atypical solubility characteristics are noted, and saturation of enzymatic processes occurs. Intestinal or hepatic enzymatic saturation or alterations in transporters enhance absorption through a decrease in *first-pass effect* defined as metabolism before the xenobiotic reaches the systemic circulation.<sup>5,85</sup> Saturation of plasma protein binding results in the availability of more unbound xenobiotic in the plasma. Saturation of hepatic enzymes or saturation of active renal tubular secretion leads to prolonged elimination (metabolism and excretion). In addition, age, obesity, gender, pharmacogenetics and pharmacogenomics, chronopharmacokinetics (diurnal variations), and the effects of illness and impairment of hepatic and renal function, as well as cardiac output and splanchnic perfusion all further limit the ability to achieve precise analyses.<sup>6,22,47,52,75,81</sup> Furthermore, various treatments may alter one or more pharmacokinetic and toxicokinetic parameters. There are numerous approaches to recognizing these variables, such as obtaining historical information from the patient's family and friends, performing pill counts, procuring sequential serum concentrations during the phases of toxicity, and occasionally repeating a pharmacokinetic evaluation of that same xenobiotic during therapeutic dosing to obtain comparative data.

Although different, *plasma concentration* and *serum concentration* are terms often used interchangeably. When a reference or calculation is made with regard to a concentration in the body, it is actually a plasma concentration. When concentrations are measured in the laboratory, a serum concentration (clotted and centrifuged blood) is often determined. In reality, the laboratory measurements of most xenobiotics in serum or plasma are nearly equivalent. Frequently, this is not the case for whole-blood determination if the xenobiotic distributes into the erythrocyte, such as lead and most other heavy metals.

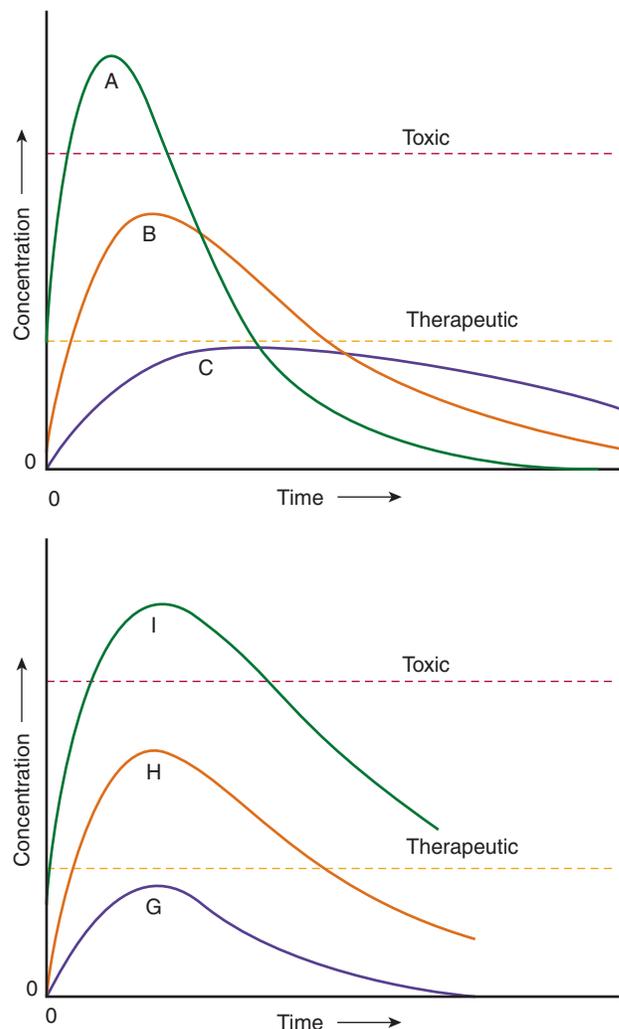

Despite all of the confounding and individual variability, toxicokinetic principles are nonetheless applied to facilitate our understanding and to make predictions. These principles are used to help evaluate whether a certain antidote or extracorporeal removal method is appropriate for use, when the serum concentration might be expected to decrease into the therapeutic range (if one exists), what dose might be considered potentially toxic, what the onset and duration of toxicity might be, and what the importance is of a serum concentration. While considering all of these factors, the clinical status of the patient is paramount, and mathematical formulas and equations can never substitute for a sound clinical assessment. This chapter explains the principles and presents the mathematics in a user-friendly fashion.<sup>90</sup>

## ABSORPTION

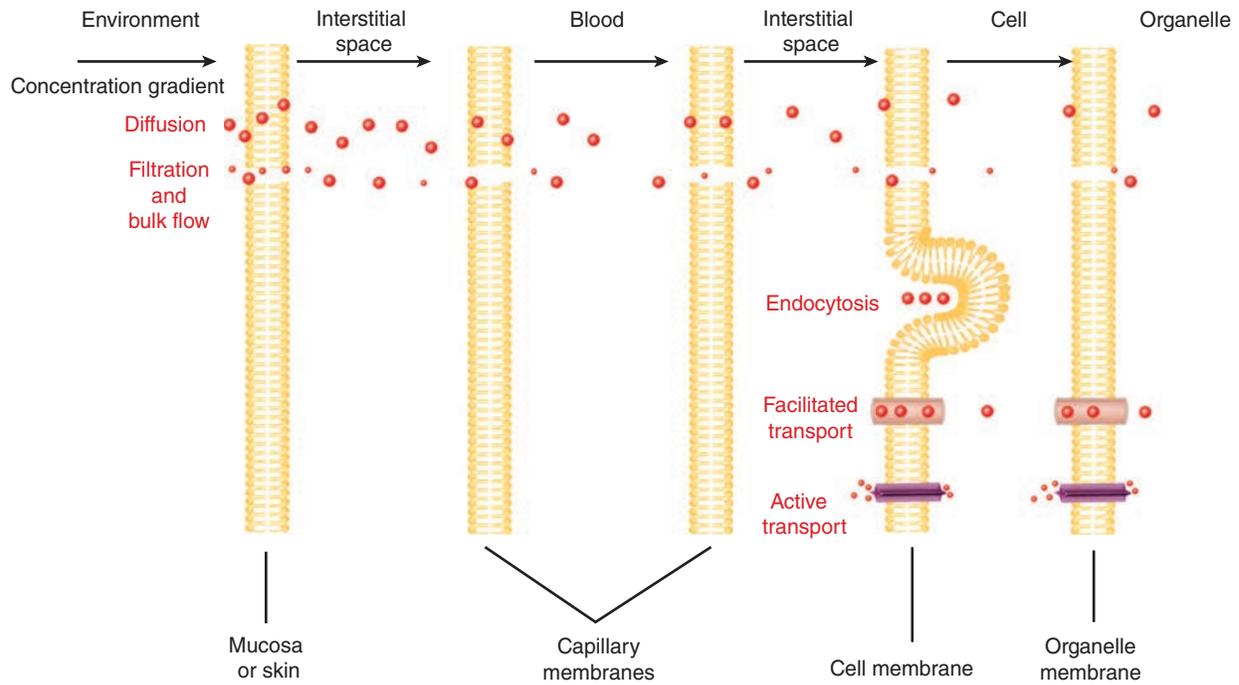

*Absorption* is the process by which a xenobiotic enters the body. A xenobiotic must reach the bloodstream and then be distributed to the site or sites of action to cause a systemic effect. Both the rate ( $k_a$ ) and extent (F) of

absorption are measurable and important determinants of toxicity. The rate of absorption often predicts the onset of action and relies on dosage form, and the extent of absorption (*bioavailability*, or F) often predicts the intensity of the effect and depends in part on first-pass effects.<sup>43,44</sup> Fig. 9-1 depicts how changes in the rate of absorption may affect toxicity when the bioavailability is held constant versus how toxicity is increased as the bioavailability increases and the elimination rate constant ( $K_e$ ) remains constant.

The route by which the xenobiotic enters the body significantly affects both the rate and extent of absorption. As an approximation, the rate of absorption proceeds in the following order from fastest to slowest: intravenous (IV), intraosseous, inhalation > sublingual > intramuscular, subcutaneous, intranasal, oral > cutaneous, rectal (may be unpredictable if bypasses first-pass elimination). After the oral intake of 200 mg (0.59 mmol) of cocaine hydrochloride, the onset of action is 20 minutes, with an average peak concentration of 200 ng/mL.<sup>80</sup> In marked contrast, smoking 200 mg (0.66 mmol) of alkaloidal cocaine (freebase) results in an onset of action of 8 seconds and a peak concentration of 640 ng/mL. When administered IV as 200 mg of

**FIGURE 9-1.** Effects of changes in  $k_a$  (rate of absorption) and F (bioavailability) on the blood concentration versus time graph and achieving a toxic threshold. In curves A, B, and C, F is constant as  $k_a$  decreases. In curves G, H, and I, toxicity increases as F increases from G to I while the  $K_e$  remains constant.<sup>51</sup>

**FIGURE 9-2.** Illustration of the number of membranes encountered by a xenobiotic in the process of absorption and distribution and the transport mechanisms involved in the passage of xenobiotics across membranes. Examples include varying types of diffusion: nonpolar and uncharged (ethanol) and nonionized forms of weak acids (salicylic acid) and bases (amphetamines); endocytosis: Sabin polio virus vaccine; facilitated: 5-fluorouracil, lead, thallium; and active: thiamine and pyridoxine.

cocaine hydrochloride, the onset of action is 30 seconds and a peak concentration of 1,000 ng/mL.<sup>80</sup>

A xenobiotic must diffuse through a number of membranes before it reaches its site of action. Fig. 9-2 shows the number of membranes through which a xenobiotic typically diffuses. Membranes are predominantly composed of phospholipids and cholesterol in addition to other lipid compounds.<sup>61</sup> A phospholipid is composed of a polar head and a fatty acid tail, which are arranged in membranes so that the fatty acid tails are inside and the polar heads face outward in a mirror image.<sup>65</sup> Proteins are found on both sides of the membranes and often traverse the membrane.<sup>61</sup> Some of these proteins function as receptors and channels. Pores are found throughout the membranes. The principles relating to diffusion apply to absorption, distribution, certain aspects of elimination, and each mechanism that permits a xenobiotic to be transported through a membrane.

Transport through membranes occurs via (1) passive diffusion; (2) filtration or bulk flow, which is most important in renal and biliary secretion as the mechanism of transport associated with the movement of molecules with a molecular weight less than 100 Da, with water directly through aquapores; (3) carrier-mediated active and facilitated transports, which are saturable; and (4) rarely, endocytosis (Fig. 9-2). Most xenobiotics traverse membranes via simple passive diffusion. The rate of diffusion is determined by the Fick's law of diffusion:

$$\text{Rate of diffusion} = \frac{-dQ}{dt} = \frac{-DAK_{ow}(C_1 - C_2)}{h} \quad (\text{Eq. 9-1})$$

where:

D = diffusion coefficient

A = surface area of the membrane

h = membrane thickness

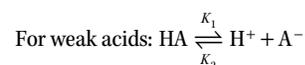

$K_{ow}$  = partition coefficient

$C_1 - C_2$  = difference in concentrations of the xenobiotic on each side of the membrane

The driving force for passive diffusion is the difference between the concentrations of the xenobiotic on the opposing sides of the membrane. Each

xenobiotic has a constant D is derived when the difference in concentrations between the two sides of the membrane is one. The larger the surface area A, the higher the rate of diffusion. Most ingested xenobiotics are absorbed more rapidly in the small intestine than in the stomach because of the tremendous increase in surface area created by the presence of microvilli. The partition constant or ratio (previously called the coefficient)  $K_{ow}$  represents the lipid-to-water partitioning of the nonionized xenobiotic with pH adjustment to favor nonionized xenobiotic. To a substantial degree, the more lipid soluble a xenobiotic is, the more easily it crosses membranes. The logarithm of the  $K_{ow}$  is known as log P. Whereas log P represents the partitioning of the nonionized form, log D (logarithm of the distribution constant) represents the lipid-to-water partitioning of the sum of the nonionized plus ionized forms in the octanol and water phase and is pH dependent. Log D is most useful when measured at physiologic pH. Membrane thickness (h) is inversely proportional to the rate at which a xenobiotic diffuses through the membrane. Xenobiotics that are uncharged, nonpolar, of low molecular weight, and lipid soluble have the highest rates of passive diffusion.

The extent of ionization of weak electrolytes (weak acids and weak bases) affects their rate of passive diffusion. Nonpolar and uncharged molecules penetrate faster. The Henderson-Hasselbalch relationship is used to determine the degree of ionization. An acid (HA), by definition, gives up a proton, and a base (B) accepts a proton. Acids and bases can be nonionized (uncharged, molecular, free), positively charged (cationic), or negatively charged (anionic). Aspirin and phenobarbital are uncharged acids (RCOOH), and pseudoephedrine HCl is a cationic acid. Morphine, amphetamine, and amitriptyline are uncharged bases (RNH<sub>2</sub>), and sodium valproate is an anionic base. The equilibrium dissociation constants  $K_a$  and  $K_b$  can then be described.  $K_a \times K_b = K_w$ , and  $K_w$  is the dissociation constant of water. Because these numbers are difficult to work with, they are transformed using logarithms. By Equations 9-2A and 9-2B:

$$K_a = \frac{[H^+][A^-]}{[HA]} \quad (\text{Eq. 9-2A})$$

$$K_b = \frac{[\text{H}^+][\text{B}]}{[\text{BH}^+]} \quad (\text{Eq. 9-2B})$$

For a more facile mathematical utilization, the negative log of both sides is determined. The results are given in Equations 9-3A and 9-3B.

$$\text{For weak acids: } -\log K_a = -\log[\text{H}^+] - \log \frac{[\text{A}^-]}{[\text{HA}]} \quad (\text{Eq. 9-3A})$$

$$\text{For weak bases: } -\log K_b = -\log[\text{H}^+] - \log \frac{[\text{B}]}{[\text{BA}^+]} \quad (\text{Eq. 9-3B})$$

By definition, the negative log of  $[\text{H}^+]$  is expressed as pH, and the negative log of  $K_a$  is  $\text{p}K_a$ . Rearranging the equations gives the familiar forms of the Henderson-Hasselbalch equations, as shown in Equations 9-4A, 9-4B, and 9-4C:

$$\text{pH} = \text{p}K_a + \log \frac{\text{Unprotonated species}}{\text{Protonated species}} \quad (\text{Eq. 9-4A})$$

$$\text{For weak acids: } \text{pH} = \text{p}K_a + \log \frac{[\text{A}^-]}{[\text{HA}]} \quad (\text{Eq. 9-4B})$$

$$\text{For weak bases: } \text{pH} = \text{p}K_b + \log \frac{[\text{B}]}{[\text{BH}^+]} \quad (\text{Eq. 9-4C})$$

Because uncharged molecules traverse membranes more rapidly, it is understood that weak acids cross membranes more rapidly in an acidic environment, and weak bases move more rapidly in a basic environment. When the pH equals the  $\text{p}K_a$ , half of the xenobiotic is charged (ionized), and half is uncharged (nonionized). An acid with a low  $\text{p}K_a$  is a strong acid, and a base with a low  $\text{p}K_a$  is a weak base. For an acid, a pH less than the  $\text{p}K_a$  favors the protonated or uncharged species facilitating membrane diffusion, and for a base, a pH greater than the  $\text{p}K_a$  achieves the same result. Table 9-1 lists the pH of selected body fluids, and Fig. 9-3 illustrates the extent of charged versus uncharged xenobiotic at different pH and  $\text{p}K_a$  and  $\text{p}K_b$  values.

Lipid solubility and ionization each have a distinct influence on absorption. Fig. 9-4 demonstrates these characteristics for three different xenobiotics. Although the three xenobiotics have similar  $\text{p}K_a$  and  $\text{p}K_b$  values, their different partition constants result in different degrees of absorption from the stomach.

Fluids	pH
Cerebrospinal	7.3
Gastric	1-3
Large intestine (adult stool)	>6
Ophthalmic (tears)	7-8
Plasma	7.4
Stool: Infants and children	7.2-12
Saliva	6.4-7.2
Small intestine: duodenum	5-6
Small intestine: ileum	8
Urine	4-8
Vaginal	3.8-4.5

Specialized transport mechanisms are either adenosine triphosphate (ATP) dependent to transport xenobiotics against a concentration gradient (ie, active transport) or ATP independent and lack the ability to transport against a concentration gradient (ie, facilitated transport). These transport mechanisms are of importance in numerous parts of the body, including the intestines, liver, lungs, kidneys, and biliary system. These same principles apply to a small number of lipid-insoluble molecules that resemble essential endogenous molecules.<sup>34,71</sup> For example, 5-fluorouracil resembles pyrimidine and is transported by the same system, and thallium and lead are actively absorbed by the endogenous transport mechanisms that absorb and transport potassium and calcium, respectively. Filtration is generally considered to be of limited importance in the absorption of most xenobiotics but is substantially more important with regard to renal and biliary elimination. Endocytosis, which describes the encircling of a xenobiotic by a cellular membrane, is responsible for the absorption of large macromolecules such as the oral Sabin polio vaccine.<sup>71</sup>

Gastrointestinal (GI) absorption is affected by xenobiotic-related characteristics, such as dosage form, degree of ionization, partition constant, and patient factors (eg, GI blood flow; GI motility; and the presence or absence of food, ethanol, or other interfering substances such as calcium) (Fig. 9-5).

**FIGURE 9-4.** Influence of increasing lipid solubility on the amount of xenobiotic absorbed from the stomach for three xenobiotics with similar pK<sub>a</sub> values. The number above each column is the oil/water equilibrium partition coefficient. (Reproduced with permission from Brody TM, Larner J, Minneman KP, et al: *Human Pharmacology: Molecular to Clinical*, 2nd ed. St. Louis, MO: Mosby; 1994.)

The formulation of a xenobiotic is extremely important in predicting GI absorption; for example, disintegration and dissolution must precede absorption. Disintegration is usually much more rapid than dissolution except for modified-release products. *Modified release* is a broad term that encompasses products that are delayed-release and extended-release formulations. These modified-release formulations are designed to release the xenobiotic over a prolonged period of time to attempt to produce the blood concentrations achieved with the use of a constant IV infusion. By definition, extended-release formulations decrease the frequency of drug administration by at least 50% compared with immediate-release formulations, and they include controlled-release, sustained-release, and prolonged-release formulations. These formulations minimize blood concentration fluctuations, reduce peak-related side effects, reduce dosing frequency, and improve patient compliance because fewer pills per day are needed. A variety of products use different pharmaceutical strategies, including dissolution control (encapsulation or matrix; Feosol—iron), diffusion control (membrane or matrix; Plendil ER—felodipine), erosion (Sinemet CR—levodopa carbidopa), osmotic pump systems (Procardia XL—nifedipine, Glucotrol XL—glipizide), and ion exchange resins (MS Contin suspension—morphine). Overdoses with modified-release formulations often result in a prolonged absorption phase, a delay to peak concentrations, and a prolonged duration of effect.<sup>10</sup> Some

Extended release (Acetaminophen, quetiapine)	Salicylates
Glutethimide	Verapamil

delayed-release preparations are enteric coated and specifically designed to bypass the stomach and to release drug in the small intestine. Other delayed-release formulations (eg, Verelan PM—verapamil) are designed to release the drug later but not specifically designed to bypass release in the stomach. Enteric-coated (acetylsalicylic acid, divalproex sodium—valproic acid) formulations resist disintegration and delay the time to onset of effect.<sup>9</sup> Dissolution is affected by ionization, solubility, and the partition coefficient. For example, only 1 g of aspirin is soluble in 100 mL of water at body temperature. In the overdose setting, the formation of poorly soluble or adherent masses such as concretions of foreign material termed *bezoars* significantly delay the time to onset of toxicity (Table 9-2).<sup>7,14,35,37,67</sup>

Most ingested xenobiotics are primarily absorbed in the small intestine as a result of the large surface area and extensive blood flow of the small intestines.<sup>66</sup> Critically ill patients who are hypotensive, have a reduced cardiac output, or are receiving vasopressors such as norepinephrine have a decreased perfusion of vital organs, including the GI tract, kidneys, and liver.<sup>6</sup> Not only is absorption delayed, but elimination is also diminished.<sup>64</sup> Total GI transit time ranges from 0.4 to 5 days, and small intestinal transit time is usually 3 to 4 hours. Extremely short GI transit times reduce absorption. This change in transit time is the unproven rationale for use of whole-bowel irrigation (WBI). Delays in emptying of the stomach impair absorption as a result of the delay in delivery to the small intestine. Delays in gastric emptying occur as a result of the presence of food, especially fatty meals; xenobiotics with anticholinergic, opioid, or antiserotonergic properties; ethanol; and any xenobiotic that results in pylorospasm (salicylates, iron).

Bioavailability is a measure of the amount of xenobiotic that reaches the systemic circulation unchanged (Equation 9-5).<sup>45</sup> The fractional absorption (F) of a xenobiotic is defined by the area under the plasma drug concentration versus time curve (AUC) of the designated route of absorption compared with the AUC of the IV route. The AUC for each route represents the amount absorbed.

$$F = \frac{(\text{AUC})_{\text{route under study}}}{(\text{AUC})_{\text{IV}}} \quad (\text{Eq. 9-5})$$

Gastric emptying and activated charcoal are used to decrease the bioavailability of ingested xenobiotics. The oral administration of certain chelators (deferoxamine, D-penicillamine) actually enhances the bioavailability of the complexed xenobiotic. The net effect of some chelators, such as succimer, is a reduction in body burden via enhanced urinary elimination even though GI absorption is enhanced.<sup>38</sup>

Presystemic metabolism may decrease or increase the bioavailability of a xenobiotic or a metabolite.<sup>60</sup> The GI tract contains microbial organisms (*Eggerthella lentum*) that can metabolize or degrade xenobiotics such as digoxin and oral contraceptives and enzymes, such as peptidases, that metabolize insulin.<sup>61</sup> However, in rare cases, GI hydrolysis can convert a xenobiotic into a toxic metabolite, as occurs when amygdalin is enzymatically hydrolyzed to produce cyanide, a metabolic step that does not occur when amygdalin is administered intravenously.<sup>33</sup> Xenobiotic metabolizing enzymes and influx and efflux transporters such as organic anion transporting polypeptides (OATPs) and P-glycoprotein (P-gp), respectively, also affect bioavailability. Xenobiotic-metabolizing enzymes are found in the lumen of the small intestine and can substantially decrease or increase the absorption of a xenobiotic.<sup>51,82,89</sup> Some of the xenobiotic that enters the cell is subsequently removed from the cell by the P-gp transporter and returned to the GI lumen, where it is reexposed to the metabolic enzymes.<sup>51,82</sup> Venous drainage from the stomach and intestines delivers orally (and intraperitoneally) administered xenobiotics to the liver via the portal vein and avoids direct delivery to the systemic circulation. This venous drainage allows hepatic metabolism to occur before the xenobiotic reaches the systemic circulation, and as previously mentioned, is referred to as the first-pass effect.<sup>5,85</sup> The hepatic extraction ratio is the percentage of xenobiotic metabolized in one pass of portal blood through the liver.<sup>54</sup> Xenobiotics that undergo significant first-pass metabolism (eg, propranolol, verapamil) are used at much lower IV doses than oral doses. Some drugs, such as lidocaine and nitroglycerin, are not administered by the oral route because of significant first-pass effect.<sup>7</sup> Instead, sublingual, transcutaneous (topical), and rectal administrations of drugs are used to bypass the portal circulation and avoid first-pass metabolism.

In the overdose setting, presystemic metabolism is often saturated, leading to an increased bioavailability of xenobiotics such as cyclic antidepressants, phenothiazines, opioids, and many  $\beta$ -adrenergic antagonists.<sup>63</sup> Hepatic metabolism usually transforms the xenobiotic into a less active metabolite but occasionally results in the formation of a more active or even toxic xenobiotic such as occurs with the transformation of parathion to paraoxon.<sup>58</sup> Biliary excretion into the small intestine usually occurs for these transformed xenobiotics of molecular weights greater than 350 Da and results in a xenobiotic appearing in the feces even though it had not been administered orally.<sup>41,61,74</sup> Hepatic conjugated metabolites such as glucuronides are hydrolyzed in the intestines to the parent form or to another active metabolite that can be reabsorbed by the enterohepatic circulation.<sup>48,56,59,61</sup> The enterohepatic circulation is responsible for what is termed a *double-peak phenomenon* after the administration of certain xenobiotics.<sup>71</sup> The double-peak phenomenon is characterized by a serum concentration that decreases (after an initial increase) and then increases again as xenobiotic is reabsorbed from the GI tract. Other causes include variability in stomach emptying, the presence of food, or failure of a tablet dosage form.<sup>71</sup>

## DISTRIBUTION

After the xenobiotic reaches the systemic circulation, it is available for transport to peripheral tissue compartments and to the liver and kidney for elimination. Both the rate and extent of distribution depend on many of the same principles discussed with regard to diffusion. Additional factors include affinity of the xenobiotic for plasma (plasma protein binding) and tissue proteins, acid–base status of the patient (which affects ionization), drug transporters, and physiologic barriers to distribution (blood–brain barrier, placental transfer, blood–testis barrier).<sup>29,42,65</sup> Blood flow, the percentage of free xenobiotic in the plasma and the activity of transporters account for the initial phase of distribution, and xenobiotic affinities determine the final distribution pattern. Whereas the adrenal glands, kidneys, liver, heart, and

brain receive blood flow from 55 to 550 mL/min/100 g of tissue, the skin, muscle, connective tissue, and fat receive 1 to 5 mL/min/100 g of tissue.<sup>69</sup> Hypoperfusion of the various organs in the critically volume depleted ill and injured patients affects absorption, distribution, and elimination.<sup>83</sup>

Adenosine triphosphate-binding cassette (ABC) transporters are active ATP-dependent transmembrane protein carriers of which P-gp was the initial example.<sup>12</sup> P-glycoprotein (P-gp) is coded by the multiple drug resistance *MDRI* gene.<sup>15</sup> Approximately 50 ABC transporters have been identified, and they are divided into subfamilies based on their similarities. Several members of the ABC superfamily, including P-gp, are under extensive investigation because of their role in controlling xenobiotic entry into, distribution within, and elimination from the body as well as their contributions to xenobiotic interactions through P-gp inhibition or induction.<sup>27,39,82</sup> The discovery of P-gp resulted from an investigation into the reasons that certain tumors exhibit multidrug resistance to many chemotherapeutics. P-glycoprotein (ABCB1) as well as ABCC and ABCG2 are known to be efflux transporters located in the intestines, renal proximal tubules, hepatic bile canaliculi, placenta, and blood–brain barrier and are responsible for the intra- to extracellular transport of various xenobiotics.<sup>21</sup> Chemotherapy often induces P-gp expression, and extensive genetic polymorphism exists as in the case of CYPs.<sup>15</sup> First-generation transport inhibitors such as amiodarone, ketoconazole, quinidine, and verapamil are responsible for increasing body concentrations of P-gp substrates such as digoxin, the protease inhibitors, vinca alkaloids, and paclitaxel. St. John's wort is a transport inducer, and it lowers serum concentrations of these same xenobiotics. Second- and third-generation xenobiotics that will affect transport with a higher affinity and specificity are in development.<sup>24,72</sup> Many of the same xenobiotics that affect CYP3A4 also affect P-gp (Appendix Chap. 11: Cytochrome P450 Substrates Inhibitors and Inducers).

Other groups of transporters are found in the liver, kidneys, intestines, brain, and placenta that affect the absorption, distribution, and elimination of many xenobiotics and contribute to xenobiotic interactions. They include the organic anion transporters (OATs) and the organic cation transporters (OCTs).<sup>24</sup> For example, probenecid increases the serum concentrations of penicillin by inhibiting the OAT responsible for the active secretion of penicillin by the renal tubular cells, and cimetidine inhibits the OCT responsible for the renal elimination of procainamide and metformin. A variety of OAT inhibitors are being investigated to decrease the hepatic uptake of amatoxins<sup>24</sup> (Chap. 117).

*Volume of distribution* ( $V_d$ ) is the proportionality term used to relate the dose of the xenobiotic that the individual receives with the resultant plasma concentration. Volume of distribution is an apparent or theoretical volume into which a xenobiotic distributes. It is a measure of how much xenobiotic is located inside versus outside of the plasma compartment after administration of a xenobiotic. Because only the plasma compartment is routinely assayed, the amount of xenobiotic that remains in the plasma can be used to calculate the movement out of the blood. In a 80-kg man, the total body water (TBW) is 60% of total body weight, or 48 L, with two-thirds (32 L) of the fluid accounted for by intracellular fluid. Of the 16 L of extracellular fluid, 13 L is considered interstitial or between the cells; 3.2 L, or 0.04 L/kg, is plasma; and 6.4 L, or 0.08 L/kg, is blood. If 48 g of a xenobiotic is administered and remains in the plasma compartment ( $V_d = 0.04$  L/kg), the concentration would be 15 g/L. If the distribution of the 48 g of xenobiotic approximated TBW (methanol; 0.6 L/kg), the concentration would be 1 g/L (usually reported as 100 mg/dL). These calculations can be performed by using Equation 9–6, where S equals the percent pure xenobiotic if a salt form is used and F is the bioavailability or fraction absorbed.

$$V_d = \frac{S \times F \times \text{Dose}}{C_0} \quad (\text{Eq. 9-6})$$

Experimental determination of  $V_d$  involves administering an IV dose of the xenobiotic and extrapolating the plasma concentration time curve back to time zero ( $C_0$ ). If the determination takes place after steady state is achieved, the volume of distribution is then referred to as the  $V_{d,ss}$ . For many xenobiotics, the  $V_d$  is known and readily available in the literature (Table 9–3). If the

TABLE 9-3 Pharmacokinetic Characteristics of Xenobiotics Associated with Significant Morbidity and Mortality

peak plasma concentration and the  $V_d$  are known, then an approximation of total-body burden can be made ( $C_p \times V_d / S \times F = \text{Total-body burden}$ ). When the  $V_d$  and the dose ingested are known, a maximum predicted plasma concentration can be calculated after assuming all of the xenobiotic is absorbed and no elimination has occurred. This assumption usually overestimates the plasma concentration. Distribution is complex, and differential affinities for various storage sites in the body, such as plasma proteins, liver, kidney, fat, and bone, determine where a xenobiotic ultimately resides.

For the purposes of determining the utility of extracorporeal removal of a xenobiotic, a low  $V_d$  is often considered to be less than 1–2 L/kg. For some xenobiotics, such as digoxin ( $V_d = 5\text{--}7$  L/kg) and the cyclic antidepressants ( $V_d = 10\text{--}20$  L/kg), the  $V_d$  is much larger than the actual volume of the body. A large  $V_d$  indicates that the xenobiotic resides outside of the plasma compartment, but it is important to remember that it does not describe the actual site of distribution.

The site of accumulation of a xenobiotic is not necessarily the site of action or toxicity. If the site of accumulation is not a site of toxicity, then the storage depot is relatively inactive, and the accumulation at that site is theoretically protective.<sup>65</sup> Selective accumulation of xenobiotics occurs in certain areas of the body because of affinity for certain tissue-binding proteins. For example, the kidney contains metallothionein, which has a high affinity for metals such as cadmium, lead, and mercury.<sup>29</sup> The retina contains the pigment melanin, which binds and accumulates chlorpromazine, thioridazine, and chloroquine.<sup>29</sup> Other examples of xenobiotics accumulating at primary sites of toxicity are carbon monoxide binding to hemoglobin and myoglobin and paraquat distributing to type II alveolar cells in the lungs.<sup>62</sup> Dichlorodiphenyltrichloroethane (DDT), chlordane, and polychlorinated biphenyls are stored in fat and are mobilized should malnutrition develop.<sup>86</sup> Lead sequestered in bone<sup>40</sup> is not immediately toxic, but mobilization of bone through an increase in osteoclast activity<sup>65</sup> (hyperparathyroidism, pregnancy, immobilization) may liberate lead for distribution to sites of toxicity in the central nervous system (CNS) or blood.

Several plasma proteins bind xenobiotics and act as carriers and storage depots. The percentage of protein binding varies among xenobiotics, as do their affinities and potential for reversibility. After it is bound to a plasma protein, a xenobiotic with high binding affinity will remain largely confined to the plasma until elimination occurs. However, dissociation and reassociation may occur if another carrier is available with a higher binding affinity. Most plasma measurements of xenobiotic concentrations reflect

total xenobiotic (bound plus unbound). Only the unbound xenobiotic is free to diffuse through membranes for distribution or for elimination. Albumin binds primarily to weakly acidic, poorly water-soluble xenobiotics, which include salicylates, phenytoin, and warfarin, as well as endogenous substances, including free fatty acids, cortisone, aldosterone, thyroxine, and unconjugated bilirubin.<sup>69</sup>  $\alpha_1$ -Acid glycoprotein usually binds basic xenobiotics, including lidocaine, imipramine, and propranolol.<sup>69</sup> Transferrin, a  $\beta_2$ -globulin, transports iron, and ceruloplasmin carries copper.

Phenytoin is an example of a xenobiotic whose effects are significantly influenced by changes in concentration of plasma albumin because only free phenytoin is active. When albumin concentrations are in the normal range, approximately 90% of phenytoin is bound to albumin. As the albumin concentration decreases, more phenytoin is free for distribution, and a greater clinical response to the same serum phenytoin concentration is often observed. The free plasma phenytoin concentration can be calculated based on the albumin concentration. This achieves an appropriate interpretation (adjusted) of total phenytoin within the conventional therapeutic range of 10 to 20 mg/L of free plus bound phenytoin (Equation 9-7).

$$\text{Adjusted phenytoin concentration} = \frac{\text{Actual phenytoin concentration}}{0.25 \times [(\text{albumin}) + 0.1]} \quad (\text{Eq. 9-7})$$

The clinical implications are that a malnourished or chronically ill patient with an albumin of 2 g/dL receiving phenytoin can manifest toxicity with a plasma phenytoin concentration of 14 mg/L. This measurement is total phenytoin (bound + unbound). Because the patient has a reduced albumin concentration, this actually represents a substantially higher proportion and absolute amount of active unbound phenytoin. Substitution into the above equation of 14 mg/L for actual plasma phenytoin concentration and 2 g/dL for albumin gives an adjusted plasma phenytoin concentration of 23.3 mg/L (therapeutic range, 10–20 mg/L).

Although drug interactions are often attributed to the displacement of xenobiotics from plasma protein binding, concurrent metabolic interactions are usually more consequential. Displacement transiently increases the amount of unbound, active drug. This results in an immediate increase in drug effect. This is usually followed by enhanced distribution of unbound drug out of the plasma compartment followed by elimination of unbound drug. Gradually, the unbound plasma concentration returns to predisplacement concentrations.<sup>66</sup>

Saturation of plasma proteins may occur in the therapeutic range for a drug such as valproic acid. Acute saturation of plasma protein binding after an overdose often leads to consequential adverse effects. Saturation of plasma protein binding with salicylates and iron after an overdose increase distribution to the CNS (salicylates) or to the liver, heart, and other tissues (iron), increasing toxicity.

Specific therapeutic interventions after an overdose are designed to alter xenobiotic distribution by inactivating or enhancing elimination to limit toxicity. These therapeutic interventions include manipulation of serum pH (tricyclic antidepressants, salicylates) or urine pH (salicylates), the use of chelators (lead), and the use of antibodies or antibody fragments (digoxin).

The  $V_d$  permits predictions about plasma concentrations and assists in defining whether an extracorporeal method of removal is beneficial for a particular toxin. If the  $V_d$  is large (>2 L/kg), it is unlikely that hemodialysis, hemoperfusion, or exchange transfusion would be effective because most of the xenobiotic is outside of the plasma compartment. Plasma protein binding also influences this decision. If the xenobiotic is more tightly bound to plasma proteins than to activated charcoal, then hemoperfusion is unlikely to be beneficial even if the  $V_d$  of the xenobiotic is small. In addition, high plasma protein binding limits the effectiveness of hemodialysis because only unbound xenobiotic will freely cross the dialysis membrane. However, in certain situations, although a xenobiotic such as valproic acid is highly protein bound at therapeutic concentrations, protein binding is saturated after an overdose, allowing free drug to be removed by extracorporeal methods.<sup>77</sup> Exchange transfusion can be effective for a xenobiotic with a small  $V_d$  and substantial plasma protein binding because both bound and free xenobiotic are removed simultaneously.

## ELIMINATION

Removal of a parent xenobiotic from the body (elimination) begins as soon as the xenobiotic is delivered to clearance organs such as the liver, kidneys, and lungs. Elimination includes biotransformation and excretion. Elimination begins immediately but may not be the predominant kinetic process until absorption and distribution are substantially completed. The functional integrity of the cardiovascular, pulmonary, renal, and hepatic systems are major determinants of the efficiency of xenobiotic removal and of administered antidotes. Some xenobiotics themselves cause kidney or liver failure, subsequently compromising their own elimination. Other factors that influence elimination include older age, competition or inhibition of elimination processes by interacting xenobiotics, saturation of enzymatic processes, gender, pharmacogenetics and pharmacogenomics, obesity, and the physicochemical properties of the xenobiotic.<sup>53</sup>

Elimination can be accomplished by biotransformation to one or more metabolites or by excretion from the body of the parent xenobiotic. Excretion may occur via the kidneys, lungs, GI tract, and body secretions (sweat, tears, breast milk). Because of their water solubility, hydrophilic (polar) or charged xenobiotics and their metabolites are generally excreted via the kidney. The majority of xenobiotic metabolism occurs in the liver, but it also occurs in the blood, skin, GI tract, placenta, or kidneys. Lipophilic (uncharged or nonpolar) xenobiotics are usually metabolized in the liver to hydrophilic metabolites, which are then excreted by the kidneys.<sup>30,58</sup> These metabolites are generally inactive, but if active, they may contribute to toxicity. Examples of active metabolites include nortriptyline (derived from amitriptyline), normeperidine (derived from meperidine), hydroxybupropion (derived from bupropion), and desmethylcitalopram (derived from citalopram).

Metabolic reactions catalyzed by enzymes, categorized as either phase I or phase II, may result in pharmacologically active metabolites; frequently, the latter have toxicities that differ from those of the parent compounds. Phase I (asynthetic), or preparative metabolism, which may or may not precede phase II, is responsible for introducing polar groups onto nonpolar xenobiotics by oxidation (hydroxylation, dealkylation, deamination), reduction (alcohol dehydrogenase, azo reduction), and hydrolysis (ester hydrolysis).<sup>28,56</sup> Phase II, or synthetic reactions conjugate the polar group with a glucuronide, sulfate, acetate, methyl group, glutathione, or amino acids (eg, glycine, taurine, and glutamic acid), creating more polar metabolites.<sup>18,28,56</sup>

Comparatively, phase II reactions produce a much larger increase in hydrophilicity than phase I reactions. The enzymes involved in these reactions have low substrate specificity, and those in the liver are usually localized to either the endoplasmic reticulum (microsomes) or the soluble fraction of the cytoplasm (cytosol).<sup>56</sup> The location of the enzymes becomes important if they form reactive metabolites, which then concentrate at the sites of metabolism and cause toxicity. For example, acetaminophen (APAP) causes centrilobular necrosis because CYP2E1 that forms *N*-acetyl-*p*-benzoquinoneimine (NAPQI), the toxic metabolite, is located in their highest concentration in that zone of the liver.

The enzymes that metabolize the largest variety of xenobiotics are heme-containing proteins referred to as CYP monooxygenase enzymes.<sup>34,56</sup> This group of enzymes, formerly called the mixed function oxidase system, is found in abundance in the microsomal endoplasmic reticulum of the liver. These cytochrome P450 metabolizing enzymes (CYPs) primarily catalyze the oxidation of xenobiotics. Cytochrome P450 in a reduced state ( $Fe^{2+}$ ) binds carbon monoxide. Its discovery and initial name resulted from spectral identification of the colored CO-bound cytochrome P450, which absorbs light maximally at 450 nm. The cytochrome P450 system is composed of many enzymes grouped according to their respective gene families and subfamilies, of which approximately 57 of these functional human genes have been sequenced. Members of a gene family have more than 40% similarity of their amino acid sequencing, and subfamilies have more than 55% similarity. For example, the *CYP2D6\*1a* gene encodes wild-type protein (enzyme) CYP2D6, where 2 represents the family, D the subfamily and 6 the individual gene, and \*1a the mutant allele; *CYP2D6\*1* represents the most common or wild-type allele.

Toxicity may result from induction or inhibition of CYP enzymes by another xenobiotic, resulting in a consequential drug interaction (Chap. 11). Many of these interactions are predictable based on the known xenobiotic affinities and their capability to induce or inhibit the P450 system.<sup>16,49,56,57,73</sup> However, polymorphism (individual genetic expression of enzymes),<sup>3</sup> stereoisomer variability<sup>84</sup> (enantiomers with different potencies and isoenzyme affinities), and the capability to metabolize a xenobiotic by alternate pathways contribute to unexpected metabolic outcomes. The pharmaceutical industry is now using the concept of chiral switching (marketing a single enantiomer instead of the racemic mixture) to alter efficacy or side effect profiles. Enantiomers are named either according to the direction in which they rotate polarized light (*l* or – for levorotatory, and *d* or + for dextrorotatory) or according to the absolute spatial orientation of the groups at the chiral center (S or R). Chiral means “hand” in Greek, and the latter designations refer to either sinister (left-handed) or rectus (right-handed). There is no direct correlation between levorotatory or dextrorotatory and S and R, which indicates the direction polarized light is rotated by a solution of the xenobiotic.<sup>78</sup>

The percent of xenobiotic extracted from the blood during passage through the liver is termed the *hepatic extraction ratio*.<sup>2,79</sup> High extraction occurs when the liver can remove almost the entire drug (extraction ratio >0.7), and removal is based largely on hepatic blood flow. In this circumstance, the liver enzymes are so efficient that little xenobiotic passes through intact (Table 9–4, Equation 9–8).

**TABLE 9–4 Hepatic Extraction of Xenobiotics**

High Liver Extraction (ER >0.7)	Low Liver Extraction (ER <0.3)
Cocaine	Acetaminophen
Desipramine	Carbamazepine
Lidocaine	Diazepam
Morphine	Phenobarbital
Nicotine	Salicylate
Nitroglycerin	Theophylline
Propranolol	Valproic acid
Verapamil	Warfarin

ER = extraction ratio.

$$Cl_H = Q \times ER, \text{ and if ER approaches 1, then } Cl_H = Q \quad (\text{Eq. 9-8})$$

where  $Cl_H$  = hepatic clearance

$Q$  = blood flow

$ER$  = extraction ratio =  $(C_{in} - C_{out})/C_{in}$

$C_{in}$  = xenobiotic concentration in fluid (blood or serum) entering the organ or device

$C_{out}$  = xenobiotic concentration in fluid (blood or serum) leaving the organ or device

For oral drugs:

$$Cl_{\text{oral}} = f_u \times Cl_{\text{int}} \\ (f_u \times Cl_{\text{int}})$$

where  $f_u$  = fraction unbound

On the other hand, when the drug is poorly extracted by the liver ( $ER < 0.3$ ), it means that any change in protein binding or intrinsic metabolic activity will greatly influence hepatic clearance. In this case, the hepatic clearance is directly proportional to the unbound fraction ( $f_u$ ) multiplied by intrinsic clearance ( $Cl_{\text{int}}$ ) and hepatic blood flow has a limited impact.

The oral clearance of xenobiotics depends on their fraction unbound and the intrinsic ability of the liver to metabolize them.<sup>79</sup> High-extraction drugs have very low oral bioavailability. The fraction unbound times the intrinsic hepatic clearance is already more than liver blood flow, so the final clearance is dependent on liver blood flow. The fraction unbound times the intrinsic hepatic clearance for low extraction drugs is much lower than hepatic blood flow, so clearance is dependent on enzyme induction or inhibition and the amount of unbound xenobiotic.

Excretion is primarily accomplished by the kidneys, with biliary, pulmonary, and body fluid secretions contributing to lesser degrees. Urinary excretion occurs through glomerular filtration, tubular secretion, and passive tubular reabsorption. The glomerulus filters unbound xenobiotics of a particular size and shape in a manner that is not saturable (but is subject to renal blood flow and perfusion). Passive tubular reabsorption accounts for the reabsorption of uncharged, lipid-soluble xenobiotics and is therefore influenced by the pH of the urine and the  $pK_a$  of the xenobiotic. The principles of diffusion discussed earlier permit, for example, the ion trapping of salicylate ( $pK_a = 3.0$ ) in the urine through urinary alkalization. Tubular secretion is an active process carried out by drug transporters (OATs, OCTs) and subject to saturation and drug interactions (Table 9-5).

**TABLE 9-5** Xenobiotics Secreted by Renal Tubules

Organic Anion Transport	Organic Cation Transport
ACEIs	Acetylcholine
Acetazolamide	Amiodarone
Acyclovir	Atropine
Bile salts	Cimetidine
Cephalosporins	Ciprofloxacin

ACEI = angiotensin-converting enzyme inhibitor.

The effects of obesity on elimination are intensely under study. Obesity is the accumulation of adipose tissue far in excess of what is considered normal for a person's age and gender. The National Institutes of Health defines obesity as a body mass index (BMI) greater than 30 and overweight as a BMI between 25 and 29.9. The BMI is calculated by dividing a person's weight in kilograms by the individual's height in meters squared ( $m^2$ ). By this criterion, about one-third of the adult US population is obese. Obesity poses problems in determining the correct loading dose and maintenance dose for therapeutic xenobiotics and for the estimation of serum concentrations and elimination times in the overdose setting.<sup>13,32,46,55</sup> A number of formulas have been proposed to classify body size in addition to BMI, but none has been tested adequately in the obese population. Obese patients not only have an increase in adipose tissue but also an increase in lean body mass of 20% to 55%, which results in the alteration of the distribution of both lipophilic and hydrophilic xenobiotics. In general, the oral absorption of xenobiotics in obese patients does not appear to be affected, but subcutaneous and intramuscular absorption are affected.<sup>91</sup> A recent example of concern is whether an epinephrine autoinjector can achieve therapeutic plasma concentrations expeditiously.

Whereas distribution is often affected, the effect of obesity on hepatic metabolism requires additional study, although some studies suggest a non-linear increase in clearance and differential effects depending on the CYP under study. The glomerular filtration rate increases in obesity but is not proportional to total body weight. For example, although aminoglycosides are hydrophilic, because of an increase in fat-free mass in obese patients, a dosing weight correction of 40% is used to calculate both the loading dose and the maintenance dose (Dosing body weight =  $0.4 \times \{\text{Actual body weight} - \text{Ideal body weight}\} + \text{Ideal body weight}$ ). Preliminary studies with propofol, a very lipophilic drug, suggest that whereas induction doses correlate better with lean body weight, maintenance doses correlate better with actual body weight.<sup>20,36</sup> These equations are found in Table 9-6. One recent evaluation suggests using 40% of actual body weight instead of ideal body weight in the Cockcroft-Gault formula to estimate kidney function in obese patients.<sup>87</sup>

Now that bariatric surgery is more common, many pharmacokinetic issues arise in post-bariatric surgery patients.<sup>1,4,23</sup> Bariatric surgery works by increasing a patient's feeling of fullness by decreasing the size of the stomach (adjustable gastric banding, sleeve gastrectomy) or malabsorption in which the duodenum and parts of the jejunum are bypassed (Roux-en-Y gastric bypass {RYGB}). Absorption is particularly affected by gastric bypass. Calcium, vitamin D, iron, folate, vitamin B<sub>12</sub>, and thiamine absorption is reduced and often needs supplementation. Modified-release xenobiotics are likely to have reduced absorption, but the onset of effect is quicker. First-pass metabolism is affected when a significant amount of the small intestine containing CYP3A4 is removed. Distribution and excretion are unlikely to be affected. Finally, after significant weight loss is achieved, the doses of medications often need to be reduced.

**TABLE 9-6** Equations for Determining Body Size

$$BMI = \frac{\text{Weight (kg)}}{\text{Height (m)}^2}$$

$$BSA (m^2) = \frac{\sqrt{\text{Height (cm)} \times \text{Weight (kg)}}}{\sqrt{3600}}$$

$$IBW: \text{Males (kg)} = 50 + 2.3 (\text{Height} > 60 \text{ in})$$

$$IBW: \text{Females (kg)} = 45.5 + 2.3 (\text{Height} > 60 \text{ in})$$

$$LBW: \text{Males (kg)} = \frac{9270 \times \text{Weight (kg)}}{6680 + \{(216 \times BMI (kg/m^2))\}}$$

$$LBW: \text{Females (kg)} = \frac{9270 \times \text{Weight (kg)}}{8780 + \{(244 \times BMI (kg/m^2))\}}$$

BMI = body mass index; BSA = body surface area; IBW = ideal body weight; LBW = lean body weight.

### CLASSICAL VERSUS PHYSIOLOGIC COMPARTMENT TOXICOKINETICS

Models exist to study and describe the movement of xenobiotics in the body with mathematical equations. Traditional compartmental models (one or two compartments) are data based and assume that changes in plasma concentrations represent proportional changes in tissue concentrations (Fig. 9-6).<sup>54</sup> Advances in computer technology facilitate the use of the classic concepts developed in the late 1930s.<sup>76</sup> Physiologic models describe the unique movement characteristics of xenobiotics based on known or theoretical biologic processes. This allows the prediction of tissue concentrations while incorporating the effects of changing physiologic parameters and affording better extrapolation from laboratory animals.<sup>90</sup> Unfortunately, physiologic modeling is still in its infancy, and the mathematical modeling it entails is often very complex.<sup>25</sup> The most common mathematical equations used are based on traditional compartmental modeling.

The one-compartment model is the simplest approach for analytic purposes and is applied to xenobiotics that enter and rapidly distribute throughout the body. This model assumes that changes in plasma concentrations will result in and reflect proportional changes in tissue concentrations. Many xenobiotics, such as digoxin, lithium, and lidocaine, do not instantaneously equilibrate with the tissues and are better described by a two-compartment model. In the two-compartment or more than two-compartment models, a xenobiotic is distributed instantaneously to highly perfused tissues (central compartment) and then is secondarily, and more slowly, distributed to a peripheral compartment. Elimination is assumed to take place from the central compartment.

If the rate of a reaction is directly proportional to the concentration of xenobiotic, it is termed *first order* or *linear* (Equation 9-9).

$$\text{Rate} \propto \text{concentration (C)} \quad (\text{Eq. 9-9})$$

Processes that are capacity limited or saturable are termed *nonlinear* (not proportional to the concentration of xenobiotic) and are described by the Michaelis-Menten equation, which is derived from enzyme kinetics. Calculus is used to derive the first-order equation.<sup>90</sup> Rate is directly proportional to concentration of xenobiotic, as in Equation 9-8.

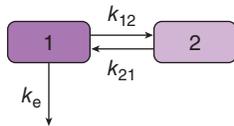

Model 1. One-compartment open model, IV injection.

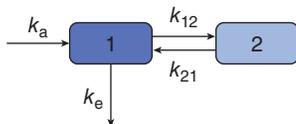

Model 2. One-compartment open model with first-order absorption.

Model 3. Two-compartment open model, IV injection.

Model 4. Two-compartment open model with first-order absorption.

**FIGURE 9-6.** Various classical compartmental models. 1, plasma or central compartment; 2 = tissue compartment; IV = intravenous;  $k_a$  = absorption rate constant;  $k_e$  = elimination rate constants;  $k_{12}$  = rate constant into tissue from plasma;  $k_{21}$  = rate constant into plasma from tissue.

An infinitesimal change in concentration of a xenobiotic ( $dC$ ) with respect to an infinitesimal change in time ( $dt$ ) is directly proportional to the concentration ( $C$ ) of the xenobiotic as in Equation 9-10:

$$\frac{dC}{dt} \propto C \quad (\text{Eq. 9-10})$$

The proportionality constant  $k$  is added to the right side of the expression to mathematically allow the introduction of an equality sign. The constant  $k$  represents all of the bodily factors, such as metabolism and excretion, that contribute to the determination of concentration (Equation 9-10).

$$\frac{dC}{dt} = kC \quad (\text{Eq. 9-11})$$

Introducing a negative sign to the left-hand side of the equation describes the “decay” or decreasing xenobiotic concentration (Equation 9-11).

$$-\frac{dC}{dt} = kC \quad (\text{Eq. 9-12})$$

This equation is impractical because of the difficulty of measuring infinitesimal changes in  $C$  or  $t$ . Therefore, the use of calculus allows the integration or summing of all of the changes from one concentration to another beginning at time zero and terminating at time  $t$ . This relationship is mathematically represented by the integration sign ( $\int$ ). The sign  $\int$  means to integrate the term from concentration at time zero ( $C_0$ ) to concentration at a given time  $t$  ( $C_t$ ). The second  $\int$  means the same action with respect to time, where  $t_0 = \text{zero}$ . Before this application, the previous equation is first rearranged (Equation 9-13).

$$\begin{aligned} -\frac{dC}{C} &= kdt \\ \int_{C_0}^{C_t} -\frac{dC}{C} &= k \int_0^t dt \end{aligned} \quad (\text{Eq. 9-13})$$

The integration of  $dC$  divided by  $C$  is the natural logarithm of  $C$  ( $\ln C$ ), and the integration of  $dt$  is  $t$  (Equation 9-14).

$$-\ln C \Big|_{C_0}^{C_t} = kt \Big|_0^t \quad (\text{Eq. 9-14})$$

The vertical straight lines proscribe the evaluation of the terms between those two limits. The following series of manipulations is then performed (Equation 9-15A-D).

$$-(\ln C_t - \ln C_0) = k(t - 0) \quad (\text{Eq. 9-15A})$$

$$-\ln C_t + \ln C_0 = kt \quad (\text{Eq. 9-15B})$$

$$-\ln C_t = -\ln C_0 + kt \quad (\text{Eq. 9-15C})$$

$-\ln C_t =$	$\ln C_0 -$	$kt$	
Can be	Can be	Constant	(Eq. 9-15D)
measured	selected		

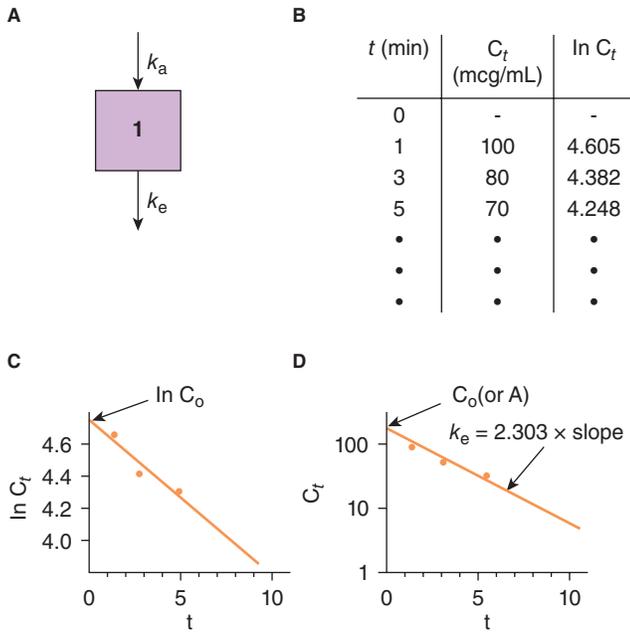

Equation 9-15D can be recognized as taking the form of an equation of a straight line (Equation 9-15), where the slope is equal to the negative rate constant  $k$  and the intercept is  $C_0$ .

$$y = b + mx \quad (\text{Eq. 9-16})$$

Instead of working with natural logarithms, an exponential form (the antilog) of Equation 9-15D may be used (Equation 9-17).

$$C_t = C_0 e^{-kt} \quad (\text{Eq. 9-17})$$

Graphing the (natural logarithm) of the concentration of the xenobiotic at various times for a first-order reaction is a straight line. Equation 9-17

**FIGURE 9-7.** A one-compartment pharmacokinetic model demonstrating graphical illustration (A), hypothetical dataset (B), linear plot (C), and semilogarithmic plot (D).

describes the events when only one first-order process occurs. This is appropriate for a one-compartment model (Fig. 9-7).

In this model, regardless of the concentration of the xenobiotic, the rate (percentage) of decline is constant. The absolute amount of xenobiotic eliminated changes continuously while the percent eliminated remains constant. The rate constant *k* is reported in h<sup>-1</sup>. A *k<sub>e</sub>* of 0.10 h<sup>-1</sup> means that the xenobiotic is being processed (eliminated) at a rate of 10% per hour. The rate constant *k* is often designated as *k<sub>e</sub>* and referred to as the elimination rate constant. The time necessary for the xenobiotic concentration to be reduced by 50% is called the half-life. The half-life is determined by a rearrangement of Equation 9-15D whereby C<sub>2</sub> becomes C at time t<sub>2</sub> and C<sub>1</sub> becomes C at t<sub>1</sub> and by rearrangement giving Equation 9-18:

$$(t_1 - t_2) = \frac{(\ln C_1 - \ln C_2)}{k_e} \quad (\text{Eq. 9-18})$$

Substitution of 2 for C<sub>1</sub> and 1 for C<sub>2</sub> or 100 for C<sub>1</sub> and 50 for C<sub>2</sub> gives Equations 9-19A and 9-19B:

$$t_{1/2} = \frac{(\ln 2 - \ln 1)}{k_e} \quad (\text{Eq. 9-19A})$$

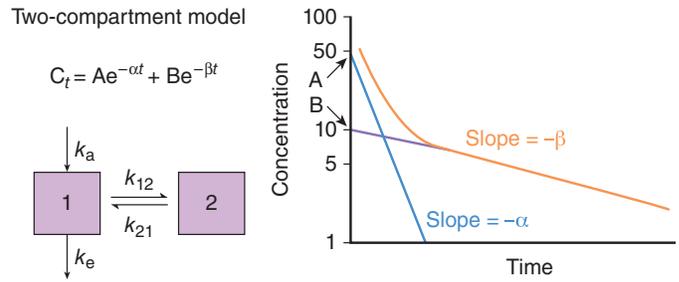

$$t_{1/2} = \frac{0.693}{k_e} \quad (\text{Eq. 9-19B})$$

The use of semilog paper facilitates graphing the first-order equation. If natural logs are used to calculate slope, then *k<sub>e</sub>* = -slope, and if common logs are used to calculate slope, then *k<sub>e</sub>* = -2.303 × slope (Fig. 9-7).

The mathematical modeling becomes more complex when more than one first-order process contributes to the overall elimination process. The equation that incorporates two first order rates is used for a two-compartment model and is Equation 9-20.

$$C_t = Ae^{-\alpha t} + Be^{-\beta t} \quad (\text{Eq. 9-20})$$

Fig. 9-8 demonstrates a two-compartment model where α often represents the distribution phase and β is the elimination phase.

**FIGURE 9-8.** Mathematical and graphical forms of a two-compartment classical pharmacokinetic model. *k<sub>a</sub>* represents the absorption rate constant, *k<sub>e</sub>* represents the elimination rate constant, α represents the distribution phase, and β represents the elimination phase.

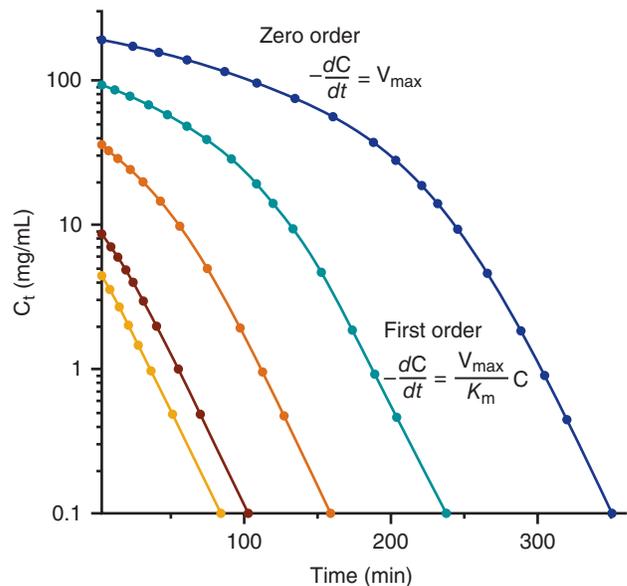

The rate of reaction of a saturable process is not linear (ie, not proportional to the concentration of xenobiotic) when saturation occurs (Fig. 9-9). This model is best described by the Michaelis-Menten equation used in enzyme kinetics (Equation 9-20) in which *v* is the velocity or rate of the enzymatic reaction, C is the concentration of the xenobiotic, V<sub>max</sub> is the maximum velocity of the reaction between the enzyme and the xenobiotic at high xenobiotic concentrations, and K<sub>m</sub> is the substrate concentration at which the reaction rate is half of the V<sub>max</sub>.

$$v = \frac{V_{\max} \times C}{K_m + C} \quad (\text{Eq. 9-21})$$

Application of this equation to toxicokinetics requires *v* to become the infinitesimal change in concentration of a xenobiotic (*dC*) with respect to an infinitesimal change in time (*dt*) as previously discussed (Equation 9-11). V<sub>max</sub> and K<sub>m</sub> both reflect the influences of diverse biologic processes. The Michaelis-Menten equation then becomes Equation 9-22, in which the negative sign again represents decay:

$$-\frac{dC}{dt} = \frac{V_{\max} \times C}{K_m + C} \quad (\text{Eq. 9-22})$$

When the concentration of the xenobiotic is very low (C <<< K<sub>m</sub>), it can be dropped from the bottom right of the equation because its contribution becomes negligible, and the resultant equation is described as a first-order

**FIGURE 9-9.** Concentration versus time curve for a xenobiotic showing nonlinear pharmacokinetics where concentrations below 10 mg/mL represent first-order elimination. C = concentration; K<sub>m</sub> = affinity constant; V = velocity; V<sub>max</sub>, maximum velocity.

process (Equations 9–23A and 9–23B). Conceptually, this is understandable because at a very low xenobiotic concentration, the process is not saturated.

$$-\frac{dC}{dt} = \frac{V_{\max} \times C}{K_m} \quad (\text{Eq. 9-23A})$$

Because  $V_{\max}$  divided by  $K_m$  is a constant,  $k$ , then:

$$-\frac{dC}{dt} = kC \quad (\text{Eq. 9-23B})$$

However, when the concentrations of the xenobiotic are extremely high and exceed the capacity of the system ( $C \gg K_m$ ), the rate becomes fixed at a constant maximal rate ( $V_{\max}$ ) regardless of the exact concentration of the xenobiotic, termed a *zero-order reaction*. Tables 9–7A and 9–7B compare a first-order reaction with a zero-order reaction. In this example, zero order is faster, but if the fraction of xenobiotic eliminated in the first-order example were 0.4, then the amount of xenobiotic in the body would decrease below 100 before the xenobiotic in the zero-order example. It is inappropriate to perform half-life calculations on a xenobiotic displaying zero-order behavior because the metabolic rates are continuously changing. Sometimes the term *apparent half-life* is used if it is unclear if the xenobiotic is exhibiting zero-order or first-order pharmacokinetics. After an overdose, enzyme saturation is a common occurrence because the capacity of enzyme systems is overwhelmed.

## CLEARANCE

Clearance (Cl) is the relationship between the rate of transfer or elimination of a xenobiotic from a reference fluid (usually plasma) to the plasma concentration ( $C_p$ ) of the xenobiotic and is expressed in units of volume per unit time (milliliters per minute) (Equation 9–24).<sup>31,54,68</sup>

$$Cl = \frac{\text{Rate of elimination}}{C_p} \quad (\text{Eq. 9-24})$$

The determination of creatinine clearance is a well-known example of the concept of clearance. Creatinine clearance ( $Cl_{CR}$ ) is determined by Equation 9–25:

$$Cl_{\text{creatinine}} = \frac{U \times V}{C_p} \quad (\text{Eq. 9-25})$$

in which  $U$  is the concentration of creatinine in urine (mg/mL),  $V$  is the volume flow of urine (mL/min), and  $C_p$  is the plasma concentration of creatinine (mg/mL) and the units for clearance are milliliters per minute. A creatinine clearance of 100 mL/min means that 100 mL of plasma is completely cleared of creatinine every minute. Clearance for a particular eliminating organ or for extracorporeal elimination is calculated with Equation 9–26:

**TABLE 9–7A** Illustration of 1,000 mg of a Xenobiotic in the Body after First-Order Elimination

Time After Administration (hour)	Amount in Body (mg)	Amount Eliminated over Preceding Hour (mg)	Fraction Eliminated over Preceding Hour
0	1,000	—	—
1	850	150	0.15
2	723	127	0.15
3	614	109	0.15
4	522	92	0.15
5	444	78	0.15
6	377	67	0.15

**TABLE 9–7B** Illustration of 1,000 mg of a Xenobiotic in the Body after Zero-Order Elimination

Time After Administration (hour)	Amount of Drug in Body (mg)	Amount of Drug Eliminated over Preceding Hour (mg)	Fraction of Drug Eliminated over Preceding Hour
0	1,000	—	—
1	850	150	0.15
2	700	150	0.18
3	550	150	0.21
4	400	150	0.27
5	250	150	0.38
6	100	150	0.60

$$Cl = Q_b \times (ER) = Q_b \times \frac{(C_{in} - C_{out})}{C_{in}} \quad (\text{Eq. 9-26})$$

Cl = clearance for the eliminating organ or extracorporeal device

$Q_b$  = blood flow to the organ or device

ER = extraction ratio

$C_{in}$  = xenobiotic concentration in fluid (blood or serum) entering the organ or device

$C_{out}$  = xenobiotic concentration in fluid (blood or serum) leaving the organ or device

Clearance can be applied to any elimination process independent of the precise mechanisms (ie, first order, Michaelis-Menten) and represents the sum total of all of the rate constants for xenobiotic elimination. Total body clearance ( $Cl_{\text{total body}}$ ) is the sum of the clearances of each of the individual eliminating processes, as seen in Equation 9–27:

$$Cl_{\text{total body}} = Cl_{\text{renal}} + Cl_{\text{hepatic}} + Cl_{\text{chelation}} + \dots \quad (\text{Eq. 9-27})$$

For a first-order process (one-compartment model), clearance is given by Equation 9–28:

$$Cl = k_e V_d \quad (\text{Eq. 9-28})$$

Experimentally, the clearance can be derived by examining the IV dose of xenobiotic in relation to the AUC from time zero to time  $t$  (Equation 9–29). The AUC is calculated using the trapezoidal rule or through integral calculus (units, eg, {mg × hour}/mL) (Figs. 9–10 and 9–11).

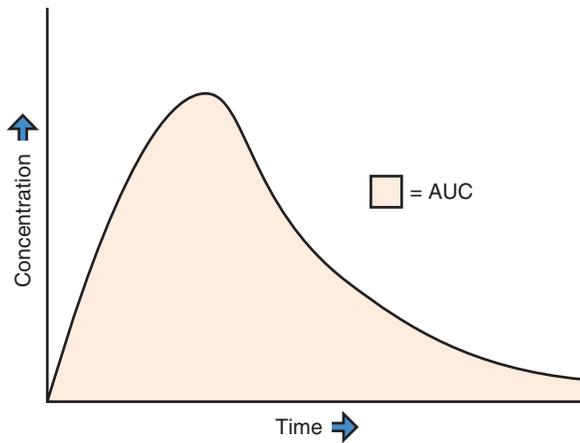

$$Cl = \frac{\text{Dose}_{IV}}{\text{AUC}_{0-t}} \quad (\text{Eq. 9-29})$$

## STEADY STATE

When exposure to a xenobiotic occurs at a fixed rate, the plasma concentration of the xenobiotic gradually achieves a plateau concentration at which the rate of absorption equals the rate of elimination and is termed *steady state* (Equations 9–30 and 9–31). The time to achieve 95% of steady-state concentration for a first-order process depends on the half-life and usually necessitates 5 half-lives; 10 half-lives are needed to achieve 99.9% of steady-state concentration. Similarly, after steady state is achieved, it would require 5 half-lives or 10 half-lives to remove 97% or 99.9% of the drug, respectively. The concentration achieved at steady state ( $C_{\text{pss}}$ ) depends on the rate of exposure, the  $V_d$ , and the clearance (Cl).

$$\text{Rate of input} = (\text{Dose} \times S \times F/\tau) \quad (\text{Eq. 9-30})$$

$$\text{Rate of elimination} = C_p \times Cl \quad (\text{Eq. 9-31})$$

**FIGURE 9-10.** The area under the curve (AUC) profile obtained after extravascular administration of a xenobiotic.

At steady state, the rate of input is equal to the rate of elimination (Equations 32–35). Therefore, when the rate of input and the rate of elimination have remained constant for 4 to 5 half-lives:

$$[\text{Dose} \times S \times F / \text{tau}] = C_{\text{pss}} \times \text{Cl} \quad (\text{Eq. 9-32})$$

$$\text{and } C_{\text{pss}} = (\text{Dose} \times S \times F / \text{tau}) \quad (\text{Eq. 9-33})$$

$$\text{Cl for first-order elimination } \text{Cl} = k_e V_d \quad (\text{Eq. 9-34})$$

$$\text{Therefore: } C_{\text{pss}} = (\text{Dose} \times S \times F / \text{tau}) / (k_e V_d) \quad (\text{Eq. 9-35})$$

where S = fraction of administered salt or ester form of the drug that is active  
 F = bioavailability or the fraction of the administered dose that reaches the systemic circulation  
 tau = dosing interval

Iatrogenic toxicity occurs in the therapeutic setting when dosing decisions are based on serum concentrations determined before achieving a

steady state. This adverse event is particularly common when using xenobiotics with long half-lives such as digoxin<sup>88</sup> and phenytoin.

**PEAK PLASMA CONCENTRATIONS**

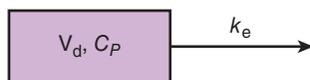

Peak plasma concentrations ( $C_{\text{max}}$ ) of a xenobiotic occur at the time of peak absorption. At this point in time, the absorption rate is at least equal to the elimination rate. Thereafter, the elimination rate predominates, and plasma concentrations begin to decline. Whereas the  $C_{\text{max}}$  depends on the dose, the rate of absorption ( $k_a$ ), and the rate of elimination ( $k_e$ ), and the time to peak ( $t_{\text{max}}$ ) are independent of dose and only depend on the  $k_a$  and  $k_e$ . For the same dose of xenobiotic, if the  $k_a$  remains constant and the rate of absorption decreases, then the  $t_{\text{max}}$  will occur later, and the  $C_{\text{max}}$  will be slightly lower (Table 9–8). Xenobiotics delivered with modified-release dosage forms or that form concretions have a decreased rate of absorption and will not achieve peak concentrations until many hours later than with an immediate-release preparation. The AUC will remain the same. However, if the  $k_a$  remains constant and the  $k_e$  is increased, then the  $t_{\text{max}}$  occurs sooner, the  $C_{\text{max}}$  decreases, and the AUC decreases (Table 9–8).<sup>59</sup> Values are based on a single oral dose (100 mg) that is 100% bioavailable ( $F = 1$ ) and has an apparent  $V_d$  of 10 L. The drug follows a one-compartment open model. The AUC is calculated by the trapezoidal rule from 0 to 24 hours.

In the overdose setting, gastric emptying, single-dose activated charcoal, and WBI decrease  $k_a$ . Multiple-dose activated charcoal, manipulation of pH to promote ion trapping to facilitate elimination, and certain chelators (ie, succimer, deferoxamine) increase  $k_e$  and are likely to decrease  $C_{\text{max}}$ ,  $t_{\text{max}}$ , and AUC.

**INTERPRETATION OF SERUM CONCENTRATIONS**

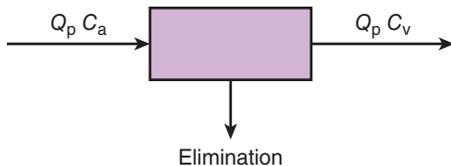

For serum concentrations to have significance, there must be an established relationship between effect and serum concentration. Many xenobiotics, such as valproic acid, digoxin, carbamazepine, lithium, and cyclosporine, have established therapeutic ranges. However, there are also many drugs (eg, diazepam, propranolol, verapamil) for which there is no established therapeutic range. Some xenobiotics (eg, physostigmine) exhibit hysteresis in which the effect increases as the serum concentration decreases. For many xenobiotics, very little information on toxicodynamics is available. Sequential serum concentrations are often collected for retrospective analysis in an attempt to correlate serum concentrations and toxicity. Tolerance to xenobiotics, such as

**Compartment model**

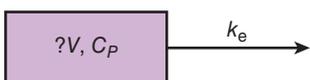

Static volume and first-order elimination are assumed. Plasma flow is not considered.  $\text{Cl}_T = k_e V_d$ .

**Physiologic model**

Clearance is the product of the plasma flow ( $Q_p$ ) and the extraction ratio (ER). Thus,  $\text{Cl}_T = Q_p \text{ER}$ .

**Model independent**

Volume and elimination rate constant not defined.  $\text{Cl}_T = \text{Dose} \div [\text{AUC}]_0^\infty$ .

**TABLE 9–8** Pharmacokinetic Effects of the Absorption Rate Constant and Elimination Rate Constant

Absorption Rate Constant $k_a$ ( $h^{-1}$ )	Elimination Rate Constant $k_e$ ( $h^{-1}$ )	$t_{\text{max}}$ (h)	$C_{\text{max}}$ (mcg/mL)	AUC (mcg.hr/mL)
0.1	0.2	6.93	2.50	50
0.2	0.1	6.93	5.00	100

**FIGURE 9-11.** General approaches to clearance.

ethanol, also influences the interpretation of serum concentrations. Tolerance is an example of a pharmacodynamic or toxicodynamic effect as a result of cellular adaptation, and it occurs when larger doses of a xenobiotic are necessary to achieve the same clinical or pharmacologic result.

Other factors that influence the interpretation of serum concentrations include chronicity of dosing (a single dose versus multiple doses); whether absorption is still ongoing and therefore concentrations are still increasing; whether distribution is still ongoing and therefore concentrations are uninterpretable (Fig. 9–12); or whether the value is a peak, trough, or steady-state concentration. Collection of accurate data for analysis requires at least four data points during at least one elimination half-life. Clinical examples in which interpretation is dependent on the dosing pattern of a single dose versus multiple doses include digoxin, lithium, vancomycin, and APAP. Modified-release preparations and xenobiotics that delay gastric emptying or form concretions are expected to have prolonged absorptive phases and require serial serum concentrations to obtain a meaningful analysis of serum concentrations (Chap. 7). A combination of trough, peak, and minimum inhibitory concentrations is often consequential for monitoring antibiotics such as gentamicin.<sup>11,50</sup>

Pitfalls in interpretation arise when the units for a particular serum concentration are not obtained or are unfamiliar (eg, mmol/L) to the clinician.

**FIGURE 9–12.** A theoretical two-compartment model for digoxin. Assume **A** to **E** represent the digoxin serum concentration equilibria at different *t* (time) intervals between the plasma compartment and the tissue compartment. *V<sub>i</sub>* (initial volume of distribution) is smaller than *V<sub>t</sub>* (tissue volume of distribution). The myocardium sits in *V<sub>t</sub>*. **A** is the time at which digoxin is administered. **E** represents distribution at 5 half-lives and it is assumed that the plasma and tissue compartments are now in equilibrium. The tissue compartments are extensive, and the graphic only represents the estimated cardiac fraction of the total distribution of this drug in the body.<sup>78</sup> (Reproduced with permission from Winter ME. Basic Clinical Pharmacokinetics. 5th ed. Vancouver, WA: Applied Therapeutics; 2010.)

The type of analysis generally applied clinically may not be appropriate to massive overdoses, and the laboratory may make errors in dilution, or errors can be inherent in the assay (Chap. 7). In these cases, the director of the laboratory should be consulted for advice with regard to the availability of a reference laboratory. The type of collection tube (eg, plasma or serum instead of whole blood for certain metals), the receptacle (metal free for certain metals, free of lithium heparin as the anticoagulant for serum lithium determinations), or the conditions during delivery of the sample result in inaccurate or inadequate information. When in doubt, the laboratory toxicologist or chemist should be called before sample collection. The laboratory usually measures total xenobiotic (free plus bound), and for xenobiotics that are highly plasma protein bound, reductions in albumin increase free concentrations and alter the interpretation of the reported concentration (Equation 9–7). Active metabolites may contribute to toxicity and are not measured.<sup>44</sup> During extracorporeal methods of elimination, ideal criteria for determining the amount removed require assay of the dialysate or activated charcoal cartridge or multiple simultaneous serum concentrations going into and out of the device along with timed urine concentrations and urine volume if renal elimination is significant rather than random serum concentrations (Chap. 6). Clearance calculations for drugs such as lithium that partition significantly into the red blood cells are more accurate when measurements are taken on whole blood.<sup>17,26</sup> The patient's weight and height and, when indicated, hemoglobin, creatinine, albumin, and other parameters to assess elimination pathways are helpful.

## SUMMARY

- Pharmacokinetics and toxicokinetics are the study of the absorption, distribution, metabolism, and excretion of xenobiotics in the therapeutic and overdose settings, respectively (ie, what the body does to the xenobiotic).
- Pharmacokinetics and toxicokinetics can help predict the onset and duration of toxicity when serum concentrations are related to therapeutic and toxic effects.
- Pharmacodynamics and toxicodynamics are the study of the relationship of the xenobiotic concentration to clinical effect in the therapeutic and overdose settings, respectively (ie, what the xenobiotic does to the body).
- Interpretation of serum concentrations relies on many factors dependent on the xenobiotics (eg, dosage form, single versus multiple doses) and the patient (tolerance, genetic profile).

## Section I Biochemical and Molecular Concepts

# 10

## CHEMICAL PRINCIPLES

Stephen J. Traub and Lewis S. Nelson

Chemistry is the science of matter; it encompasses the structure, physical properties, and reactivities of atoms and their compounds. In many respects, toxicology is the science of the interactions of matter with living entities; chemistry and toxicology are therefore intimately linked. The study of the principles of inorganic, organic, and biologic chemistry offers important insight into the mechanisms and clinical manifestations of xenobiotics and poisoning.<sup>5</sup> This chapter reviews many of these tenets and provides relevance to the current practice of medical toxicology.

### THE STRUCTURE OF MATTER

#### Basic Structure

*Matter* includes the substances of which everything is made. *Elements* are the foundation of matter, and all matter is made from one or more of the known elements. An *atom* is the smallest quantity of a given element that retains the properties of that element. Atoms consist of a nucleus, incorporating protons and neutrons, coupled with its orbiting electrons. The *atomic number* is the number of protons in the nucleus of an atom, and it is a whole number that is unique for each element. Thus, elements with 6 protons are always carbon, and all forms of carbon have exactly 6 protons. However, although the vast majority of carbon nuclei have 6 neutrons in addition to the protons, accounting for an *atomic mass* (protons plus neutrons) of 12 (<sup>12</sup>C), a small proportion of naturally occurring carbon nuclei, called *isotopes*, have 8 neutrons and a mass number of 14 (<sup>14</sup>C). This is the reason that the *atomic weight* of carbon displayed on the periodic table is 12.011, and not 12, as it actually represents the average atomic masses of all isotopes found in nature weighted by their frequency of occurrence. <sup>14</sup>C is also a *radioisotope*, which is an isotope with an unstable nucleus that emits radiation until it achieves a stable state (Chap. 128). The atomic weight, measured in grams per mole (g/mol), also indicates the molar mass of the element. That is, in one atomic weight of matter (12.011 g for carbon) there is one mole ( $6.022140857 \times 10^{23}$ ) of atoms as defined by Avogadro's constant.

Elements combine chemically to form *compounds*, which generally have physical and chemical properties that differ from those of the constituent elements. The elements in a compound can be separated only by chemical means that destroy the original compound, as occurs during the burning (ie, oxidation) of a hydrocarbon, a process that releases the carbon principally as carbon dioxide and the hydrogen principally as water (H<sub>2</sub>O). This important property differentiates compounds from *mixtures*. Mixtures are combinations of elements or compounds that can be separated by physical means, such as the distillation of petroleum into its hydrocarbon components or the evaporation of seawater to separate water from sodium chloride and other substances. With notable exceptions, such as the elemental forms of many metals or halogens (eg, Cl<sub>2</sub>), most xenobiotics are compounds or mixtures.

Dmitri Mendeleev, a Russian chemist in the mid-19th century, recognized that when all of the known elements were arranged in order of atomic weight, certain patterns of reactivity became apparent. The result of his work was the Periodic Table of the Elements (Fig. 10–1), which, with some minor alterations, is still an essential tool today. All of the currently recognized elements are represented; those heavier than uranium do not occur in nature. Many of the symbols used to identify the elements refer to the Latin name of

the element. For example, silver is Ag, for argentum, and mercury is Hg, for hydrargyrum, literally “silver water.”

The periodicity of the table relates to the electrons that circle the nucleus in discrete orbitals. Although the details of quantum mechanics and electronic configuration are complex, it is important to review some aspects in order to predict chemical reactivity. Orbitals, or quantum shells, represent the energy levels in which electrons exist around the nucleus. The orbitals are identified by various schemes, but the maximum number of electrons each orbital can contain is calculated as  $2x^2$ , where  $x$  represents the numerical rank order of the orbital. Thus, the first orbital may contain 2 electrons, the second orbital may contain 8, the third may contain 18, and so on. However, the outermost shell (designated by s, p, d, f nomenclature) of each orbital may only contain up to 8 electrons. This is irrelevant through element 20, calcium, because there is no need to fill the third-level or d shells. Even though the third orbital may contain 18 electrons, once 8 are present the 4s electrons dip below the 3d electrons in energy and this shell begins to fill. This occurs at element 21, scandium, and accounts for its chemical properties and those of the other transition elements. Transition elements are chemically defined as elements that form at least one ion with a partially filled subshell of d electrons. The inert gas elements, which are also known as noble gases, have complete outermost orbitals, accounting for their lack of reactivity under standard conditions.

In general, only electrons in unfilled shells, or *valence shells*, are involved in chemical reactions. This property relates to the fact that the most stable form of an element occurs when the configuration of its valence shell resembles that of the nearest noble gas, found in group 18 on the periodic table. This state can be obtained through the gaining, losing, or sharing of electrons with other elements and is the basis for virtually all chemical reactions.

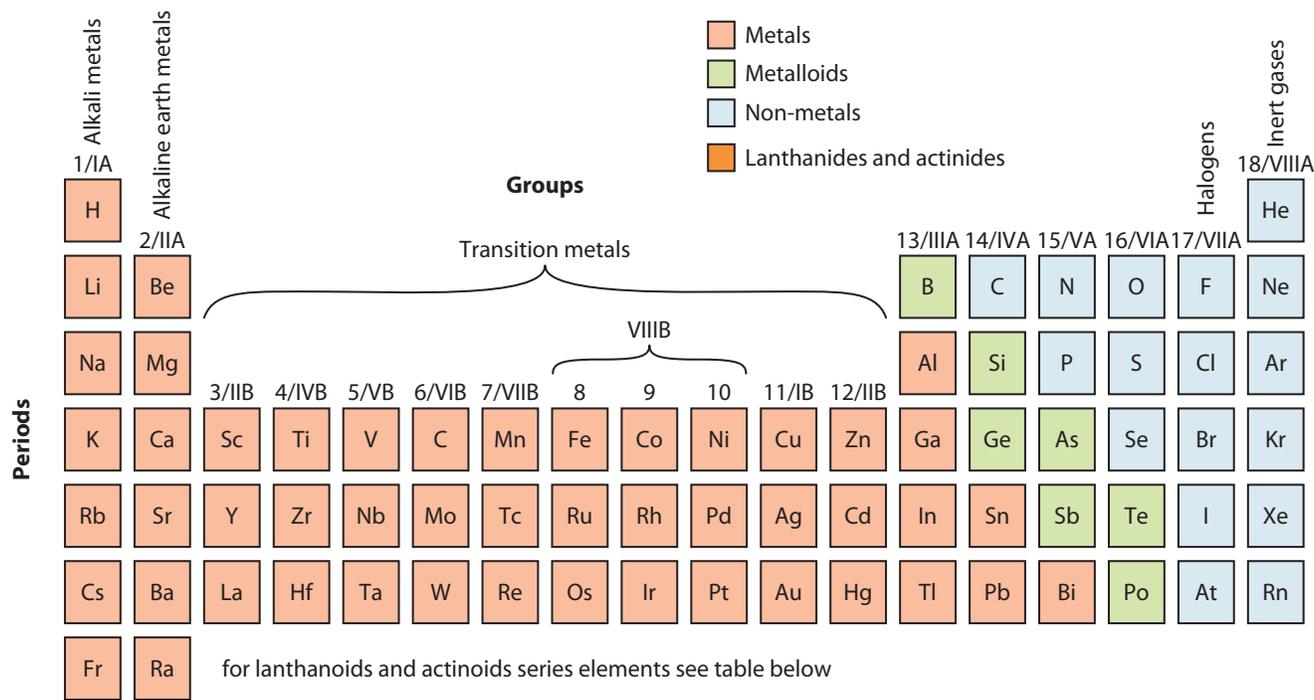

### INORGANIC CHEMISTRY

#### The Periodic Table

##### Chemical Reactivity

Broadly, the periodic table is divided into metals and nonmetals. Metals, in their elemental form, are typically malleable solids that conduct electricity, whereas nonmetals are usually dull, fragile, nonconductive compounds (C, N, P, O, S, Se, and the halogens). Metals are found on the left side of the periodic table, and account for the majority of the elements, whereas nonmetals are on the right side. Separating the 2 groups are the metalloids, which fall on a jagged line starting with boron (B, Si, Ge, As, Sb, Te, At). Metalloids have chemical properties that are intermediate between the metals and the nonmetals. Each column of elements is termed a family or group, and each row is a period. Although the table is conceived and organized in periods, trends in the chemical reactivity, and therefore toxicity, typically exist within the groups.

In 1990, the International Union of Pure and Applied Chemistry (IUPAC) replaced the existing numbering schemes for the periodic table columns with a unified and simplified nomenclature. Using this format, which is included in this chapter, the groups are simply incrementally numbered from 1 to 18 from left to right.<sup>2</sup>

Symbol	Name	Atomic number	Atomic weight
Ac	Actinium	89	227.0278
Al	Aluminum	13	26.9815

FIGURE 10-1. The Periodic Table of the Elements. Group numbering: 2 (Modern IUPAC) IIA (Classical).

The ability of any particular element to produce toxicologic effects relates directly to one or more of its many physicochemical properties. These properties will, to some extent, be predicted by their location on the periodic table. For example, arsenate will substitute for phosphate in the mitochondrial production of adenosine triphosphate (ATP), creating adenosine diphosphate monoarsenate (Chap. 11). Because this compound is unstable and not useful as an energy source, energy production by the cell fails; in this manner, arsenic interferes with oxidative phosphorylation. The existence of an interrelationship between  $\text{Ca}^{2+}$  and either  $\text{Mg}^{2+}$  or  $\text{Ba}^{2+}$  is predictable, although the actual effects are not. Under most circumstances,  $\text{Mg}^{2+}$  is a  $\text{Ca}^{2+}$  antagonist, and patients with hypermagnesemia present with neuromuscular weakness caused by the blockade of myocyte calcium channels. Alternatively,  $\text{Ba}^{2+}$  mimics  $\text{Ca}^{2+}$  and closes  $\text{Ca}^{2+}$ -dependent  $\text{K}^+$  channels in myocytes, producing life-threatening hypokalemia. The physiologic relationships among the ions of lithium ( $\text{Li}^+$ ), potassium ( $\text{K}^+$ ), and sodium ( $\text{Na}^+$ ) are also consistent with their chemical similarities (all alkali metals in Group IA). However, the clinical similarity between thallium (thallous) ion ( $\text{Tl}^+$ ) and  $\text{K}^+$  is not immediately predictable. Other than their monovalent nature (ie, 1+ charge), it is difficult to predict the substitution of  $\text{Tl}^+$  (Group 13, Period 6) for  $\text{K}^+$  (Group 1, Period 4) in membrane ion channel functions, until the similarity of their ionic radii is known ( $\text{Tl}^+$ , 1.47 Å;  $\text{K}^+$ , 1.33 Å).

An emerging physicochemical property of toxicologic interest is particle size. The chemical and toxicologic properties of a given element or molecule change as the particle size is reduced. An entire field of nanotoxicology has emerged to study the adverse health effects of nanoparticles, which are ultrafinely divided particles, ranging from approximately 1 to 100 nm in diameter. Differences in absorption, biodistribution, and structure-activity effects, for example, enhance the toxicologic potential of otherwise nontoxic xenobiotics.<sup>7</sup>

### Alkali and Alkaline Earth Metals

Alkali metals (Group 1, formerly Group IA: Li, Na, K, Rb, Cs, Fr) and hydrogen (not an alkali metal on Earth) have a single outer valence electron and lose this electron easily to form compounds with a valence of 1+. The alkaline earth metals (Group 2, formerly Group IIA: Be, Mg, Ca, Sr, Ba, Ra) are located between the alkali and rare earth (Group 3, formerly Group IIIB), readily lose 2 electrons, and form cations with a 2+ charge. In their metallic form, members of both of these groups react violently with water to liberate strongly basic solutions, accounting for the word alkali in their group names ( $2\text{Na}^0 + 2\text{H}_2\text{O} \rightarrow 2\text{NaOH} + \text{H}_2$ ).

The soluble ionic forms of sodium, potassium, or calcium, which are critical to survival, also produce life-threatening symptoms following excessive intake (Chap. 12). Xenobiotics interfere with the physiologic role of these key electrolytes.  $\text{Li}^+$  mimics  $\text{K}^+$  after entering neurons through  $\text{K}^+$  channels, and serves as an inadequate substrate for the repolarizing of  $\text{Na}^+/\text{K}^+$ -ATPase.  $\text{Li}^+$  thus interferes with cellular  $\text{K}^+$  homeostasis and alters neuronal repolarization, accounting for the neuroexcitability manifesting as tremor. Similarly, as noted previously, the molecular effects of  $\text{Mg}^{2+}$  and  $\text{Ba}^{2+}$  supplant those of  $\text{Ca}^{2+}$ .

More commonly, the consequential toxicities ascribed to alkali or alkaline earth salts relate to the anionic component. In the case of  $\text{NaOH}$  or  $\text{Ca}(\text{OH})_2$ , it is the hydroxide anion, whereas with potassium cyanide ( $\text{KCN}$ ) it is the cyanide ( $\text{CN}^-$ ) anion. When the chemical reactivity of an ionic compound (including its cellular toxicity) can be ascribed solely to one of the ions, any other ion in the compound is referred to as a *spectator* ion.

### Transition Metals

Unlike the alkali and alkaline earth metals, most other metallic elements are neither soluble nor reactive. This includes the transition metals (Groups 4-12; formerly Groups IB to VIIB, VIII, IB and IIB), a large group that contains several ubiquitous metals such as iron (Fe) and copper (Cu). These elements, in their metallic form, are widely used in both industrial and household applications because of their high tensile strength, density, and melting point, which is partly a result of their ability to delocalize the

electrons in the d orbital throughout the metallic lattice. Transition metals also form brightly colored salts that find widespread applications, including as pigments for paints or fireworks. The ionic forms of these elements are of greater toxicologic importance than their metallic/elemental forms. Chemically, transition elements form at least one ion with a partially filled subshell of d electrons. Because the transition metals have partially filled valence shells, they are capable of obtaining several, usually positive, oxidation states. This important mechanism explains the role of transition metals in oxidation/reduction (redox) reactions, generally as electron acceptors (see Reduction-Oxidation below). This reactivity is used by organisms in various physiologic, catalytic, and coordination roles, such as at the active sites of enzymes and in hemoglobin. As expected, the substantial reactivity of these transition metal elements is associated with cellular injury caused by several mechanisms, including the generation of reactive oxygen species (Fig. 10-2). Manganese ion, as an example, is implicated in free radical damage of the basal ganglia, causing parkinsonism.

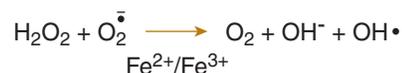

### Heavy Metals

*Heavy metal* is often loosely used to describe all metals of toxicologic significance, but in reality the term should be reserved to describe only those metals in the lower period of the periodic table, particularly those with atomic masses greater than 200 Da. The chemical properties and toxicologic predilection of these elements vary, but a unifying toxicologic mechanism is electrophilic interference with nucleophilic sulfhydryl-containing enzymes. Some of the heavy metals also participate in the generation of free radicals through Fenton chemistry (Fig. 10-2). The likely determinant of the specific toxicologic effects produced by each metal is the tropism for various physiologic systems, enzymes, or microenvironments; thus, lipophilicity, water solubility, ionic size, and other physicochemical parameters are undoubtedly critical. Also, because the chemistry of metals varies dramatically based on the chemical form (ie, organic, inorganic, or elemental), as well as the charge on the metal ion, prediction of the clinical effects of a particular metal is often difficult.

**Mercury.** Elemental mercury ( $\text{Hg}^0$ ) is unique in that it is the only metal that exists in liquid form at room temperatures. As such, it is capable of creating semisolid solutions, or amalgams, with other metals. Although relatively innocuous if ingested as a liquid, elemental mercury is readily volatilized (as a result of its high vapor pressure), transforming it into a significant pulmonary mucosal irritant upon inhalation. Pulmonary exposure increases its systemic bioavailability. Elemental mercury undergoes biotransformation in the erythrocyte and brain to the mercuric ( $\text{Hg}^{2+}$ ) form, which has a high affinity for sulfhydryl-containing molecules, such as proteins. This causes a depletion of glutathione in organs such as the kidney, and also initiates lipid peroxidation. The mercurous form ( $\text{Hg}^+$ ) is considerably less toxic than the mercuric ( $\text{Hg}^{2+}$ ) form, perhaps because of its reduced water solubility, which limits absorption. Organic mercurial compounds, such as methylmercury and dimethylmercury, are formed environmentally by anaerobic bacteria containing the methylating compound methylcobalamin, a vitamin  $\text{B}_{12}$  analog (Chap. 95).

Fenton

Haber-Weiss

**FIGURE 10-2.** The Fenton and Haber-Weiss reactions, which are the 2 most important mechanisms to generate hydroxyl radicals, are both mediated by transition metals. Typical transition metals include iron ( $\text{Fe}^{2+}$ , shown) or copper ( $\text{Cu}^+$ ).

**Thallium.** Metallic thallium ( $Tl^0$ ) is used in the production of electronic equipment, and is itself minimally toxic. Thallium ions, however, have physicochemical properties that closely mimic potassium ions, allowing them to participate in and often alter the myriad physiologic activities related to potassium. This property is exploited during a thallium-stress test to assess for myocardial ischemia or infarction; because ischemic myocardial cells lack adequate energy for normal  $Na^+, K^+$ -ATPase function, they cannot exchange sodium for potassium (or radioactive thallium administered during a stress test). This produces a “cold spot” in the ischemic areas on cardiac scintigraphy (Chap. 99).

**Lead.** Lead is not abundant in the Earth's crust (0.002%), but mining and industrial use make it a significant toxicologic concern. Lead exposure occurs during the smelting process or from one of its diverse commercial applications. Most of the useful lead compounds are inorganic plumbous ( $Pb^{2+}$ ) salts, but plumbic ( $Pb^{4+}$ ) compounds are also used. The  $Pb^{2+}$  compounds are typically ionizable, releasing  $Pb^{2+}$  when dissolved in a solvent, such as water. Lead ions are absorbed in place of  $Ca^{2+}$  ions by the gastrointestinal tract and replace  $Ca^{2+}$  in certain physiologic processes. This mechanism is implicated in the neurotoxic effect of lead ions. Lead compounds tend to be covalent compounds that do not ionize in water. Some  $Pb^{4+}$  compounds are oxidants. Although elemental lead is not itself toxic, it rapidly develops a coating of toxic lead oxide or lead carbonate on exposure to air or water (Chap. 93).

### Metalloids

Although the metalloids (B, Si, Ge, As, Sb, Te, At) share many physical properties with metals, they differ in their propensity to form compounds with both metals and the nonmetals carbon, nitrogen, or oxygen. Metalloids are either oxidized or reduced in chemical reactions.

**Arsenic.** Toxicologically important inorganic arsenic compounds exist in either the pentavalent arsenite ( $As^{3+}$ ) form or the trivalent arsenate ( $As^{5+}$ ) form. The reduced water solubility of arsenate compounds (such as arsenic pentoxide) accounts for its limited clinical toxicity when compared to trivalent arsenic trioxide. The trivalent form of arsenic is primarily a nucleophilic toxin, binding sulfhydryl groups and interfering with enzymatic function (Chaps. 11 and 86).

### Nonmetals

The nonmetals (C, N, P, O, S, Se, halogens) are highly electronegative and are toxic in either their compounded or their elemental form. The nonmetals with large electronegativity, such as  $O_2$  or  $Cl_2$ , generally oxidize other elements in chemical reactions. Those with lesser electronegativity, such as C, behave as reducing agents.

**Halogens.** In their highly reactive elemental form, which is a covalent dimer of halogen atoms, the halogens (F, Cl, Br, I, At) carry the suffix *ine* (eg,  $Cl_2$ , chlorine). Halogens require the addition of one electron to complete their valence shell, and are strong oxidizing agents. Because they are highly electronegative, they readily form halides (eg,  $Cl^-$ , chloride) by abstracting electrons from less electronegative elements. Thus, the halogen ions, in their stable ionic form, generally carry a charge of  $-1$ . The halides, although much less reactive than their respective elemental forms, are reducing agents. The hydrogen halides (eg, HCl, hydrogen chloride) are gases under standard conditions, but they ionize when dissolved in aqueous solution to form hydrohalic acids (eg, HCl, hydrochloric acid). All hydrogen halides except HF (hydrogen fluoride) ionize nearly completely in water to release  $H^+$  and are considered *strong acids*. Because of its small ionic radius, lack of charge dispersion, and the intense electronegativity of the fluorine atom, HF ionizes poorly and is a *weak acid*. This specific property of HF has important toxicologic implications (Chap. 104).

**Group 18 (formerly Group VIIIA): Inert Gases.** Inert gases (He, Ne, Ar, Kr, Xe, Rn), also known as noble gases, maintain completed valence shells and are thus unreactive except under extreme experimental conditions. Despite their lack of chemical reactivity, the inert gases are toxicologically important as simple asphyxiants, causing hypoxia if they displace ambient oxygen from

a confined space (Chap. 121). During high-concentration exposure, inert gases produce anesthesia, and xenon is used as an anesthetic agent. Radon, although chemically unreactive, is radioactive, and prolonged exposure is associated with the development of lung cancer.

### Bonds

Electrons are not generally shared evenly between atoms when they form a compound unless the bond is between the same elements, as in  $Cl_2$ . When different elements are involved, one will exert a larger attraction for the shared electrons. The degree to which an element draws the shared electron is determined by the *electronegativity* of the element (Fig. 10–3). The electronegativity of each element was catalogued by Linus Pauling and relates to the ionic radius, or the distance between the orbiting electron and the nucleus, and the shielding effects of the inner electrons. Electronegativity rises toward the right of the periodic table, corresponding with the expected charge obtained on an element when it forms a bond. Fluorine has the highest electronegativity of all elements, which explains many of the toxicologic properties of fluorine.

Several types of bonds exist between elements when they form compounds. When one element gains valence electrons and another loses them, the resulting elements are charged and attract one another in an *ionic*, or *electrovalent*, bond. An example is sodium chloride (NaCl), or table salt, in which the electronegativity difference between the elements is 1.9, or greater than the electronegativity of the sodium (Fig. 10–3). Thus, the chloride wrests control of the electrons in this bond. In solid form, ionic compounds exist in a crystalline lattice, but when put into solution, as in water or in blood (serum), the elements separate and form charged particles, or *ions* ( $Na^+$  and  $Cl^-$ ). The ions are stable in solution because their valence shells contain 8 electrons and are complete. The properties of ions differ from both the original atom from which the ion is derived and the noble gas with which it shares electronic structure.

It is important to recognize that when a mole of a salt, such as NaCl (molecular weight 58.45 g/mol), is put in aqueous solution, 2 moles of particles result. This is because NaCl is essentially fully ionized in water; that is, it produces one mole of  $Na^+$  (23 g/mol) and one mole of  $Cl^-$  (35.5 g/mol). For salts that do not ionize completely, less than the intrinsic number of moles are released and the actual quantity liberated can be predicted based on the defined solubility of the compound, or the solubility product constant ( $K_{sp}$ ). For ions that carry more than a single charge, the term *equivalent* is often used to denote the number of moles of other particles to which one mole of the substance will bind. Thus, one equivalent of calcium ions will typically bind 2 moles (or equivalents) of chloride ions (which are monovalent) because calcium ions are divalent. Alternatively stated, a 10% calcium chloride ( $CaCl_2$ ) aqueous solution contains approximately 1.4 mEq/mL or 0.7 mmol/mL of  $Ca^{2+}$ .

Compounds formed by 2 elements of similar electronegativity have little ionic character because there is little impetus for separation of charge.

1/IA								18/VIIIA

**FIGURE 10–3.** Electronegativity of the common elements. Note that the noble gases are not reactive and thus do not have electronegativity. The top row indicates modern IUPAC nomenclature/classical nomenclature.

Instead, these elements share pairs of valence electrons, a process known as *covalence*. The resultant molecule contains a *covalent bond*, which is typically very strong and generally requires a high-energy chemical reaction to disrupt it. There is wide variation in the extent to which the electrons are shared between the participants of a covalent bond, and the physicochemical and toxicologic properties of any particular molecule are in part determined by its nature. Sharing is rarely symmetric (as in oxygen {O<sub>2</sub>} or chlorine {Cl<sub>2</sub>}). When electrons are shared asymmetrically (localized to a greater degree around one of the component atoms), the bond is called *polar*. Importantly, however, the presence of polar bonds does not mean that the compound itself is polar. For example, methane contains a carbon atom that shares its valence electrons with 4 hydrogen atoms, in which there is a small charge separation between the elements (electronegativity {EN} difference = 0.40). Although each of the carbon hydrogen bonds is polar, however, the tetrahedral configuration of the molecule means that the asymmetries cancel each other out, resulting in no net polarity, rendering the compound *nonpolar*. The lack of polarity demonstrates that methane molecules have little affinity for other methane molecules and they are held together only by weak intermolecular bonds. This explains why methane is highly volatile and therefore exists as a gas under standard temperature and pressure.

Because the EN differences between hydrogen (EN = 2.20) and oxygen (EN = 3.44) are significant (EN difference = 1.24), the electrons in the hydrogen-oxygen bonds in water are drawn toward the oxygen atom, giving it a partial negative charge and the hydrogen a partial positive charge. Because H<sub>2</sub>O is angular, not linear or symmetric, water is a polar molecule. Water molecules are held together by *hydrogen bonds*, which are bonds between electropositive hydrogen atoms and the strongly electronegative oxygen atoms. Hydrogen bonds are stronger than other intermolecular bonds (eg, *van der Waals forces*; see later). Hydrogen bonds have sufficient energy to open many ionic bonds and *solvate* ions (ie, cause ionic compounds to go into solution). In this process, the polar ends of the water molecule surround the charged particles of the dissolved salt. As one corollary, nonpolar molecules are relatively insoluble in polar compounds such as water, as there is little similarity between the nonpolar methane and the polar water molecules. As a second corollary, salts cannot be solvated by nonpolar compounds, and thus a salt, such as sodium chloride, has almost no solubility in a nonpolar solvent such as carbon tetrachloride.

Alternatively, the stability and irreversibility of the bond between an organic phosphorus compound and the cholinesterase enzyme are a result of covalent phosphorylation of an amino acid at the active site of the enzyme. The resulting bond is essentially irreversible in the absence of another chemical reaction (Fig. 110–3).

Compounds often share multiple pairs of electrons. For example, the 2 carbon atoms in acetylene (HC≡CH) share 3 pairs of electrons between them, and each shares one pair with a hydrogen. Carbon and nitrogen share 3 pairs of electrons in forming cyanide (C≡N<sup>-</sup>), making this bond very stable and accounting for the large number of xenobiotics capable of liberating cyanide. Complex ions are covalently bonded groups of elements that behave as a single element. For example, hydroxide (OH<sup>-</sup>) and sulfate (SO<sub>4</sub><sup>2-</sup>) form sodium salts as if they were simply the ion of a single element (such as chloride).

Noncovalent bonds, such as hydrogen or ionic bonds, are important in the interaction between ligands and receptors as well as between ion channels and enzymes. These are low-energy bonds and easily broken. Van der Waals forces, also known as London dispersion forces, are intermolecular forces that arise from induced dipoles as a consequence of nonuniform distribution of the molecular electron cloud. These forces become stronger as the atom (or molecule) becomes larger because of the increased polarizability of the larger, more dispersed electron clouds. This accounts for the fact that under standard temperature and pressure, fluorine and chlorine are gases, whereas bromine is a liquid, and iodine is a solid.

## Reduction-Oxidation

Reduction-oxidation (*redox*) reactions involve the movement of electrons from one atom or molecule to another, and comprise 2 interdependent

reactions (reduction and oxidation). *Reduction* is the gain of electrons by an atom that is thereby *reduced*. The electrons derive from a *reducing agent*, which in the process becomes *oxidized*. *Oxidation* is the loss of electrons from an atom, which is, accordingly, *oxidized*. An *oxidizing agent* accepts electrons and, in the process, is reduced. By definition, these chemical reactions involve a change in the valence of an atom. It is also important to note that acid-base and electrolyte chemical reactions involve electrical charge interactions but no change in valence of any of the involved components. The implications of redox chemistry for toxicology are significant. For example, the oxidation of ferrous (Fe<sup>2+</sup>) to ferric (Fe<sup>3+</sup>) iron within the hemoglobin molecule creates the dysfunctional methemoglobin molecule (Chap. 124).

The *oxidation state* of an atom or molecule plays an important role in its toxicity. Elemental lead and mercury are both intrinsically harmless metals, but when oxidized to their cationic forms produce devastating clinical effects. The metabolism of ethanol to acetaldehyde involves a change in the oxidation state of the molecule. In this case, an enzyme, alcohol dehydrogenase, oxidizes (ie, removes electrons from) the C-O bond and delivers the electrons to oxidized nicotinamide adenine dinucleotide (NAD<sup>+</sup>), reducing it to NADH. As in this last example, *oxidation* is occasionally used to signify the gain of oxygen by a substance. That is, when elemental iron (Fe<sup>0</sup>) undergoes rusting to iron oxide (Fe<sub>2</sub>O<sub>3</sub>), it is said to oxidize. The use of this term is consistent because in the process of oxidation, oxygen derives electrons from the atom with which it is reacting and combining.

## Reactive Oxygen Species

*Free radicals* are reactive molecules that contain one or more unpaired electrons. They are typically neutral but also can be anionic or cationic. However, because certain toxicologically important reactive molecules, such as hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) and ozone (O<sub>3</sub>), do not contain unpaired electrons, the term *reactive species* is preferred. The reactivity of these molecules directly relates to their attempts to fill their outermost orbitals by receiving an electron; the result is *oxidative stress* on the biologic system. Molecular oxygen is actually a diradical with 2 unpaired electrons in the outer orbitals. However, its reactivity is less than that of the other radicals because the unpaired electrons have parallel spins, so catalysts (ie, enzymes or metals) are typically involved in the use of oxygen in biologic processes.

Reactive species are continuously generated as a consequence of endogenous metabolism, and there is an efficient detoxification system for their control. However, under conditions of either excessive endogenous generation or exposure to exogenous reactive species, the physiologic defenses against these toxic products are overwhelmed. When this occurs, reactive species induce direct cellular damage and initiate a cascade of additional harmful oxidative reactions.<sup>4</sup>

Intracellular organelles, particularly the mitochondria, are damaged by various reactive species. This causes further injury to the cell as energy failure occurs. This initial damage is exacerbated by the activation of the host inflammatory response by chemokines that are released from cells in response to reactive species-induced damage. This inflammatory response aggravates cellular damage. The resultant membrane dysfunction or damage causes cellular apoptosis or necrosis.

The most important reactive oxygen species in medical toxicology are derived from oxygen, although those derived from nitrogen are also important. Table 10–1 lists some of the important reactive oxygen and nitrogen species.

The biradical nature of oxygen explains both the physiologic and toxicologic importance of oxygen in biologic systems. Physiologically, the majority of oxygen used by the body serves as the ultimate electron acceptor in the mitochondrial electron transport chain. In this situation, 4 electrons are added to each molecule of oxygen to form 2 water molecules (O<sub>2</sub> + 4H<sup>+</sup> + 4e<sup>-</sup> → 2H<sub>2</sub>O).

Superoxide (O<sub>2</sub><sup>-</sup>) is “mutated” from oxygen within neutrophil and macrophage lysosomes as part of the oxidative burst, which serves to help eliminate infectious agents and damaged cells. Superoxide is subsequently enzymatically converted, or “disrupted,” into hydrogen peroxide by superoxide

TABLE 10–1 Structure of Important Reactive Species

	Structure
<b>Reactive Oxygen Species</b>	
<i>Free radicals</i>	
Hydroxyl radical	OH•
Alkoxyl radical	RO•
Peroxyl radical	ROO•
Superoxide radical	O <sub>2</sub> <sup>•-</sup>
<i>Nonradicals</i>	
Hydrogen peroxide	H <sub>2</sub> O <sub>2</sub>
Hypochlorous acid	HOCl
Singlet oxygen	[O] or <sup>1</sup> O <sub>2</sub>
Ozone	O <sub>3</sub>
<b>Reactive Nitrogen Species</b>	
<i>Free radicals</i>	
Nitric oxide	NO•
Nitrogen dioxide	NO <sub>2</sub> •
<i>Nonradicals</i>	
Peroxynitrite anion	ONOO <sup>-</sup>
Nitronium cation	NO <sub>2</sub> <sup>+</sup>

dismutase (SOD). Hydrogen peroxide also can subsequently converted into hypochlorous acid by the enzymatic addition of chloride by myeloperoxidase. Both hydrogen peroxide and hypochlorite ion are more potent reactive oxygen species than superoxide. However, this lysosomal protective system is also responsible for tissue damage following poisoning as the innate inflammatory response attacks xenobiotic-damaged cells. Examples include acetaminophen (APAP)-induced hepatotoxicity (Chap. 33), carbon monoxide neurotoxicity (Chap. 122), and chlorine-induced pulmonary toxicity (Chap. 121), each of which is altered, at least in experimental systems, by the addition of scavengers of reactive species.

Although superoxide and hydrogen peroxide are reactive species, it is their conversion into the hydroxyl radical (OH•) that accounts for their most consequential effects. The hydroxyl radical is generated by the Fenton reaction (Fig. 10–2), in which hydrogen peroxide is decomposed in the presence of a transition metal.<sup>3</sup> This catalysis typically involves Fe<sup>2+</sup>, Cu<sup>+</sup>, Cd<sup>2+</sup>, Cr<sup>5+</sup>, Ni<sup>2+</sup>, or Mn<sup>2+</sup>. The Haber-Weiss reaction (Fig. 10–2), in which a transition metal catalyzes the combination of superoxide and hydrogen peroxide, is another important means of generating the hydroxyl radical. Alternatively, superoxide dismutase, within the erythrocyte, contains an ion of copper (Cu<sup>2+</sup>) that participates in the catalytic reduction of superoxide to hydrogen peroxide and the subsequent detoxification of hydrogen peroxide by glutathione peroxidase or catalase.

Transition metal cations frequently bind to the cellular nucleus and locally generate reactive oxygen species, most importantly hydroxyl radicals. This results in DNA strand breaks and modification, accounting for the mutagenic effects of many transition metals. In addition to the important role that transition metal chemistry plays following iron or copper salt poisoning, the long-term consequences of chronic transition metal poisoning are exemplified by asbestos. The iron contained in asbestos serves as the source of the Fenton-generated hydroxyl radicals that are responsible for the pulmonary fibrosis and cancers associated with long-term exposure.

The most important toxicologic effects of reactive oxygen species occur on the cell membrane, and are caused by the initiation by hydroxyl radicals of the lipid peroxidative cascade. The alteration of these lipid membranes ultimately causes membrane destruction. Identification of released oxidative products such as malondialdehyde is a common method of assessing lipid peroxidation.

Under normal conditions, there is a delicate balance between the formation and immediate detoxification of reactive oxygen species. For example,

the conversion of the superoxide radical to hydrogen peroxide via SOD is rapidly followed by the transformation of hydrogen peroxide to water by glutathione peroxidase or catalase. The fact that transition metals exist in “free” form in only minute quantities in biologic systems minimizes the formation of hydroxyl radicals; that is, cells have developed extensive systems by which transition metal ions are sequestered and rendered harmless. Ferritin (binds iron), ceruloplasmin (binds copper), and metallothionein (binds cadmium) are all specialized proteins that safely sequester transition metal ions. Certain proteins and enzymes such as hemoglobin or SOD have critical biological functions associated with the transition metals at their active sites.

Detoxification of certain reactive species is difficult because of their extreme reactivity. Widespread antioxidant systems typically scavenge reactive species before tissue damage occurs. An example is glutathione, a reducing agent and nucleophile, which prevents both exogenous oxidants from producing hemolysis and the APAP metabolite *N*-acetyl-*p*-benzoquinoneimine (NAPQI) from damaging the hepatocyte (Chap. 33).

The key reactive nitrogen species is nitric oxide. At typical physiologic concentrations, this radical is responsible for vascular endothelial relaxation through stimulation of guanylate cyclase. However, during oxidative burst, high concentrations of nitric oxide are formed from L-arginine. At these concentrations, nitric oxide is directly damaging to tissue and also reacts with the superoxide radical to generate the peroxynitrite anion. This is particularly important because peroxynitrite spontaneously degrades to form the hydroxyl radical. Peroxynitrite ion is implicated in both the delayed neurologic effects of carbon monoxide poisoning and the hepatic injury from APAP.

**Redox Cycling.** Although transition metals are an important source of reactive species, certain xenobiotics are also capable of independently generating reactive species. Most do so through a process called *redox cycling*, in which a molecule accepts an electron from a reducing agent and subsequently transfers that electron to oxygen, generating the superoxide radical. At the same time, this second reaction regenerates the parent molecule, which itself can gain another electron and restart the process. The toxicity of paraquat (Chap. 109) is selectively localized to pulmonary endothelial cells. Its pulmonary toxicity results from redox cycling generation of reactive oxygen species (Fig. 109–3). A similar process, localized to the heart, occurs with anthracycline antineoplastics such as doxorubicin.

### Acid-Base Chemistry

Water is *amphoteric*, which means that it can function as either an acid or a base, much the same way as the bicarbonate ion (HCO<sub>3</sub><sup>-</sup>). Because of the amphoteric nature of water, H<sup>+</sup>, despite the nomenclature, does not ever actually exist in aqueous solution; rather, it is covalently bound to a molecule of water to form the hydronium ion (H<sub>3</sub>O<sup>+</sup>). However, the term H<sup>+</sup>, or proton, is used for convenience.

Even in a neutral solution, a tiny proportion of water is always undergoing ionization to form both H<sup>+</sup> and OH<sup>-</sup> in exactly equal amounts. By convention, however, it is the quantity of H<sup>+</sup> that is measured to determine the acidity or alkalinity of the solution. The units for this measurement are pH, which is  $-\log[H^+]$ . In a perfect system at equilibrium, the concentration of H<sup>+</sup> ions in water is precisely 0.0000001, or 10<sup>-7</sup>, mol/L and that of OH<sup>-</sup> is the same. The number of H<sup>+</sup> ions increases when an acid is added to the solution and falls when an alkali is added. The negative log of 10<sup>-7</sup> is 7, and the pH of a neutral aqueous solution is thus 7. In actuality, the pH of water is approximately 6 because of dissolution of ambient carbon dioxide to form carbonic acid (H<sub>2</sub>O + CO<sub>2</sub> → H<sub>2</sub>CO<sub>3</sub>), which ionizes to form H<sup>+</sup> and bicarbonate (HCO<sub>3</sub><sup>-</sup>).

There are many definitions of acid and base. The 3 commonly used definitions are those advanced by (1) Svante Arrhenius, (2) Brønsted and Lowry, and (3) Lewis. Because our focus is on physiologic systems, which are most commonly aqueous solutions, the original definition by the Swedish chemist Arrhenius is the most practical. In this view, an acid releases hydrogen ions, or protons (H<sup>+</sup>), in water. Conversely, a base produces hydroxyl ions (OH<sup>-</sup>) in water. Thus, hydrogen chloride (HCl), a neutral gas under standard conditions, dissolves in water to liberate H<sup>+</sup> and is therefore an acid.

For nonaqueous solutions, the Brønsted-Lowry definition is preferable. An acid, in this schema, is a substance that donates a proton and a base is one that accepts a proton. Thus, any molecule that has a hydrogen atom in the 1+ oxidation state is technically an acid, and any molecule with an unbound pair of valence electrons is a base. Because most of the acids or bases of toxicologic interest have ionizable protons or available electrons, respectively, the Brønsted-Lowry definition is most often considered when discussing acid-base chemistry (ie,  $\text{HA} + \text{H}_2\text{O} \rightarrow \text{H}_3\text{O}^+ + \text{A}^-$ ;  $\text{B}^- + \text{H}_2\text{O} \rightarrow \text{HB} + \text{OH}^-$ ). However, this is not a defining property of all acids or bases.

The Lewis classification offers the least-restrictive definition of such substances. A Lewis acid is an electron acceptor and a Lewis base is an electron donor.

Simplistically, acids are sour and turn litmus paper red; bases feel slippery (due to the dissolution of skin), are bitter, and turn litmus paper blue. Of note, the tasting and tactile assessment of substances to determine their acid-base status is not recommended.

Because acidity and alkalinity are determined by the number of available  $\text{H}^+$  ions, it is useful to classify chemicals by their effect on the  $\text{H}^+$  concentration. Strong acids ionize almost completely in aqueous solution, and very little of the parent compound remains. Thus, 0.001 (or  $10^{-3}$ ) mol of HCl, a strong acid, added to 1 L of water produces a solution with a pH of 3. Weak acids, on the other hand, reach an equilibrium between parent and ionized forms, and thus do not alter the pH to the same degree as a similar quantity of a strong acid. This chemical notation defines the strength or weakness of an acid and should not be confused with the concentration of the acid. Thus, the pH of a dilute strong acid solution is substantially less than that of a concentrated weak acid (Table 10-2).

The degree of ionization of an acid is determined by the  $\text{pK}_a$ , or the negative log of the *ionization constant*, which represents the pH at which an acid is half dissociated in solution. The same relationship applies to the  $\text{pK}_b$  of an

alkali, although  $\text{pK}_b$  is rarely used and the degree of ionization of bases is also expressed as  $\text{pK}_a$  (of note,  $\text{pK}_a = 14 - \text{pK}_b$ ). The lower the  $\text{pK}_a$ , the stronger the acid; the higher the  $\text{pK}_a$ , the stronger the base. The  $\text{pK}$  of a strong acid is clinically irrelevant because it is nearly fully ionized under all but the most extremely acidic conditions. Importantly, knowledge of the  $\text{pK}_a$  does not itself denote the strength of an acid or an alkali. To some extent, this quality is predicted by its chemical structure or reactivity, or it can be obtained through direct measurement or from a reference source.

Because only uncharged compounds cross lipid membranes spontaneously, the  $\text{pK}_a$  has strong clinical relevance. Salicylic acid, a weak acid with a  $\text{pK}_a$  of 3, is nonionized in the stomach (pH = 2) and passive absorption occurs (Fig. 9-3). Because it is predominantly in the ionized form (ie, salicylate) in blood, which has a pH of 7.4, little of the ionized blood-borne salicylate passively enters the tissues. However, because in overdose the serum salicylate rises considerably, enough enters the tissue to result in clinical toxicity. Salicylate is the conjugate base of a weak acid (and thus itself a strong base). It diffuses into the mitochondrial intermembrane space (between the inner and outer mitochondrial membrane), where abundant protons exist that have been transported there via the electron transport chain of this organelle (Fig. 11-3). Because salicylate is a strong base, it protonates easily in this environment. In this nonionized form, some of the salicylic acid passes through the inner mitochondrial membrane, into the mitochondrial matrix, and again establish equilibrium by losing a proton. This is the uncoupling of oxidative phosphorylation, dispersing highly concentrated protons in the intermembrane space that are normally used to generate adenosine triphosphate (Chap. 11). Uncoupling contributes to a metabolic acidosis, which shifts the blood equilibrium of aspirin toward the nonionized, protonated form (salicylic acid), enabling it to cross the blood-brain barrier. Presumably, once in the brain, the salicylate uncouples the metabolic activity of neurons with the subsequent development of cerebral edema. Part of the treatment of patients with salicylate toxicity is interrupting the above chain of events with serum alkalization (Chap. 37).

In a related manner, alkalization of the patient's urine prevents reabsorption by ionization of the urinary salicylate. Salicylate anion excreted into acidic urine protonates, and the uncharged moiety then back-diffuses across the renal tubular epithelium and re-enters the body. Alkalization of the urine "traps" salicylate in the deprotonated form, enhancing excretion. Conversely, because cyclic antidepressants are organic bases, alkalization of the urine reduces their ionization and actually decreases the urinary elimination of the drug. However, in the management of cyclic antidepressant poisoning, because the other beneficial effects of sodium bicarbonate on the sodium channel outweigh the negative effect on drug elimination, serum alkalization is recommended (Chap. 68).

## ORGANIC CHEMISTRY

The study of carbon-based chemistry and the interaction of inorganic molecules with carbon-containing compounds is called *organic chemistry*, because the chemistry of living organisms is carbon based. *Biochemistry* (Chap. 11) is a subdivision of organic chemistry; it is the study of organic chemistry within biologic systems. This section reviews many of the salient points of organic chemistry, focusing on those with the most applicability to medicine and the study of toxicology: nomenclature, bonding, nucleophiles and electrophiles, stereochemistry, and functional groups.

### Chemical Properties of Carbon

Carbon, atomic number 6, has a molecular weight of 12.011 g/mol. With few exceptions (notably cyanide ion and carbon monoxide), carbon forms 4 bonds in stable organic molecules. In organic compounds, carbon is commonly bonded to other carbon atoms, as well as to hydrogen, oxygen, nitrogen, or halides. Under certain circumstances, carbon is bonded to metals, as is the case with methylmercury.

### Nomenclature

The most systematic method to name organic compounds is in accordance with standards adopted by the International Union of Pure and Applied

**TABLE 10-2** pH of 0.10 M Solutions of Common Acids and Bases Represents the Strength of the Acid or Base

Acid/Base	pH
HCl (hydrochloric acid)	1.1
$\text{H}_2\text{SO}_4$ (sulfuric acid)	1.2
$\text{H}_2\text{SO}_3$ (sulfurous acid)	1.5
$\text{H}_3\text{PO}_4$ (phosphoric acid)	1.5
HF (hydrofluoric acid)	2.1
$\text{CH}_3\text{CO}_2\text{H}$ (acetic acid)	2.9
$\text{H}_2\text{CO}_3$ (carbonic acid)	3.8
$\text{H}_2\text{S}$ (hydrogen sulfide)	4.1
$\text{NH}_4\text{Cl}$ (ammonium chloride)	4.6
HCN (hydrocyanic acid)	5.1
$\text{NaHCO}_3$ (sodium bicarbonate)	8.3
$\text{NaCH}_3\text{CO}_2$ (sodium acetate)	8.9
$\text{Na}_2\text{HPO}_4$ (sodium hydrogen phosphate)	9.3
$\text{Na}_2\text{SO}_3$ (sodium sulfite)	9.8
NaCN (sodium cyanide)	11.0
$\text{NH}_4\text{OH}$ (ammonium hydroxide)	11.1
$\text{Na}_2\text{CO}_3$ (sodium carbonate)	11.6
$\text{Na}_3\text{PO}_4$ (sodium phosphate)	12.0
NaOH (sodium hydroxide)	13.0

Chemistry (IUPAC); these names are infrequently used, especially for larger molecules, and alternative names are common. The complete details of the IUPAC naming system are beyond the scope of this text and can be reviewed elsewhere ([www.iupac.org](http://www.iupac.org)), but a brief description of the fundamentals of this system is included here.

The carbon backbone of a molecule serves as the basis of its chemical name. Once the carbon backbone is identified and named, *substituents* (atoms or groups of atoms that substitute for hydrogen atoms) are identified, named, and numbered. The number refers to the carbon to which the substituent is attached. Some of the common substituents in organic chemistry are  $-\text{OH}$  (hydroxy),  $-\text{NH}_2$  (amino),  $-\text{Br}$  (bromo),  $-\text{Cl}$  (chloro), and  $-\text{F}$  (fluoro). Substituents are then alphabetized and placed as prefixes to the carbon chain.

As an example, consider the molecule 2-bromo-2-chloro-1,1,1-trifluoroethane. The molecule has a 2-carbon backbone (ethane), 3 fluoride atoms on the first carbon, a bromine atom on the second carbon, and a chlorine atom on the second carbon (Fig. 10-4A). A basic understanding of a few simple rules of nomenclature thus allows one to quickly generate the molecular structure of a familiar compound, halothane.

Although the above-mentioned rules suffice to name simple structures, they are inadequate to describe many others, such as molecules with complex branching or ring structures. The IUPAC rules for naming compounds such as [1*R*-(*exo,exo*)]-3-(benzoyloxy)-8-methyl-8-azabicyclo[3,2,1]octane-2-carboxylic acid methyl ester, for example, are too complex to include here. Fortunately, many compounds with complex chemical names have simpler names for day-to-day use; as an example, this molecule is commonly referred to as cocaine (Fig. 10-4B).

Cocaine is an example of a *common* or *trivial* name: one without a systematic basis, but which is generally accepted as an alternative to (frequently unwieldy) proper chemical names. Common names often refer to the origin of the substance; for example, cocaine is derived from the coca leaf, and wood alcohol (methanol) can be prepared from wood. Alternatively, a common name frequently refers to the way in which a compound is used; for example, rubbing alcohol is a common name for isopropanol. Common names are often imprecise and generate some confusion, however, as evidenced by the fact that rubbing alcohol, when commercially marketed, is either ethanol or isopropanol.

An even less precise system of nomenclature is the use of *street* names. A street name is a slang term for a drug of abuse, such as “blow” (cocaine), “weed” (marijuana), or “smack” (heroin). The street name *ecstasy* refers to the stimulant 3,4-methylenedioxyamphetamine (MDMA), which is most frequently consumed in pill form. It would stand to reason that *liquid ecstasy* might refer to a solution of MDMA, but street names are not necessarily logical. Instead, liquid ecstasy refers to the drug  $\gamma$ -hydroxybutyrate, a sedative-hypnotic with a completely different pharmacologic and toxicologic profile. Furthermore, there are no standards for the content of ecstasy, and many street pills contain other chemicals.

A final consideration must be given to *product names*. Product names are trade names under which a given compound might be marketed and are frequently different from both the chemical name and common name. Thus, the inhalational anesthetic in Fig. 10-4A with the chemical name

2-bromo-2-chloro-1,1,1-trifluoroethane has the common name halothane and the trade name Fluothane.

## Bonding in Organic Chemistry

While much of the bonding in inorganic chemistry is ionic, the vast majority of bonding in organic molecules is *covalent*. Whereas electrons in ionic bonds are described as predominately “belonging” to one atom or another, electrons in covalent bonds are shared between 2 atoms; this type of bonding occurs when the difference in electronegativity between 2 atoms is insufficient for one atom to wrest control of an electron from another. Bonds are represented by lines between the atoms: one for a single bond, 2 for a double bond, and 3 for a triple bond.

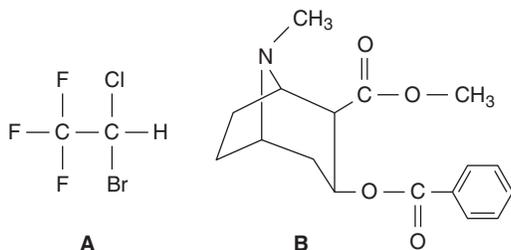

## Nucleophiles and Electrophiles

Many organic reactions of toxicologic importance are described as the reactions of *nucleophiles* with *electrophiles*. *Nucleophiles* (literally, nucleus-loving) are species with increased electron density, frequently in the form of a lone pair of electrons (as in the cases of cyanide ion and carbon monoxide). *Nucleophiles*, by virtue of their increased electron density, have an affinity for atoms or molecules that are electron deficient; such moieties are called *electrophiles* (literally, electron-loving). The electron deficiency of electrophiles is described as absolute or relative. Absolute electron deficiency occurs when an electrophile is charged, as is the case with cations such as  $\text{Pb}^{2+}$  and  $\text{Hg}^{2+}$ . Relative electron deficiency occurs when one atom or group of atoms shifts electrons away from a second atom, making the second atom relatively electron deficient. This is the case for the neurotoxin 2,5-hexanedione (Fig. 10-5); the electronegative oxygen of the carbon-oxygen double bond pulls electron density away from the second and fifth carbon atoms of this molecule, making these carbon atoms electrophilic.

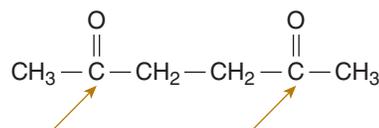

The reaction of a nucleophile with an electrophile involves the movement of electrons, by forming or breaking bonds. This movement of electrons is frequently denoted by the use of curved arrows, which better demonstrates how the nucleophile and electrophile interact. The interaction of acetylcholinesterase with acetylcholine, organic phosphorus compounds, and pralidoxime hydrochloride provides an example of how the use of curved arrow notation leads to a better understanding of the reactions involved.

Under normal circumstances, the action of acetylcholine is terminated when the serine residue in the active site of acetylcholinesterase attacks this neurotransmitter, forming a transient serine-acetyl complex and liberating choline. This serine-acetyl complex is then rapidly hydrolyzed, producing an acetic acid molecule and regenerating the serine residue for another round of the reaction (Fig. 10-6A). In the presence of an organic phosphorus compound, however, this serine residue attacks the electrophilic phosphate atom, forming a stable serine-phosphate bond, which is not hydrolyzed (Fig. 10-6B). The enzyme, thus inactivated, can no longer break down acetylcholine, leading to an increase of this neurotransmitter in the synapse and possibly a cholinergic crisis.

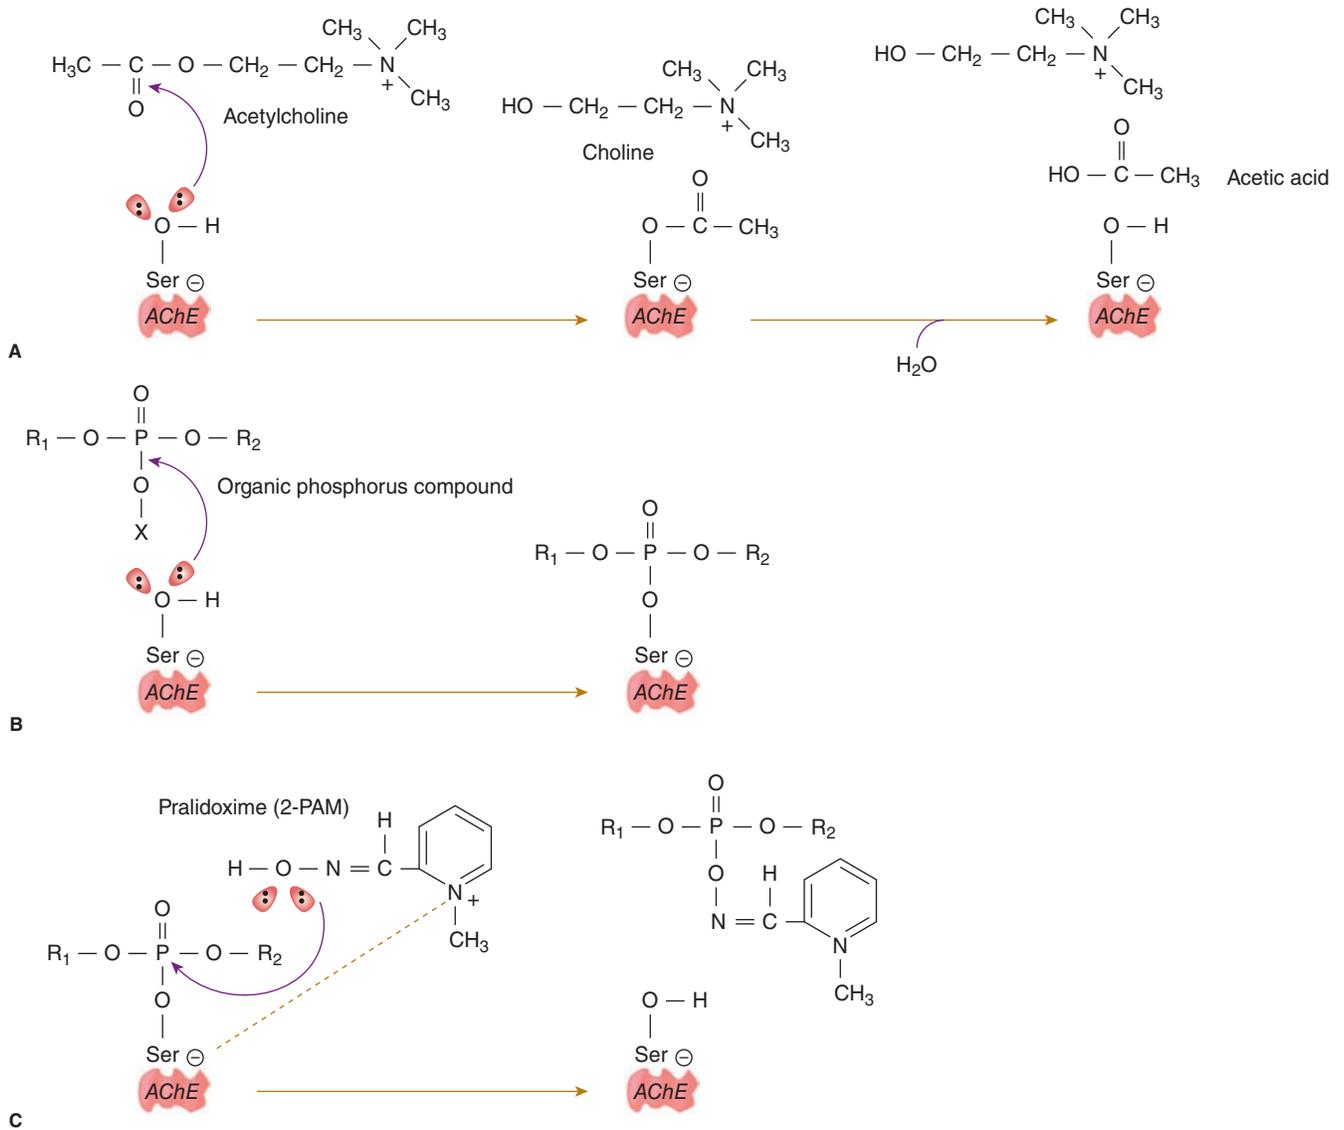

The enzyme can be reactivated, however, by the use of another nucleophile. Pralidoxime hydrochloride (2-PAM) is referred to as a *site-directed nucleophile*. Because part of its chemical structure (the charged nitrogen atom) is similar to the choline portion of acetylcholine, this antidote is directed to the active site of acetylcholinesterase. Once in position, the nucleophilic oxime moiety ( $-\text{NOH}$ ) that is remote from the positive charge of pralidoxime attacks the electrophilic phosphate moiety. This displaces the serine residue, regenerating the enzyme (Fig. 10-6C) (Chap. 110 and Antidotes in Depth: A36).

**FIGURE 10-4.** Nomenclature. (A) 2-Bromo-2-chloro-1,1,1-trifluoroethane, or halothane. (B) [1*R*-(*exo,exo*)]-3-(benzoyloxy)-8-methyl-8-azabicyclo[3,2,1]-octane-2-carboxylic acid methyl ester, or cocaine.

Curved arrows represent the movement of electrons as bonds are formed or broken. **(A)** Normal hydrolysis of acetylcholine by AChE. **(B)** Inactivation (phosphorylation) of AChE by organic phosphorus compound. **(C)** Reactivation by 2-PAM of functional AChE.

A second toxicologically important electrophile is NAPQI (Fig. 10-7). NAPQI is formed when the endogenous detoxification pathways of APAP metabolism (glucuronidation and sulfation) are overwhelmed (Chap. 33). As a result of the electron configuration of NAPQI, the carbon atoms adjacent to the *carbonyl carbon* (a carbon that is double bonded to an oxygen) are very electrophilic; the sulfur groups of cysteine residues of

hepatocyte proteins react with NAPQI to form a characteristic *adduct* (formed when one compound is added to another), 3-(cystein-S-yl)APAP, in a multistep process. These adducts are released as hepatocytes die, and can be found in the blood of patients with APAP-related liver toxicity. Figure 10-7 diagrams the mechanism of the protein-NAPQI reaction (Chap. 33).

**FIGURE 10-7.** The reaction of cysteine residues on hepatocyte proteins with *N*-acetyl-*p*-benzoquinoneimine (NAPQI) to form the characteristic adducts 3-(cystein-S-yl) APAP.

Nucleophiles are often described by their strength, which by convention is related to the rate at which they react with a reference electrophile ( $\text{CH}_3\text{I}$ ). Of more common use in pharmacology and toxicology, however, are the descriptive terms “hard” and “soft.” Although imprecise, the designations hard and soft help to predict, qualitatively, how nucleophiles and electrophiles interact with one another.

Hard species have a charge (or partial charge) that is highly localized; that is, their charge-to-radius ratio is high. Hard nucleophiles are molecules in which the electron density or lone pair is tightly held; fluoride, a small atom that cannot spread its electron density over a large area, is an example. Similarly, hard electrophiles are species in which the positive charge cannot be spread over a large area; ionized calcium, a small ion, is a hard electrophile.

Soft species, on the other hand, are capable of delocalizing their charge over a larger area. In this case the charge-to-mass ratio is low, either because the atom is large or because the charge can be spread over a number of atoms within a given molecule. Sulfur is the prototypical example of a soft nucleophile, and the lead ion,  $\text{Pb}^{2+}$ , is a typical soft electrophile.

The utility of this classification lies in the observation that hard nucleophiles tend to react with hard electrophiles, and soft nucleophiles with soft electrophiles. For example, a principal toxicity of fluoride ion poisoning (Chap. 104) is hypocalcemia; this is because the fluoride ions (hard nucleophiles) readily react with calcium ions (hard electrophiles). On the other hand, the soft nucleophile lead is effectively chelated by soft electrophiles such as the sulfur atoms in the chelators dimercaprol (Antidotes in Depth: A28) and succimer (Antidotes in Depth: A29).<sup>1</sup>

## Isomerism

*Isomerism* describes the different ways in which molecules with the same chemical formula (ie, the same number and types of atoms) can be arranged to form different compounds. These different compounds are called *isomers*. Isomers always have the same chemical formula but differ either in the way that atoms are bonded to each other (*constitutional isomers*) or in the spatial arrangement of these atoms (*geometric isomers* or *stereoisomers*).

Constitutional isomers are conceptually the easiest to understand, because a quick glance shows them to be very different molecules. The chemical formula  $\text{C}_2\text{H}_6\text{O}$ , for example, can refer to either dimethyl ether or ethanol (Fig. 10-8). These molecules have very different physical and chemical characteristics, and they have little in common other than the number and type of their atomic constituents.

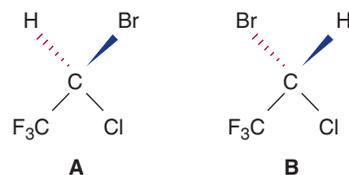

*Stereoisomerism*, also referred to as *geometric isomerism*, refers to the different ways in which atoms of a given molecule, with the same number and types of bonds, might be arranged. The most important type of stereoisomerism in pharmacology and toxicology is the stereochemistry around a *stereogenic* (sometimes called *chiral*) carbon.

Consider the 2 representations of halothane shown in Fig. 10-9. In this figure, the straight solid lines and the atoms to which they are bonded exist in the plane of the paper, the solid triangle and the atom to which they are bonded are coming out of the paper, and the dashed triangle and the atom to which they are bonded are receding into the paper. It is clear that, for the molecules in Figs. 10-9A and 10-9B, no amount of rotation or manipulation will make these molecules superimposable. They are, therefore, different compounds.

These molecules are *enantiomers* or *optical isomers*. They differ only in the way in which their atoms are bonded to a chiral carbon.<sup>6</sup> It is important to define the stereochemical configuration of these 2 molecules, which is done in one of 2 ways. In the first classification—the *d*(+)/*l*(-) system—molecules are named empirically based on the direction in which they rotate plane-polarized light. Each enantiomer will rotate plane-polarized light in one direction; the enantiomer that rotates light clockwise (to the right) is referred to as

**FIGURE 10-8.** Two molecules with chemical formula  $\text{C}_2\text{H}_6\text{O}$ . (A) Dimethylether. (B) Ethanol (ethyl alcohol).

**FIGURE 10-9.** The graphic representation of the enantiomers of halothane.

*d*(+), or *dextrorotatory*; the *l*(-), or *levorotatory*, enantiomer rotates plane-polarized light in a counterclockwise fashion (to the left).

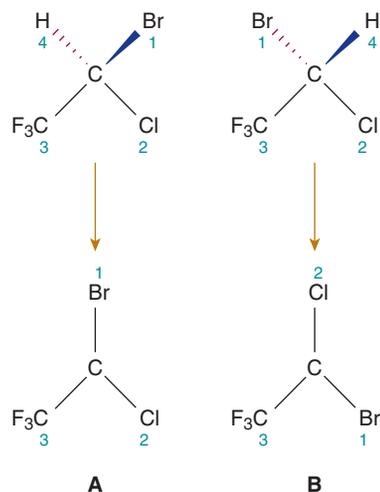

Alternatively, enantiomers are named using an elaborate and formal set of rules known as *Cahn-Ingold-Prelog*. These rules establish priority for substituents, based primarily on molecular weight, and then use the arrangement of substituents to assign a configuration. To correctly assign configuration in this system, the molecule is rotated into a projection in which the chiral carbon is in the plane of the page, the lowest priority substituent is directly behind the chiral carbon (and therefore behind the plane of the page), and the other 3 substituents are arranged around the chiral carbon. Figure 10-10 assigns Cahn-Ingold-Prelog priority to the halothane enantiomers of Fig. 10-9, and rearranges the molecules in the appropriate projections.

If the priority of the substituents increases as one moves clockwise (to the right), the enantiomer is *R* (Latin, *rectus* = right); if it increases as one moves counterclockwise, the enantiomer is *S* (Latin, *sinister* = left). Thus, the one in Fig. 10-10A is the *R* enantiomer of halothane and Fig. 10-10B represents the *S* enantiomer.

Enantiomers have identical physical properties, such as boiling point, melting point, and solubility in different solvents; they differ from each other in only 2 significant ways. The first, as mentioned before, is that enantiomers rotate plane-polarized light in opposite directions; this point has no practical toxicologic importance. The second is that enantiomers interact in different ways with other chiral structures (such as proteins, DNA, and other cell receptors), which is of both pharmacologic and toxicologic significance.<sup>6</sup>

The best analogy to explain the toxicologic and pharmacologic importance of stereochemistry is that of the way a hand (analogous to a molecule of xenobiotic) fits into a glove (analogous to the biologic site of activity). Consider the left hand as the *S* enantiomer and the right hand as the *R* enantiomer. There are, qualitatively, 3 different ways in which the hand can fit into (interact with) a glove.

First, if the glove is pliable and relatively fluid (such as a disposable latex glove), it can accept either the left hand or the right hand without difficulty;

**FIGURE 10-10.** *R* and *S* enantiomers of halothane. (A) The substituents increase in a clockwise fashion, so the configuration is *R*. (B) The substituents increase in a counterclockwise fashion, so the configuration is *S*. In this projection, hydrogen atoms are directly behind the carbon atoms.

this is the case for halothane, whose *R* and *S* enantiomers interact with cell membranes rather than specific receptors and possess equal activity. Second, if a glove is constructed with greater (but imperfect) specificity, one hand will fit well and the other poorly; this is the case for many substances, such as epinephrine and norepinephrine, whose naturally occurring levorotatory enantiomers are 10-fold more potent than the synthetic dextrorotatory enantiomers. Finally, a glove can be made with exquisite precision, such that one hand fits perfectly, while the other hand does not fit at all. This is the case for physostigmine, in which the (–) enantiomer is biologically active whereas the (+) enantiomer is not.

Even the above analogy is oversimplified, however, as there are examples where one enantiomer of a drug is an agonist whereas the other enantiomer is an antagonist. Dobutamine, has one stereogenic carbon and thus 2 stereoisomers; at the  $\alpha_1$ -adrenergic receptor, *l*-dobutamine is a potent agonist and *d*-dobutamine is a potent antagonist. Because dobutamine is marketed as a *racemic mixture* (a racemic mixture is a 1:1 mixture of enantiomers), however, these effects cancel each other out. Interestingly, at the  $\beta_1$ -adrenergic receptor, *d*- and *l*-dobutamine have unequal agonist effects, with *d*-dobutamine approximately 10 times more potent than *l*-dobutamine.

### Functional Groups

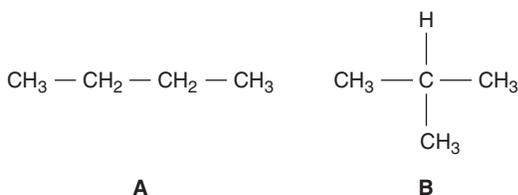

There is perhaps no concept in organic chemistry as powerful as that of the *functional group*. Functional groups are atoms or groups of atoms that confer similar reactivity on a molecule; of less importance is the molecule to which it is attached. *Alcohols*, *carboxylic acids*, and *thiols* are functional groups; *hydrocarbons* are generally not considered functional groups per se, but rather are the structural backbone to which functional groups are attached. The functional groups discussed below are included to illustrate important principles, not because they represent an exhaustive list of important functional groups in toxicology.

*Hydrocarbons*, as their name implies, consist of only carbon and hydrogen. *Alkanes* are hydrocarbons that contain no multiple bonds; they are straight chain, usually designated by the prefix *n*- as in *n*-butane (Fig. 10–11A) or iso- if branched, as in isobutane (Fig. 10–11B). *Alkenes* contain carbon-carbon double bonds. *Alkynes*, which contain carbon-carbon triple bonds, are of limited toxicologic importance. Butane (found in lighter fluid) is an alkane, and gasoline is a mixture of alkanes.

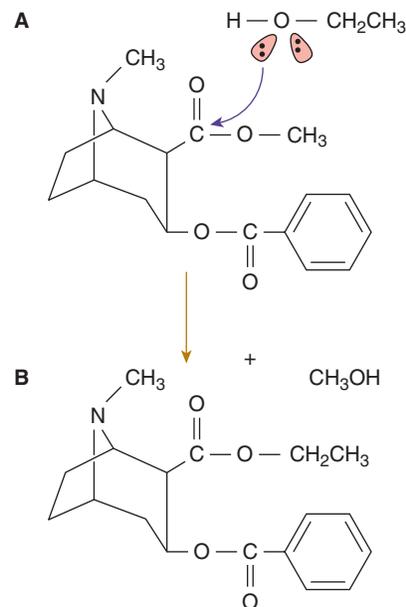

Hydrocarbons are of toxicologic importance for 2 reasons. They are widely abused as inhalational drugs for their central nervous system (CNS) depressant effects, and cause profound toxicity when aspirated. Although these effects are physiologically disparate, they are readily understood in the context of the chemical characteristics of the hydrocarbon functional group.

Hydrocarbons do not contain *polar groups* (ie, groups that introduce full or partial charges into the molecule). As such, they interact readily with other nonpolar substances, such as lipids or lipophilic substances. Hydrocarbons readily interact with the myelin of the CNS, disrupting normal ion channel function and causing CNS depression. When aspirated, hydrocarbons interact with the fatty acid tail of surfactant, dissolving this protective substance and contributing to acute respiratory distress syndrome (Chap. 105).

*Alcohols* possess the hydroxyl (–OH) functional group, which adds polarity to the molecule and makes alcohols highly soluble in other polar substances, such as water. For example, ethane gas (CH<sub>3</sub>CH<sub>3</sub>) has negligible solubility in water, whereas ethanol (CH<sub>3</sub>CH<sub>2</sub>OH) is *miscible*, or infinitely soluble, in water. In biologic systems, alcohols are generally CNS depressants,

**FIGURE 10–11.** Two isomers of the 4-carbon alkane, butane. (A) *n*-Butane. (B) Isobutane.

**FIGURE 10–12.** Transesterification reaction of cocaine with ethanol (A) to form cocaethylene and methanol (B).

but they can also act as nucleophiles. Ethanol reacts with cocaine to form cocaethylene, a longer-acting and more vasoactive substance than cocaine itself (Fig. 10–12) (Chap. 75).

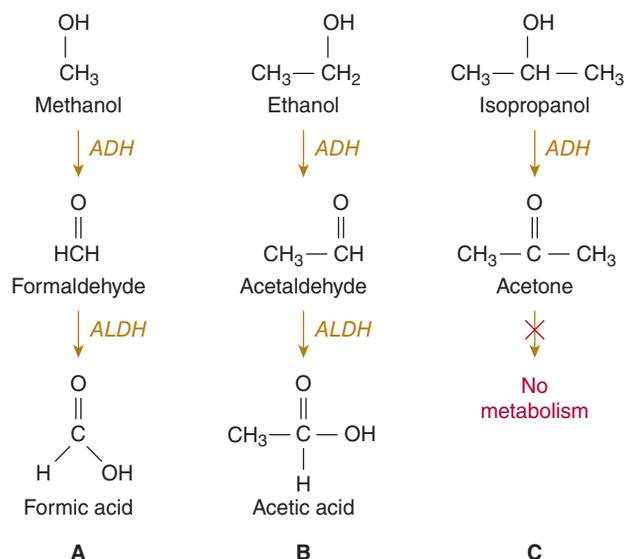

Alcohols are categorized as primary, secondary, or tertiary, in which the reference carbon is bonded to 1, 2, or 3 carbons (respectively) in addition to the hydroxyl group. Methanol, in which the reference carbon is bonded to no other carbons, is not a primary alcohol per se but shares many of the reactivity patterns of primary alcohols. The difference between primary, secondary, and tertiary structures is important, because although the alcohol functional group imparts many qualities to the molecule, the degree of substitution can affect the chemical reactivity. Primary alcohols can undergo multistep oxidation to form carboxylic acids, whereas secondary alcohols generally undergo one-step metabolism to form ketones, and tertiary alcohols do not readily undergo oxidation. This is a point of significant toxicologic importance, and is discussed in more detail below.

Alcohols are named in several ways; the most common is to add *-ol* or *-yl alcohol* to the appropriate prefix. If the alcohol group is bonded to an interior carbon, the number to which the carbon is bonded precedes the suffix.

*Carboxylic acids* contain the functional group –COOH. As their name implies, they are (weakly) acidic, and the  $pK_a$  of carboxylic acids is generally 4 or 5, depending on the substitution of the molecule. Small-molecular-weight carboxylic acids are capable of producing an elevated anion gap metabolic acidosis, which is true whether the acids are endogenous or exogenous. Examples of endogenous acids are  $\beta$ -hydroxybutyric acid and lactic acid; examples of exogenous acids are formic acid (produced by the metabolism of methanol) and glycolic, glyoxylic, and oxalic acids (produced by the metabolism of ethylene glycol). Carboxylic acids are named by adding *-oic acid* to the appropriate prefix; the 4-carbon straight-chain carboxylic acid is thus butanoic acid.

*Thiols* contain a sulfur atom, which usually functions as a nucleophile. The sulfur atom of *N*-acetylcysteine regenerates glutathione reductase and also reacts directly with NAPQI to detoxify this electrophile. The sulfur atoms of many chelators, such as dimercaprol and succimer, are nucleophiles that are very effective at chelating electrophiles such as heavy metals. Thiols are generally named by adding the word *thiol* to the appropriate base. Thus, a 2-carbon thiol is ethane thiol.

As noted above, molecules with a given functional group often have more in common with molecules with the same functional group than they have in common with the molecules from which they were derived. The alkanes

**FIGURE 10–13.** Oxidative metabolism of (A) methanol, (B) ethanol, and (C) isopropanol. Note that acetone does not undergo further oxidation in vivo. ADH = alcohol dehydrogenase; ALDH = aldehyde dehydrogenase.

methane, ethane, and propane are straight-chain hydrocarbons with similar properties. All are gases at room temperature, have almost no solubility in water, and have similar melting and boiling points. When these molecules are substituted with one or more hydroxide functional groups, they become alcohols: examples are methanol, ethanol, ethylene glycol (a *glycol* is a molecule that contains 2 alcohol functional groups), the primary alcohol 1-propanol, and the secondary alcohol 2-propanol (isopropanol). Each of these alcohols is a liquid at room temperature, and all are very soluble in water. All have boiling points that are markedly different from the alkane from which they were derived, and are very close to each other.

In addition to conferring different physical properties on the molecule, the addition of the alcohol functional group also confers different chemical properties and reactivities. For example, methane, ethane, and propane are virtually incapable of undergoing oxidation in biologic systems. The alcohols formed by the addition of one or more hydroxyl groups, however, are readily oxidized by alcohol dehydrogenase (Fig. 10–13).

As Fig. 10–13 indicates, the oxidation of the primary alcohols methanol and ethanol results in the formation of *aldehydes* (functional groups in which a carbon atom contains a double bond to oxygen and a single bond to hydrogen), whereas the oxidation of the secondary alcohol isopropanol results in the formation of a *ketone* (a functional group in which a carbon is double-bonded to an oxygen atom and single-bonded to 2 separate carbon atoms). Although both aldehydes and ketones contain the *carbonyl group* (a carbon-oxygen double bond), aldehydes and ketones are distinctly different functional groups, and they have different reactivity patterns. For

instance, aldehydes can undergo enzymatic oxidation to carboxylic acids (Figs. 10–13A and 13B), whereas ketones cannot (Fig. 10–13C).

It is here that recognition of functional groups helps to understand the potential toxicity of an alcohol. Methanol, ethanol, and isopropanol are all alcohols; as such, their toxicity before metabolism is expected to be (and in fact is) quite similar to that of ethanol, producing CNS sedation. Because these toxins are primary and secondary alcohols, all can be metabolized to a carbonyl compound, either an aldehyde or a ketone. Here, however, the functional groups on the molecules have changed; whereas aldehydes can undergo metabolism to carboxylic acids (which can, in turn, cause an anion gap acidosis), ketones cannot. It is for this reason that methanol and ethylene glycol cause an anion gap acidosis whereas isopropanol does not (Chap. 106).

The concept of functional groups, however useful, has limitations. For example, although both formic acid and oxalic acid are organic acids, they cause different patterns of organ system toxicity. Formic acid is a mitochondrial toxin and exerts effects primarily in areas (such as the retina or basal ganglia) that poorly tolerate an interruption in the energy supplied by oxidative phosphorylation. Conversely, oxalic acid readily precipitates calcium and is toxic to renal tubular cells, which accounts for the nephrotoxicity that is characteristic of severe ethylene glycol poisoning. The concept of the functional group is thus an aid to understanding chemical reactivity, but not a substitute for a working knowledge of the toxicokinetic or toxicodynamic effects of xenobiotics in living systems.

## SUMMARY

- Understanding key principles of inorganic and organic chemistry provide insight into the mechanisms by which xenobiotics function.
- The periodic table forms the basis for understanding inorganic chemistry and provides insight into the expected reactivity, and to a large extent the clinical effects, of an element.
- A growing understanding of how reactive species are formed and how they interfere with physiologic processes has led to new insights in the pathogenesis and treatment of toxin-mediated diseases.
- Changes in functional groups on organic molecules dramatically changes their chemical and toxicologic effects, and knowing the relevant general principles is essential to an understanding of biochemistry and pharmacology.

# BIOCHEMICAL AND METABOLIC PRINCIPLES

James D. Cao and Kurt C. Kleinschmidt

Xenobiotics are compounds that are foreign to a living system. Toxic xenobiotics interfere with critical metabolic processes, cause structural damage to cells, or alter cellular genetic material. The specific biochemical sites of actions that disrupt metabolic processes are well characterized for many xenobiotics although mechanisms of cellular injury are not. This chapter reviews the biochemical principles that are relevant to an understanding of the biotransformation enzymes and their clinical implications and the damaging effects of toxic xenobiotics.

## XENOBIOTIC CHARACTERISTICS AND TOXICITY

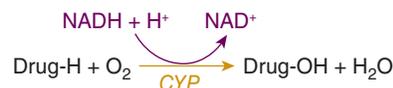

The capacity of a xenobiotic to produce injury is affected by many factors, including its absorption, distribution, elimination, genotypic/phenotypic states, synergistic/antagonistic coingestants, site of activation or detoxification, and site of action. This section focuses on how the route of exposure (absorption) and the ability to cross membranes in order to access particular organs (distribution) affect toxicity.

The route of exposure to a xenobiotic often confines damage primarily to one organ, for example, pulmonary injury that follows inhalation of an irritant gas or gastrointestinal (GI) injury that follows ingestion of a caustic. However, most xenobiotics have lipophilic properties that facilitate absorption across cell membranes of organs that are portals of entry into the body: the skin, GI tract, and lungs. Systemically circulating xenobiotics, such as cyanide or carbon monoxide, affect toxicity in multiple organs. The liver is particularly susceptible to xenobiotic-induced injury as it receives blood supply from both the portal venous system and from the hepatic artery containing xenobiotics absorbed from multiple sites of exposure.

Once systemically absorbed, various factors affect the distribution of a xenobiotic to a particular organ, including its molecular weight, protein binding, plasma pH/drug pKa, lipophilicity, in addition to the presence of membrane transporters, and physiologic barriers (Chap. 9). Restriction of distribution or preferential distribution into a target organ determines the ability of a xenobiotic to mediate tissue injury. For example, many potentially toxic xenobiotics fail to produce central nervous system (CNS) injury because they cannot cross the blood–brain barrier. The negligible CNS effects of the mercuric salts when compared with organic mercury compounds are related to their relative inability to penetrate the CNS. With respect to target organs, 2 potent biologic xenobiotics—ricin (from *Ricinus communis*) and  $\alpha$ -amanitin (from *Amanita phalloides*)—block protein synthesis through the inhibition of RNA polymerase. However, they result in different clinical effects because they access different tissues. Ricin has a special binding protein that enables it to gain access to the endoplasmic reticulum in GI mucosal cells, where it inhibits cellular protein synthesis and causes severe diarrhea.  $\alpha$ -Amanitin is transported into hepatocytes by bile salt transport systems, where inhibition of protein synthesis results in cell death. Finally, the electrical charge of a xenobiotic at tissue pH affects its ability to enter a cell. Unlike the ionized (charged) form of a xenobiotic, the un-ionized (uncharged) form is often lipophilic and passes through lipid cell membranes to enter the cells. The pK<sub>a</sub> of an acidic xenobiotic ( $\text{HA} \rightleftharpoons \text{A}^- + \text{H}^+$ ) is the pH at which 50% of the molecules are ionized (A<sup>-</sup> form) and 50% is un-ionized (HA form). A xenobiotic with a low pK<sub>a</sub> is more likely to be absorbed in an acidic environment in which the un-ionized form predominates. This concept is the basis for urine alkalization and ion trapping in the management of salicylate toxicity (Chap. 37).

## GENERAL ENZYME CONCEPTS

The capability to detoxify and eliminate both endogenous toxins and xenobiotics is crucial to the maintenance of physiologic homeostasis. A simple example is the detoxification of cyanide, a potent cellular poison that is

**FIGURE 11-1.** A common oxidation reaction catalyzed by CYP enzymes: the hydroxylation of Drug-H to Drug-OH.

common in the environment and is also a product of normal metabolism. Mammals have evolved to have the enzyme rhodanese, which combines cyanide with thiosulfate to create the less toxic, renally excreted compound thiocyanate.<sup>7</sup>

The liver has the highest concentration of enzymes that metabolize xenobiotics. Enzymes found in the cytosol of hepatocytes that are specific for alcohols, aldehydes, esters, or amines act on many different substrates within these broad chemical classes. Enzymes that act on more lipophilic xenobiotics, including the cytochrome enzymes, are embedded in the lipid membranes of the cytosol-based endoplasmic reticulum. Cytochromes are a class of hemoprotein enzymes whose function is electron transfer, using a cyclical transfer of electrons between oxidized (Fe<sup>3+</sup>) or reduced (Fe<sup>2+</sup>) forms of iron. One type of cytochrome is cytochrome P450 (CYP) whose nomenclature derives from the spectrophotometric characteristics of its associated heme molecule. When bound to carbon monoxide, the maximal absorption spectrum of the reduced CYP (Fe<sup>2+</sup>) enzyme occurs at 450 nm.<sup>79</sup> These CYP enzymes commonly split the 2 oxygen atoms of an oxygen molecule, incorporating one into the substrate and one into water and thus are called mixed-function oxidases or monooxygenases (Fig. 11-1). This differs from dioxygenases that incorporate both oxygen atoms into the substrate.<sup>79,108</sup>

Microsomes are the pieces of the endoplasmic reticulum that result when cells are disrupted. When cells are mechanically disrupted and centrifuged, these membrane-bound enzymes are found in the pellet, or microsomal fraction; hence, they are called *microsomal enzymes*. Enzymes located in the liquid matrix of cells are called *cytosolic enzymes* and are found in the supernatant when disrupted cells are centrifuged.<sup>22</sup>

## BIOTRANSFORMATION OVERVIEW

The study of xenobiotic metabolism was established as a scientific discipline by the seminal publication of Williams in 1949.<sup>120</sup> Biotransformation is the physiochemical alteration of a xenobiotic, usually as a result of enzyme action. Most definitions also include that this action converts lipophilic substances into more polar, excretable substances.<sup>70,108</sup> Most xenobiotics undergo some biotransformation, the degree of which is affected by their chemical nature. The hydrophilic nature of ionized compounds such as carboxylic acids enables the kidneys to rapidly eliminate them. Very volatile compounds, such as enflurane, are expelled promptly via the lungs. Neither of these groups of xenobiotics undergo significant enzymatic metabolism.

Biotransformation usually results in “detoxification,” a reduction in the toxicity, by the conversion to hydrophilic metabolites of the xenobiotic that can be renally eliminated.<sup>70</sup> However, this is not always the case. Many parent xenobiotics are inactive and must undergo “metabolic activation.”<sup>72</sup> When metabolites are more toxic than the parent xenobiotic, biotransformation is said to have resulted in “toxicification.”<sup>108</sup> Biotransformation via acetylation or methylation enhances the lipophilicity of a xenobiotic. Biotransformation is accomplished by impressively few enzymes, reflecting broad substrate specificity. The predominant pathway

for the biotransformation of an individual xenobiotic is determined by many factors, including the availability of cofactors, changes in the concentration of the enzyme caused by induction, and the presence of inhibitors. The predominant pathway is also affected by the rate of substrate metabolism, reflected by the  $K_m$  (Michaelis–Menten dissociation constant) of the biotransformation enzyme (Chap. 9).<sup>108</sup>

Biotransformation is often divided into phase I and phase II reactions, terminology first introduced in 1959.<sup>120</sup> Phase I reactions prepare lipophilic xenobiotics for the addition of functional groups or actually add the groups, converting them into more chemically reactive metabolites. This is usually followed by phase II synthetic reactions that conjugate the reactive products of phase I with other molecules that render them more water soluble, further detoxifying the xenobiotics and facilitating renal elimination. However, biotransformation often does not follow this stepwise process.<sup>52</sup> Some xenobiotics undergo only a phase I or a phase II reaction prior to elimination. Additionally, phase II reactions can precede phase I. While virtually all phase II synthesis reactions cause inactivation, a classic exception is fluoroacetate being metabolized to fluorocitrate, a potent inhibitor of the citric acid (tricarboxylic acid, or Krebs) cycle (Chap. 113).<sup>90</sup>

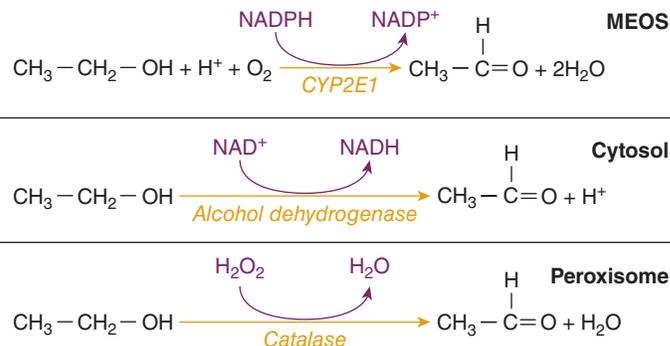

Biotransformed xenobiotics cannot be eliminated until they are moved back across cell membranes and out of the cells. Membrane transporters are proteins that move xenobiotics/xenobiotics across the membranes without altering their chemical compositions. Most membrane transporters are in the adenosine triphosphate binding cassette (ABC) family of transmembrane proteins that use energy from adenosine triphosphate (ATP) hydrolysis to move xenobiotics.<sup>14,45,52</sup> This family includes the P-glycoprotein family and the glutathione S-conjugate export pump.<sup>103</sup> The process of transport is sometimes termed a “phase III reaction.” However, membrane transport does not always occur after phase I or II reactions, and some parent compounds, such as digoxin, are transported across membranes without any biotransformation at all.<sup>25</sup>

### Phase I Biotransformation Reactions

Oxidation is the predominant phase I reaction, adding reactive functional groups suitable for synthetic conjugation during phase II. These groups include hydroxyl (–OH), sulfhydryl (–SH), amino (–NH<sub>2</sub>), aldehyde (–CHO), or carboxyl (–COOH) moieties. Noncarbon elements such as nitrogen, sulfur, and phosphorus are also oxidized in phase I reactions. Other phase I reactions include hydrolysis (the splitting of a large molecule by the addition of water that is divided among the 2 products), hydration (incorporation of water into a complex molecule), hydroxylation (the attachment of –OH groups to carbon atoms), reduction, dehalogenation, dehydrogenation, and dealkylation.<sup>70,108</sup>

The CYP enzymes are the most numerous and important of the phase I enzymes. A common oxidation reaction catalyzed by CYP enzymes is illustrated by the hydroxylation of a xenobiotic R–H to R–OH (Fig. 11–1).<sup>30</sup> Membrane-bound flavin monooxygenase (FMO), a nicotinamide adenine dinucleotide phosphate (NADPH)-dependent oxidase located in the endoplasmic reticulum, is an important oxidizer of amines and other compounds containing nitrogen, sulfur, or phosphorus.<sup>70</sup>

The alcohol, aldehyde, and ketone oxidation systems use predominantly cytosolic enzymes that catalyze these reactions using nicotinamide adenine dinucleotide (NADH/NAD<sup>+</sup>), but alcohol oxidation can also occur in microsomes via CYP enzymes and in peroxisomes via the enzyme catalase (Fig. 11–2).<sup>65,108,123</sup> Two classic phase I oxidation reactions are the metabolism of ethanol to acetaldehyde by alcohol dehydrogenase (ADH) followed by the metabolism of acetaldehyde to acetic acid by aldehyde dehydrogenase (ALDH). Alcohol dehydrogenase, which oxidizes many different alcohols, is found in the liver, lungs, kidneys, and gastric mucosa.<sup>65</sup> Variations in these enzymes have clinical implications. For example, young women have less ADH in their gastric mucosa than young men. This results in decreased first-pass metabolism of ethanol and increased ethanol absorption. Some populations, particularly Asians, are deficient in ALDH, resulting in increased acetaldehyde concentrations and symptoms (Chap. 78).<sup>65</sup>

**FIGURE 11–2.** The conversion of ethanol to acetaldehyde by three pathways. In the microsomal ethanol oxidizing system (MEOS), CYP2E1 uses nicotinamide adenine dinucleotide phosphate (NADPH) and oxygen for the conversion. In the cytosol, alcohol dehydrogenase uses NAD<sup>+</sup>. In peroxisomes, catalase uses H<sub>2</sub>O<sub>2</sub>. This illustrates how NAD<sup>+</sup> and NADPH can function in oxidation reactions in both their oxidized and reduced forms. Alcohol dehydrogenase has a low  $K_m$  for ethanol and is the predominant metabolic enzyme in moderate drinkers. (Adapted with permission from Zakhari S: *Overview: how is alcohol metabolized by the body?* *Alcohol Res Health* 2006;29(4):245–254.)

### Oxidation Overview

Biotransformation often results in the oxidation or reduction of carbon. A substrate is oxidized when it transfers electrons to an electron-seeking (electrophilic or oxidizing) molecule, leading to reduction of the electrophilic molecule. These oxidation-reduction reactions are usually coupled to the cyclical oxidation and reduction of a cofactor, such as the pyridine nucleotides, NADH/NAD<sup>+</sup>, or NADPH/NADP<sup>+</sup>. The nucleotides alternate between their reduced (NADPH, NADH) and oxidized (NADP<sup>+</sup>, NAD<sup>+</sup>) forms. Because xenobiotic oxidation is the most common phase I reaction, the newly created reduced cofactors must have a place to unload their electrons; otherwise, biotransformation ends. The electron transport chain serves as the major electron recipient.

Electrons resulting from the catabolism of energy sources are extracted primarily by NAD<sup>+</sup>, forming NADH. Within the mitochondria, NADH transports its electrons to the cytochrome-mediated electron transport chain. This results in the production of ATP, the reduction of molecular oxygen to water, and the regeneration of NAD<sup>+</sup>—all parts critical to the maintenance of oxidative metabolism. Nicotinamide adenine dinucleotide phosphate, generated by the hexose monophosphate shunt, is used in the synthetic (anabolic) reactions of biosynthesis (especially fatty acid synthesis). Nicotinamide adenine dinucleotide phosphate is also the cofactor in the reduction of glutathione, a molecule vital to the protection of cells from oxidative damage.

Biotransformation often results in the oxidation or reduction of carbon. The oxidation state of a specific carbon atom is determined by counting the number of hydrogen and carbon atoms to which it is connected. The more reduced a carbon, the higher the number of connections. For example, the carbon in methanol (CH<sub>3</sub>OH) has 3 carbon–hydrogen bonds and is more reduced than the carbon in formaldehyde (H<sub>2</sub>C=O), which has two. Carbon–carbon double bonds count as only one connection.

### Cytochrome Enzymes—An Overview

Cytochrome enzymes perform many functions. The biotransformation CYP enzymes are bound to the lipid membranes of the smooth endoplasmic reticulum. They execute 75% of all xenobiotic metabolism and most phase I oxidative biotransformations of xenobiotics.<sup>39</sup> A second role for CYP enzymes is synthetic: biotransforming endobiotics (chemicals endogenous to the body) to cholesterol, steroids, bile acids, fatty acids, prostaglandins, and other important lipids. Cytochromes also act within the mitochondrial electron transport chain.<sup>41,78</sup>

Although more than 6,000 CYP genes exist in nature, the human genome project determined that the number of human CYP genes was 57.<sup>78</sup> Cytochrome P450 enzymes are categorized according to the similarities of their amino acid sequences. They are in the same “family” if they are more than 40% comparable and same “subfamily” if they are more than 55% similar.<sup>77</sup> Families are designated by an Arabic numeral (n), subfamilies by a

**TABLE 11–1** Characteristics of Different Cytochrome P450 Enzymes<sup>26,33,123</sup>

CYP Enzyme	1A2	2B6	2C9	2C19	2D6	2E1	3A4

<sup>a</sup> Polymorphism is a genetic change that exists in at least 1% of the human population. Interpersonal allelic variations exist even in those listed as “No” for polymorphism.

capital letter (X), and each individual enzyme by another numeral (m), resulting in the nomenclature CYPnXm for each enzyme. For example, CYP3A4 is enzyme number 4 of the CYP3A subfamily of the CYP3 family.<sup>74</sup> Genes coding for these enzymes contain sequence variations, designated by italicized style and an asterisk followed by an Arabic numeral (ie, *CYP2D6\*4*), that lead to functional differences.<sup>49,74</sup> An allele is a form of a gene that often arises through mutation. If the same gene variation exists in greater than 1% of the human population, then the allele is termed a genetic polymorphism. Most xenobiotic metabolism is done by the CYP1, CYP2, and CYP3 families, with a small amount done by the CYP4 family.<sup>13,117</sup> Although 15 CYP enzymes metabolize xenobiotics,<sup>86</sup> nearly 90% is done by 6 CYP enzymes: 1A2, 2C9, 2C19, 2D6, 2E1, and 3A4 (Table 11–1).<sup>78</sup>

Most CYP enzymes are found in the liver, where they comprise 2% of the total microsomal protein.<sup>86</sup> High concentrations are also found in extrahepatic tissues, particularly the GI tract and kidney.<sup>26,80</sup> The lungs,<sup>126</sup> heart,<sup>84</sup> and brain<sup>27</sup> have the next highest amounts. Each tissue has a unique profile of CYP enzymes that determines its sensitivity to different xenobiotics.<sup>26</sup> The CYP enzymes in the enterocytes of the small intestine actually contribute significantly to “first-pass” metabolism of some xenobiotics.<sup>56,78</sup> Corrected for tissue mass, the CYP enzyme system in the kidneys is as active as that in the liver. The activity of the renal CYP enzymes is decreased in patients with chronic kidney disease, with relative sparing of CYPs 1A2, 2C19, and 2D6 compared with 3A4 and 2C9.<sup>13</sup>

### Cytochrome P450 Enzyme Specificity for Substrates

In vitro models are used to define the specificities of CYP enzymes for their substrates and inhibitors. However, activity in a test tube does not always correlate with that in a cell. These models use substrate and inhibitor concentrations that are much higher than would be encountered in vivo, and the mathematical models that extrapolate to clinically relevant processes yield conflicting results. Discrepancies in reported substrates, inhibitors, and inducers of specific CYP enzymes results.<sup>119</sup>

Most CYP enzymes involved in xenobiotic biotransformation have broad substrate specificity and can metabolize many xenobiotics.<sup>39</sup> This is fortunate because the number of xenobiotic substrates likely already exceeds

200,000 and continues to grow.<sup>64</sup> Broad substrate specificity often results in multiple CYP enzymes being able to biotransform the same xenobiotic. This enables the ongoing biotransformation despite an inhibition or deficiency of an enzyme. When a substrate is biotransformed by more than one enzyme, the enzyme with the highest affinity for the substrate usually predominates at low substrate concentrations, whereas enzymes with lower affinity become important at high concentrations. This transition is usually concomitant with, but not dependent on, the saturation of the catalytic capacity of the primary enzyme as it reaches its maximum rate of activity.<sup>39</sup> The  $K_m$ , which is defined as the concentration of substrate that results in 50% of maximal enzyme activity, describes this property of enzymes. For example, ADH in the liver has a very low  $K_m$  for ethanol, making it the primary metabolic enzyme for ethanol when concentrations are low.<sup>65</sup> Ethanol is also biotransformed by the CYP2E1 enzyme, which has a high  $K_m$  for ethanol and only functions when ethanol concentrations are high. The CYP2E1 enzyme metabolizes little ethanol in moderate drinkers but accounts for significantly more biotransformation in alcoholics, as it is also inducible. As another example, diazepam is metabolized by both CYP2C19 and CYP3A4 enzymes. However, the affinity of CYP3A4 for diazepam is so low (ie, the  $K_m$  is high) that most diazepam is metabolized by CYP2C19.<sup>44</sup>

The substrate selectivity of some CYP enzymes is determined by molecular and physicochemical properties of the substrates. The CYP1A subfamily has greater specificity for planar polyaromatic substrates such as benzo[*a*]pyrene. The CYP2E enzyme subfamily targets low-molecular-weight hydrophilic xenobiotics, whereas the CYP3A4 enzyme has increased affinity for lipophilic compounds. Substrates of CYP2C9 are usually weakly acidic, whereas those of CYP2D6 are more basic.<sup>64</sup> High specificity also results from key structural considerations such as stereoselectivity. Some xenobiotics are racemic mixtures of 2 stereoisomers that are substrates for different CYP enzymes and have distinct affinities for the enzymes, resulting in different rates of metabolism. For example, *R*-warfarin is biotransformed by CYP3A4 and CYP1A2, whereas *S*-warfarin is metabolized by CYP2C9.<sup>97</sup>

The CYP enzymes that biotransform a specific xenobiotic cannot be predicted by its drug class. For example, the selective serotonin reuptake inhibitors (SSRIs) fluoxetine and paroxetine are both major substrates and

potent inhibitors of CYP2D6, but sertraline is not extensively metabolized by this enzyme and exhibits minimal interaction with other antidepressants.<sup>5</sup> Most  $\beta$ -hydroxy- $\beta$ -methylglutarylcoenzyme A (HMG-CoA) reductase inhibitors are metabolized by CYP3A4 (lovastatin, simvastatin, and atorvastatin); however, fluvastatin is metabolized by CYP2D6, and pravastatin undergoes virtually no CYP enzyme metabolism at all.<sup>69</sup> Among angiotensin-II receptor blockers, losartan and irbesartan are metabolized by CYP2C9, whereas valsartan, eprosartan, and candesartan are not substrates for any CYP enzyme. In addition, losartan is a prodrug whose active metabolite provides most of the pharmacologic activity, whereas irbesartan is the primary active compound. For these 2 drugs, the inhibition of CYP2C9 is predicted to have opposite effects.<sup>31</sup>

### Cytochrome P450 and Drug–Drug/Drug–Xenobiotic Interactions

Adverse reactions to medications and drug–drug interactions are common causes of morbidity and mortality, the risk of which increases with the number of drugs taken (Chaps. 134 and 135). As many as 50% of adverse reactions are related to pharmacogenetic factors.<sup>34</sup> The most significant interactions are mediated by CYP enzymes.<sup>78</sup> The impacts of genetic polymorphism and enzyme induction or inhibition are addressed below.

The CYP enzymes are involved in many types of drug interactions. The ability of potential new drugs to induce or inhibit enzymes is an important consideration of industry. Drug development focuses on the potential of new xenobiotics to induce or inhibit other drugs or enzymes during the drug discovery phase. Various in vitro models enable this early determination.<sup>66</sup>

Many xenobiotics interact with the CYP enzymes. St. John's wort, an herb marketed as a natural antidepressant, induces multiple CYP enzymes, including 1A2, 2C9, and 3A4. The induction of CYP3A4 by St. John's wort is associated with a 57% decrease in effective serum concentrations of indinavir when given concomitantly.<sup>88</sup> Xenobiotics contained in grapefruit juice, such as naringin and furanocoumarins, are both substrates and inhibitors of CYP3A4. They inhibit the first-pass metabolism of CYP3A4 substrates by inhibiting CYP3A4 activity in both the GI tract and the liver.<sup>21</sup> Polycyclic hydrocarbons found in charbroiled meats and in cigarette smoke induce CYP1A2. Thus, for smokers who drink coffee, concentrations of caffeine, a CYP1A2 substrate, will increase following a permanent cessation of smoking.<sup>30</sup>

### Genetic Polymorphism

The response to xenobiotics and to coadministration of inhibitory or inducing xenobiotics is highly variable. The translation of DNA sequences into proteins results in the phenotypic expression of the genes. When a genetic mutation occurs, the changed DNA may continue to exist, be eliminated, or propagate into a polymorphism. A polymorphism is a genetic change that exists in at least 1% of the human population.<sup>34,74</sup> A polymorphism in a biotransformation enzyme may change its rate of activity. The heterogeneity of CYP enzymes contributes to the differences in metabolic activity among patients.<sup>34</sup> Differences in biotransformation capacity that lead to toxicity, once thought to be “idiosyncratic” drug reactions, are likely caused by these inherited differences in the genetic complement of individuals.

An individual with 2 CYP alleles of “normal” catalytic speed is called extensive metabolizer, which usually represents a majority of the population. There are 3 major metabolizer phenotypes due to polymorphism: poor, intermediate, and ultrarapid. Poor and intermediate metabolizers have either loss-of-function variants or absent CYP alleles. Poor metabolizers have 2 inactive or absent alleles, whereas intermediate metabolizers will have either 2 reduced function alleles or one “normal” allele with one inactive or absent allele. On the other hand, an ultrarapid metabolizer will have either gain-of-function variants or gene duplication.<sup>34,125</sup> The *CYP2C19* and *CYP2D6* genes are highly polymorphic (Table 11–1). The *CYP2D6* gene, which has 157 alleles, is associated with both ultrarapid and poor metabolism.<sup>49</sup> The *CYP2C19* and *CYP2C9* genes are both associated with polymorphisms, resulting in poor metabolizers.<sup>13,78</sup>

The clinical implications of polymorphisms are vast. Prodrugs have limited activation in patients who are poor metabolizers. For example, clopidogrel mediates antiplatelet effects via an active thiol metabolite generated by CYP enzymes. Individuals with the loss-of-function *CYP2C19*\*2 allele have decreased generation of the active metabolite, decreased antiplatelet effects, and increased cardiovascular events while on clopidogrel.<sup>55,99</sup> Conversely, some ultrarapid metabolizers generate toxic concentrations of an active metabolite. Codeine (inactive) metabolizes to morphine (active) via CYP2D6. Ultrarapid metabolizers with CYP2D6 can have 2 to 13 copies of the gene leading to rapid conversion of codeine to morphine and as a consequence toxicity.<sup>67</sup> Finally, some active drugs with inactive metabolites fail to reach therapeutic concentrations in patients who are ultrarapid metabolizers.<sup>34</sup>

Polymorphisms exist for enzymes other than CYP enzymes. A classic example is the inheritance of rapid or slow “acetylator” phenotypes. Acetylation is important for the biotransformation of amines (R–NH<sub>2</sub>) or hydrazines (NH<sub>2</sub>–NH<sub>2</sub>). Slow acetylators are at increased risk of toxicity associated with the slower biotransformation of certain nitrogen-containing xenobiotics such as isoniazid, procainamide, hydralazine, and sulfonamides.<sup>101</sup> Genetic polymorphism of UDP-glucuronosyl transferase 2B17 (*UGT2B17*) contributes to a bimodal distribution of urinary conjugated testosterone excretion. Since the testosterone isomer, epitestosterone, has little genetic variation and is not affected by testosterone metabolism, an elevated testosterone:epitestosterone (T:E) is indicative of the exogenous administration of testosterone.<sup>115</sup> The World Anti-Doping Agency sets the suspicious threshold ratio of T:E ratio at 4:1 in response to genetic variations.<sup>95,121</sup> Athletes with homozygote deletions of *UGT2B17* have less conjugation of testosterone and have had false negative testing using the previous ratio of 6:1 (Chap. 41).<sup>51</sup>

Polymorphic genes that code for enzymes in important metabolic pathways affect the toxicity of a xenobiotic by altering the response to, or the disposition of, the xenobiotic. An example occurs in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Glucose-6-phosphate dehydrogenase is a critical enzyme in the hexose monophosphate shunt, a metabolic pathway located in the red blood cell (RBC) that produces NADPH, which is required to maintain RBC glutathione in a reduced state. In turn, reduced glutathione prevents hemolysis during oxidative stress.<sup>15</sup> In patients deficient in G6PD, oxidative stress produced by electrophilic xenobiotics results in hemolysis.

### Induction of CYP Enzymes

Biotransformation by induced CYP enzymes results in either increased activity of prodrugs or enhanced elimination of drugs. Stopping an inducer results in the opposite effects. Either way, maintaining therapeutic concentrations of affected drugs is difficult, resulting in either toxic or subtherapeutic concentrations. Interestingly, not all CYP enzymes are inducible. The inducible enzymes include CYP1A, CYP2A, CYP2B, CYP2C, CYP2E, and CYP3A.<sup>66</sup>

Although varied mechanisms of induction exist, the most common and significant is nuclear receptor (NR)-mediated increase in gene transcription.<sup>66</sup> Nuclear receptors are the largest group of transcription factors (proteins) that switch genes on or off.<sup>113</sup> They regulate reproduction, growth, and biotransformation enzymes, including CYP enzymes.<sup>109</sup> Nuclear receptors exist mostly within the cytoplasm of cells. The CYP families 2 and 3 both have gene activation triggered through the NR pregnane X receptor (PXR) and the constitutive androstane receptor (CAR). The CYP1A subfamily uses the aryl hydrocarbon receptor (AhR) as its NR. Ligands, molecules that bind to and affect the reactivity of a central molecule, are typically small and lipophilic, enabling them to enter cells. Many xenobiotics are themselves ligands. Ligands bind the NRs, resulting in structural changes that enable the NR–ligand complexes to be translocated into the cell nucleus. Within the nucleus, NR–ligand complexes bind to proteins to create a heterodimer such as the retinoid X receptor (RXR) with either the PXR or the CAR. Similarly, the AhR interacts with the AhR nuclear translocator (Arnt) to create the nuclear heterodimer. This new heterodimer complex then interacts with specific response elements of DNA, initiating the transcription of a segment of DNA, and translation of its RNA resulting in the phenotypic expression of the respective CYP enzyme.

The ligand-binding domain of the PXR is very hydrophobic and flexible, enabling this pocket to bind many substrates of varied sizes and reflecting why the PXR is activated by a broad group of ligands.<sup>85,109</sup> For example, xenobiotic ligands that bind the NR PXR that targets the *CYP3A4* gene include rifampin, omeprazole, carbamazepine, and troleandomycin. Phenobarbital, a classic inducing xenobiotic, is a ligand that binds the CAR.<sup>113</sup> The induction of CYP1A subfamily enzymes is through the interaction with the NR AhR. Exogenous AhR ligands are hydrophobic, cyclic, planar molecules. Classic AhR ligands include polycyclic aromatic hydrocarbons (PAHs) such as 2,3,7,8-tetrachlorodibenzo-*p*-dioxin and benzo[*a*]pyrene.<sup>85</sup>

Induction requires time to occur because it involves *de novo* synthesis of new proteins. Similarly, withdrawal of the inducer results in a slow return to the original enzyme concentration.<sup>66</sup> Polycyclic aromatic hydrocarbons (PAHs) result in CYP1A subfamily induction within 3 to 6 hours with a maximum effect within 24 hours.<sup>104</sup> The inducer rifampin does not affect verapamil trough concentrations maximally until one week; followed by a 2-week return to baseline steady state after withdrawal of rifampin.<sup>66</sup> Xenobiotics with long half-lives require longer periods of time to reach steady-state concentrations that maximize induction. Phenobarbital and fluoxetine, which have long half-lives, fully manifest induction only after weeks of exposure. Conversely, xenobiotics with short half-lives, such as rifampin or venlafaxine reach maximum induction within days.<sup>13</sup>

Inconsistency in CYP induction exists in all organs and among individuals.<sup>66,85</sup> In an *in vitro* study of the effects of inducing xenobiotics on 60 livers, differences in enzyme induction ranged from 5-fold for CYP3A4 and CYP2C9 up to more than 50-fold for CYP2A6 and CYP2D6.<sup>66</sup> The inconsistency likely results from both polymorphisms and multiple environmental factors including diet, tobacco, and pollutants.<sup>66</sup> There is variation in the extent to which inducers generate new CYP enzymes. Identical dosing regimens with rifampin resulted in induction of *in vivo* hepatic CYP3A4 with up to 18-fold differences between subjects.<sup>66</sup> There is an inverse correlation of the degree of inducibility of an enzyme and the baseline enzyme concentration. Patients with a relatively low baseline concentration of a CYP enzyme will be more inducible than those with a high baseline concentration. Interestingly, the maximum concentrations of CYP enzymes seem to be quantitatively similar among individuals, suggesting a limit to which enzymes can be induced.<sup>66</sup>

Although the focus of this section is on CYP enzymes, it appears that most phases of xenobiotic metabolism are regulated by NRs.<sup>11</sup> Also, just as genetic polymorphisms exist for CYP enzymes, they exist for NRs including the AhR, the CAR, and the PXR. This results in varied sensitivities to the ligands that complex with the NRs, ultimately resulting in differences in CYP enzyme induction.<sup>66,113</sup>

## Inhibition of CYP Enzymes

Inhibition of CYP enzymes result in either increased bioavailability of a drug or decreased bioactivation of a prodrug, and is the most common cause of harmful drug–drug interactions.<sup>86</sup> Severe inhibition of CYP enzymes by a coadministered xenobiotic resulted in the removal of many medications from the market, including terfenadine, mibefradil, bromfenac, astemizole, cisapride, cerivastatin, and nefazodone.<sup>119</sup> The appendix at the end of this chapter includes a comprehensive listing of CYP enzyme substrates, inhibitors, and inducers.

Inhibition mechanisms include irreversible (mechanism-based inhibition) and, the more common, reversible processes. The most common type of reversible inhibition is competitive, where the substrate and inhibitor both bind the active site of the enzyme.<sup>86,119</sup> Binding is weak and is formed and broken down easily, resulting in subsequent enzyme liberation. It occurs rapidly, usually beginning within hours.<sup>13</sup> Because the degree of inhibition varies with the concentration of the inhibitor, the time to reach the maximal effect correlates with the half-life of the xenobiotic in question.<sup>13</sup> A competitive inhibitor can be overcome by increasing the substrate concentration. Each substrate of a CYP enzyme is an inhibitor of the metabolism of all the other substrates of the same enzyme, thereby increasing their concentrations and half-lives. Reversible, noncompetitive inhibition occurs when an

inhibitor binds a location on an enzyme that is not the active site, resulting in a structural change that inhibits the active enzyme site. For example, noncompetitive inhibitors of CYP2C9 include nifedipine, tranlycypromine, and medroxyprogesterone.<sup>100</sup> Another reversible mechanism results from competition between one xenobiotic and a metabolite of a second xenobiotic at its CYP enzyme substrate binding site. For example, the metabolites of clarithromycin and erythromycin produced by CYP3A inhibit further CYP3A activity. The effect is reversible and usually increases with repeated dosing.<sup>100</sup> Some reversible inhibitors bind so tightly to the enzyme that they essentially function as irreversible inhibitors.<sup>86</sup>

Irreversible inhibitors have reactive groups that covalently, and thus permanently, bind the enzyme. They display time-dependent inhibition because the amount of active enzyme at a given concentration of irreversible inhibitor will be different depending on how long the inhibitor is preincubated with the enzyme. Because the enzyme will never be reactivated, inhibition lasts until new enzyme is synthesized.<sup>86</sup> One measure of inhibitor potency is the inhibitory concentration,  $K_i$ , the concentration of the inhibitor that produces 50% inhibition of the enzyme. The more potent the inhibitor, the lower the value.<sup>104</sup> Values below 1.0  $\mu\text{mol/L}$  are regarded as potent.<sup>82</sup> The azole antifungals are very potent, with  $K_i$  values of 0.02  $\mu\text{mol/L}$ .<sup>104</sup>

The impact of an inhibitor is also affected by the fraction of the substrate that is biotransformed by the inhibited, target enzyme. The inhibition of a CYP enzyme will have little impact if the enzyme only metabolizes a fraction of the affected xenobiotic.<sup>82</sup> Conversely, xenobiotics that are primarily metabolized by a single CYP enzyme are more susceptible to interactions.<sup>86</sup> Simvastatin is biotransformed primarily by CYP3A4. The potent and specific CYP3A inhibitor itraconazole prevents its metabolism, resulting in an increased risk of rhabdomyolysis.<sup>1</sup>

## Specific CYP Enzymes

### CYP1A1 and 1A2

Whereas 1A1 is located primarily in extrahepatic tissue, 1A2 is a hepatic enzyme and is involved in the metabolism of 10% to 15% of xenobiotics.<sup>13,66</sup> They both are very inducible by polycyclic aromatic hydrocarbons, including those in cigarette smoke and charred food. They bioactivate several procarcinogens, including benzo[*a*]pyrene.<sup>57</sup> Xenobiotics activated by the CYP1 enzyme family in the GI tract are linked to colon cancer.<sup>78</sup> A xenobiotic interaction through CYP1A2 involves the addition of ciprofloxacin, a moderate inhibitor of CYP1A2, to a patient using tizanidine for muscle spasms. Oral administration of tizanidine, an  $\alpha_2$  adrenergic agonist, yields low serum concentration because of extensive first-pass metabolism through CYP1A2. With concurrent ciprofloxacin dosing, serum tizanidine concentration increases significantly, and the interaction causes a clinically significant hypotension.<sup>37</sup>

### CYP2B6

This enzyme metabolizes approximately 7% of xenobiotics with many overlapping substrates with other CYP enzymes, especially CYP3A4.<sup>43,125</sup> CYP2B6 comprises between 4% and 14% of total hepatic CYP enzymes and is polymorphic with 38 allele variations.<sup>49,125</sup> Cyclophosphamide and ifosfamide are commonly used nitrogen mustard class of chemotherapeutics that require bioactivation. Metabolism through CYP2B6 yields the therapeutic phosphamide mustard metabolite, whereas metabolism through CYP3A4 inactivates the compound. Preferential metabolism through the induction of CYP2B6 increases therapeutic efficacy of cyclophosphamide and ifosfamide.<sup>43</sup>

### CYP2C9 and 2C19

The CYP2 enzyme family, with its 60 *CYP2C9* alleles and 35 *CYP2C19* alleles, is one of the most polymorphic of the CYP enzymes families (Table 11–1).<sup>30,49,114</sup> The CYP2C9 enzyme is the most abundant enzyme of the CYP2C enzyme subfamily, which, with CYP2C19, comprises approximately 10% to 20% of the CYP enzymes in the liver and is involved in 15% to 20% of all xenobiotic metabolism.<sup>30,114</sup> CYP2C9 biotransforms *S*-warfarin, the more active isomer of warfarin. Warfarin is one of the most commonly reported causes of

adverse drug events. There is an association between slow metabolism and an increased risk of bleeding in patients taking warfarin.<sup>16,97</sup>

### CYP2D6

This enzyme is of historical significance because the exploration of differences in pharmacokinetics among individuals taking the antihypertensive debrisoquine led to the discovery of CYP2D6 and marked the beginning of pharmacogenetics.<sup>48</sup> Debrisoquine through its effects on blood pressure acts as a probe molecule for enzymatic variations of CYP2D6. In fact, CYP2D6 is highly polymorphic with more than 109 allelic variants.<sup>49</sup> Twenty-five percent of pharmaceuticals, including 50% of the commonly used antipsychotics and antidepressants, are substrates for CYP2D6.<sup>42,48,78,83</sup> Because CYP2D6 is the only drug-metabolizing CYP enzyme that is noninducible, the polymorphisms are the primary reason for the substantial interindividual variation in enzyme activity.<sup>50</sup> CYP2D6 enzyme is strongly inhibited by common antidepressants such as bupropion, fluoxetine, and paroxetine. Between inhibitors and poor metabolizers, opioid substrates such as codeine, tramadol, and hydrocodone that are bioactivated through CYP2D6 have less clinical efficacy.<sup>42</sup> Ultrarapid metabolizers have higher incidences of postoperative and chemotherapy-induced vomiting when given ondansetron, a commonly used antiemetic metabolized by CYP2D6.<sup>9</sup>

### CYP2E1

This enzyme comprises 7% of the total CYP enzyme content in the human liver.<sup>79</sup> It metabolizes small organic compounds, including ethanol, carbon tetrachloride, and halogenated anesthetics.<sup>104</sup> It also biotransforms low-molecular-weight xenobiotics, including benzene, acetone, and *N*-nitrosamines.<sup>104</sup> Some of its substrates are procarcinogens, which are bioactivated by CYP2E1.<sup>78</sup> The assessment for a relationship between CYP2E1 and cancer is intense because many of its substrates are environmental xenobiotics. The induction of CYP2E1 is associated with increased liver injury by reactive metabolites of carbon tetrachloride and vinyl chloride (Chap. 21).<sup>36</sup> During the metabolism of substrates that include carbon tetrachloride, ethanol, acetaminophen (APAP), aniline, and *N*-nitrosodimethylamine, CYP2E1 actively produces free radicals and other reactive metabolites associated with adduct formation and lipid peroxidation (Chaps. 9 and 33).<sup>17</sup> CYP2E1 is inhibited by acute elevations of ethanol, an effect illustrated by the acute administration of ethanol inhibiting the metabolism of APAP. The chronic ingestion of ethanol hastens its own metabolism through CYP2E1 induction.<sup>36</sup>

### CYP3A4

CYP3A4 is the most abundant CYP in the human liver, comprising 40% to 55% of the mass of hepatic CYP enzymes.<sup>13,30</sup> The CYP3A4 enzyme is the most common one found in the intestinal mucosa and is responsible for much first-pass drug metabolism.<sup>13</sup> It is involved in the biotransformation of 50% to 60% of all pharmaceuticals.<sup>79,127</sup> It has broad substrate specificity because it accommodates large lipophilic substrates and can adopt multiple conformations. It can even simultaneously fit 2 relatively large compounds (ketoconazole, erythromycin) in its active site.<sup>96</sup>

Methadone, extensively metabolized by CYP3A4, is associated with many examples of adverse drug interactions.<sup>54</sup> Torsade de pointes due to the methadone dose-related prolongation of the QT<sub>c</sub> interval is reported in patients who take methadone in addition to CYP3A4 inhibitors including ciprofloxacin,<sup>75</sup> itraconazole,<sup>81</sup> and the antiretrovirals atazanavir and ritonavir.<sup>29</sup> Ketoconazole inhibits CYP3A4, causing a 15- to 72-fold increase in serum concentrations of terfenadine, which also causes torsade de pointes.<sup>78</sup> Bioflavonoids in grapefruit juice decrease metabolism of some substrates by 5- to 12-fold.<sup>13,78</sup> The CYP3A4 enzyme does not exhibit significant genetic polymorphism; however, there are large interindividual variations in enzyme concentrations that can affect metabolic rates.<sup>127</sup>

## Phase II Biotransformation Reactions

Phase II biotransformation reactions are synthetic, catalyzing the conjugation of products of phase I reactions or xenobiotics with endogenous molecules that are generally hydrophilic. Conjugation usually terminates the

pharmacologic activity of xenobiotics and greatly increases their water solubility and excretability.<sup>70,108,124</sup> Conjugation occurs most commonly with glucuronic acid, sulfates, and glutathione. Less common phase II reactions include conjugation with amino acids such as glycine, glutamic acid, and taurine as well as acetylation and methylation.

Glucuronidation is the most common phase II synthesis reaction.<sup>70</sup> Glucuronyl-transferase has relatively low substrate affinity, but it has high capacity at higher substrate concentrations.<sup>108</sup> The glucuronic acid, donated by uridine diphosphate glucuronic acid, is conjugated with the nitrogen, sulfhydryl, hydroxyl, or carboxyl groups of substrates. Smaller conjugates usually undergo renal elimination, whereas larger ones undergo biliary elimination.<sup>70</sup> The process of glucuronidation is reversible via  $\beta$ -glucuronidases. Although the liver has an overall low concentration of  $\beta$ -glucuronidases, the gut flora have high  $\beta$ -glucuronidase activity. Cleavage of the glucuronide metabolite enhances the lipophilicity and thus reabsorption through intestinal walls. This process is termed enterohepatic circulation, which decreases elimination and prolong toxicity from xenobiotics such as carbamazepine and phenobarbital.<sup>3,124</sup> Multiple-dose activated charcoal provides therapeutic benefit to break enterohepatic circulation (Antidotes in Depth: A1).

Sulfation complements glucuronidation because it is a high-affinity but low-capacity reaction that occurs primarily in the cytosol. For example, the affinity of sulfate for phenol is very high (the  $K_m$  is low), so that when low doses of phenol are administered, the predominant excretion product is the sulfate ester. Because the capacity of this reaction is readily saturated, glucuronidation becomes the main method of detoxification when high doses of phenol are administered.<sup>70,124</sup> Sulfate conjugates are highly ionized and very water soluble.

Glutathione *S*-transferases are important because they catalyze the conjugation of the tripeptide glutathione (glycine-glutamate-cysteine, or GSH) with a diverse group of reactive, electrophilic metabolites of phase I CYP enzymes. The reactive compounds initiate an attack on the sulfur group of cysteine, resulting in conjugation with GSH that detoxifies the reactive metabolite. Of the 3 phase II reactions addressed, hepatic concentrations of glutathione by far account for the greatest amount of cofactors used. Although intracellular glutathione is difficult to deplete, when it does occur, severe hepatotoxicity often follows.<sup>124</sup> Some GSH conjugates are directly excreted. More commonly, the glycine and glutamate residues are cleaved and the remaining cysteine is acetylated to form a mercapturic acid conjugate that is readily excreted in the urine. A familiar example of this detoxification is the avid binding of *N*-acetyl-*p*-benzoquinoneimine (NAPQI), the toxic metabolite of APAP, by glutathione.<sup>5,12</sup>

As with the CYP enzymes, many phase II enzymes are inducible. For example, UDP-glucuronosyltransferase, which performs glucuronidation, is inducible via the PXR, CAR, and AhR nuclear receptors after binding with rifampin, phenobarbital, and PAHs, respectively. Its activity varies 6- to 15-fold in liver microsomes.<sup>113</sup> Similarly, UDP-glucuronosyltransferases are inhibited by xenobiotics such as amitriptyline, indinavir, phenylbutazone, and quinidine.<sup>63,111</sup> Inhibition of glucuronidation exacerbates hyperbilirubinemia in patients with underlying Gilbert syndrome (reduced UDP-glucuronosyltransferase activity on bilirubin).<sup>111</sup> Although inhibition of a high-capacity phase II metabolism step has theoretical implications and potential drug-drug interactions, the clinical implications are not well-studied.

## Membrane Transporters

Although the focus on drug disposition has traditionally been on biotransformation, membrane transporter proteins greatly impact drug disposition.<sup>45</sup> Transporter proteins mediate the cellular uptake and efflux of endogenous compounds and xenobiotics.<sup>128</sup> Their baseline physiologic role is to transport sugars, lipids, amino acids, and hormones so as to regulate cellular solute and fluid balance. Biotransformation cannot occur unless xenobiotics are taken up into the cells via transport proteins. After xenobiotics have undergone phase I and II metabolism, the metabolites undergo transport protein mediated efflux from the cell, an action that has been called phase III metabolism.<sup>52</sup>

Xenobiotic absorption, compartmentalization, and elimination are facilitated or prevented by the transport proteins.<sup>58</sup> In the apical (luminal) membrane of the intestinal enterocytes, P-glycoprotein, part of the ABC family of transmembrane proteins, is important because it can actively extrude xenobiotics back into the intestinal lumen and effectively decreases absorption.<sup>14</sup> The degree of phenotypic expression of P-glycoprotein affects the bioavailability of many xenobiotics, including paclitaxel, digoxin, and protease inhibitors.<sup>45</sup> Transporter-mediated uptake of xenobiotics also occurs from the portal venous blood into the hepatocytes or from renal filtrate back into proximal tubular cells.  $\alpha$ -Amanitin uses the sodium-dependent bile acid transporter, Na<sup>+</sup>-taurocholate cotransporting polypeptide, to enter hepatocytes, where it inhibits RNA-polymerase II and mediates cellular toxicity.<sup>40</sup> Alternatively, transport proteins decrease xenobiotic entry into specific cells or compartments. P-glycoprotein in endothelial cells of the blood-brain barrier prevent CNS entry of substrate xenobiotics. Finally, transport proteins mediate xenobiotic elimination via hepatocyte efflux transporters that move biotransformed xenobiotics into bile and via efflux from renal proximal tubular cells into urine.<sup>14,45,128</sup> Organs important for drug disposition have multiple transporters that have overlapping substrate capabilities, a redundancy that enhances protection.<sup>45</sup>

As with biotransformation enzymes and nuclear receptors, membrane transporters are also inhibited or induced. Digoxin, a high-affinity substrate for P-glycoprotein, has increased bioavailability when administered with P-glycoprotein inhibitors such as clarithromycin or atorvastatin.<sup>45</sup> Loperamide is a substrate for P-glycoprotein that limits its intestinal absorption

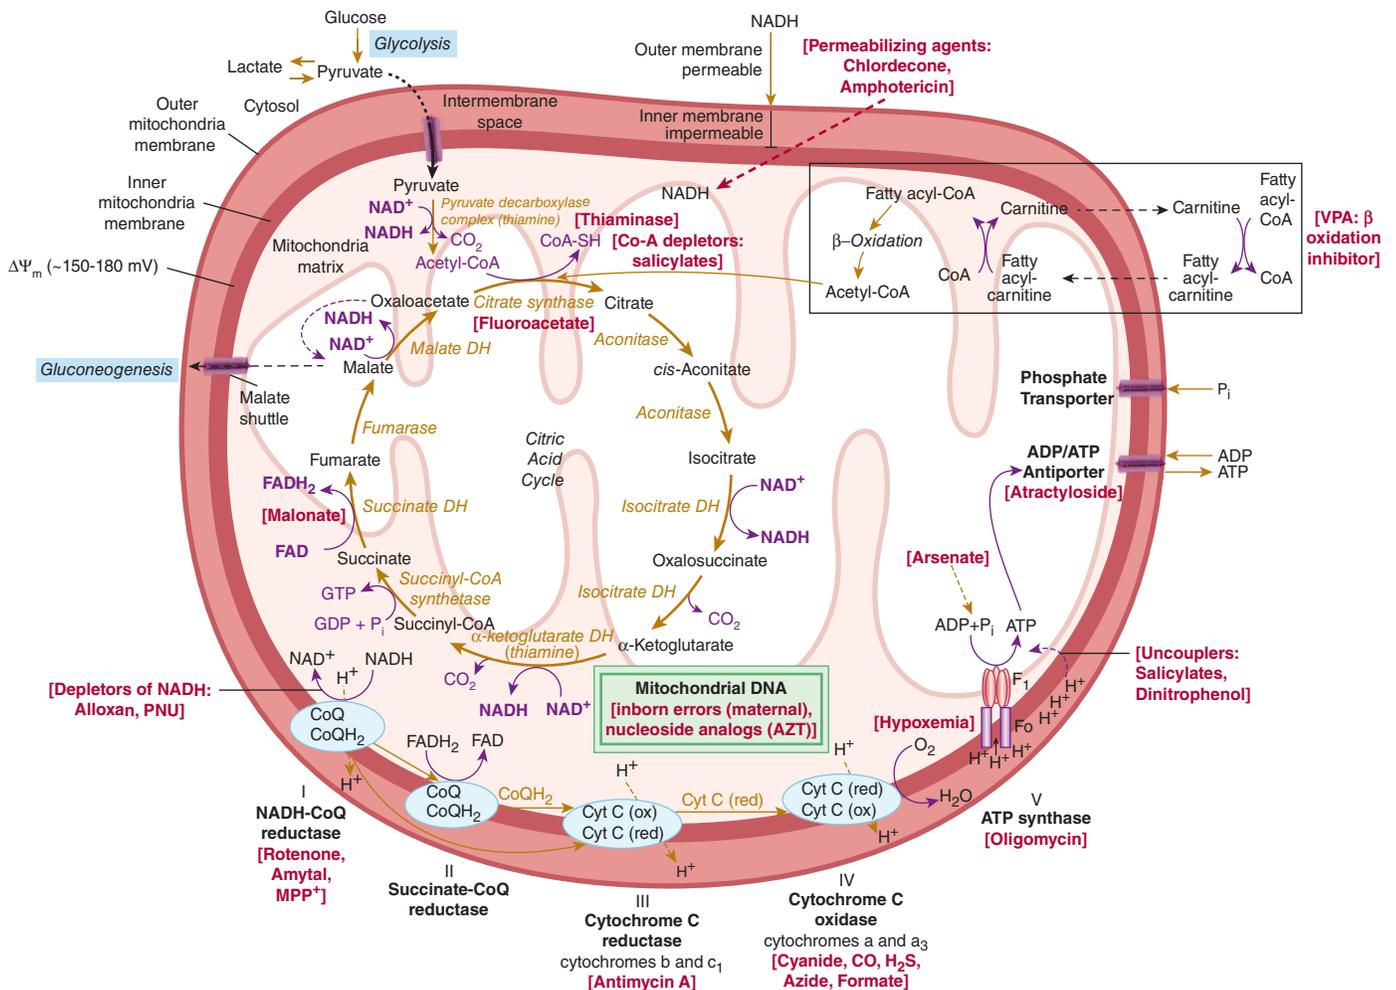

or CNS entry. Coadministration with quinidine, a P-glycoprotein inhibitor, or large dose ingestions (70–200 mg daily) that overwhelm the P-glycoprotein capacity result in increased opioid CNS effects of loperamide.<sup>24,45</sup> As with the biotransformation enzymes, polymorphisms exist for membrane transporters. However, the clinical significance of these is not clear.<sup>19</sup>

### MECHANISMS OF CELLULAR INJURY

Ideally and commonly, potentially toxic metabolites produced by phase I reactions are detoxified during phase II reactions. However, detoxification does not always occur. This section reviews mechanisms of cellular injury related to xenobiotic biotransformation.

#### Synthesis of Toxins

Sometimes a xenobiotic is mistaken for an endogenous substrate by synthetic enzymes that biotransform it into an injurious compound. The incorporation of the rodenticide fluoroacetate into the citric acid cycle is an example of this mechanism of toxic injury (Fig. 11-3).<sup>90</sup> Another example is illustrated by analogs of purine or pyrimidine bases that are phosphorylated and inserted into growing DNA or RNA chains, resulting in mutations and disruption of cell division. This mechanism is used therapeutically with 5-fluorouracil (5-FU), an antitumor pyrimidine base analog. When phosphorylated to 5-fluoro-dUTP and incorporated into growing DNA chains, it causes structural instability of the cellular DNA and inhibits tumor growth.<sup>94</sup>

**FIGURE 11-3.** Pyruvate is converted to acetylcoenzyme A (acetyl-CoA), which enters the citric acid cycle as shown. Reducing equivalents, in the form of NADH and FADH, donate electrons to a chain of cytochromes beginning with NADH dehydrogenase. These reactions “couple” the energy released during electron transport to the production of ATP. Ultimately, electrons combine with oxygen to form water. The sites of action of xenobiotics that inhibit oxidative metabolism are shown. The sites where thiamine functions as a coenzyme are also illustrated.<sup>87</sup>  $\Delta\Psi_m$  = mitochondrial membrane potential; DH = dehydrogenase. MPP<sup>+</sup> = 1-methyl-4-phenylpyridinium; PNU = N-3-pyridylmethyl-N-nitrophenyl urea; VPA = valproic acid.

### Injury by Metabolites of Biotransformation

Many toxic products result from metabolic activation (Table 11–2).<sup>53</sup> The CYP enzymes most associated with bioactivation are 1A1, 1B1, 2A6, and 2E1, whereas 2C9 and 2D6 yield little toxic activation.<sup>39</sup>

Highly reactive metabolites exert damage at the site where they are synthesized; reacting too quickly with local molecules to be transported

elsewhere. This commonly occurs in the liver, the major site of biotransformation of xenobiotics (Chap. 21).<sup>38,102</sup> However, metabolism in the lungs, skin, kidneys, GI tract, and nasal mucosa also create toxic metabolites that cause local injury.<sup>12,61</sup> Overdoses of APAP lead to excessive hepatic CYP2E1 production of the highly reactive, semiquinoneimine, electrophile NAPQI, which initiates a damaging covalent bond with hepatocytes (Chap. 33).<sup>5</sup> Acute renal tubular necrosis also occurs in patients with overdose of APAP, attributed to its biotransformation to NAPQI by prostaglandin H synthase within renal tubular cells.<sup>28,118</sup> Other toxic metabolites cause systemic toxicity. Dapsone (4,4'-diphenyldiaminosulfone) is a medication used in the treatment of *Pneumocystis jiroveci* pneumonia, malaria, and leprosy. Dapsone is metabolized primarily by CYP2C19 with contributions from CYP2B6, CYP2D6, and CYP3A4 to *N*-hydroxy metabolites such as dapsone hydroxylamine and monoacetyl hydroxylamine, which induce methemoglobinemia and cause hemolytic anemia.<sup>6,33</sup> These metabolites have a prolonged elimination half-life of approximately 30 hours and cause the well-described prolonged methemoglobinemia associated with dapsone.<sup>6</sup>

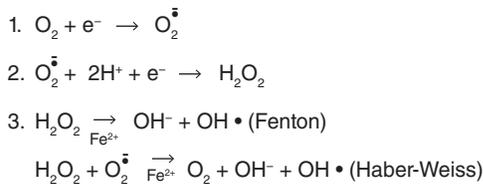

Monoamine oxidases (MAOs) are mitochondrial enzymes present in many tissues. They oxidize many amines, including dopamine, epinephrine, and serotonin, and xenobiotics such as primaquine and haloperidol. The metabolic activity of MAOs was responsible for the outbreak of parkinsonism associated with the use of methylphenyltetrahydropyridine (MPTP), an unintended by-product of attempts to synthesize a “designer” analog of meperidine, methylphenylpropionoxypiperidine (MPPP). After crossing the blood–brain barrier, MPTP is biotransformed by MAO in glial cells to methylphenyldihydropyridine (MPDP<sup>+</sup>), which is converted to the 1-methyl-4-phenylpyridinium cation (MPP<sup>+</sup>). The MPP<sup>+</sup> is subsequently taken up by specific dopamine transport systems into dopaminergic neurons in the substantia nigra, resulting in inhibition of oxidative phosphorylation and subsequent neuronal death.<sup>35</sup>

### Free Radical Formation

Within an atom, it is energetically favorable for electrons to exist in pairs or as a part of a chemical bond. An element or compound with an unpaired electron, called a *radical* or *free radical*, is highly reactive and short-lived. It rapidly seeks other species in order to obtain another electron. Radicals include the superoxide anion O<sub>2</sub><sup>•-</sup>, which is produced by adding an electron to O<sub>2</sub>, and the highly reactive hydroxyl radical HO•, which is produced by splitting the H<sub>2</sub>O<sub>2</sub> molecule into 2 equal halves. The H<sub>2</sub>O<sub>2</sub> molecule itself is reactive and is also associated with injury. The superoxide and hydroxyl radicals react with other molecules in order to stabilize themselves; however, by taking an electron in order to do so, they generate new free radical species, potentially initiating a chain reaction. Because the production of radicals occurs continually, the human body has developed effective defense mechanisms against these reactive molecules. However, some xenobiotics promote the formation of reactive oxidant species to the extent that antioxidant mechanisms are overwhelmed, a condition called *oxidative stress*. Oxidizing species are called such because, by reducing themselves by taking away electrons, they oxidize the species from which they took the electrons.<sup>8</sup>

Although oxidative stress results in oxidative damage to nucleic acids and proteins, other targets exist such as polyunsaturated fatty acids (PUFAs) in cellular membranes, resulting in lipid peroxidation (the oxidative destruction of lipids). This attack removes the particularly reactive hydrogen atom, with its lone electron, from a methylene carbon of a PUFA, leaving an unpaired electron and causing the formation of a lipid radical. This lipid radical attacks other PUFAs, initiating a chain reaction that destroys the cellular membrane. Membrane degradation products initiate inflammatory reactions in the cells, resulting in further damage.<sup>8,102</sup>

Molecular oxygen (O<sub>2</sub>) has a lone pair of electrons in its orbit. Because oxygen is a relatively weak univalent electron acceptor (and most organic molecules are weak univalent electron donors), oxygen cannot efficiently oxidize amino acids and nucleic acids. However, the unpaired electrons of O<sub>2</sub> readily interact with the unpaired electrons of transition metals and

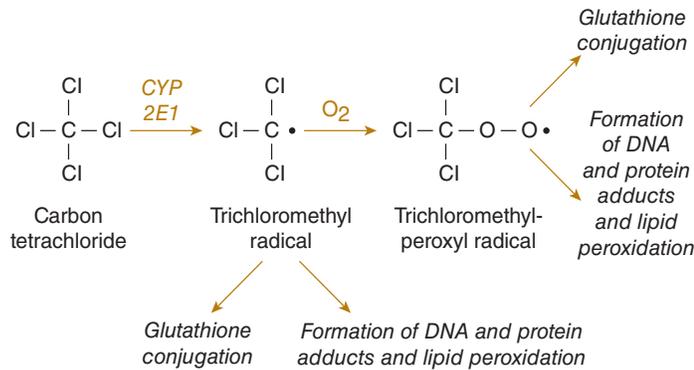

**FIGURE 11-4.** Hydroxyl radical formation. (1) First is the addition of an electron to  $O_2$  to create the superoxide ion. (2) Then the very reactive superoxide combines with hydrogen and another electron to produce hydrogen peroxide. (3) Finally, in the presence of a metal ion catalyst such as iron, hydrogen peroxide undergoes various reactions to produce the hydroxyl radical. The dot in these formulas represents an unpaired electron, the hallmark of a free radical.<sup>47,70</sup>

organic radicals. Metals frequently catalyze the creation of oxygen free radicals. Fig. 11-4 reflects the typical steps in the formation of a hydroxyl radical. The damaging effects of the free radicals are decreased by reaction with antioxidants such as ascorbate, tocopherols, and glutathione.<sup>70</sup> Deficiencies of antioxidants, especially glutathione, are associated with increased oxidative damage. Free radicals are also neutralized by several enzymes, including peroxidase, superoxide dismutase, and catalase.

The ethanol-inducible CYP2E1 enzyme produces significant amounts of superoxide and peroxide free radicals. In the presence of iron, these hydroxyl free radicals readily initiate lipid peroxidation. This was studied extensively in models of the metabolism of carbon tetrachloride, ethanol, and APAP.<sup>23</sup> The formation of free radicals is implicated in the pulmonary injury caused by paraquat, the myocardial injury caused by doxorubicin, and the hepatic injury caused by carbon tetrachloride.<sup>73,91</sup> Paraquat reacts with NADPH to form a pyridinyl free radical, which, in turn, reacts with oxygen to generate the superoxide anion radical. Doxorubicin is metabolized to a semiquinone free radical in the cardiac mitochondria, which, in the presence of oxygen, forms a superoxide anion radical that initiates myocardial lipid peroxidation.<sup>73</sup> Carbon tetrachloride ( $CCl_4$ ) is metabolized to the trichloromethyl radical ( $\bullet CCl_3$ ) that binds covalently to cellular macromolecules. In the presence of oxygen, this is converted to the trichloromethylperoxyl radical ( $\bullet CCl_3O_2$ ) that can initiate lipid peroxidation (Fig. 11-5).<sup>92</sup> (Chap. 105 offers a more extensive discussion.)

### CRITICAL BIOCHEMICAL PATHWAYS AND XENOBIOTICS THAT AFFECT THEM

Energy metabolism is the foundation of cellular function. It provides high-energy fuel, predominantly in the form of ATP, for all energy-dependent cellular processes such as synthesis, active transport, and maintenance of

**FIGURE 11-5.** This is carbon tetrachloride metabolism by the hepatocyte. Under hypoxic conditions, the  $CCl_3$  radical is the predominant species formed. At higher oxygen tensions, the  $CCl_3$  radical is oxidized to the  $CCl_3OO^{\bullet}$  radical, which is more readily detoxified by glutathione. Both free radicals bind to hepatocytes and cause cellular injury.

electrolyte balance and membrane integrity. Numerous pathways interconnect glycogen, fat, and protein reserves in many tissues that store and retrieve ATP and glucose. The brain and red blood cells (RBCs) are entirely dependent on glucose for energy production, although other tissues can also use ketone bodies and fatty acids to synthesize ATP. Rapid cell death occurs if the production or use of ATP is inhibited; thus, the goal of many metabolic processes is the production and mobilization of cellular energy.

Catabolic pathways, those that break down molecules into smaller units enabling the production of cellular energy, include glycolysis, the citric acid cycle, and oxidative phosphorylation via the electron transport chain. Glycolysis produces small amounts of ATP through the anaerobic metabolism of glucose. Pyruvate, the end product of glycolysis, yields far more ATP when it is converted to acetyl-coenzyme A (acetyl-CoA) and “processed” in the citric acid cycle (Fig. 11-3). Fat and protein yield their energy through their conversion to acetyl-CoA and other intermediates of the citric acid cycle. The citric acid cycle and oxidative phosphorylation, via the electron transport chain, result in most ATP synthesis. Oxidative phosphorylation disposes of electrons or “reducing equivalents” and converts their energy to ATP. A lack of oxygen stops the electron transport chain and ATP production. Oxidative metabolism is highly energy efficient, producing 36 moles of ATP for each mole of glucose metabolized, compared to the 2 moles of ATP produced by anaerobic glycolysis. The following sections review the basics of cellular energy metabolism and several important xenobiotics that affect these critical metabolic functions (Table 11-3).<sup>30,59</sup>

### Glycolysis

Glycolysis is the first biochemical pathway in the metabolism of glucose. Other sugars enter this pathway after conversion to glycolytic intermediates (Fig. 11-6). The glycolytic process converts one molecule of glucose to 2 of pyruvate plus 2 molecules of ATP plus 2 molecules of NADH. Pyruvate may follow many paths. Under anaerobic conditions, the 2 pyruvate molecules produced from one glucose molecule are reduced by lactate dehydrogenase to 2 lactate molecules in an NADH-requiring step that regenerates  $NAD^+$ . Thus, anaerobic glycolysis yields 2 molecules of lactate plus 2 molecules of ATP. When  $NAD^+$  and oxygen are available, pyruvate is transported from the cytosol into the mitochondria where it enters the citric acid cycle by being converted by pyruvate decarboxylase to acetyl-CoA (Fig. 11-3).<sup>30,59</sup> In energy-rich conditions, pyruvate is used for fatty acid synthesis, whereas in energy-poor situations, it is used for gluconeogenesis.

Arsenate ( $As^{5+}$ ) affects the glycolytic step where 3-phosphoglyceraldehyde dehydrogenase (3-PGA) catalyzes the oxidation of glyceraldehyde-3-phosphate to 1,3-diphosphoglycerate, a reaction that preserves a high-energy phosphate bond used to synthesize ATP in the next step of glycolysis (Fig. 11-6).<sup>46</sup> Arsenate acts as an analog of phosphate at this step, resulting in an unstable arsenate intermediate that is rapidly hydrolyzed to 3-phosphoglycerate. While glycolysis continues, there is the loss of ATP synthesis because 1,3 biphosphoglycerate is not made.<sup>46</sup>

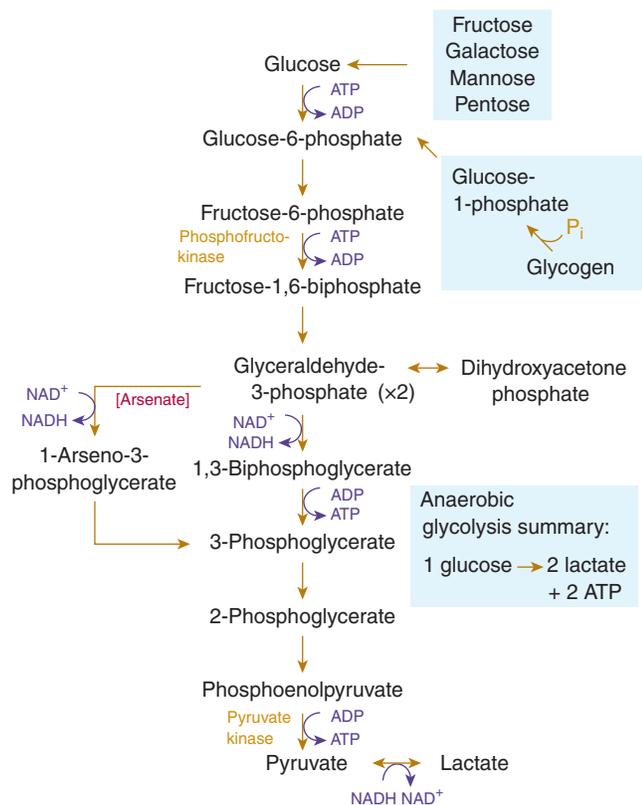

### Citric Acid Cycle

The citric acid cycle uses acetyl-CoA derived from glycolysis, fat, or protein to regenerate NADH from  $NAD^+$ . The cycle is a major source of electrons (in the form of NADH) and is critical to the aerobic production of ATP (Fig. 11-3). Each acetyl-CoA molecule that is oxidized within the citric acid cycle ultimately forms one molecule each of  $CO_2$  and guanosine triphosphate (GTP), and more importantly, 3 molecules of NADH and one molecule of reduced flavin adenine dinucleotide ( $FADH_2$ ). Both NADH and  $FADH_2$  enter the electron transport chain to generate ATP via oxidative phosphorylation (details below). In addition, the citric acid cycle provides important intermediates for amino acid synthesis and for gluconeogenesis.<sup>59</sup>

Various xenobiotics inhibit the citric acid cycle. The rodenticides, sodium fluoroacetate and fluoroacetamide, are combined with coenzyme A, CoASH, to create fluoroacetyl CoA (FACoA). The FACoA substitutes for acetyl CoA, entering the citric acid cycle by condensation with oxaloacetate to form fluorocitrate. Fluorocitrate metabolism results in a metabolite that blocks

TABLE 11-3 Inhibitors of Glucose Metabolism and ATP Synthesis		
Step/Location	Examples	Action
Glycolysis	Iodoacetate (at GAPDH) NO <sup>+</sup> (at GAPDH) Arsenate, (As <sup>5+</sup> )	Inhibits NADH production Bypasses ATP producing step
Gluconeogenesis	4-(Dimethylamino)phenol <i>p</i> -benzoquinone Hypoglycin A (ackee fruit) Methylenecyclopropylacetic acid (lychee fruit)	Inhibits NADH production
Fatty acid metabolism	Aflatoxin Amiodarone Hypoglycin Perhexiline Protease inhibitors Salicylates Tetracycline Valproic acid	Inhibits NADH production
Citric acid cycle	Arsenite, (As <sup>3+</sup> ) <i>p</i> -Benzoquinone Fluoroacetate	Inhibits NADH production
Electron-transport chain at complex I	MPP <sup>+</sup> Paraquat Rotenone	Inhibits electron transport
Electron-transport chain at complex III	Antimycin-A Fusiculosin Cations: Zn <sup>2+</sup> , Hg <sup>2+</sup> , Cu <sup>2+</sup> , and Cd <sup>2+</sup> Substituted phenols (pentachlorophenol and dinitrophenol) (also uncouplers)	Inhibits electron transport
Electron-transport chain at complex IV	Azide Carbon monoxide Cyanide Formate Hydrogen sulfide Nitric oxide Phosphine Protamine	Inhibits electron transport
Electron-transport chain at ATP synthase	Arsenate, (As <sup>5+</sup> ) Mycotoxins (numerous, including oligomycin) Organic chlorines (DDT and chlordane) Organotin (cyhexatin) Paraquat	Inhibits ATP production
Mitochondria ADP/ATP antiporter	Atractyloside DDT Free fatty acids	Disrupts the movement of ADP into and ATP out of the mitochondria at the ADP/ATP antiporter
Mitochondria inner membrane	Substituted phenols (pentachlorophenol and dinitrophenol) Lipophilic amines (amiodarone, perhexiline, buprenorphine) Benzonitrile Thiadiazol herbicides NSAIDs with ionizable groups (salicylates, diclofenac, indomethacin, piroxicam) Valinomycin Chlordecone	Uncouples oxidative phosphorylation by disrupting the proton gradient → stops proton flow at ATP synthase → stops ATP synthesis
Mitochondria inner membrane	Doxorubicin MPP <sup>+</sup> Naphthoquinones (menadione) <i>N</i> -nitrosamines Paraquat	Diverts electrons to alternate pathways (as opposed to the electron-transport chain)

ADP = adenosine diphosphate; ATP = adenosine triphosphate; DDT = dichlorodiphenyltrichloroethane; GAPDH = glyceraldehyde 3-phosphate dehydrogenase; MPP<sup>+</sup> = 1-methyl-4-phenylpyridinium. NADH = Nicotinamide adenine dinucleotide; NSAIDs = nonsteroidal antiinflammatory drugs.

**FIGURE 11-6.** During glycolysis, the anaerobic metabolism of 1 mole of glucose to 2 moles of pyruvate results in the net production of 2 moles of ATP. Arsenate ( $\text{As}^{5+}$ ) results in the creation of an unstable intermediary that bypasses a step that typically creates one of those moles of ATP. Pyruvate kinase and phosphofructokinase, the enzymes whose activities are regulated by glucagon via cyclic adenosine monophosphate-dependent phosphokinase, are shown.

aconitase within the cycle, resulting in citrate accumulation and the termination of oxidative metabolism (Fig. 11-3) (Chap. 113).

Thiamine is an important cofactor for 2 citric acid cycle enzymes: the conversion of pyruvate to acetyl-CoA by pyruvate decarboxylase and for the conversion of  $\alpha$ -ketoglutarate to succinyl-CoA by  $\alpha$ -ketoglutarate dehydrogenase (Fig. 11-3).<sup>30</sup> The life-threatening effects of thiamine deficiency are likely related to impairment of these enzyme functions (Antidotes in Depth: A27). Chronic alcoholics have poor nutrition intake with impaired thiamine absorption. Thiamine deficiency damages cholinergic neurons in the basal forebrain leading to a syndrome of diencephalic amnesia and contributes to the pathophysiology of Wernicke encephalopathy and the Korsakoff psychosis. These cholinergic neurons have high energy demands and are more sensitive to inhibitions of glucose metabolism through thiamine-dependent enzymes.<sup>76</sup>

## The Electron Transport Chain

The electron transport chain is the location where the “phosphorylation” of oxidative phosphorylation occurs. Oxidative phosphorylation is the creation of high-energy bonds by phosphorylation of adenosine diphosphate (ADP) to ATP, “coupled” to the transfer of electrons from reduced coenzymes to molecular oxygen via the electron transport chain. The success of aerobic metabolism requires the disposal of electrons within NADH and  $\text{FADH}_2$ , generated by oxidative metabolism within glycolysis and the citric acid cycle. The electron transport chain consists of a series of cytochrome–enzyme complexes within the inner mitochondrial membrane (Fig. 11-3). Within these complexes, NADH is split into  $\text{NAD}^+ + \text{H}^+$  plus 2 electrons at complex I at the beginning of the chain whereas  $\text{FADH}_2$  is split into  $\text{FAD} + 2\text{H}^+$  plus 2 electrons at complex II. These reactions have 2 results. First, the regenerated  $\text{NAD}^+$  and  $\text{FAD}$  are recycled back to the citric acid cycle, enabling oxidative metabolism to continue. Second, these actions provide the energy required to pump

protons ( $\text{H}^+$ ) from the mitochondrial matrix into the intermembrane space. This action causes the matrix to become relatively alkaline compared to the now acidified intermembrane space and the creation of a proton gradient across the inner mitochondrial membrane (mitochondrial membrane potential,  $\Delta\Psi_m \sim 150\text{--}180\text{ mV}$ ).<sup>87</sup> The final step in the electron flow of oxidative phosphorylation is the reduction of molecular oxygen to water by complex IV, cytochrome  $a\text{-}a_3$  (Fig. 11-3).<sup>30,59</sup> This  $\text{H}^+$  gradient provides the energy needed to create the high-energy bonds of ATP at complex V (ATP synthase).

In total, aerobic glucose metabolism generates 36 moles of ATP. Glycolysis contributes 2 moles of ATP, 2 moles of NADH, and 2 moles of pyruvate. Pyruvate dehydrogenase converts pyruvate to acetyl-CoA while generating another 2 moles of NADH per mole of glucose. The citric acid cycle uses acetyl-CoA to generate 6 moles of NADH, 2 moles of  $\text{FADH}_2$ , and 2 mol of GTP per mole of glucose. Each mole of NADH via the electron transport chain produces 3 moles of ATP. Flavin adenine dinucleotide donates electrons later in the chain, so it only produces 2 moles of ATP. The entire process generates 2 moles of ATP, 10 moles of NADH (30 moles of ATP), and 2 moles of  $\text{FADH}_2$  (4 moles of ATP) for a total of 36 moles of ATP and 2 moles of GTP per mole of glucose.

Mitochondria oxidize substrates, consume oxygen, produce  $\text{CO}_2$ , and make ATP. Xenobiotics that interrupt oxidative phosphorylation impair ATP production either by inhibiting specific electron chain complexes or by acting as “uncouplers.” Both of these mechanisms result in rapid depletion of cellular energy stores, followed by failure of ATP-dependent active transport pumps, loss of essential electrolyte gradients, and increases in cell volume.<sup>59</sup>

Inhibitors of specific cytochromes block electron transport and cause an accumulation of reduced intermediates proximal to the site of inhibition. This stops the regeneration of oxidized substrates for the citric acid cycle, particularly  $\text{NAD}^+$  and  $\text{FAD}$ , further impairing oxidative metabolism. Cyanide, carbon monoxide, and hydrogen sulfide block the cytochrome  $a\text{-}a_3$ -mediated reduction of  $\text{O}_2$  to  $\text{H}_2\text{O}$ . The very dramatic clinical effects of these exposures illustrate the importance of aerobic metabolism (Chap. 123). Other xenobiotics are less commonly associated with inhibition of the electron transport chain (Table 11-3).<sup>110,116</sup>

Severe metabolic acidosis is a clinical manifestation of xenobiotics that inhibit aerobic respiration. Lactate (the base form of lactic acid) accumulates during anaerobic respiration but is only a surrogate marker for metabolic acidosis associated with the impairment of oxidative metabolism.<sup>60</sup> The process of anaerobic glycolysis from glucose to pyruvate and subsequently to lactate is  $\text{H}^+$  neutral (Fig. 11-7, Equation 1). The  $\text{H}^+$  excess results from ATP hydrolysis by energy-requiring cellular processes. The hydrolysis of a high-energy bond in ATP yields ADP, phosphate,  $\text{H}^+$ , and energy (Fig. 11-7, Equation 2). In total, 1 mole of glucose via anaerobic glycolysis yields 2 moles of lactate and 2 moles of  $\text{H}^+$  (Fig. 11-7, Equation 3). Therefore, the hydrolysis of ATP under anaerobic conditions contributes to metabolic acidosis rather than the dissociation of lactic acid to lactate.<sup>68</sup> Conversely during aerobic respiration and oxidative phosphorylation, the process of ATP generation via ATP synthase consumes the  $\text{H}^+$  gradient created by the electron transport chain and largely balances  $\text{H}^+$  production during ATP hydrolysis.

Xenobiotics that uncouple oxidative phosphorylation, like inhibitors of the electron transport chain, reduce ATP synthesis. However, with uncouplers, protons continue to be pumped into the intermembrane space, electrons continue to flow down the chain to reduce oxygen, and substrate consumption continues. Uncouplers dissipate the proton gradient across the mitochondrial inner membrane by allowing the protons to cross back into the mitochondrial matrix. Because it is the proton gradient that drives the production of ATP at complex V, ATP production is reduced. Thus, oxygen consumption is “uncoupled” from ATP production. The redox energy created by electron transport that cannot be coupled to ATP synthesis is released as heat. Various xenobiotics uncouple ATP synthesis (Table 11-3). A classic one is dinitrophenol, used as an herbicide and as a weight-loss product (Chap. 40). Xenobiotics that are capable of carrying hydrogen ions across membranes are generally lipophilic weak acids. These xenobiotics must have an acid-dissociable group to carry the proton and a bulky lipophilic group

**FIGURE 11-7.** Equation 1 describes anaerobic glycolysis. Glucose is initially converted to 2 moles of pyruvate via glycolysis and then under anaerobic conditions, pyruvate is converted to lactate. The net gain from these 2 processes is 2 moles of ATP. No change in  $\text{H}^{+}$  concentration occurs. Equation 2 describes the hydrolysis of ATP, which yields both energy for cellular processes and  $\text{H}^{+}$ . Equation 3 is the summation of anaerobic glycolysis with ATP hydrolysis, which shows the conversion of 1 mole of glucose to 2 moles of lactate and 2  $\text{H}^{+}$ . Therefore, the hydrolysis of ATP under anaerobic conditions contributes to metabolic acidosis rather than the dissociation of lactic acid to lactate. P: Inorganic phosphate.

to cross a membrane.<sup>62</sup> Dinitrophenol is able to carry its proton from the cytosol into the more alkaline mitochondrial matrix where it dissociates, acidifying the matrix and destroying the proton gradient across the inner mitochondrial membrane. Interestingly, the phenolate anion of dinitrophenol is relatively lipophilic and can cross back out to the cytosol where it gains a new proton and starts the process over again. Long-chain fatty acids uncouple oxidative phosphorylation by a similar mechanism.<sup>62,116</sup> Fatal exposures to dinitrophenol and to pentachlorophenol, a wood preservative, are associated with severe hyperthermia attributed to heat generation by uncoupled oxidative phosphorylation.<sup>89</sup> The hyperthermia and acidosis associated with severe salicylate poisoning are attributed to its uncoupling of oxidative phosphorylation.<sup>107</sup>

### Hexose Monophosphate Shunt

The hexose monophosphate shunt provides the only source of cellular NADPH. Nicotinamide adenine dinucleotide phosphate is used in biosynthetic reactions, particularly fatty acid synthesis, and is an important source of reducing power for the maintenance of sulfhydryl groups that protect the cell from free radical injury.<sup>10,47</sup> As noted earlier, G6PD is a key enzyme in the pathway (Fig. 11-8). Reduced glutathione, which is quantitatively the most important antioxidant in cells, depends on the availability of NADPH. Red blood cells are especially vulnerable to deficiency of NADPH, which results in hemolysis during oxidative stress.

Another manifestation of oxidative stress in RBCs is the oxidation of the iron in hemoglobin from  $\text{Fe}^{2+}$  to  $\text{Fe}^{3+}$ , producing methemoglobin that occurs both spontaneously and as a response to xenobiotics such as nitrites and aminophenols. Because most reduction of methemoglobin is done by NADH-dependent methemoglobin reductase, which is not deficient in persons who lack G6PD, such persons do not develop methemoglobinemia under normal circumstances. However, when oxidative stress is severe

and methemoglobinemia develops, people who have G6PD deficiency have limited ability to use the alternative NADPH-dependent methemoglobin reductase (Chap. 124).<sup>112</sup>

### Gluconeogenesis

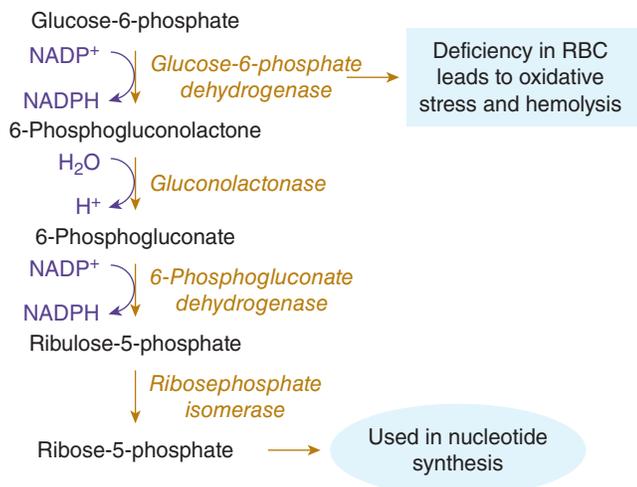

Gluconeogenesis facilitates the conversion of amino acids and intermediates of the citric acid cycle to glucose. It is an important source of glucose during fasting and enables maintenance of glycogen stores. The brain is a major consumer of glucose from both dietary intake and from gluconeogenesis. Other tissues such as the testes, erythrocytes, and kidney medulla rely exclusively on glucose for energy production.<sup>59</sup> Gluconeogenesis occurs primarily in the liver but also in the kidney. Most of the steps in the synthesis of glucose from pyruvate are simply the reverse of glycolysis, with 3 irreversible exceptions: (1) the conversion of glucose-6-phosphate to glucose; (2) the conversion of fructose-1,6-diphosphate to fructose-6-phosphate; and (3) the synthesis of phosphoenolpyruvate from pyruvate. The synthesis of phosphoenolpyruvate from pyruvate is especially complex. Pyruvate is first converted to oxaloacetate within the mitochondria; then to malate, which is transported out of the mitochondria and converted in the cytosol back to oxaloacetate; and then to phosphoenolpyruvate (Fig. 11-9). Certain amino acids—notably alanine, glutamate, and aspartate—are readily converted to citric acid cycle intermediates and can be used in the synthesis of glucose through this cycle.<sup>59</sup> Glycerol, produced by the breakdown of triglycerides in adipose tissue, is another substrate for gluconeogenesis.

The regulation of gluconeogenesis is opposite to that of glycolysis, stimulated by glucagon and catecholamines but inhibited by insulin. Gluconeogenesis requires the cytosolic  $\text{NAD}^{+}$  and mitochondrial NADH. It is impaired by processes that increase the cytosol-reducing potential as measured by the cytosol  $\text{NADH}/\text{NAD}^{+}$  ratio (see discussion below).

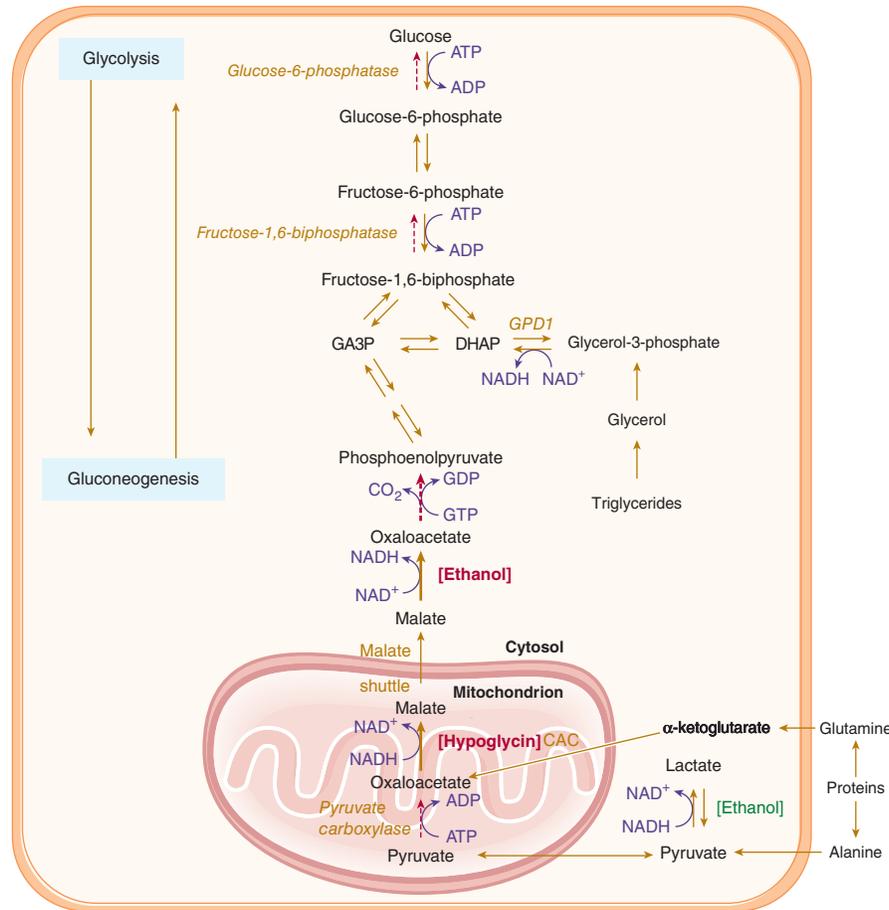

A number of xenobiotics impair gluconeogenesis, resulting in hypoglycemia when glycogen stores are depleted (Table 11-3). Hypoglycin A, an unusual amino acid found in unripe ackee fruit that is the cause of Jamaican vomiting sickness, and its metabolite, methylenecyclopropylacetic acid (MCPA), found in lychee fruit, produce profound hypoglycemia.<sup>98,105</sup> Methylenecyclopropylacetic acid indirectly inhibits gluconeogenesis by blocking the oxidation of long-chain fatty acids, an important source of NADH in mitochondria. It also inhibits the metabolism of several glycogenic amino acids, including leucine, isoleucine, and tryptophan, and blocks their entrance into the citric acid cycle. Methylenecyclopropylacetic acid also prevents the transport of malate out of the mitochondria.<sup>93,105,106</sup> Hypoglycemia often occurs in fasting patients with elevated ethanol concentrations.<sup>4,32,61</sup> This is likely a result of the impairment of gluconeogenesis by the increased cytosolic  $\text{NADH}:\text{NAD}^{+}$  ratio associated with the metabolism of ethanol. This inhibits the 2 cytosolic steps that require  $\text{NAD}^{+}$ —the conversions of lactate to pyruvate and of malate to oxaloacetate.<sup>2,61</sup>

### Fatty Acid Metabolism

Fatty acid metabolism occurs primarily in hepatocytes. Fatty acids mobilized in adipose tissue enter hepatocytes by passive diffusion. Fatty acid synthesis is stimulated by insulin and inhibited by glucagon and epinephrine. Acetyl-CoA is the primary building block of free fatty acids (FFAs). In energy-depleted cells, fatty acids are combined with glycerol phosphate to form triacylglycerol (triglycerides), the first step in the synthesis of fat for storage. Hepatic triglycerides are bound to lipoprotein to form very-low-density lipoprotein and then transported and stored in adipocytes.

**FIGURE 11-8.** The oxidation reactions of the hexose monophosphate shunt are an important source of nicotinamide adenine dinucleotide phosphate (NADPH) for reductive biosynthesis and for protection of cells against oxidative stress. Deficiency of glucose-6-phosphate dehydrogenase, the first enzyme in the pathway, may result in red blood cell (RBC) hemolysis during oxidative stress.

**FIGURE 11-9.** Gluconeogenesis reverses the steps of glycolysis, with the exception of the bypass of the 3 irreversible steps shown. The step from pyruvate to phosphoenolpyruvate involves both cytosolic and mitochondrial reactions that use ATP. Hypoglycin A inhibits the intramitochondrial conversion of oxaloacetate to malate by depleting NADH through interference with  $\beta$ -oxidation of fatty acids. Ethanol decreases cytosolic supplies of NAD<sup>+</sup>. Alternative substrates for gluconeogenesis include glycerol from triglycerides and numerous amino acids. DHAP = dihydroxyacetone phosphate, GA3P = glyceraldehyde 3 phosphate, GPD1 = glycerol-3-phosphate dehydrogenase, CAC = citric acid cycle.

When hepatocytes are energy depleted, triglycerides are broken down to FFAs and glycerol. This process is suppressed by insulin but supported by glucagon or epinephrine. Free fatty acids undergo  $\beta$ -oxidation in the mitochondria, a process that breaks the FFA into acetyl-CoA molecules that can then enter the citric acid cycle. Free fatty acids require activation before transport into the mitochondria. This is accomplished by acyl-coenzyme A (acyl-CoA) synthetase, which adds a CoA group to the FFA in an energy-dependent synthetic reaction. These are transported into the mitochondria by a process that utilizes cyclical binding to carnitine, a “carnitine shuttle” (Fig. 11-3). Once inside the mitochondria, FFAs are converted to acetyl-CoA by  $\beta$ -oxidation, involving the sequential removal of 2-carbon fragments, each time acting at the second carbon (the  $\beta$  carbon) position of the fatty acid. Each 2-carbon mole removed from the FFA produces one NADH and one FADH<sub>2</sub>, which are oxidized in the electron transport chain, and 1 mole of acetyl-CoA, which enters the citric acid cycle. This process produces 1.3 times more ATP per mole of carbon metabolized than does the oxidative metabolism of glucose or other carbohydrates.<sup>59</sup>

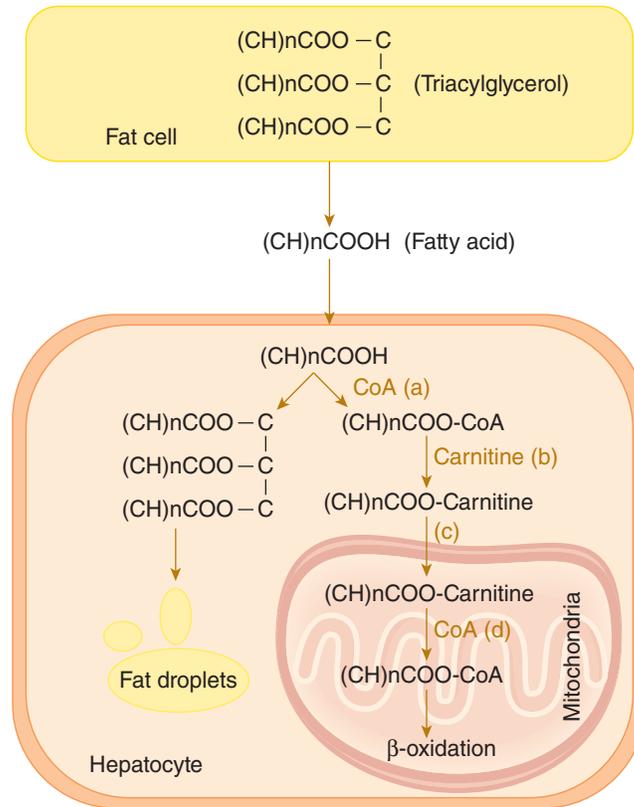

Many xenobiotics interrupt fatty acid metabolism at various steps, resulting in accumulation of triglycerides in the liver (Table 11-3; Fig. 11-10). The mechanisms of disruption of fatty acid metabolism are poorly defined.<sup>18</sup> Some xenobiotics, including ethanol, hypoglycin A, MCPA, and nucleoside analogs, inhibit  $\beta$ -oxidation, at least indirectly, through effects on NADH concentrations. Protease inhibitors are associated with a syndrome of peripheral fat wasting, central adiposity, hyperlipidemia, and insulin resistance.

The condition of alcoholic ketoacidosis is related in part to inhibition of gluconeogenesis in the alcoholic patient and in part to an exuberant response to nutritional needs by the fatty acid machinery. In a chronic alcohol-users,

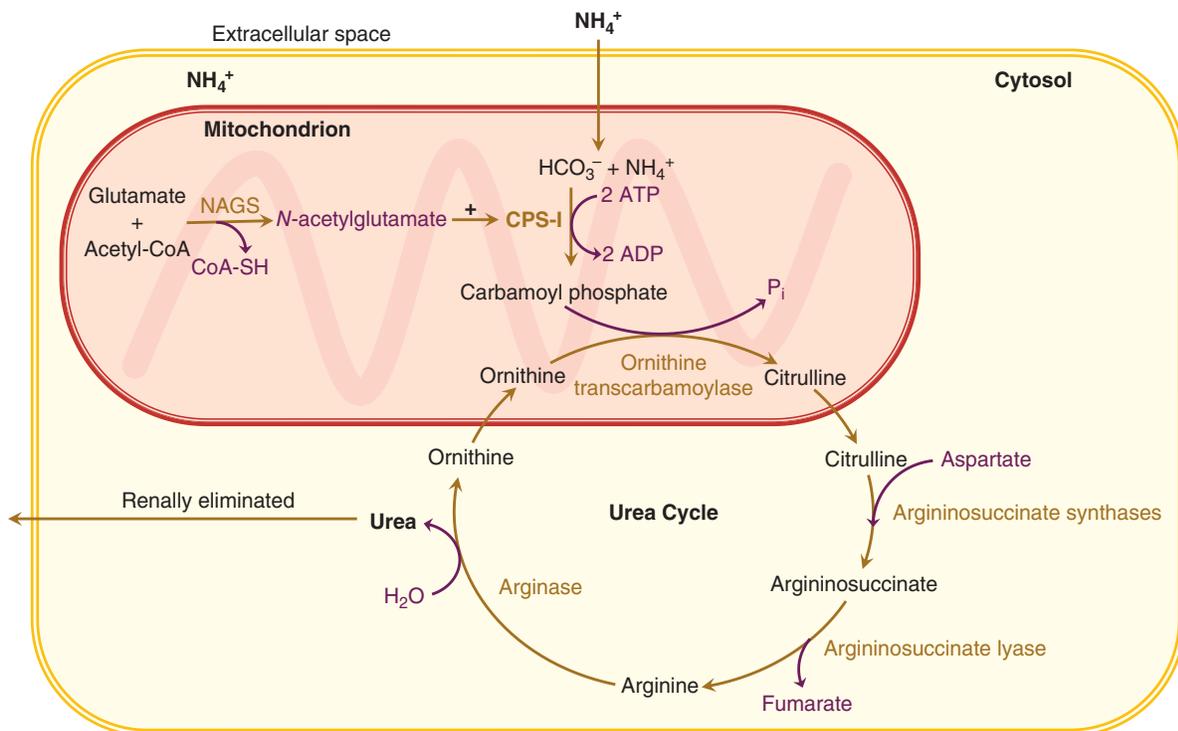

decreased intake of carbohydrates and impaired thiamine absorption stimulates a starvation response with increases in serum glucagon, cortisol, growth hormone, and epinephrine concentrations, and decreases in serum insulin. With continued ethanol intake, the metabolism of ethanol via oxidation increases the NADH:NAD<sup>+</sup> ratio, which inhibits hepatic gluconeogenesis. When the need for carbohydrate is not met by gluconeogenesis, lipolysis, which is normally inhibited by insulin, is intensified and fatty acid mobilization progresses. The increased mitochondrial NADH:NAD<sup>+</sup> ratio favors the production of  $\beta$ -hydroxybutyrate over acetoacetate, its oxidized form. The administration of fluids, dextrose, and thiamine to the alcoholic patient leads to correction of this process (Chap. 76).<sup>71</sup>

### Protein and Nitrogen Metabolism

Human nitrogen consumption occurs through dietary intake of free amino acids, polypeptides, and ammonia (via intestinal splitting of urea and amino acids). Amino acids are the basic building blocks of proteins and are built on a backbone of an amino group, a carboxylic acid group, and a middle  $\alpha$  carbon attached to a variable group. The simplest amino acid is glycine, in which the variable group is a hydrogen. Of the 20 major amino acids involved in protein synthesis, 10 are considered essential and only available through dietary intake. The other amino acids can be synthesized by the body via other carbon- and nitrogen-containing molecules. As mentioned above, amino acids such as alanine, glutamate, and aspartate are available for use as citric acid cycle intermediates. Alanine is an important molecule for skeletal muscles for the elimination of nitrogen waste and for energy generation via the glucose-alanine cycle. Myocytes release alanine to the systemic circulation through which it goes to the liver. In the hepatocytes, alanine

**FIGURE 11–10.** Steatosis, an accumulation of fat, results when xenobiotics interfere with the oxidation of fatty acids. Other processes that increase intracellular accumulation of fat include impaired lipoprotein synthesis, impaired lipoprotein release, increased mobilization of free fatty acids, increased uptake of circulating lipids, and increased production of triglycerides. β-Oxidation occurs in the mitochondria. The carnitine shuttle is used to transport long-chain fatty acids from the cellular cytosol across the mitochondrial membrane. The enzymes involved are (a) acyl-CoA synthetase, (b) carnitine palmitoyltransferase I, (c) carnitine acylcarnitine translocase, and (d) carnitine palmitoyltransferase II. Acyl-CoA is the intramitochondrial substrate for β-oxidation. Potential mechanisms of inhibition of β-oxidation include induction of carnitine deficiency, inhibition of the transferase or translocase, and increased NADH:NAD<sup>+</sup> ratio via increased use of NAD<sup>+</sup> or by inhibition of NADH use. The specific site of action is not defined for many toxins that cause steatosis.

**FIGURE 11–11.** Hepatocytes extract circulating free ammonia and combine the ammonia with an amine group from aspartate to form urea, a water-soluble compound eliminated by the kidneys. Carbamoyl phosphate synthetase-1 (CPS-1) is the rate-limiting step of ammonia entry into the urea cycle. In turn, CPS-1 is positively regulated by the formation of N-acetylglutamate via N-acetylglutamate synthetase (NAGS).

converts to pyruvate via alanine transaminase (ALT), releasing its nitrogen group to glutamate. Pyruvate then undergoes gluconeogenesis, and glucose is released back to circulation for myocytes and other cells to use.<sup>59</sup>

Glutamine is the main storage molecule for total body nitrogen/ammonia. A single glutamine molecule contains 2 amino groups. The uptake of ammonia ( $\text{NH}_4^+$ ) into glutamine protects the body from the neurotoxic and alkalemic effects of free ammonia. The removal of an ammonia yields glutamate (a neurotransmitter), and a removal of a second ammonia yields  $\alpha$ -ketoglutarate (a citric acid cycle substrate). As free ammonia is released from glutamine, hepatocytes facilitate the removal of free ammonia from the body via generation of urea by the urea cycle (Fig. 11–11). The activation step of the urea cycle combines  $\text{NH}_4^+$ , bicarbonate, and 2 ATP molecules to create carbamoyl phosphate by carbamoyl phosphate synthetase-I (CPS-I). This process requires an obligate cofactor of *N*-acetylglutamate, a product of glutamate and acetyl-CoA via *N*-acetylglutamate synthetase. Carbamoyl phosphate enters into the urea cycle through ornithine transcarbamylase (OTC), which catalyzes the addition of carbamoyl phosphate to ornithine to make citrulline. Citrulline is subsequently converted to argininosuccinate, arginine, and then back to ornithine. The final step of arginine to ornithine by arginase releases urea. Urea is highly water soluble, and it is renally eliminated from the body.<sup>59</sup>

Inborn errors of metabolism involving the deficiencies of urea cycle enzymes lead to severe hyperammonemia and death if undiagnosed and/or untreated. X-linked OTC deficiency is the most common urea cycle disorder. Several xenobiotics can also induce secondary hyperammonemia by the inhibition of enzymes in the urea cycle (Table 11–4).<sup>20</sup> For example, valproic acid undergoes  $\omega$ -oxidation to yield 2-propyl-4-pentenoate (4-en-VPA) and propionate in an overdose state or when secondary carnitine deficiencies prohibit adequate  $\beta$ -oxidation. Both 4-en-VPA and propionate decrease the generation of *N*-acetylglutamate, which effectively inhibits CPS-I and subsequently the entire urea cycle. Hyperammonemia is a common clinical feature of valproic acid in overdose and occasionally in therapeutic use (Chap. 48).<sup>122</sup>

## SUMMARY

- Biotransformation is a complex process, involving numerous enzyme systems, that usually detoxifies xenobiotics; however, “metabolic activation” occurs.
- Phase I reactions add functional groups to lipophilic xenobiotics to enhance their reactivity, preparing them for further detoxification by synthetic phase II reactions that enhance hydrophilicity and renal elimination.
- The phase I cytochrome P450 (CYP) enzymes biotransform most xenobiotics; CYP3A4 is the most abundant one, metabolizing 50% to 60% of all pharmaceuticals.

- Cytochrome P450 enzyme activity is quite variable because of genetic polymorphisms—genetic changes that exist in at least 1% of the human population. Enzyme activity also varies because of induction and inhibition.
- The most common method of induction is a nuclear receptor–mediated increase in gene transcription. Inhibition of CYP enzymes is the most common cause of harmful drug–drug interactions, the most common type being competitive, where the substrate and inhibitor both bind the active site of the enzyme.
- Xenobiotic disposition is also effected by membrane transporter (MT) proteins that mediate the cellular uptake and efflux of xenobiotics.
- P-glycoprotein is an MT protein that mediates the efflux of xenobiotics from the apical (luminal) membrane of intestinal enterocytes.

This table list is not complete and may reflect some variation in author opinions as to whether a xenobiotic is a substrate, inhibitor, or inducer.

<sup>a</sup>Ritonavir has paradoxical dose- and time-dependent inhibitory and induction effects.

<sup>b</sup>Substrate is sensitive; area under the concentration versus time curve (AUC) values have been shown to increase 5-fold or more when coadministered with a known CYP3A inhibitor.

<sup>c</sup>Substrate has a narrow therapeutic range, and safety concerns occur when coadministered with an inhibitor.

<sup>d</sup>A strong inhibitor (at least a 5-fold increase in AUC or greater than 80% decrease in clearance).

<sup>e</sup>A strong inducer (at least a 4-fold increase in enzyme activity).

ATRA = all-*trans*-retinoic acid; DMF = *N,N*-dimethylformamide; DEET = *N,N*-diethyl-meta-toluamide; MDMA = 3,4-methylenedioxymethamphetamine; NSAID = nonsteroidal antiinflammatory drug; PCB = polychlorinated biphenyl; PPI = proton pump inhibitor; SSRI = selective serotonin reuptake inhibitor; TCDD = 2,3,7,8-tetrachlorodibenzodioxin.

## FLUID, ELECTROLYTE, AND ACID–BASE PRINCIPLES

Alan N. Charney and Robert S. Hoffman

A meaningful analysis of fluid, electrolyte, and acid–base abnormalities is dependent on the history and physical examination of each patient. Although a rigorous appraisal of laboratory parameters often yields the correct differential diagnosis, the clinical characteristics provide an understanding of the extracellular fluid volume (ECFV) and pathophysiology. Thus, the evaluation always begins with an overall assessment of the patient.

### INITIAL PATIENT ASSESSMENT

#### History

The history should be directed toward clinical questions associated with fluid and electrolyte abnormalities. Xenobiotic exposure commonly results in fluid losses through the respiratory system (hyperpnea and tachypnea), gastrointestinal (GI) tract (vomiting and diarrhea), skin (diaphoresis), and kidneys (polyuria). Patients with ECFV depletion often complain of dizziness, thirst, and weakness. Usually the patients can identify the source of fluid loss.

A history of exposure to nonprescription and prescription medications, alternative or complementary therapies, and other xenobiotics can suggest the most likely electrolyte or acid–base abnormality. In addition, patient characteristics (race, gender, age), premorbid medical conditions, and the ambient temperature and humidity should always be considered.

#### Physical Examination

The vital signs are invariably affected by significant alterations in ECFV. Whereas hypotension and tachycardia often characterize life-threatening ECFV depletion, an increase of the heart rate and a narrowing of the pulse pressure are the earliest findings. Abnormalities are best recognized through an ongoing dynamic evaluation, realizing that the measurement of a single set of supine vital signs offers useful information only when markedly abnormal. Orthostatic pulse and blood pressure measurements provide a more meaningful determination of functional ECFV status (Chaps. 3 and 16).

The respiratory rate and pattern can give clues to the patient's metabolic status. In the absence of lung disease, hyperventilation (manifested by tachypnea, hyperpnea, or both) is often either caused by a primary respiratory stimulus (respiratory alkalosis) or is a response to the presence of metabolic acidosis. Although hypoventilation (bradypnea or hypopnea or both) is present in patients with metabolic alkalosis, it is rarely clinically significant except in the presence of chronic lung disease or in combination with respiratory depressant xenobiotics. More commonly, hypoventilation is caused by a primary depression of consciousness and respiration with resulting respiratory acidosis. Unless the clinical scenario (eg, nature of the poisoning, presence of renal or pulmonary disease, and findings on physical examination or laboratory testing) is classic, arterial or venous blood gas analysis is recommended to determine the acid–base disorder associated with a change in ventilation.

The skin should be evaluated for turgor, moisture, and the presence or absence of edema. The moisture of the mucous membranes can also provide valuable information. These are nonspecific parameters and often fail to correlate directly with the status of hydration. This dissociation is especially true with xenobiotic exposure because many xenobiotics alter skin and mucous membrane moisture without necessarily altering ECFV status. For example, antimuscarinics commonly result in dry mucous membranes and skin without producing ECFV depletion. Conversely, patients exposed to sympathomimetics such as cocaine or cholinergics such as organic phosphorus compounds have moist skin and mucous membranes even in the presence of significant fluid losses. This dissociation of ECFV and cutaneous characteristics reinforces the need to assess patients meticulously.

The physical findings associated with electrolyte abnormalities are generally nonspecific. Hyponatremia, hypernatremia, hypercalcemia, and hypermagnesemia all produce a depressed level of consciousness. Neuromuscular excitability such as tremor and hyperreflexia occurs with hypocalcemia, hypomagnesemia, hyponatremia, and hyperkalemia. Weakness results from both hyperkalemia and hypokalemia. Also, multiple, concurrent electrolyte disorders can produce confusing clinical presentations, or patients can appear normal. Diagnostic findings, such as Chvostek and Trousseau signs (primarily found in hypocalcemia), are useful in assessing patients with potential xenobiotic exposures.

#### Rapid Diagnostic Tools

The electrocardiogram (ECG) is a useful tool for screening several common electrolyte abnormalities (Chap. 15). It is easy to perform, rapid, inexpensive, and routinely available. Unfortunately, because poor sensitivity (0.43) and moderate specificity (0.86) were demonstrated when ECGs were used to diagnose hyperkalemia, in actuality the test is of limited diagnostic value.<sup>151</sup> However, the ECG is valuable for the evaluation of changes in serum potassium and calcium concentrations ( $[K^+]$  and  $[Ca^{2+}]$ ) in an individual patient.

Assessment of urine specific gravity by dipstick analysis provides valuable information about ECFV status. A high urine specific gravity ( $>1.015$ ) signifies concentrated urine and is often associated with ECFV depletion. However, urine specific gravity is often similarly elevated in conditions of ECFV excess, such as congestive heart failure or third spacing. Similarly, patients with excess antidiuretic hormone (ADH) secretion (eg, due to methylenedioxymethamphetamine {MDMA} exposure) excrete concentrated urine (specific gravity  $>1.015$ ) even in the presence of a normal or expanded ECFV. Furthermore, when renal impairment or diuretic use is the source of the volume loss, the specific gravity is usually approximately 1.010 (known as isosthenuria). Finally, patients with lithium-induced diabetes insipidus (DI) excrete dilute urine (specific gravity  $<1.010$ ) despite ongoing water losses and contraction of the ECFV.

The urine dipstick is highly reliable and rapidly available for determining the presence of ketones, which are often associated with common causes of metabolic acidosis (eg, diabetic ketoacidosis, salicylate poisoning, alcoholic ketoacidosis). The urine ferric chloride test rapidly detects exposure to salicylates with a high sensitivity and specificity although it is rarely used today in locations where salicylate concentrations can be obtained rapidly (Chap. 37).

#### Laboratory Studies

A simultaneous determination of the venous serum electrolytes, blood urea nitrogen (BUN), glucose, and arterial or venous blood gases are adequate to determine the nature of the most common acid–base, fluid, and electrolyte abnormalities. More complex clinical problems require determinations of urine and serum osmolalities, urine electrolytes, serum ketones, serum lactate, and other tests. A systematic approach to common problems is discussed in the following sections.

### ACID–BASE ABNORMALITIES

#### Definitions

The lack of a clear understanding and precise use of the terminology of acid–base disorders often leads to confusion and error. The following definitions provide the appropriate frame of reference for the remainder of the chapter and this textbook.

Whereas the terms *acidosis* and *alkalosis* refer to processes that tend to change pH in a given direction, *acidemia* and *alkalemia* only refer to the actual pH. By definition, a patient is said to have:

- A *metabolic acidosis* if the arterial pH is less than 7.40 and serum bicarbonate concentration ( $[\text{HCO}_3^-]$ ) is less than 24 mEq/L. Because acidemia stimulates ventilation (respiratory compensation), metabolic acidosis is usually accompanied by a  $\text{PCO}_2$  less than 40 mm Hg.
- A *metabolic alkalosis* if the arterial pH is greater than 7.40 and serum  $[\text{HCO}_3^-]$  is greater than 24 mEq/L. Because alkalemia inhibits ventilation (respiratory compensation), metabolic alkalosis is usually accompanied by a  $\text{PCO}_2$  greater than 40 mm Hg.
- A *respiratory acidosis* if the arterial pH is less than 7.40 and partial pressure of carbon dioxide ( $\text{PCO}_2$ ) is greater than 40 mm Hg. Because an elevated  $\text{PCO}_2$  stimulates renal acid excretion and the generation of  $\text{HCO}_3^-$  (renal compensation), respiratory acidosis is usually accompanied by a serum  $[\text{HCO}_3^-]$  greater than 24 mEq/L.
- A *respiratory alkalosis* if the arterial pH is greater than 7.40 and  $\text{PCO}_2$  is less than 40 mm Hg. Because a decreased  $\text{PCO}_2$  lowers renal acid excretion and increases the excretion of  $\text{HCO}_3^-$  (renal compensation), respiratory alkalosis is usually accompanied by a serum  $[\text{HCO}_3^-]$  less than 24 mEq/L.

It is important to note that under many circumstances, a venous pH permits an approximation of arterial pH. However, when rigorously compared, the arterial blood gas analysis outperforms the venous blood gas analysis especially when findings are subtle.<sup>131</sup> (See Chap. 28 for a further discussion of the relationship between arterial and venous pH.) Any combination of acidosis and alkalosis can be present in any one patient at any given time. The terms *acidemia* and *alkalemia* refer only to the resultant arterial pH of blood (acidemia referring to a pH <7.40 and alkalemia referring to a pH >7.40). These terms do not describe the processes that led to the alteration in pH. Thus, a patient with acidemia must have a primary metabolic or respiratory acidosis but potentially also has an alkalosis present at the same time. Clues to the presence of more than one acid–base abnormality include the clinical presentation, an apparent excess or insufficient “compensation” for the primary acid–base abnormality, a delta gap ratio  $\{(\Delta) \text{ anion gap} / \Delta[\text{HCO}_3^-]\}$  that significantly deviates from one, or an electrolyte abnormality that is uncharacteristic of the primary acid–base disorder.

### Determining the Primary Acid–Base Abnormality

It is helpful to begin by determining whether the patient has an acidosis or an alkalosis. This is followed by an assessment of the pH,  $\text{PCO}_2$ , and  $[\text{HCO}_3^-]$ . With these 3 parameters defined, the patient’s primary acid–base disorder can be classified using the aforementioned definitions. Next it is important to determine whether the compensation of the primary acid–base disorder is appropriate. It is generally assumed that overcompensation cannot occur.<sup>106</sup> That is, if the primary process is metabolic acidosis, respiratory compensation tends to raise the pH toward normal but never to greater than 7.40. If the primary process is respiratory alkalosis, compensatory renal excretion of  $\text{HCO}_3^-$  tends to lower the pH toward normal but not to less than 7.40. The same is true for primary metabolic alkalosis and primary respiratory acidosis. As a rule, compensation for a primary acid–base disorder that appears inadequate or excessive is indicative of the presence of a second primary acid–base disorder.

Based on patient data, the Winters equation (Equation 12–1)<sup>7</sup> predicts the degree of the respiratory compensation (the decrease in  $\text{PCO}_2$ ) in metabolic acidosis as follows:

$$\text{PCO}_2 = (1.5 \times [\text{HCO}_3^-]) + 8 \pm 2 \quad (\text{Eq. 12-1})$$

Thus, in a patient with an arterial  $[\text{HCO}_3^-]$  of 12 mEq/L, the predicted  $\text{PCO}_2$  is calculated as

$$(1.5 \times 12) + 8 \pm 2$$

or

$$26 \pm 2 \text{ mm Hg.}$$

If the actual  $\text{PCO}_2$  is substantially lower than is predicted by the Winters equation, it can be concluded that both a primary metabolic acidosis and a primary respiratory alkalosis are present. If the  $\text{PCO}_2$  is substantially higher than the predicted value, then both a primary metabolic acidosis and a primary respiratory acidosis are present.

An alternative to the Winters equation is the observation by Narins and Emmett that in compensated metabolic acidosis, the arterial  $\text{PCO}_2$  is usually the same as the last 2 digits of the arterial pH.<sup>106</sup> For example, a pH of 7.26 predicts a  $\text{PCO}_2$  of 26 mm Hg.

Guidelines are also available to predict the compensation for metabolic alkalosis,<sup>64</sup> respiratory acidosis, and respiratory alkalosis.<sup>83</sup> Patients with a metabolic alkalosis compensate by hypoventilating, resulting in an increase of their  $\text{PCO}_2$  above 40 mm Hg. However, the concomitant development of hypoxemia limits this compensation so that respiratory compensation in the presence of a metabolic alkalosis usually results in a  $\text{PCO}_2$  of 55 mm Hg or less. It is difficult to be more accurate about the expected respiratory compensation for a metabolic alkalosis, although the compensation, as in the case of metabolic acidosis, is nearly complete within hours of onset.

By contrast, the degree of compensation in primary respiratory disorders depends on the length of time the disorder has been present. In a matter of minutes, primary respiratory acidosis results in an increase in the serum  $[\text{HCO}_3^-]$  of 0.1 times the increase in the  $\text{PCO}_2$ . This increase is a result of the production and dissociation of  $\text{H}_2\text{CO}_3$ . Over a period of days, respiratory acidosis causes the compensatory renal excretion of acid. This compensation increases the serum  $[\text{HCO}_3^-]$  by 0.3 times the increase in  $\text{PCO}_2$ . Primary respiratory alkalosis acutely decreases the serum  $[\text{HCO}_3^-]$  by 0.2 times the decrease in  $\text{PCO}_2$ . If a respiratory alkalosis persists for several days, renal compensation, by the urinary excretion of  $\text{HCO}_3^-$ , decreases the serum  $[\text{HCO}_3^-]$  by 0.4 times the decrease in  $\text{PCO}_2$ .

### Calculating the Anion Gap

The concept of the anion gap is said to have arisen from the “Gamblegram” originally described in 1939<sup>51</sup>; however, its use was not popularized until the determination of serum electrolytes became routinely available. The law of electroneutrality states that the net positive and negative charges of all fluids must be equal. Thus, all of the negative charges present in the serum must equal all of the positive charges, and the sum of the positive charges minus the sum of the negative charges must equal zero. The problem that immediately arose (and produced an “anion gap”) was that all charged species in the serum are not routinely measured.

Normally present but not routinely measured cations include calcium and magnesium; normally present but not routinely measured anions include phosphate, sulfate, albumin, and organic anions (eg, lactate and pyruvate).<sup>41</sup> Whereas  $\text{Na}^+$  and  $\text{K}^+$  normally account for 95% of extracellular cations,  $\text{Cl}^-$  and  $\text{HCO}_3^-$  account for 85% of extracellular anions. Thus, because more cations than anions are among the electrolytes usually measured, subtracting the anions from the cations normally yields a positive number, known as the anion gap. The anion gap is therefore derived as shown in Equation 12–2:

$$\begin{aligned} [\text{Na}^+] + [\text{K}^+] + [\text{Unmeasured Cations } (U_c)] &= [\text{Cl}^-] + [\text{HCO}_3^-] \\ &+ [\text{Unmeasured Anions } (U_a)] \\ \text{Anion Gap} &= [U_a] - [U_c] \end{aligned}$$

or

$$\text{Anion Gap} = ([\text{Na}^+] + [\text{K}^+]) - ([\text{Cl}^-] + [\text{HCO}_3^-]) \quad (\text{Eq. 12-2})$$

Because the serum  $[\text{K}^+]$  varies over a limited range of perhaps 1 to 2 mEq/L above and below normal and therefore rarely significantly alters the anion gap, it is often deleted from the equation for simplicity. Most prefer this approach, yielding Equation 12–3:

$$\text{Anion Gap} = ([\text{Na}^+]) - ([\text{Cl}^-] + [\text{HCO}_3^-]) \quad (\text{Eq. 12-3})$$

Using Equation 12–3, the normal anion gap was initially determined to be  $12 \pm 4$  mEq/L.<sup>41</sup> However, because the normal serum  $[\text{Cl}^-]$  is higher on

**TABLE 12–1** Xenobiotic and Other Causes of a High Anion Gap

Increase in Unmeasured Anions	Decrease in Unmeasured Cations
Metabolic acidosis (Table 12–3)	Simultaneous hypomagnesemia, hypocalcemia, or hypokalemia

Sodium lactate	
Sodium acetate	
Therapy with certain antibiotics	
Carbenicillin	
Sodium penicillin	
Alkalosis	

current laboratory instrumentation, the current range for a normal anion gap is  $7 \pm 4$  mEq/L.<sup>149</sup>

A variety of pathologic conditions result in a rise or fall of the anion gap. High anion gaps result from increased presence of unmeasured anions or decreased presence of unmeasured cations (Table 12–1).<sup>41,89</sup> Conversely, a low anion gap results from an increase in unmeasured cations or a decrease in unmeasured anions (Table 12–2).<sup>41,49,59,129</sup>

### Anion Gap Reliability

Several authors have discussed the usefulness of the anion gap determination.<sup>21,50,72</sup> When 57 hospitalized patients were studied to determine the cause of elevated anion gaps in patients whose anion gap was greater than 30 mEq/L, the cause was always a metabolic acidosis with elevations of lactate or ketones.<sup>50</sup> In patients with smaller elevations of the anion gap, the ability to define the cause of the elevation diminished; in only 14% of patients with anion gaps of 17 to 19 mEq/L could the cause be determined. Another study determined that although the anion gap is often used as a screening test for hyperlactatemia (as a sign of poor perfusion), only patients with the highest serum lactate concentrations had elevated anion gaps.<sup>72</sup> Finally, in a sample of 571 patients, those with greater elevations in anion gaps tended to have more severe illness. This logically correlated with higher admission rates, a greater percentage of admissions to intensive care units, and a higher mortality rate.<sup>21</sup> Thus, although the absence of an increased anion gap does not exclude significant illness, a very elevated anion gap can generally be attributed to a specific cause (typically a disorder that is associated with elevated lactate or ketones) and usually indicates a relatively severe illness.

### Metabolic Acidosis

After the diagnosis of metabolic acidosis is established by finding an arterial pH less than 7.40,  $[\text{HCO}_3^-] < 24$  mEq/L, and  $\text{PCO}_2 < 40$  mm Hg, the serum anion gap should be analyzed. Indeed, the popularity of the anion gap is primarily based on its usefulness in categorizing metabolic acidosis as being of the high anion gap or normal anion gap type. This determination should be made after correcting the anion gap for the effect of hypoalbuminemia,

**TABLE 12–2** Xenobiotic and Other Causes of a Low Anion Gap

Increase in Unmeasured Cations	Decrease in Unmeasured Anions	Overestimation of Chloride
Hypercalcemia	Hypoalbuminemia	Bromism
Hypermagnesemia	Hemodilution	Iodism
Hyperkalemia		Nitrate excess
Lithium poisoning		
Multiple myeloma		

**TABLE 12–3** Xenobiotic and Other Causes of a High Anion Gap Metabolic Acidosis

Carbon monoxide	Methanol
Cyanide	Paraldehyde
Ethylene glycol	Phenformin
Hydrogen sulfide	Propylene glycol
Isoniazid	Salicylates
Iron	Sulfur (inorganic)
Ketoacidoses (diabetic, alcoholic, and starvation)	Theophylline
Lactate	Toluene
Metformin	Uremia (acute or chronic kidney failure)

a common and important confounding factor in chronically ill patients. The anion gap decreases approximately 3 mEq/L per 1 g/dL decrease in the serum [albumin].<sup>47</sup> In general, the electrolyte abnormalities that frequently accompany metabolic acidosis usually have only small and insignificant effects on the anion gap.

It should be noted that although many clinicians rely on the mnemonics MUDPILES (M, methanol; U, uremia; D, diabetic ketoacidosis; P, paraldehyde; I, iron; L, lactic acidosis; E, ethylene glycol; and S, salicylates) or KULT (K, ketones; U, uremia; L, lactate; T, toxins), to help remember this differential diagnosis, these mnemonics include rarely used drugs (phenformin, paraldehyde) and omit important others (eg, metformin, cyanide).

A high anion gap metabolic acidosis results from the absorption or generation of an acid that dissociates into an anion other than  $\text{Cl}^-$  that has neither been excreted nor metabolized at the time the anion gap is determined. The retention of this “unmeasured” anion (eg, glycolate in ethylene glycol poisoning) increases the anion gap. By contrast, a normal anion gap metabolic acidosis results from the absorption or generation of an acid that dissociates into  $\text{H}^+$  and  $\text{Cl}^-$ . In this case, the “measured”  $\text{Cl}^-$  is retained as  $\text{HCO}_3^-$ , is titrated, and its concentration reduced during the acidosis, and no increase in anion gap is produced. Normal anion gap acidosis, also referred to as hyperchloremic metabolic acidosis, is typically caused by intestinal or renal bicarbonate losses as in diarrhea or renal tubular acidosis, respectively. Other causes of high and normal anion gap metabolic acidoses are described elsewhere<sup>3,4</sup> and shown in Tables 12–3 and 12–4.

## Narrowing the Differential Diagnosis of a High Anion Gap Metabolic Acidosis

The ability to diagnose the etiology of a high anion gap metabolic acidosis is an essential skill in clinical medicine. The following discussion provides a rapid and cost-effective approach to the problem. As always, the clinical history and physical examination provide essential clues to the diagnosis. For example, iron poisoning is virtually always associated with significant GI symptoms, the absence of which essentially excludes the diagnosis (Chap. 45). Furthermore, when iron overdose is suspected, an abdominal radiograph often shows the presence of iron-containing tablets. The acidosis associated with isoniazid (INH) toxicity results from seizures, the absence of which excludes INH as the cause of a metabolic acidosis (Chap. 56). Methanol poisoning is classically associated with visual complaints or abnormal finding on funduscopic examination (Chap. 106). Methyl salicylate has a characteristic wintergreen odor (Chap. 37). When these findings are absent, the laboratory analysis must be relied on, as follows:

1. *Begin with the serum electrolytes, BUN, creatinine, and glucose.* A rapid blood glucose reagent test should be performed to help confirm or exclude hyperglycemia. Although hyperglycemia should raise the possibility of diabetic ketoacidosis, the absence of an elevated serum glucose does not exclude the possibility of euglycemic diabetic ketoacidosis,<sup>11,27,74</sup> alcoholic or starvation ketoacidosis, which are often associated with normal or even low serum glucose concentrations. An elevated BUN and creatinine are essential to diagnose acute or chronic kidney failure.
2. *Proceed to the urinalysis.* If there is a suspicion of a high anion gap metabolic acidosis and only the arterial or venous blood gas analysis is completed, the evaluation can easily begin here while the electrolyte determinations are pending. A urine dipstick for glucose and ketones helps with the diagnosis of diabetic ketoacidosis and other ketoacidoses. However, the absence of urinary ketones does not exclude a diagnosis of alcoholic ketoacidosis<sup>48</sup> (Chap. 76), and ketones are often present in patients with severe salicylism (Chap. 37) and biguanide-associated metabolic acidosis (Chap. 47). If timed properly, the urine of a patient who has ingested fluorescein-containing antifreeze (ethylene glycol) fluoresces when exposed to a Wood lamp. Also, because ethylene glycol is metabolized to oxalate, calcium oxalate crystals are present in the urine of approximately half of poisoned patients. Although the presence of a fluorescent urine and calcium oxalate crystals are useful findings, their absence does not exclude ethylene glycol poisoning (Chap. 106). When clinically available, a urine ferric chloride test should be performed. Although highly sensitive and specific for the presence of salicylates, this test is not specific for the diagnosis of salicylism because small amounts of salicylate will be detected in the urine even days after its last use (Chap. 37). Thus, a serum salicylate concentration must be obtained to quantify the findings of a positive urine ferric chloride test result. A negative urine ferric chloride test result essentially excludes a diagnosis of salicylism.
3. A blood lactate concentration can be helpful. In theory, if the lactate (measured in mEq/L) can entirely account for the fall in serum  $[\text{HCO}_3^-]$ , the cause of the high anion gap can be attributed to lactic acidosis. In practicality we know that this unfortunately does not work largely because the volumes of distribution of bicarbonate and lactate are not identical, with the bicarbonate volume of distribution being very dependent on pH.<sup>119</sup> Another important example is that glycolate (a metabolite of ethylene glycol) can produce a false-positive elevation of the lactate concentration with many current laboratory techniques.<sup>100,150</sup>

When the above analysis of a high anion gap metabolic acidosis is non-diagnostic, the diagnosis is usually toxic alcohol ingestion, starvation, or alcoholic ketoacidosis (with minimal urine ketones), or a multifactorial process involving small amounts of lactate and other anions. One approach is to provide the patient with 1 to 2 hours of intravenous (IV) hydration, dextrose, and thiamine. If the acidosis improves, the etiology is either ketoacidosis or

metabolic acidosis with hyperlactatemia. In the absence of improvement, a more detailed search for the toxic alcohols, involving measurement of either the osmol gap or actual methanol and ethylene glycol concentrations, should be initiated (discussed later).

### The $\Delta$ Anion Gap-to- $\Delta[\text{HCO}_3^-]$ Ratio

Many patients have mixed acid–base disorders such as metabolic acidosis and respiratory alkalosis. Depending on the relative effects of the acid–base disorders, the patient may have significant acidemia or alkalemia, minor alterations in pH, or even a normal pH. Although the clinical presentation, degree of compensation for the primary acid–base disorder, or the presence of unexpected electrolyte abnormalities suggest whether more than one primary acid–base disorder is present, comparing the  $\Delta$  anion gap ( $\Delta\text{AG}$ ) with the  $\Delta[\text{HCO}_3^-]$  provides additional information to help establish the correct diagnosis.

In a patient with a simple high anion gap metabolic acidosis, each 1 mEq/L decrease in the serum  $[\text{HCO}_3^-]$  should (at least initially) be associated with a 1 mEq/L rise in the anion gap.<sup>106</sup> This occurs because the unmeasured anion is paired with the acid that is titrating the  $\text{HCO}_3^-$ . Any deviation from this direct relationship may be an indication of a mixed acid–base disorder.<sup>60,106,111</sup> Thus, the ratio of the change in the anion gap ( $\Delta\text{AG}$ ) to the deviation of the serum  $[\text{HCO}_3^-]$  from normal (Equation 12–4) evolved:

$$\text{Anion gap ratio} = \Delta\text{AG}/\Delta[\text{HCO}_3^-] \quad (\text{Eq. 12-4})$$

A ratio close to one would suggest a pure high anion gap metabolic acidosis. When the ratio is greater than one, there is a relative increase in  $[\text{HCO}_3^-]$  that can result only from a concomitant metabolic alkalosis or renal compensation such as renal generation of  $\text{HCO}_3^-$  for a respiratory acidosis. Alternatively, when the ratio is less than one, the additional presence of either hyperchloremic (normal anion gap) metabolic acidosis or compensated respiratory alkalosis is suggested. Although the usefulness of this relationship has been supported strongly by some authors,<sup>109,111</sup> others suggest that it is often flawed and frequently misleading.<sup>34,125</sup>

After reviewing the arguments, the statements of one author<sup>34</sup> are reasonable in concluding that “the exact relationship between the  $\Delta\text{AG}$  and  $\Delta[\text{HCO}_3^-]$  in a high anion gap metabolic acidosis is not readily predictable and deviation of the  $\Delta\text{AG}/\Delta[\text{HCO}_3^-]$  ratio from unity does not necessarily imply the diagnosis of a second acid–base disorder.” Regardless, very large deviations from a value of one usually are associated with the presence of a second primary acid–base disorder.

### The Osmol Gap

The osmol gap, which is sometimes used to screen for toxic alcohol ingestion, is defined as the difference between the values for the measured serum osmolality and the calculated serum osmolality. Osmolality is a measure of the total number of particles in one liter of solution. Osmolality differs from osmolarity in that it represents the number of particles per kilogram of solution. Thus, osmolarity and osmolality represent molar and molal concentrations of solutes, respectively. In clinical medicine, osmolarity is usually calculated whereas osmolality is measured.

Calculating osmolarity requires a summing of the known particles in solution. Because molarity and milliequivalents are particle-based measurements, unlike weight or concentration, the known constituents of serum that are measured in the latter units (such as mg/dL) have to be converted to molar values. Assumptions are required based on the extent of dissociation of polar compounds (eg, NaCl), the water content of serum, and the contributions of various other solutes such as  $\text{Ca}^{2+}$  and  $\text{Mg}^{2+}$ . The nature and limitations of these assumptions are beyond the scope of this chapter. Readers are referred to several reviews for more details.<sup>67,110</sup> Many equations have been used and evaluated for calculating serum osmolarity. One investigation that used 13 different methods to evaluate sera from 715 hospitalized patients<sup>36</sup> concluded that Equation 12–5 provided the most accurate calculation:

$$1.86([\text{Na}^+] \text{ in mEq/L}) + ([\text{Glucose}] \text{ in mg/dL}/18) + ([\text{BUN}] \text{ in mg/dL}/2.8) \quad (\text{Eq. 12-5})$$

Obvious sources of potential error in this calculation include laboratory error in determining the measured parameters and the failure to account for a number of osmotically active particles.

The measurement of serum osmolality also has the potential for error stemming from the use of different laboratory technique.<sup>40</sup> It is essential to ensure that the freezing point depression technique or osmometry is used because when the boiling point elevation method is used, xenobiotics with low boiling points (ethanol, isopropanol, methanol) will not be detected.

Conceptual errors may also result. In methanol poisoning, the methanol molecule has osmotic activity that is measured but not calculated, and no increase in the anion gap is present until it is metabolized to formate. Although the metabolite also has osmotic activity, its activity is accounted for by  $\text{Na}^+$  in the osmolality calculation because it is largely dissociated, existing as  $\text{Na}^+$  formate. Thus, shortly after a methanol ingestion, the patient will have an elevated osmol gap and a normal anion gap; later, the anion gap will increase, and the osmol gap will decrease (Fig. 106–4). This effect is highlighted by several case reports.<sup>9,30</sup>

Using Equation 12–5 to calculate osmolality, it is often stated that the “normal” osmol gap is  $10 \pm 6$  mOsm/L.<sup>36</sup> However, when more than 300 adult samples were studied with a more commonly used equation (Eq. 12–6),

$$2([\text{Na}^+] \text{ in mEq/L}) + ([\text{Glucose}] \text{ in mg/dL}/18) + ([\text{BUN}] \text{ in mg/dL}/2.8) \quad (\text{Eq. 12-6})$$

normal values for the osmol gap were  $-2 \pm 6$  mOsm/L.<sup>67</sup> Almost identical results are reported in children.<sup>96</sup>

The largest limitation of the osmol gap calculation is due to the documented large standard deviation around a small “normal” number.<sup>36,67</sup> An error of 1 mEq/L (<1.0%) in the determination of the serum  $[\text{Na}^+]$  will result in an error of 2 mOsm/L in the calculation of the osmol gap. Considering this variability, the molecular weights (MWs) and relatively modest serum concentrations of the xenobiotics in question (eg, ethylene glycol; MW, 62 Da; at a concentration of 50 mg/dL theoretically contributes only 8.1 mOsm/L) and the predicted fall in the osmol gap as metabolism occurs, small or even negative osmol gaps can never be used to exclude toxic alcohol ingestion.<sup>67</sup> This overall concept is illustrated by an actual patient with an osmol gap of 7.2 mOsm (well within the normal range) who ultimately required hemodialysis for severe ethylene glycol poisoning.<sup>138</sup> An additional error may result when including ethanol in the determination of the osmol gap. When present, ethanol is osmotically active and should be included in the calculated osmolality. In theory, because the MW of ethanol is 46 g/mol, dividing the serum ethanol concentration (in mg/dL) by 4.6 will yield the osmolar contribution in mmol/L. However, because the physical interaction of ethanol with water is complex, it is more scientifically accurate to divide by lower numbers as the ethanol concentration increases.<sup>26,115</sup> Therefore because the osmol gap is a screening tool, we suggest continuing to use the 4.6 divisor (or if in SI units using the unmodified molar concentration) in an attempt to reduce clinical false-negative test results.

Finally, although exceedingly large serum osmol gaps are suggestive of toxic alcohol ingestions, common conditions such as alcoholic ketoacidosis, metabolic acidosis with elevated lactate, kidney failure, and shock are all associated with elevated osmol gaps.<sup>73,128,134</sup> This may be surprising because lactate, acetoacetate, and  $\beta$ -hydroxybutyrate should not account for any increase in the osmol gap because they are charged (and accounted for in the osmolality calculation). Apparently, these conditions are associated with the accumulation of small uncharged, unmeasured molecules in the serum.

Thus, although the negative and positive predictive values of the osmol gap are too poor to recommend this test to routinely screen for xenobiotic ingestion, the presence of very high osmol gaps (>50–70 mOsm/L) usually indicates a diagnosis of toxic alcohol ingestion (Chap. 106).

### Differential Diagnosis of a Normal Anion Gap Metabolic Acidosis

Although the differential diagnosis of a normal anion gap metabolic acidosis is extensive (Table 12–4), most cases result from either urinary or GI  $\text{HCO}_3^-$  losses: renal tubular acidosis (RTA) or diarrhea, respectively. A number of

xenobiotics also cause this disorder, including toluene,<sup>25</sup> which also may cause a high anion gap metabolic acidosis. When the findings of the history and physical examination cannot be used to narrow the differential diagnosis, the use of a urinary anion gap is suggested.<sup>15,120</sup>

The urinary anion gap is calculated as shown in Equation 12–7:

$$([\text{Na}^+] + [\text{K}^+]) - [\text{Cl}^-] \quad (\text{Eq. 12-7})$$

The size of this gap is inversely related to the urinary ammonium ( $\text{NH}_4^+$ ) excretion.<sup>58</sup> As  $\text{NH}_4^+$  elimination increases, the urinary anion gap decreases and can actually become negative because  $\text{NH}_4^+$  serves as an unmeasured urinary cation and is predominantly accompanied by  $\text{Cl}^-$ .

The normal anion gap metabolic acidosis associated with diarrhea results from  $\text{HCO}_3^-$  loss. During this process, the ability of the kidney to eliminate  $\text{NH}_4^+$  is undisturbed; in fact, it increases as a normal response to the acidemia. Thus, with gastrointestinal  $\text{HCO}_3^-$  losses, the urinary anion gap should decrease and may become negative. By contrast, a patient with RTA has lost the ability to either reabsorb  $\text{HCO}_3^-$  (type 2 RTA) or increase  $\text{NH}_4^+$  excretion in response to metabolic acidosis (types 1 and 4 RTA) and the urinary anion gap should become more positive. Indeed, when the urinary anion gap was calculated in patients with diarrhea or RTA, it was found that patients with diarrhea had a mean negative gap ( $-20 \pm 5.7$  mEq/L) compared with a positive gap ( $23 \pm 4.1$  mEq/L) in those with RTA.<sup>58</sup> Therefore, when evaluating the patient with a normal anion gap metabolic acidosis, the determination of a urinary anion gap is helpful to determine the source of the disorder when the history and physical examination are unclear.

### Adverse Effects of Metabolic Acidosis

The acuity of onset and severity of metabolic acidosis determine the consequences of this disorder. Acute metabolic acidosis is usually characterized by obvious hyperventilation (caused by respiratory compensation). At arterial pH values less than 7.20, cardiac and central nervous system abnormalities are often present. These include decreases in blood pressure and cardiac output, cardiac dysrhythmias, and progressive obtundation.<sup>3,4</sup> Chronic metabolic acidosis is often not accompanied by overt clinical symptoms. The nonspecific symptoms of anorexia and fatigue are the most typical manifestations of chronic acidosis, and compensatory hyperventilation although present is often not evident. Because the consequences of even severe metabolic acidosis are nonspecific, the presence of metabolic acidosis is most often suggested by the history and physical examination and subsequently confirmed by laboratory testing.

### Management Principles in Patients with Metabolic Acidosis

The treatment of metabolic acidosis depends on its severity and cause. In most cases of severe poisoning, with a serum  $[\text{HCO}_3^-]$  concentration less than 8 mEq/L and an arterial pH value less than 7.20, we recommend treating with  $\text{HCO}_3^-$  to increase the pH to greater than 7.20, as described in detail elsewhere.<sup>3,4</sup> As an example, to raise the serum  $[\text{HCO}_3^-]$  by 4 mEq/L in a 70-kg person with an apparent  $\text{HCO}_3^-$  distribution space of 50% of body weight, approximately 140 mEq must be administered. Unfortunately, because the apparent volume of distribution of  $\text{HCO}_3^-$  increases as the pH and serum  $[\text{HCO}_3^-]$  fall, any given dose of exogenous  $\text{HCO}_3^-$  will have less of an effect on pH. When ECFV overload (caused by heart failure, kidney failure, or the sodium bicarbonate therapy itself) cannot be prevented or managed by administering loop diuretics, hemofiltration or hemodialysis will be necessary.

In patients with arterial pH values greater than 7.20, the cause of the acidosis should guide therapy. Metabolic acidosis primarily caused by the overproduction of acid, as in the case of ketoacidosis and toxic alcohol poisoning, requires very large quantities of  $\text{HCO}_3^-$  and typically does not respond well to sodium bicarbonate therapy. Treatment in these patients should be directed at the cause of acidosis (eg, insulin and IV fluids in diabetic ketoacidosis; fomepizole in methanol, ethylene glycol, and DEG poisonings (Antidotes in Depth: A33), fluids, dextrose, and thiamine in alcoholic ketoacidosis; fluid resuscitation, antibiotics, and vasopressors in sepsis-induced hyperlactatemia). Patients with metabolic acidosis primarily caused by insufficient excretion

of acid (eg, acute or chronic kidney failure, RTA) should be treated with a low-protein diet (if feasible) and oral sodium bicarbonate or substances that generate  $\text{HCO}_3^-$  during metabolism. We recommended an oral sodium citrate solution such as Shohl solution, which yields 1 mEq base/mL. The goal of therapy is to increase the serum  $[\text{HCO}_3^-]$  to 20 to 22 mEq/L and the pH to 7.30.

## METABOLIC ALKALOSIS

### Adverse Effects of Metabolic Alkalosis

Life-threatening metabolic alkalosis is rare but can result in tetany (from decreased ionized  $[\text{Ca}^{2+}]$ ); weakness (from decreased serum  $[\text{K}^+]$ ); or altered mental status leading to coma, seizures, and cardiac dysrhythmias. In addition, metabolic alkalosis shifts the oxyhemoglobin dissociation curve to the left, impairing tissue oxygenation (Chap. 28). The expected compensation for a metabolic alkalosis is hypoventilation and increased  $\text{PCO}_2$ . As discussed before, respiratory compensation is inadequate at best, invoking the teleological argument that hypoxia is more undesirable than alkalemia.<sup>106</sup> Several authors, however, have reported that severe hypoventilation and respiratory failure can occur in response to metabolic alkalosis, suggesting an actual, although uncommon, risk.<sup>112</sup>

### Approach to the Patient with Metabolic Alkalosis

Metabolic alkalosis results from GI or urinary loss of acid, administration of exogenous base, or renal  $\text{HCO}_3^-$  retention (ie, impaired renal  $\text{HCO}_3^-$  excretion). Table 12–5 lists the causes of metabolic alkalosis. Compared with metabolic acidosis, metabolic alkalosis is less common and less frequently a consequence of xenobiotic exposure.

The etiologies of metabolic alkalosis are classically characterized from a therapeutic standpoint as chloride responsive or chloride resistant. Chloride-responsive etiologies such as diuretic use, vomiting, nasogastric suction, and  $\text{Cl}^-$  diarrhea are usually associated with a urinary  $[\text{Cl}^-] < 10 \text{ mEq/L}$ .<sup>64</sup> Patients with these disorders respond rapidly to infusion of 0.9% NaCl solution when concomitant therapy addresses the underlying problem.<sup>34</sup> Chloride resistant disorders exemplified by hyperaldosteronism and severe  $\text{K}^+$  depletion are characterized by urinary  $[\text{Cl}^-] > 10 \text{ mEq/L}$  and tend to be resistant to 0.9% NaCl solution therapy.<sup>53,64</sup> Patients with these disorders often require  $\text{K}^+$  repletion or drugs that reduce mineralocorticoid effects, such as spironolactone or eplerenone, before correction can occur.<sup>53</sup> When 0.9% NaCl solution repletion is ineffective or emergent correction of the alkalosis is required, some authors have suggested infusions of lysine or arginine HCl or dilute HCl.<sup>34</sup> However, this technique is rarely necessary and we do not routinely recommend it.

## XENOBIOTIC-INDUCED AND OTHER ALTERATIONS OF WATER BALANCE

Significant fluid abnormalities commonly occur following xenobiotic exposure. Gastrointestinal losses in the form of vomiting, diarrhea, GI hemorrhage, and third spacing such as from GI burns result from a variety of xenobiotic toxicities and their management with emetics and cathartics. Renal fluid losses result from the ability of many xenobiotics to increase the glomerular filtration rate (inotropes), impair  $\text{Na}^+$  reabsorption (diuretics), or increase urine volume in response to an obligate solute load (salicylates).

Fluid losses also occur through the skin as a result of sweating (sympathomimetics, cholinergics, and uncouplers of oxidative phosphorylation) or the lung as a result of increased minute ventilation (salicylates and sympathomimetics) or bronchorrhea (cholinergics). To the extent that these lost fluids contain  $\text{Na}^+$ , various signs, symptoms, and laboratory evidence of ECFV depletion develop.

The diagnosis and treatment of abnormal serum electrolyte concentrations are usually addressed after repletion of the ECFV deficit with isotonic,  $\text{Na}^+$ -containing fluids (eg, blood products, 0.9% NaCl solution, lactated Ringer solution). Other fluid balance issues are discussed in Chaps. 16 and 27 and other chapters relating to individual xenobiotics. This section focuses on body water balance (abnormalities of which manifest as hypernatremia and hyponatremia) and specifically on the toxicologically relevant syndromes of diabetes insipidus (DI) and the syndrome of inappropriate secretion of antidiuretic hormone (SIADH).

Sodium concentration in the extracellular space is intrinsically related to and directly reflects total body water balance. This occurs because the sodium cation is largely restricted to the extracellular space, and its serum concentration is primarily, if indirectly, controlled by factors that control water balance. Thus, both the serum  $[\text{Na}^+]$  and plasma osmolality vary inversely with changes in the quantity of body water.

Plasma osmolality is maintained through a complex interaction between dietary water intake; the hypothalamus, pituitary gland, and kidney; and the effects of hormones such as arginine vasopressin (ADH) and adrenal mineralocorticoids.<sup>17,20,108,146</sup> Briefly, changes in osmolality are caused by changes in water intake and insensible (dermal, respiratory, and stool) and sensible (urinary, sweat) water losses. Urinary water losses are controlled by ADH. Increases in the osmolality of the extracellular fluid (ECF) stimulate anterior hypothalamic osmoreceptors, thereby stimulating thirst and ADH synthesis and release by the posterior pituitary gland. Arginine vasopressin release reaches its maximum concentration at a plasma osmolality of about 295 mOsm/kg. Arginine vasopressin is transported to the kidney via the bloodstream, where it stimulates the synthesis of cyclic adenosine monophosphate (cAMP). Cyclic adenosine monophosphate increases the water permeability of the distal convoluted tubule and collecting duct by stimulating the insertion of aquaporin (water) channels in the apical membrane, and thereby increasing water reabsorption and urine concentration, and minimizing urinary water losses. Conversely, as plasma osmolality falls, thirst and ADH release are diminished. This results in decreased renal cAMP generation, decreased water permeability of the distal convoluted tubule and collecting duct, and excretion of a relatively dilute urine that ultimately corrects the body water excess. Marked alterations in water intake combined with perturbations of these various processes often lead to hypernatremia or hyponatremia.

### Hypernatremia

Table 12–6 summarizes the xenobiotics that cause hypernatremia. Hypernatremia occasionally results from the parenteral administration of sodium-containing drugs or rapid and excessive oral  $\text{Na}^+$  intake.<sup>1</sup> Oral NaCl and oral sodium citrate were once used as emetics and antiemetics, respectively. As might be expected, they produced severe hypernatremia.<sup>20</sup> One case of unintentional fatal hypernatremia resulted from gargling with a supersaturated NaCl solution.<sup>99</sup> Similarly, massive ingestion of sodium hypochlorite bleach

TABLE 12–5 Xenobiotic and Other Causes of Metabolic Alkalosis

Gastrointestinal Acid Loss	Urinary Acid Loss	Base Administration	Renal Bicarbonate Retention
Nasogastric suction (protracted)	Common	Acetate (dialysis or hyperalimentation)	Hypercapnia (chronic)
Vomiting	Diuretics	Bicarbonate	Hypochloremia
	Glucocorticoids	Carbonate (antacids)	Hypokalemia
	Rare	Citrate (posttransfusion)	Volume contraction
	Hypercalcemia	Milk alkali syndrome	
	Licorice (containing glycyrrhizic acid)		
	Magnesium deficiency		

TABLE 12–6 Xenobiotic Causes of Hypernatremia

Sodium Gain	Water Loss	Water Loss Due to Diabetes Insipidus
Antacids sodium bicarbonate	Cholestyramine	$\alpha$ -Adrenergic antagonists
Sodium salts (acetate, ascorbate, bicarbonate, chloride, citrate, hypochlorite, polystyrene sulfonate)	Diuretics	Amphotericin
Seawater	Lactulose	Antivirals: abacavir, adefovir, cidofovir, tenofovir
	Mannitol	Colchicine
	Povidone-iodine	Demeclocycline
	Sorbitol	Ethanol
	Urea	Foscarnet
		Glufosinate
		Ifosfamide
		Lithium
		Lobenzarit disodium
		Methoxyflurane
		Mesalazine
		Minocycline
		Opioid antagonists
		Propoxyphene
		Rifampin
		Streptozotocin
		Temozolomide
		V <sub>2</sub> -receptor antagonists: conivaptan, tolvaptan
		Valproic acid

was associated with hypernatremia.<sup>123</sup> Unfortunately intentional salt poisoning is also reported.<sup>37</sup>

More commonly, hypernatremia results from relatively electrolyte-free (hypotonic) water losses due to xenobiotics or conditions that cause urinary, GI, and dermal fluid losses.<sup>1</sup> Indeed, all fluid losses from the body, except hemorrhage and those from fistulas, are hypotonic (and have the potential to cause hypernatremia). The lack of adequate fluid replacement is a key element in the development of hypernatremia because even the large fluid losses caused by DI or cholera-induced diarrhea will not cause hypernatremia if they are adequately replaced. Thus, in patients with hypernatremia caused by fluid losses, the reason why the losses were not replaced by the patient should always be sought.

Xenobiotics that produce significant diarrhea, such as lactulose, cause hypernatremia through unreplaced stool water losses. A similar pathogenesis accounts for the hypernatremia caused by the polyethylene-containing solution used for bowel preparation for colonoscopy.<sup>13</sup> Of particular concern is the use of cathartics in the management of poisonings, especially when fluid losses are not anticipated. For example, multiple doses of sorbitol reportedly produce severe hypernatremic dehydration and death in both children and adults.<sup>23,44,55,147</sup>

Significant water loss also occur through the skin. Although diffuse diaphoresis resulting from cocaine or organic phosphorus insecticide toxicity has the potential to produce hypernatremia, this rarely, if ever, occurs. However, application of a remedy containing hyperosmolar povidone–iodine to the skin of burned patients is reported to produce significant water losses and hypernatremia.<sup>130</sup>

### Diagnosis and Treatment

The symptoms of significant hypernatremia consist largely of altered mental status ranging from confusion to coma, and neuromuscular weakness that occasionally results in respiratory paralysis. If hypernatremia is associated with Na<sup>+</sup> losses and marked ECFV depletion, cardiovascular symptoms, tachycardia, and orthostatic hypotension may be present. Treatment

consists of first replacing the Na<sup>+</sup> deficit if present (with isotonic fluids such as 0.9% NaCl solution), and then replacing the water deficit. The water deficit is estimated by assuming that the fractional increase in serum [Na<sup>+</sup>] is equal to the fractional decrease in total body water. Thus, a serum [Na<sup>+</sup>] that has increased by 10% (from 144 mEq/L to 158 mEq/L) indicates that the water deficit is 10% (3.6 L in a 60-kg person with 36 L of body water).

When hypernatremia develops over several hours, for example, as occurs after ingestion or administration of a sodium salt, rapid correction is indicated. However, when hypernatremia develops over several days or when the duration is unknown, slow correction of hypernatremia (over several days) is recommended.<sup>1</sup> The adaptation of brain cells to the water deficit (including the gain of intracellular solute including K<sup>+</sup>, Na<sup>+</sup>, inositol, glutamate, taurine, and creatine) makes cerebral edema a frequent complication of rapid water replacement. Although some sources suggest that 0.9% NaCl solution is an appropriate replacement fluid regardless of the magnitude of the water deficit, a more refined analysis emphasizes the use of hypotonic fluids to correct hypernatremia in the absence of a significant sodium deficit.<sup>1</sup>

### Diabetes Insipidus

The greatest water losses and therefore the potentially most severe cases of hypernatremia occur during DI, which is always characterized by greater or lesser degrees of hypotonic polyuria. Diabetes insipidus is either characterized as neurogenic, resulting from failure to sense a rising osmolality or from a failure to release ADH, or nephrogenic, resulting from failure of the kidney to respond appropriately to ADH. Although there are many nontoxicologic causes of DI (eg, trauma, tumor, sarcoidosis, vascular, and congenital), xenobiotic-induced DI is also common and is mediated through either central or peripheral mechanisms.

Ethanol, opioid antagonists, and  $\alpha$ -adrenergic agonists all suppress ADH release.<sup>103,104</sup> Lithium,<sup>88,133</sup> demeclocycline,<sup>132</sup> methoxyflurane,<sup>83,92</sup> propoxyphene, foscarnet,<sup>107</sup> mesalazine,<sup>90</sup> streptozotocin, amphotericin,<sup>69</sup> glufosinate,<sup>141</sup> lobenzarit,<sup>124</sup> rifampin,<sup>116</sup> temozolomide,<sup>42</sup> and colchicine<sup>146</sup> are associated with nephrogenic DI (Table 12–6). In addition, nephrogenic DI is reportedly caused by severe hypokalemia from diuretic use and hypercalcemia from vitamin D poisoning.<sup>146</sup> Of all of these xenobiotics, lithium has been the most extensively evaluated. Although polyuria is a common finding with lithium therapy (occurring in 20%–70% of patients on maintenance therapy), the exact incidence of DI and hypernatremia is unknown. Estimates range from 10% to 20% to as high as 80%.

### Diagnosis

Patients with DI complain of polyuria and polydipsia. Urine volumes typically exceed 30 mL/kg/d<sup>146</sup> and can be as high as 9 L/d with nephrogenic DI<sup>88</sup> and 12 to 14 L/d with neurogenic (central) DI.<sup>104</sup> Nocturia, fatigue, and decreased work performance are often noted.<sup>146</sup> Neurogenic DI resulting from hypothalamic or pituitary damage is typically associated with other signs of neuroendocrine dysfunction.<sup>104</sup>

After polyuria is confirmed (eg, in adults, by measuring a urine output >200 mL over one hour), the urine osmolality or specific gravity should be measured. The diagnosis of DI is established by the occurrence of dilute urine (urine osmolality <300 mOsm/kg, urine specific gravity <1.010) in the presence of increased serum [Na<sup>+</sup>] and a serum osmolality greater than 295 mOsm/kg.<sup>146</sup> After this determination, a trial of desmopressin, an arginine vasopressin analog, helps to differentiate between neurogenic and nephrogenic DI. If the etiology of the DI is neurogenic, the patient will promptly respond to desmopressin with a decrease in urine output and increase in urine osmolality. In nephrogenic DI, desmopressin will have no significant effect.

### Treatment

The initial approach to a hypernatremic patient with DI involves the repletion of the water deficit (as described earlier) and the restoration of electrolyte depletion, if necessary. If a reversible cause for the DI can be established,

it should be corrected. Specifically, xenobiotics implicated as the cause of DI should be discontinued or their dose reduced. Patients with neurogenic DI should be maintained on either vasopressin or desmopressin. The latter is preferred because of the lack of vasopressor effects and ease of administration. In the past, patients were occasionally treated with oral medications known to produce SIADH (see later). Patients with nephrogenic DI can be treated with thiazide diuretics,<sup>38</sup> prostaglandin inhibitors,<sup>33,86</sup> or amiloride, all of which reduce the urine flow rate.<sup>16</sup>

### Hyponatremia

Hyponatremia may be associated with a high, normal, or low serum osmolality. Some patients with myeloma or severe hyperlipidemia exhibit artifactual hyponatremia whenever the measurement technique requires dilution of the serum sample rather than direct measurement by a sodium electrode. These patients have a normal serum osmolality and no symptoms related to their artifactual hyponatremia, and they require no therapy for their “pseudohyponatremia.”

Hyperglycemic patients develop hyponatremia because the increase in plasma osmolality caused by hyperglycemia results in a water shift from the intracellular to the extracellular space. The reduction in serum  $[Na^+]$ , which may cause symptoms, is approximately 1.6 mEq/L for every 100 mg/dL increase in serum glucose concentration above normal. The contribution of hyperglycemia to the hyponatremia should be calculated to determine if other causes of hyponatremia should also be sought. All other causes of hyponatremia are associated with a low plasma osmolality. In fact, in the absence of myeloma, hyperlipidemia, and hyperglycemia, the serum osmolality need not be measured in hyponatremic patients and should be assumed to be low.

Hyponatremia associated with a low plasma osmolality usually results from water intake in excess of the renal capacity to excrete it. When renal water excretion is normal, very large intake is required to cause hyponatremia. For example, large quantities of water are ingested over a short period of time by people with psychiatric or neurologic disorders such as psychogenic polydipsia.<sup>57,121</sup> Xenobiotic-induced water excess comparable to psychogenic polydipsia is quite uncommon. An example occurred during urologic procedures, such as transurethral resection of the prostate (TURP), in which large volumes of irrigation solution are required. Because the wounds were electrically cauterized, these fluids did not contain conductive electrolytes such as sodium. Sorbitol, dextrose, and mannitol were tried as irrigation solutions in an attempt to maintain a normal osmolality, but their optical characteristics were undesirable during the surgery. Thus, irrigation during TURP was performed with glycine-containing solutions. If a large volume of 1.5% glycine (osmolality, 220 mOsm/kg) is absorbed through the prostatic venous plexus, a rapid reduction in serum  $[Na^+]$  results and will persist until the glycine is metabolized.<sup>66,98</sup> Symptoms in these patients are probably a result of several factors: hyponatremia, the glycine itself, and  $NH_3$ , a glycine metabolite. A similar complication is also described during hysteroscopy.<sup>113</sup>

Rarely, hyponatremia results from the loss of a body fluid with a  $[Na^+]$  greater than the ECF  $[Na^+]$  (of 145 mEq/L). This rarely occurs in patients with adrenal insufficiency through hypertonic urinary losses (although increased ADH secretion as a consequence of ECF sodium depletion is probably a more important mechanism; see later discussion). In burn patients,  $Na^+$  may be lost directly from the ECF. When treated with topical applications of silver nitrate cream, hyponatremia developed from the diffusion of sodium through permeable skin into the hypotonic dressing.<sup>28</sup> Ingestion of licorice that contains glycyrrhizic acid produces a syndrome of hyponatremia, hypokalemia, and hypertension that resembles mineralocorticoid excess. Although the exact mechanism of hyponatremia is debated, one report suggested that a glycyrrhizic acid–induced reduction in 11- $\beta$ -hydroxysteroid dehydrogenase activity, an enzyme that metabolizes cortisol, could account for the findings.<sup>43</sup> Lithium, which is usually associated with DI and hypernatremia, is rarely reported to cause renal sodium wasting and hyponatremia that seems to be unrelated to ADH effects.<sup>97</sup>

Most cases of hyponatremia are caused by water intake in excess of a reduced renal excretory capacity. This reduction in urinary water excretion

may be physiologic (as during ECF sodium depletion) or pathologic (in association with kidney, heart, or liver failure).<sup>2</sup> Because these conditions are accompanied by alterations in renal sodium handling, signs and symptoms of ECFV depletion, such as postural hypotension, or ECFV excess, such as edema, usually accompany the hyponatremia. Other patients cannot excrete water normally because malignancy or various brain or pulmonary diseases cause ADH secretion.<sup>2</sup> In some cases, the tumors are associated with paraneoplastic disease and directly secrete ADH. Xenobiotics, such as diuretics, cause ECFV depletion, but most directly stimulate ADH secretion or augment the renal effects of ADH. Drugs such as the thiazide diuretics cause hyponatremia by several mechanisms, including interference with maximal urinary dilution, and by ADH-induced water retention in response to decreased ECFV.<sup>2,46</sup> Patients with excess secretion or action of ADH who have near-normal ECFV have the syndrome of inappropriate antidiuretic hormone (SIADH) secretion. Table 12–7 summarizes these and other causes of hyponatremia.

**TABLE 12–7 Xenobiotic and Other Causes of Hyponatremia**

Angiotensin-converting enzyme inhibitors
Arginine
Diuretics
Glycine (transurethral prostatectomy syndrome)

Tranylcypromine
Trimethoprim
Valproate
Vasopressin
Vincristine and vinblastine
Vinorelbine

### Syndrome of Inappropriate Antidiuretic Hormone (SIADH)

The SIADH is characterized by hyponatremia and plasma hypotonicity in the absence of abnormalities of ECFV, or abnormal adrenal, thyroid, or kidney function. Early reviews claimed that SIADH was a disorder of volume overload based largely on evidence of weight gain.<sup>103</sup> The consistent absence of edema, however, and the fact that the decrease in serum  $[\text{Na}^+]$  cannot be accounted for by the fluid gain (weight gain) suggest that water retention is only part of the mechanism.<sup>82</sup> Urinary  $\text{Na}^+$  loss and  $\text{Na}^+$  redistribution from the extracellular to the intracellular space is apparently important as well.

There are many nontoxicologic etiologies of SIADH, most of which result from pulmonary or intracranial pathology. These causes include infections, malignancies, and surgery.<sup>2,82,104</sup> Table 12–7 summarizes xenobiotics and other causes known to produce SIADH. The antidiabetics, including both the sulfonylurea (eg, chlorpropamide) and biguanide (eg, metformin) classes, produce hyponatremia more commonly than other drugs.<sup>102</sup> Their actions are multifactorial and can include both the potentiation of endogenous ADH and the stimulation of ADH release.<sup>102</sup> Many psychiatric medications, including the selective serotonin reuptake inhibitors, cyclic antidepressants, and antipsychotics, are implicated in causing SIADH.<sup>79,87,137,144</sup> The effects of these drugs are mediated by the complex interactions between the dopaminergic and noradrenergic systems that control ADH release.<sup>137</sup> Additional evidence supports a role of serotonin in drug-induced SIADH. Serotonin (specifically 5-HT<sub>2</sub> or 5-HT<sub>1C</sub> agonism) directly stimulates ADH release<sup>10</sup> and water intake.<sup>71</sup> An important role of serotonin is supported by the occurrence of SIADH with MDMA use.<sup>70</sup>

### Diagnosis

The clinical presentation of patients with hyponatremia depends on the cause, the absolute serum  $[\text{Na}^+]$ , and the rate of decline in serum  $[\text{Na}^+]$ . Patients with associated ECFV excess or depletion present with evidence of altered ECFV, as well as signs and symptoms of the disease that caused the abnormality in ECFV, such as adrenal insufficiency or heart failure.<sup>2</sup> Rarely do these patients exhibit symptoms of hyponatremia and hyposmolality of body fluids per se. This is because of the moderate degree of hyponatremia (usually  $> 130$  mEq/L) or the moderate rate of decline in  $[\text{Na}^+]$  or because the loss of  $\text{Na}^+$  and water limits the development of cerebral edema.<sup>85</sup> It is important to note that patients with hyponatremia and a low plasma osmolality (excluding those with primary polydipsia) all have a urinary osmolality that is relatively high regardless of whether they have excess, diminished, or normal ECFV. Consequently, these disorders can only be differentiated by the history, physical examination, and other laboratory test results.

Patients with SIADH, if symptomatic, usually present with signs and symptoms of hyponatremia. As noted earlier, the clinical manifestations of hyponatremia are dependent on both the absolute serum  $[\text{Na}^+]$  and its rate of decline.<sup>85,104</sup> Whereas chronic slow depression of the  $[\text{Na}^+]$  is usually well tolerated, rapid decreases are associated with symptoms and sometimes catastrophic events. Symptoms include headache, nausea, vomiting, restlessness, disorientation, depression, apathy, irritability, lethargy, weakness, and muscle cramps. In more severe cases, respiratory depression, coma, and seizures develop.

The diagnosis of SIADH is based on establishing the presence of hyponatremia, a low serum osmolality, and impaired urinary dilution in the absence of edema, hypotension, hypovolemia, and kidney, adrenal, or thyroid dysfunction.<sup>82</sup> As discussed earlier, the presence of any of these clinical findings suggests that another cause of hyponatremia is present. A serum uric acid concentration is helpful in differentiating SIADH from other causes of hyponatremia. In the presence of hyponatremia and impaired urinary dilution, patients with SIADH have hypouricemia, whereas patients exhibiting ECFV excess or depletion characteristically have hyperuricemia.<sup>31</sup>

### Treatment

Treatment of patients with demonstrable ECFV excess or depletion should be directed at the abnormal ECFV and its cause rather than the hyponatremia. In almost all cases, the hyponatremia will improve with correction of the ECFV.<sup>2,85</sup> In a similar way, correction of the serum glucose in hyperglycemic patients and the removal of glycine by hemodialysis in patients with the

TURP syndrome will correct the serum  $[\text{Na}^+]$ . The rate of correction of the serum  $[\text{Na}^+]$  in these patients is generally not of concern.

In patients with SIADH, treatment begins with fluid restriction. Because the goal of this therapy is to establish a negative fluid balance, careful attention to intake and output is required. If an offending xenobiotic is identified, it should be discontinued. Although most cases resolve in 1 to 2 weeks,<sup>82,104</sup> SIADH caused by chronic cerebral or pulmonary conditions or by malignancy often persists. If this occurs, therapy with demeclocycline, lithium, or tolvaptan is suggested because severe fluid restriction is often intolerable. Tolvaptan, an oral ADH antagonist with specificity for the V<sub>2</sub> receptor, is currently the recommended treatment for chronically hyponatremic patients in whom fluid restriction is unsuccessful because it is easier to titrate with fewer potential side effects than demeclocycline and lithium. In all asymptomatic or mildly symptomatic patients (usually patients with chronic hyponatremia of more than 2 days' duration), correction should proceed slowly and certainly at a rate less than 8.0 mEq/L during the first 24 hours and less than 16 mEq/L during the first 48 hours. This approach to correction is indicated because if hyponatremia resolution is faster than the reuptake of the solutes ( $\text{K}^+$ ,  $\text{Na}^+$ , inositol, glutamate, taurine, and creatine) extruded from brain cells during the development of hyponatremia, brain shrinkage will occur with disruption of the blood–brain barrier. This effect is responsible for the osmotic demyelination syndrome (ODS), which is associated with central pontine and extrapontine myelinolysis, often has a delayed onset of 2 to 6 days and causes irreversible brain damage and death in 50% and 15% of patients, respectively.<sup>2,12,139</sup> Risk factors for ODS, in addition to too rapid correction of chronic hyponatremia, include serum  $[\text{Na}^+]$  below 115 mEq/L and patients who are elderly, hypokalemic, alcoholic, or malnourished. In asymptomatic patients, as described earlier, water restriction is recommended and usually sufficient, but occasionally tolvaptan (an ADH V<sub>2</sub> receptor antagonist) is appropriate. When hyponatremia is associated with life-threatening clinical presentations, including respiratory depression, altered mental status, seizures, or coma, careful infusion of hypertonic 3% saline ( $[\text{Na}^+] = 513$  mEq/L) (eg, 1–2 mL/kg/h), with or without furosemide, is indicated.<sup>2,82</sup> Alternatively, conivaptan (another ADH V<sub>2</sub> receptor antagonist) can be administered intravenously as an initial bolus of 20 mg followed by a continuous infusion of 40 mg/d for no more than 4 days.<sup>62,65</sup> In these symptomatic patients, the goal is to increase the serum  $[\text{Na}^+]$  1 mEq/L/h (5–6 mEq/L over 6 hours) or until life-threatening symptoms resolve.<sup>2,85</sup> After this initial correction and improvement of symptoms, the serum  $[\text{Na}^+]$  should be increased at a rate less than 0.3 mEq/L/h, preferably by water restriction alone. Formulas are available to help calculate the rate of correction of hyponatremia.<sup>2</sup> Equation 12–8 is the equation we prefer.

When 1 L of fluid is infused:

$$\text{Change in serum } [\text{Na}^+] = \frac{\text{infusate } [\text{Na}^+] - \text{serum } [\text{Na}^+]}{\text{Total body water} + 1\text{L}} \quad (\text{Eq. 12-8})$$

where the infusate  $[\text{Na}^+]$  in mEq/L equals:

3% sodium chloride	513
0.9% sodium chloride	154
Lactated Ringer solution	130
0.45% sodium chloride	77
0.33% sodium chloride	56

## XENOBIOTIC-INDUCED ELECTROLYTE ABNORMALITIES

### Potassium

Xenobiotic-induced alterations in serum  $[\text{K}^+]$  are potentially more serious than alterations in other electrolyte concentrations because of the critical role of potassium in a variety of homeostatic processes, most importantly, muscle strength and cardiac function. The total body potassium content of an average adult is about 54 mEq/kg, of which only 2% is located in the intravascular space. The large intracellular store of potassium is maintained by a variety of systems, the most important of which is membrane  $\text{Na}^+\text{K}^+$ -adenosine triphosphatase (ATPase). The relationship between total body stores and

serum  $[K^+]$  is not linear, and small changes in the total body potassium often result in dramatic alterations in serum concentrations and, more importantly, in the ratio of extracellular to intracellular  $[K^+]$ .

People eating a Western diet ingest 50 to 150 mEq/d of potassium, approximately 90% of which is subsequently eliminated in the urine. The body has 2 major defenses against a potassium load: acutely, potassium is transferred into cells; chronically, potassium is excreted in the urine by decreased proximal tubular reabsorption and increased distal tubular secretion (to a maximum of 600–700 mEq/d).<sup>22</sup> After a meal,  $K^+$  transfers into the intracellular space through insulin and catecholamine-mediated uptake of potassium in liver and muscle cells.<sup>122</sup> Renal potassium excretion is primarily modulated by the renin–angiotensin–aldosterone system. In addition, the GI absorption of potassium decreases as the serum  $[K^+]$  increases.

Hypokalemia results from decreased oral intake, GI losses caused by repeated vomiting or diarrhea, urinary losses through increased  $K^+$  secretion or decreased reabsorption, and processes that shift potassium into the intracellular compartment.<sup>20,22,148</sup> Table 12–8 summarizes the xenobiotics and other causes commonly associated with hypokalemia.

The neuromuscular manifestations of hypokalemia are reviewed elsewhere.<sup>80</sup> Patients with hypokalemia are often asymptomatic when the decrease in serum  $[K^+]$  is mild (serum concentrations of 3.0–3.5 mEq/L). Occasionally, hypokalemia interferes with renal concentrating mechanisms, and polyuria is noted. More significant potassium deficits (serum concentrations of 2.0–3.0 mEq/L) cause generalized malaise and weakness. As the  $[K^+]$  falls to less than 2 mEq/L, weakness becomes prominent, and areflexic paralysis and respiratory failure occur, often necessitating intubation and mechanical ventilation.<sup>80</sup> Rhabdomyolysis also occurs. These neuromuscular

manifestations are so prominent that they are potentially erroneously attributed to a neuromuscular syndrome such as Guillain-Barré. Other clinical findings associated with hypokalemia include GI hypoperistalsis (ileus); manifestations of cardioactive steroid toxicity; worsening hyperglycemia in patients with diabetes; and the symptoms and signs of the metabolic abnormalities that often accompany hypokalemia, such as hyponatremia, metabolic acidosis, or alkalosis.<sup>148</sup>

Electrocardiographic changes also are common, even with mild potassium depletion, although the absence of ECG changes should never be used to exclude significant hypokalemia. Common ECG findings of hypokalemia include depression of the ST segment, decreased T-wave amplitude, and increased U-wave amplitude (Chap. 15). These findings may herald life-threatening rhythm disturbances, particularly polymorphic ventricular tachycardia.<sup>148</sup>

Treatment of hypokalemia involves discontinuing or removing the offending xenobiotic and correcting the potassium deficit. Potassium supplementation should be given, either orally or intravenously as acceptable. The choice of potassium salt should be based on the associated acid–base abnormality, if present. Thus, potassium chloride is preferred when metabolic alkalosis is present, and another salt of potassium (eg, potassium citrate or potassium bicarbonate) is preferable when metabolic acidosis is present.<sup>148</sup> Potassium phosphate should be used as part of the  $K^+$  supplement when hypophosphatemia is also present, as occurs in diabetic ketoacidosis, or when hyperchloremia is present. Hypomagnesemia, which either causes or accompanies hypokalemia (eg, in diuretic-induced hypokalemia), must be corrected because this abnormality often prevents successful potassium replacement.

The debate over the maximum safe infusion rate for IV potassium is summarized elsewhere.<sup>84,148</sup> Based on experience with more than 1300 infusions, one group concluded that under intensive care monitoring, IV administration of 20 mEq/h (by central or peripheral vein) is well tolerated. They also found that each 20 mEq of potassium administered resulted in an average increase in serum  $[K^+]$  of 0.25 mEq/L. Under most circumstances we agree with these recommendations, but acknowledge that others have used significantly larger doses (up to 100 mEq/h) in unique life-threatening circumstances.<sup>32</sup>

Hyperkalemia results from decreased urinary elimination (renal insufficiency, potassium-sparing diuretics, hypoaldosteronism), increased intake (either orally or intravenously), or redistribution from tissue stores.<sup>20,22</sup> The last mechanism is of major toxicologic importance. Overdoses of both cardioactive steroids (Chap. 62) and  $\beta$ -adrenergic antagonists (Chap. 59) cause hyperkalemia by promoting net potassium release from intracellular reservoirs. Presumably because of other protective mechanisms, overdose with a  $\beta$ -adrenergic antagonist produces only a moderate rise in serum  $[K^+]$  (usually to 5.0–5.5 mEq/L). By contrast, a similar rise in serum  $[K^+]$  as a consequence of blockade of the  $Na^+,K^+$ -ATPase pump during acute cardioactive steroid toxicity may be lethal (Chap. 62). This suggests that hyperkalemia per se is not the cause of the lethality of cardioactive steroid toxicity. Thus, the focus of therapy should involve efforts to neutralize or eliminate the cardioactive steroid rather than reduce the serum  $[K^+]$ .<sup>18</sup> Table 12–8 lists xenobiotics and other causes of hyperkalemia.

After oral overdoses of potassium salts, patients usually complain of nausea and vomiting. Ileus, intestinal irritation, bleeding, and perforation reportedly complicate the clinical course.<sup>126,127</sup> In the absence of potassium ingestion, GI symptoms of hyperkalemia are usually very mild. Neuromuscular manifestations include weakness with an ascending flaccid paralysis and respiratory compromise, with intact sensation and cognition.<sup>80,94,114</sup> The similarity of these signs and symptoms to those associated with hypokalemia is striking, suggesting that hyperkalemia should only be diagnosed with certainty by laboratory measurement.

The cardiac manifestations of hyperkalemia are distinct, prominent, and life threatening. ECG patterns progress through characteristic changes.<sup>127</sup> Although the progression of ECG changes is reproducible, there is great individual variation with respect to the serum  $[K^+]$  at which these ECG findings occur. Initially, the only ECG finding is the presence of tall, peaked

**TABLE 12–8** Xenobiotic and Other Causes of Altered Serum Potassium

Hypokalemia	Hyperkalemia
$\beta$ -Adrenergic agonists	$\alpha$ -Adrenergic agonists (phenylephrine)
Aminoglycosides	$\beta$ -Adrenergic antagonists
Amphotericin	Aliskerin
Barium (soluble salts)	Amiloride
Bicarbonate	Angiotensin-converting enzyme inhibitors
Caffeine	Angiotensin receptor blockers
Carbonic anhydrase inhibitors	Arginine hydrochloride
Cathartics	Cardioactive steroids
Chloroquine	Cyclosporine
Cisplatin	Dabigatran
Dextrose	Drospiridone
Hydroxychloroquine	Fluoride
Infliximab	Glyphosate
Insulin	Heparin

Sodium polystyrene sulfate	Triamterene
Sulfonyleureas	Trimethoprim
Sympathomimetics	
Tenofovir	
Theophylline	
Thiazide diuretics	
Toluene	

T waves. As the serum  $[K^+]$  concentration increases, the QRS complex tends to blend into the T waves, the P-wave amplitude decreases, and the PR interval becomes prolonged. Next, the P wave is lost, and ST-segment depression occurs. Finally, the distinction between the S and T waves becomes blurred, and the ECG takes on a sine wave configuration (Chap. 16). Hemodynamic instability and cardiac arrest can result. As the patient's serum  $[K^+]$  falls with therapy, these ECG changes resolve in a reverse fashion.

The treatment of severe hyperkalemia focuses on methods to (1) reverse the ECG effects, (2) transfer  $K^+$  to the intracellular space, and (3) enhance  $K^+$  elimination. Pharmacologic interventions, extensively discussed elsewhere,<sup>126</sup> are summarized here. Calcium salts (eg, 10–20 mEq administered intravenously) (Antidotes in Depth: A29) work almost immediately to protect the myocardium against the effects of hyperkalemia, although it does not reduce the serum  $[K^+]$ . However, a potentially life-threatening interaction occurs when the patient with cardioactive steroid toxicity is given calcium salts (Chap. 62).

The administration of insulin (and dextrose to prevent hypoglycemia unless hyperglycemia is present), sodium bicarbonate, or inhalation of a  $\beta$ -adrenergic agonist all stimulate potassium entry into cells.<sup>8</sup> They reduce the serum  $[K^+]$  over approximately 30 minutes, but potassium begins to reenter the extracellular space over the next several hours. Caution is advised, when using insulin in patients with chronic kidney disease because hypoglycemia can be prolonged as a result of reduced insulinase function. Cationic exchange resins, such as  $Na^+$  polystyrene sulfonate and patiromer, nonabsorbable polymers that binds potassium in exchange for calcium take longer to reduce the serum  $[K^+]$  as they enhance GI potassium loss.<sup>14,63,81</sup> Hemodialysis or peritoneal dialysis are the most efficient means of rapidly reducing total body potassium stores, especially when significant renal impairment is present.

## Calcium

Calcium is the most abundant mineral in the body, and 98% to 99% is located in bone. Approximately half of the remaining 1% to 2% of calcium in the body is bound to plasma proteins (mostly albumin), and most of the rest is complexed to various anions, with free, ionized calcium representing a very small fraction of extraosseous stores. The serum  $[Ca^{2+}]$  is maintained through interactions between dietary intake and renal elimination, modulated by vitamin D activity, parathyroid hormone, and calcitonin. More extensive discussions of calcium physiology are found elsewhere.<sup>6,105</sup>

Xenobiotic-induced hypercalcemia is uncommon and usually caused by increased dietary calcium as a result of milk or antacid usage, calcium supplements, or a decrease in its renal excretion such as occurs with thiazide use.<sup>6,20</sup> Cholecalciferol, available as a rodenticide, can increase the serum  $[Ca^{2+}]$  by increasing its release from bone, increasing GI absorption, and decreasing renal elimination. Vitamin D toxicity from excessive vitamin or milk intake also can cause hypercalcemia.<sup>76</sup> Table 12–9 lists other causes of hypercalcemia.

Symptoms of hypercalcemia consist of lethargy, muscle weakness, nausea, vomiting, and constipation. Life-threatening manifestations include complications from altered mental status such as aspiration pneumonia and cardiac dysrhythmias (Chap. 15). Treatment of clinically significant hypercalcemia focuses on removing the offending xenobiotic when possible, decreasing GI absorption by administering a binding agent, increasing distribution into bone with a bisphosphonate (onset 1–2 days), and enhancing renal excretion through forced diuresis with IV 0.9% NaCl solution and furosemide (onset 4–6 hours).<sup>6,140</sup> Hemodialysis is often required when significant renal impairment is present.

Xenobiotics more commonly cause hypocalcemia than hypercalcemia. Minor, usually clinically insignificant, decreases in serum  $[Ca^{2+}]$  can occur in association with anticonvulsant and aminoglycoside therapy.<sup>20</sup> Severe, life-threatening hypocalcemia can occur, however, from ethylene glycol poisoning (Chap. 106) or as a manifestation of fluoride toxicity from either fluoride salts or hydrofluoric acid (Chap. 103).<sup>39,142</sup> Calcium complex formation with fluoride or oxalate ions is responsible for the rapid development of hypocalcemia

TABLE 12–9 Xenobiotic Causes of Altered Serum Calcium

Hypocalcemia	Hypercalcemia
Aminoglycosides	All- <i>trans</i> -retinoic acid (ATRA)
Bicarbonate	Aluminum
Bisphosphonates	Androgens

in these settings. Similar effects occur with excess phosphate<sup>145</sup> or citrate.<sup>93,143</sup> intake. This mechanism (calcium complex formation) decreases the ionized  $[Ca^{2+}]$  but may or may not reduce the measured total serum  $[Ca^{2+}]$ . Other xenobiotics that produce hypocalcemia decrease absorption, enhance renal loss, or stimulate calcium entry into cells (Table 12–9).

Symptoms of hypocalcemia consist largely of neuromuscular findings, including paresthesias, cramps, carpopedal spasm, tetany, and seizures. Although ECG abnormalities are common (Chap. 15), life-threatening dysrhythmias are rare. Treatment strategies focus on calcium replacement. When hypomagnesemia or hyperphosphatemia is present, these abnormalities should be corrected, or calcium replacement will likely fail.

## Magnesium

Magnesium is the fourth most abundant cation in the body (after  $Ca^{2+}$ ,  $Na^+$ , and  $K^+$ ), with a normal total body store of about 2000 mEq in a 70-kg person.<sup>117</sup> Approximately 50% of magnesium is stored in bone, with most of the remainder distributed in the soft tissues. Because only approximately 1% to 2% of magnesium is located in the ECF, serum concentrations correlate poorly with total body stores.<sup>118</sup> Magnesium homeostasis is maintained through dietary intake and renal and GI excretion modulated by hormonal effects.<sup>5</sup>

Clinically significant hypermagnesemia is uncommon in the absence of kidney failure except when massive doses of magnesium salts overwhelm renal excretory mechanisms. This has been reported with inadvertent IV infusion,<sup>19,24,68,101</sup> urologic procedures involving irrigation with magnesium salts,<sup>45,77</sup> and ingestion of large quantities of magnesium-containing antacids<sup>95</sup> or cathartics.<sup>52,56</sup> Iatrogenic overdose was formerly of concern when magnesium-containing cathartics were routinely used in poison management.<sup>54,78,135</sup> In a series of poisoned patients, a single oral dose of a magnesium-containing cathartic (30 g of magnesium sulfate) failed to produce any demonstrable rise in serum  $[Mg^{2+}]$ .<sup>136</sup> However, patients who received 3 oral doses of magnesium sulfate over 8 hours had a significant increase in their serum  $[Mg^{2+}]$ .<sup>136</sup> Thus, the potential for iatrogenic toxicity exists, mandating cautious use of magnesium-containing cathartics, especially in patients with renal insufficiency. Table 12–10 lists xenobiotic causes of hypermagnesemia.

The symptoms of hypermagnesemia correlate with serum concentrations but depend somewhat on the rate of increase and host factors.

TABLE 12–10 Xenobiotic Causes of Altered Serum Magnesium

Hypomagnesemia	Hypermagnesemia
Aminoglycosides	Antacids (magnesium containing)
Amphotericin	Cathartics (magnesium containing)
Cetuximab	Lithium
Cisplatin	Magnesium salts
Citrate	
Cyclosporine	
DDT	
EGRF antibodies (panitumumab and cetuximab)	
Ethanol	
Fluoride	
Foscarnet	
Insulin	
Laxatives	
Levetiracetam	
Loop diuretics	
Methylxanthines	
Osmotic diuretics	
Phosphates	
Proton pump inhibitors	
Strychnine	
Tacrolimus	
Thiazides	

At serum  $[Mg^{2+}]$  of about 3 to 10 mEq/L, patients feel weak, nauseated, flushed, and thirsty. Bradycardia, a widened QRS complex on ECG, hypotension, and decreased deep tendon reflexes are typically noted. As the  $[Mg^{2+}]$  increases, hypoventilation, muscle paralysis, and ventricular dysrhythmias occur. Serum  $[Mg^{2+}]$  greater than 10 mEq/L, especially those concentrations greater than 15 mEq/L, often cause death.

Hypermagnesemia is a life-threatening disorder. When significant neuromuscular or ECG manifestations are noted, administration of 5 to 20 mEq of  $Ca^{2+}$  should be administered by slow intravenous infusion to competitively antagonize the effects of the magnesium ion.<sup>6,61</sup> (Antidotes in Depth: A32) Further therapy should focus on enhancing renal excretion by administering fluids and loop diuretics such as furosemide.<sup>61</sup> In the presence of renal failure or inadequate renal excretion, hemodialysis will rapidly correct hypermagnesemia.

Xenobiotic-induced hypomagnesemia is common but rarely life threatening. Renal losses (caused by diuretics), GI losses (caused by ethanol), intracellular shifts caused by insulin<sup>91</sup> or  $\beta$ -adrenergic agonists, and complex formation (by fluoride or phosphate) are common.<sup>5,6</sup> Table 12–10 lists these and other xenobiotic causes of hypomagnesemia. Of note, many causes of hypomagnesemia also cause hypokalemia and hypocalcemia.<sup>5</sup> Therefore, when hypomagnesemia is suspected or discovered, the presence of other electrolyte abnormalities should be sought.

The symptoms of hypomagnesemia are lethargy, weakness, fatigue, neuromuscular excitation (tremor and hyperreflexia), nausea, and vomiting.<sup>29,35</sup> Dysrhythmias are reported, especially in patients treated with cardioactive steroids. Signs and symptoms consistent with hypocalcemia and hypokalemia also may be present.

Treatment involves removing the offending xenobiotic (if it can be identified) and restoring magnesium balance. Although either oral or parenteral supplementation is usually acceptable for mild hypomagnesemia, parenteral therapy is required when significant clinical manifestations are present. When oral therapy is indicated, a normal diet or magnesium oxide, magnesium chloride, or magnesium lactate in divided doses (magnesium 20–100 mEq/d) will often correct the hypomagnesemia.<sup>5,6</sup> When hypomagnesemia

is severe or symptomatic, and kidney function is normal, 16 mEq (2 g) of magnesium sulfate can be given intravenously over several minutes to a maximum of 1 mEq/kg of magnesium in a 24-hour period.<sup>6,29,75</sup> During any continuous magnesium infusion, frequent serum  $[Mg^{2+}]$  determinations should be obtained and the presence of reflexes documented. If hyporeflexia occurs, the magnesium infusion should be discontinued and the patient assessed and treated for respiratory muscle weakness if present.

## SUMMARY

- The management of poisoned patients must include an evaluation of their fluid, electrolyte, and acid–base status.
- Developing a stepwise approach to the evaluation of patients with a high anion gap metabolic acidosis is essential.
- The osmol gap can help confirm a suspicion of toxic alcohol poisoning but cannot exclude the diagnosis.
- Disorders of sodium (water) are common manifestations of xenobiotic exposure. Because fluid and electrolyte abnormalities result from both poisoning and the therapy of poisoned patients, reassessment and monitoring are essential to ensure a good clinical outcome.

## NEUROTRANSMITTERS AND NEUROMODULATORS

Steven C. Curry, Ayrn D. O'Connor, Kimberlie A. Graeme, and A. Min Kang

This chapter reviews the normal physiology of neurotransmission, the molecular action and biochemistry of several major neurotransmitters and their receptors, and the toxicologic mechanisms by which numerous xenobiotics act at the molecular level. Acetylcholine, norepinephrine, epinephrine, dopamine, serotonin,  $\gamma$ -aminobutyric acid (GABA),  $\gamma$ -hydroxybutyrate (GHB), glycine, glutamate, and adenosine are neurotransmitters and neuromodulators of toxicologic interest discussed herein.

When examining molecular actions of xenobiotics on neurotransmitter systems, it quickly becomes apparent that xenobiotics rarely possess single pharmacologic actions. As examples, doxepin, in part, antagonizes voltage-gated sodium channels, voltage-gated potassium channels, histaminic  $H_1$  and  $H_2$  receptors,  $\alpha$ -adrenergic receptors, muscarinic acetylcholine receptors, dopamine  $D_2$  receptors, and GABA<sub>A</sub> receptors; and inhibits norepinephrine, serotonin, and adenosine reuptake. Similarly, carbamazepine blocks voltage-gated sodium channels; inhibits the reuptake of norepinephrine, adenosine, and serotonin; antagonizes adenosine and muscarinic receptors; activates GABA<sub>B</sub> receptors; and binds to benzodiazepine-binding sites on mitochondria. For obvious reasons, then, this chapter cannot include every action of every xenobiotic on the nervous system. Nor is it meant to be a complete discussion of toxidromes produced by various xenobiotics, as these are discussed in specific chapters. Rather, this chapter provides a general and basic understanding of mechanisms of action of various xenobiotics affecting neurotransmitter function and receptors, especially in the central nervous system. With this focus, the clinical effects produced are more easily understood and predicted, and specific treatments can be rationally undertaken. Given the complexity of the nervous system and the numerous actions of a given xenobiotic, it is not always clear which neurotransmitter system is producing an observed effect. Therefore, specific xenobiotics are found in several sections. An attempt is made to note the major mechanism of action of a xenobiotic, although other actions are noted when possible.

### NEURON PHYSIOLOGY AND NEUROTRANSMISSION

#### Membrane Potentials, Ion Channels, and Nerve Conduction

Membrane-bound sodium, potassium adenosine triphosphatase (ATPase) moves 3 sodium ions ( $Na^+$ ) from inside the cell to the interstitial space while pumping 2 potassium ions ( $K^+$ ) into the cell. Because the cell membrane is not freely permeable to large, negatively charged intracellular molecules, such as proteins, an equilibrium results in which the inside of the neuron is negative with respect to the outside. This typical neuronal resting membrane potential is  $-65$  mV.

Sodium, calcium ( $Ca^{2+}$ ),  $K^+$ , and chloride ( $Cl^-$ ) ions move into and out of neurons through ion channels. When moving through ion channels, which are long polypeptides comprising several subunits that span the plasma membrane multiple times, ions always move passively down electrochemical gradients. Many different ion channels are structurally comparable, sharing similar amino acid sequences.<sup>29</sup> Channels for a specific ion also vary in structure, depending on the specific subunits that have combined to form the channel. Because of structural similarity of different channels, it is not surprising that many xenobiotics are able to bind to more than one type of ion channel.

More than 40 different ion channels have been described in various nerve terminals,<sup>182</sup> and it is estimated that a human being contains hundreds of different varieties of ion channels for  $Na^+$ ,  $Cl^-$ ,  $Ca^{2+}$ , and  $K^+$ . Most ion channels fall into 2 general classes: voltage-gated (voltage-dependent) ion channels and ligand-gated ion channels.<sup>182</sup> Voltage-gated channels open or close in response to changes in membrane potential. Ligand-gated channels open or close when a ligand (eg, neurotransmitter) binds to and changes the conformation of the channel.

A commonly accepted model describes voltage-gated  $Na^+$  channels and some other voltage-gated ion channels in 3 possible states. Using  $Na^+$  channels as an example, the  $Na^+$  channel is closed at rest and impermeable to  $Na^+$ , preventing  $Na^+$  from moving into the cell. When the channel undergoes activation, the channel opens, allowing  $Na^+$  to move intracellularly, down its electrochemical gradient. The channel then undergoes a third conformational change by becoming inactivated, preventing further influx of  $Na^+$ . The term *recovery* describes the conversion of inactive channels back to the resting state, a process that requires repolarization of the cell membrane.

Depolarization of a neuron usually results from an initial inward flux of cations ( $Na^+$  or  $Ca^{2+}$ ), or prevention of  $K^+$  efflux. The fall in membrane potential (movement toward 0 mV) results in further activation of these voltage-gated  $Na^+$  channels, allowing yet a greater influx of cations. When the membrane potential falls to threshold,  $Na^+$  channels are activated en masse, and there is a large influx of  $Na^+$ .

Depolarization of a segment of the neurolemma causes the adjacent neuronal membrane to reach threshold, resulting in the propagation of an action potential down the neuron. Sodium channel activation is quickly followed by inactivation, ending depolarization. Over the short term, repolarization of the neuron subsequently occurs mainly from efflux of  $K^+$  and some influx of  $Cl^-$ .

#### Neurotransmitter Release

Neurotransmitters are chemicals that are released from nerve endings into the synapse, where they produce effects by binding to receptors on postsynaptic or presynaptic cell membranes. The receptors are also found on other neurons or effector organs such as smooth muscle. Concentrations of neurotransmitters in cytoplasm are kept low to prevent passive movement out of the nerve ending. To provide a source of neurotransmitters that is protected from cytoplasmic enzymatic degradation and that can rapidly be released, neurotransmitters are concentrated and stored within vesicles in the nerve terminal. As a wave of depolarization from  $Na^+$  influx reaches the nerve ending, membrane depolarization opens voltage-gated  $Ca^{2+}$  channels, allowing  $Ca^{2+}$  to move rapidly into the cell. This influx of  $Ca^{2+}$  triggers exocytosis of vesicle contents into the synapse via the *snare* complex. The voltage-gated  $Ca^{2+}$  channels responsible for inward  $Ca^{2+}$  currents that trigger neurotransmitter release are members of the  $Ca_v2$  subfamily (N, P/Q, and R subtypes).<sup>188,233</sup> Ziconotide, is a conotoxin derivative that is used for analgesia blocking N-type  $Ca^{2+}$  channels on nociceptive neurons in the dorsal root to prevent neurotransmitter release. Cardiovascular calcium channel blockers used in clinical practice do not block these subtypes of voltage-dependent  $Ca^{2+}$  channels, but block the L-subtype. However, L-subtype  $Ca^{2+}$  channels reside elsewhere on neurons.

#### Vesicle Transport of Neurotransmitters

The pH inside neurotransmitter vesicles is about 5.5, which is lower than that in the cytoplasm. A vacuolar ATPase in the vesicular membrane is responsible for movement of protons into the vesicular lumen at the expense of ATP hydrolysis. Vesicular uptake pumps (transporters) that move neurotransmitters or their precursors from the cytoplasm into the vesicle lumen, in turn, are powered by the electrochemical  $H^+$  gradient. That is, the movement of an  $H^+$  out of the vesicle into the cytoplasm is coupled to the movement of a neurotransmitter from the cytoplasm into the vesicle.

Various vesicular transporters for neurotransmitters have been sequenced to date. Vesicular GABA transporter (VGAT) (also known as VIAAT) transports GABA and glycine. Vesicular monoamine transporter (VMAT2) transports all 3 monoamines, dopamine, norepinephrine, and serotonin (VMAT1 transports monoamines into non-neuronal vesicles). Vesicular acetylcholine transporter (VACHT) is responsible for acetylcholine (ACh)

transport, and 3 vesicular glutamate transporter (VGluTs) (VGluT1-3) move glutamate into vesicles.

Neurotransmitters are confined within the vesicle, to a great extent, by ion trapping, as they are more ionized and less able to diffuse back out of the vesicle at the lower pH. Anything that causes a decrease in the pH gradient across the vesicle membrane results in the movement of neurotransmitters into the cytoplasm.<sup>274</sup> For example, amphetamine moves into vesicles, where it buffers protons, causing the movement of monoamine neurotransmitters out of vesicles, and raising cytoplasmic concentrations of neurotransmitters, and ultimately raising the synaptic monoamine concentrations.<sup>274,275</sup>

### Neurotransmitter Reuptake

Although ACh is inactivated in the synapse by enzymatic degradation, other neurotransmitters have their synaptic effects terminated by active uptake into neurons or glial cells. These plasma membrane neurotransmitter transporters are distinct from those transporters responsible for movement of neurotransmitters into vesicles. Cell membrane transporters for different neurotransmitters are Na<sup>+</sup>-dependent transport proteins, during which the uptake of neurotransmitters is accompanied by the movement of Na<sup>+</sup> across the synaptic membrane.<sup>5</sup> These uptake transporters are commonly known as either uptake or reuptake pumps; the term “reuptake” will be used in this chapter for purposes of consistency.

Neurotransmitter reuptake transporters are subdivided into 2 main families.<sup>5</sup> One family (SLC6) includes structurally similar uptake pumps for GABA, glycine, norepinephrine, dopamine, and serotonin. They generally comprise 600 to 700 amino acids and form loops spanning the plasma membrane 12 times. Four GABA reuptake transporters (GAT-1 through GAT-4) transport GABA into neurons and glial cells. Reuptake of dopamine, serotonin, and norepinephrine is achieved by DAT, SERT, and NET respectively. Glycine uptake into neurons and astrocytes is achieved by GLYT-1 and GLYT-2.

The second family (SLC1) comprises 5 glutamate reuptake transporters (excitatory amino acid transporters; EAATs), which appear to traverse the plasma membrane 10 times and move glutamate from the synapse into glial cells and neurons.

Several properties make transporter proteins of particular toxicologic significance. First, they are capable of moving neurotransmitters in either direction; when cytoplasmic neurotransmitter concentrations are significantly elevated, neurotransmitters are transported back into the synapse. Second, these transporters are not always completely specific. For instance, the uptake transporter for norepinephrine moves dopamine and other bioactive amines into the neuron. Third, a xenobiotic that acts at the level of the membrane transporter affects functions of several different neurotransmitters, depending on its specificity for a particular transporter. As an example, fluoxetine is fairly specific at inhibiting reuptake of serotonin, whereas cocaine inhibits the reuptake of serotonin, norepinephrine, and dopamine.

### Neurotransmitter Receptors

#### Channel Receptors

The first general class of neurotransmitter receptors comprises ligand-gated ion channels (LGICs; channel receptors; ionotropic receptors), in which the receptor for the neurotransmitter is part of an ion channel. These channels comprise multiple subunits that combine in various combinations to create channels that vary in response to a given neurotransmitter or other agonist/antagonist. Ligand-gated ion channels for neurotransmitters discussed in this chapter are divided into 2 main groups, based on structure of subunits and assemblies. Most neurotransmitter LGICs are pentameric and display 4 transmembrane helices. Ligand-gated ion channels for glutamate, however, are tetrameric and comprise 3 transmembrane helices.<sup>173</sup>

By binding to its LGIC receptor, the neurotransmitter allosterically changes the configuration of the ion channel so that ions traverse the channel in greater quantities per unit time. As an example, the acetylcholine nicotinic ACh receptor at the neuromuscular junction is a ligand-gated Na<sup>+</sup> channel. When acetylcholine binds to the nicotinic receptor, the configuration of the channel changes, allowing Na<sup>+</sup> to move into the cell and trigger

**TABLE 13–1** Types of Neurotransmitter and Neuromodulator Receptors

<i>Ion Channel</i>	<i>G Protein–Coupled Receptor</i>
ACh nicotinic	ACh muscarinic
GABA <sub>A</sub>	Adenosine
Glycine (Inhibitory)	Dopamine
Glutamate AMPA	GABA <sub>B</sub>
Glutamate NMDA	GHB
Glutamate kainate <sup>a</sup>	Glutamate metabotropic
5-HT <sub>3</sub>	Norepinephrine
	5-HT <sub>1,2,4-7</sub>

<sup>a</sup>There are data supporting a subset of glutamate kainate receptors coupled to G-proteins.

ACh = acetylcholine; AMPA = amino-3-hydroxy-5-methyl-4-isoxazole propionate;

GABA =  $\gamma$ -aminobutyric acid; 5-HT = 5-hydroxytryptamine (serotonin);

NMDA = *N*-methyl-D-aspartate; GHB =  $\gamma$ -hydroxybutyrate.

an action potential. The action potential then propagates down muscle via voltage-gated Na<sup>+</sup> channels. **Table 13–1** lists other examples of channel receptors.

#### G Protein–Coupled Receptors

The second general class of neurotransmitter receptors are linked to G proteins, which are part of a superfamily of proteins with guanosine triphosphatase (GTPase) activity responsible for signal transduction across plasma membranes.<sup>264</sup> G proteins comprise 3 polypeptide subunits:  $\alpha$ ,  $\beta$ , and  $\gamma$  chains. These chains span the plasma membrane several times, and they associate with a separately transcribed neurotransmitter receptor that spans the cell membrane 7 times, with an external binding site for neurotransmitters. Some receptors (eg, GABA<sub>B</sub> receptor) coupled to G proteins are obligatory heterodimers comprising 2 separate proteins, both of which must be present for activity.

The  $\alpha$  chain normally binds guanosine diphosphate (GDP) in the cytoplasm and is inactive. When a neurotransmitter binds to its receptor externally on the cell membrane, GDP dissociates from the  $\alpha$  chain and guanosine triphosphate (GTP) binds in its place, activating the  $\alpha$  subunit. The activated  $\alpha$  subunit then dissociates from the receptor and from the  $\beta$ - $\gamma$  chains. Both the activated  $\alpha$  subunit and  $\beta$ - $\gamma$  subunits modulate effectors in the plasma membrane.<sup>264</sup> The effector influenced by  $\alpha$  or  $\beta$ - $\gamma$  subunits is frequently an enzyme that the subunits stimulate or inhibit (eg, adenylate cyclase) or an ion channel that is opened or closed directly or through other chemical reactions (eg, channel phosphorylation).<sup>48</sup> Intrinsic GTPase activity in the  $\alpha$  chain eventually converts the GTP to GDP, inactivating the  $\alpha$  subunit and allowing it to reassociate with the  $\beta$ - $\gamma$  chains and the neurotransmitter receptor, terminating the consequences of neurotransmitter binding.<sup>264</sup>

The type of the  $\alpha$  chain that the G proteins contain determines the categorization. The 3 main families of G proteins coupled to neurotransmitter receptors are G<sub>s</sub> (containing  $\alpha_s$ ), G<sub>i/o</sub> (containing  $\alpha_i$  or  $\alpha_o$ ), and G<sub>q</sub> (or G<sub>q/11</sub>, containing  $\alpha_q$ ). G<sub>s</sub> stimulates membrane-bound adenylate cyclase; activation of a neurotransmitter receptor coupled to G<sub>s</sub> causes a rise in intracellular 3',5'-cyclic adenosine monophosphate (cAMP) concentration. Neurotransmitter receptors activating G<sub>i</sub> may inhibit adenylate cyclase or modulate K<sup>+</sup> and Ca<sup>2+</sup> channels. Receptors coupled to G<sub>q</sub> act through membrane-bound phospholipase C to increase intracellular calcium concentrations. See **Table 13–1** for a list of the neurotransmitter receptors coupled to G proteins. A given neurotransmitter can activate different classes of receptors (eg, ion-channel and G protein) or different types of receptors in the same class. For example, GABA<sub>A</sub> receptors are Cl<sup>-</sup> channels, whereas GABA<sub>B</sub> receptors are coupled to G proteins. Dopamine D<sub>1</sub>-like receptors (D<sub>1</sub> and D<sub>5</sub>) are linked to G<sub>s</sub>, whereas D<sub>2</sub>-like receptors (D<sub>2</sub>, D<sub>3</sub>, and D<sub>4</sub>) are most commonly linked to G<sub>i</sub> or G<sub>o</sub>.

Importantly, some single G protein–coupled receptors activate more than one type of G protein in the same cell, depending on various circumstances, including duration of receptor activation. Evidence continues to accumulate indicating that G protein–coupled receptors for the same or different neurotransmitters form both heterodimers and oligomers, resulting in yet more variation in response to neurotransmitter binding. Examples include combinations of various dopamine receptors, combinations of dopamine and 5-HT receptors, and combinations of dopamine and glutamate receptors.<sup>189,191,245</sup>

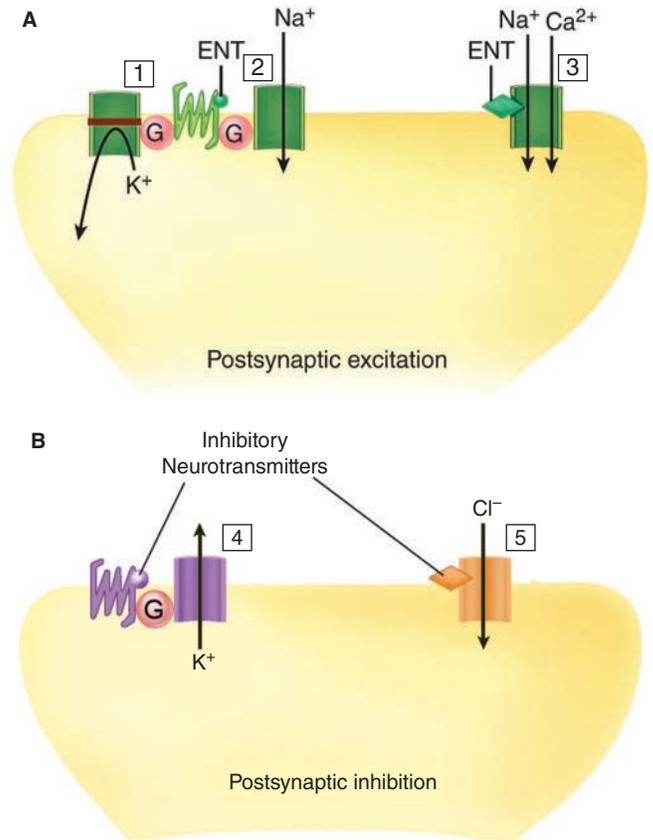

Receptor downregulation occurs at various levels. For example, prolonged receptor activation results in receptor phosphorylation by G protein kinases (GPKs), causing receptor binding to a member of the arrestin family of proteins. This, in turn, prevents further activation of the G protein by the receptor and eventually triggers receptor endocytosis.<sup>7,150,259</sup>

### Neuronal Excitation and Inhibition

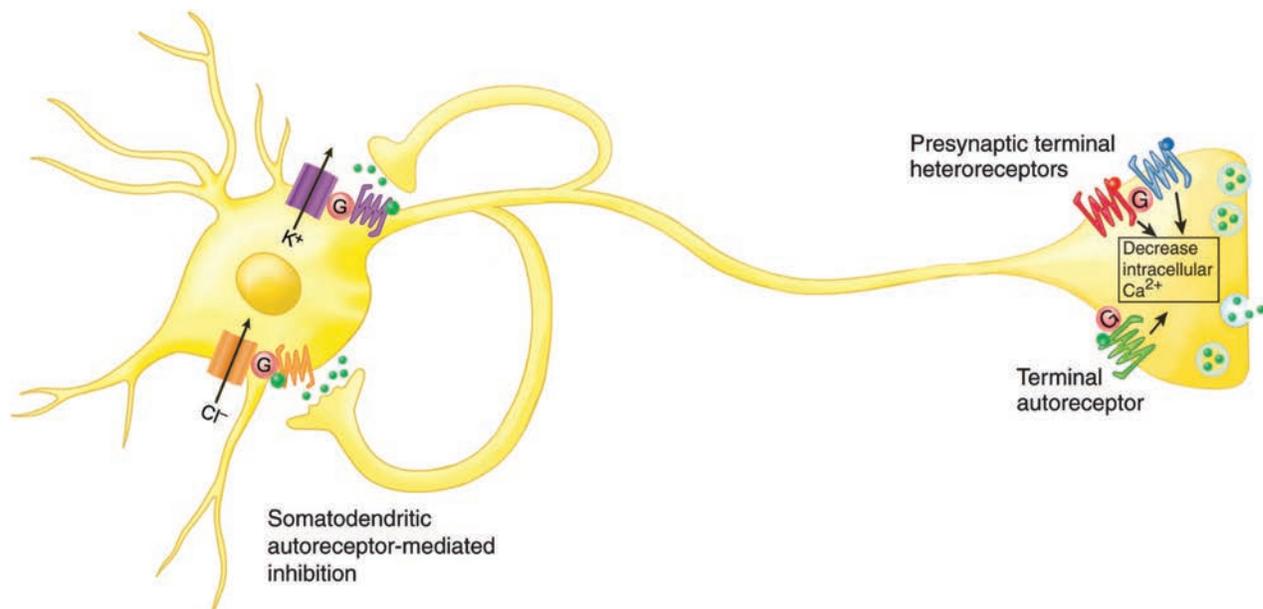

Excitatory neurotransmitters usually act postsynaptically by causing  $\text{Na}^+$  or  $\text{Ca}^{2+}$  influx, or by preventing  $\text{K}^+$  efflux, triggering depolarization and an action potential (Fig. 13–1). These effects usually are mediated by either ion channel or G protein–coupled receptors.

Postsynaptic inhibition results from actions on ion channel receptors or receptors coupled to G proteins (Fig. 13–1). Inhibition is usually accomplished by neuronal influx of  $\text{Cl}^-$  or efflux of  $\text{K}^+$  to hyperpolarize the neuron and move membrane potential farther away from threshold, making it more difficult for a given stimulus to depolarize the membrane to threshold voltage.

Presynaptic inhibition, the prevention of neurotransmitter release, is usually mediated by receptors coupled to G proteins, but ligand-gated ion channels such as kainate glutamate receptors are found on neuronal terminals, as well. When a neurotransmitter released from a neuron binds to a receptor on that same neuron to limit further neurotransmitter release, the receptor is termed an *autoreceptor*.<sup>252</sup> Autoreceptors reside on dendrites, cell bodies, axons, and presynaptic terminals. Activation of autoreceptors on dendrites and cell bodies (somatodendritic autoreceptors) usually impairs neurotransmitter release by increasing  $\text{K}^+$  efflux, thereby hyperpolarizing the neuron away from threshold (Fig. 13–2). However, activation of autoreceptors found on presynaptic terminals (terminal autoreceptors) usually limits

**FIGURE 13–1.** Common mechanisms of postsynaptic excitation and inhibition. (A) An excitatory neurotransmitter (ENT) binds to receptors linked to G proteins to prevent  $\text{K}^+$  efflux [1] or to allow  $\text{Na}^+$  influx [2], producing membrane depolarization. An ENT may bind to and activate a cation channel [3] to allow  $\text{Na}^+$  and/or  $\text{Ca}^{2+}$  influx with resultant membrane depolarization. (B) An inhibitory neurotransmitter hyperpolarizes the membrane (makes membrane potential more negative) by binding to receptors linked to G proteins to enhance  $\text{K}^+$  efflux [4], or to  $\text{Cl}^-$  channels to allow  $\text{Cl}^-$  influx [5]. Some  $\text{Cl}^-$  channels are regulated by G proteins as well. G = G protein.

**FIGURE 13–2.** Common mechanisms of presynaptic inhibition (the inhibition of neurotransmitter [NT] release). A neuron releases NT (green dots), which returns to activate receptors on the cell body or dendrites (somatodendritic autoreceptors), or on the axonal terminal (terminal autoreceptors). Such activation limits further release of NT by completing a negative feedback loop. At somatodendritic autoreceptors, NT binding produces activation of G proteins, which promote either  $\text{K}^+$  efflux or  $\text{Cl}^-$  influx; both processes hyperpolarize the neuron away from threshold. At terminal autoreceptors, NT binding activates G proteins, which, through various mechanisms, lower intracellular  $\text{Ca}^{2+}$  concentrations to prevent exocytosis of NT vesicles, despite depolarization. Presynaptic inhibitory receptors for other types of NTs (heteroreceptors) are also shown. Excitatory axonal terminal autoreceptors and heteroreceptors that serve to enhance neurotransmitter release are not illustrated. G = G protein.

increases in intracellular  $\text{Ca}^{2+}$  concentration by limiting  $\text{Ca}^{2+}$  influx or preventing  $\text{Ca}^{2+}$  release from intracellular stores, impairing exocytosis of neurotransmitter vesicles (Fig. 13–2). Types of neurotransmitter receptors that serve as autoreceptors also usually reside postsynaptically, where they may mediate different physiologic effects.

Inhibition of neurotransmitter release from nerve terminals is not limited to actions by autoreceptors. Presynaptic terminal inhibitory receptors for various neurotransmitters are sometimes found on a single neuron (heteroreceptors). For example, stimulation of presynaptic  $\alpha_2$  receptors found on postganglionic parasympathetic nerve terminals prevents ACh release.

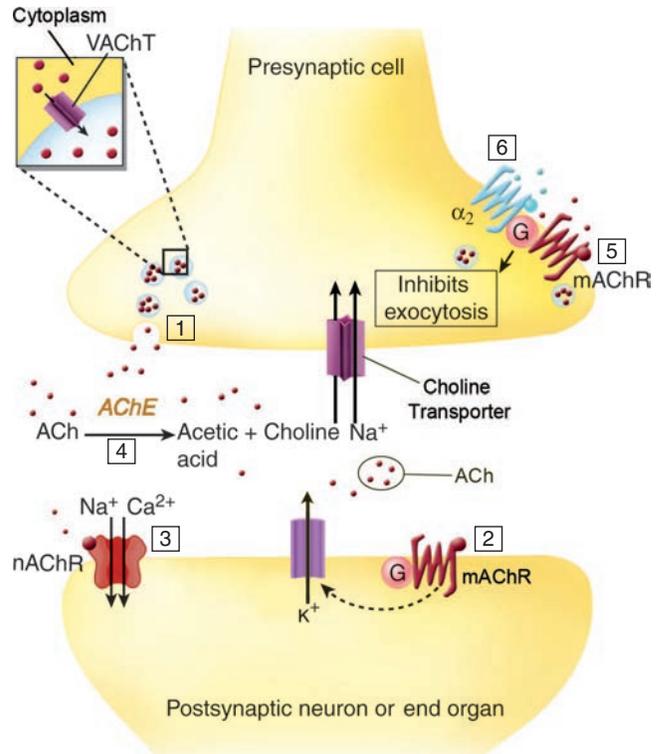

Finally, stimulation of receptors on presynaptic nerve endings sometimes enhances, rather than inhibits, neurotransmitter release. Such receptors also are usually coupled to G proteins. For example, activation of  $\beta_2$  receptors on adrenergic nerve terminals enhances norepinephrine release.

## ACETYLCHOLINE

Acetylcholine (ACh) is a neurotransmitter of the central and peripheral nervous system. Centrally, it is found in both brain and spinal cord; cholinergic fibers project diffusely to the cerebral cortex. Peripherally, ACh serves as a neurotransmitter in autonomic and somatic motor fibers (Fig. 13–3).

### Synthesis, Release, and Inactivation

Acetylcholine is synthesized from acetylcoenzyme A and choline by the enzyme choline acetyltransferase. Acetylcholine moves into synaptic

**FIGURE 13–4.** Cholinergic nerve ending. Activation of postsynaptic muscarinic receptors (mAChR) hyperpolarizes the postsynaptic membrane through G protein–mediated enhancement of  $\text{K}^+$  efflux. Several subtypes of muscarinic receptors coupled to various G proteins exist—a muscarinic receptor coupled to a G protein that opens  $\text{K}^+$  channels is shown only as an example [2]. Postsynaptic nicotinic receptor (nAChR) activation causes  $\text{Na}^+$  influx and membrane depolarization [3].  $\text{Ca}^{2+}$  influx appears to be the main cation involved with some neuronal nicotinic receptors. Presynaptic muscarinic and  $\alpha_2$ -adrenergic receptor activation prevents ACh release through lowering of intracellular  $\text{Ca}^{2+}$  concentrations. The xenobiotics listed in Table 13–2 may act to enhance or prevent release of ACh [1]; activate or antagonize postsynaptic muscarinic (M) receptors [2]; activate or antagonize nicotinic (N) receptors [3]; inhibit acetylcholinesterase [4]; prevent ACh release by stimulating presynaptic muscarinic autoreceptors [5] or  $\alpha_2$ -adrenergic heteroreceptors [6]; or enhance ACh release by antagonizing presynaptic autoreceptors [5] or by antagonizing presynaptic  $\alpha_2$ -adrenergic heteroreceptors [6] (on parasympathetic postganglionic terminals). ACh = acetylcholine; AChE = acetylcholinesterase; G = G protein; VACHT = vesicular transporter for ACh. Norepinephrine is shown as light blue dots.

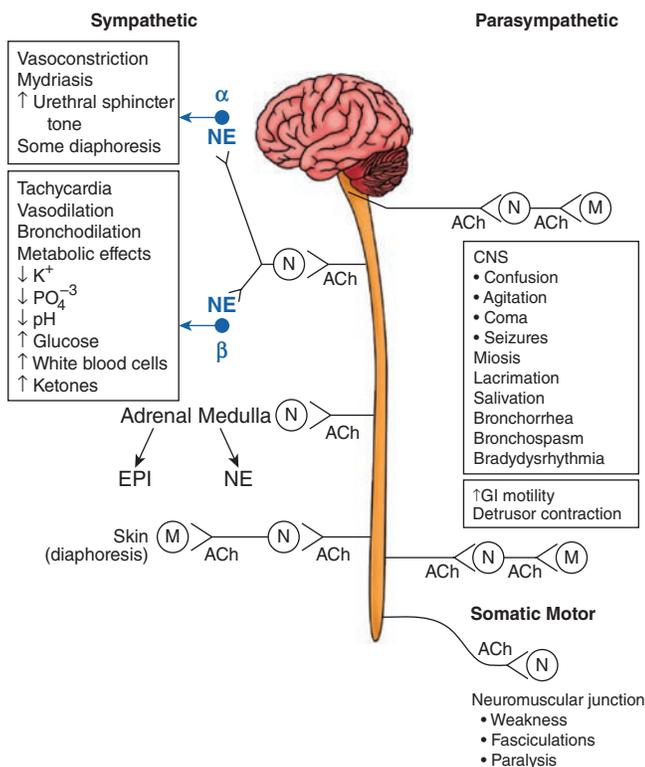

vesicles via the vesicular membrane transporter, VACHT, where it is stored before release into the synapse by  $\text{Ca}^{2+}$ -dependent exocytosis. Acetylcholine undergoes enzymatic degradation in the synapse to choline and acetic acid by acetylcholinesterase. A  $\text{Na}^+$ -dependent transporter in the neuronal membrane (ChT) then pumps choline back into the cytoplasm to be used again as a substrate for ACh synthesis (Fig. 13–4). Pseudocholesterase (also known as plasma cholinesterase or butyryl cholinesterase) is made in the liver and plays no role in the degradation of synaptic ACh. However, it does metabolize some xenobiotics, including cocaine and succinylcholine.

## Acetylcholine Receptors

### Nicotinic Receptors

After release from cholinergic nerve endings, ACh activates 2 main types of receptors: nicotinic and muscarinic.<sup>151</sup> Nicotinic receptors (nAChRs) reside in the CNS (mainly in spinal cord), on postganglionic autonomic neurons (both sympathetic and parasympathetic), in the adrenal medulla, and at skeletal neuromuscular junctions, where they mediate muscle contraction (Fig. 13–3).

Nicotinic receptors at neuromuscular junctions (NMJ) nAChRs are part of a  $\text{Na}^+$  channel made from 5 protein subunits. Stimulation of these receptors by ACh results mainly in  $\text{Na}^+$  influx, depolarization of the endplate,

**FIGURE 13–3.** Diagram of the cholinergic nervous system, including adrenergic involvement in the autonomic nervous system. ACh binds to various nicotinic receptors (N) in CNS, in sympathetic and parasympathetic ganglia, and the adrenal glands. All nicotinic receptors shown are neuronal nicotinic receptors (neuronal nAChRs) except for those at skeletal muscle, which are neuromuscular junction nicotinic receptors (NMJ nAChRs). Acetylcholine (ACh) also binds to various subtypes of muscarinic (M) receptors in the CNS and on effector organs innervated by postsynaptic parasympathetic neurons and to most sweat glands. NE and/or EPI released in response to ACh stimulation of neuronal nAChRs activates  $\alpha$ - and  $\beta$ -adrenergic receptors. ACh = acetylcholine; CNS = central nervous system; EPI = epinephrine; NE = norepinephrine.

and triggering of an action potential that is propagated down the muscle by voltage-gated Na<sup>+</sup> channels.

Nicotinic receptors on central or peripheral neurons or in the adrenal gland are termed neuronal nAChRs. Neuronal nAChRs are also ion channels, although in some cases Ca<sup>2+</sup> influx through the receptor may be more important than Na<sup>+</sup> influx. Neuronal nAChRs also comprise 5 subunits.

### Muscarinic Receptors

Muscarinic receptors reside in the CNS (mainly in the brain), on end organs innervated by postganglionic parasympathetic nerve endings, and at most postganglionic sympathetically innervated sweat glands (Fig. 13–3). Five subtypes of muscarinic receptors, M<sub>1–5</sub>, are recognized and linked to several G proteins. For example, in the heart, ACh released from the vagus nerve binds to M<sub>2</sub> receptors linked to G<sub>i</sub> in pacemaker cells. G<sub>i</sub> opens K<sup>+</sup> channels, allowing efflux of K<sup>+</sup> down its concentration gradient, which makes the inside of the cell more negative and more difficult to depolarize, slowing the heart rate. Different subtypes of muscarinic receptors also act as autoreceptors in various locations, M<sub>1</sub> being the most common.

### Xenobiotics

Table 13–2 provides examples of xenobiotics that affect cholinergic neurotransmission.

**TABLE 13–2** Examples of Xenobiotics Affecting Cholinergic Neurotransmission

Cholinomimetics	Cholinolytics
Cause ACh release	Direct nicotinic antagonists
α <sub>2</sub> -Adrenergic receptor antagonists <sup>a</sup>	α-Bungarotoxin <sup>c</sup>
Aminopyridines	Nondepolarizing neuromuscular blockers
Black widow spider venom	Trimethaphan
Carbachol	Indirect neuronal nicotinic antagonists
Guanidine	Galantamine
Anticholinesterases	Physostigmine
Donepezil	Tacrine
Edrophonium	Direct muscarinic antagonists
N-Methylcarbamate compounds	Antihistamines
Organic phosphorus compounds	Atropine
Physostigmine	Benztropine
Rivastigmine	Clozapine
Direct nicotinic agonists	Cyclic antidepressants
Carbachol	Cyclobenzaprine
Coniine	Disopyramide
Cytisine	Orphenadrine
Nicotine	Phenothiazines
Succinylcholine <sup>b</sup>	Procainamide
Varenicline	Scopolamine
Indirect neuronal nicotinic agonists	Trihexyphenidyl
Chlorpromazine	Inhibit ACh release
Ethanol	α <sub>2</sub> -Adrenergic receptor agonists <sup>d</sup>
Ketamine	Botulinum toxins
Local anesthetics	Crotalinae venoms
Phencyclidine	Elapidae β-neurotoxins
Volatile anesthetics	Hypermagnesemia
Direct muscarinic agonists	
Arecoline	
Bethanechol	
Carbachol	
Cevimeline	
Methacholine	
Muscarine	
Pilocarpine	

<sup>a</sup>Antagonism of α<sub>2</sub>-adrenoceptors enhances ACh release from parasympathetic nerve endings.

<sup>b</sup>Depolarizing neuromuscular blockers. <sup>c</sup>α-Bungarotoxin exemplifies many elapid α-neurotoxins that produce paralysis and death from respiratory failure. <sup>d</sup>Stimulation of presynaptic α<sub>2</sub>-adrenergic receptors on parasympathetic nerve endings prevents ACh release.

ACh = acetylcholine.

### Modulators of Acetylcholine Release

Figure 13–4 illustrates sites of actions of numerous xenobiotics that influence the cholinergic nervous system. Botulinum toxins, some neurotoxins from pit vipers, and elapid β-neurotoxins prevent release of ACh from peripheral nerve endings.<sup>101</sup> This results in ptosis, other cranial nerve findings, weakness, and respiratory failure. Hypermagnesemia also inhibits ACh release, probably by inhibiting Ca<sup>2+</sup> influx into the nerve endings.<sup>151</sup>

Guanidine, aminopyridines, and black widow spider venom enhance the release of ACh from nerve endings. Aminopyridines, in part, block voltage-gated K<sup>+</sup> channels to prevent K<sup>+</sup> efflux; the resultant action potential widening (delayed repolarization) causes prolongation of Ca<sup>2+</sup>-channel activation, enhancing influx of Ca<sup>2+</sup>, which promotes neurotransmitter release. Aminopyridines are used therapeutically in Lambert–Eaton syndrome, myasthenia gravis, multiple sclerosis, and experimentally in Ca<sup>2+</sup>-channel channel blocker overdose.

Black widow spider venom causes ACh release by opening neuronal Ca<sup>2+</sup>-channels with resultant muscle cramping and diaphoresis.<sup>12</sup>

### Nicotinic Receptor Agonists and Antagonists

Xenobiotics that bind to and activate nicotinic receptors stimulate postganglionic sympathetic and parasympathetic neurons, skeletal muscle endplates, the adrenal medulla, and/or neurons within the CNS (Fig. 13–3). Prolonged depolarization at the receptor eventually causes diminution of responses to receptor occupancy.<sup>214</sup> For example, poisoning by nicotine, both a neuronal and NMJ nAChR agonist, produces hypertension, tachycardia, vomiting, diarrhea, muscle fasciculations, and convulsions, followed by hypotension, bradydysrhythmias, paralysis, and coma. Succinylcholine is a neuromuscular blocker that initially stimulates and then blocks muscular activity through prolonged depolarization of NMJ nAChRs.

Xenobiotics that block NMJ nAChRs without stimulation at skeletal neuromuscular junctions produce weakness and paralysis. Examples include tubocurarine and atracurium. α-Neurotoxins from elapids (eg, α-bungarotoxin) directly antagonize NMJ nAChRs, producing ptosis, weakness, and respiratory failure from paralysis.<sup>296</sup>

Peripheral neuronal nAChR blockade produces autonomic ganglionic blockade. Trimethaphan was used as a pharmacologic ganglionic blocker; however, it is not entirely specific for neuronal nAChRs. Occasionally, trimethaphan caused weakness and paralysis from NMJ nAChR blockade.

The functions of neuronal nAChRs are modulated by a variety of xenobiotics that do not bind to the ACh binding site, but bind instead to a number of distinct allosteric sites. For example, aside from their ability to inhibit acetylcholinesterase, physostigmine, tacrine, and galantamine bind to a noncompetitive allosteric activator site on neuronal nAChRs to enhance channel opening and ion conductance. Furthermore, a diverse range of xenobiotics, including chlorpromazine, phencyclidine, ketamine, local anesthetics, and ethanol bind to a noncompetitive negative allosteric site(s) on nAChRs to inhibit inward ion fluxes without directly affecting ACh binding. Some steroids desensitize neuronal nAChRs by binding to yet an additional allosteric site.<sup>219</sup>

### Muscarinic Receptor Agonists and Antagonists

Peripheral muscarinic agonists produce bradycardia, miosis, salivation, lacrimation, vomiting, diarrhea, bronchospasm, bronchorrhoea, and micturition. Central muscarinic agonists produce sedation, extrapyramidal dystonias, rigidity, coma, and convulsions. The anticholinergic toxidrome results from blockade of muscarinic receptors and is more appropriately referred to as an antimuscarinic toxidrome.<sup>255</sup> Central nervous system muscarinic blockade produces confusion, agitation, myoclonus, tremor, picking movements, abnormal speech, hallucinations, and coma. Peripheral antimuscarinic effects include mydriasis, anhidrosis, tachycardia, and urinary retention. Muscarinic antagonists number in the hundreds (Table 13–2 for common examples).

### Acetylcholinesterase Inhibition

Xenobiotics inhibiting acetylcholinesterase (ie, anticholinesterase) raise ACh concentrations at both nicotinic and muscarinic receptors, producing a variety of CNS, sympathetic, parasympathetic, and skeletal muscle signs and

symptoms.<sup>50</sup> Anticholinesterases include organic phosphorus compounds and *N*-methylcarbamates. Organic phosphorus compounds are usually encountered as insecticides, although topical medicinal organic phosphorus compounds are used for the treatment of glaucoma and lice. *N*-Methylcarbamates are found as insecticides and pharmaceuticals. Medicinal *N*-methylcarbamates include physostigmine, pyridostigmine, rivastigmine, and neostigmine. Edrophonium, galantamine, tacrine, donepezil, and metrifonate are non-carbamate, reversible anticholinesterases.

### $\alpha_2$ -Adrenergic Receptor Agonists and Antagonists

Agonists and antagonists of  $\alpha_2$ -adrenergic receptors are discussed in detail below. Briefly, stimulation of presynaptic  $\alpha_2$ -adrenergic receptors on postganglionic parasympathetic nerve endings decreases ACh release. Conversely, presynaptic  $\alpha_2$  antagonism increases ACh release (Fig. 13–4).

## NOREPINEPHRINE AND EPINEPHRINE

Norepinephrine (NE), epinephrine (EPI), dopamine (DA), and serotonin (5-hydroxytryptamine [5-HT]) are similar in many respects. Neurotransmitter synthesis, vesicle transport and storage, uptake, and degradation share many enzymes and structurally similar transport proteins. Cocaine, reserpine, amphetamine, and monoamine oxidase inhibitors (MAOIs) affect all four types of neurons. In addition, these xenobiotics produce several different effects in the same system. For example, in the noradrenergic neuron, amphetamines work mainly by causing the release of cytoplasmic NE, but they also inhibit NE reuptake, and their metabolites inhibit monoamine oxidase. Actions of xenobiotics that affect all bioactive amine neurotransmitters are described in the most detail for noradrenergic neurons. For the sake of brevity, similar mechanisms of action are simply noted in discussions of dopaminergic and serotonergic neurotransmission.

Norepinephrine is released from postganglionic sympathetic terminals (Fig. 13–3). The adrenal gland, acting as a modified sympathetic ganglion, releases EPI and lesser amounts of NE in response to stimulation of neuronal nAChRs. Epinephrine-containing neurons also reside in the brain stem.

The locus ceruleus is the main noradrenergic nucleus and resides in the floor of the fourth ventricle on each side of the pons. Axons radiate from this nucleus out to all layers of the cerebral cortex, to the cerebellum, and to other structures. Norepinephrine demonstrates both excitatory and inhibitory actions in the CNS. Norepinephrine released from locus ceruleus projections in the hippocampus increases cortical neuron activity through  $\beta$ -adrenergic receptor activation and G protein–mediated inhibition of  $K^+$  efflux. Norepinephrine released in outer cortical areas produces inhibitory effects mediated by  $\alpha_2$ -adrenergic receptor activation. Consistent with this, NE demonstrates antiepileptic actions in animals. The antiepileptic action of carbamazepine may partly result from inhibition of NE uptake.<sup>76</sup> Despite antagonistic actions on different cortical neurons, electrical stimulation of the locus ceruleus produces widespread cortical activation and excitation. This overall effect explains a great deal of the hyperattentiveness and lack of fatigue that accompanies use of xenobiotics that mimic or increase noradrenergic activity in the brain. Neuronal firing in the locus ceruleus increases during waking and dramatically falls during sleep.

### Synthesis, Release, and Reuptake

Figure 13–5 is a representation of a noradrenergic neuron. Tyrosine hydroxylase is the rate-limiting enzyme in NE synthesis and is sensitive to negative feedback by NE. This enzyme requires  $Fe^{2+}$  as a cofactor and exists as a homotetramer that is upregulated by chronic exposure to caffeine and nicotine. Under normal dietary conditions, tyrosine hydroxylase is completely saturated by tyrosine, and increasing dietary tyrosine does not appreciably increase dopa synthesis. Dopa undergoes decarboxylation by L-amino acid decarboxylase (DOPA decarboxylase) to DA. DOPA decarboxylase is not specific for DOPA. For example, it also catalyzes the formation of serotonin from 5-HT.

About one-half of cytoplasmic DA is actively pumped into vesicles by VMAT2. The remaining DA is quickly deaminated. In the vesicle, DA is converted to NE by dopamine- $\beta$ -hydroxylase. Vesicles isolated from peripheral nerve endings contain DA, NE, dopamine- $\beta$ -hydroxylase,

and ATP, and all of these substances are released into the synapse during  $Ca^{2+}$ -dependent exocytosis triggered by neuronal firing. In neurons containing EPI as a neurotransmitter, NE is released from vesicles into the cytoplasm, where it is converted to EPI by phenylethanolamine-*N*-methyl-transferase. Epinephrine is then transported back into vesicles before synaptic release.<sup>151</sup>

Norepinephrine is removed from the synapse, mainly by reuptake into the presynaptic neuron by the NE transporter (NET). Although this transporter has great affinity for NE, it also transports other amines, including DA, tyramine, MAOIs, and amphetamines. Once pumped back into the cytoplasm, NE is either transported back into vesicles for further storage and release, or quickly degraded by monoamine oxidase (MAO), an enzyme expressed on the outer mitochondrial membrane.

Monoamine oxidase (MAO) is present in all human tissues except red blood cells. It exists as 2 isoenzymes, MAO-A and MAO-B,<sup>181</sup> each with partially overlapping substrate affinities (Table 13–3). Neuronal MAO, bound to the outer mitochondrial membrane, oxidatively deaminates cytoplasmic amines, including neurotransmitters, to attenuate elevated cytoplasmic concentrations of bioactive amines. Hepatic and intestinal MAO prevents large quantities of dietary bioactive amines from entering the circulation and producing systemic effects.

Catechol-*O*-methyltransferase (COMT) mainly exists as a membrane-bound enzyme widely distributed throughout the body, including the central nervous system, which is responsible for metabolism of DA, L-dopa, NE, and EPI. It remains controversial as to whether enzymatic activity is focused on extracellular (synaptic) or cytoplasmic degradation of catecholamines. In extraneuronal tissue, COMT metabolizes catecholamines, including those that have entered the systemic circulation.

## Adrenergic Receptors

The 2 main types of adrenergic receptors are  $\alpha$ -adrenergic receptors and  $\beta$ -adrenergic receptors. All adrenergic receptors are coupled to G proteins.<sup>222</sup>

### $\beta$ -Adrenergic Receptors

$\beta$ -Adrenergic receptors are divided into 3 major subtypes ( $\beta_1$ ,  $\beta_2$ , and  $\beta_3$ ), depending on their affinity for various agonists and antagonists.<sup>257</sup>  $\beta_1$ -adrenergic receptors and  $\beta_2$ -adrenergic receptors are linked to  $G_s$ , and their stimulation raises cAMP concentration and/or activates protein kinase A, which, in turn, produces several effects, including regulation of ion channels. At least some  $\beta_3$ -adrenergic receptors are coupled to  $G_{i/o}$  proteins.

TABLE 13–3 Characteristics of Monoamine Oxidase (MAO) Isoenzymes

Tyramine	++	++

Upregulation of  $\beta_3$  receptors responsible for a negative inotropic effect in diseased myocardium appears to protect against adverse effects of chronic excessive catecholamine stimulation.  $\beta_3$ -receptor activation by nebigolol probably is responsible for nitric oxide production in some vascular beds.<sup>88</sup>

The  $\beta$ -adrenergic receptors are polymorphic, with genetic variation in humans.<sup>41,121</sup> Polymorphism influences response to medications, regulation of receptors, and clinical course of disease.<sup>41,123,156</sup> In general, peripheral  $\beta_1$ -adrenergic receptors are found mainly in the heart and in the juxtaglomerular apparatus.  $\beta_2$ -adrenergic receptors also reside in the heart as well as other organs where their activation mediates additional adrenergic effects such as bronchodilation and vasodilation.<sup>123</sup> Presynaptic  $\beta_2$ -adrenergic receptor activation causes release of NE from nerve endings (positive feedback).  $\beta_3$ -adrenergic receptors reside mainly in fat, but they also reside in skeletal muscle, gallbladder, and colon where they regulate metabolic processes. Polymorphism of  $\beta_3$ -adrenergic receptors is associated with clinical expressions of non-insulin-dependent diabetes and obesity.<sup>41,273,298</sup>

**$\alpha$ -Adrenergic Receptors**

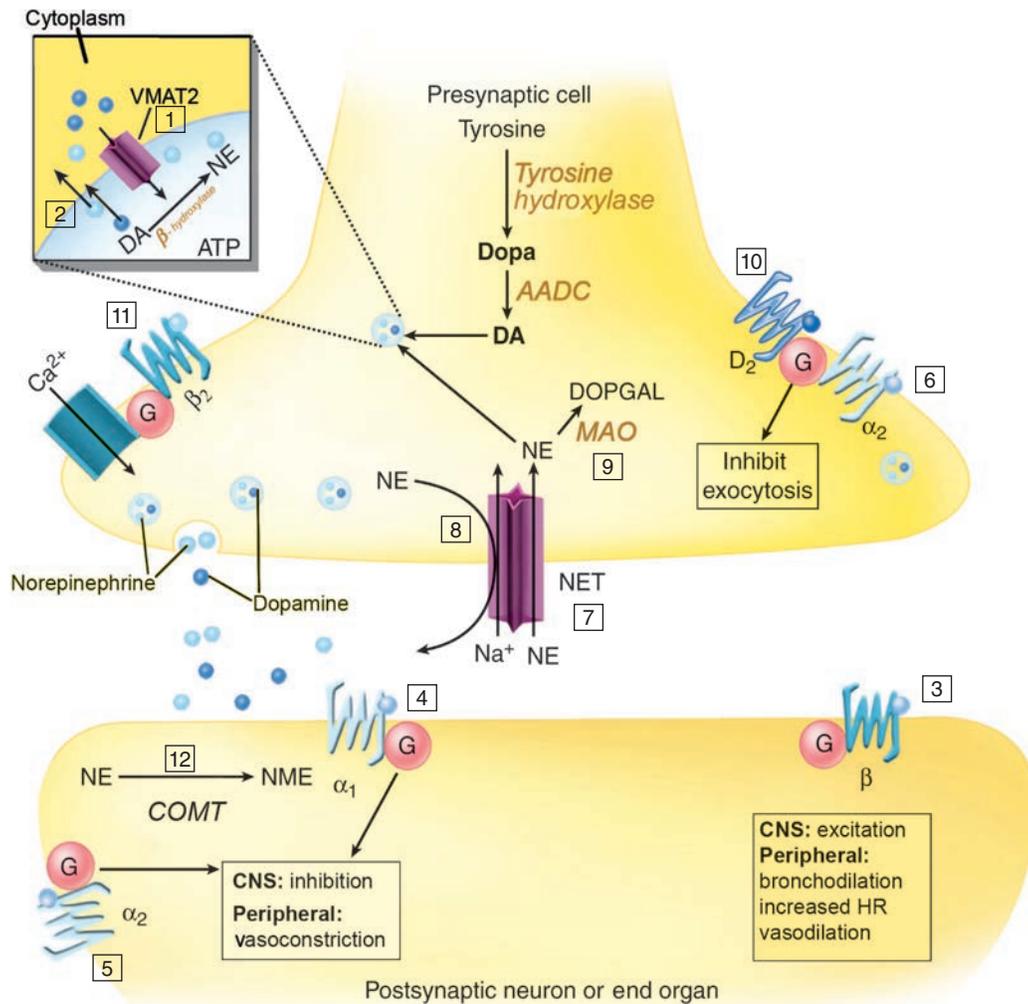

$\alpha$ -Adrenergic receptors are linked to G proteins that inhibit adenylate cyclase to affect cAMP concentrations, affect ion channels, increase intracellular

$Ca^{2+}$  through inositol triphosphate and diacylglycerol production, or produce other actions.<sup>222</sup> These receptors are divided into 2 main types,  $\alpha_1$  and  $\alpha_2$ , and at least 6 subtypes— $\alpha_{1A}$ ,  $\alpha_{1B}$ ,  $\alpha_{1D}$ ,  $\alpha_{2A}$ ,  $\alpha_{2B}$ , and  $\alpha_{2C}$ .<sup>68,110,257</sup> Most  $\alpha_1$ -adrenergic receptors are coupled to  $G_q$ , whereas most  $\alpha_2$ -adrenergic receptors are coupled to  $G_{i/o}$ , although at least some  $\alpha_{2A}$ -adrenergic receptors are coupled to  $G_s$ . The roles of  $\alpha_2$  receptor subtypes are not fully elucidated. Receptors of the  $\alpha_{2A}$  type are the predominant form found in the CNS and are responsible mediating sedative, hypotensive and analgesic effects from  $\alpha_2$  agonists.<sup>120,213</sup>

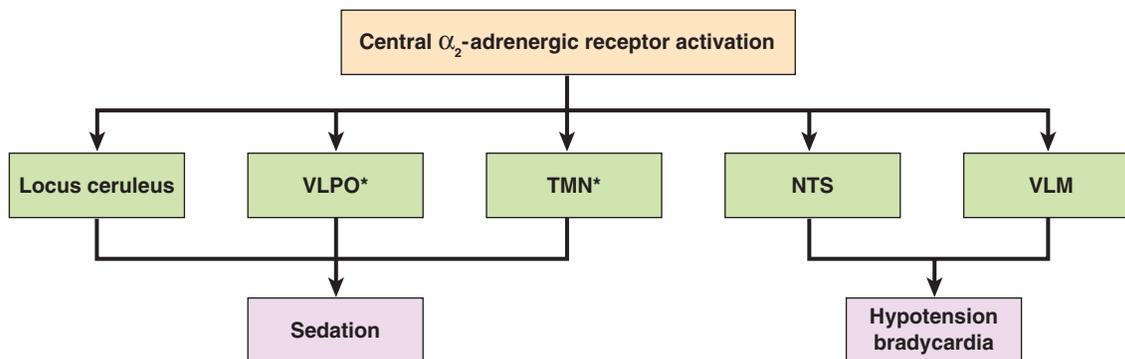

In peripheral tissue,  $\alpha_1$ -adrenergic receptors reside on the postsynaptic membrane in continuity with the synaptic cleft. Stimulation of these receptors on blood vessels results in vasoconstriction.

Central and peripheral  $\alpha_2$ -adrenergic receptors are found at presynaptic and postganglionic sites. Presynaptic  $\alpha_2$ -adrenergic receptor activation mediates negative feedback, limiting further release of NE (Fig. 13-5). Postganglionic parasympathetic neurons also contain presynaptic  $\alpha_2$ -adrenergic receptors that, when stimulated, prevent release of ACh (Fig. 13-4).

Postsynaptic  $\alpha_2$ -adrenergic receptors on vasculature also mediate vasoconstriction.<sup>222</sup> Initially, it was suggested that postsynaptic  $\alpha_2$ -adrenergic receptors resided mainly outside of the synapse and mediated vasoconstrictive responses to circulating  $\alpha$ -adrenergic agonists such as NE, whereas

**FIGURE 13-5.** Noradrenergic nerve ending. The postsynaptic membrane may represent an end organ or another neuron in the CNS. Brief examples of effects resulting from postsynaptic receptor activation are shown. Xenobiotics in Tables 13-4 and 13-5 produce effects by inhibiting transport of dopamine (DA) or norepinephrine (NE) into vesicles through VMAT2 [1]; causing movement of NE and DA from vesicles into the cytoplasm [2]; activating or antagonizing postsynaptic  $\alpha$ - and  $\beta$ -adrenergic receptors [3-5]; modulating NE release by activating or antagonizing presynaptic  $\alpha_2$ -autoreceptors [6], dopamine<sub>2</sub> ( $D_2$ ) heteroreceptors [10], or  $\beta_2$ -autoreceptors [11]; blocking reuptake of NE (NET inhibition) [7]; causing reverse transport of NE from the cytoplasm into the synapse via NET by raising cytoplasmic NE concentrations [8]; inhibiting monoamine oxidase (MAO) to prevent NE degradation [9]; or inhibiting COMT to prevent NE degradation [12]. Controversy exists as to whether COMT's enzymatic action mainly occurs in the synapse or intracellularly. AADC = aromatic L-amino acid decarboxylase;  $\beta$ -hydroxylase = dopamine- $\beta$ -hydroxylase; COMT = catechol-O-methyltransferase; CNS = central nervous system; DOPGAL = 3,4-dihydroxyphenylglycolaldehyde; G = G protein; NET = membrane NE reuptake transporter; NME = normetanephrine; VMAT2 = vesicle uptake transporter for NE.

**FIGURE 13-6.** Central action of xenobiotics that activate  $\alpha_2$ -adrenergic receptors. Activation of  $\alpha_2$ -adrenergic receptors on noradrenergic neurons in the locus ceruleus produces sedation. Activation of receptors in the nucleus tractus solitarius (NTS) and ventrolateral medulla (VLM) contributes to hypotension and bradycardia. \*In animal models,  $\alpha_2$ -receptor activation of GABAergic neurons in the ventrolateral preoptic nucleus (VLPO) and of histaminergic neurons in the tuberomammillary nucleus (TMN) also contribute to sedation.

postsynaptic  $\alpha_1$ -adrenergic receptors responded to NE released from nerve endings. However, in at least some tissues (eg, saphenous vein), NE released following nerve stimulation produces vasoconstriction through action at  $\alpha_2$ -adrenergic receptors, making the previous differentiation not as distinct.<sup>68,135</sup> Because both  $\alpha_1$ -adrenergic receptors and  $\alpha_2$ -adrenergic receptors on non-cerebral vasculature mediate vasoconstriction, a patient with hypertension from high concentrations of circulating catecholamines (eg, pheochromocytoma or clonidine withdrawal) or from extravasation of NE from an intravenous line commonly requires both  $\alpha_1$ -adrenergic receptor and peripheral  $\alpha_2$ -adrenergic receptor blockade to vasodilate adequately (eg, phentolamine).

Activation of postsynaptic  $\alpha_2$ -adrenergic receptors in the brain stem inhibits sympathetic output and produces sedation.  $\alpha_{2A}$ -Adrenergic heteroreceptor activation on non-noradrenergic cells is important in explaining sedation, antinociception, hypothermia, effects on cognition, and centrally mediated bradycardia and hypotension in response to administration of  $\alpha_2$  agonists (Fig. 13-6).<sup>93</sup> Dexmedetomidine, an imidazole and potent  $\alpha_{2A}$ -adrenergic receptor agonist, is used for sedation in intensive care patients, although hypotension and bradycardia occur as expected side effects.<sup>27</sup>

### Xenobiotics

Xenobiotics producing pharmacologic effects that result in or mimic increased activity of the adrenergic nervous system are *sympathomimetics* (Table 13-4). Those with the opposite effect are *sympatholytics* (Table 13-5).

### Sympathomimetics

**Direct-Acting** Xenobiotics whose sympathomimetic actions result from direct binding to  $\alpha$ -adrenergic receptors or  $\beta$ -adrenergic receptors are called *direct-acting sympathomimetics*. Most do not cross the blood-brain barrier in significant quantities.

**Indirect-Acting** Xenobiotics that produce sympathomimetic effects by causing the release of cytoplasmic NE from the nerve ending in the absence of vesicle exocytosis are called *indirect-acting sympathomimetics*. Amphetamine is the prototype of indirect-acting sympathomimetics and is used for the discussion of what is known about their mechanisms of action.<sup>45</sup> In general, mechanisms of indirect release of NE by amphetamines, cocaine, phencyclidine, MAOIs, and mixed-acting xenobiotics noted in Table 13-4 are similar in that their actions depend on their ability to produce elevated cytoplasmic NE concentrations.

Amphetamine and structurally similar indirect-acting sympathomimetics move into the neuron mainly by the membrane transporter that transports NE into the neuron. Lipophilic indirect-acting sympathomimetics frequently move into the neuron by diffusion. From the cytoplasm, amphetamine is transported into neurotransmitter vesicles, where it buffers protons

to raise intravesicular pH. As noted earlier, much of the ability of the vesicle to concentrate NE (and other neurotransmitters) is a result of ion trapping of NE at the lower pH. The rise in intravesicular pH produced by amphetamine causes NE to leave the vesicle and move into the cytoplasm.<sup>274,275</sup> This movement results from diffusion or reverse transport of NE by VMAT2. In the

**TABLE 13-4** Examples of Sympathomimetics

Direct acting	Selective $\alpha_2$ -adrenergic receptor antagonists
$\alpha$ -Adrenergic receptor agonists	Yohimbine
Epinephrine	Mirtazapine
Ergot alkaloids	MAOIs
Methoxamine	Amphetamine
Midodrine	Clorgyline
Norepinephrine	Isocarboxazid
Phenylephrine	Linezolid
$\beta$ -Adrenergic receptor agonists	Methylene blue
Albuterol	Moclobemide
Clenbuterol	Pargyline
Dobutamine	Phenelzine
Epinephrine	Rasagiline
Isoproterenol	Selegiline
Metaproterenol	Tranylcypromine
Norepinephrine	Inhibit norepinephrine reuptake
Terbutaline	Amphetamine
Indirect acting	Atomoxetine
Amphetamine	Benztrapine
Cocaine	Bupropion
Fenfluramine	Carbamazepine
MAOIs	Cocaine
Methylphenidate	Cyclic antidepressants
Pemoline	Diphenhydramine
Phenmetrazine	Duloxetine
Propylhexedrine	Orphenadrine
Tyramine	Pemoline
Mixed acting	Reboxetine
Dopamine	Tramadol
Ephedrine	Trihexyphenidyl
Mephentermine	Venlafaxine
Metaraminol	
Phenylpropanolamine	
Pseudoephedrine	

MAOI = monoamine oxidase inhibitor.

<sup>a</sup>Partial  $\beta$ -adrenergic receptor agonist. <sup>b</sup>Xenobiotics in these categories vary in their relative selectivity for  $\alpha_2$ -adrenergic receptors or imidazoline-binding sites. <sup>c</sup>Metabolized to  $\alpha$ -methylnorepinephrine, which activates  $\alpha_2$ -adrenergic receptors. <sup>d</sup>Common examples.

MAOI = monoamine oxidase inhibitor.

cytoplasm, amphetamine also competes with NE and DA for transport into vesicles, which further contributes to elevated cytoplasmic NE concentrations. In the case of amphetamine, the rise in cytoplasmic concentrations of NE is further enhanced by the ability of amphetamine metabolites to inhibit MAO, which impairs NE degradation.

Every time the Na<sup>+</sup>-dependent uptake transporter, NET, moves a bioactive amine (eg, tyramine) into the neuron from which it is released, a binding site for NE on NET conceptually transiently faces inward and becomes available for reverse transport of NE out of the neuron. The normally low concentration of cytoplasmic NE prevents significant reverse transport. In the face of elevated cytoplasmic NE concentrations produced by indirect-acting sympathomimetics, NET moves NE out of the neuron and back into the synapse, where the neurotransmitter activates adrenergic receptors (indirect action). This process is sometimes referred to as facilitated exchange diffusion or displacement of NE from the nerve ending. Evidence supporting reverse transport produced by amphetamine is that inhibitors of the transporter (eg, tricyclic antidepressants) prevent amphetamine induced NE release.

While all indirect-acting sympathomimetics cause reverse NE transport by increasing cytoplasmic NE concentrations, those that move into the neuron by the membrane transporter (eg, amphetamines, MAOIs, DA, tyramine) further enhance reverse transport because their uptake causes more NE-binding sites on NET to face inward per unit time.

Although cocaine inhibits NET, it also causes some NE release. In fact, cocaine similarly lessens pH gradients across vesicle membranes to raise cytoplasmic concentrations of NE.<sup>275</sup> That cocaine produces less NE release than amphetamines is partly explained by cocaine induced inhibition of the

membrane transporter and possibly by the fact that cocaine does not move into the neuron by active uptake (ie, does not increase the number of NE-binding sites facing inward), but diffuses into the neuron. In fact, most of the severe sympathomimetic effects of cocaine appear to result from action on the brain rather than peripheral nerve endings.<sup>284</sup>

Phencyclidine (PCP) is a hallucinogen that possesses multiple pharmacologic actions. Like toxicity from many hallucinogens, PCP toxicity is accompanied by increased adrenergic activity, which results, in part, from PCP induced decreases in pH gradients across the vesicle membrane<sup>275</sup> and indirect release of NE. Like cocaine, PCP moves into the neuron by diffusion rather than uptake through the membrane transporter, at least partly explaining less PCP induced NE release than which contains typically occurs in amphetamine poisoning.

In addition to causing ACh release, black widow spider venom  $\alpha$ -latrotoxin causes vesicle exocytosis of NE, producing hypertension and diaphoresis over the palms, soles, upper lip, and nose. All of the aforementioned indirectly acting sympathomimetics, except  $\alpha$ -latrotoxin, enter the CNS.

**Mixed-Acting** Mixed-acting sympathomimetics act directly and indirectly. For example, ephedrine indirectly causes NE release and directly activates adrenergic receptors. Intravenously administered DA indirectly causes NE release, explaining most of its vasoconstricting activity, but also directly stimulates dopaminergic and  $\beta$ -adrenergic receptors. Direct  $\alpha$ -agonism occurs at high doses. Except for DA, these xenobiotics cross the blood-brain barrier to produce central effects.

**Reuptake Inhibitors** Inhibitors of NE reuptake raise concentrations of NE in the synapse to produce excessive stimulation of adrenergic receptors.

There are 2 main means by which inhibitors of bioactive amine inhibit reuptake: competitive and noncompetitive. Noncompetitive inhibitors, such as cyclic antidepressants, carbamazepine, venlafaxine, methylphenidate, and cocaine, bind at or near the carrier site on NET to prevent NET from moving NE and similar xenobiotics into or out of the neuron. Various xenobiotics used for their antimuscarinic effects also block NET noncompetitively. These include atomoxetine, benztrapine, diphenhydramine, trihexyphenidyl, and orphenadrine.<sup>193</sup>

The second mechanism, competitive inhibition of NET, characterizes most indirect-acting sympathomimetics, including amphetamine and structurally similar xenobiotics (eg, mixed-acting agents, MAOIs). These xenobiotics prevent NE reuptake by competing with synaptic NE for binding to the carrier site on NET, a mechanism by which they move into the neuron. In fact, an additional adrenergic action of amphetamines, mixed-acting xenobiotics, MAOIs, and tyramine is to raise synaptic NE concentrations by competing for uptake, thereby compounding their indirect or direct actions.

**MAOIs** Monoamine oxidase inhibitors (MAOIs) are transported by NET into the neuron, where in which they act through several mechanisms (Table 13–4).<sup>3,181</sup> Inhibition of MAO, their main pharmacologic effect, results in increased cytoplasmic concentrations of NE and some indirect release of neurotransmitter into the synapse. As a minor effect they also displace NE from vesicles by raising pH in a manner similar to amphetamines. These actions explain the initial sympathomimetic findings following MAOI overdose and also account for occasional and unpredictable adrenergic crises that occur despite dietary compliance.

Nonspecific MAOIs inhibit both enzymes of MAO, preventing intestinal and hepatic degradation of bioactive amines. A person taking such an MAOI who then is exposed to indirect-acting sympathomimetics (eg, tyramine in cheese, ephedrine, DA, amphetamines) has a much larger cytoplasmic concentration of NE to transport into the synapse and, therefore, develops central and peripheral sympathomimetic findings. Monoamine oxidase inhibitors (MAOIs) specific for the MAO-B enzyme are less likely to predispose to food or drug interactions by maintaining significant hepatic and intestinal MAO activity. Furthermore, reversible

MAO-A specific inhibitors are also less likely to provoke this reaction because their reversibility allows competition of exogenous amines with the inhibitor, resulting in its displacement from the enzyme and normal metabolism of the bioactive amines.<sup>303</sup> Isoenzyme specificity is lost as the dose of the MAOI is increased. In fact, selegiline, currently marketed as a selective MAO-B inhibitor, partially inhibits MAO-A activity at therapeutic doses. Rasagiline is a newer MAO-B inhibitor that has 100-fold greater affinity for MAO-B than MAO-A, but still loses specificity at supratherapeutic doses.<sup>96,109</sup> Monoamine oxidase inhibitors (MAOI) enzyme specificity is of lesser importance when indirect-acting xenobiotics are administered parenterally (eg, intravenous DA or amphetamines). Linezolid is an antibiotic that displays nonspecific MAO inhibition,<sup>201</sup> while methylene blue mainly inhibits MAO-A.<sup>253</sup>

Occasionally, patients suffering from refractory depression respond to a combination of MAOIs and tricyclic antidepressants. This combination therapy is usually unaccompanied by excessive adrenergic activity because the inhibition of the membrane uptake transporter by the tricyclic antidepressant attenuates excessive reverse transport of elevated cytoplasmic NE concentrations produced by MAOIs.

**COMT Inhibitors** Inhibitors of COMT are administered in the treatment of Parkinson disease to prevent the catabolism of concomitantly administered L-dopa. Entacapone only acts peripherally, whereas tolcapone also crosses the blood-brain barrier where it also prevents DA degradation as well.

**$\alpha_2$ -Adrenergic Receptor Antagonists** Yohimbine produces selective competitive antagonism of  $\alpha_2$ -adrenergic receptors to produce a mixed clinical picture. Peripheral postsynaptic  $\alpha_2$  blockade produces vasodilation. Blockade of presynaptic  $\alpha_2$ -adrenergic receptors on cholinergic nerve endings (Fig. 13-4) enhances ACh release, occasionally producing bronchospasm<sup>146</sup> and contributing to diaphoresis. Similar presynaptic actions on peripheral noradrenergic nerves enhance catecholamine release (Fig. 13-5). Antagonism of central  $\alpha_2$ -adrenergic receptors in the locus ceruleus results in CNS stimulation, whereas blockade of postsynaptic  $\alpha_2$ -adrenergic receptors in the nucleus tractus solitarius may enhance sympathetic output (Fig. 13-6). The final result includes hypertension, tachycardia, anxiety, fear, agitation, mania, mydriasis, diaphoresis, and bronchospasm.<sup>158</sup> Mirtazapine, an antidepressant, antagonizes central  $\alpha_2$ -adrenergic receptors, which increases serotonin and NE release in the CNS.

### Sympatholytics

**Direct Antagonists** Direct  $\alpha$ -adrenergic receptor and  $\beta$ -adrenergic receptor antagonists are noted in Table 13-5. After overdose,  $\beta$ -adrenergic receptor selectivity is less significant. Some  $\beta$ -adrenergic receptor antagonists also are partial agonists.

**Xenobiotics That Prevent Norepinephrine Release** Xenobiotics that block the vesicle uptake transporter prevent the movement of NE into vesicles and deplete the nerve ending of this neurotransmitter, preventing NE release after depolarization. Reserpine and ketanserin inhibit both VMAT1 and VMAT2, whereas tetrabenazine only inhibits VMAT2. Like guanethidine, reserpine causes transient NE release with the initial dose or early in overdose.  $\beta$ -Adrenergic receptor antagonists block presynaptic  $\beta_2$ -adrenergic receptors to limit catecholamine release from nerve endings, although most of the antihypertensive action of  $\beta$ -adrenergic antagonists at therapeutic doses results from inhibition of renin release in the kidney.

**$\alpha_2$ -Adrenergic Receptor Agonists** Numerous imidazoline derivatives (eg, clonidine) and structurally similar xenobiotics used as centrally acting antihypertensives or long-acting topical vasoconstrictors act by activating  $\alpha_2$ -adrenergic receptors. These xenobiotics also display various affinities for what are termed imidazoline-binding sites, apart from  $\alpha_2$ -adrenergic receptors. Although imidazoline-binding sites are proposed and subdivided into I<sub>1</sub>, I<sub>2</sub>, and I<sub>3</sub>,<sup>73</sup> and endogenous ligands for these binding sites are identified (eg, agmatine, imidazole acetic acid ribotide, harmaline, other  $\beta$ -carbolines),<sup>25,102,237</sup> it must be recognized that the molecular structures

of imidazoline-binding sites have not been determined, nor have signaling pathways been characterized. As a result, major professional societies such as the International Union of Pharmacology Committee on Receptor Nomenclature and Drug Classification have not adopted the term imidazoline receptor.<sup>154</sup> The role of imidazoline-binding sites in mediating responses to xenobiotics remains controversial and ill-defined.

The ventromedial (depressor) and the rostral-ventrolateral (pressor) areas of the ventrolateral medulla (VLM) are responsible for the central regulation of cardiovascular tone and blood pressure. They receive afferent fibers from the carotid and aortic baroreceptors, which form the tractus solitarius via the nucleus tractus solitarius (NTS).<sup>132</sup>

Ingestions of xenobiotics that activate  $\alpha_2$ -adrenergic receptors (Table 13-5) produce a mixed clinical picture. Peripheral postsynaptic  $\alpha_2$ -adrenergic receptor stimulation produces vasoconstriction, pallor, and hypertension, often with reflex bradycardia (Fig. 13-5). Peripheral presynaptic  $\alpha_2$ -adrenergic receptor stimulation prevents NE release (Fig. 13-5), reducing sympathetic activation. Central  $\alpha_2$ -adrenergic receptor stimulation in the locus ceruleus accounts for CNS and respiratory depression (Fig. 13-6). Recently acquired knowledge about  $\alpha_2$ -adrenergic receptor subtypes and their effects on non-adrenergic neurons makes analysis of their hypotensive and sedative effects complex. Recent animal evidence suggests that sedation is not entirely mediated by  $\alpha_2$ -adrenergic receptor activation on noradrenergic neurons in the locus ceruleus.<sup>93</sup> Stimulation of postsynaptic  $\alpha_{2A}$ -adrenergic receptors in the NTS in the VLM is thought to inhibit sympathetic output and enhance parasympathetic tone, explaining hypotension with bradycardia (Fig. 13-6).<sup>132</sup>

**Dopamine- $\beta$ -Hydroxylase Inhibition** Inhibition of dopamine- $\beta$ -hydroxylase, a copper-containing enzyme (Fig. 13-5), prevents the conversion of DA to NE, resulting in less NE release and less  $\alpha$ - and  $\beta$ -adrenergic receptor stimulation. Disulfiram and diethylthiocarbamate, copper chelators, produce such inhibition.<sup>75</sup> Because NE release mediates most of the ability of DA to cause vasoconstriction, NE is the vasopressor of choice in a hypotensive patient taking disulfiram. Monoamine oxidase inhibitors and  $\alpha$ -methyl dopa also inhibit dopamine- $\beta$ -hydroxylase, although this is not their main mechanism of action.<sup>181</sup>

Dopamine is relatively contraindicated in hypotensive patients who have overdosed on MAOIs. First, DA acts indirectly, and its administration might produce excessive adrenergic activity and exaggerated rises in blood pressure. Second, even if an adrenergic storm does not occur, most of the  $\alpha$ -mediated vasoconstriction of dopamine is secondary to NE release. In the presence of MAOIs, NE synthesis may be impaired from concomitant dopamine- $\beta$ -hydroxylase inhibition, and DA might not reliably raise blood pressure if cytoplasmic and vesicular stores are depleted. In the presence of impaired NE release or  $\alpha$ -adrenergic receptor blockade from any cause, unopposed dopamine-induced vasodilation from action on peripheral DA and  $\beta$ -adrenergic receptors paradoxically lowers blood pressure further. Norepinephrine and EPI are used to support blood pressure relatively safely in patients taking MAOIs because they have little or no indirect action and are metabolized by COMT when given intravenously.

## DOPAMINE

Because DA is the direct precursor of NE, noradrenergic vesicles contain DA. The release of NE from peripheral sympathetic nerves, therefore, always results in release of some DA (Fig. 13-5), as does the release of NE and EPI from the adrenal gland, explaining most of DA in blood. In peripheral tissues, activation of DA receptors causes vasodilation of renal, mesenteric, and coronary vascular beds. Dopamine also stimulates  $\beta$ -adrenergic receptors and, at high doses, directly stimulates  $\alpha$ -adrenergic receptors. When DA is administered intravenously, most vasoconstriction is caused by dopamine-induced NE release.

Dopamine accounts for about one-half of all catecholamines in the brain and is present in greater quantities than NE or 5-HT. By contrast to the diffuse projections of noradrenergic neurons, dopaminergic neurons and

receptors are highly organized and concentrated in several areas, especially in the basal ganglia and limbic system.<sup>144,254</sup>

Excessive dopaminergic activity in the striatum and/or other areas from any cause (eg, increased release, impaired uptake, increased receptor sensitivity) produces acute choreoathetosis<sup>136</sup> and acute Gilles de la Tourette syndrome, with tics, spitting, and cursing. Excessive dopaminergic activity in the limbic system and frontal cortex, and perhaps in other areas, produces paranoia and psychosis. Dopaminergic activity in the nucleus accumbens is thought responsible for much of the drug craving and addictive behavior in patients abusing sympathomimetics, opioids, alcohol, and nicotine. Diminished dopaminergic tone (eg, impaired release, receptor blockade) in the striatum produces various extrapyramidal disorders such as acute dystonias and parkinsonism.<sup>235,269,287</sup>

**Synthesis, Release, and Reuptake**

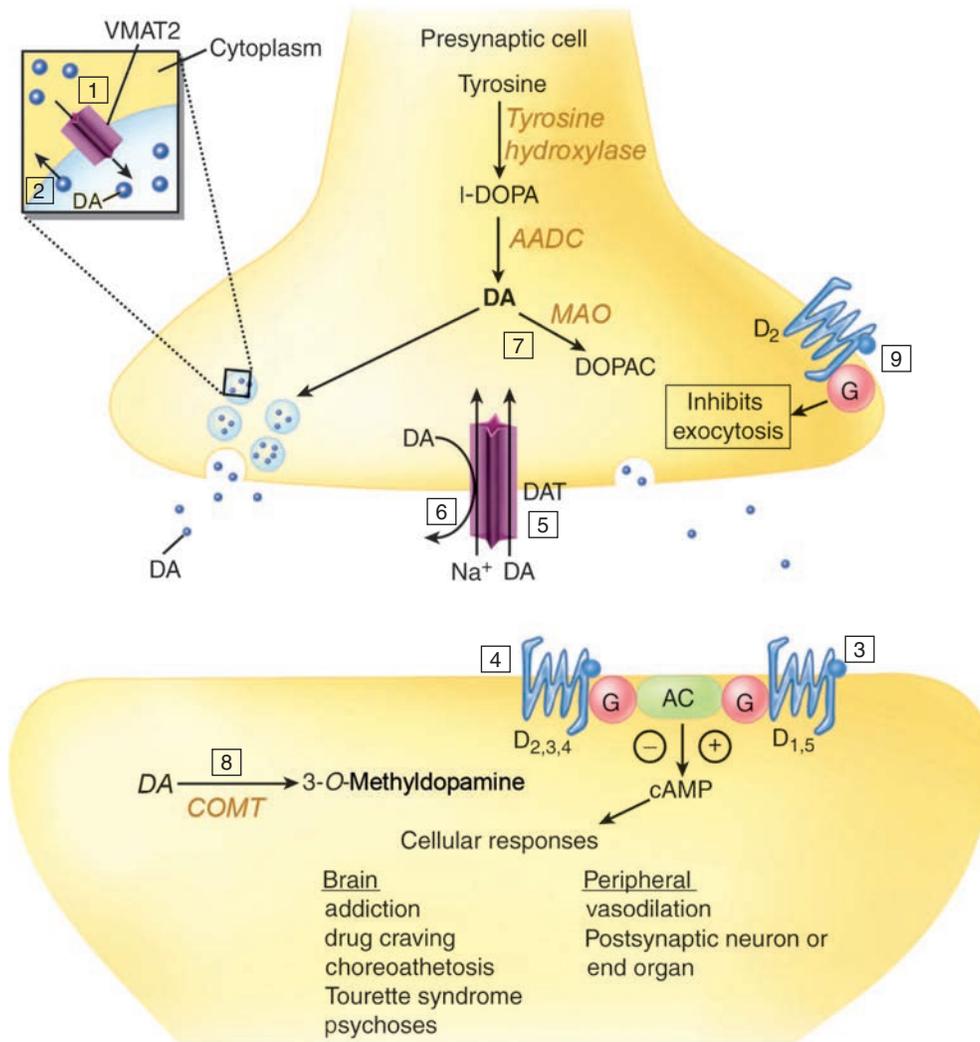

The steps of DA synthesis and vesicle storage are the same as those for NE, except that DA is not converted to NE after transport into vesicles (Fig. 13–7). Dopamine is removed from the synapse via reuptake by DAT, the membrane-bound DA transporter. Dopamine transporter and NET exhibit 66% homology in their amino acid sequences. Like NET, DAT is not

completely specific for DA and transports amphetamines and other structurally similar sympathomimetics. Cytoplasmic DA has a fate similar to NE. It is pumped back into vesicles by VMAT2 (brain) and VMAT1 (neuroendocrine tissue, adrenal glands) or degraded by MAO and COMT.

**Dopamine Receptors**

All DA receptors are coupled to G proteins and are divided into 2 main groups. Dopamine D<sub>1</sub>-like receptors (D<sub>1</sub> and D<sub>5</sub>) are expressed as various subtypes and are linked to G<sub>s</sub> to stimulate adenylate cyclase and to raise cAMP concentrations.<sup>257</sup> Dopamine (D<sub>2</sub>) receptors are found in the nuclei of the basal ganglia and the cerebral cortex, and D<sub>5</sub> receptors are concentrated in the hippocampus and hypothalamus. Dopamine is 5 to 10 times more potent at D<sub>5</sub> receptors than it is at D<sub>1</sub> receptors.

Dopamine (D<sub>2</sub>)-like receptors (D<sub>2</sub>, D<sub>3</sub>, D<sub>4</sub>) most commonly are linked to G<sub>i/o</sub> to produce several actions, including inhibition of adenylate cyclase and the lowering of cAMP concentrations. Again, numerous subtypes of receptors exist (eg, D<sub>2s</sub>, D<sub>2l</sub>). Dopamine (D<sub>2</sub>) receptors are concentrated in the basal ganglia and limbic system. Some D<sub>2</sub> receptors also reside on presynaptic membranes, where their activation limits neurotransmitter release, including the peripheral release of NE (Figs. 13–5 and 13–7). Dopamine (D<sub>3</sub>)

**FIGURE 13–7.** A dopaminergic nerve ending and postsynaptic membrane. Dopamine (DA) released from nerve endings binds to various postsynaptic DA receptors (D) on neurons or peripheral end organs. Stimulation of presynaptic D<sub>2</sub> receptors [9] lessens DA release. Xenobiotics in Table 13–6 have diverse activities including to inhibit vesicle uptake [1]; cause DA to leave the vesicle and move into the cytoplasm [2]; activate or antagonize DA receptors [3, 4, 9]; inhibit DAT to prevent DA reuptake [5]; cause reverse transport of cytoplasmic DA (via DAT) into the synapse by raising cytoplasmic DA concentrations [6]; prevent DA degradation by inhibiting monoamine oxidase (MAO) [7]; or prevent DA degradation by inhibiting catechol-O-methyltransferase (COMT) [8]. (Both DA and dopa are substrates for COMT.) Inhibition or stimulation of adenylate cyclase by DA receptors is shown for illustration, though other G protein–mediated effects can result. AADC = L-aromatic amino acid decarboxylase; DAT = membrane DA reuptake transporter; DOPAC = 3,4-dihydroxyphenylacetic acid; L-DOPA = L-tyrosine-3-O-methyltransferase; VMAT2 = vesicle membrane uptake transporter.

receptors are concentrated in the hypothalamic and limbic nuclei, whereas D<sub>4</sub> receptors are concentrated in the frontal cortex and limbic nuclei (rather than basal ganglia nuclei). Most agonists bind to the D<sub>3</sub> receptors with higher affinity than to D<sub>2</sub> receptors, whereas most antagonists bind preferentially to D<sub>2</sub> receptors.<sup>144,254</sup> Most agonists and antagonists express a lower affinity for D<sub>4</sub> receptors than they express for D<sub>2</sub> receptors; a notable exception is clozapine.

## Xenobiotics

Table 13–6 provides examples of xenobiotics that affect dopaminergic neurotransmission.

### Dopamine Agonism

**Indirect-Acting and Mixed-Acting Xenobiotics** Most indirect-acting and mixed-acting sympathomimetics cause DA release. The mechanism of action is similar to that causing NE release. These xenobiotics diffuse into the neuron or undergo uptake by DAT before being transported into vesicles by VMAT2 where they buffer protons and displace DA into the cytoplasm for reverse transport by DAT into the synapse. Benztropine, diphenhydramine, trihexyphenidyl, and orphenadrine also cause DA release, perhaps contributing to their abuse potential, which is noted below.<sup>193</sup> Excessive dopaminergic

activity following therapeutic doses or overdoses of decongestants (eg, pseudoephedrine), amphetamines, methylphenidate, and pemoline can produce acute choreoathetosis and the Tourette Syndrome.<sup>39,165</sup> Ingestion of excessive doses of L-dopa (which is converted to DA) produces similar symptoms.

**Direct Agonists** Bromocriptine is an ergot derivative that directly activates DA receptors (mainly D<sub>2</sub>-like). Toxic effects include those described above for indirect-acting xenobiotics. Apomorphine directly activates D<sub>2</sub> receptors. Such action at the chemoreceptor trigger zone (CTZ) produces vomiting, whereas agonism in the basal ganglia explains the use of apomorphine in the treatment of Parkinson disease. Fenoldopam is a D<sub>1</sub> receptor agonist that is used as a vasodilator in the treatment of hypertensive emergencies.

Dopamine (D<sub>1</sub>-) and D<sub>2</sub>-like receptor activation is the predominant mediator of locomotor effects from DA agonists. Activation of either D<sub>1</sub>- or D<sub>2</sub>-like receptors produces antiparkinsonian effects.<sup>106,254</sup> Cabergoline, ropinirole, and pramipexole are D<sub>2</sub>-like receptor agonists used to treat Parkinson disease.<sup>19,73,99</sup>

**Reuptake Inhibition** Xenobiotics inhibiting DAT prevent DA reuptake and include cocaine, amphetamines, methylphenidate, and probably amantadine. Increased dopaminergic activity from cocaine toxicity produces choreoathetosis and Gilles de la Tourette syndrome. In general, antidepressants are not strong DA reuptake blockers. However, bupropion is more active in this regard.<sup>247</sup>

As noted earlier, much of the craving and addiction produced by sympathomimetics probably results from excessive dopaminergic activity in the mesolimbic system.<sup>269</sup> Interestingly, the anticholinergics benztropine, diphenhydramine, trihexyphenidyl, and orphenadrine are also DA reuptake inhibitors, possibly explaining their abuse potential.<sup>193,265</sup> In fact, benztropine is one of the most potent DA reuptake inhibitors known. Amantadine, an antiparkinsonian drug that causes DA release and some inhibition of DA reuptake (as well as being anticholinergic), is also abused.

**Increased Receptor Sensitivity** Several xenobiotics are thought to increase sensitivity of DA receptors, resulting in choreoathetosis, even with therapeutic doses such as is the case of phenytoin. Evidence exists that increased DA receptor sensitivity contributes to movement disorders resulting from amphetamines.<sup>44</sup> Tardive dyskinesia (discussed below) results, at least in part, from increased DA receptor sensitivity and occurs following chronic administration of D<sub>2</sub> receptor antagonists.

**MAO Inhibition** Monoamine oxidase inhibitors (MAOIs) inhibit the breakdown of cytoplasmic DA. Some of the food and drug interactions with MAOIs result from excessive release of DA from nerve endings.

**COMT Inhibition** Substrates of COMT include dopa, DA, NE, EPI, and their hydroxylated metabolites. Catechol-*o*-methyltransferase inhibitor (COMT) inhibitors (eg, entacapone, tolcapone) are given with levodopa to patients with Parkinson disease to prevent peripheral degradation of levodopa to 3-*O*-methyldopa. This allows more levodopa to traverse the blood–brain barrier and to be converted to DA by neuronal dopa decarboxylase. Tolcapone also inhibits COMT in the brain to prevent degradation of dopamine.<sup>125</sup>

### Dopamine Antagonism

**Direct Receptor Blockade** Blockade of DA receptors is the specific aim of many therapeutics. The antipsychotic actions of butyrophenones, phenothiazines, and atypical antipsychotics mainly correlate with their ability to block D<sub>2</sub> receptors. Many phenothiazines block both D<sub>1</sub>-like and D<sub>2</sub>-like receptors, whereas haloperidol mainly blocks D<sub>2</sub>-like receptors. Unfortunately, antipsychotics and metoclopramide also block DA receptors in the striatum, producing various extrapyramidal symptoms, including acute parkinsonism and dystonias.

Atypical antipsychotics produce fewer extrapyramidal effects and are thought to carry less risk of producing tardive dyskinesia.<sup>241</sup> The relative affinity of an antipsychotic for 5-HT<sub>2A</sub> receptors over D<sub>2</sub> receptors has predictive value for atypical antipsychotics, with a lower risk of extrapyramidal

**TABLE 13–6** Examples of Xenobiotics Affecting Dopaminergic Neurotransmission

<b>Dopamine agonism</b>	Increase dopamine receptor sensitivity
Direct stimulation of dopamine receptors	Amphetamine
Apomorphine	Antipsychotics
Bromocriptine	Metoclopramide
Cabergoline <sup>a</sup>	Phenytoin
L-Dopa <sup>b</sup>	<b>Dopamine antagonism</b>
Fenoldopam	Direct dopamine antagonists
Lisuride	Amoxapine
Pramipexole	Aripiprazole
Ropinirole	Buspirone
Inhibit dopamine metabolism	Butyrophenones
MAOIs	Clozapine
COMTIs	Cyclic antidepressants
<b>Indirect acting</b>	Domperidone
Amantadine	Loxapine
Amphetamine	Metoclopramide
Benzotropine	Olanzapine
Diphenhydramine	Phenothiazines
MAOIs	Pimozide
Methylphenidate	Quetiapine
Pemoline	Risperidone
Trihexyphenidyl	Thioxanthenes
Inhibit dopamine reuptake	Ziprasidone
Amantadine	Destroy dopaminergic neurons
Amphetamine	MPTP/MPP <sup>+</sup>
Benzotropine	Prevent vesicle dopamine uptake
Bupropion	Reserpine
Cocaine	Tetrabenazine
Diphenhydramine	Valbenazine
Methylphenidate	
Orphenadrine	
Trihexyphenidyl	

<sup>a</sup>Associated with fibrotic valvulopathy due to 5-HT<sub>2B</sub> agonism. <sup>b</sup>Metabolized to dopamine, which acts as an agonist.

COMT = catechol-*o*-methyltransferase inhibitor; MAOI = monoamine oxidase inhibitor; MPTP = 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine; MPP<sup>+</sup> = 1-methyl-4-phenylpyridinium

symptoms.<sup>228</sup> These include clozapine, olanzapine, quetiapine, risperidone, and ziprasidone.

The ratio of muscarinic ( $M_1$ ) blockade to  $D_2$ -receptor blockade is also important in limiting extrapyramidal symptoms. Antipsychotics exhibiting strong antimuscarinic effects (eg, olanzapine, clozapine, thioridazine) are also less likely to induce extrapyramidal symptoms.<sup>241</sup>

Bupirone, an anxiolytic, antagonizes  $D_2$  receptors, which explains occasional extrapyramidal reactions. Various cyclic antidepressants, especially amoxapine, block  $D_2$  receptors to some extent.

The chronic use of dopamine receptor antagonists causes upregulation of DA receptors. The continued use of or, especially, withdrawal of DA receptor antagonists (antipsychotics, metoclopramide, and occasionally antidepressants) results in excessive dopaminergic activity and tardive dyskinesia, characterized by choreiform movements typical of excessive dopaminergic influence in the striatum.

The blockade of DA receptors by numerous xenobiotics, including butyrophenones, phenothiazines, and metoclopramide, produces a poorly understood disorder called neuroleptic *malignant syndrome*. Neuroleptic malignant syndrome also rarely follows acute withdrawal of DA agonists (eg, stopping L-dopa, bromocriptine, or tolcapone). Neuroleptic malignant syndrome is characterized, in part, by mental status changes, autonomic instability, rigidity, and hyperthermia.

### Indirect Antagonism

Reserpine and tetrabenazine inhibit VMAT to prevent transport of DA into storage vesicles and deplete nerve endings of DA. In fact, reserpine was used as an antipsychotic before the introduction of phenothiazines. 1-Methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), a meperidine analog, undergoes activation by MAO-B, including that in glial cells, to a metabolite, 1-methyl-4-phenylpyridinium ( $MPP^+$ ), that undergoes uptake by and causes death of dopaminergic neurons. Both MAOIs and inhibitors of DA transporters prevent MPTP-induced destruction of dopaminergic neurons.

## SEROTONIN

Serotonin (5-hydroxytryptamine, 5-HT) is an indole alkylamine found throughout nature (animals, plants, venoms). The serotonergic system is extremely diverse, with 14 subtypes of receptors organized into 7 classes. All of the receptor classes are coupled to G proteins except for  $5-HT_3$ , which is a ligand-gated ion channel.

In the CNS, several hundred thousand serotonergic neurons lie in or in juxtaposition to numerous midline nuclei in the brain stem (raphe nuclei), from which they project to virtually all areas of the brain and spinal cord. Serotonin is involved with mood, emotion, learning, memory, personality, affect, appetite, aggression, motor function, temperature regulation, sexual activity, pain perception, sleep induction, and other basic functions. Serotonin is not essential for any of these processes, but modulates their quality and extent. A number of psychiatric disorders, including depression, anxiety, obsessive-compulsive disorder, dementia, schizophrenia, and eating disorders, are linked to altered serotonin function. Consequently, modification of serotonergic neurotransmission is an integral part of the treatment plan for most of these conditions.<sup>234</sup> Serotonin is also the precursor for the pineal hormone, melatonin.

Despite the important role 5-HT plays in the CNS, less than 5% of the body's 5-HT is found within the CNS. The great majority of the body's 5-HT is located within enterochromaffin cells of the intestine, and a small amount is sequestered by platelets.<sup>24</sup> Peripherally, 5-HT is released by enterochromaffin cells in response to intestinal stimulation, which contributes to peristalsis and fluid secretion. Platelets take up 5-HT while passing through the enteric circulation. Serotonin is released from activated platelets to interact with other platelet membranes (promote aggregation) and with vascular smooth muscle.<sup>24</sup>

Experimentally, 5-HT exhibits diverse effects on the cardiovascular and peripheral nervous systems, although the importance of these actions

remains uncertain in the normal physiologic state. Serotonin-induced vasoconstriction or vasodilation found in experimental studies involves multiple types of 5-HT receptors and, in turn, is influenced by multiple other factors.  $5-HT_{1B}$  receptor agonists (eg, sumatriptan) produce coronary artery vasoconstriction in some patients as an adverse event.<sup>202,289</sup>

Centrally, it is particularly difficult to ascribe a specific symptom or physical finding to serotonergic neurons because of the diversity of their physiologic actions. However, 5-HT plays an important role in the action of many hallucinogenic or illusionogenic xenobiotics, which act as partial agonists at cortical  $5-HT_2$  receptors. Proserotonergic drugs are used to treat depression, whereas 5-HT receptor ( $5-HT_2$ ) antagonists have greater importance in the management of schizophrenia.<sup>89</sup>

Generally, in areas where they overlap, 5-HT acts in opposition to DA. For example, 5-HT serves to increase prolactin, adrenocorticotrophic hormone (ACTH), and growth hormone secretion, whereas DA decreases prolactin secretion. As another example, activation of basal ganglial  $5-HT_{2A}$  receptors inhibits DA release.<sup>89</sup> However, well-known exceptions exist, such as cortical  $5-HT_3$  receptors<sup>47</sup> and  $5-HT_{1A}$  receptors that are capable of promoting DA release under certain circumstances.<sup>199</sup>

### Synthesis, Release, and Reuptake

Serotonin does not cross the blood-brain barrier but, rather, is synthesized from the amino acid L-tryptophan, which passes through the blood-brain barrier through a neutral amino acid transporter. Figure 13-8 illustrates 5-HT synthesis. Tryptophan-5-hydroxylase is the rate-limiting enzyme and converts L-tryptophan to 5-hydroxytryptophan (5-OHT) within the cytoplasm. Increasing tryptophan predictably increases 5-HT production. 5-Hydroxytryptophan (5-OHT) is then converted to 5-HT by L-amino acid decarboxylase (DOPA decarboxylase). 5-HT is transported into vesicles by VMAT2, where it is concentrated by ion trapping before release by  $Ca^{2+}$ -dependent exocytosis. In contrast to vesicles containing DA or NE, 5-HT vesicles contain almost no ATP. After release into the synapse, a transporter (SERT) in the neuronal membrane moves 5-HT back into the neuron, where it reenters vesicles or is degraded by MAO.<sup>234</sup>

Serotonin is preferentially metabolized by the MAO-A enzyme. Paradoxically, the serotonergic nerve terminal is almost devoid of MAO-A, but contains abundant amounts of MAO-B. It is hypothesized that the large amounts of MAO-B metabolize other xenobiotics that might inappropriately promote 5-HT release (eg, dopamine). However, the small amount of MAO-A found in serotonergic neurons provides adequate degradation of 5-HT.<sup>196</sup>

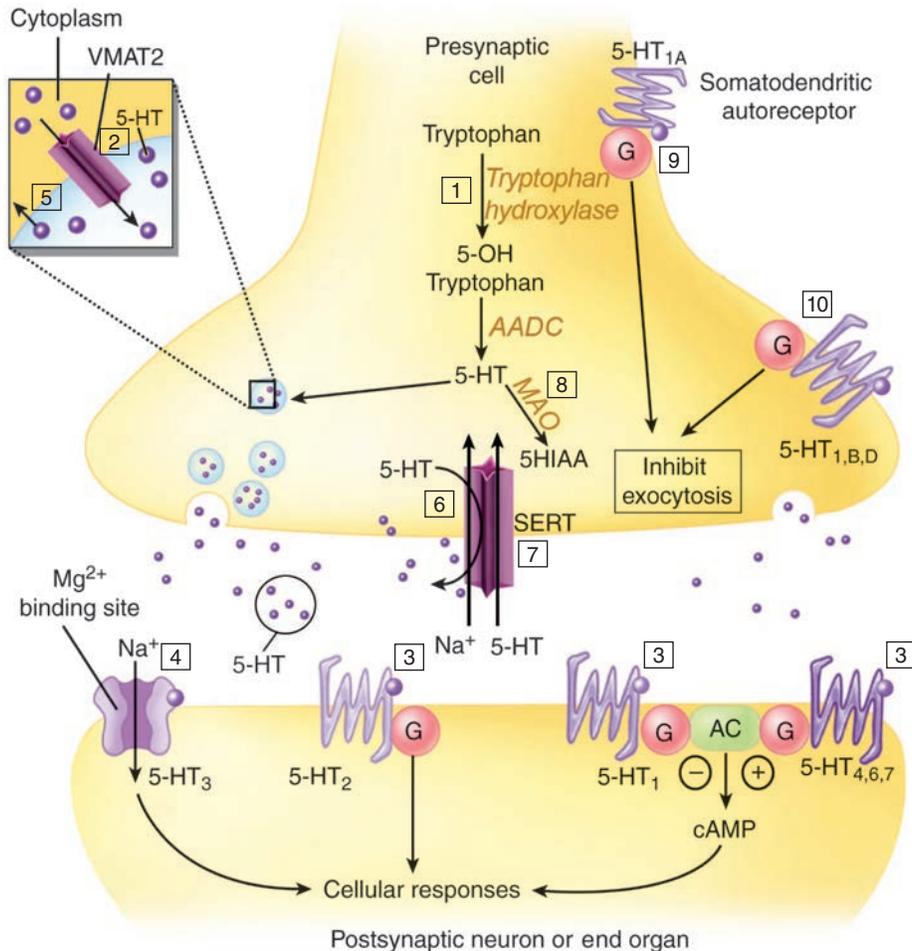

### Serotonin Receptors

There are 7 major functioning receptor types ( $5-HT_1$ – $5-HT_7$ ), numerous subtypes, splice variants, and post-translational modifications that result in wide variation.

#### 5-HT<sub>1</sub> Receptors

Five subtypes of  $5-HT_1$  receptors are known, encoded by the genes *HTR1A*, *HTR1B*, and *HTR1D* to *HTR1F* (1C was reclassified to 2C). These receptors are linked to  $G_i$  and inhibit adenylate cyclase, decreasing cAMP concentrations. Members of the  $5-HT_1$  receptor class express greatest affinity for 5-HT and are, thus, biologically active under normal physiologic conditions. 5-Hydroxytryptamine ( $5-HT_{1A}$ ) receptors reside predominantly on raphe nuclei, where they act as somatodendritic autoreceptors.<sup>145,186,210</sup> Hippocampal  $5-HT_{1A}$  receptors reside postsynaptically, where they also inhibit through similar mechanisms.<sup>145</sup>

Central  $5-HT_{1B}$  and  $5-HT_{1D}$  receptors primarily act as inhibitory terminal autoreceptors and heteroreceptors. They are found less commonly on postsynaptic membranes.<sup>234</sup> Originally  $5-HT_{1B}$  receptors were not believed to exist in humans. However, most of the actions described in older literature regarding  $5-HT_{1D}$  receptors are now attributed to  $5-HT_{1B}$  receptors. Cranial blood vessels (eg, meninges) possess  $5-HT_{1B}$  and  $5-HT_{1D}$  receptors, whose activation produces vasoconstriction and decreased inflammation.<sup>202,234</sup> 5-Hydroxytryptamine ( $5-HT_{1B}$ ) receptors are also found on smooth muscle cells in other

**FIGURE 13-8.** A serotonergic nerve ending and postsynaptic membrane. Tryptophan hydroxylase [1] converts tryptophan to 5-hydroxytryptophan (5-OHT). Aromatic L-amino acid decarboxylase (AADC) then metabolizes 5-OHT to serotonin (5-HT). Serotonin is concentrated within vesicles through uptake by VMAT2 before exocytosis [2]. After uptake into the neuron by SERT [7], 5-HT is transported back into vesicles or undergoes degradation by monoamine oxidase (MAO) to an intermediate compound, which is converted to 5-hydroxyindoleacetic acid (5-HIAA) [8]. 5-HT<sub>1,2,4,6,7</sub> receptors [3,9,10] are coupled to G proteins, whereas 5-HT<sub>3</sub> receptors [4] are ligand-gated cation channels that may conduct Na<sup>+</sup> and/or Ca<sup>2+</sup> (only Na<sup>+</sup> is illustrated). 5-HT<sub>3</sub> cation channels also appear to be blocked by Mg<sup>2+</sup> until the cell is depolarized, allowing Mg<sup>2+</sup> to dissociate—a mechanism similar to that found at NMDA glutamate receptors. In addition to residing on postsynaptic membranes, 5-HT<sub>1A</sub>, 5-HT<sub>1B</sub>, and 5-HT<sub>1D</sub> receptors serve as presynaptic autoreceptors that, when stimulated, decrease further release of 5-HT [9,10]. Presynaptic 5-HT<sub>1A</sub> receptors mainly serve as somatodendritic autoreceptors, whereas presynaptic 5-HT<sub>1B</sub> and 5-HT<sub>1D</sub> receptors serve as terminal autoreceptors. Xenobiotics in Table 13-7 act to enhance 5-HT synthesis [1]; inhibit VMAT2 to prevent vesicle uptake of 5-HT [2]; raise cytoplasmic concentrations of 5-HT, resulting in reverse transport of 5-HT into the synapse by SERT [6]; by displacing 5-HT from vesicles [5] or inhibiting MAO [8]; activate or antagonize 5-HT receptors [3,4,9,10]; or by inhibiting 5-HT reuptake [7]. G = G protein; SERT = membrane 5-HT uptake transporter; VMAT2 = vesicle membrane uptake transporter.

blood vessels, and this is a consideration when using 5-HT<sub>1B/1D</sub> agonists for migraine.

5-Hydroxytryptamine (5-HT<sub>1F</sub>) receptors are highly expressed in the frontal cortex, hippocampus, and the olfactory bulb.<sup>137</sup> The 5-HT<sub>1F</sub> receptor is also found in brain and studies are under way to investigate its role in migraine using a new class of selective agonists.<sup>239</sup>

### 5-HT<sub>2</sub> Receptors

The 3 subtypes of 5-HT<sub>2</sub> receptors are encoded by *HTR2A* to *HTR2C*. These receptors are coupled to G proteins, thus serving to decrease K<sup>+</sup> efflux and/or increase intracellular Ca<sup>2+</sup> concentration by raising concentrations of inositol triphosphate and diacylglycerol.<sup>234</sup> The 3 subtypes of 5-HT<sub>2</sub> receptors are so similar in characterization that investigational probes have great difficulty in distinguishing the subtypes. 5-Hydroxytryptamine (5-HT<sub>2A</sub>) receptors are most concentrated in the cerebral cortex, where they serve as excitatory postsynaptic receptors. Their activation increases glutamate release from pyramidal cells, but also lead to release of GABA.<sup>184</sup> They also are a cellular receptor for JC virus, the cause of progressive multifocal leukoencephalopathy.<sup>74</sup>

Activation of 5-HT<sub>2A</sub> receptors on platelets produces platelet aggregation. 5-Hydroxytryptamine (5-HT<sub>2C</sub>) receptors (previously 5-HT<sub>1C</sub>) reside on the

choroid plexus, where they regulate cerebrospinal fluid production. Activation of 5-HT<sub>2B</sub> receptors in the GI tract promotes gastric contraction.<sup>234</sup> At least some xenobiotics that activate 5-HT<sub>2B</sub> receptors on cardiac valves cause a valvulopathy identical to that of carcinoid syndrome, though both sides of the heart commonly are involved following 5-HT<sub>2B</sub> agonists, whereas carcinoid syndrome usually affects the right-sided valves.<sup>38</sup>

### 5-HT<sub>3</sub> Receptors

The 5-HT<sub>3</sub> receptor is unique among the 5-HT receptor family members in being an ion channel, instead of being linked to a G protein. It belongs to the family of Cys-loop receptors and is a pentamer with the 5 subunits surrounding a central cation-selective pore, similar to the nicotinic acetylcholine receptor.<sup>100</sup> In humans, 5 different subunits are known, encoded by the genes *HTR3A* to *HTR3E*. Moreover, subunits have different splice isoforms and also have differential tissue expression. For example, while subunits HTR3A, B, and C are found in the brain, HTR3D subunits reside primarily in the GI tract, and HTR3E is found exclusively in the GI tract.<sup>204</sup> Functional homomeric receptors composed only of A subunits can form, but it appears receptors with other subunits require at least one A subunit.<sup>168</sup> Upon activation, postsynaptic receptors stimulate the neuron by opening the channel to cause depolarization through Na<sup>+</sup> and/or Ca<sup>2+</sup> influx. In addition, these

channels are normally blocked by  $Mg^{2+}$  in a voltage-dependent manner similar to glutamatergic NMDA receptors (see *Glutamate* later).

The chemoreceptor trigger zone (CTZ) has a large concentration of 5-HT<sub>3</sub> receptors, where their activation causes emesis. Consequently, 5-HT<sub>3</sub> receptor antagonists are used as antiemetics. These receptors also have a role in gut motility, and antagonists are finding use as treatment for diarrhea-predominant irritable bowel syndrome (IBS-D).

#### 5-HT<sub>4</sub> Receptors

5-Hydroxytryptamine (5-HT<sub>4</sub>) receptors (*HTR4*) have numerous splice variants and are found in the brain, intestines, and heart. They signal through G protein and G protein-independent pathways as well.<sup>31</sup> 5-Hydroxytryptamine (5-HT<sub>4</sub>) receptors were investigated for effects on memory<sup>134</sup> and depression,<sup>31</sup> but their exact role in the brain is not yet clear. In the intestine, they are being investigated for constipation-predominant irritable bowel syndrome.<sup>290</sup>

#### 5-HT<sub>5</sub> Receptors

The 5-HT<sub>5A</sub> receptor (*HTR5A*) is the only receptor from this subfamily found in humans and is limited to the brain,<sup>236</sup> particularly the cerebral cortex, hippocampus, and cerebellum.<sup>218</sup> The receptor is coupled to G<sub>i</sub> and inhibits both adenylate cyclase and ADP ribosyl cyclase, while stimulating a Ca<sup>2+</sup>-dependent K<sup>+</sup> current.<sup>206</sup> Although there are hypotheses, the role of this receptor is unknown.<sup>280</sup>

#### 5-HT<sub>6</sub> Receptors

5-Hydroxytryptamine (5-HT<sub>6</sub>) receptors (*HTR6*) reside in several brain regions, especially in the caudate and putamen,<sup>177</sup> where their activation stimulates adenylate cyclase through coupling to G<sub>s</sub>.<sup>138</sup> Although many antipsychotics antagonize these receptors,<sup>30,138</sup> and there are hypothesized effects on learning and memory,<sup>134</sup> their role remains unclear.

#### 5-HT<sub>7</sub> Receptors

The 5-HT<sub>7</sub> receptor (*HTR7*) has several isoforms found in both brain and peripheral tissues, including liver, pancreas, spleen, and kidney.<sup>18,104</sup> The receptor is coupled to both G<sub>s</sub><sup>18,246</sup> and G<sub>12</sub>.<sup>143</sup> One of the brain regions in which this receptor is found is the suprachiasmatic nucleus of the hypothalamus, where it appears to participate in regulating circadian rhythms, as agonists advance circadian rhythms *in vitro*<sup>163</sup> and *in mice*.<sup>2</sup> Other possible roles for this receptor, including neuroprotection against *N*-methyl-D-aspartate-induced toxicity and enhancement of morphine-induced antinociception, are also being investigated.<sup>66</sup> Additionally, some antipsychotics also antagonize this receptor.<sup>30,281</sup>

### Xenobiotics

Table 13–7 provides examples of xenobiotics that affect serotonergic neurotransmission.

#### Serotonin Agonists

Orally ingested 5-HT is rapidly metabolized via intestinal and hepatic MAO. However, L-tryptophan, the amino acid precursor to 5-HT, is readily absorbed by the intestines. In fact, it was used as an unproven sleep aid until it was associated with the eosinophilia myalgia syndrome in 1990.<sup>28</sup> 5-Hydroxytryptophan (5-OHT), the immediate precursor to 5-HT, is available without a prescription. The anxiolytics, buspirone, gepirone, and ipsapirone act as partial agonists at somatodendritic and postsynaptic 5-HT<sub>1A</sub> receptors. Sumatriptan, an antimigraine medication, mainly activates 5-HT<sub>1B</sub> and 5-HT<sub>1D</sub> receptors.<sup>202</sup> The action of sumatriptan results from vasoconstriction of meningeal and other cranial, extracerebral vasculature; no impairment of cerebral blood flow follows its use. Other members of the triptan class include almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, and zolmitriptan. Vilazodone is an antidepressant with both partial 5-HT<sub>1A</sub> receptor agonism and SERT inhibition.<sup>62</sup> Flibanserin, approved for hypoactive sexual desire disorder in women, is both a 5-HT<sub>1A</sub> agonist and 5-HT<sub>2A</sub> antagonist.<sup>33</sup>

Metoclopramide and tegaserod are prokinetic drugs that activate 5-HT<sub>4</sub> receptors to increase gut motility.<sup>194</sup> Because 5-HT<sub>4</sub> receptors are also found

**TABLE 13–7** Examples of Xenobiotics Affecting Serotonergic Neurotransmission

<b>Serotonin Agonism</b>	Lamotrigine
Enhance 5-HT synthesis	Meperidine
L-Tryptophan	Nefazodone
5-Hydroxytryptophan	NSSRIs
Direct 5-HT agonists	SSRIs
Buspirone	Tramadol
Cisapride	Vilazodone
Ergots and indoles	Vortioxetine
Fibanserin	<b>Serotonin Antagonism</b>
Hallucinogenic substituted amphetamines	Direct 5-HT antagonists
mCPP	Agomelatine
Lisuride	Alosetron
Lurasidone	Aripiprazole
Mescaline	Clozapine
Metoclopramide	Cyclic antidepressants
Tegaserod	Cyproheptadine
Triptans	Ergots and indoles (eg, LSD)
Vilazodone	Flibanserin
Vortioxetine	Granisetron
Increase 5-HT release	Haloperidol
Amphetamine	Ketanserin
Cocaine	Lurasidone
Dexfenfluramine	Mescaline
Dextromethorphan	Methysergide
L-DOPA	Metoclopramide
Fenfluramine	Mirtazapine
MDMA	Nefazodone
Mirtazapine	Olanzapine
Reserpine (initial)	Ondansetron
Increase 5-HT tone by unknown mechanism	Paliperidone
Lithium	Palonosetron
Inhibit 5-HT breakdown	Phenothiazines
MAOIs	Phentolamine
Inhibit 5-HT reuptake	Propranolol
Amoxapine	Quetiapine
Amphetamines	Risperidone
Atomoxetine	Trazodone
Carbamazepine	Vortioxetine
Clomipramine <sup>a</sup>	Ziprasidone
Cocaine	Enhance 5-HT uptake
Cyclic antidepressants	Tianeptine
Dextromethorphan	Inhibit vesicle uptake
Duloxetine	Reserpine
	Ketanserin
	Tetrabenazine

<sup>a</sup>Clomipramine is the most potent 5-HT uptake inhibitor of the cyclic antidepressants.

5-HT, serotonin; LSD = lysergic acid diethylamide; MAOI = monoamine oxidase inhibitor; mCPP = *m*-chlorophenylpiperazine (metabolite of trazodone and nefazodone); MDMA = methylenedioxymethamphetamine.

SSRIs=selective serotonin reuptake inhibitors; NSSRIs=nonselective serotonin reuptake inhibitors

in the heart and urinary bladder detrusor muscle, 5-HT<sub>4</sub> agonists occasionally produce urinary incontinence and tachycardia.

Numerous indoles and phenylalkylamines, including ergot alkaloids, lysergic acid diethylamide (LSD), psilocybin, and mescaline, exhibit both agonistic and antagonistic properties at multiple 5-HT receptors. Their hallucinogenic/illusionogenic action is best explained by partial agonism

at 5-HT<sub>2A</sub> receptors.<sup>89</sup> Some substituted amphetamines (eg, methylenedioxymethamphetamine, XTC) directly stimulate 5-HT receptors.<sup>275</sup>

Cocaine and indirect-acting sympathomimetics, especially amphetamines, cause 5-HT release as previously described.<sup>275</sup> Centrally, DA undergoes uptake into serotonergic neurons to displace 5-HT from the neuron. Ingestion of L-dopa or other xenobiotics that increase synaptic DA concentrations can cause 5-HT release.<sup>186</sup>

Inhibitors of 5-HT reuptake include amphetamines, cocaine, various antidepressants, meperidine, tramadol, and dextromethorphan. Several antidepressants more specifically inhibit 5-HT reuptake. Examples of selective 5-HT reuptake inhibitors (SSRIs) include fluoxetine, sertraline, paroxetine, and citalopram. The use of SSRIs sometimes produces extrapyramidal side effects for reasons that remain unclear because of the numerous actions of 5-HT in the basal ganglia.<sup>103</sup> Vortioxetine is an SSRI that acts as a full agonist at the 5-HT<sub>1A</sub> and a partial agonist at the 5-HT<sub>1B</sub> receptors; conversely, it acts as an antagonist at 5-HT<sub>1D</sub>, 5-HT<sub>3</sub>, and 5-HT<sub>7</sub> receptors.<sup>251</sup> Two antiepileptics, carbamazepine and lamotrigine, inhibit 5-HT reuptake.<sup>268</sup> Again, reserpine and tetrabenazine prevent 5-HT uptake into vesicles.

Monoamine oxidase (MAO-A) accounts for most 5-HT degradation, and nonspecific MAOIs and MAO-A inhibitors (clorgyline, moclobemide) raise cytoplasmic 5-HT concentrations and, through indirect action, probably cause 5-HT release. Some medications (eg, methylene blue, procarbazine, linezolid) have the undesired side effect of causing MAO inhibition, which occasionally produces serotonin toxicity when combined with other serotonergic drugs.

### Serotonin Antagonists

Trazodone and nefazodone act mainly as antagonists at 5-HT<sub>2</sub> receptors, but are also weak reuptake inhibitors. Both undergo metabolism to *m*-chlorophenylpiperazine (mCPP), which activates most 5-HT receptors, but is especially active at 5-HT<sub>2C</sub> receptors. Agomelatine is an antidepressant that antagonizes 5-HT<sub>2C</sub> receptors and stimulates melatonin MT<sub>1</sub> and MT<sub>2</sub> receptors.<sup>71</sup> Ketanserin and ritanserin specifically antagonize 5-HT<sub>2C</sub> receptors, while methysergide and cyproheptadine antagonize 5-HT<sub>1</sub> and 5-HT<sub>2</sub> receptors.<sup>196</sup>

Mirtazapine exhibits complex actions, including antagonism of 5-HT<sub>2A</sub>, 5-HT<sub>2C</sub>, and 5-HT<sub>3</sub> receptors.<sup>92</sup> It also indirectly increases 5-HT<sub>1A</sub> activity and enhances release of NE through antagonism of  $\alpha_2$ -adrenergic receptors. Mirtazapine demonstrates potent antagonism of histaminic and muscarinic receptors.<sup>92</sup>

Most antipsychotics and cyclic antidepressants antagonize 5-HT<sub>2A</sub> and, to a lesser extent, 5-HT<sub>2C</sub> receptors. In fact, investigators are interested in developing antipsychotics similar to risperidone that possess potent antagonistic properties at 5-HT<sub>2</sub> receptors, without accompanying potent DA receptor antagonism, in order to limit extrapyramidal side effects. These investigations resulted in the introduction of olanzapine, sertindole, ziprasidone, zotepine, quetiapine, and amisulpride.<sup>184</sup>

5-Hydroxytryptamine (5-HT<sub>3</sub>) receptor antagonists are commonly used as antiemetics. The first-generation 5-HT<sub>3</sub> receptor antagonists include ondansetron, granisetron, and dolasetron. Their antiemetic action is explained by several mechanisms, including antagonism of 5-HT<sub>3</sub> receptors in the CTZ and on visceral afferent neurons leading to the vomiting center in the medulla. Peripheral 5-HT<sub>3</sub> receptor antagonism in the gut prevents ACh release, decreasing gut motility. Alosetron was taken off the market because of ischemic colitis and severe constipation before being reintroduced with an indication for severe diarrhea-predominant irritable bowel syndrome (IBS-D) in women, only. Palonosetron is a second-generation receptor antagonist that causes receptor internalization and inhibits cross-talk with the neurokinin-1 receptor, making it effective for both acute and delayed phase chemotherapy-induced nausea and vomiting.<sup>243</sup> Metoclopramide antagonizes 5-HT<sub>3</sub> and D<sub>2</sub> receptors.

Tianeptine is an antidepressant with several pharmacologic effects, including enhancement of 5-HT reuptake, thus lowering synaptic 5-HT concentrations.<sup>232</sup>

### Serotonin Toxicity

Serotonin toxicity (formerly called serotonin syndrome) represents an iatrogenic and largely idiosyncratic condition that is most commonly caused by the combination of 2 or more proserotonergic xenobiotics, although it can happen following single 5-HT agonists in overdose or at therapeutic dosages.<sup>190</sup> Animal models indicate that serotonin toxicity is prevented by the blockade of 5-HT<sub>1A</sub> receptors and 5-HT<sub>2A</sub> receptors.<sup>111,196,199</sup> Serotonin toxicity is characterized by alterations in mentation and cognition, autonomic nervous system dysfunction, and neuromuscular abnormalities. Symptoms include confusion, agitation, convulsions, coma, tachycardia, diaphoresis, hyperthermia, hypertension, shivering, myoclonus, tremor, hyperreflexia, and muscle rigidity (especially of legs).<sup>190</sup> Serotonin toxicity is often confused with neuroleptic malignant syndrome in its more severe presentation due to their similar manifestations. Serotonin toxicity usually responds to supportive care alone but temporally improves with 5-HT<sub>1A</sub> and 5-HT<sub>2A</sub> receptor antagonists such as cyproheptadine.<sup>35,190</sup> Serotonin toxicity results from xenobiotics that increase CNS 5-HT neurotransmission (Table 13-7). In addition, xenobiotics that act to increase CNS DA concentrations, such as levodopa and bromocriptine, have potential to precipitate serotonin toxicity by indirectly causing 5-HT release (Chap. 69).

### $\gamma$ -AMINO BUTYRIC ACID

$\gamma$ -Aminobutyric acid (GABA) is one of 2 main inhibitory neurotransmitters of the central nervous system (glycine is discussed later). Xenobiotics that enhance GABA activity are generally used as antiepileptics, sedative-hypnotics, anxiolytics, and general anesthetics. Xenobiotics that antagonize GABA activity typically produce CNS excitation and convulsions. GABA is synthesized from glutamate, the brain's main excitatory neurotransmitter.

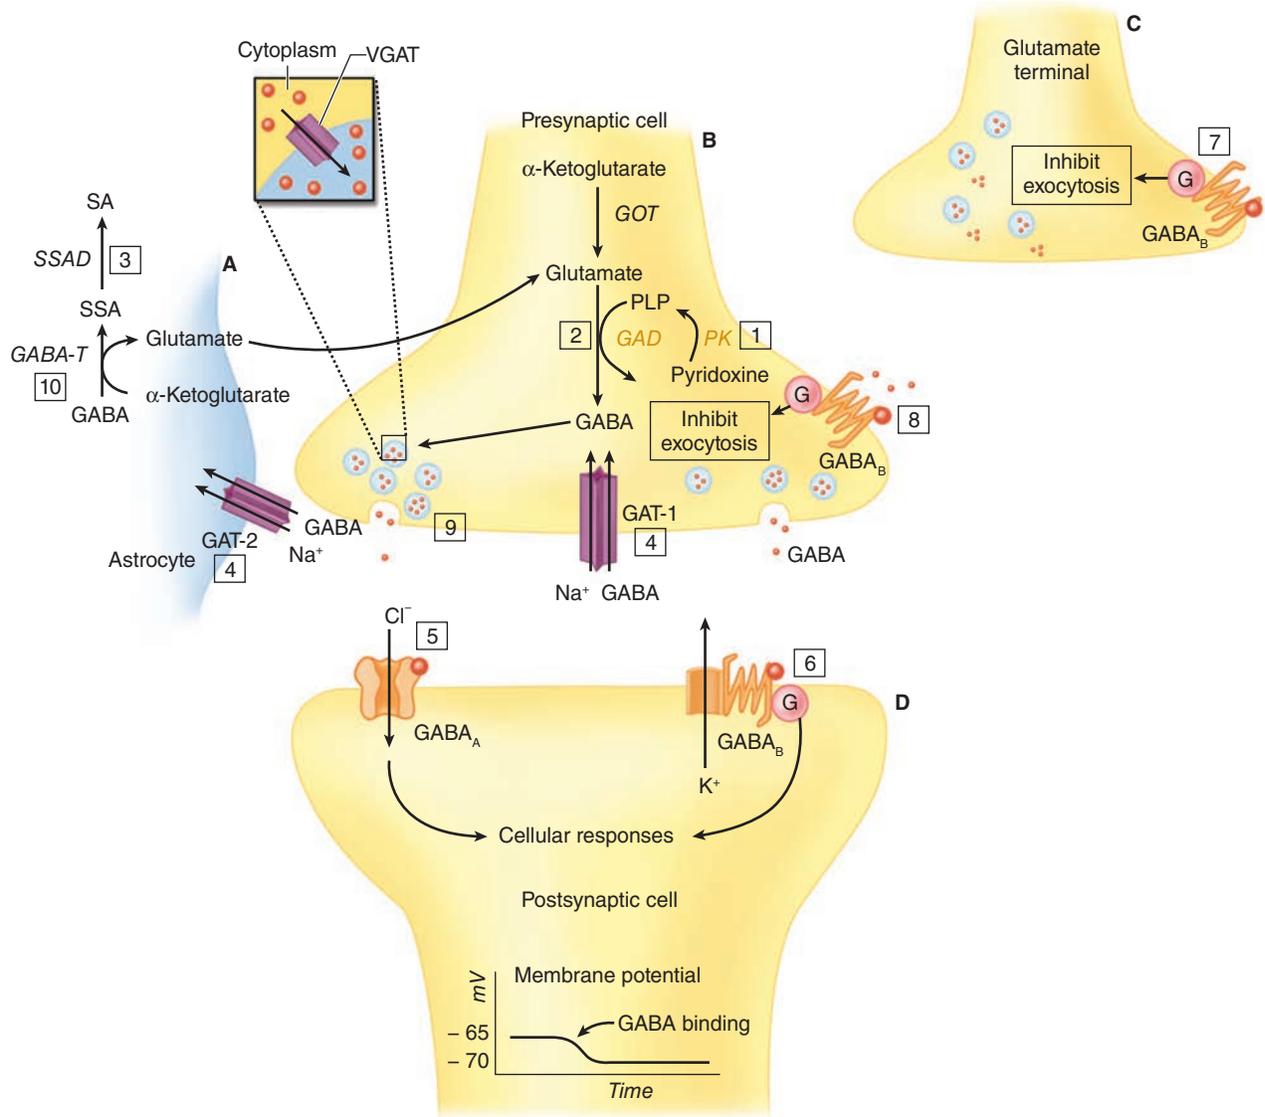

In general, GABA inhibition predominates in the brain. In the spinal cord, through monosynaptic and polysynaptic reflex pathways, GABA mediates a number of physiologically minor peripheral effects outside the CNS (eg, vasodilation, bladder relaxation). Spinal cord GABA is important in attenuating skeletal muscle reflex arcs.<sup>175</sup>

### Synthesis, Release, and Reuptake

Figure 13-9 illustrates GABA synthesis. Glutamate is converted to GABA via glutamic acid decarboxylase (GAD), which requires pyridoxal phosphate (PLP) as a cofactor. Pyridoxal phosphate is synthesized from pyridoxine (vitamin B<sub>6</sub>) by the enzyme pyridoxine kinase (PK).<sup>187</sup> VGAT, also known as VIAAT (vesicular inhibitory amino acid transporter), transports GABA into vesicles from where it is released through Ca<sup>2+</sup>-dependent exocytosis into the synapse.<sup>175</sup> Reuptake of GABA from the synapse back into the presynaptic neurons is mediated by the Na<sup>+</sup>-dependent transporter, GAT-1, whereas uptake into glial cells and possibly postsynaptic neurons is mediated by GAT-2, GAT-3, and GAT-4. Evidence also suggests that GABA is released into the synapse from cytoplasm by reverse transport under some conditions. In glial cells, cytoplasmic GABA can undergo degradation by GABA-transaminase (GABA-T) to succinic semialdehyde (SSA), part of which then undergoes oxidation to succinate. GABA-T also requires PLP as a cofactor.<sup>209</sup> The transamination of GABA to SSA by GABA-T results in the conversion of  $\alpha$ -ketoglutarate to glutamate, which then moves back into neurons to be used for resynthesis of GABA.

### GABA Receptors

There are 2 main types of GABA receptors (Table 13-8). GABA<sub>A</sub> receptors are members of pentameric ligand-gated ion channel family, along with nicotinic ACh, 5-HT<sub>3</sub>, and inhibitory glycine receptors.<sup>211</sup>  $\gamma$  Aminobutyric acid (GABA<sub>A</sub>) receptors are Cl<sup>-</sup> channels that mediate inhibition by allowing Cl<sup>-</sup> to move into and hyperpolarize the neuron. Most GABA<sub>A</sub> receptors are located postsynaptically and mediate fast or *phasic* inhibition. About 5% to 10% of GABA<sub>A</sub> receptors are located outside the synapse and are responsible for slower *tonic* current that is present at resting membrane potential.<sup>102,164,195,250</sup> Situated at various sites in relation to the GABA recognition site on the Cl<sup>-</sup> channel are sites for exogenous and endogenous modulators where numerous excitatory and depressant xenobiotics bind, and through

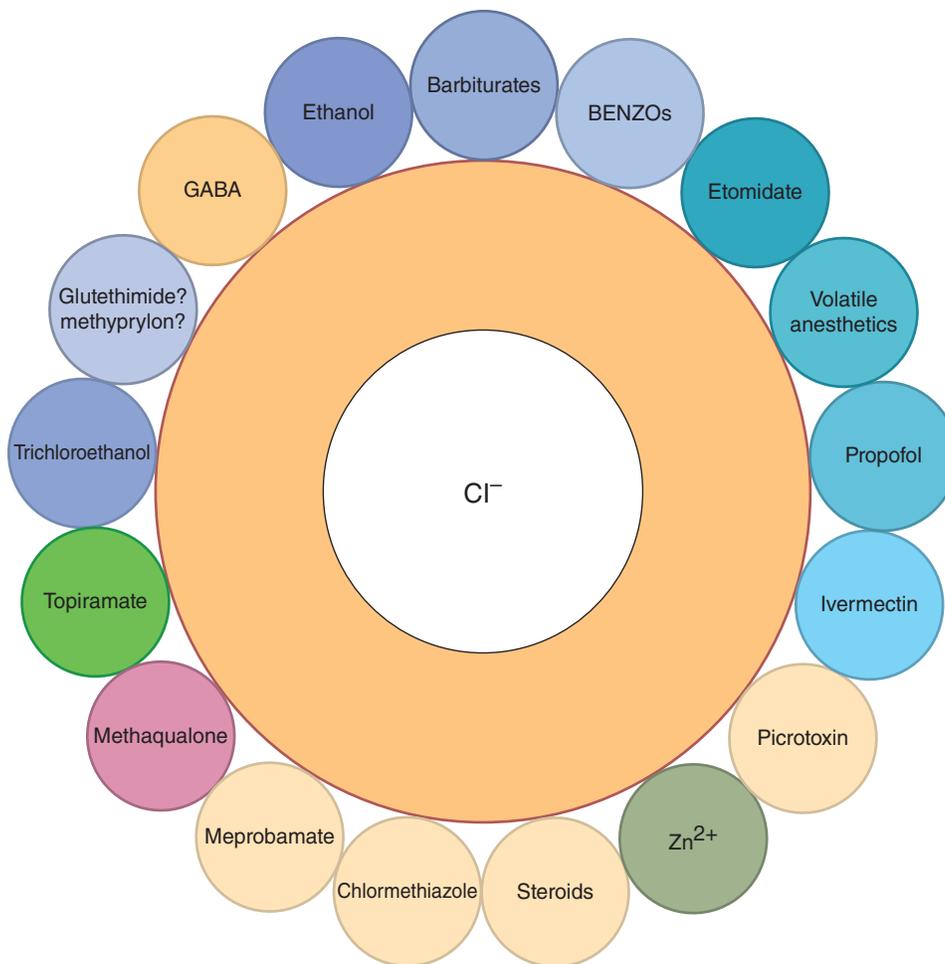

**FIGURE 13-9.** GABAergic neurotransmission.  $\gamma$ -aminobutyric acid (GABA) released from a presynaptic neuron (B) binds to postsynaptic GABA<sub>A</sub> or GABA<sub>B</sub> receptors to hyperpolarize and inhibit neuron D [5,6] or to presynaptic GABA<sub>B</sub> heteroreceptors on neuron C [7] to inhibit neurotransmitter release by blocking Ca<sup>2+</sup> influx (an excitatory glutamatergic neuron is shown as an example). Stimulation of GABA<sub>B</sub> autoreceptors on neuron B [8] also reduces further release of GABA. Synaptic GABA undergoes reuptake into the presynaptic neuron by GAT-1, and uptake into glial cells and possibly postsynaptic neurons by GAT-2, GAT-3, and GAT-4 (GAT-2 is shown mediating uptake into glial cell A as an example.) Acute falls in pyridoxal phosphate (PLP) lead to impaired glutamic acid decarboxylase (GAD) activity and low GABA concentrations. Although GABA-transaminase (GABA-T) also requires PLP, acute falls in PLP do not affect this enzyme as dramatically because of tight PLP binding to the GABA-T complex. Xenobiotics in Table 13-9 act to impair PLP formation by inhibiting pyridoxine kinase (PK) [1]; to increase GABA concentrations by either stimulating GAD [2] or inhibiting SSAD [3]; to inhibit GABA reuptake [4]; to stimulate or block GABA receptors [5-8]; to cause GABA release [9]; or to inhibit GABA-T [10]. Glutamic-oxaloacetic transaminase (GOT), GABA-T, and SSAD are mitochondrial enzymes. G = G protein; GAT = membrane GABA reuptake transporter; SA = succinic acid; SSA = succinic semialdehyde; SSAD = SSA dehydrogenase; VGAT = vesicle membrane GABA uptake transporter; VGAT = Vesicular GABA transporter.

TABLE 13-8 GABA Receptors and Their Characteristics		
Receptor	GABA <sub>A</sub> Cl <sup>-</sup> Channel	GABA <sub>B</sub> G Protein-Coupled
Baclofen agonism	Yes	No

Picrotoxin antagonism	Yes	No

which GABA<sub>A</sub> receptor responsiveness is regulated under normal physiologic conditions (Fig. 13-10). The common denominator for modulation at the GABA<sub>A</sub> complex is an increase or decrease in inward Cl<sup>-</sup> current.

$\gamma$  Aminobutyric acid (GABA<sub>A</sub>) receptors exist as pentamers, composed of various subunits, and throughout the CNS there are regional variations in expressions of multiple subunit genes for GABA<sub>A</sub> complexes.<sup>211</sup> To date 19 subunits are identified ( $\alpha_1$ - $\alpha_6$ ,  $\beta_1$ - $\beta_3$ ,  $\gamma_1$ - $\gamma_3$ ,  $\delta$ ,  $\epsilon$ ,  $\theta$ ,  $\pi$ ,  $\rho_1$ - $\rho_3$ ).  $\gamma$  Aminobutyric acid (GABA<sub>A</sub>) receptors are composed most commonly of 2  $\alpha$  subunits, 2  $\beta$  subunits, and either a  $\gamma$  or  $\delta$  subunit. Multiple isoforms of subunits exist, but within a single receptor, the isoforms of individual subunits appear to be identical. Although the large numbers of isoforms and different combinations of subunits could theoretically produce more than 2,000 different GABA<sub>A</sub> Cl<sup>-</sup> channels, only a few dozen combinations exist naturally.<sup>60,195</sup> The

**FIGURE 13–10.** Representation of the GABA<sub>A</sub> Cl<sup>−</sup> channel receptor complex. Benzodiazepines (BENZOs), barbiturates, picrotoxin, steroids, and GABA (γ-aminobutyric acid) clearly bind to different sites on the channel. Although separate circles represent different agents capable of binding to and of modulating Cl<sup>−</sup> influx through the GABA<sub>A</sub> receptor complex, it is not always apparent where these xenobiotics bind on the channel. Chloral hydrate undergoes metabolism to trichloroethanol, which interacts with the GABA<sub>A</sub> receptor complex. Zolpidem, zopiclone, and zaleplon are nonbenzodiazepines that bind to the benzodiazepine site. Given the structural similarity of glutethimide and methyprylon to barbiturates, it is speculated that their action may be mediated at GABA<sub>A</sub> receptors.

most common is  $\alpha_1\beta_2\gamma_2$ .<sup>19,263</sup> Previously, GABA<sub>C</sub> receptors were classified as a separate type of GABA receptor, but are now classified as GABA<sub>A</sub> receptors comprising homo-oligomers and hetero-oligomers formed by  $\rho$  subunits ( $\rho_1$  to  $\rho_3$ ).

The second type of GABA receptor, GABA<sub>B</sub>, is a G protein–coupled receptor found presynaptically, postsynaptically, and on extrasynaptic membranes.<sup>211</sup> GABA<sub>B</sub> receptors are obligate heterodimers formed by 2 subunits, GABA<sub>B1</sub> and GABA<sub>B2</sub>. The GABA<sub>B1</sub> subunit exists as multiple isoforms, with GABA<sub>B1a</sub> and GABA<sub>B1b</sub> apparently the most relevant in human CNS.<sup>129</sup> γ-Aminobutyric acid or other GABA<sub>B</sub> receptor ligands such as baclofen bind to the GABA<sub>B1</sub> subunit, whereas the GABA<sub>B2</sub> subunit couples the receptor with the effector G<sub>i/o</sub> protein.<sup>23</sup>

γ-Aminobutyric acid (GABA<sub>B</sub>) receptors are distributed both in the CNS and peripheral nervous system and mediate both presynaptic and postsynaptic inhibition.<sup>34</sup> Presynaptic inhibition results from preventing Ca<sup>2+</sup> influx so as to impair exocytosis of neurotransmitter vesicles, including those containing glutamate. γ-Aminobutyric acid (GABA<sub>B</sub>) receptors are found in high density in the ventral tegmental area (VTA) of the midbrain at presynaptic DA and glutamatergic neurons, and animal studies show that their activation reduces DA release in regions crucial in reward pathways associated with addiction.<sup>129,226</sup>

Through presynaptic actions, GABA<sub>B</sub> receptors serve not only as heteroreceptors on glutamatergic and other nerve terminals but also as autoreceptors, where their activation in response to synaptic GABA provides feedback inhibition of further neurotransmitter release (Fig. 13–9).

Postsynaptic inhibition is mediated by increasing K<sup>+</sup> efflux through K<sup>+</sup> channels, resulting in hyperpolarization of the membrane away from threshold. In addition to their effects on ion channels, GABA<sub>B</sub> receptors inhibit adenylate cyclase via G<sub>i/o</sub> proteins and thus, the cAMP–protein kinase A pathway, which is necessary for phosphorylation and upregulation of glutamatergic NMDA receptors.<sup>22</sup>

### Xenobiotics

Table 13–9 provides examples of xenobiotics that affect GABAergic neurotransmission.

### Modulation of GABA Production and Degradation

Isoniazid (INH) and other hydrazines such as monomethylhydrazine lower CNS GABA concentrations by several mechanisms. Most important, they compete with pyridoxine for binding to PK, impairing PLP production.<sup>187</sup> Pyridoxal phosphate binding to the GAD complex is easily reversible.<sup>209</sup> The acute decrease in PLP concentration is rapidly accompanied by impaired GABA synthesis and a decrease in GABA concentration. Lack of normal GABA inhibition produces seizures typical of hydrazine toxicity. Although PLP is also required for GABA degradation by GABA-T, acute decreases in PLP do not affect this enzyme nearly as much, because PLP is more tightly bound to the GABA-T complex and remains associated with the enzyme.<sup>209</sup> To a lesser extent, isoniazid binds to the GAD–PLP complex to prevent GABA formation.

Large ingestions of *Ginkgo biloba* seeds produce recurrent seizures that may result from decreased GABA concentrations. Ginkgo seeds contain

**TABLE 13–9** Examples of Xenobiotics Affecting GABAergic Neurotransmission

GABA Agonism	GABA Antagonism
Stimulate GAD	Direct GABA <sub>A</sub> antagonists
Valproate	Bicuculline
Direct GABA <sub>A</sub> agonists	Cephalosporins
Muscimol	Fluoroquinolones
Progabide <sup>a</sup>	Imipenem
Indirect GABA <sub>A</sub> agonists	Nalidixic acid
Barbiturates	Penicillins
Benzodiazepines	Indirect GABA <sub>A</sub> antagonists
Chloral hydrate	Aztreonam
Clomethiazole	Clozapine
Ethanol	Cyclic antidepressants
Etomidate	Flumazenil
Felbamate	Lindane
Ivermectin	MAOIs
Meprobamate	Maprotiline
Methaqualone	Organic chlorine insecticides
Propofol	Penicillins
Steroids	Pentylene-tetrazol
Topiramate	Picrotoxin
Trichloroethanol	Inhibit GAD
Volatile anesthetics	Cyanide
Zaleplon	Domoic acid
Zolpidem	Hydrazines
Zopiclone	Isoniazid
Direct GABA <sub>B</sub> agonists	4-Methoxy pyridoxine <sup>d</sup>
Baclofen	Direct GABA <sub>B</sub> antagonists
GHB	Phaclofen <sup>b</sup>
Phenibut	Saclofen <sup>b</sup>
Inhibit GABA-T	Inhibit PK
Vigabatrin	Hydrazines <sup>c</sup>
Inhibit GABA reuptake	Isoniazid <sup>c</sup>
Tiagabine	
Valproate	

<sup>a</sup>Directly activates GABA<sub>A</sub> and GABA<sub>B</sub> receptors as well as being metabolized to GABA. <sup>b</sup>Thought not to cross the blood–brain barrier in meaningful amounts. <sup>c</sup>Major site of action is PK inhibition, though some direct GAD inhibition occurs. <sup>d</sup>Found in *Ginkgo biloba*.

GABA =  $\gamma$ -aminobutyric acid; GABA-T = GABA transaminase; GAD = glutamic acid decarboxylase; GHB =  $\gamma$ -hydroxybutyric acid; PK = pyridoxine kinase; MAOI = monoamine oxidase inhibitor.

4-methoxy pyridoxine, which acts as a competitive antagonist of pyridoxal kinase, thereby inhibiting glutamate decarboxylase and impairing GABA synthesis.<sup>127,192</sup>

Cyanide inhibits numerous enzymes besides cytochrome oxidase, including GAD. Domoic acid (see Glutamate later) inhibits GAD.<sup>61</sup>

In vitro studies demonstrate the ability of valproate to increase brain GABA concentrations, either by inhibition of succinic semialdehyde dehydrogenase or by activation of GAD.<sup>124</sup> Gabapentin may increase the rate of GABA synthesis in the brain by stimulating GAD, although the main mechanism of action of gabapentin is to bind to calcium channels.<sup>279</sup> Vigabatrin, an antiepileptic, acts by irreversibly inhibiting GABA-T.<sup>271</sup>

### GABA<sub>A</sub> Agonism

**Figure 13–10** schematically illustrates the GABA<sub>A</sub> receptor complex. In general, GABA<sub>A</sub> agonists cause CNS depression, ranging from mild sedation and nystagmus to ataxia, stupor, and coma. Many indirect agonists that bind to the GABA<sub>A</sub> complex have no activity in the absence of GABA. With some exceptions, their pharmacologic actions require the binding of GABA to its

receptor and do not result from a direct effect on Cl<sup>-</sup> conductance exclusive of GABA binding. Many of these xenobiotics demonstrate additional actions that are not mediated through the GABA<sub>A</sub> complex.

**Direct GABA Agonists** The main direct GABA agonist of toxicologic interest is muscimol, found in some poisonous mushrooms. Muscimol binds at the GABA binding site on the GABA<sub>A</sub> complex to mimic the action of GABA.<sup>212</sup> Ibotenic acid, a direct glutamate agonist found in the same mushrooms, is decarboxylated to muscimol just as glutamate is decarboxylated to GABA.

**Indirect GABA Agonists** Benzodiazepines bind to GABA<sub>A</sub> complexes to increase the affinity of GABA for its receptor and to increase the frequency of Cl<sup>-</sup> channel opening in response to GABA binding.<sup>262</sup> The benzodiazepine binding site on the GABA<sub>A</sub> receptor is located in a pocket between an  $\alpha$  subunit and a  $\gamma_2$  subunit.<sup>291</sup> Benzodiazepines also inhibit adenosine uptake apart from GABA<sub>A</sub> activity (see Adenosine later). The historical terms “benzodiazepine receptor” and “omega receptor” (for benzodiazepines) were abandoned, and benzodiazepine-binding sites on subtypes of GABA<sub>A</sub> receptors are categorized as high, intermediate, or low affinity benzodiazepine-binding sites, based on zolpidem binding.<sup>249</sup>

It follows that various isoforms of GABA<sub>A</sub> Cl<sup>-</sup> channels differ in their affinity for different benzodiazepines.  $\gamma$  Aminobutyric acid (GABA<sub>A</sub>) receptors containing  $\gamma_2$  subunits are more sensitive to benzodiazepines than are GABA<sub>A</sub> receptors containing  $\gamma_1$  and  $\gamma_3$  subunits. Sensitivity and response to benzodiazepine binding is also highly dependent on the specific  $\alpha$  subunit composition of the GABA<sub>A</sub> receptor.  $\gamma$  Aminobutyric acid (GABA<sub>A</sub>) receptors containing an  $\alpha_4$  or  $\alpha_6$  subunit are completely insensitive to and will not bind benzodiazepines, whereas GABA<sub>A</sub> receptors containing  $\alpha_1$ ,  $\alpha_2$ ,  $\alpha_3$ , or  $\alpha_5$  subunits are sensitive to benzodiazepine binding. This has important implications in that development of tolerance to ethanol confers cross-tolerance to benzodiazepines through a change in  $\alpha$  subunits. In addition, specific subunits mediate different effects of benzodiazepines. For example, sedating and amnesic effects are mediated through binding to  $\alpha_1$  subunits, whereas anxiolytic and myorelaxant effects are mediated by binding to  $\alpha_2$  and  $\alpha_3$  subunits.<sup>81</sup>

Zolpidem, zaleplon, and zopiclone are non-benzodiazepines that act as agonists at the benzodiazepine binding site on the GABA<sub>A</sub> receptor. They exhibit a high selectivity for the  $\alpha_1$  subunit and low selectivity for  $\alpha_2$ ,  $\alpha_3$ , and  $\alpha_5$  subunits.<sup>266,291</sup> Selective binding to  $\alpha_1$  subunits accounts for their relatively selective sedative properties at therapeutic doses and lack of anxiolysis, as compared to benzodiazepines.

Barbiturates bind to the GABA<sub>A</sub> complex to produce several effects.<sup>140,262</sup> All barbiturates enhance the action of GABA by producing more Cl<sup>-</sup> influx for a given amount of GABA binding by increasing the duration of Cl<sup>-</sup> channel opening. Whereas phenobarbital does not change the affinity of GABA or benzodiazepines for their binding sites, depressant barbiturates, such as pentobarbital, do increase GABA and benzodiazepine binding site affinities for their ligands, further enhancing inward Cl<sup>-</sup> currents. At high concentrations, at least some barbiturates directly open Cl<sup>-</sup> channels to cause Cl<sup>-</sup> influx.<sup>140</sup> Phenobarbital can directly open the Cl<sup>-</sup> channel at antiepileptic concentrations. In addition, barbiturates possess other actions that depress all excitable membranes, including cardiac and smooth muscle.

The intravenous anesthetics propofol and etomidate enhance inward GABA<sub>A</sub> Cl<sup>-</sup> currents, and at high concentrations they directly open chloride channels in the absence of GABA.<sup>15</sup> The respiratory depressant and immobilizing effects of etomidate and propofol are mediated by  $\beta_3$  subunits, whereas the sedative effects are mediated through agonism at  $\beta_2$  subunits.<sup>267,307</sup> Volatile general anesthetics also directly activate GABA<sub>A</sub> Cl<sup>-</sup> channels.

Some of the action of ethanol is mediated through binding to the GABA<sub>A</sub> complex. The degree to which ethanol enhances the effect of GABA on Cl<sup>-</sup> influx depends on the GABA<sub>A</sub> receptor subunit composition. For example, receptors with an  $\alpha_4$  or  $\alpha_6$  subunit and a  $\delta$  subunit respond to very low concentrations of ethanol.<sup>276,294</sup>

Methaqualone produces at least part of its pharmacologic effect through indirect GABA<sub>A</sub> activity. Little is known of the mechanisms of action of glutethimide

and methyprylon. Their structural similarities to barbiturates suggest that they have activity at the GABA<sub>A</sub> receptor. Trichloroethanol, a metabolite of chloral hydrate, and clomethiazole interact at the GABA<sub>A</sub> complex in a manner similar to barbiturates, although it is not clear whether they are binding to an identical site on the Cl<sup>-</sup> channel.<sup>298</sup> Ivermectin, an anthelmintic, activates GABA<sub>A</sub> Cl<sup>-</sup> channels by increasing GABA binding. Meprobamate displays barbiturate like action at the GABA<sub>A</sub> receptor and, at high concentrations, is able to cause Cl<sup>-</sup> influx in the absence of GABA.<sup>240</sup> High concentrations of felbamate also cause inward Cl<sup>-</sup> currents in the presence of GABA, although this seems unimportant at therapeutic doses.<sup>240</sup> Part of the antiepileptic action of topiramate results from enhanced Cl<sup>-</sup> influx through binding to GABA<sub>A</sub> receptors.<sup>256</sup>

**Inhibition of GABA Reuptake** Valproate and the antiepileptics guvacine and tiagabine work, in part, by inhibiting GABA reuptake. Although valproate is structurally similar to GABA, its inhibition of the GABA transporter does not appear to be competitive.<sup>205</sup>

### GABA<sub>A</sub> Antagonism

**Direct GABA<sub>A</sub> Antagonists** Xenobiotics that act by any mechanism to decrease GABA<sub>A</sub> activity cause CNS excitation and convulsions by decreasing inhibitory inward Cl<sup>-</sup> currents. Direct antagonists bind to the same site as GABA to prevent GABA binding, the prototype being bicuculline. Various antibiotics interact with the GABA<sub>A</sub> receptor to antagonize the action of GABA. In a dose-dependent manner, both imipenem and cephalosporins directly antagonize GABA binding and produce seizures at high doses or at therapeutic doses in susceptible individuals.<sup>293</sup> Evidence suggests that penicillin also directly antagonizes GABA binding. Electrophysiologic and radioligand-binding studies indicate that norfloxacin, ciprofloxacin, ofloxacin, and enoxacin interact with the GABA binding site to prevent GABA binding.<sup>293</sup> Theophylline and at least some nonsteroidal antiinflammatory drugs markedly enhance GABA antagonism by some fluoroquinolones in vitro.<sup>293</sup> Virol A, from *Cicuta virosa*, appears to directly antagonize binding of GABA to the GABA<sub>A</sub> receptor.<sup>285</sup>

**Indirect GABA<sub>A</sub> Antagonists** Penicillin is well known for producing convulsions at high doses (eg, >20 million units of penicillin per day with renal insufficiency), and both penicillin and aztreonam, a monobactam, block the Cl<sup>-</sup> channel to prevent GABA-mediated inward Cl<sup>-</sup> currents.<sup>293</sup>

Picrotoxin, from *Anamirta cocculus* (fish berries), is an equimolar mixture of picrotoxinin and picrotin and binds to the picrotoxin site of the GABA<sub>A</sub> receptor to block the Cl<sup>-</sup> channel. Excessive doses produce CNS excitation and convulsions. Some organochlorine insecticides (eg, lindane) also inhibit the action of GABA by binding to what appears to be the picrotoxin site and cause convulsions.<sup>167</sup> Both  $\alpha$ -thujone, the active component in wormwood oil, and cicutoxin from the water hemlock noncompetitively antagonize GABA<sub>A</sub> activity.<sup>108,286</sup> The explosive RDX (cyclotrimethylenetrinitramine) binds to the picrotoxin site to produce seizures.

Flumazenil competitively antagonizes benzodiazepines, zolpidem, zaleplon, and zopiclone at their binding sites to reverse their pharmacologic effects.<sup>32,263</sup> Paradoxically, large doses of flumazenil exhibit antiepileptic activity in animals. This is explained, at least in part, by the ability of flumazenil to inhibit adenosine reuptake.<sup>227,272</sup>

Cyclic antidepressants, including amoxapine and maprotiline, and at least 2 MAOIs (isocarboxazid and tranylcypromine) inhibit GABA-mediated Cl<sup>-</sup> influx at GABA<sub>A</sub> receptors.<sup>174,270</sup> Their potency at inhibiting Cl<sup>-</sup> influx correlates with the frequency of seizures that occur in patients taking therapeutic doses of these medications. Impaired GABA<sub>A</sub> activity is believed to contribute to or is primarily responsible for seizures in those patients who overdose on these medications. Their exact binding on the GABA<sub>A</sub> receptor remains unknown, although some evidence suggests at least indirect activity at the picrotoxin-binding site.

Some subtypes of GABA<sub>A</sub> receptors are susceptible to inhibition by zinc ions.<sup>262</sup> What role this plays in normal physiology or toxicology is not established.

**GABA<sub>A</sub> Withdrawal** Acute withdrawal from all GABA<sub>A</sub> direct and indirect agonists clinically appears the same except for time course; the common

denominator is impaired Cl<sup>-</sup> influx. Withdrawal of all GABA<sub>A</sub> agonists causes tremor, hypertension, tachycardia, respiratory alkalosis, diaphoresis, agitation, hallucinations, and convulsions. When GABA<sub>A</sub> receptors are chronically exposed to an agonist, changes in gene expression of receptor subunits occur, which lessens Cl<sup>-</sup> influx in response to GABA or drug binding, producing tolerance. Importantly, withdrawal of the agonist produces yet further changes in subunit expression. For example, benzodiazepine-insensitive  $\alpha_4$ -subunit expression is increased following discontinuation of many GABA agonists, including benzodiazepines, zolpidem, zopiclone, zaleplon, neurosteroids, and ethanol. Expression of other subunits, including  $\alpha_1$ ,  $\gamma_2$ ,  $\beta_2$ , and  $\beta_1$ , also change in response to exposure and/or withdrawal of GABA<sub>A</sub> agonists.<sup>81</sup> Alterations in GABA<sub>A</sub> receptor subunit composition following chronic exposure to and withdrawal of an agonist can, therefore, affect the ability to successfully treat withdrawal symptoms. Although any GABA<sub>A</sub> receptor agonist can be used to treat withdrawal from another, some xenobiotics work better than others in different clinical settings. For example, patients experiencing severe alcohol withdrawal have an increased proportion of GABA<sub>A</sub> receptors containing benzodiazepine-insensitive  $\alpha_4$  subunits, and contain fewer GABA<sub>A</sub> receptors with benzodiazepine-sensitive  $\alpha_1$  subunits.<sup>42</sup> Even extremely high doses of benzodiazepines in these patients often fail to effectively control severe alcohol withdrawal. A better treatment option in such a setting would be GABA<sub>A</sub> agonists such as propofol or phenobarbital that either act on a different site on the GABA<sub>A</sub> receptor or directly open the Cl<sup>-</sup> channel.<sup>15,42</sup> Phenytoin and carbamazepine do not stop GABA<sub>A</sub> withdrawal seizures because their pharmacologic effects are independent of GABA<sub>A</sub> agonism.

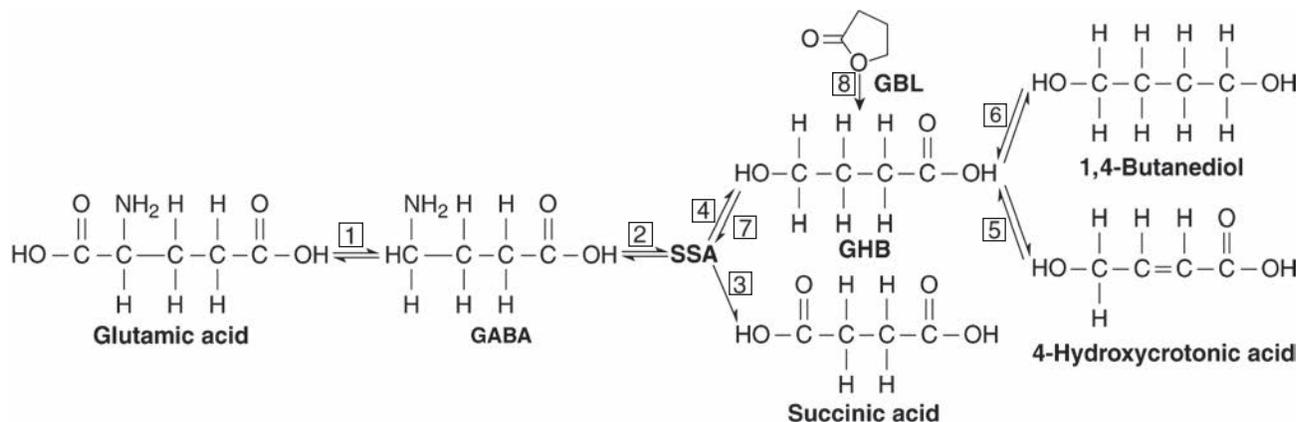

**GABA<sub>B</sub> Agonists** The main GABA<sub>B</sub> receptor agonist of toxicologic significance is baclofen, which is used for treatment of spasticity and some types of neuropathic pain. Coma, hypothermia, hypotension, bradyarrhythmias, and seizures characterize its toxicity. The convulsions that occur in patients with baclofen overdose are proposed to result from disinhibition (inhibition of inhibitory neurons). Carbamazepine activates GABA<sub>B</sub> receptors, although this is not thought to explain most of its antiepileptic action. Some of the actions of  $\gamma$ -hydroxybutyrate following pharmacologic doses are mediated by activation of GABA<sub>B</sub> receptors.  $\beta$ -Phenyl- $\gamma$ -amino butyric acid, or Phenibut, is structurally similar to baclofen and activates GABA<sub>B</sub> receptors.

**GABA<sub>B</sub> Withdrawal** Baclofen withdrawal is similar clinically to GABA<sub>A</sub> withdrawal. Hallucinations, agitation, tremor, increased sympathetic activity, and convulsions are the main characteristics. Withdrawal from chronic intrathecal baclofen administration is also accompanied by large swings in autonomic tone (hypotension, hypertension, tachycardia, bradycardia) and transient cardiomyopathy and shock. Reinstitution of oral baclofen therapy following oral withdrawal, or intrathecal baclofen following intrathecal withdrawal is the treatment of choice, when possible.<sup>175</sup>

### $\gamma$ -HYDROXYBUTYRATE

$\gamma$ -Hydroxybutyrate (GHB,  $\gamma$ -hydroxybutyric acid) exists endogenously and is thought to affect sleep cycles, temperature regulation, cerebral glucose metabolism and blood flow, memory, and emotional control. Toxicologic interest stems from its use in supraphysiologic doses as a drug of abuse and as a treatment for narcolepsy.<sup>26,78,153</sup>  $\gamma$ -Hydroxybutyrate is rapidly absorbed and freely crosses the blood-brain barrier. Toxicity resulting from ingestion of GHB is explained by GHB receptor and GABA<sub>B</sub> receptor activation, comprising agitation, tremor, rapid onset of coma, vomiting, bradycardia, hypotension, hypotonia, and apnea that usually resolve within several hours. Although seizures are noted in experimental animals, it is debated whether GHB causes true convulsive activity in human beings. Human experiments with "therapeutic" doses of GHB do not demonstrate EEG changes consistent with seizure activity.<sup>153</sup> Interestingly, patients with the rare inborn error of metabolism, succinic semialdehyde dehydrogenase (SSAD) deficiency, have elevated GHB concentrations and experience seizures.<sup>91</sup> Valproate elevates endogenous GHB concentrations by inhibiting SSAD.

Controversy exists as to whether GHB should be considered a neurotransmitter or simply a neuromodulator, because it is unclear whether GHB is

**FIGURE 13-11.** Potential pathways of  $\gamma$ -hydroxybutyrate (GHB) synthesis and degradation. GABA =  $\gamma$ -aminobutyric acid; GBL =  $\gamma$ -butyrolactone; SSA = succinic semialdehyde; [1] = glutamic acid decarboxylase; [2] = GABA-transaminase; [3] = succinic semialdehyde dehydrogenase; [4] = specific succinic semialdehyde reductase and/or nicotinamide adenine dinucleotide phosphate (NADPH)-dependent aldehyde reductase 2; [5] = mitochondrial  $\beta$  oxidation; [6] = alcohol dehydrogenase and aldehyde dehydrogenase; [7] = GHB dehydrogenase; [8] =  $\gamma$ -lactonase.

concentrated within vesicles for synaptic release. There is evidence supporting a sodium-dependent reuptake transporter for GHB.  $\gamma$ -Hydroxybutyrate (GHB) receptors or binding sites are heterogeneously distributed throughout the brain, with highest concentrations in the hippocampus, cortex, limbic areas, and thalamus, as well as in regions innervated by dopaminergic terminals and dopaminergic nuclei.  $\gamma$ -Hydroxybutyrate receptors exist on neurons, mainly at the synaptic level, but are absent from glial or peripheral cells. At least 2 general GHB receptors are thus far described, based on binding affinity for GHB and other ligands.

Several proposed pathways for endogenous GHB formation exist (Fig. 13-11).<sup>26</sup> Evidence exists for the metabolism of GHB back to GABA, although this appears minimal at physiologic GHB concentrations.<sup>78</sup> However, effects resulting from pharmacologic doses of GHB may result, in part, from secondary GABA formation.

Therapeutic doses of GHB inhibit DA release through activation of GABA<sub>B</sub> receptors<sup>299</sup> and GHB affects firing rates of DA neurons, and DA synthesis. Specific interactions between GHB and DA are not fully delineated. Although GHB suppresses signs of alcohol withdrawal, it is also addictive, and both tolerance and a withdrawal syndrome are described. Withdrawal is characterized, in part, by insomnia, cramps, paranoia, hallucinations, tremor, and anxiety.

## GLYCINE

Glycine acts as an inhibitory neurotransmitter in the spinal cord, lower brain stem, and retina. In the CNS, serine is converted to glycine by serine hydroxymethyltransferase (SHMT). Some sources of serine include degradation of proteins and phospholipids through dietary intake and formation from 3-phosphoglycerate in a 3-step biosynthetic pathway. It is well established that both GABA and glycine are excitatory in the embryonic central nervous system prior to becoming the main inhibitory neurotransmitters of the mature CNS.<sup>67,148,231</sup>

### Release and Reuptake

Glycine is transported into storage vesicles by VGAT (also known as VIAAT) and undergoes Ca<sup>2+</sup>-dependent exocytosis upon neuronal depolarization (Fig. 13-12). Glycine is removed from the synapse through reuptake by a Na<sup>+</sup>-dependent transporter into presynaptic neurons and into glial cells. Two glycine membrane transporters were cloned and share homology with GABA uptake transporters. Membrane glycine transporter (GLYT-1) is found both in astrocytes and neurons, whereas GLYT-2 is localized on axons and terminal boutons of neurons that contain vesicular glycine. Although both transporters are associated with glycinergic neurons in the brain stem and spinal cord, GLYT-1 is also found in the forebrain in regions devoid of glycinergic neurotransmission. At the latter location, GLYT-1 regulates extracellular glycine that is available for NMDA receptor activation, and

GLYT-1 inhibitors could then enhance NMDA responses (Table 13-11). Glycine transporters also function in reverse, moving glycine out of the cell.<sup>9</sup>

### Glycine Receptors

The glycine receptor is a member of the Cys-loop family of ligand-gated ion channel receptors and is a Cl<sup>-</sup> channel that shares significant amino acid homology with the GABA<sub>A</sub> Cl<sup>-</sup> channel.<sup>169</sup> Glycine receptors are pentameric proteins made up of  $\alpha$  and  $\beta$  subunits. To date, 4 isoforms of the  $\alpha$  subunit and one isoform of the  $\beta$  subunit are described.<sup>185</sup> An anchoring protein, gephyrin, binds to the  $\beta$  subunit and allows for clustering of glycine receptors at postsynaptic membranes. Glycine receptor activation causes an inward Cl<sup>-</sup> current that hyperpolarizes the membrane. Presynaptic glycine receptors are identified that are also Cl<sup>-</sup> channels; the Cl<sup>-</sup> influx from their activation enhances release of several neurotransmitters. Glycine binding is also important for functioning of the NMDA receptor, as discussed later.

### Xenobiotics

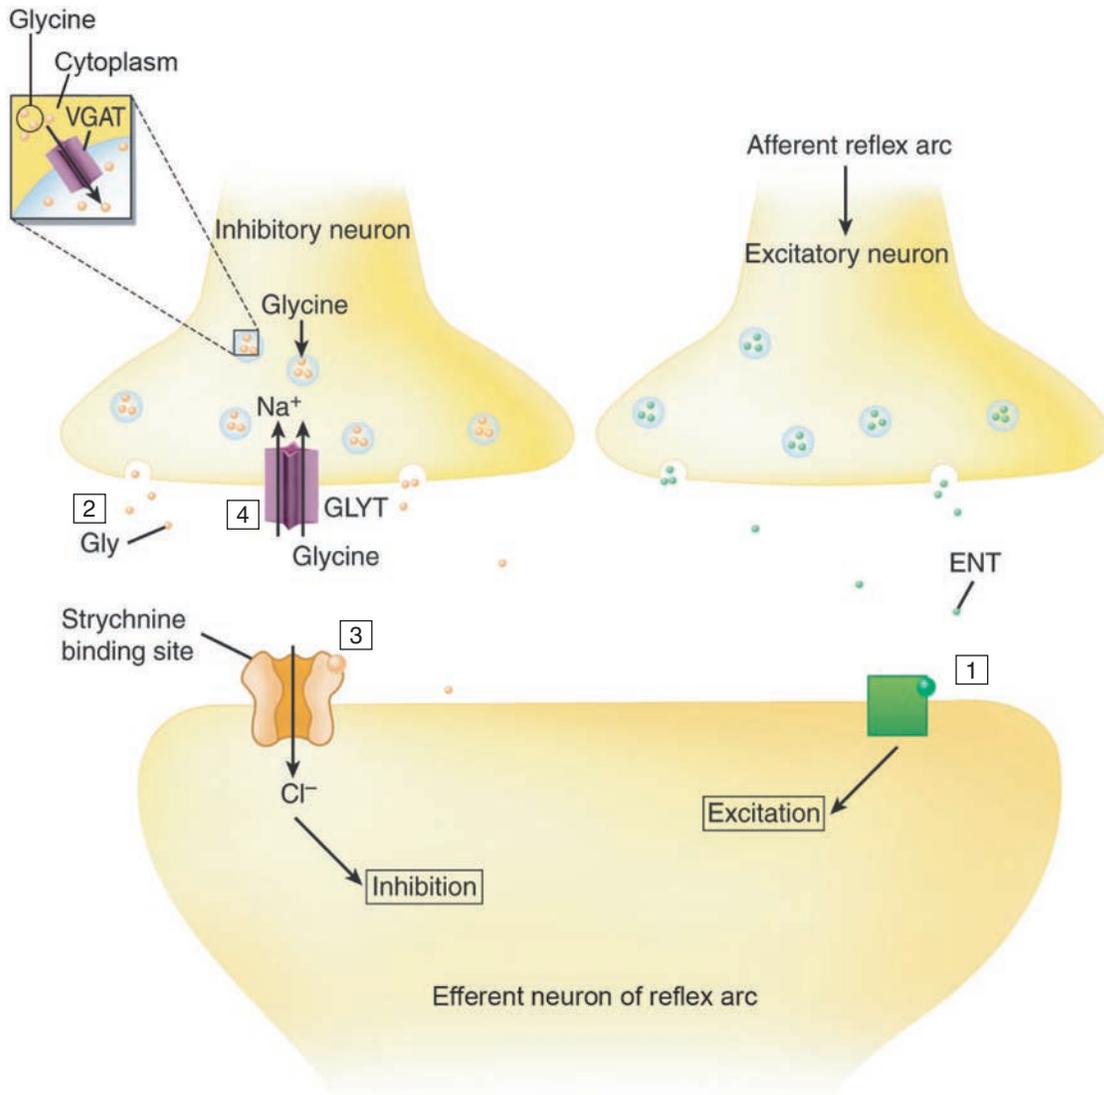

Table 13-10 provides examples of xenobiotics that affect inhibitory glycine Cl<sup>-</sup> channels. The amino acids  $\beta$ -alanine, taurine, and serine also activate glycinergic Cl<sup>-</sup> channels. Both ethanol and propofol potentiate glycine-mediated inward Cl<sup>-</sup> currents, just as they do at GABA<sub>A</sub> Cl<sup>-</sup> channels.<sup>179,185</sup> Volatile halogenated anesthetics, ivermectin,  $\delta$ -9-tetrahydrocannabinol, and chlormethiazole also potentiate glycinergic transmission.<sup>297</sup> Clozapine inhibits glycine reuptake.<sup>114</sup>

Strychnine and tetanospasmin are the main xenobiotic affecting glycinergic transmission. Strychnine competitively inhibits glycine binding to its receptor, decreasing Cl<sup>-</sup> influx.<sup>8,297</sup> Antagonism of glycine produces increased muscle tone, rigidity, opisthotonus, trismus, rhabdomyolysis, and death from respiratory failure. Given the similarity in Cl<sup>-</sup> channels, it is not surprising that strychnine binds to the GABA<sub>A</sub> complex in vitro. However, the affinity of strychnine for this complex is less than that for glycine receptors, and most of its toxicologic action is a result of physiologic antagonism of glycine-induced inhibition.

Picrotoxin binds to the glycine receptor to impair Cl<sup>-</sup> influx.<sup>170</sup> Evidence exists for a direct antagonistic effect of picrotoxin at the glycine-binding site(s), in contrast to GABA<sub>A</sub> Cl<sup>-</sup> channels, where it acts at a site separate from where GABA binds. Ginkgolide X inhibits the glycine receptor by directly blocking the Cl<sup>-</sup> channel.<sup>116</sup> Tetanus toxin (tetanospasmin) produces rigidity and trismus by preventing glycine release from neuronal terminals in the spinal cord and brain stem.

### GLUTAMATE

Glutamate is the main excitatory neurotransmitter in the CNS and the immediate precursor to the main inhibitory neurotransmitter, GABA. Balance between glutamatergic neuronal stimulation and GABAergic neuronal

**FIGURE 13–12.** Inhibitory glycinergic neurotransmission. Glycine is concentrated within vesicles by uptake via VGAT, the vesicle membrane transporter. Signals from the afferent limb of a reflex arc (top right) cause the release of an excitatory neurotransmitter (ENT) that crosses the synapse to bind to a neuron in the efferent limb of the reflex arc [1]. To prevent excessive neuronal firing and motor activity, glycine (Gly) released from a glycinergic inhibitory neuron [2] binds to glycine  $\text{Cl}^-$  channel receptors [3] and causes inhibition by hyperpolarization through  $\text{Cl}^-$  influx. Synaptic glycine is transported back into the neuron by at least 2 subtypes of membrane glycine transporters, GLYT-1 and GLYT-2 [4]. Strychnine binds to the glycinergic  $\text{Cl}^-$  channel to decrease the binding of glycine, which prevents  $\text{Cl}^-$  influx. Although strychnine is shown to bind to a separate site from glycine, there is evidence that these sites may overlap. GLYT = glycine reuptake transporter.

inhibition is essential to maintain normal CNS function.<sup>72,114,126,308</sup> Glutamate is essential for memory, learning, perception, attention, locomotion, and neuropsychiatric well-being.<sup>22,52,67,97</sup> Although glutamate receptor stimulation is essential for normal brain activity, excessive endogenous or exogenous stimulation plays a significant role in mediating neuronal damage in acute, progressive, and chronic psychiatric and neurologic diseases, including trauma, ischemia, hypoglycemia, and status epilepticus.<sup>22,180</sup> A rise in synaptic glutamate concentrations after neurologic insult that induces further damage and apoptosis is termed glutamate-related excitotoxicity.<sup>36,67,171,308</sup> Conversely, glutamate antagonists demonstrate neuroprotective properties and antiepileptic activity in animal models of CNS injury. Unfortunately, clinical trials with currently available glutamate antagonists for treatment of patients with ischemic stroke and traumatic brain injury have proved disappointing.<sup>36,67</sup>

A number of psychiatric and neurologic disorders are associated with altered glutamatergic function, including schizophrenia, depression, anxiety, posttraumatic stress disorder, obsessive-compulsive disorder (OCD), substance use disorders and withdrawal, autism, intellectual disability, attention deficit hyperactivity disorder (ADHD), epilepsy, Alzheimer disease,

Parkinson disease, Huntington disease, amyotrophic lateral sclerosis (ALS) and neuropathic pain.<sup>1,6,52,67,86,87,90,97,114,122,149,171,244</sup>

Glutamatergic pathways intertwine with dopaminergic, serotonergic, and adenosinergic pathways, among others. For instance, illicit drug use may alter glutamatergic pathways, via interactive pathways involving dopaminergic neurons—heavy cannabis and cocaine users having decreased glutamate

**TABLE 13–10** Examples of Xenobiotics Affecting Inhibitory Glycine Chloride Channels

in various brain areas.<sup>43,53</sup> It is thought that striatal dopamine modulates glutamate concentrations in the basal ganglia, and glutamate is involved in Parkinson disease with glutamatergic signals from the cortex interacting with the dopaminergic network of the substantia nigra; ionotropic glutamate receptors are being targeted to ameliorate the motor symptoms of Parkinson disease.<sup>43,87,97</sup> Although glutamate-modulating xenobiotics are being developed, with the hope of treating various neuropsychiatric illnesses, initial studies are disappointing.<sup>97,112,292</sup>

### Synthesis, Release, and Reuptake

Glutamate does not cross the blood–brain barrier and must be synthesized from products of glucose metabolism or other precursors within the CNS. Glutamate primarily is synthesized from glutamine by the enzyme glutaminase located within the mitochondrial compartment.<sup>82</sup> Glutamate is stored within vesicles and then released into the synapse by Ca<sup>2+</sup>-dependent exocytosis. Synaptic glutamate that is taken up by glial cells undergoes conversion back to glutamine by the enzyme glutamine synthase. Glial cells then release glutamine, which is taken up by neurons before conversion back to glutamate and subsequent transport into vesicles (Fig. 13–13).<sup>36</sup> Reverse transport of glutamate from the cytoplasm into the synapse by the membrane transporter occurs under some circumstances.<sup>13</sup> There are 5 different plasma membrane excitatory amino acid transporters (EAAT1–5) that differ in their predominant CNS locations. The EAATs play a role in controlling extracellular glutamate concentrations and cross-talk between synapses, making them important therapeutic targets.<sup>36,215,308</sup> Some EAATs function as chloride channels and function more as inhibitory glutamate receptors than as transporters. Interestingly, beta-lactam antibiotics, such as ceftriaxone, and orb weaver spider venom enhance EAAT2 transport activity.<sup>308</sup> Another membrane transporter is the glutamate-cystine exchanger (SLC7A11), by which uptake of cystine causes glutamate release.<sup>308</sup>

### Glutamate Receptors

Once glutamate undergoes release into the synapse, it binds to one of 3 ionotropic receptors or 8 metabotropic receptors. The 3 ionotropic glutamate receptors are cation channels and named according to their affinity for specific agonists: kainate, AMPA ( $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole propionate), and NMDA (*N*-methyl-D-aspartate). All comprise 4 subunits, with associated modulatory sites that bind small ligands, termed allosteric modulators.<sup>51,67,79,126,131,183,215,229,308</sup> The NMDA and AMPA receptors compose the core of glutamatergic synapses and are responsible for fast excitatory glutamatergic activity, necessary for higher cognitive functions, such as memory and learning.<sup>215</sup> The NMDA receptors are critical for synaptic plasticity and play prominent roles in neurologic diseases.<sup>215</sup>

The 8 metabotropic receptors are linked to G proteins and produce actions that are slower, more diverse, and longer-lasting than those of ionotropic receptors.<sup>79,131</sup> A single neuron may express numerous types of glutamate receptors. Every type of glutamate receptor has been identified on both presynaptic and postsynaptic membranes, but many are not active under normal physiologic conditions. This complexity offers protection against the devastating effects of uncontrolled excitatory neurotransmission.

### Ionotropic Glutamate Receptors

Ionotropic cationic glutamate receptors share structural similarity, especially kainate and AMPA receptors. These receptors are homomeric or heteromeric tetramers with a central ion channel pore. The inward current carried through most ionotropic glutamate receptors results from Na<sup>+</sup> and/or Ca<sup>2+</sup> influx.<sup>126,183,282</sup>

AMPA receptors are hetero- and homotetramers comprising GluA1–4 subunits and are the most common ionotropic glutamate receptors found in the brain. These receptors are responsible for most glutamatergic excitation, mainly through Na<sup>+</sup> influx under normal conditions.<sup>46,126,200,217,282</sup> Post-transcriptional modification or RNA editing of AMPA receptor subunits alters ion permeability and function. In adults, nearly all GluA2 subunits are edited, resulting in maintenance of Na<sup>+</sup> permeability, but loss of Ca<sup>2+</sup>

permeability. In contrast, some unedited GluA2 subunits demonstrate Ca<sup>2+</sup> and Zn<sup>2+</sup> permeability.<sup>67,126,183,200,223</sup> These AMPA receptors permeable to Ca<sup>2+</sup> are more prevalent in many neurologic diseases where they contribute to excitotoxicity.<sup>126,183</sup>

Kainate receptors are named for their affinity for kainate, found in red algae. These receptors comprise GluK1–5 subunits joined in homomeric and heteromeric tetramers.<sup>57,119,126,242</sup> Activation allows Na<sup>+</sup> influx, and lesser K<sup>+</sup> efflux, resulting in neuronal depolarization. Ribonucleic acid (RNA) editing of GluK1 and GluK2 subunits abolishes Ca<sup>2+</sup> permeability while maintaining Na<sup>+</sup> conductance, but some subunits remain unedited and permeable to Ca<sup>2+</sup>.<sup>46,223</sup> Recent studies indicate that some kainate receptors also signal through G proteins and are involved in long-term potentiation for learning and memory.<sup>54,225</sup>

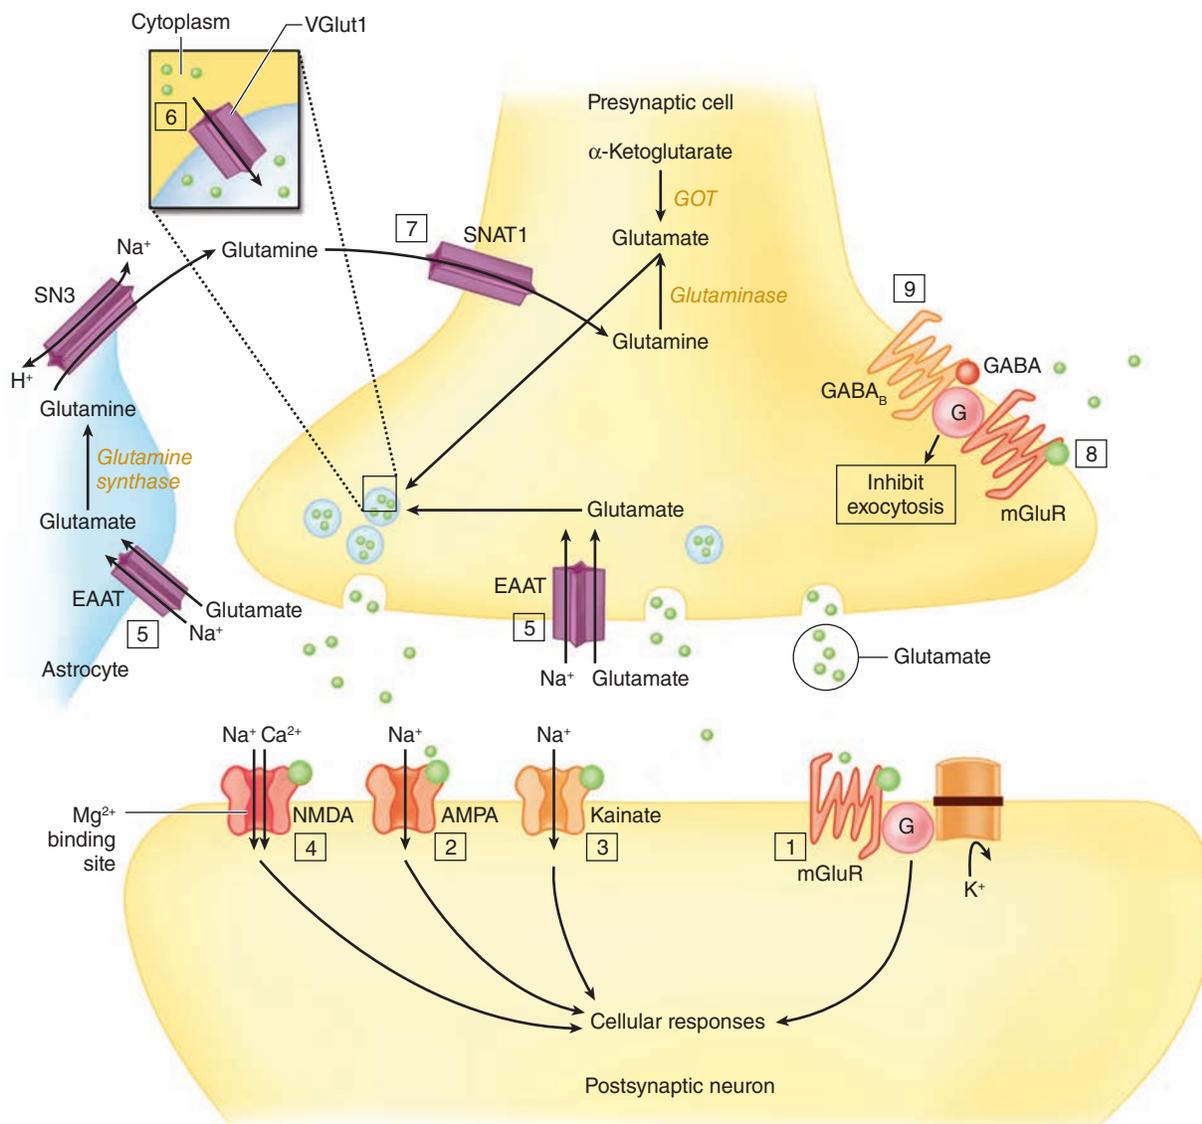

*N*-methyl-D-aspartate (NMDA) receptors are heteromeric tetramers of subunits that may include GluN1, GluN2A–2D, and GluN3A–3B (7 isoforms), but most commonly comprise 2 GluN1 and 2 GluN2 subunits.<sup>22,67,126,128,282,309</sup> The principal endogenous agonists that bind to the GluN1 subunit are glycine and D-serine, whereas the principal endogenous agonist that binds to the GluN2 subunit is glutamate.<sup>122</sup> *N*-methyl-D-aspartate (NMDA) receptors reside near AMPA receptors, forming a functional synaptic unit at virtually all central synapses.<sup>282</sup> *N*-methyl-D-aspartate (NMDA) receptor activation allows for Ca<sup>2+</sup> and Na<sup>+</sup> influx (and some K<sup>+</sup> efflux), resulting in neuronal depolarization and excitation (Fig. 13–14). The NMDA ion channel is normally blocked by Mg<sup>2+</sup> in a voltage-dependent manner, preventing Ca<sup>2+</sup> influx despite glutamate binding (Fig. 13–14).<sup>114,128</sup> For Ca<sup>2+</sup> to flow through the channels, 3 conditions must be met: (1) the neuronal membrane must be depolarized by at least 20 to 30 mV through some other mechanism (eg, activation of an adjacent AMPA receptor) so that Mg<sup>2+</sup> will leave the channel, (2) 2 molecules of glutamate must bind to the receptor, and (3) 2 molecules of glycine must bind to their binding sites on the receptor.<sup>67,79,128,171</sup> The amino acid D-serine may substitute for glycine at the glycine modulatory site.<sup>17,22,126,215</sup> Evidence suggests that D-serine is the primary co-agonist for synaptic, but not extra synaptic, NMDARs.<sup>17</sup> Thus, the NMDA receptor is both a ligand-gated and voltage-gated ion channel (Fig. 13–14).

Direct Ca<sup>2+</sup> influx through both NMDA and Ca<sup>2+</sup>-selective AMPA channel receptors contributes to excitotoxicity. Excessive stimulation of NMDA and AMPA receptors by glutamate released during times of ischemia, trauma, hypoglycemia, or convulsions triggers damaging rises in intracellular Ca<sup>2+</sup> concentrations, activation of numerous enzymes, and free radical formation, all of which incite cell death.<sup>180</sup> Antagonists of NMDA Ca<sup>2+</sup> channels are antiepileptic and neuroprotective. Zinc is packaged into synaptic vesicles in axons and is co-released with glutamate into the synaptic cleft during neuronal activity where it acts as a negative allosteric modulator of NMDA receptors.<sup>282,309</sup> Other endogenous substances, such as Mg<sup>2+</sup>, protons, polyamines, neurosteroids, and fatty acids also modulate NMDA receptor activity.<sup>122</sup>

### Metabotropic Glutamate Receptors

Metabotropic glutamate receptors (mGlu) are linked to various G proteins on post- and presynaptic membranes (Fig. 13–13). Eight different receptors (mGlu1–8) were isolated. In contrast to ionotropic glutamate receptors, metabotropic glutamate receptors either excite or inhibit at postsynaptic membranes, and mainly inhibit at presynaptic locations, regulating synaptic transmission and neuronal excitability.<sup>215</sup>

Metabotropic glutamate receptors are commonly subdivided into 3 main groups based on their sequence homology, intracellular signaling mechanisms, and response to specific experimental agonists.<sup>258,277</sup> As a general rule, group I receptors (mGlu1 [a,b,c,d] and mGlu5 [a,b]) reside postsynaptically; activation produces excitation through blockade of K<sup>+</sup> efflux or by activating phospholipase C, producing rises in intracellular Ca<sup>2+</sup>, resulting in cell depolarization.<sup>52,79,215,258,277</sup> The mGlu5 receptors are physically coupled to NMDA receptors by scaffolding proteins and are functionally coupled to NMDA receptors by protein kinase C.<sup>52,79,258,292</sup> In animal experiments, agonists of group I receptors produce convulsions, while antagonists display antiepileptic action.<sup>79,162,171,258</sup> Negative allosteric modulators (NAMs)

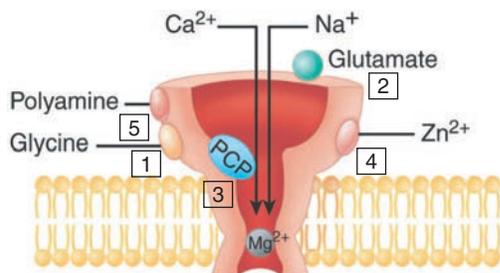

**FIGURE 13–13.** Glutamatergic neurotransmission. Aspartate aminotransferase (AST) converts  $\alpha$ -ketoglutarate to glutamate in mitochondria. Glutamate also forms from glutamine via mitochondrial glutaminase. Glutamate is transported into vesicles [6] by VGLut1 (or possibly other subtypes) for exocytotic release into the synapse. Synaptic glutamate activates 4 main types of receptors. AMPA [2], kainate [3], and NMDA [4] receptors are cation channels. Membrane depolarization in response to their activation causes neuronal excitation through cation influx. All types of glutamate receptors have been found on pre- and postsynaptic membranes, including kainate receptors. However, ligand-gated ion channel glutamate receptors on the postsynaptic membrane only are illustrated in this figure. Metabotropic receptors (mGluR) [1,8] are coupled to G proteins and are expressed on pre- and postsynaptic membranes. In addition, some mGluRs reside outside of the synapse. Postsynaptic mGluR excitation in this example [1] results from preventing  $\text{K}^+$  efflux, but other mechanisms of excitation exist. Presynaptic mGluRs act to inhibit [8] glutamate (and other neurotransmitter) release through modulating intracellular  $\text{Ca}^{2+}$  concentrations, as do presynaptic  $\text{GABA}_B$  receptors in response to GABA binding [9]. Figure 13–14 provides a more detailed illustration of the NMDA receptor. Excessive influx of  $\text{Ca}^{2+}$  through NMDA receptors (and through some AMPA and kainate receptors) causes neuronal damage and cell death. A  $\text{Mg}^{2+}$  ion normally blocks the NMDA receptor channel to prevent  $\text{Ca}^{2+}$  influx despite glutamate binding. However, depolarization of the neuronal membrane by cation influx resulting from activation of any of the other receptor types causes  $\text{Mg}^{2+}$  to dissociate from the NMDA receptor and to allow potentially damaging inward  $\text{Ca}^{2+}$  currents in response to glutamate binding. Glutamate undergoes reuptake by neurons and glial cells by various subtypes of EAAT, the membrane-bound glutamate transporter [5]. In glial cells, glutamate is converted to glutamine by glutamine synthase, and glutamine is transported out of glial cells by the system N amino acid transporter (SN3). Glutamine then moves back into neurons through another amino acid transporter (SNAT1) [7] where it undergoes conversion back to glutamate. Various xenobiotics in Table 13–11 affect glutamatergic neurotransmission, in part, by stimulating or blocking the various glutamate receptors [1–4,8] or by preventing glutamate reuptake [5]. G = G protein.

for mGlu5 receptors are being investigated for the treatment of addiction, L-dopa-induced dyskinesia, depression, and OCD.

Group II (mGlu2, mGlu3) and Group III (mGlu4, mGlu6, mGlu7, mGlu8) metabotropic receptors most commonly serve as presynaptic autoreceptors and heteroreceptors and, when activated, inhibit adenylate cyclase activity.<sup>52,79,215,229,245,277</sup> This, in turn, prevents  $\text{Ca}^{2+}$  influx and inhibits release of neurotransmitters, including glutamate, GABA, DA, and adenosine. Group II presynaptic autoreceptors are believed to play an important role in decreasing further glutamate release during pathologic conditions, when extracellular concentrations of glutamate exceed

normal physiologic levels. They are positioned outside the synaptic active zone and, therefore, only become activated when glutamate spills out of the synapse.<sup>229</sup> Positive allosteric modulators of mGlu2 receptors are being investigated for the treatment of addiction relapse, depression, and schizophrenia. The mGlu7 receptor is positioned within the active zone of the synapse, but has a low affinity for glutamate, allowing for a continuous but mild inhibitory effect on glutamate release.<sup>229,277</sup> Agonists for mGlu7 receptors are being studied for analgesic effects.<sup>261</sup> Agonists of group II and III metabotropic receptors produce antiepileptic effects in animals.<sup>178</sup> Positive allosteric modulators of mGlu4 receptors are being

**FIGURE 13–14.** Representation of the NMDA glutamate receptor. The NMDA receptor is a voltage-gated and ligand-gated  $\text{Ca}^{2+}$  channel. Glutamate binds to its receptor on the channel [2] to open the  $\text{Ca}^{2+}$  channel and to allow  $\text{Ca}^{2+}$  and  $\text{Na}^{+}$  influx and lesser amounts of  $\text{K}^{+}$  efflux.  $\text{Mg}^{2+}$  normally blocks the  $\text{Ca}^{2+}$  channel, preventing cation influx in response to glutamate binding.  $\text{Mg}^{2+}$  leaves the channel when the membrane is depolarized by 20–30 mV. Glycine must also bind to its site on the NMDA receptor complex for successful glutamate agonism. Polyamines bind on the extracellular surface of the receptor [5].  $\text{Zn}^{2+}$  binds [4] to inhibit  $\text{Ca}^{2+}$  influx. The phencyclidine (PCP) binding site [3] lies within the channel. Xenobiotics in Table 13–11 may antagonize glycine binding [1]; block the  $\text{Ca}^{2+}$  channel by binding to the PCP binding site [3]; bind to the polyamine binding site [5]; or directly stimulate the glutamate-binding site [2].

investigated for the treatment of Parkinson disease, anxiety, OCDs, and psychosis.

The glutamate-binding pocket is so well conserved among the metabotropic glutamate receptors that it is difficult to find subtype selective agonists or competitive antagonists. Therefore, drug development is now focused on negative and positive allosteric modulators (NAMs and PAMs).<sup>245</sup> Allosteric modulators bind to metabotropic glutamate receptors at a site distinct from the glutamate binding site and alter the functioning of the receptor in the presence of glutamate. The NAMs block activation of G proteins by the receptor, while PAMs facilitate the action of direct receptor agonists. Allosteric modulators are being developed to treat hyperlocomotion, psychosis, and schizophrenia.<sup>52,79,245</sup>

## Xenobiotics

Table 13–11 provides examples of xenobiotics that affect glutamatergic neurotransmission.

### Glutamate Agonism

Kainate is a strong neurotoxin that produces seizures through activation of kainate receptors.<sup>57,95</sup> Domoic acid, a kainate analog, produces amnesic shellfish poisoning, partly characterized by confusion, agitation, convulsions, memory disturbance, neuronal damage, and death.<sup>95,105</sup> The structural similarity between domoic acid and glutamate is thought to explain excessive activation of AMPA and kainate receptors with secondary NMDA receptor activation and resultant neuronal damage.<sup>107</sup> Domoic acid toxicity in birds is thought to have explained their attack on the city of Capitola, CA, in 1961, and may have partly inspired Hitchcock's creation of the movie, *The Birds*.<sup>56</sup> More recently, domoic acid toxicosis produced epidemics of bizarre behavior among coastal California sea lions.<sup>95</sup>

Investigators hypothesize that other naturally occurring glutamate receptor agonists produce additional neurologic diseases. The neurogenic form of lathyrism results from using chickling peas (*Lathyrus sativus*) as a food staple. Neurolathyrism was common in German concentration and prisoner of war camps during World War II and still occurs in some parts of the world. Chickling peas contain L- $\beta$ -N-oxalyl- $\alpha,\beta$ -diaminopropionic acid (ODAP), previously known as  $\beta$ -N-oxalylamino-L-alanine (BOAA), an agonist of AMPA receptors.<sup>142,288</sup> Excitotoxicity with influx of  $\text{Ca}^{2+}$  likely contributes to motor neuron cell death in neurolathyrism.<sup>288</sup>

Endemic ALS–Parkinson disease in Guam is hypothesized to result from chronic toxicity by  $\beta$ -methylamino-L-alanine (BMAA), which is formed by cyanobacteria symbiotically residing within the roots of Cycads (*Cycas micronesica*).  $\alpha$ -Amino- $\beta$ -methylaminopropionic acid (BMAA) and its carbamate

BMAA	Quinoxalinediones
Cinnabarinic acid	Talampanel
Domoic acid	Topiramate
Homoquinolinic acid	NMDA receptor antagonists
Ibotenic acid	Acamprosate
ODAP (previously BOAA)	Amantadine
Quisqualate ( <i>Quisqualis indica</i> )	Atomoxetine
Willardine ( <i>Acacia willardina</i> )	Buprenorphine
Xanthurenic acid	Chlorpromazine
AMPA receptor modulators	Conatokin ( <i>Conus</i> genus snails)
Aniracetam	Desipramine
BMAA	Dextromethorphan
Cyclothiazide	Dextrorphan
Dysiherbaine	Dimebon
Minocycline	Dizocilpine (MK801)
ODAP (previously BOAA)	Dynorpin peptides
Racetams	Esketamine
Thiazides	Ethanol <sup>a</sup>
Kainate receptor modulators	Ifenprodil
Concavalin A	Ketamine
Domoic acid	Kynurenic acid
Dysiherbaine	Magnesium
Neodysiherbaine A	Memantine
NMDA receptor modulators	Meperidine
Aspartic acid	Methadone
Cannabidiol	Methoxetamine
N-Acetylcysteine	Neramexane
Nitric oxide	Orphenadrine
Piracetam	Pentamidine
Pregnenolone	Phencyclidine
Spermine	Promethazine
Glycine NMDA receptor agonists	Remacemide
Alanine	Sefotel
D-Cycloserine	Tramadol
Kynurenic acid	NMDA glycine antagonists
Milacemide	Felbamate
Rapastinel (Glyx-13)	Kynurenic acid
D- and L-serine**	Meprobamate
Glutamate uptake inhibitor	Xenon
Clozapine	Kainate receptor antagonists
Nitropropionic acid	Quinoxalinediones
Glycine reuptake inhibitor (GlyT1 antagonist)	Topiramate
Chlorpromazine	Metabotropic negative allosteric modulators (NAMs)
Clozapine	Dipraglurant
Haloperidol	Fenobam
Sarcosine (N-methylglycine)	Rufinamine
Thioridazine	Polyamine antagonists
Polyamine agonists	Aptiganel
Neomycin	Arcaïne
<b>Glutamate antagonism</b>	Argiotoxin (spider toxin)
Prevent glutamate release	Diethylenetriamine
Diazoxide	Eliprodil
Felbamate	Ifenprodil
Lamotrigine	Joro spider toxins
Nimodipine	Philanthotoxins (digger wasp)
Riluzole	Glutamate scavengers
Sulfasalazine	Oxaloacetate
Increase glutamate reuptake	Pyruvate
Ceftriaxone	
Lithium	
Riluzole	

BMAA =  $\alpha$ -amino- $\beta$ -methylaminopropionic acid; ODAP = L- $\beta$ -N-oxalyl- $\alpha,\beta$ -diaminopropionic acid; BOAA =  $\beta$ -N-oxalylamino-L-alanine; NMDA = N-methyl-D-aspartate; NAM = negative allosteric modulator; PAM = positive allosteric modulator.

<sup>a</sup>Ethanol is a noncompetitive antagonist of NMDA receptors, with sensitivity dependent upon the GluN2 subunit.

are structurally similar to glutamate,<sup>37</sup> and experiments demonstrate that prolonged exposure to BMAA produces Ca<sup>2+</sup> influx into substantia nigra pars compacta dopaminergic neurons and excitotoxic effects through activation of metabotropic glutamate receptors (mGlu1), and to a lesser extent, AMPA receptors.<sup>58</sup> Consumption of raw *Cycas* seeds, or flour made from *Cycas*, or of animals that have eaten *Cycas*, results in an accumulation of protein-bound BMAA within brain tissues of humans that can be demonstrated at autopsy. However, autopsies of patients throughout the world with ALS, Alzheimer disease, and Parkinson disease, in absence of *Cycas* exposure, also demonstrate elevated brain BMAA concentrations, and cyanobacteria that produce BMAA are ubiquitous, making interpretation of BMAA's role in producing ALS–Parkinson disease difficult.

Ibotenic acid, from poisonous mushrooms, activates NMDA and some metabotropic glutamate receptors. It undergoes decarboxylation to muscimol, a direct agonist of GABA<sub>A</sub> receptors. Glufosinate is a tripeptide and glutamate analogue isolated from *Streptomyces* and utilized in herbicides. Glufosinate produces excitotoxicity in humans, manifesting as drowsiness, amnesia, confusion, coma, seizures or death, through activation of NMDA receptors.<sup>176</sup>

There is *in vitro* evidence that ketamine causes glutamate release from neuronal terminals. Ketamine and methoxetamine directly activate AMPA glutamate receptors, and this effect may explain their potential antidepressant action.<sup>55,190,157,171,183,217</sup> Despite memantine and ketamine both antagonizing NMDA receptors by occupying the ion channel, overlying the Mg<sup>2+</sup> binding site, and occluding current flow, memantine has failed to show antidepressant action; this may be due to differences in downstream signaling and expression of key proteins.<sup>122,130</sup> Memantine and amantadine improve the motor effects of Parkinson disease when used in conjunction with levodopa.<sup>87</sup>

Because noncompetitive NMDA receptor antagonism reproduces many signs and symptoms of schizophrenia and autism, investigators are directing efforts at increasing activity at NMDA channels in an effort to treat these diseases,<sup>149,260,305</sup> and potentiating activity at the glycine-binding site should enhance NMDA receptor function. After crossing the blood–brain barrier, milacemide undergoes conversion to glycine, which is required for NMDA receptor activation.<sup>260</sup> D-Cycloserine also crosses the blood–brain barrier to stimulate glycine receptors on NMDA calcium channels.<sup>128</sup> D-Cycloserine significantly ameliorates social withdrawal and repetitive behaviors in patients with autism spectrum disorders.<sup>149</sup> Rapastinel (GLYX-13) is a NMDA receptor modulator with glycine-site partial agonist properties that produces antidepressant-like effects.<sup>65,197</sup> Sarcosine (*N*-methylglycine) is a glycine transporter-1 inhibitor, raising synaptic glycine concentrations near NMDA receptors.<sup>115</sup>

*N*-Acetylcysteine (NAC) modulates glutamate through the astrocytic antiporter cysteine/glutamate, resulting in stimulation of metabotropic glutamate receptors and activation of NMDA receptors. Also, NAC likely potentiates AMPA receptors. Some have suggested NAC as a treatment for Parkinson disease and for depressive symptoms of bipolar disease.<sup>157</sup> More recently, it was discovered that NAC activates mGlu2 receptors, and it is under evaluation for ethanol, cocaine, cannabis, and methamphetamine addiction treatment.<sup>203</sup>

L-Acetylcarnitine produces rapid, long-lasting antidepressantlike effects by up-regulating mGlu2 receptors and is utilized to treat persistent depressive disorders.<sup>203</sup> L-Acetylcarnitine is also being studied for the treatment of chronic pain.<sup>207</sup>

Aniracetam inhibits deactivation of AMPA receptors and is advocated as a nootropic agent for patients with dementia.<sup>126,139</sup> Minocycline and cyclothiazide attenuate receptor desensitization and demonstrate neuroprotective effects.<sup>118,126,183</sup>

### Glutamate Antagonism

**Prevention of Glutamate Release** Riluzole is used to treat ALS and is being considered for neuroprotection in Parkinson disease and for treatment of depression. Overall, riluzole increases glutamine/glutamate ratios. It indirectly prevents release of glutamate by inhibiting voltage-dependent Na<sup>+</sup> channels and facilitates uptake of glutamate from the synapse by

stimulating EAAT activity.<sup>67,171,183</sup> Riluzole also enhances AMPA trafficking, enhances membrane insertion of AMPA receptors, and promotes neurogenesis through stimulation of growth factors.<sup>67,128,171</sup> Lamotrigine diminishes glutamate release through blockade of voltage-gated Na<sup>+</sup> channels and increases AMPA receptor activity.<sup>171</sup> Felbamate antagonizes NMDA receptors and prevents glutamate release.<sup>67</sup> Gabapentin and pregabalin inhibit presynaptic Ca<sup>2+</sup> channels to lessen glutamate release. The α<sub>2</sub>-adrenergic agonists, clonidine, guanfacine, and tizanidine inhibit glutamate release. This action is proposed to explain their efficacy in the treatment of ADHD and the neuroprotective effects in animal models.<sup>141,300</sup> Tizanidine is used to treat stiff person syndrome.<sup>306</sup>

**AMPA Receptor Antagonists** Talampanel, a noncompetitive AMPA receptor antagonist, was investigated in the treatment of ALS and demonstrated antiepileptic properties.<sup>183</sup> Some wasp and spider venoms contain AMPA receptor antagonists.<sup>183</sup> Fluoxetine and desipramine inhibit Ca<sup>2+</sup>-permeable AMPA receptors.<sup>20,302</sup>

**NMDA Receptor Antagonists** Phencyclidine, ketamine, and methoxetamine act as noncompetitive antagonists by binding within the ion channel (PCP-binding site) to block Ca<sup>2+</sup> influx following glutamate binding (Fig. 13–14).<sup>114,128</sup> Tiletamine is an NMDA receptor antagonist utilized, in conjunction with the benzodiazepine zolazepam, in veterinary medicine as a tranquilizer. There are concerns of human misuse.<sup>64</sup>

Dextromethorphan and its metabolite, dextrorphan, exhibit antiepileptic activity and psychoactive effects in animals. Most of the actions of dextromethorphan are due to its metabolite, dextrorphan, which antagonizes the actions of glutamate at NMDA receptors by binding to the PCP binding site. Both compounds directly block N- and L-subtype voltage-dependent Ca<sup>2+</sup> channels.<sup>128,238</sup>

Tramadol has multiple mechanisms of action as an analgesic, including a weak affinity for opioid receptors, inhibition of monoamine reuptake, and inhibition of glutamatergic activity at clinically relevant concentrations by an unknown mechanism.<sup>98,117</sup> Methadone, meperidine, and buprenorphine are opioid analgesics that antagonize NMDA receptors at therapeutic doses, and this mechanism of action may contribute to their analgesic effect.<sup>63</sup>

Dizocilpine (MK-801) antagonizes NMDA receptors by binding to the PCP binding site in the NMDA Ca<sup>2+</sup> channel, producing adverse effects, similar to phencyclidine.<sup>70</sup> Amantadine, memantine, and orphenadrine act as low-affinity antagonists at the PCP site, but are not associated with psychotomimetic adverse effects from such action.<sup>128</sup> Memantine is a low-affinity NMDA receptor antagonist, which is approved for the treatment of Alzheimer disease, but was also recently utilized for the treatment of other neurologic and psychiatric disorders.<sup>22,67,77,171,278,282</sup> Ifenprodil is a GluN2B-subunit-selective antagonist of NMDA receptors that is advocated for neuroprotection in stroke patients.<sup>208</sup> Pentamidine antagonizes glutamate binding at NMDA channels.<sup>70</sup>

Ethanol noncompetitively antagonizes NMDA receptors, resulting in upregulation of this glutamatergic system.<sup>282</sup> Ethanol-tolerant individuals show marked reductions to subjective intoxicating effects of ketamine.<sup>171</sup> In some animal models of ethanol withdrawal seizures, NMDA receptor antagonists demonstrate better antiepileptic action than GABA<sub>A</sub> agonists.

Desipramine, atomoxetine, chlorpromazine, minocycline, and atomoxetine antagonize NMDA receptors.<sup>20,166,244</sup>

**Glycine Antagonism** The antiepileptic activity of felbamate results, in part, from antagonism of glycine at NMDA receptors.<sup>221,301</sup> Kynurenic acid, a metabolite of L-tryptophan, prevents NMDA activation through glycine antagonism. Meprobamate also antagonizes NMDA glutamate receptors by a yet-to-be-determined mechanism.<sup>221</sup> However, given the structural similarity to felbamate, meprobamate might antagonize the action of glycine.

**Polyamine Antagonism** Polyamines are GluN2B subunit allosteric modulators.<sup>40</sup> Ifenprodil and eliprotil antagonize the action of glutamate at NMDA channels by preventing polyamine binding.<sup>94</sup>

**Glutamate Scavengers** Glutamate scavengers are beneficial in nonhuman studies of traumatic brain injury, subarachnoid hemorrhage, epilepsy, glioma, and organic phosphorus-induced neuronal damage.<sup>36</sup> Oxaloacetate, pyruvate, glutamate-oxaloacetate transaminase, and glutamate-pyruvate transaminase reduce blood glutamate concentrations, and subsequently brain glutamate concentrations.<sup>36</sup> Other glutamate scavengers include estrogen, progesterone, beta-adrenergic activation, hypothermia, insulin, and glucagon.

**Glutamate Receptor Antibodies** Glutamate receptor antibodies (eg, anti-AMPA-GluR3, anti-NMDA-NR1, anti-NMDA-NR2A/B, anti-mGluR1, and anti-BluR5 antibodies) are associated with neurologic diseases (eg, epilepsy, encephalitis, neuropsychiatric systemic lupus erythematosus, schizophrenia), and some glutamate receptor antibodies, such as anti-NMDA-NR2A/B and GluR3B antibodies, activate glutamate receptors, resulting in excitotoxicity.<sup>152,160</sup> Perampanel is an antiepileptic that acts like talampanel.

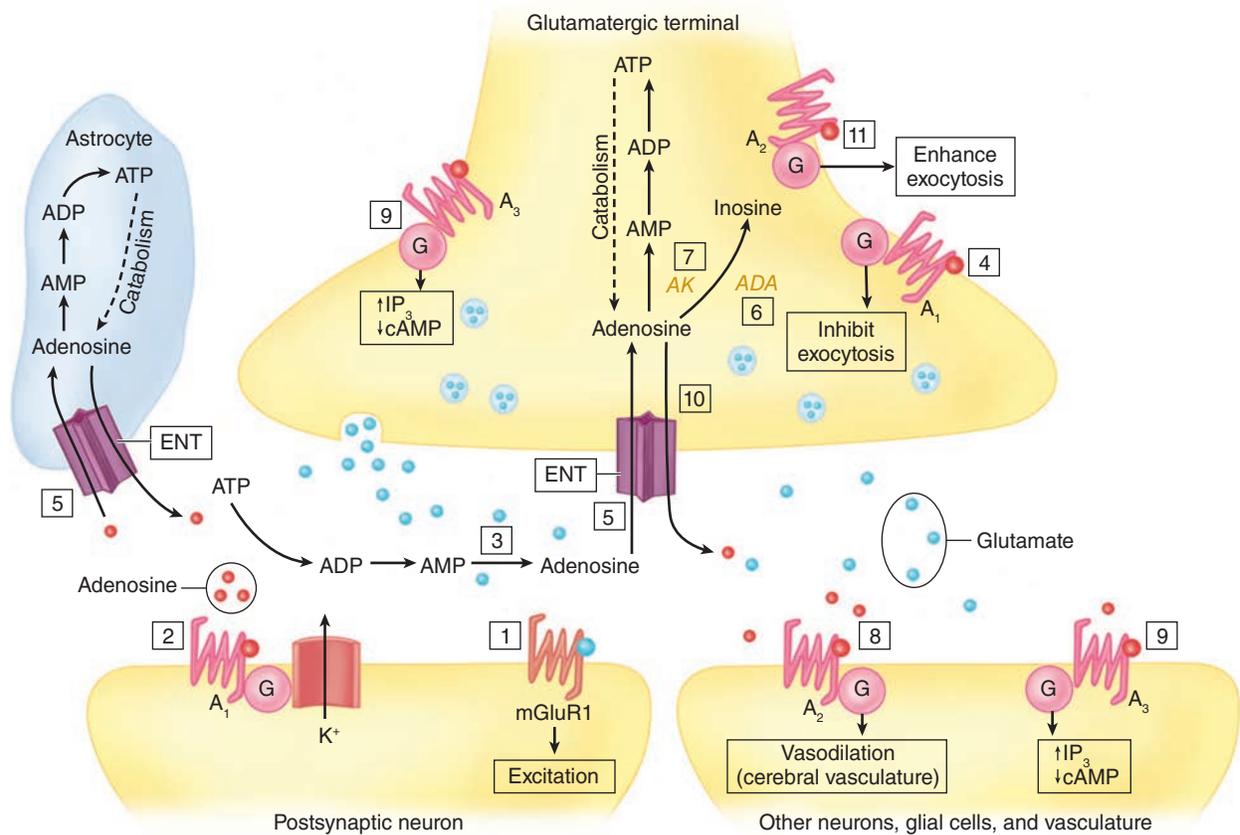

**ADENOSINE**

Adenosine is an important modulator of brain activity and body physiology. Adenosine receptors are distributed throughout the body, emphasizing its pivotal role in neurotransmission and metabolic activity. The overall action of adenosine is to decrease oxygen requirements and to

increase oxygen and substrate delivery.<sup>83</sup> In contrast to classical neurotransmitters that are secreted in discrete quanta upon stimulation of presynaptic neurons, adenosine is found in small concentrations in most extracellular fluids as a consequence of ATP metabolism. In fact, basal in vivo extracellular adenosine concentrations in the striatum are estimated to range from 40 to 460 nM (rat).<sup>16</sup> In the brain, adenosine primarily limits glutamate and ACh release, thereby preventing excessive postsynaptic neuronal stimulation.<sup>161,283</sup> Adenosine also counterbalances the effects of DA stimulation in the basal ganglia.<sup>161,283</sup>

**Synthesis, Release, and Reuptake**

Adenosine is commonly co-released with other neurotransmitters (eg, NE, ACh, glutamate) into the synapse before subsequent degradation by ectonucleotidases (Fig. 13–15). Intracellular adenosine concentrations increase rapidly during ischemia, hypoxia, or elevated metabolic activity (eg, seizures).<sup>83,161</sup> Synaptic adenosine then activates adenosine receptors on neuronal and non-neuronal tissue (eg, vasculature). The normal cellular preference is to convert adenosine back to ATP via adenosine kinase, but some adenosine also undergoes conversion to inosine by adenosine deaminase.<sup>161</sup> The actions of adenosine are terminated by reuptake into glial cells and neurons (Fig. 13–15).<sup>161,283</sup> Several members of a family of bidirectional equilibrative nucleoside transporters (ENTs) move adenosine down its concentration gradient.<sup>14,295</sup> Under normal conditions, transport is from the

**FIGURE 13–15.** The role of adenosine in regulating excitatory neurotransmission, using glutamate as an example. In this example, glutamate excites a postsynaptic neuron by activating metabotropic glutamate receptors (mGluR1) [1]. ATP enters the synapse when glutamate is released. Adenosine formed from metabolism of ATP within the synapse [3] binds to postsynaptic A<sub>1</sub> receptors [2], which open K<sup>+</sup> channels to inhibit the neuron through hyperpolarization. Adenosine also activates presynaptic A<sub>1</sub> receptors [4] to lower intracellular Ca<sup>2+</sup> concentrations, thereby impairing further glutamate release. Activation of presynaptic A<sub>2</sub> receptors has the opposite effect, enhancing glutamate exocytosis [11]. After uptake by ENT [5], adenosine is acted upon either by adenosine kinase (AK) [7] to form AMP, or by adenosine deaminase (ADA) [6] to form inosine. Adenosine also binds to neuronal postsynaptic A<sub>2</sub> receptors (especially in the striatum) and to vascular A<sub>2</sub> receptors to cause vasodilation [8]. A<sub>3</sub> receptors [9] are not activated by normal concentrations of adenosine. During times of excessive catabolism (eg, seizures, hypoglycemia, stroke) when intracellular adenosine concentrations rise markedly, adenosine moves into the synapse through reverse transport via ENT [5]. Resultant stimulation of A<sub>1</sub> and A<sub>2</sub> receptors results in inhibitory actions to decrease oxygen requirements and to increase substrate delivery through vasodilation as described above. However, the resultant stimulation of A<sub>3</sub> receptors [9] may contribute to neuronal damage and death. Not illustrated are cation-dependent adenosine transporters. Xenobiotics in Table 13–12 act to inhibit adenosine uptake [5]; to inhibit ADA [6]; to inhibit AK [7]; to increase adenosine release; and to antagonize A<sub>1</sub> [2,4] and A<sub>2</sub> [8,11] receptors. ADP = adenosine diphosphate; ATP = adenosine triphosphate; cAMP = cyclic adenosine monophosphate; ENT = equilibrative nucleoside transporter; G = G protein; IP<sub>3</sub> = inositol triphosphate.

**TABLE 13–12** Examples of Xenobiotics Affecting Adenosine Receptors

<b>Adenosine agonism</b>	Inhibit adenosine deaminase
Direct nonselective agonists	Acadesine
Adenosine	Dipyridamole
ADAC (adenosine amine congener)	Pentostatin
Inosine	Inhibit adenosine kinase
Direct selective A <sub>1</sub> agonists	Acadesine
Tecadenoson	Increase adenosine release
Direct selective A <sub>2</sub> agonists	Opioids
Regadenoson	Inhibit xanthine oxidase
Inhibit reuptake	Allopurinol
Acadesine	Increase A <sub>1</sub> receptor activity
Acetate <sup>a</sup>	Isoflurane
Benzodiazepines	Sevoflurane
Calcium channel blockers	<b>Adenosine antagonism</b>
Carbamazepine	A <sub>1</sub> blockade
Cyclic antidepressants	Caffeine
Dipyridamole	Carbamazepine
Ethanol <sup>a</sup>	Theophylline
Indomethacin	A <sub>2</sub> blockade
Papaverine	Caffeine
	Theophylline
	A <sub>2A</sub> blockade
	Istradefylline

<sup>a</sup>The inhibition of adenosine uptake by ethanol might, at least in part, be explained by metabolism to acetate.

synapse back into the neuron, but reverse transport occurs when intracellular adenosine concentrations become elevated (Fig. 13–15). Adenosine is also transported across cell membranes by a family of cation-dependent concentrative transporters that are responsible for transporting various nucleosides, nucleobases, and several drugs used in cancer chemotherapy and treatment of viral infections.<sup>304</sup> Exogenously administered adenosine used in the treatment of supraventricular tachycardia does not cross the blood–brain barrier and, therefore, is not centrally active. The half-life of adenosine in the blood is less than 10 seconds.

## Adenosine Receptors

The purine P1 receptor family comprises 4 adenosine receptor subtypes, all linked to G proteins: A<sub>1</sub>, A<sub>2A</sub>, A<sub>2B</sub>, and A<sub>3</sub>.

### A<sub>1</sub> Receptors

A single subtype of A<sub>1</sub> receptor is encoded by the gene *ADORA1* and inhibits adenylate cyclase.<sup>155</sup> These receptors reside mainly in the brain, but also in the heart, kidney, and lung.<sup>248</sup> Presynaptic A<sub>1</sub> stimulation modifies voltage-gated Ca<sup>2+</sup>-channels, decreasing Ca<sup>2+</sup> influx during depolarization, which limits exocytosis of neurotransmitter. Postsynaptic A<sub>1</sub> stimulation results in K<sup>+</sup> channel opening and K<sup>+</sup> efflux, with subsequent hyperpolarization of the neuron (Fig. 13–15). G protein mediated Cl<sup>-</sup> influx explains postsynaptic hyperpolarization by A<sub>1</sub> activation in some cases. Therefore, activation of presynaptic A<sub>1</sub> receptors prevents release of neurotransmitters, while activation of postsynaptic receptors inhibits neuronal response.<sup>161</sup>

In the central and autonomic nervous systems, A<sub>1</sub> receptors serve as inhibitory modulators for numerous neurotransmitter systems; they are particularly prevalent in association with glutamatergic neurons in the CNS.<sup>161</sup> This receptor is prevalent throughout the central nervous system, with high concentrations in the cerebral cortex, hippocampus, cerebellum, thalamus, brain stem, and spinal cord. Agonism of A<sub>1</sub> receptors by adenosine produces sedation, neuroprotection, anxiolysis, temperature reduction, antiepileptic activity, and spinal analgesia.<sup>84,283</sup>

Peripheral A<sub>1</sub> receptor activation produces bronchoconstriction, decreased glomerular filtration, decreased heart rate, slowed atrioventricular conduction, and decreased atrial myocardial contractility.<sup>84</sup>

A mutation in *ADORA1* is suggested to cause a form of hereditary early-onset Parkinson disease and dementia.<sup>113</sup> Also, single-nucleotide polymorphisms in this gene are associated with aspirin-intolerant asthma in a South Korean sample of patients.<sup>133</sup>

### A<sub>2</sub> Receptors

The 2 known types of A<sub>2</sub> receptors are encoded by *ADORA2A* and *ADORA2B*, and both stimulate adenylate cyclase.<sup>172</sup> In the CNS, A<sub>2A</sub> receptors are colocalized with and inhibit D<sub>2</sub> receptors in the basal ganglia.<sup>230,283</sup>

Adenosine (A<sub>2B</sub>) receptors are expressed diffusely throughout the brain, and are most commonly identified on glial cells. Adenosine (A<sub>2B</sub>) receptors have low affinity for adenosine, and little is known of their physiologic role.<sup>283</sup> Both types of A<sub>2</sub> receptors cause vasodilation of most vascular beds, including the coronary circulation.<sup>147</sup>

### A<sub>3</sub> Receptors

The A<sub>3</sub> receptor is encoded by *ADORA3* and inhibits adenylate cyclase.<sup>248</sup> It is expressed in many tissues, especially lung and liver,<sup>248</sup> but is also highly expressed in inflammatory cells where agonists are being investigated for treatment of conditions such as rheumatoid arthritis.<sup>80</sup>

## Adenosine and Seizure Termination

In humans and in animal models of status epilepticus, including those from xenobiotics, there are 2 alternating phases of electrical activity noted on electroencephalography. Periods of high-frequency spike activity (ictal) are accompanied by marked increases in cerebral oxygen consumption and metabolic requirements and alternate with interictal periods of isolated spike waves during which metabolic demands are less. The high-frequency phase lasts only a few minutes before suddenly terminating, sometimes with a few seconds of electrocerebral silence. A gradual increase in electrical activity during the interictal phase eventually leads to a recurrence of high-frequency spike activity.<sup>11</sup>

These periodic, spontaneous self-terminations of high-frequency electrical activity initially occur before neurons exhaust oxygen and energy supplies and result from adenosine released from depolarizing neurons and glial cells.<sup>11,69</sup> Adenosine acts on presynaptic receptors to prevent further release of excitatory neurotransmitters and acts on postsynaptic receptors to inhibit their actions.<sup>69,283</sup>

Any xenobiotic that directly or indirectly enhances the action of adenosine at A<sub>1</sub> receptors in the brain will usually exhibit antiepileptic activity. Conversely, A<sub>1</sub> receptor antagonists lower the seizure threshold and make seizure termination more difficult and less likely to respond to antiepileptics. Xenobiotics that antagonize A<sub>2A</sub> receptors produce cerebral vasoconstriction and may limit oxygen delivery during times of increased demand.<sup>11</sup>

## Xenobiotics

Table 13–12 provides examples of xenobiotics that affect adenosine receptors.

### Direct Adenosine Agonists

Tecadenoson is a selective A<sub>1</sub> receptor agonist that is being studied for treatment of supraventricular tachycardia.<sup>224</sup> Regadenoson is a selective A<sub>2A</sub> agonist used clinically as a coronary vasodilator for pharmacological stress testing.<sup>4</sup>

### Indirect Adenosine Agonists

Papaverine and dipyridamole inhibit adenosine reuptake.<sup>84,85</sup> Like other adenosine agonists, papaverine and dipyridamole demonstrate antiepileptic activity when injected into the CNS. Such actions are not achievable with safe systemic doses. Sevoflurane and isoflurane are 2 commonly used general anesthetic gases that activate adenosine receptors.<sup>84</sup>

In addition to their actions at GABA<sub>A</sub> receptors, benzodiazepines inhibit adenosine reuptake.<sup>159</sup> This might explain observations that methylxanthines, potent adenosine receptor antagonists, have reversed benzodiazepine-induced sedation in humans. The potencies of benzodiazepines as inhibitors of adenosine uptake show good correlation with clinical anxiolytic

and anticonflict potencies, suggesting that such inhibition contributes to their action. The antiepileptic effect of large doses of flumazenil also results, at least in part, from inhibition of adenosine uptake. Carbamazepine inhibits adenosine reuptake, although this is not thought to account for most antiepileptic action.

Evidence suggests adenosine mediates many of the acute and chronic motor effects of ethanol on the brain. Ethanol, possibly through its metabolite, acetate, prevents adenosine reuptake to raise synaptic adenosine concentrations.<sup>10</sup> Excessive stimulation of several adenosine receptors in the cerebellum could explain much of the motor impairment from low ethanol concentrations. In fact, animals made tolerant to ethanol develop cross-tolerance to adenosine agonists. In mice, adenosine receptor agonists increase ethanol-induced incoordination whereas adenosine antagonists decrease this intoxicating response.<sup>10</sup>

There are numerous inhibitors of adenosine reuptake, including propentofylline, nimodipine, and other calcium channel blockers and cyclic antidepressants.<sup>216,220</sup> Adenosine (A<sub>1</sub>) receptors located at the spinal cord are important modulators of pain transmission. Cyclic antidepressant-induced inhibition of adenosine uptake might explain some of their effectiveness in treating neuropathic pain.<sup>85</sup> The analgesic effectiveness of opioids is partially attributed to their ability to increase the release of adenosine within the spinal cord.<sup>21,85</sup>

Dipyridamole inhibits adenosine deaminase, raising adenosine concentrations. During times of elevated adenosine concentrations that occur with cardiac or cerebral ischemia, adenosine further enhances the beneficial actions of adenosine by 3 mechanisms: inhibition of adenosine kinase, inhibition of adenosine deaminase, and inhibition of adenosine reuptake.<sup>198</sup>

### Adenosine Antagonists

The main adenosine antagonists of toxicologic concern are methylxanthines. Theophylline and caffeine are selective P<sub>1</sub> antagonists, blocking both A<sub>1</sub> and A<sub>2</sub> receptors.<sup>11,21</sup> Human A<sub>3</sub> receptors demonstrate very low affinity for methylxanthines.<sup>84</sup>

Peripherally, methylxanthines cause excessive release of catecholamines from peripheral nerve endings (and probably the adrenal gland) by blocking presynaptic A<sub>1</sub> receptors. In turn, catecholamine-mediated responses are exaggerated by blockade of inhibitory postsynaptic A<sub>1</sub> receptors on end organs.<sup>84</sup>

Centrally, enhanced release and actions of excitatory neurotransmitters (eg, glutamate) explain methylxanthine-induced convulsions that are frequently refractory to antiepileptics. The reasons why theophylline convulsions carry such a high mortality stem from lack of A<sub>1</sub>-mediated self-termination (continual high-frequency spike activity and large metabolic demands), compounded by vasoconstriction caused by blockade of vascular A<sub>2</sub> receptors.

Like phenytoin, the major antiepileptic effect of carbamazepine results from Na<sup>+</sup>-channel blockade. Unlike phenytoin, carbamazepine antagonizes A<sub>1</sub> receptors.<sup>49,59</sup> This explains the higher frequency of seizures after carbamazepine overdose than after phenytoin overdose. The absence of A<sub>2</sub> blockade by carbamazepine theoretically allows for increases in cerebral blood flow to meet metabolic demands of the seizing brain.

Selective A<sub>2A</sub> receptor antagonists are being studied in the treatment of Parkinson Disease. Istradefylline is used as an adjunct to decrease OFF time in patients being treated with levodopa.<sup>230</sup>

### SUMMARY

- Neurotransmitter systems share common physiologic features, including neurotransmitter reuptake, vesicle membrane pumps, ion trapping of neurotransmitters within vesicles, calcium-dependent exocytosis, and receptors coupled to either G proteins or to ion channels.
- It is not surprising, then, that a single xenobiotic frequently produces effects on several different neurotransmitter systems. As the number of new xenobiotics encountered by man continues to grow, an understanding of their molecular actions in the nervous system helps to anticipate and better understand various pharmacologic and adverse effects resulting from therapeutic or toxic doses.

Glutamate receptor antibodies in neurological diseases: anti-AMPA-GluR3 antibodies, anti-NMDA-NR1 antibodies, anti-NMDA-NR2A/B antibodies, anti-mGluR1 antibodies or anti-mGluR5 antibodies are present in subpopulations of patients with either: epilepsy, encephalitis, cerebellar ataxia, systemic lupus erythematosus (SLE) and neuropsychiatric SLE, Sjogren's syndrome, schizophrenia, mania or stroke. These autoimmune anti-glutamate receptor antibodies can bind neurons in few brain regions, activate glutamate receptors, decrease glutamate receptor's expression, impair glutamate-induced signaling and function, activate blood brain barrier endothelial cells, kill neurons, damage the brain, induce behavioral/psychiatric/cognitive abnormalities and ataxia in animal models, and can be removed or silenced in some patients by immunotherapy. *J Neural Transm (Vienna)*. 2014;121:1029-1075.

# 14 WITHDRAWAL PRINCIPLES

Nicholas J. Connors and Richard J. Hamilton

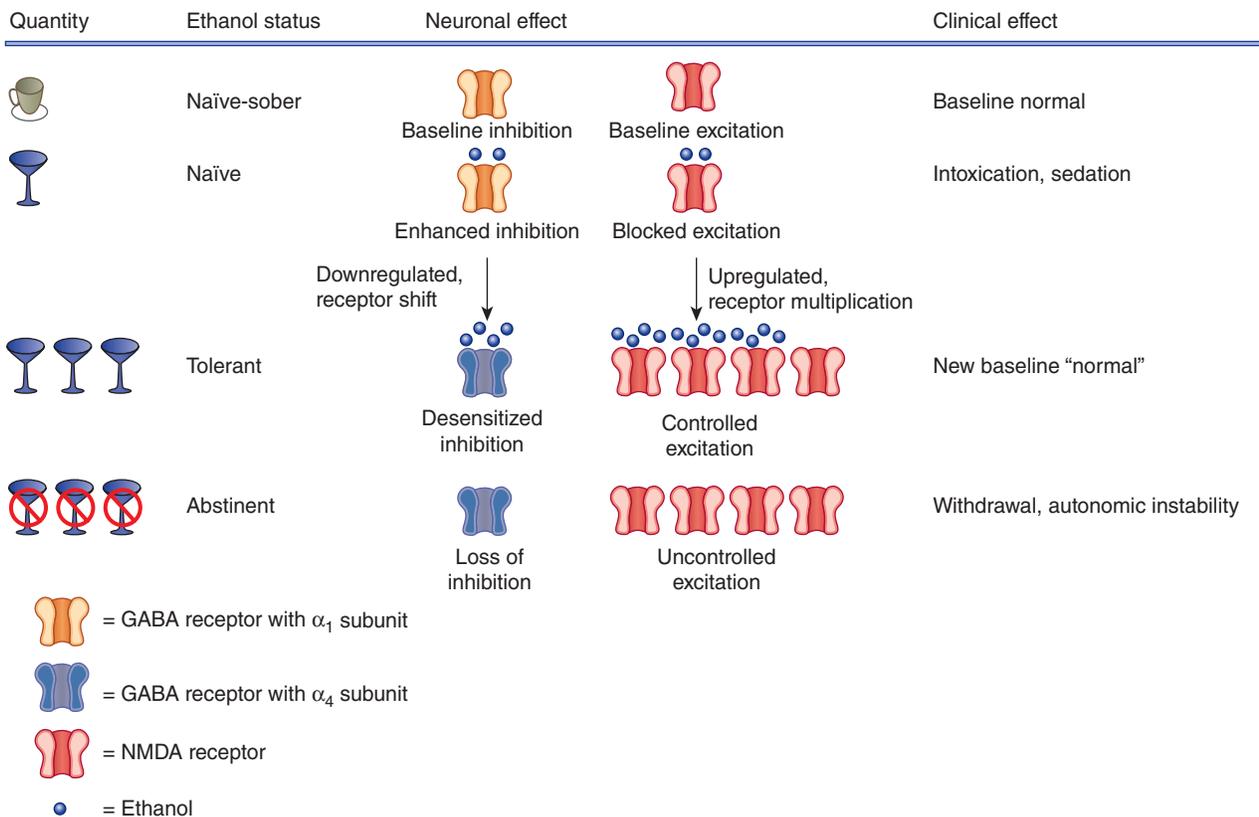

In the central nervous system (CNS), excitatory neurons fire regularly, and inhibitory neurons inhibit the transmission of these impulses. Whenever action is required, the inhibitory tone diminishes, permitting the excitatory nerve impulses to travel to their end organs. Thus, all action in human neurophysiology can be considered to result from disinhibition.

Tonic inhibition (sustained, as opposed to phasic or transient inhibition) triggered by the constant presence of a xenobiotic produces an adaptive change in the affected neuron such that the constant presence of that xenobiotic is required to prevent dysfunction. A withdrawal syndrome occurs when the constant presence of this xenobiotic is removed or reduced and the adaptive changes persist. Withdrawal is a dysfunctional condition in which tonic inhibitory neurotransmission is significantly reduced, essentially producing excitation (Fig. 14-1). Every withdrawal syndrome has 2 characteristics: (1) a preexisting compensatory physiologic adaptation to the continuous presence of a xenobiotic and (2) decreasing concentrations of that xenobiotic below some threshold necessary to prevent physiologic derangement. In contrast, simple tolerance to a xenobiotic is characterized by a shift in the dose-response curve to the right; that is, greater amounts of a xenobiotic are required to achieve a given effect. Physiologic dependence, commonly referred to as dependence, occurs when the absence of the xenobiotic leads to the development of a specific withdrawal syndrome. Dependence needs to be distinguished from addiction, which is compulsive drug-seeking

behavior. The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5), uses the term *substance use* to combine the DSM-IV disorders of substance abuse and substance dependence.<sup>1</sup>

Withdrawal is manifested by either of the following: (1) a characteristic withdrawal syndrome for the xenobiotic, or (2) the same (or a closely related) xenobiotic is taken to relieve withdrawal symptoms. Note that either criterion fulfills this definition. Logically, all syndromes meet the first criterion, so it is the presence of the second criterion that is critical to understanding physiology and therapy.

For the purposes of defining a unifying pathophysiologic pattern of withdrawal syndromes, this chapter considers syndromes in which both features are present. An analysis from this perspective distinguishes xenobiotics that affect the inhibitory neuronal pathways from those that affect the excitatory neuronal pathways, such as cocaine. According to this definition, cocaine does not produce a withdrawal syndrome but rather a posttoxicity syndrome that often results in lethargy, hypersomnolence, movement disorders, and irritability. Although referred to as withdrawal, this syndrome does not meet the definition for a withdrawal syndrome because the same (or a closely related) xenobiotic is not taken to relieve or avoid withdrawal symptoms. This posttoxicity syndrome, the so-called “crack crash” or “washed-out syndrome,” is caused by prolonged use of cocaine, and patients ultimately return to their premonitory function without intervention. This distinction is

**FIGURE 14-1.** Ethanol intoxication, tolerance, and withdrawal. Ethanol consumption in an ethanol-naïve person produces intoxication and sedation by simultaneous agonism at the  $\gamma$ -aminobutyric acid (GABA) receptor–chloride channel complex and antagonism at the N-methyl-D-aspartate (NMDA) receptor. Continuous ethanol consumption leads to the development of tolerance through changes in both the GABA receptor–chloride channel complex (a subunit shift from  $\alpha_1$  to  $\alpha_4$ , resulting in reduced sensitivity to the sedating effects of ethanol) and the NMDA subtype of glutamate receptor (upregulation in number, resulting in enhanced wakefulness). There is conceptually a concentration at which the tolerant patient may appear clinically normal despite having an elevated blood ethanol concentration. Tolerant patients who are abstinent lose the tonic effects of ethanol on these receptors, resulting in withdrawal.

important for toxicologists, because (1) withdrawal syndromes that demonstrate both features of the *DSM-5* criteria are treated with reinstatement and gradual withdrawal of a xenobiotic that has an effect on the receptor and (2) withdrawal syndromes that do not demonstrate the second feature require only supportive care and resolve spontaneously. The term “drug discontinuation syndrome” is used instead of withdrawal, for example, with serotonin reuptake inhibitors to describe the symptoms that result when a drug used therapeutically is discontinued, but this is in fact a withdrawal syndrome. Addiction and dependence are terms often used in the context of the psychosocial aspects of xenobiotic use and are meant to convey the continued use of a xenobiotic despite adverse consequences.

Finally, withdrawal syndromes are best described and treated according to the class of receptors primarily affected because this concept also organizes the approach to patient care. For each receptor and its agonists, research has identified genomic and nongenomic effects that produce neuroadaptation and withdrawal syndromes. Six mechanisms appear to be involved: (1) epigenetic mechanisms via micro-RNA (miRNA) and messenger RNA (mRNA) expression, DNA methylation, and histone modification; (2) second-messenger effects via protein kinases, cyclic adenosine monophosphate (cAMP),<sup>44,48</sup> or calcium ions; (3) receptor endocytosis; (4) expression of various receptor and neurotransmitter transporter subtypes depending on location within the synapse (synaptic localization); (5) intracellular signaling via effects on other receptors; and (6) neurosteroid modulation. Some or all of these mechanisms are demonstrated in each of the known withdrawal syndromes.<sup>52,53</sup> These mechanisms develop in a surprisingly rapid fashion and modify the receptor and its function in such complex ways as to depend on the continued presence of the xenobiotic to prevent dysfunction.<sup>50,59,72,80,81</sup>

## GABA<sub>A</sub> RECEPTORS (BARBITURATES, BENZODIAZEPINES, ETHANOL, VOLATILE SOLVENTS)

$\gamma$ -Aminobutyric acid type A (GABA<sub>A</sub>) receptors are part of a superfamily of ligand-gated ion channels, including nicotinic acetylcholine receptors and glycine receptors, which exist as pentamers arranged around a central ion channel. When activated, they hyperpolarize the postsynaptic neuron by facilitating an inward chloride current (without a G protein messenger), decreasing the likelihood of the neuron firing an action potential.  $\gamma$ -Aminobutyric acid type A (GABA<sub>A</sub>) receptors have separate binding sites for GABA, barbiturates, benzodiazepines, loreclezole, and picrotoxin (Chap. 13).<sup>65</sup> Barbiturates and benzodiazepines bind to separate receptor sites and enhance the affinity for GABA<sub>A</sub> at its receptor site.

The GABA receptor is a pentamer composed of 2  $\alpha$  subunits, 2  $\beta$  subunits, and 1 additional subunit, most commonly  $\gamma$ , which is a key element in the benzodiazepine-binding site. Each receptor has 2 GABA-binding sites that are located in a homologous position to the benzodiazepine site between the  $\alpha$  and  $\beta$  subunits. Although the mechanism is unclear, benzodiazepines have no direct functional effect without the presence of GABA. Conversely, certain barbiturates in a dose-dependent manner and propofol can directly increase the duration of channel opening, thereby producing a net increase in current flow without GABA binding. This process has therapeutic implications and explains why high-dose barbiturates are nearly universally successful in stopping status epilepticus and treating severe withdrawal.

This prototypical pentameric GABA<sub>A</sub> receptor assembly is derived from permutations and combinations of 2, 3, 4, or even 5 different protein subunits. The subtypes of GABA receptors can even vary on the same cell. In fact, GABA receptors are heterogeneous receptors with different subunits and distinct regional distribution. Although the preponderance of subtypes  $\alpha_1\beta_2\gamma_2$ ,  $\alpha_2\beta_3\gamma_2$ , and  $\alpha_3\beta_3\gamma_2$  accounts for 75% of GABA receptors, there are at least 16 other significant subtypes.<sup>81</sup> The recognition of additional subunits of GABA<sub>A</sub> receptors facilitated the development of targeted pharmaceuticals, such as zolpidem.<sup>10</sup>

Previously, ethanol was thought to have GABA receptor activity, although a clearly identified binding site was not evident. Traditional explanations for this effect included (1) enhanced membrane fluidity and allosteric potentiation (so-called cross-coupling) of the 5 proteins that construct the GABA<sub>A</sub>

receptor; (2) interaction with a portion of the receptor; and/or (3) enhanced GABA release. Research with chimeric reconstruction of GABA<sub>A</sub> and *N*-methyl-D-aspartate (NMDA) channels demonstrates highly specific binding sites for high doses of ethanol that enhance GABA<sub>A</sub> and inhibit NMDA receptor-mediated glutamate neurotransmission. However, research has not clarified whether ethanol at low concentrations is a direct agonist of GABA<sub>A</sub> receptors or a potentiator of GABA<sub>A</sub> receptor binding.<sup>66</sup>

There are 6 mechanisms of adaptation to chronic ethanol exposure making it the prototypical xenobiotic for the study of neuroadaptation and withdrawal.<sup>25,52,58</sup> These 6 mechanisms appear to apply to benzodiazepines as well.<sup>66</sup> The 6 mechanisms are (1) altered GABA<sub>A</sub> receptor gene expression via alterations in miRNA, mRNA, and protein concentrations of GABA<sub>A</sub> receptor subunits in numerous regions of the brain (genomic mechanisms); (2) post-translational modification through phosphorylation of receptor subunits with protein kinase C (second-messenger effects); (3) subcellular localization by an increased internalization of GABA<sub>A</sub> receptor  $\alpha_1$ -subunit receptors (receptor endocytosis); (4) modification of GABA and NMDA receptor subtypes with differing affinities for agonists to the synaptic or nonsynaptic sites (synaptic localization) reducing the sensitivity of the receptor; (5) regulation via intracellular signaling by the NMDA, acetylcholine, serotonin, and  $\beta$ -adrenergic receptors; and (6) neurosteroid modulation of GABA receptor sensitivity and expression.<sup>20,21,44,54</sup> Furthermore, changes in GABA<sub>A</sub> subunit composition and function are evident within one hour of administration of a single exposure to ethanol in animals.<sup>57</sup>

Intracellular signaling via the NMDA subtype of the glutamate receptor appears to explain the “kindling” hypothesis, in which successive withdrawal events become progressively more severe.<sup>17,58</sup> The activity of excitatory neurotransmission increases the more it fires, a phenomenon known as *long-term potentiation*, and is the result of increased activity of mRNA and receptor protein expression, a genomic effect of intracellular signaling.<sup>77</sup> As NMDA and other glutamatergic receptors (kainite and  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid {AMPA}) increase in number and function (upregulation) and GABA<sub>A</sub> receptor activity diminishes, withdrawal becomes more severe.<sup>42,58,75</sup> The dizocilpine (MK-801)-binding site of the NMDA receptor appears to be the major contributor, and this effect is recognized in neurons that express both NMDA and GABA<sub>A</sub> receptors.<sup>5</sup> When the concentration of ethanol or any xenobiotic with GABA agonist activity is diminished, inhibitory control of excitatory neurotransmission, such as that mediated by the now upregulated NMDA receptors, is lost.<sup>59</sup> Additionally, increased presynaptic glutamate release is noted in withdrawal.<sup>27</sup> These effects result in the clinical syndrome of withdrawal: CNS excitation (tremor, hallucinations, seizures) and autonomic stimulation (tachycardia, hypertension, hyperthermia, diaphoresis) (Chap. 77).<sup>72</sup>

Volatile solvents, such as gasoline, diethyl ether, and toluene, are widely abused xenobiotics whose effects also appear to be mediated by the GABA receptor (Chap. 81).<sup>70,74</sup> These solvents produce CNS inhibition and anesthesia at escalating doses via the GABA<sub>A</sub> receptor in a fashion similar to that of ethanol.<sup>16,47,83</sup>

In addition to GABA receptor/neurotransmitter effects, other neurotransmitters are important in the development of ethanol tolerance and withdrawal. These include an NMDA receptor subunit and anchoring protein, the dynorphin/kappa opioid receptor, the 5-HT<sub>2C</sub> serotonergic receptors, serum nerve growth protein, and brain voltage-gated calcium channels.<sup>34,60</sup> Ethanol use is also associated with increased expression of nociceptin and increased activity in the dynorphin/kappa opioid receptor system causing an altered affective condition.<sup>22,31</sup> Symptoms of ethanol withdrawal correlate with increased synthesis of mRNA for the nociceptin/orphanin FQ (N/OFQ)-opioid peptide receptor, which are involved in CNS stress-regulatory systems.<sup>11</sup> Once withdrawal has started, increases are noted in serum nerve growth protein, which is theorized to counteract excitatory states, and decreases in methylation of the gene coding for its transcription.<sup>43</sup> Finally, electrical current through brain voltage-gated calcium channels is increased in those chronically exposed to ethanol, and increased Ca<sup>2+</sup> conduction may play a role in ethanol withdrawal seizures.<sup>62</sup>

## GABA<sub>B</sub> RECEPTORS (GHB AND BACLOFEN)

GABA<sub>B</sub> agonists such as  $\gamma$ -hydroxybutyric (GHB) acid,  $\gamma$ -hydroxybutyrate (GHB) precursors and analogs, and baclofen have similar clinical characteristics with regard to adaptation and withdrawal.<sup>84</sup> The GABA<sub>B</sub> receptor is a heterodimer of the GABA<sub>B1</sub> and GABA<sub>B2</sub> receptors. Unlike GABA<sub>A</sub>, the GABA<sub>B</sub> receptor couples to various effector systems through a signal-transducing G protein.<sup>24,84</sup> GABA<sub>B</sub> receptors mediate presynaptic inhibition (by preventing Ca<sup>2+</sup> influx) and postsynaptic inhibition (by increasing K<sup>+</sup> efflux). The postsynaptic receptors appear to have an inhibitory effect similar to that of the GABA<sub>A</sub> receptors, though the mechanism differs. The presynaptic receptors provide feedback inhibition of GABA release.

$\gamma$ -Hydroxybutyric acid is a naturally occurring inhibitory neurotransmitter with its own distinct receptor (Chap. 80).<sup>7</sup> Physiologic concentrations of GHB activate at least 2 subtypes of a distinct GHB receptor (antagonist-sensitive and antagonist-insensitive). However, at supraphysiologic concentrations, such as those that occur after overdose and abuse, GHB binds directly to the GABA<sub>B</sub> receptor and is metabolized to GABA (which then activates the GABA<sub>B</sub> receptor). The GHB withdrawal syndrome clinically resembles the withdrawal syndrome from ethanol and benzodiazepines and can be severe. In most cases, distinctive clinical features of GHB withdrawal are relatively mild with brief autonomic instability and the persistence of psychotic symptoms.<sup>79</sup>

Baclofen is also a GABA<sub>B</sub> agonist. The presynaptic and postsynaptic inhibitory properties of baclofen allow it, paradoxically, to cause seizures associated with both acute overdose because of decreased release of presynaptic GABA via autoreceptor stimulation and withdrawal. Withdrawal is probably a result of the loss of the chronic inhibitory effect of baclofen on postsynaptic GABA<sub>B</sub> receptors. Discontinuation of baclofen produces hyperactivity of neuronal Ca<sup>2+</sup> channels (N, P/Q type),<sup>32</sup> leading to seizures, hypertension, hallucinations, psychosis, and coma. However, many of these manifestations do not differ clinically from the withdrawal symptoms of GABA<sub>A</sub> agonists.

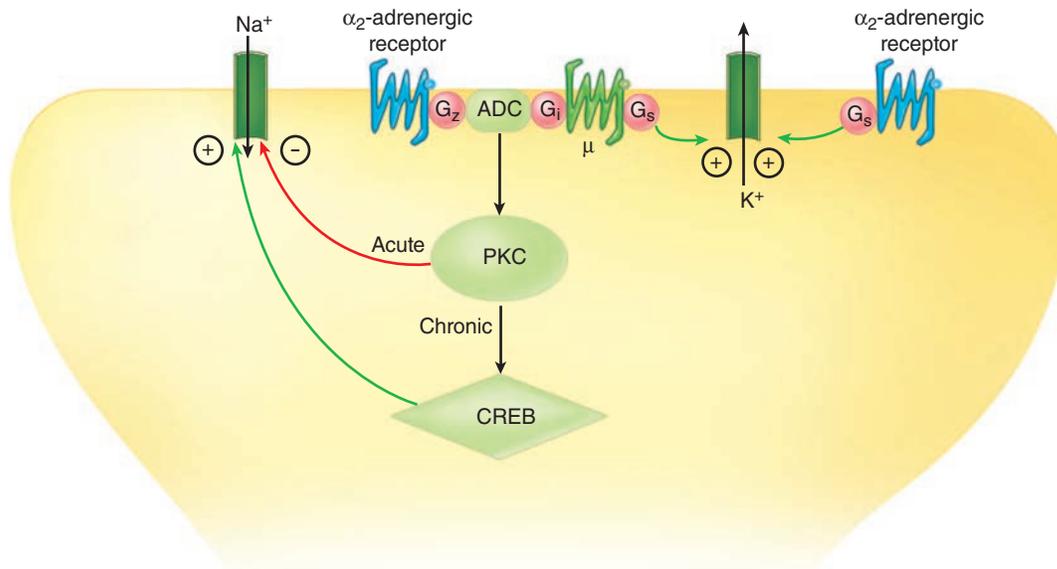

Typically, the development of a baclofen withdrawal occurs 24 to 48 hours after discontinuation or a reduction in the dose of baclofen. Case reports highlight the development of seizures, hallucinations, psychosis, dyskinesias, and visual disturbances. Additionally, the intrathecal baclofen pump is an effective replacement for oral dosing, but severe withdrawal can occur when the pump malfunctions or becomes disconnected.<sup>12</sup> Reinstatement of the prior baclofen-dosing schedule appears to resolve these symptoms within 24 to 48 hours. Benzodiazepines and GABA<sub>A</sub> agonists are the appropriate treatment for seizures induced by baclofen withdrawal.<sup>73</sup>

## OPIOID RECEPTORS (OPIOIDS)

Similar to the behavior of ethanol and GABA<sub>A</sub> receptors, opioid binding to the opioid receptors results in a series of genomic and nongenomic neuroadaptations, especially via second-messenger effects. When opioids bind to opioid receptors, they alleviate pain by activating G<sub>s</sub> proteins and stimulating K<sup>+</sup> efflux currents hyperpolarizing the cell and inhibiting these neurons. Opioid receptors are also linked to the G<sub>i/o</sub> proteins that dissociate into the G $\alpha$  and G $\beta\gamma$  subunits and go on to other intracellular effects such as inhibition of adenylate cyclase through the G $\alpha$  subunit and inactivation of the inward Ca<sup>2+</sup> current via the  $\beta\gamma$  subunit, thus suppressing the intrinsic excitability of a neuron by limiting its ability to depolarize (Chap. 36).<sup>14,30,78</sup> This inhibition permits the downstream disinhibition of dopaminergic neurons.<sup>19</sup> After chronic stimulation of opioid receptors, there is uncoupling of the receptor to the G<sub>i/o</sub> proteins, and coupling to the G<sub>z</sub> protein that upregulates the adenylate cyclase/cAMP pathway and results in multiple effects such as hyperalgesia.<sup>69,78</sup>

Chronic use of all xenobiotics with opioid-receptor affinity results in a decreased efficacy of the receptor to open potassium channels by genomic mechanisms and second-messenger effects. Following chronic opioid use, the expression of adenylate cyclase increases through activation of the transcription factor known as cAMP response element-binding protein (CREB) (Fig. 14-2).<sup>41,63</sup> This results in upregulation of cAMP-mediated responses like the inward Na<sup>+</sup> channels responsible for intrinsic excitability.

The net effect is that only higher concentrations of opioids result in analgesia and other opioid effects. In the dependent patient, when opioid concentrations drop, inward Na<sup>+</sup> flux occurs unchecked, and the patient experiences the opioid withdrawal syndrome. The clinical findings associated with this syndrome are largely a result of uninhibited activity at the locus ceruleus, mediated by orexin agonism at orexin receptors, thus decreasing the inhibitory activity of GABAergic neurons.<sup>3,35,50,63</sup> Chronic opioid use results in decreased expression of the excitatory amino acid transporter 3 (EAAT3), which prevents glutamate reuptake from the synapse and causes postsynaptic neuroexcitation.<sup>39</sup> Further, in the nucleus accumbens, opioid withdrawal causes activation of the NMDA receptor, increasing receptor phosphorylation and is associated with increased cell surface expression of excitatory NMDA receptors.<sup>6</sup> Additionally, there seems to be a role for peroxisome proliferator-activated receptor gamma (PPAR- $\gamma$ ) in the development of tolerance as PPAR- $\gamma$  agonists decrease opioid tolerance and attenuate withdrawal through inhibition of cellular antiinflammatory effects.<sup>26,38</sup> Tolerance to

**FIGURE 14-2.** Immediate and long-term effects of opioids. The immediate effects of both opioids and  $\alpha_2$ -adrenergic agonists are to increase inhibition through enhanced potassium efflux and inhibited sodium influx. Long-term effects alter gene expression to enhance sodium influx and restore homeostasis. CREB = cAMP response element-binding protein; ADC = adenylate cyclase; PKC = protein kinase C. (■) =  $\alpha_2$ -adrenergic receptor; (■) =  $\mu$  opioid receptor.

opioids is also mediated through histone acetylation by 2 enzymes, histone acetyltransferase (associated with the development of tolerance) and histone deacetylase (mediates the resolution of tolerance back to normal homeostasis).<sup>56</sup> Opioid tolerance and naloxone-precipitated withdrawal can be demonstrated in humans naïve to opioids after just 1 or 2 doses of morphine 15 mg/70 kg.<sup>13</sup>

Functional MRI data in humans with precipitated opioid withdrawal show increased neuronal activity in the caudate, pregenual cingulate, orbitofrontal gyrus, middle orbital gyrus, and putamen, areas associated with reward processing. There is decreased activity in networks involved in sensorimotor integration including bilateral precentral and postcentral gyri.<sup>28</sup> After precipitated opioid withdrawal, histone acetylation and increased expression of genes associated with neuronal plasticity are noted.<sup>29</sup>

In addition, opioid receptors and central  $\alpha_2$ -adrenergic receptors both exert an analogous effect on the potassium channel in the locus ceruleus. Clonidine binds to the central  $\alpha_2$ -adrenergic receptor and stimulates potassium efflux, as do opioids, and produces similar clinical findings, which explains why clonidine has efficacy in treating certain aspects of the opioid withdrawal syndrome (cross tolerance). In addition, the antagonistic effect of naloxone at the opioid receptor seems to partially reverse the effect of clonidine on this shared potassium efflux channel.

Rapid and ultrarapid opioid detoxification are forms of intentional iatrogenic withdrawal that use opioid antagonists to accelerate a return to pre-morbid receptor physiology. In theory, although not necessarily in practice, inducing opioid withdrawal under general anesthesia with high-dose opioid antagonists permits the transition from drug dependency to naltrexone maintenance without enduring an intense withdrawal syndrome (Chap. 36).<sup>36,40,49</sup>

### $\alpha_2$ -ADRENERGIC RECEPTORS (CLONIDINE)

In a manner related to their role in treating opioid withdrawal, prolonged exposure to clonidine and related medications is associated with a withdrawal syndrome.  $\alpha_2$ -Adrenergic receptors are located in the central and peripheral nervous systems. Clonidine is a central and peripheral  $\alpha_2$ -adrenergic agonist. Stimulation of central presynaptic  $\alpha_2$ -adrenergic receptors inhibits sympathomimetic output and results in bradycardia and hypotension. Within 24 hours after the discontinuation of chronic clonidine use, norepinephrine concentrations rise as a result of enhanced efferent sympathetic activity. This increase results in hypertension, tachycardia, anxiety, diaphoresis, and hallucinations.

Dexmedetomidine is widely used as a sedative in the intensive care unit. Like clonidine it is a central and peripheral presynaptic  $\alpha_2$ -adrenergic agonist, but dexmedetomidine has greater specificity for the  $\alpha_2$ -adrenergic receptor and hence stronger sedative properties. It cannot be given in bolus doses because it causes hypertension by stimulating peripheral  $\alpha_2$  receptors on vascular smooth muscle (much like the initial phase of a clonidine overdose) (Chap. 61).<sup>51</sup> Dexmedetomidine is occasionally used as an adjunct to treat ethanol, benzodiazepine, and opioid withdrawal and is reported to cause less respiratory depression than benzodiazepines but more bradycardia.<sup>68</sup> Importantly, dexmedetomidine has a withdrawal syndrome exactly like that of clonidine, including hypertension, tachycardia, and agitation. In fact, clonidine is reportedly used to treat this withdrawal successfully.<sup>71,82</sup>

### ADENOSINE (A) RECEPTORS (CAFFEINE)

The release of most neurotransmitters is accompanied by the passive release of adenosine as a by-product of adenosine triphosphate (ATP) breakdown. The released adenosine binds to postsynaptic  $A_1$  receptors where it typically has inhibitory effects on the postsynaptic neuron. It also binds to presynaptic  $A_1$  autoreceptors to limit further release of neurotransmitters.  $A_2$  receptors are found on the cerebral vasculature and peripheral vasculature where stimulation promotes vasodilation. Caffeine and other methylxanthines, such as theophylline, antagonize the inhibitory effect of adenosine, primarily on postsynaptic  $A_1$  receptors. As a result, acute use results in increases in heart rate, ventilation, gastrointestinal motility, gastric acid secretion, and motor activity. Chronic caffeine use results in tolerance and the above symptoms diminish. Caffeine use upregulates  $A_1$  receptors by a variety of

mechanisms, including increases in receptor number, increases in receptor affinity, enhancement of receptor coupling to the G protein, and increases in G protein-stimulated adenylyl cyclase. An animal study demonstrates that the adenosine receptor has a 3-fold increase in affinity for adenosine at the height of withdrawal symptoms. This model suggests that long-term caffeine administration results in an increase in receptor affinity for adenosine, thus restoring a state of physiologic balance (normal motor inhibitory tone). When caffeine concentrations are reduced below the concentration necessary to maintain this physiologic balance, the enhanced receptor affinity results in a strong adenosine effect and clinical symptoms of withdrawal: headache (cerebral vasodilation), fatigue, and hypersomnia (motor inhibition).

### ACETYLCHOLINE RECEPTORS (NICOTINE)

The neuronal nicotinic acetylcholine receptors are pentamers made up of  $\alpha$  and  $\beta$  subunits located in the autonomic ganglia, adrenal medulla, CNS, spinal cord, neuromuscular junction, and carotid and aortic bodies. Nicotinic receptors are upregulated in the brain in the setting of chronic nicotine exposure.<sup>61</sup> Nicotinic receptors are fast-response calcium channels that are not coupled to G proteins, distinguishing them from muscarinic receptors, but rather open voltage-gated calcium channels and thereby increasing intracellular calcium concentrations. Activation of calcium/calmodulin-dependent protein kinase II (CaMKII) causes downstream effects, partly through activation of GTPase proteins, and cause the release of GABA, glutamate, and dopamine. CaMKII is upregulated in chronically exposed neurons and synthesis decreases significantly in withdrawal.<sup>45</sup> GTPase activity is mediated by the upregulation of prenyltransferase enzyme systems in chronic nicotine exposure.<sup>76</sup> Nicotinic acetylcholine receptors have both excitatory and inhibitory effects. In the habenulo-interpeduncular pathway, specific nicotinic receptor subtypes ( $\alpha 5$  and  $\beta 4$ ) are concentrated and are associated with aversive effects of nicotine withdrawal. Of note, animal knockouts for  $\alpha 2$ ,  $\alpha 5$ , and  $\beta 4$  display no somatic signs of withdrawal.<sup>8,33</sup> Physical signs of withdrawal in animals are also reduced by blocking  $\alpha 3\beta 4$  receptor subunits.<sup>46</sup> Additionally, severe withdrawal occurs in people with variants of the gene encoding for the  $\alpha 4$  subunit, making it significantly more sensitive to acetylcholine. Varenicline, a treatment for nicotine abuse, is a partial agonist at  $\alpha 4\beta 2$  nicotinic receptors.<sup>55</sup> As in other withdrawal syndromes, changes brought on by chronic use of nicotinic agonists, such as nicotine in cigarettes, appear to be related to selective upregulation of cAMP.<sup>18,80</sup> Decreased concentrations of synaptic glutamate are associated with the nicotine withdrawal syndrome.<sup>23</sup> Additionally, withdrawal is potentiated by increased concentrations of corticotropin-releasing factor and expression of mRNA for the receptor CRFIR.<sup>15</sup>

### CANNABINOID RECEPTORS

Chronic use of cannabinoid receptor agonists causes dependence, and abrupt cessation results in a drug discontinuation syndrome (not withdrawal) that includes anxiety, irritability, abdominal pain, and insomnia.  $\Delta^9$ -Tetrahydrocannabinol is an agonist at 2 G-protein coupled receptors,  $CB_1$  and  $CB_2$ .<sup>37</sup> Agonism of the  $CB_1$  receptor results in its downregulation whereas discontinuation of cannabinoids results in increased gene expression.<sup>9</sup>

### SEROTONIN REUPTAKE INHIBITOR DISCONTINUATION SYNDROME

As mentioned above, *drug discontinuation syndrome* is a term used to describe the withdrawal syndrome associated with the therapeutic use of serotonin reuptake inhibitors. It meets the definition of withdrawal syndromes in that symptoms begin when xenobiotic concentrations diminish, and the syndrome abates when the xenobiotic is reintroduced.<sup>64</sup> Headache, nausea, fatigue, dizziness, and dysphoria are commonly described symptoms, with tremor, increased reflexes and muscle tone, tachypnea, and irritability noted in newborns.<sup>2</sup> The condition appears to be uncomfortable but not life threatening, rapidly resolves with reinstatement of a xenobiotic of the same class, and slowly resolves when the medication is discontinued after a more gradual taper (Chap. 69).<sup>67</sup>

## SUMMARY

- Withdrawal occurs when a xenobiotic that has produced neuronal adaptive changes is removed.
- The treatment of a withdrawal or a discontinuation syndrome generally involves reintroduction of the xenobiotic from which the patient is withdrawing.
- In some situations, cross-tolerant xenobiotics (those with activity at the same receptor) are administered to treat withdrawal. Examples include the use of benzodiazepines and barbiturates to treat ethanol withdrawal or clonidine for opioid withdrawal.

## SECTION II PATHOPHYSIOLOGIC BASIS: ORGAN SYSTEMS

### CASE STUDY 3

**History** A 54-year-old man presented to the emergency department (ED) complaining that he was weak, dizzy, and felt as if he was about to pass out. His past medical history was significant for opioid dependence. Three hours earlier he saw an alternative medical provider and was given a natural remedy to help him “detoxify.” Prior to this therapy, he was receiving daily methadone, but transitioned to hydrocodone in preparation for treatment. He denied nausea, vomiting, diarrhea, lacrimation, or other symptoms consistent with opioid withdrawal. In triage, his pulse was 35 beats/min, so the patient was immediately triaged to the critical care area.

**Physical Examination** On arrival to the critical care area he was awake but complaining of weakness. Vital signs were: blood pressure, 128/62 mm Hg; pulse, 35 beats/min; respiratory rate, 14 breaths/min; rectal temperature, 98.4°F (36.9°C); oxygen saturation, 98% on room air; and glucose, 110 mg/dL. A general physical examination was unremarkable and specifically noted the absence of mydriasis, piloerection, rhinorrhea, or lacrimation.

**Initial Management** The patient was immediately attached to continuous cardiac monitoring and an electrocardiogram (ECG) was obtained (Fig. CS3-1), which

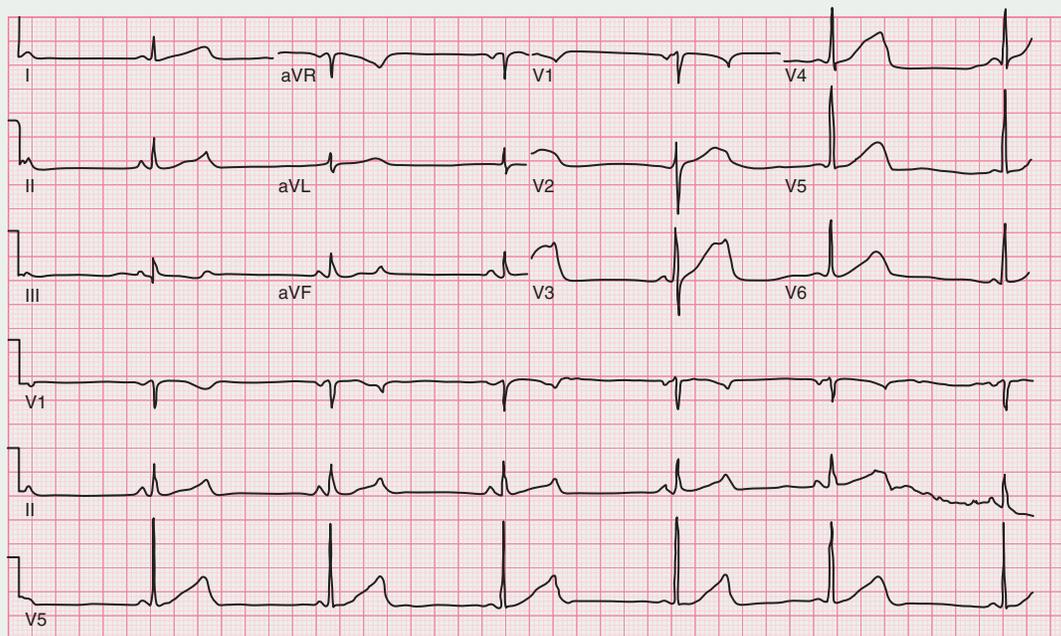

was notable for sinus bradycardia with a QT interval of approximately 600 ms and an abnormally shaped T wave. An intravenous catheter (IV) was inserted and blood was sent for a complete blood count and electrolytes.

Suddenly, the patient lost consciousness and became pulseless. A rhythm strip captured the event (Fig. CS3-2), which was torsade de pointes (TdP) (Chap. 15). The event self-terminated, and the patient awoke, but syncope recurred 5 minutes later. Although he spontaneously recovered again, at this time he was administered 2 g of magnesium sulfate intravenously over several minutes followed by a continuous magnesium infusion at 1 g/h. His cardiac rhythm was converted to a normal sinus rhythm, and he was transferred to the cardiac intensive care unit (CCU), where a temporary transvenous pacemaker was inserted.

**What Is the Differential Diagnosis?** In addition to congenital and acquired intrinsic cardiac conditions and electrolyte abnormalities (Chap. 12), numerous xenobiotics from diverse chemical classes are associated with QT interval prolongation and the risk of TdP. These xenobiotics, which typically share an ability to block myocardial potassium channels (Chap. 15), can be found throughout this textbook. Common classes of xenobiotics that are associated with QT interval prolongation, and some

specific examples, are listed in Table CS3-1. Readers are referred to [www.crediblemeds.com](http://www.crediblemeds.com), a comprehensive website that risk stratifies a myriad of pharmaceuticals. It is noteworthy that many nonpharmaceutical xenobiotics also are listed in the table and textbook.

**What Rapid Clinical and Laboratory Analyses Can Help Determine the Etiology and Guide Therapy for This Patient’s Presentation?** Because the differential diagnosis is so extensive, broad laboratory testing is not advocated to determine the etiology in patients with unclear causes for QT interval prolongation. Instead, efforts should be directed at a thorough history, because the cause may then become evident. Patients should have routine electrolytes measured, because hypokalemia, hypocalcemia, and hypomagnesemia can all either be the primary cause of QT interval prolongation or be contributory when another primary etiology exists. Because these electrolyte abnormalities can be rapidly corrected in most circumstances, they represent easy and important interventions. When acute overdose is suspected, gastrointestinal decontamination can help limit drug absorption or enhance elimination (Chap. 5 and Antidotes in Depth: A1, A2).

**FIGURE CS3-1.** Initial electrocardiogram demonstrating sinus bradycardia at a heart rate of 35 beats/min with a normal axis, normal PR interval of 120 ms, a normal QRS duration of 80 ms, and prolonged QT interval at nearly 600 ms with an abnormal T-wave morphology. (Used with permission from *The Fellowship in Medical Toxicology*, New York University School of Medicine, New York City Poison Center.)

## CASE STUDY 3 (CONTINUED)

**FIGURE CS3-2.** Electrocardiograph associated with loss of consciousness demonstrating the transition from bradycardia to ventricular ectopy followed by an episode of torsade de pointes. (Used with permission from *The Fellowship in Medical Toxicology*, New York University School of Medicine, New York City Poison Center.)

**TABLE CS3-1** Xenobiotics Associated With QT Interval Prolongation and Torsade de Pointes

Class	Specific Examples
β-Adrenergic antagonists	Sotalol
Antibiotics	Macrolides and fluoroquinolones
Antidysrhythmics	(Class IA, IC, and III)
Antiepileptics	Carbamazepine
Antimalarials	Chloroquine, mefloquine, halofantrine
Antipsychotics	Phenothiazines
Caustics	Hydrofluoric acid
Cyclic antidepressants	Most
Drugs of abuse	Cocaine
Herbals	Ibogaine
Metals	Arsenic, barium, cesium
Opioids	Methadone
Pesticides	Organic phosphorus compounds
Serotonin reuptake inhibitors	Citalopram

#### Further Diagnosis and Treatment

Laboratory evaluation demonstrated normal concentrations of magnesium whereas his calcium and potassium were low. The patient stated that he had received ibogaine therapy to treat his opioid dependence, which is associated with both bradycardia and QT interval prolongation. While in the CCU, he had several episodes of ventricular ectopy but no recurrent TdP. His hypokalemia was corrected with supplemental potassium chloride, stress echocardiogram showed no signs of structural heart disease. Several days later he was discharged with a normal heart rate and a minimally prolonged mild QT interval 470 ms.

# CARDIOLOGIC PRINCIPLES I: ELECTROPHYSIOLOGIC AND ELECTROCARDIOGRAPHIC PRINCIPLES

Cathleen Clancy

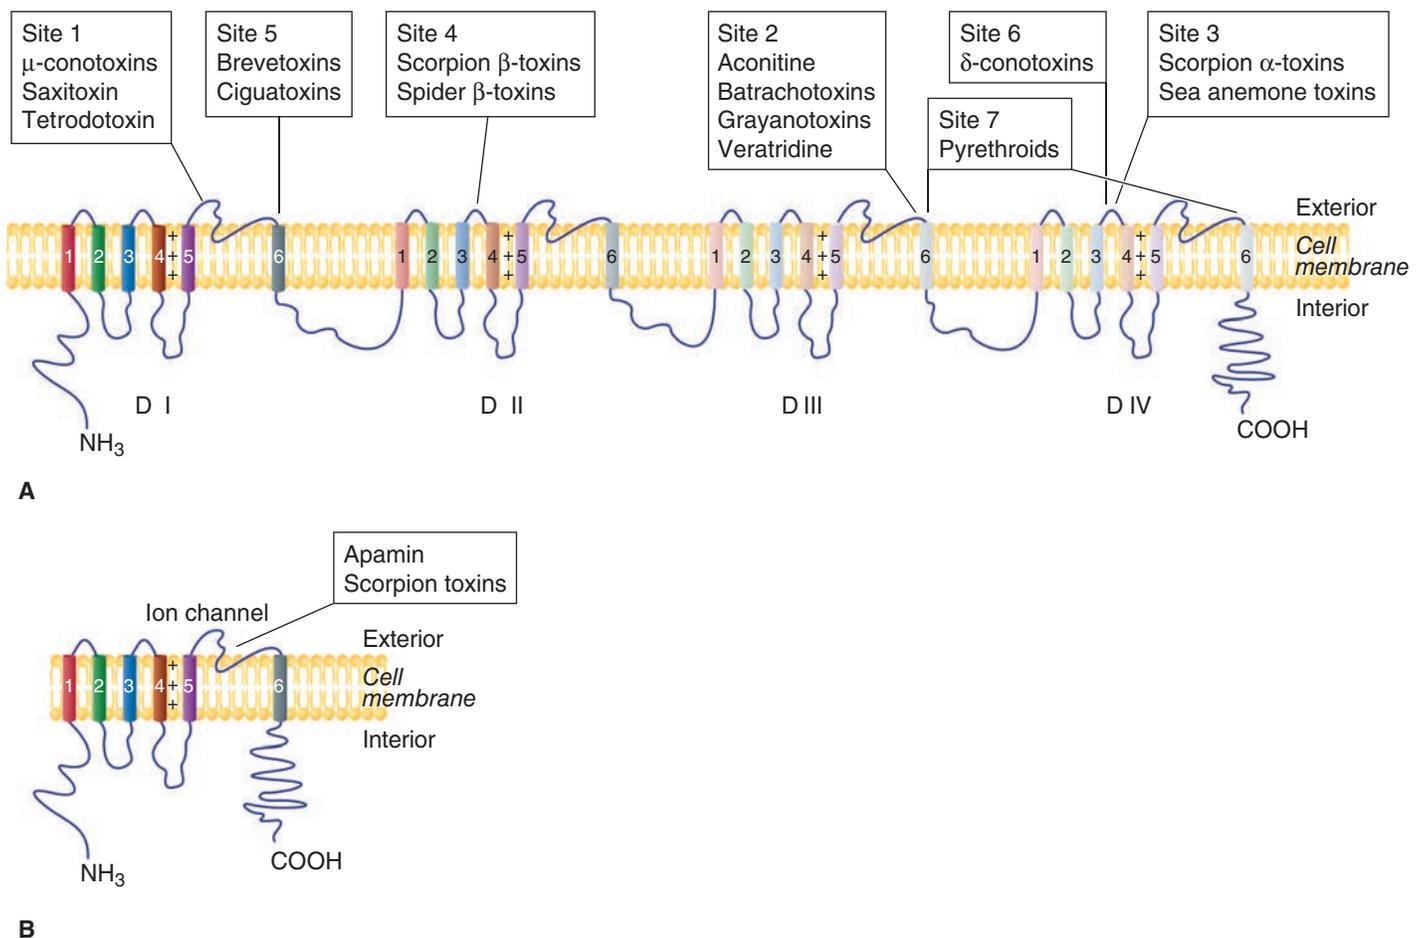

## ELECTROPHYSIOLOGIC PRINCIPLES

The clinical tool most commonly used to assess cardiac function is the surface electrocardiogram (ECG). The ECG records the sum of the electrical changes occurring within the myocardium. The electrophysiologic basis of cardiac function and the ECG are complex and are subject to alteration by numerous xenobiotics. Ion currents flowing through various ion channels are responsible for cardiac function. Electrophysiologic studies identify the functional types of membrane receptors and ion channels. Molecular genetic studies identify the gene coding for the key cardiac ion channels and elucidate the structural and physiologic relationships that lead to the toxic effects of many xenobiotics. These channels are critical for maintenance of the intracellular ion concentrations necessary for action potential development, impulse conduction throughout the heart, and myocyte contraction. This chapter will first review the individual ion channels and their currents, and then summarize their contribution and effects on the ECG.

## ION CHANNELS OF THE MYOCARDIAL CELL MEMBRANE

### Sodium Channels

The voltage-sensitive sodium channels are responsible for the initiation of depolarization of the myocardial membrane. All currently identified voltage-sensitive channels, including the sodium and calcium channels, have structures similar to the potassium channel assembly. The sodium channel gene encodes a single protein that contains 4 functional domains (D I to D IV). Each of these domains has the 6 membrane-spanning regions characteristic of the voltage-gated potassium channel and is structurally similar to the  $\alpha$  subunit of the potassium channel. The single, large  $\alpha$  subunit of the sodium channel assembles with regulatory  $\beta$  subunits to form the functional unit of the sodium channel (Fig. 15-1A). The best characterized of the sodium channels, the *SCN5A* gene-encoded  $\alpha$  channel, is inactivated by xenobiotic interactions between the D III and the D IV domains to physically block the inner mouth of the sodium channel pore.<sup>29</sup> Seven specific receptor sites are

**FIGURE 15-1.** Structure of the sodium and potassium channels. **(A)** The structure of the  $\alpha$  subunit of the sodium channel. The protein molecule has 4 functional domains (D I–D IV) each analogous to one of the potassium channel  $\alpha$  subunits. One of these molecules assembles with  $\beta$  subunits to form the membrane sodium channel. Sites 1–7 are shown with individual toxins known to bind at these sites. **(B)** The structure of the  $\alpha$ -subunit of the voltage-gated potassium channel. The protein molecule has 6 membrane-spanning regions (1–6); the voltage-sensitive region is at 4 and the actual ion channel is located between regions 5 and 6, similar to the  $\alpha$  sodium channel. Four of these  $\alpha$ -subunits assemble with 4  $\beta$  subunits to form the potassium channel complex.

currently identified on the  $\alpha$  subunit, with different xenobiotics binding at the specific sites: tetrodotoxin, saxitoxin,  $\mu$ -conotoxin (site 1); aconitine, batrachotoxin, grayanotoxin, veratridine (site 2);  $\alpha$  scorpion toxins, sea anemone toxins (site 3);  $\beta$  scorpion toxins, Chinese bird spider toxin (site 4); brevetoxins, ciguatoxins (site 5);  $\delta$ -conotoxins (site 6); pyrethroids (site 7), and local anesthetics and related antidysrhythmics and antiepileptics binding at overlapping receptor sites.<sup>14,57,61,71</sup>

### Potassium Channels

Ion channels that change their conductance of current with changes in the transmembrane voltage potential are called *rectifying channels*. The voltage-sensitive potassium channels are categorized based on their speed of activation and their voltage response. They include the “delayed rectifier” potassium currents, particularly the  $I_{Kr}$  (rapidly activating) and the  $I_{Ks}$  (slowly activating) channels.<sup>43</sup> Potassium channels form large multimolecular complexes with regulatory kinases, phosphatases, anchoring proteins, accessory subunits, and with each other.

The various voltage-gated potassium channels share an underlying structural similarity. The  $\alpha$  subunit is a protein molecule with 6 membrane-spanning  $\alpha$ -helical regions, 1 to 6 (Fig. 15-1B). The pore domain is located between the regions five and six of the  $\alpha$  subunit. Region 4 is the voltage sensor region.<sup>53,64</sup> Apamin, found in apitoxin obtained from bee venom, is a potent blocker of a specific subset of  $Ca^{2+}$ -activated  $K^+$  channels conferring atrial antidysrhythmic effects. The scorpion toxins scyllatoxin and tamapin block similar  $K^+$  channels although they are structurally dissimilar.<sup>57</sup> There are more than 70 genes encoding  $K^+$  channels in the human genome.<sup>3</sup> Human Ether-à-go-go Related Gene (hERG) encodes the  $\alpha$  subunit that assembles with  $\beta$  subunit proteins to form the  $I_{Kr}$  potassium channel. The C-terminus region of the  $\alpha$  subunit encoded by hERG has a cyclic nucleotide binding domain and an N-terminus region similar to domains involved in signal transduction in cells.<sup>64</sup>

Many xenobiotics interact with the hERG-encoded subunit of the potassium channel to reduce the current through the  $I_{Kr}$  channel and prolong the action potential duration. The hERG  $\alpha$  subunit of the channel is particularly susceptible to xenobiotic-induced interactions because of 2 important differences from the other channels. First, region 6 of the hERG channel has aromatic side chains on the inner cavity pore that can bind to aromatic xenobiotics, for example, cisapride, haloperidol, and terfenadine.<sup>55</sup> Additionally, the inner cavity and entrance of the hERG channel is larger than the other voltage-gated potassium channels. This larger pore can accommodate larger xenobiotics that get trapped within the pore when the channel closes.<sup>52,53,64</sup>

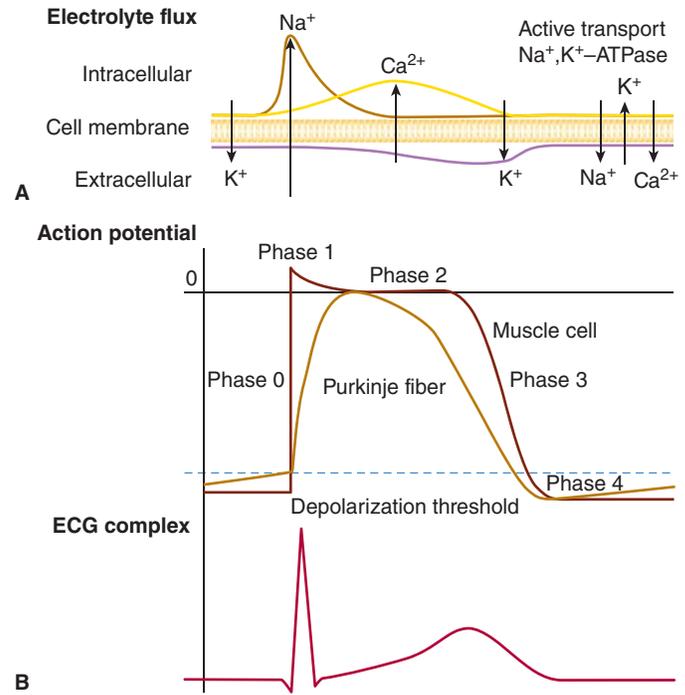

### Calcium Channels

Calcium channel conductivity across the myocardial cell membrane is critical for the maintenance of the appropriate duration of cell membrane depolarization and for initiation of cellular contraction. The best characterized of the calcium channels are the slow (L-type), the fast (T-type), and the ryanodine receptor calcium channel. They are more prominently involved in cardiac contractility and discussed in Chapter 16.

## ION CHANNELS AND MYOCARDIAL CELL ACTION POTENTIAL

An understanding of the basic electrophysiology of the myocardial cell is essential to understand the toxicity of xenobiotics and to plan appropriate therapy. Figure 15-2A shows the typical action potential of myocardial cell depolarization, the electrolyte fluxes responsible for the action potential, and the resulting ECG complex (Fig. 15-2B). The action potentials of the contractile and the conductive cells are also shown.

The action potential is divided into 5 phases: phase 0, depolarization; phase 1, overshoot; phase 2, plateau; phase 3, repolarization; and phase 4, resting. Phase 0 begins when the cell is excited either by a stimulus from an adjoining cell or by spontaneous depolarization of a pacemaker cell. The stimulus causes selective voltage-gated fast sodium channels ( $I_{Na^+}$ ) to open, resulting in rapid depolarization of the membrane. At the end of phase 0, the

**FIGURE 15-2.** Relationship of electrolyte movement across the cell membrane (A) to the action potential and the surface ECG recording (B) over a single cardiac cycle.

voltage-sensitive sodium channels close and a transient outward potassium current ( $I_{To}$ ) occurs, resulting in a partial repolarization of the membrane—this constitutes phase 1.

During phase 2 (plateau phase), the inward depolarizing calcium currents are largely balanced by the outward repolarizing potassium currents. Voltage-sensitive calcium channels that open allow  $Ca^{2+}$  movement down the 5,000–10,000-fold concentration gradient into the cell. These channels are categorized based on their conductance (fast or slow) and their sensitivity to voltage changes.<sup>57</sup> The calcium currents (mostly the “long-lasting” current) gradually decrease as the channels inactivate. Simultaneously, the outward potassium “delayed rectifier” currents, particularly the  $I_{Ks}$  (slowly activating) current increases, terminating the plateau phase of the action potential and initiating cellular repolarization (phase 3). Other, smaller, outward potassium currents (not shown in Fig. 15-2A) play a lesser role in the duration of the action potential and development of phase 3, including  $I_{Kur}$  (ultrarapid),  $I_{Kr}$  (rapidly activating),  $I_{K_{Ach}}$  (acetylcholine-dependent), and  $I_{K_{ATP}}$  (adenosine triphosphate-dependent) currents.

In phase 3, the rapid repolarization phase, the cell membrane repolarizes as a result of the voltage-gated currents, the delayed rectifier currents ( $I_{Kr}$ ,  $I_{Ks}$ ), and to a lesser extent the other  $K^+$  currents, the  $Na^+, Ca^{2+}$  exchanger current, and the sodium/potassium pump (active transport via  $Na^+, K^+ - ATPase$ ).

Phase 4 is the resting state for much of the myocardium, except the pacemaker cells, and it corresponds to diastole in the cardiac cycle. During phases 3 and 4, active transport of  $Na^+$ ,  $K^+$ , and  $Ca^{2+}$  against their electrochemical gradients returns the myocyte to its baseline resting state. The transmembrane electrochemical gradient is maintained during the resting state by a  $Ca^{2+}, Na^+$  exchange mechanism and by ATP-dependent pumps in the membrane that together move  $Ca^{2+}$  out of the cells.<sup>57</sup>

In the pacemaker cells during phase 4 of the action potential, gradual electrical depolarization of the membrane occurs due to potassium currents called the  $I_{kf}$  for “funny” or the  $I_{kh}$  for “hyperpolarization-activated” current.<sup>61,66</sup> The membrane potential gradually increases in these pacemaker cells until the threshold potential is reached, the fast inward sodium channels open, and the  $I_{Na}$  current initiates the next phase 0. This electrical impulse is then propagated via the His-Purkinje conducting system of the heart.

In addition to its role in myocardial contractility,  $\text{Ca}^{2+}$  influx is also important in pacemaker function. Although spontaneous pacemaker cell depolarization has traditionally been ascribed to inward cation current through “pacemaker channels,”<sup>16</sup> more recent research suggests that it is actually driven by rhythmic release of calcium from the sarcoplasmic reticulum.<sup>36,37</sup> Regardless,  $\text{Ca}^{2+}$  flux plays an important role in the spontaneous depolarization (phase 4) of the action potential in the sinoatrial (SA) node.<sup>38</sup> The rate of pacemaker cell depolarization is enhanced by  $\beta$ -adrenergic stimulation through phosphorylation of proteins on the sarcoplasmic reticulum and by a phosphorylation-independent action of cAMP at the pacemaker channels.<sup>42</sup> Depolarization of cells in the SA node spreads to surrounding atrial cells where it triggers the opening of fast sodium channels and causes impulse propagation. Calcium flux also allows normal propagation of electrical impulses via the specialized myocardial conduction tissues in the atrioventricular (AV) node.

During phases 0 to 2, the cell cannot be depolarized again with another stimulus; the cell is absolutely *refractory*. During the latter half of phase 3, as the calcium channels recover from their inactivated to their resting state, an electrical stimulus of sufficient magnitude will cause another depolarization; the cell is said to be *relatively refractory*. During phase 4, the cell is no longer refractory and any appropriate stimulus that reaches the threshold level will cause depolarization.

## ELECTROCARDIOGRAPHY

The ECG measures the sum of all electrical activity in the heart. It is used extensively in medicine and its interpretation is widely understood by physicians of nearly all disciplines. It is an invaluable diagnostic tool for patients with cardiovascular complaints. However, it is also a valuable source of information in poisoned patients and has the potential to enhance and direct their care. Although it seems obvious that an ECG would be required following exposure to a medication used for cardiovascular indications, many medications with no overt cardiovascular effects at therapeutic doses are cardiotoxic in overdose, for example loperamide. Furthermore, in patients with unknown exposures, the ECG can suggest specific xenobiotics or demonstrate electrolyte abnormalities, long before blood is drawn. For example, oropharyngeal or dermal burns in a patient whose ECG has evidence of hyperkalemia or hypocalcemia suggests exposure to hydrofluoric acid (Chap. 104).<sup>69</sup> Alternatively, a patient manifesting signs of the opioid toxidrome with runs of torsade de pointes might have ingested methadone (Chap. 36).<sup>21</sup> QT interval prolongation is a clue to the etiology of an overdose with an atypical antipsychotic such as quetiapine (Chap. 67). The ECG is used to predict complications of poisoning, such as seizures following a cyclic antidepressant overdose (Chap. 68). Therefore, an ECG should be examined early in the initial evaluation of most poisoned patients.

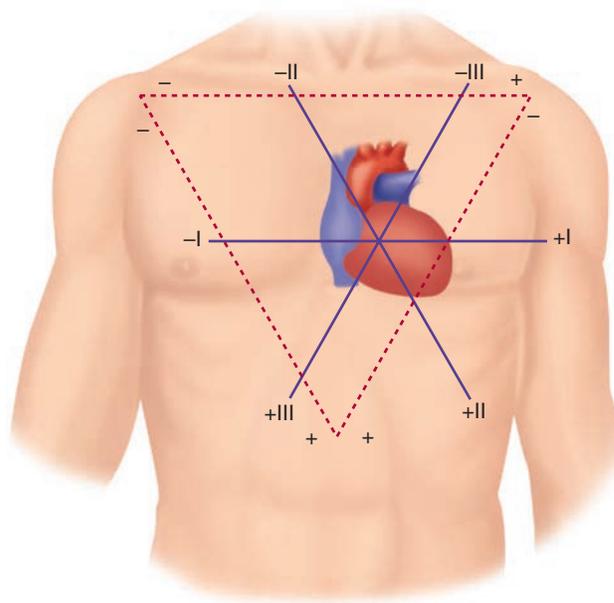

### History of the ECG

In the 1900s, Willem Einthoven graphically displayed the electrical activity of the heart and named the different waves—P, QRS, and T. He called this tracing an “elektrokardiogramme,” and was awarded a Nobel Prize in 1924 for his efforts. The acronym *EKG*, still employed by some authors, was derived from Einthoven’s spelling. The acronym *ECG*, which is consistent with our current spelling of electrocardiogram, is used throughout this text.

Since this initial description, both the normal electrophysiology of the heart and the pharmacologic effects of various xenobiotics on the ECG have been described. Despite the large number, diversity, and complexity of the various cardiac toxins, there are a limited number of electrocardiographic manifestations.

### Basic Electrophysiology of an ECG

Simplistically, a positive or upward deflection on the oscilloscope is generated when an electrical force moves toward an electrical sensor or electrode, and a downward deflection occurs if the force moves away. An ECG represents the sum of movement of all electrical forces in the heart in relation to the surface electrode, and the height above baseline represents the magnitude of the force (Fig. 15-2B). Only during depolarization or repolarization

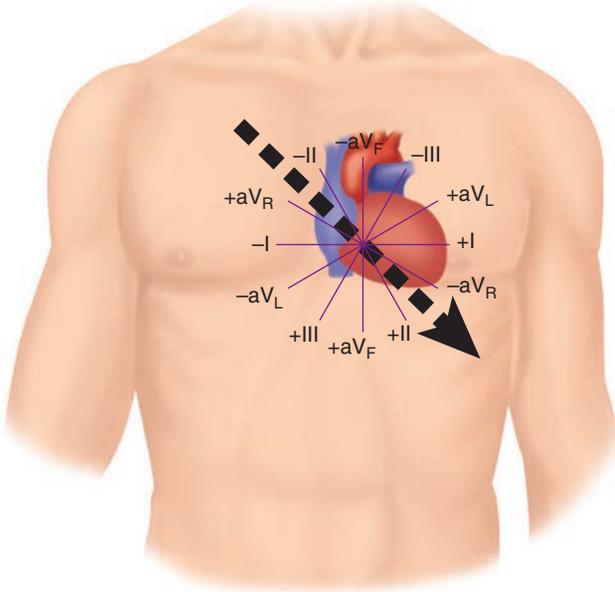

**FIGURE 15-3.** The hexaxial reference system derived from the Einthoven equilateral triangle defining the electrical potential vectors of electrocardiography. The relationships of the original 3 limb leads are illustrated. The equiangular (60°) Einthoven triangle formed by leads I, II, and III is shown (dotted lines), with positive and negative poles of each of the leads indicated. Leads I, II, and III are also presented as a triaxial reference system that intersects in the center of the ventricles.

does the ECG tracing leave the isoelectric baseline, because it is only during these periods that measurable net currents are flowing in the heart. During the other periods, mechanical effects are occurring in the myocardium, but large amounts of current are not flowing.

### Leads

Although the reading from a single ECG lead can provide valuable information, to visualize the heart in a nearly 3-dimensional perspective, multiple leads must be assessed simultaneously. Given the cylindrical nature of both the heart and thorax, at any given moment some of these leads will record positive voltage and others negative. The lead placement that was described and refined by Einthoven forms the basis for the bipolar or limb leads, described as I, II, and III (Fig. 15-3). The Einthoven triangle is an equilateral triangle formed by the sum of these leads. Unipolar limb leads and precordial leads were subsequently added to the standard ECG. Unipolar leads were created when the limb leads were connected to a common point where the sum of the potentials from leads I, II, and III was zero. The currently used unipolar augmented (a) leads ( $aV_R$ ,  $aV_L$ , and  $aV_F$ ) are based on these unipolar leads (Fig. 15-4). The voltage potential of these unipolar, “augmented leads” is small; thus, it is amplified by incorporating the voltage change of the other 2 augmented leads. Together, leads I, II, III,  $aV_R$ ,  $aV_L$ , and  $aV_F$  form the hexaxial reference system that is used to calculate the electrical axis of the heart in the frontal plane. The precordial leads, called  $V_1$  through  $V_6$ , are also unipolar measurements of the change in electric potential measured from a central point to the sixth anterior and left lateral chest positions (Fig. 15-5). If  $V_2$  is placed over the right ventricle, part of the initial positive ventricular deflection (QRS complex) reflects right ventricular activation, with electrical forces moving toward the electrode. The majority of the subsequent terminal negative deflection reflects activation of other muscle tissue (septum, left ventricular wall) when the electrical forces are moving away from the electrode. Recordings from each of these 12 leads (I, II, III,  $aV_R$ ,  $aV_L$ ,  $aV_F$ ,  $V_1$ – $V_6$ ) evaluate the heart from 2 different planes in 12 different positions, yielding a 3-dimensional electrical “picture” of the heart, with respect  $aV_R$ ,  $aV_L$ ,  $aV_F$ , to time and voltage.

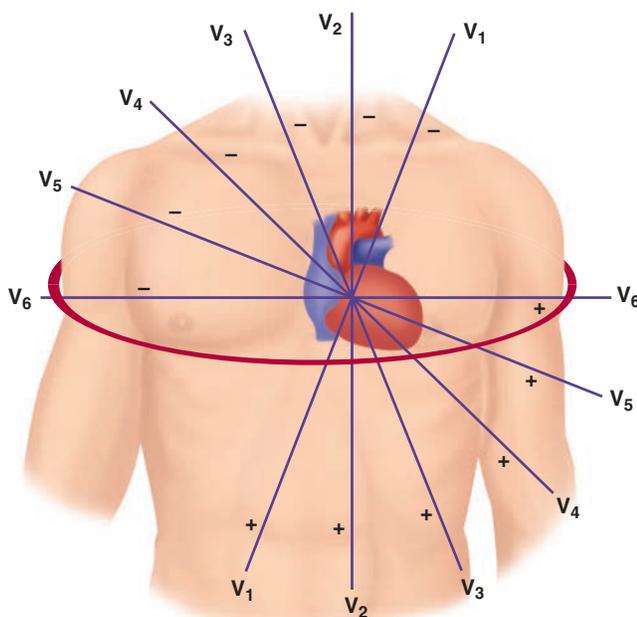

**FIGURE 15-4.** The hexaxial reference system derived from the Einthoven equilateral triangle defining the electrical potential vectors of electrocardiography showing the relationship between cardiac anatomy and electrocardiographic leads.

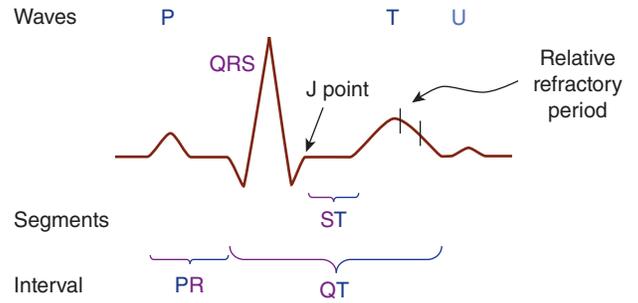

A continuous cardiac monitor often relies on recordings from one of 2 bipolar leads: a modified left chest lead ( $MCL_1$ ) or a lead II. The recording from an  $MCL_1$ , in which the positive electrode is in the  $V_1$  position, is similar in appearance to a  $V_1$  recording on a 12-lead ECG. This lead visualizes ventricular activity well; however, lead II shows atrial activity (ie, the P wave) much more clearly. Right ventricular precordial leads ( $V_1, V_{3-6R}$ ) are sensitive and specific for determining the presence of right ventricular myocardial infarctions, although specific applications to poisoning are not reported.

### Various Intervals and Waves

The ECG tracing has specific nomenclature to define the characteristic patterns. Waves refer to positive or negative deflections from baseline, such as the P,

**FIGURE 15-5.** Visualized as a cross-section, each of the chest lead is oriented through the atrioventricular (AV) node and exits through the patient's back, which is negative.

**FIGURE 15-6.** The normal ECG. The U wave is the small, positive deflection following the T wave. P wave, PR interval, atrial depolarization; QRS complex, ventricular depolarization; ST segment, T wave, QT interval, and U wave, and ventricular repolarization demonstrate the normal ECG.

T, or U waves. A segment is defined as the distance between 2 waves, such as the ST segment, and an interval measures the duration of a wave plus a segment, such as QT or PR interval. Complexes are a group of waves without intervals or segments between them (QRS complex). Electrophysiologically, the P wave and PR interval on the ECG tracing represent the depolarization of the atria. The QRS complex represents the depolarization of the ventricles. The plateau is depicted by the ST segment and repolarization is visualized as the T wave and the QT interval (QT). The U wave, when present, generally represents an afterdepolarization (Fig. 15-6).

### The P Wave

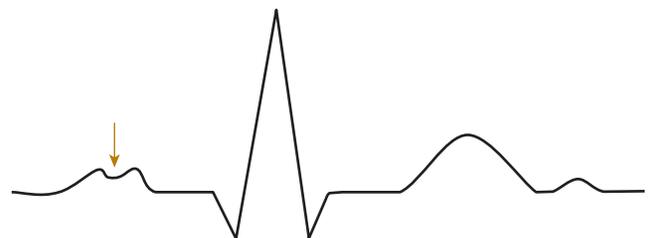

The P wave is the initial deflection on the ECG that occurs with the initiation of each new cardiac cycle.

### Electrophysiology

The early, middle, and late portions of the P wave are represented sequentially by the electrical potential initiated by the sinus node. The impulse is propagated directly through the right atrial muscle, producing contraction. The impulse is also propagated by specialized conduction tissue across the interatrial septum, to produce contraction of the left atrium. Additionally, internodal pathways rapidly conduct the impulse to the AV node. The electrical excitation of the sinus node differs from that of the ventricular myocardium in that current is mediated primarily by  $Ca^{2+}$  influx via slow T-type calcium channels, following hyperpolarization by the  $I_{kr}$ , mixed sodium-potassium current (f for “funny”). The “funny” current is also called the  $I_{kh}$  (h for “hyperpolarization-activated”). The vagus nerve and  $\beta$ -adrenergic stimulation also affect conduction across nodal tissues.<sup>6</sup>

### Abnormal P Wave

Clinically, abnormalities of the P wave occur with xenobiotics that depress automaticity of the sinus node, causing sinus arrest and nodal or ventricular escape rhythms ( $\beta$ -adrenergic antagonists, calcium channel blockers). The P wave is absent in rhythms with sinus arrest, such as occurs with xenobiotics that increase vagal tone such as cardioactive steroids and cholinergics. A notched P wave suggests delayed conduction across the atrial septum and is characteristic of quinidine poisoning or atrial enlargement (Fig. 15-7). P waves

**FIGURE 15-7.** A notched P wave (arrow) suggests delayed conduction across the atrial septum and is characteristic of quinidine poisoning.

decrease in amplitude as hyperkalemia becomes more severe until they become indistinguishable from the baseline (Chap. 12).

### PR Interval

The PR interval is measured from the beginning of the P wave to the beginning of the QRS complex (normal is 120–200 milliseconds {ms}).

### Electrophysiology

Despite rapid conduction by specialized conduction tissue from the SA to the AV node, the AV node delays transmission of the impulse into the ventricles, ostensibly to allow for complete atrial emptying. Thus, the PR interval represents the interval between the onset of atrial depolarization and the onset of ventricular depolarization. Children usually have more rapid conduction and a shortened PR interval, and older adults generally have a prolonged PR interval. The segment between the end of the P wave and the beginning of the QRS complex (the PQ segment) reflects atrial contraction and is usually isoelectric. Atrial repolarization coincides with the Q wave, but the ECG evidence, or atrial T waves, are obscured by the QRS complex.

### Abnormal PR Interval

Xenobiotics that decrease interatrial or AV nodal conduction cause marked prolongation of the PR segment until such conduction completely ceases. At this point, the P wave no longer relates to the QRS complex; this is AV dissociation, or complete heart block. Some xenobiotics suppress AV nodal conduction by blocking calcium channels in nodal cells, as does magnesium,  $\beta$ -adrenergic antagonists, or muscarinics through enhanced vagal tone. Although the therapeutic concentrations of digoxin, as well as early cardioactive steroid poisoning, cause PR prolongation through vagal tone, direct electrophysiologic effects account for the bradycardia of poisoning (Chap. 62 and Antidotes in Depth: A22).

### QRS Complex

The QRS complex is the second and typically largest deflection on the ECG. The normal QRS duration in adults varies between 60 and 100 ms. A QRS duration that is prolonged from the patient's baseline in the setting of poisoning indicates toxicity even if the QRS is within the normal range. The normal QRS complex axis in the frontal plane lies between  $-30^\circ$  and  $90^\circ$ , although most individuals have an axis between  $30^\circ$  and  $75^\circ$ . This axis will vary with the weight and age of the patient. Alterations in myocardial function will also alter the electrical axis of the heart.

### Electrophysiology

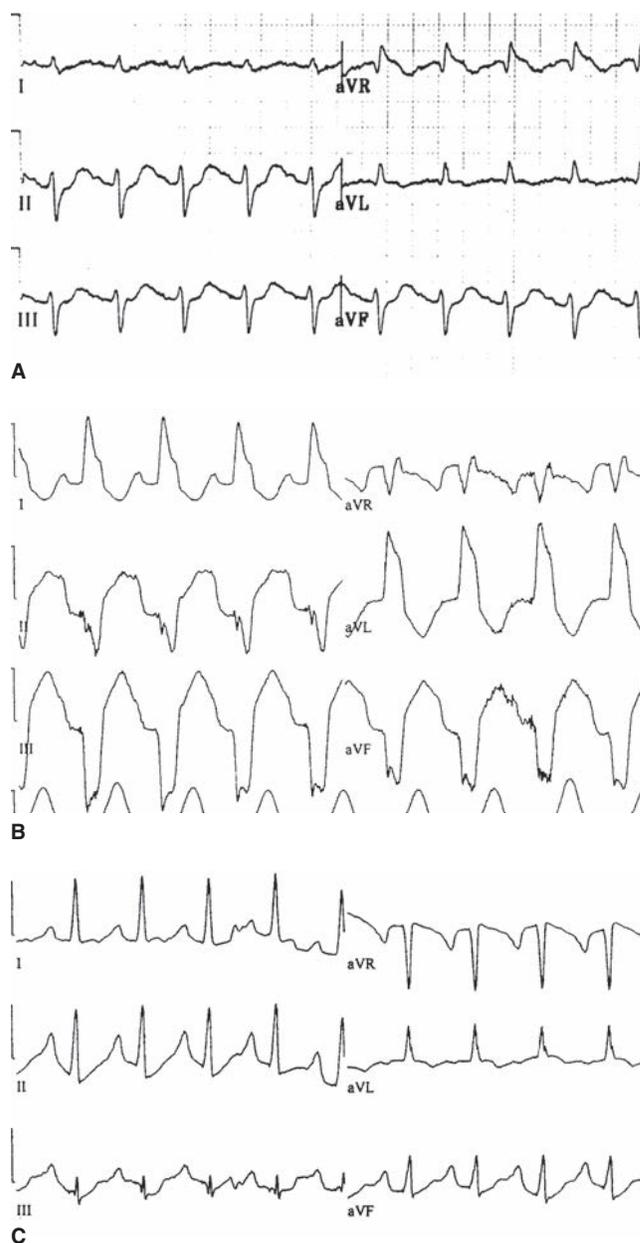

The QRS complex reflects the electrical forces generated by ventricular depolarization mediated primarily by  $\text{Na}^+$  influx into the myocardial cells. Although under normal conditions both ventricles depolarize nearly simultaneously, the greater mass of the left ventricle causes it to contribute the majority of the electrical forces. The QRS complex is primarily positive in leads I and  $\text{aV}_L$  on the surface ECG recording because under normal conditions the depolarization vector is directed at  $60^\circ$  and is thus moving toward these leads.

The simultaneous and rapid depolarization of the ventricles results in a very short period of electrical activity recorded on the electrocardiogram. Mechanical systole lasts well past the end of the QRS complex and is maintained by continued depolarization during the plateau phase of the action potential. The return to, and maintenance of, the baseline, or isoelectric potential, simply represents that the entire heart is depolarized and there is no significant net flow of current during this period.

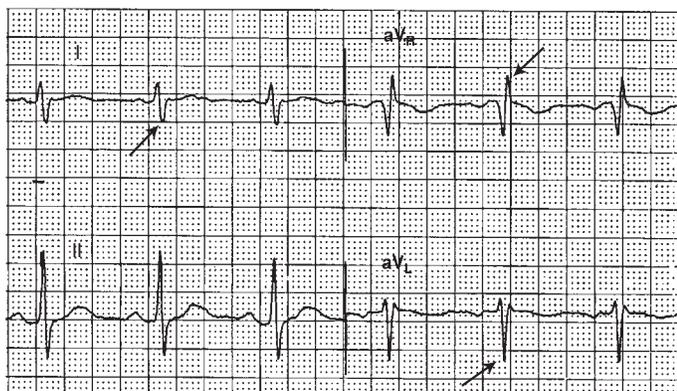

The axis of the terminal 40 ms (0.04 seconds) of the QRS complex represents the late stages of ventricular depolarization and generally follows the direction of the overall axis. This axis is determined by examining the last small box (0.04 seconds or 40 ms) of the QRS complex on the ECG. A leftward shift of the terminal 40 ms axis of the QRS complex correlates with toxicity from xenobiotics with  $\text{Na}^+$ -channel-blocking effects (Chap. 68).

### Abnormal QRS Complex

In the presence of a bundle-branch block, the 2 ventricles depolarize sequentially rather than concurrently. Although, conceptually, conduction through either the left or right bundle may be affected, many xenobiotics preferentially affect the right bundle (Fig. 15–8). The specific reasons for this effect are unclear, but it is likely related to differing refractory periods of the tissues. This effect typically results in the left ventricle depolarizing slightly more rapidly than the right. The consequence on the ECG is both a widening of the QRS complex and the appearance of the right ventricular electrical forces that were previously obscured by those of the left ventricle. These changes are typically the result of the effects of a xenobiotic that blocks fast  $\text{Na}^+$  channels. Implicated xenobiotics include amantadine,<sup>56</sup> bupropion,<sup>22</sup> carbamazepine,<sup>30</sup> cocaine,<sup>1</sup> cyclic antidepressants,<sup>11,12</sup> diphenhydramine,<sup>58</sup> lamotrigine,<sup>45</sup> phenothiazines, quinidine and other type IA and IC anti-dysrhythmics,<sup>17</sup> and topiramate. In the setting of cyclic antidepressant

**FIGURE 15–8.** A 35-year-old woman was found unresponsive in a hallway with an empty bottle of doxepin. Note the progression from (A) a wide QRS interval (108 ms, axis  $+10^\circ$ ); to (B) at  $>35$  min: a right bundle branch block (RBBB) with an axis of  $-50^\circ$  and a rightward shift of the terminal 40 ms of the QRS axis; and (C) in the next hour, marked improvement occurred after infusion of hypertonic sodium bicarbonate.

**FIGURE 15-9.** ECG of a patient with a tricyclic antidepressant overdose. The arrows highlight prominent S wave in leads I and  $aV_L$ , and the R wave in  $aV_R$ , demonstrates the terminal 40-ms rightward axis shift. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

poisoning, a prolonged QRS duration has both prognostic and therapeutic value (Chap. 68).<sup>8,12,25</sup> In one prospective analysis of ECGs in cyclic antidepressant poisoned patients, the maximal limb lead QRS duration was prognostic of seizures (0% if <100 ms; 30% if greater) and ventricular dysrhythmias (0% if <160 ms; 50% if greater).<sup>12</sup>

The terminal 40-ms axis of the QRS complex also contains information regarding the likelihood, but not the extent, of poisoning by  $Na^+$  channel blockers. In a patient poisoned by a  $Na^+$  channel blocker, the terminal portion of the QRS has a rightward deviation greater than  $120^\circ$ . The common abnormalities include an R wave (positive deflection) in lead  $aV_R$  and an S wave (negative deflection) in leads I and  $aV_L$ .<sup>33</sup> The combination of a rightward axis shift in the terminal 40 ms of the QRS complex (Fig. 15-9) with a prolonged QT interval and a sinus tachycardia is highly specific and sensitive for cyclic antidepressant poisoning.<sup>44</sup> Another study suggests that although ECG changes, like a prolonged QRS duration, are better at predicting severe outcomes than the cyclic antidepressant concentration, neither is very accurate.<sup>8</sup> One retrospective study suggests that an absolute height of the terminal portion of  $aV_R$  that is greater than 3 mm predicted seizures or dysrhythmias in cyclic antidepressant-poisoned patients.<sup>32</sup> However, in infants younger than 6 months, a rightward deviation of the terminal 40-ms QRS axis is physiologic and not predictive of cyclic antidepressant toxicity.<sup>11</sup>

An apparent increase in QRS complex duration and morphology, which is an elevation or distortion of the J point called a J wave or an Osborn wave (Fig. 29-3) is a common finding in patients with hypothermia.<sup>47,65</sup> Hypermagnesemia is also associated with prolongation of the QRS complex duration. A slight narrowing of the QRS complex may occur with hypomagnesemia. Significant hyperkalemia also causes prolongation and distortion of the QRS complex.

### ST Segment

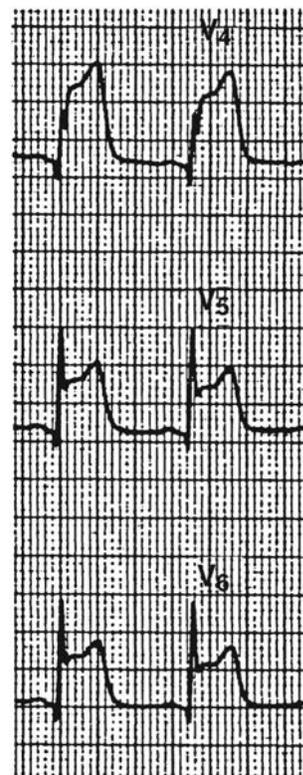

The ST segment is defined as the distance between the end of the QRS complex and the beginning of the T wave.

#### Electrophysiology

The ST segment reflects the period of time between depolarization and the start of repolarization, or the plateau phase of the action potential. During this period, no major currents flow within the myocardium, which explains why under normal circumstances the ST segment is isoelectric. Although both the degree of displacement from the baseline and the length of this segment are important, the ST segment duration is usually measured by its effects on the QT interval duration (see “QT Interval”).

#### Abnormal ST Segment

Displacement of the ST segment from its baseline typically characterizes myocardial ischemia or infarction (Fig. 15-10). The subsequent appearance of a Q wave is diagnostic of myocardial infarction. The ECG patterns of these

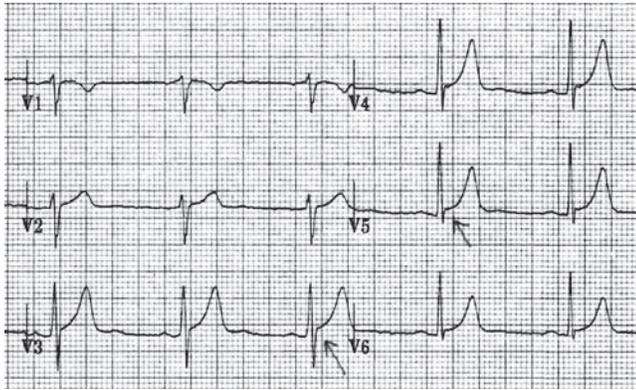

**FIGURE 15-10.** Leads  $V_4$  to  $V_6$  suggestive of a lateral ST elevation myocardial infarction (STEMI) are shown from the ECG of a 27-year-old man with substernal chest pain after using crack cocaine. (Used with permission from The Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

entities reflect the different underlying electrophysiologic states of the heart. Ischemic regions are highly unstable and produce currents of injury because of inadequate repolarization, which is related to lack of energy substrate to power the  $Na^+, K^+$ -ATPase pump. Myocardial infarction represents the loss of electrical activity from the necrotic, inactive ventricular tissue, allowing the contralateral ventricular forces to be predominant on the ECG. Patients who are poisoned by xenobiotics that cause vasoconstriction, such as cocaine (Chap. 75), other  $\alpha$ -adrenergic agonists, or the ergot alkaloids, are particularly prone to develop focal myocardial ischemia and infarction. The specific ECG manifestations help to identify the region of injury and are correlated with an arterial flow pattern: inferior (leads II, III,  $aV_F$ ; right coronary artery); anterior (leads I,  $aV_L$ ; left anterior descending artery); or lateral (leads  $aV_L$ ,  $V_5-6$ ; circumflex branch). However, any poisoning that results in profound hypotension or hypoxia also results in ECG changes of ischemia and injury. In these patients, the injury is more global, involving more than one arterial distribution. Diffuse myocardial damage may not be identifiable on the ECG because of global, symmetric electrical abnormalities. Under these circumstances, the diagnosis is established by other noninvasive testing, such as by echocardiogram or by finding elevated concentrations of serum markers for myocardial injury such as troponin.

Many young, healthy patients have ST segment abnormalities that mimic those of myocardial infarction. The most common normal variant is termed “early repolarization” or “J point elevation,” and is identified as diffusely elevated, upwardly concave ST segments, located in the precordial leads and typically with corresponding T waves of large amplitude (Fig. 15-11).<sup>13</sup> The J point is located at the beginning of the ST segment just after the QRS complex. Because this ECG variant is common in patients with cocaine-associated chest pain (Chap. 75),<sup>24</sup> its recognition is critical to instituting appropriate therapy.

The Brugada electrocardiographic pattern (Fig. 15-12) is characterized by terminal positivity of the QRS complex and ST segment elevation in the right precordial leads. The Brugada pattern is found in some patients with mutations of the gene that codes for the  $\alpha$  subunit of the sodium channel.

**FIGURE 15-11.** Healthy 34-year-old man whose ECG demonstrates diffusely elevated, upwardly concave ST segments in leads V3 to V5, and T waves of large amplitude suggestive of an “early repolarization” abnormality (J point).

These patients are at risk for sudden death, and a similar ECG pattern often occurs in patients who are poisoned by sodium-channel-blocking xenobiotics, including cyclic antidepressants, cocaine,<sup>23</sup> class IA (procainamide) antidysrhythmics and class IC (flecainide, encainide) antidysrhythmics.<sup>34</sup> In cyclic antidepressant-poisoned patients, this pattern is associated with an increased risk of hypotension, but not sudden death or dysrhythmias.<sup>10</sup> This pattern is also associated with lithium toxicity.<sup>70</sup>

Sagging ST segments, inverted T waves, and normal or shortened QT intervals are characteristic effects of cardioactive steroids, such as digoxin. These repolarization abnormalities are sometimes identified by their similar appearance to “Salvador Dali’s mustache” (Fig. 15-13). As a group, these findings, along with PR prolongation, are commonly described as the “digitalis effect.” They are found in patients with therapeutic digoxin concentrations and in patients with cardioactive steroid poisoning. As the serum concentration or, more precisely, the tissue concentration increases, clinical and electrocardiographic manifestations of toxicity will appear, which include profound bradycardia, AV nodal blockade, or ventricular dysrhythmias.

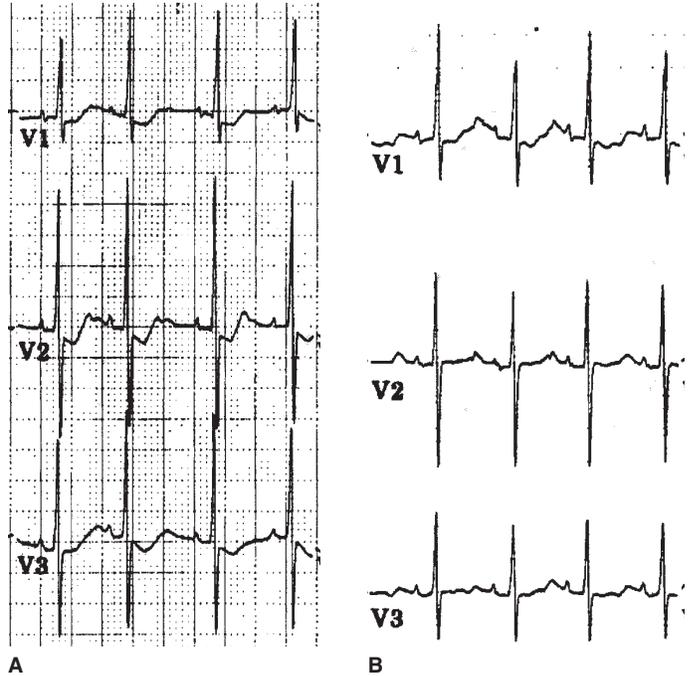

Changes in the ST segment duration are frequently caused by abnormalities in the serum Ca<sup>2+</sup> concentration. Hypercalcemia causes shortening of the ST segment through enhanced Ca<sup>2+</sup> influx during the plateau phase of the cardiac cycle, speeding the onset of repolarization. For practical purposes, this effect is more commonly identified by shortening of the QT duration (Fig. 15-14). In patients with hypercalcemia, the morphology and duration of the QRS complex and T and P waves remain unchanged. Xenobiotic-induced hypercalcemia results from exposure to antacids (ie, milk alkali syndrome), diuretics (eg, hydrochlorothiazide), cholecalciferol (vitamin D), vitamin A, and other retinoids. Hypocalcemia causes prolongation of the ST segment and QT interval.

**T Wave**

The T wave is the third deflection that occurs on the ECG.

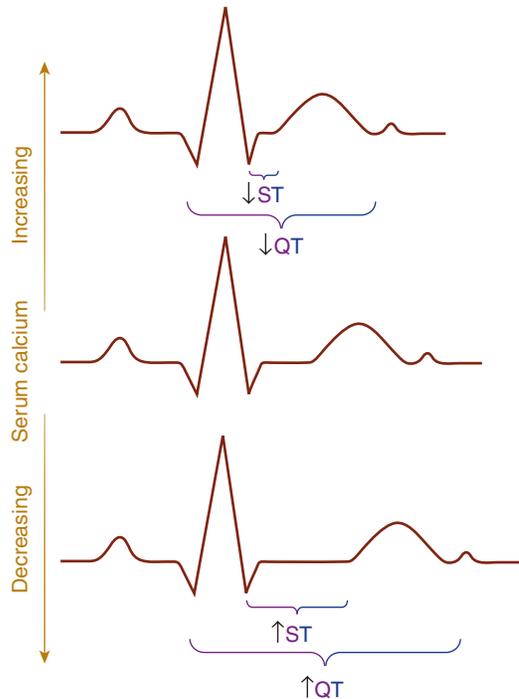

**FIGURE 15-12.** The Brugada pattern is characterized by terminal positivity of the QRS complex and ST segment elevation in the right precordial leads and is a similar ECG pattern to that noted in patients poisoned by sodium channel blocking xenobiotics such as cyclic antidepressants.<sup>4</sup> (Used with permission from Vikhyat Bebar, MD.)

**FIGURE 15-13.** Two-day-old boy erroneously given 50 mcg/kg of digoxin initially presented with heart rate 60 beats/min, given Digibind. (A) ECG from hospital day 2, before digoxin-specific Fab, and shows “digitalis effect” of the ST segment in leads V1 to V3 (digoxin concentration 4 ng/mL). (B) This finding resolves after the child was switched to amiodarone; notice the QT interval prolongation.

**Electrophysiology**

The T wave represents ventricular repolarization, during which time current is again flowing, although at a cellular level in the opposite direction from that during depolarization. Cardiac repolarization on the larger level generally follows the same pattern as depolarization and thus the deflection is usually in the same direction as the QRS complex. During repolarization, the intracellular potential of the cardiac myocyte becomes more negative as a

**FIGURE 15-14.** Electrocardiographic findings associated with changes in serum calcium concentration.

result of a net loss of positive charge because of the increasing outward flow of potassium ions. As repolarization progresses, the voltage-dependent ion channels “reset” themselves as the intracellular potential falls past their set points. Thus, the initial part of the T wave represents the absolute refractory period of the heart, because at this time there are an insufficient number of reset voltage-dependent calcium channels to allow an impulse to cause a contraction. The latter part of the T wave represents the relative refractory period of the heart, during which time a sufficient number of these calcium channels are available to open with an aberrant depolarization and initiate a contraction.

### Abnormal T Wave

Isolated peaked T waves are usually evidence of early hyperkalemia.<sup>39</sup> Hyperkalemia initially causes tall, tented T waves with normal QRS and QT intervals, and a normal P wave (Fig. 15-15A). As the serum potassium concentration acutely rises to 6.5 to 8 mEq/L, the P wave diminishes in amplitude and the PR and QRS intervals prolong. Progressive widening of the QRS complex causes it to merge with the ST segment and T wave, forming a “sine wave” (Fig. 15-15B). ECG manifestations of hyperkalemia occur following chronic exposure to numerous xenobiotics, including potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, or potassium supplements (Chap. 12). Fluoride, arsine, and cardioactive steroid poisoning can cause acute hyperkalemia, but the latter rarely produces hyperkalemic ECG changes. Peaked T waves also occur following myocardial ischemia and are often confused with early repolarization effects (ST segment). Consequently, the ability to properly identify electrolyte abnormalities by electrocardiography is often limited.

Hypokalemia typically reduces the amplitude of the T wave and, ultimately, causes the appearance of prominent U waves (Fig. 15-15A). Its effects on the ECG are manifestations of altered myocardial repolarization. Lithium similarly affects myocardial ion fluxes and causes reversible changes on the ECG that may mimic mild hypokalemia, although documentation of low cellular potassium concentrations is lacking.<sup>59,68</sup> Patients chronically poisoned with lithium have more T-wave abnormalities (typically flattening) than do those who are poisoned acutely, but these abnormalities are rarely of clinical significance.<sup>60</sup>

### QT Interval

The QT interval is measured from the beginning of the QRS complex to the end of the T wave. The QT interval normally varies because of biologic diurnal effects and autonomic tone, age, gender, technical issues with the environment or with processing and acquiring the ECG, and observer variability.<sup>2,40,41,49</sup> The bipolar limb lead with the largest T wave should therefore be used for this measurement.

The QT interval is normally prolonged at slower heart rates and shortens as the heart rate increases. This is especially important since many of the xenobiotics that affect the QT interval also affect the heart rate. As the normal QT also varies with the heart rate, numerous formulas and tables are available to obtain the corrected QT, known as the QTc. Using the QTc allows the determination of the appropriateness of the QT independent of the heart rate.

With a rate of 50 to 90 beats/min, the commonly used Bazett formula ( $QTc \text{ ms} = QT \text{ (ms)} / \sqrt{RR \text{ interval (seconds)}}$ ) is adequate for determining a rate-corrected QT interval (QTc). If the RR interval is calculated as 60 beats/min, 99% of men have a QTc <450 ms and 99% of women have a QTc <460 ms.<sup>42</sup> A QTc interval >500 ms weakly correlates with an increased risk of developing ventricular dysrhythmias. However, at higher heart rates, a normal patient will have an inaccurately calculated “prolonged” QTc interval using the Bazett formula. Studies suggest that medications such as bupropion prolong the QT interval when the “increase” in the QTc may be only a result of the increased heart rate.<sup>26</sup> A variety of formulas and corrections are proposed to attempt to identify normal QT intervals on ECGs at higher heart rates,<sup>7,35</sup> including the Fridericia formula ( $QTc = QT / \sqrt[3]{RR \text{ interval (seconds)}}$ ) and the Framingham linear regression analysis ( $QT_{1c} = QT + 0.154 (1 - RR)$ ).<sup>54</sup> Which

correction formula is optimal remains unknown, and the FDA requests that “presentation of data with a Fridericia correction is likely to be appropriate in most situations, but other methods could be more appropriate” when performing a “thorough QT study” for any drug with prodysrhythmic potential. A QT nomogram that plots QT interval duration versus heart rate may better predict the risk for lethal dysrhythmia.<sup>15</sup> The conventional use of QTc as a marker for dysrhythmia risk has a high false positive rate. The greatest discrepancy occurs during slow heart rates, 30 to 60 beats/min, when patients are at the highest risk for torsade de pointes. The nomogram that plots absolute QT interval duration versus heart rate is more sensitive. It is important to consider the known risk of the xenobiotic involved and whether the patient has an underlying abnormal QT interval (Fig. 15-16).<sup>15,66</sup> There is also evidence that the normal QT interval is shortened in adolescent males and varies substantially by age and gender.<sup>49</sup>

With slow heart rates, a prominent U wave can obscure the terminal portion of the T wave, and with fast heart rates the subsequent P wave can obscure the terminal portion of the T wave. In these patients, estimate the QTc by following the downslope of the T wave.

QT interval measurements from the computerized ECG algorithms are less accurate than careful manual determinations of the interval. In August 2000, a panel of experts convened to address these issues and suggested that the QT interval should be measured manually in one of the limb leads that best shows the end T wave; the QT interval should be measured and averaged over 3 to 5 beats; and large U waves should be included in the QT interval measurement if they merge into the T wave and obscure the end of the T wave.<sup>5</sup> However, a subsequent study of 334 health care professionals found that only 60% of the physicians were able to correctly measure a sample QT interval on the survey, although nearly all indicated correctly that the measurement should be from the beginning of the QRS to the end of the T wave.<sup>31</sup>

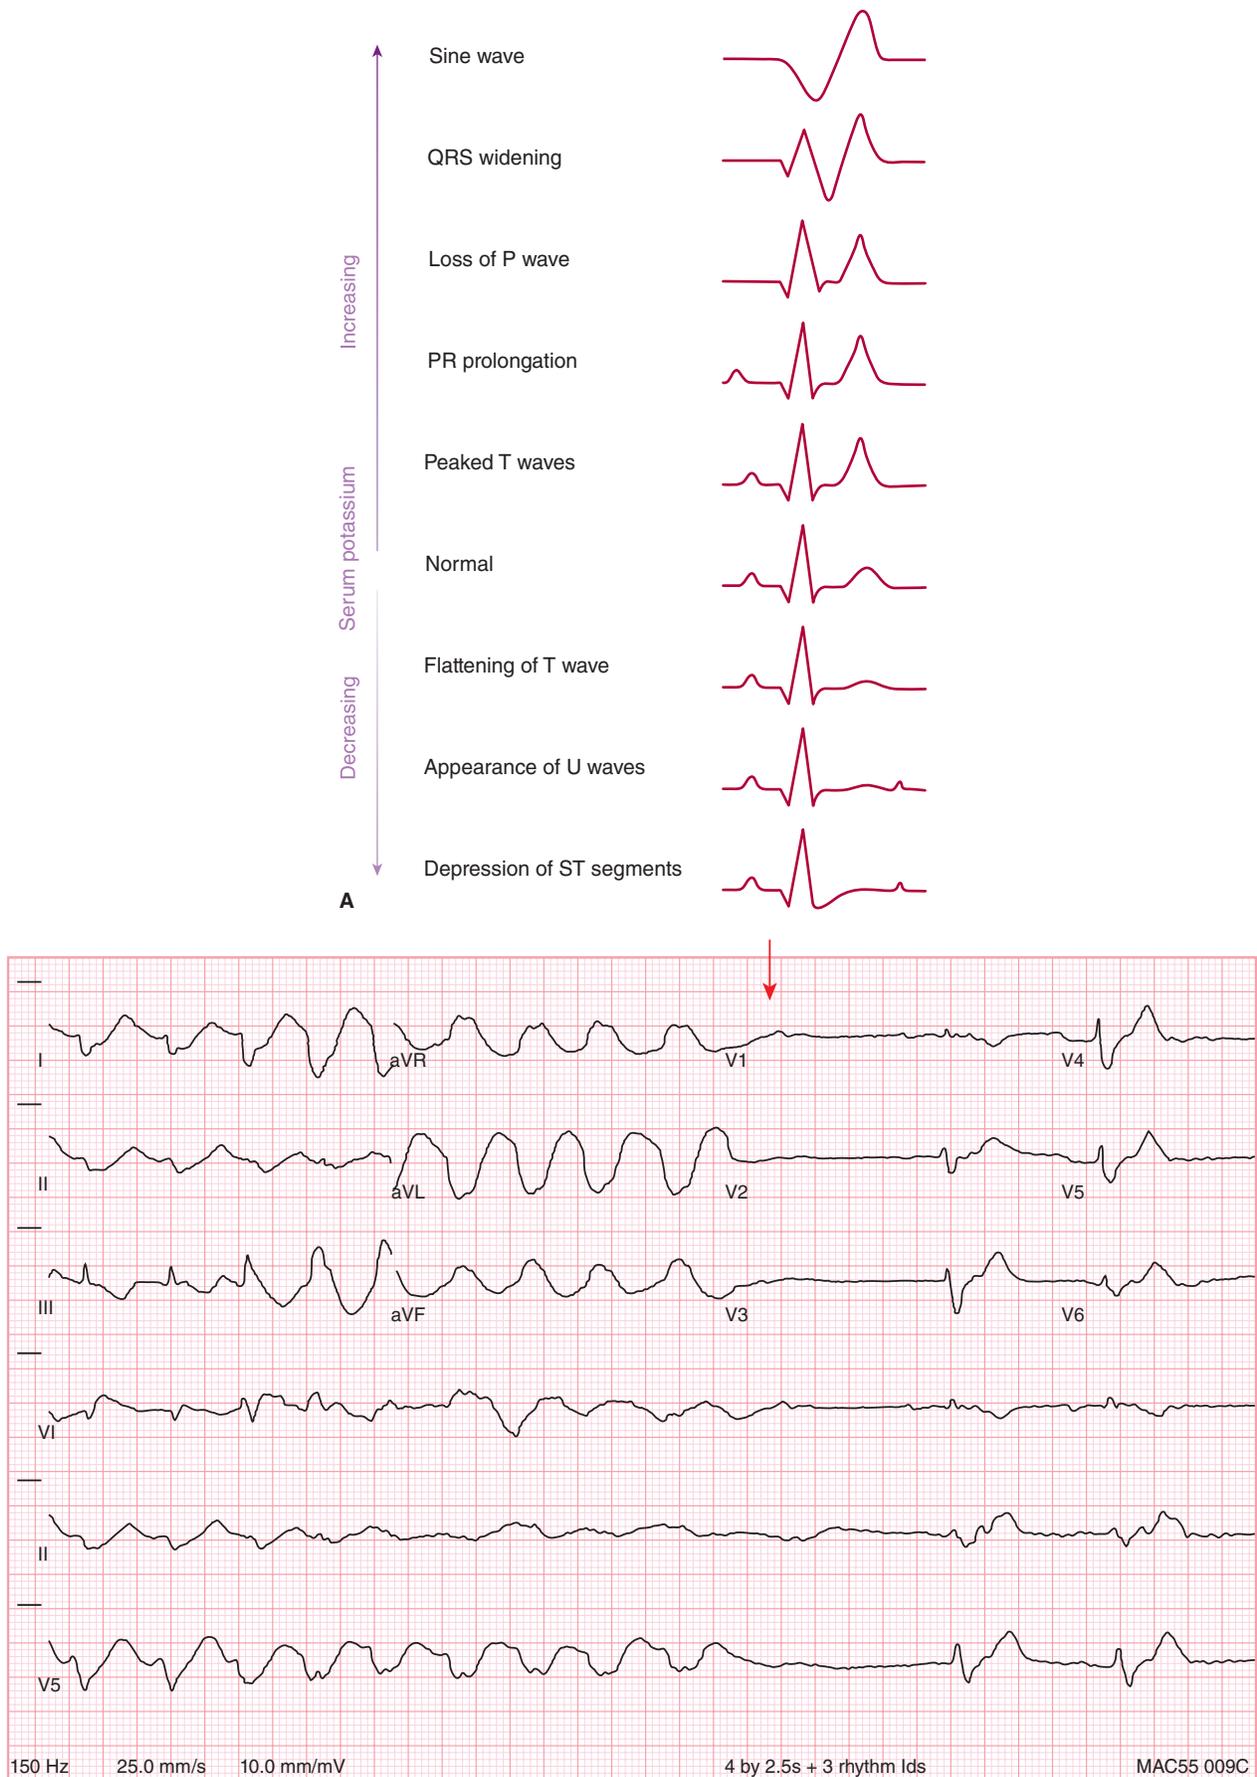

### Electrophysiology

The QT represents the entire duration of ventricular systole and thus is composed of several electrophysiologic periods. Prolongation of the QT interval generally corresponds to a lengthening of the duration of phase 2 or 3 of the action potential. Although as noted above, depolarization abnormalities can affect the QT. These are uncommon, and the plateau phase and repolarization are primarily reflected by the QT. Variations in the speed of the paper,<sup>19</sup> T wave morphology, irregular baseline, and the presence of U waves makes this determination difficult.<sup>5</sup>

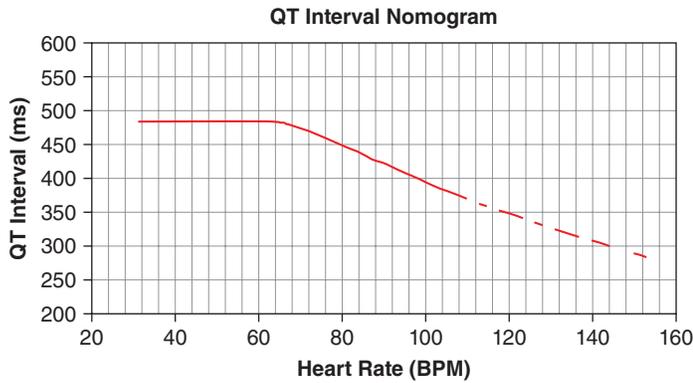

### Abnormal QT Interval

A prolonged QT reflects more time that the heart is “vulnerable” to the initiation of ventricular dysrhythmias (Table 15-1, Fig. 15-17). This occurs because although some myocardial fibers are refractory during this time period, others are not (ie, relative refractory period). Early afterdepolarizations (EADs) occur in patients with a prolonged repolarization time (Table 15-2). An EAD occurs when a myocardial cell spontaneously depolarizes before its repolarization is complete (Fig. 15-18). If this depolarization is of sufficient magnitude, it captures and initiates a premature ventricular contraction, which itself initiates ventricular tachycardia, ventricular fibrillation, or torsade de pointes. There are 2 types of EADs based on whether they occur during phase 2 (type 1) or phase 3 (type 2) of the cardiac action potential. Early afterdepolarizations are primarily due to reactivation of the voltage-gated L-type calcium channels. The importance of a pathologic rise in the late  $Na^+$  channel current ( $I_{Na-L}$ ) in the genesis of EADs was studied using a sea anemone toxin (ATX II). ATX II specifically blocks  $I_{Na-L}$  with minimal effects on other ion currents, resulting in decreased EADs.<sup>28</sup> Early afterdepolarizations are also suppressed by magnesium.<sup>9</sup>

Xenobiotics that cause  $Na^+$  channel blockade (Chaps. 64 and 68), prolong the QT duration by slowing cellular depolarization during phase 0. Thus, the QT duration lengthens because of a prolongation of the QRS complex duration, and the ST segment duration remains near normal. Xenobiotics that cause potassium channel blockade similarly prolong the QT, but through

**FIGURE 15-15** (A) Electrocardiographic manifestations associated with changes in serum potassium concentration. (B) A 45-year-old woman with chronic renal failure presents with a  $K^+$  of 7.2 mEq/L. This ECG reveals the sine-wave associated with severe hyperkalemia. Following treatment (↓) with calcium gluconate, her rhythm improved. (Used with permission from Diane Sauter, MD, Washington Hospital Center.)

**FIGURE 15-16.** QT Interval Nomogram.<sup>15</sup> Solid line (—) indicates heart rates that are not tachycardic. Dashed line (---) is extrapolated to allow assessment of faster heart rates. The QT nomogram is a plot of the QT interval versus the heart rate. A QT heart rate pair plotted above the line is associated with an increased risk of torsade de pointes. (Reproduced with permission from Chan A, Isbister GK, Kirkpatrick CM, Dufful SB. Drug-induced QT prolongation and torsades de pointes: evaluation of a QT nomogram. *QJM* 2007 Oct;100(10):609-615.)

prolongation of the plateau and repolarization phases. This specifically prolongs the ST segment duration. Although at a cellular level these xenobiotics are antidysrhythmic, the multicellular effects are prodysrhythmic. The highly selective serotonin reuptake inhibitors citalopram/escitalopram cause QT prolongation due to the potassium and calcium channel–blocking effects of the metabolite didesmethyl-citalopram. In a large retrospective cohort study, users of both typical antipsychotics (thioridazine and haloperidol) and atypical antipsychotics (clozapine, quetiapine, olanzapine, risperidone) had a risk of sudden cardiac death that was twice that of nonusers of antipsychotics. Xenobiotic-induced QT prolongation and the subsequent risk of dysrhythmias is the postulated etiology.<sup>50</sup> Loperamide has recently been recognized as a cause of QT prolongation and life-threatening ventricular tachycardia via inhibition of cardiac hERG channels.<sup>18,63</sup>

Hypocalcemia of sufficient severity produces a prolonged QT interval and is caused by a number of xenobiotics, including fluoride, calcitonin, phosphates, and mithramycin (Table 12-9). Hypokalemia alone does not usually prolong the QT. Arsenic poisoning cause prolongation of the QT and results in torsade de pointes. The mechanism is unknown, although increases in cardiac  $Ca^{2+}$  currents and reduction in surface expression of the cardiac potassium channel hERG are postulated.<sup>20</sup>

**TABLE 15-1** Common Xenobiotic Causes of Prolonged QT\*

Antidysrhythmics
Classes IA, IC, and III antidysrhythmics
Antifungals: fluconazole, itraconazole, ketoconazole
Antihistamines: diphenhydramine
Antimicrobials: amantadine, chloroquine, fluoroquinolones, macrolides, pentamidine
Antiretrovirals: efavirenz, ritonavir-boosted saquinavir
Electrolyte disturbances
Hypocalcemia: fluoride, oxalate (eg, ethylene glycol)
Hypokalemia: barium soluble
Hypomagnesemia: cathartics, diuretics
Other: arsenic trioxide, cocaine, foscarnet, hydroxychloroquine, loperamide, methadone, ondansetron, organic phosphorus compounds, tacrolimus
Psychotropics: atypical antipsychotics, citalopram, cyclic antidepressants, droperidol, escitalopram, haloperidol, pimozide, phenothiazines, quetiapine, venlafaxine, ziprasidone

\*Additional information can be found at [www.crediblemeds.org](http://www.crediblemeds.org), hosted by the Arizona CERT.

**FIGURE 15-17.** A 33-year-old woman who ingested excessive methadone along with ethanol 3 hours before admission. Her ECG shows a sinus bradycardia and QT prolongation (A) of 500 ms.

### QT Dispersion

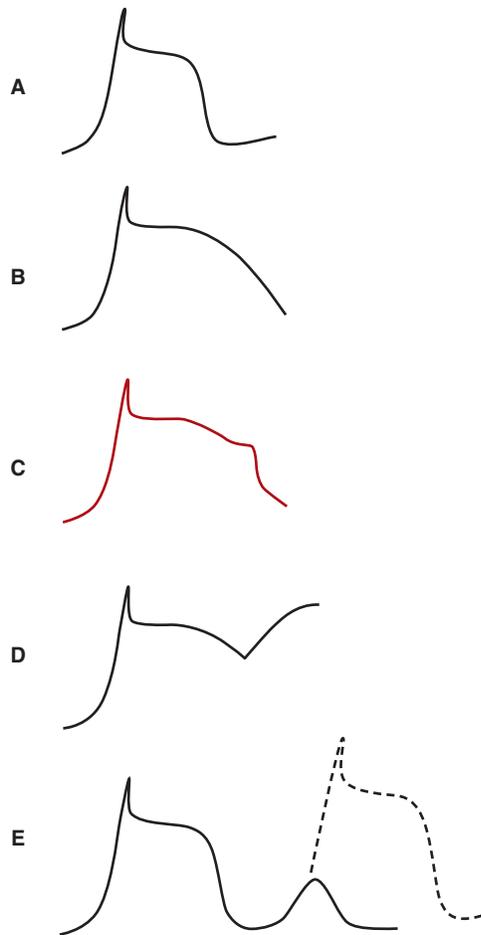

The QT interval varies in duration from lead to lead, reflecting a dispersion or variability in regional myocardial repolarization. Both QT and QTc dispersion can be calculated. The normal QT and QTc interval dispersions are 30 to 50 ms and 40 to 60 ms, respectively. The conduction characteristics vary regionally throughout the heart. For example, the subendocardial cells have a longer action potential duration than do epicardial cells; this is called dispersion of repolarization and is normal. This is important to allow the heart to contract and relax in an appropriate manner even though the impulse takes time to travel through the full thickness of the myocardial wall, from endocardium to epicardium. The subpopulations of the various ion channels (primarily potassium channels in the setting of repolarization) differ in character and density and account for this variation.<sup>43</sup> Ischemia and xenobiotics preferentially affect certain layers of the myocardium and alter—generally increasing—the regional heterogeneity of repolarization. M cells, located in the mid-myocardium, are very sensitive to the effects of xenobiotics that increase the repolarization heterogeneity.<sup>27</sup> This is reflected on the ECG as an increase in QT dispersion and a prolongation of the vulnerable period. This prolonged vulnerable phase is associated with occurrences of ventricular dysrhythmias. A measured QT dispersion greater than 80 ms after myocardial infarction was associated with ventricular tachycardia with a sensitivity rate of 73% and a specificity rate of 86%.<sup>48</sup> This heterogeneity is also correlated with both the efficacy and prodysrhythmic potential of therapy.<sup>62</sup> However, the overall assessment of QT dispersion (from a standard 12-lead ECG) has not gained popularity as a useful clinical tool.

### U Wave

The U wave is a small deflection that occurs after the T wave and usually with a similar orientation. Distinguishing a U wave from a notched T wave is difficult. The apices of a notched T wave are usually <150 ms apart, and the peaks of a TU complex are >150 ms apart.

**TABLE 15-2** Electrophysiologic Basis for Delayed Afterdepolarization and Early Afterdepolarization

	Phase of Action Potential Affected by Depolarization	Clinical Effect	Mechanism
Delayed afterdepolarization	Phase 4	Cardioactive steroid–induced dysrhythmias	↑ Intracellular $Ca^{2+}$ → Activation of a nonselective cation channel or $Na^+$ , $Ca^{2+}$ exchanger → Transient inward current carried mostly by $Na^+$ ions
Early afterdepolarization	Phase 2 Phase 3	↑ Repolarization time Long QT syndrome (hereditary and acquired) Drug-induced torsade de pointes, ventricular tachycardia	Multifactorial ( $K^+$ , $Na^+$ - $K^+$ , $Ca^{2+}$ , $Na^+$ currents)

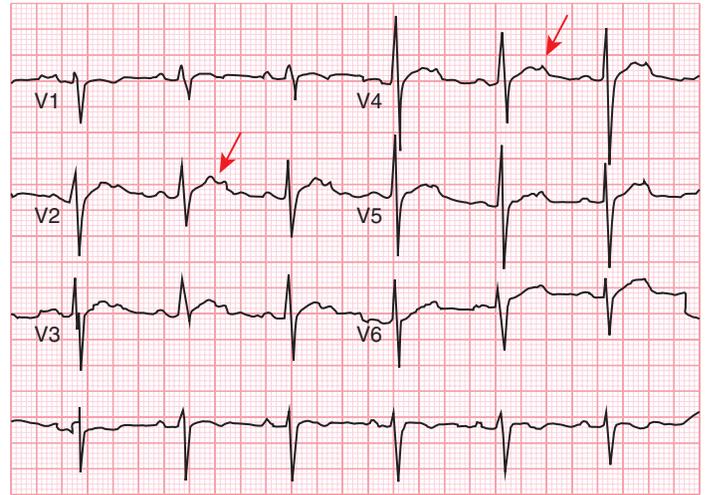

**FIGURE 15-18.** Afterdepolarization. (A) The normal action potential. (B) Prolonged duration action potential with an early afterdepolarization (EAD) occurring during the downslope of phase 3 of the action potential. (C) Prolonged duration action potential with an early afterdepolarization (EAD) occurring during the downslope of phase 3 of the action potential. (D) Early afterdepolarization that reaches the depolarization threshold and initiates another depolarization, or a triggered beat. (E) Delayed afterdepolarization, which occurs after repolarization is complete.

### Electrophysiology

U waves occur when there is fluctuation in the membrane potential following myocardial repolarization. Prominent U waves are generally representative of an underlying electrophysiologic abnormality, although they may be physiologic. Physiologic U waves are caused by repolarization of the Purkinje fibers, or they correspond to late repolarization of myocardial cells in the midmyocardium, and are implicated in the initiation of cardiac dysrhythmias.<sup>5</sup>

### Abnormal U Wave

Abnormal U waves are typically caused by spontaneous afterdepolarization of membrane potential that occurs in situations where repolarization is prolonged (Fig. 15-18). An EAD occurs in situations where the prolonged repolarization period allows calcium channels (which are both time and voltage dependent) to close and spontaneously reopen because they may close at a membrane potential that is above their threshold potential for opening. M cells in the mid-myocardium are particularly sensitive to xenobiotics causing prolonged repolarization and EADs. In this situation, the opening of the calcium channels produces a slight membrane depolarization identified as a U wave (Fig. 15-19). A delayed afterdepolarization (DAD) occurs during phase 4 of the action potential when the myocyte is overloaded with  $Ca^{2+}$ , as in the setting of cardioactive steroid toxicity. The excess intracellular  $Ca^{2+}$  can trigger the ryanodine receptors on the myocyte sarcoplasmic reticulum to release  $Ca^{2+}$ , causing slight depolarization that is erroneously recognized

**FIGURE 15-19.** A 20-year-old man with a loperamide overdose. ECG shows QT prolongation (420 ms) and possible U waves with T wave notching. (A) (Used with permission from Thomas Oliver MD, Walter Reed National Military Medical Center Endocrinology.)

as a U wave. If the afterdepolarization is of sufficient magnitude to reach the threshold, the cell can depolarize and initiate a premature ventricular contraction. Transient U-wave inversion can also be caused by myocardial ischemia or left ventricular overload as occurs in systemic hypertension.

### Abnormal QU Interval

The QU interval is the distance between the end of the Q wave and the end of the U wave. Differentiation between the QU and the QT intervals is difficult if the T and U waves are superimposed (Fig. 15-19). When hypomagnesemia coexists with hypokalemia, as is usually the case, QU prolongation and torsade de pointes can occur.

## CARDIAC DYSRHYTHMIAS AND CONDUCTION ABNORMALITIES

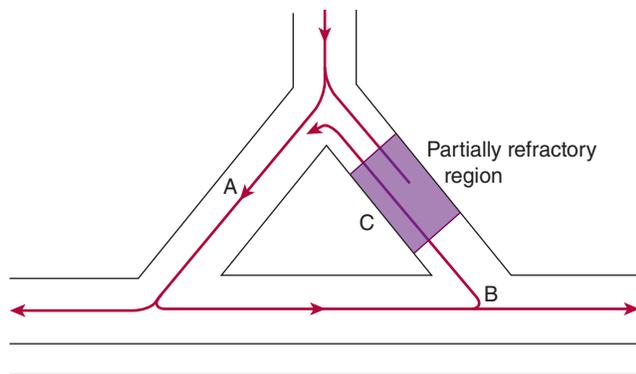

Xenobiotics produce adverse effects on the electrical activity of the heart, often by acting directly on the myocardial cells. Because metabolic abnormalities (especially acidemia, hypotension, hypoxia, and electrolyte abnormalities) further exacerbate the toxicity, or can actually be the sole cause of the cardiovascular abnormalities, correction of metabolic abnormalities must be a high priority in the treatment of patients with cardiovascular manifestations of poisoning. The terminal phase of any serious poisoning includes nonspecific hemodynamic abnormalities and cardiac dysrhythmias. However, many xenobiotics directly or indirectly affect cardiac rhythm or conduction, often through effects on the cardiac ion channels.

The distinction between xenobiotics that cause a rapid rate and those that cause a slow rate on the ECG is somewhat artificial, because many can do both. For example, patients poisoned by cyclic antidepressants almost always develop sinus tachycardia, but most who die will have a wide complex bradycardia immediately prior to death. In either case, abnormalities in the pattern or rate on the ECG can provide the clinician with immediate information about a patient's cardiovascular status. ECG disturbances in many poisoned patients are categorized in more than one manner (abnormal pattern, fast rate, slow rate). In any case, when ECG abnormalities are detected, appropriate interpretation, evaluation, and therapy must be rapidly performed.

Xenobiotics that directly cause dysrhythmias or cardiac conduction abnormalities usually affect the myocardial cell membrane. Other xenobiotics that modify ion channels alter the transmembrane potentials within myocytes and may result in the spontaneous generation of an abnormal rhythm.

### Mechanisms of Dysrhythmia Initiation and Propagation

Dysrhythmias are related to one or more of 3 mechanisms: abnormal spontaneous depolarization (enhanced automaticity), afterdepolarization

**FIGURE 15–20.** Mechanism of reentrant dysrhythmias. An impulse traveling down a conduction pathway reaches a branch point with one branch refractory (C). The impulse is conducted down branch A and spreads through the myocardium eventually to reach B, the distal end of the originally refractory branch. However, branch C is no longer refractory, and the impulse is conducted retrograde up through branch C, again to be conducted down branch A. The myocardium is depolarized during each loop around the circuit as the impulse spreads from the distal end of branch A to the rest of the heart.

(triggered automaticity), and reentry.<sup>43</sup> In normal myocardium, spontaneous, phase 4 depolarization occurs most rapidly in the sinus node, the normal pacemaker for the heart. Speeding or slowing the rate of phase 4 depolarization of the pacemaker cell results in sinus tachycardia or sinus bradycardia, respectively. However, xenobiotics can also speed the depolarization of other myocardial cells with pacemaker potential allowing them to overtake the sinus node as the primary pacemaker. This mechanism, called increased automaticity, accounts for many of the dysrhythmias that occur with cardioactive steroid and  $\beta$ -adrenergic agonist poisoning.

Afterdepolarizations, mentioned above, typically occur during phase 3 or 4 of the action potential and may reach the threshold potential, causing the fast  $\text{Na}^+$  channels to open and initiate an action potential. EADs account for the “trigger beats” that initiate episodes of ventricular tachycardia, commonly torsade de pointes (TdP), when the action potential is prolonged, as discussed below. DADs are typically associated with cardioactive steroid toxicity<sup>43</sup> and excessive sympathetic stimulation.

Most afterdepolarizations do not propagate rapidly throughout the myocardium and do not generate ectopic beats. However, because the normal dispersion of repolarization is increased by certain xenobiotics, ectopic beats (eg, atrial premature contraction or ventricular premature contraction) may propagate abnormally within the myocardium. Ectopy is the ECG manifestation of myocardial depolarization initiated from a site other than the sinus node. Ectopy may be lifesaving under circumstances in which the atrial rhythm cannot be conducted to the ventricles (ie, “escape rhythm”), as during high-degree AV blockade induced by cardioactive steroids (Chap. 62). Alternatively, ectopy may lead to dramatic alterations in the physiologic function of the heart or deteriorate into lethal ventricular dysrhythmias.

Occasionally, because of the altered regional repolarization (ie, increased dispersion of repolarization), an impulse reaches a branch point with a partial block (ie, relatively refractory) to conduction in one of the branches (Fig. 15–20). The impulse is carried through only one of the branches and then spreads through the myocardial cells. After a short delay, the impulse reaches the distal end of the previously blocked pathway. By this time, the region is no longer refractory and conducts the impulse in a retrograde fashion. The impulse continues in a continuous loop circuit, depolarizing the heart with each passage; this process is called reentry. Reentrant mechanisms appear to be responsible for the majority of the malignant tachydysrhythmias attributable to poisoning.

### Tachydysrhythmias

Both supraventricular and ventricular tachydysrhythmias occur in poisoned patients (Table 15–3). Sinus tachycardia is the most common rhythm disturbance that occurs in poisoned patients. Parasympatholytic xenobiotics, such

as atropine, raise the heart rate to its innate rate by eliminating the inhibitory tonic vagal influence. However, more rapid rates require direct myocardial stimulatory effects, generally mediated by  $\beta$ -adrenergic agonism. For example, catecholamine excess, as occurs in patients with cocaine use, psychomotor agitation, or fever, may cause sinus tachycardia with rates faster than 150 beats/min. Ventricular dysrhythmias frequently accompany hypotension, hypoxia, acidemia, electrolyte abnormalities, and other metabolic derangements that are present in poisoned patients or are a direct effect of the xenobiotic.

The intrinsic pacemaker cells of the heart undergo spontaneous depolarization and reach threshold at a predictable rate. Under normal circumstances, the sinus node is the most rapidly firing pacemaker cell of the heart; and as a result it controls the heart rate. Other potential pacemakers exist in the heart, but their rate of spontaneous depolarization is considerably slower than that of the sinus node. Thus, they are reset during depolarization of the myocardium and they never spontaneously reach threshold. Xenobiotics, such as sympathomimetics, which speed the rate of rise of phase 4, or diastolic depolarization, speed the rate of firing of the pacemaker cells. As long as the sinus node is preferentially affected, it maintains the pacemaker activity of the heart. If the firing rate of another intrinsic pacemaker exceeds that of the sinus node, ectopic rhythms develop.

Certain xenobiotics are highly associated with ventricular tachydysrhythmias following poisoning. Those that increase the adrenergic tone on the heart, either directly, or indirectly, cause ventricular dysrhythmias. Whether a result of excessive circulating catecholamines observed with cocaine and sympathomimetics, myocardial sensitization secondary to halogenated hydrocarbons or thyroid hormone, or increased second messenger activity secondary to methylxanthines, the extreme inotropic and chronotropic effects cause dysrhythmias. Altered repolarization, increased intracellular

**FIGURE 15-21.** Digoxin-induced bidirectional ventricular tachycardia. The ECG demonstrates the alternating QRS axis characteristic of bidirectional ventricular tachycardia and is nearly pathognomonic for cardioactive steroid poisoning. The 89-year-old patient's serum digoxin concentration was 4.0 ng/mL. (Used with permission from Ruben Olmedo, MD, Mount Sinai School of Medicine.)

Ca<sup>2+</sup> concentrations, or myocardial ischemia often cause dysrhythmias. Additionally, xenobiotics that produce focal myocardial ischemia, such as cocaine, ephedrine, or ergots often lead to malignant ventricular dysrhythmias. Finally, an uncommon cause of xenobiotic-induced ventricular dysrhythmias is persistent activation of sodium channels, such as following aconitine poisoning. Although not all prolonged QRS complex tachydysrhythmias are ventricular in origin, making this assumption is generally considered to be prudent. For example, in a patient poisoned with cyclic antidepressants or cocaine, the differentiation of aberrantly conducted sinus tachycardia (common) from ventricular tachycardia (rare) is important, but difficult. Although guidelines for determining the origin of a wide complex tachydysrhythmia exist, they are imperfect, difficult to apply, and unstudied in poisoned patients.<sup>4,67</sup>

Bidirectional ventricular tachycardia is associated with severe cardioactive steroid toxicity and results from alterations of intraventricular conduction, junctional tachycardia with aberrant intraventricular conduction, or, on rare occasions, alternating ventricular pacemakers (Fig. 15-21). Aconitine, usually obtained from traditional Chinese or other alternative therapies that contain plants of the *Aconitum* spp. (such as *Aconitum napellus* {monkshood}), cause bidirectional ventricular tachycardia (Chaps. 43 and 118).

### Tachydysrhythmia Associated With a Prolonged QT Interval: Torsade de Pointes

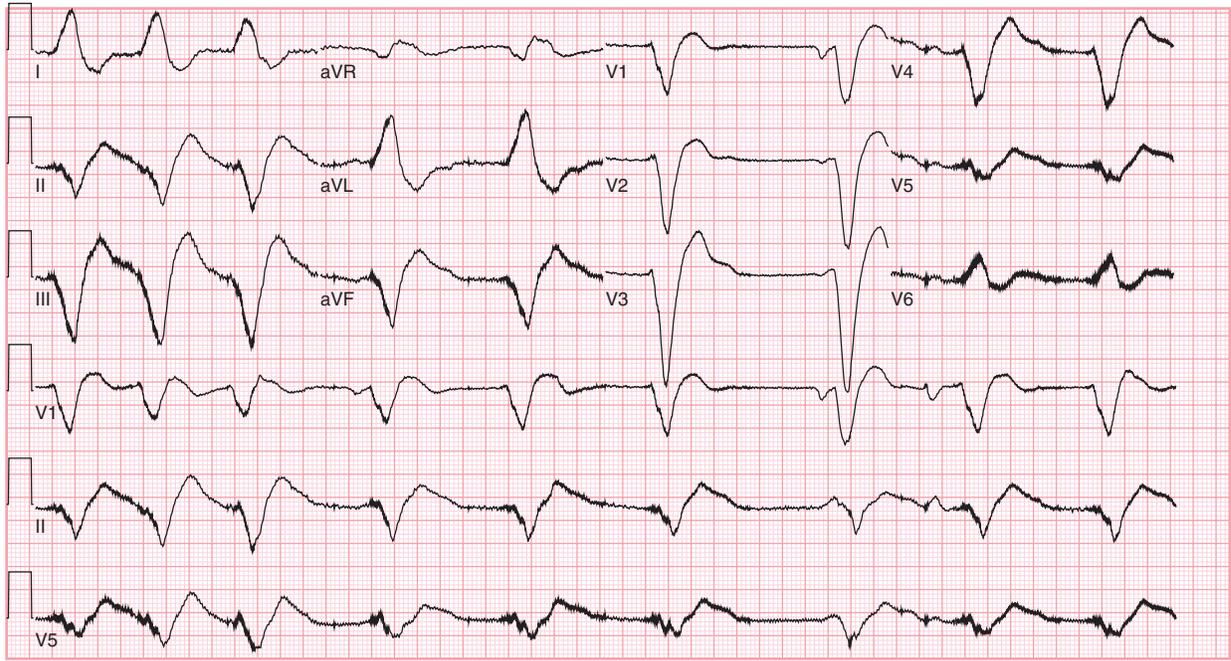

Xenobiotics that alter myocardial repolarization and prolong the QT interval predispose to the development of afterdepolarization-induced contractions during the relative refractory period (R on T phenomena), which initiates ventricular tachycardia. If torsade de pointes (TdP) is noted, this is undoubtedly the mechanism, and the QT interval should be carefully assessed and appropriate treatment initiated (Fig. 15-22).

Ventricular tachycardia, including TdP, is usually a reentrant-type rhythm. The presence of a prolonged QT interval on the ECG indicates the possible existence of conditions within the myocardium that favor occurrence of reentry dysrhythmias, as discussed above. The long action potential duration resulting from prolongation in the duration of phase 2 or 3 increases the occurrence of EADs. These, in combination with an increased dispersion of repolarization, increase the risk for reentrant dysrhythmias, particularly TdP.

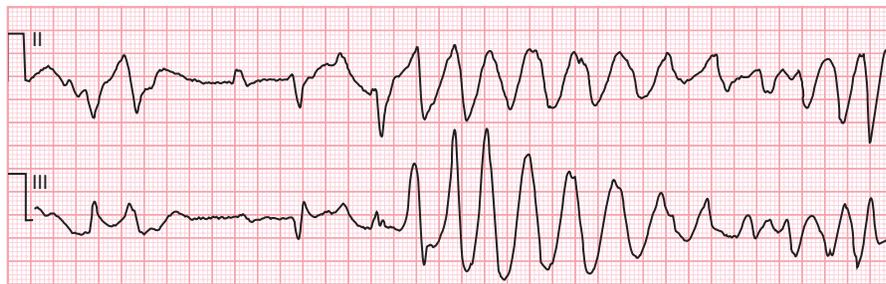

Many xenobiotics interact with cardiac membrane ion channels and increase the risk of TdP. Most of these xenobiotics interact with the hERG-encoded subunit of the potassium channel to reduce the current through the I<sub>Kr</sub> channel and prolong the action potential duration. The hERG subunit of the channel is particularly susceptible to xenobiotic interactions because of the larger inner cavity with aromatic-binding domains.<sup>51,512</sup> Acquired QT interval prolongation and TdP from xenobiotics occur most often with class IA and IC antidysrhythmics, the cyclic antidepressants, and the antipsychotics. Although class IC antidysrhythmics (such as encainide and flecainide) cause greater QT interval prolongation, class IA antidysrhythmics (such as quinidine and procainamide) are responsible for more reported cases. This is probably a result of the relatively infrequent use of the class IC antidysrhythmics, due paradoxically, to concerns about the higher risk of proarrhythmic effects. Class IB antidysrhythmics, such as lidocaine, have no significant effect on potassium channels and the QT interval, and do not cause TdP. Acquired QT interval prolongation and TdP also commonly result from metabolic and electrolyte abnormalities, particularly hypocalcemia, hypomagnesemia, and hypokalemia (Chaps. 12 and 57).

### Bradycardias

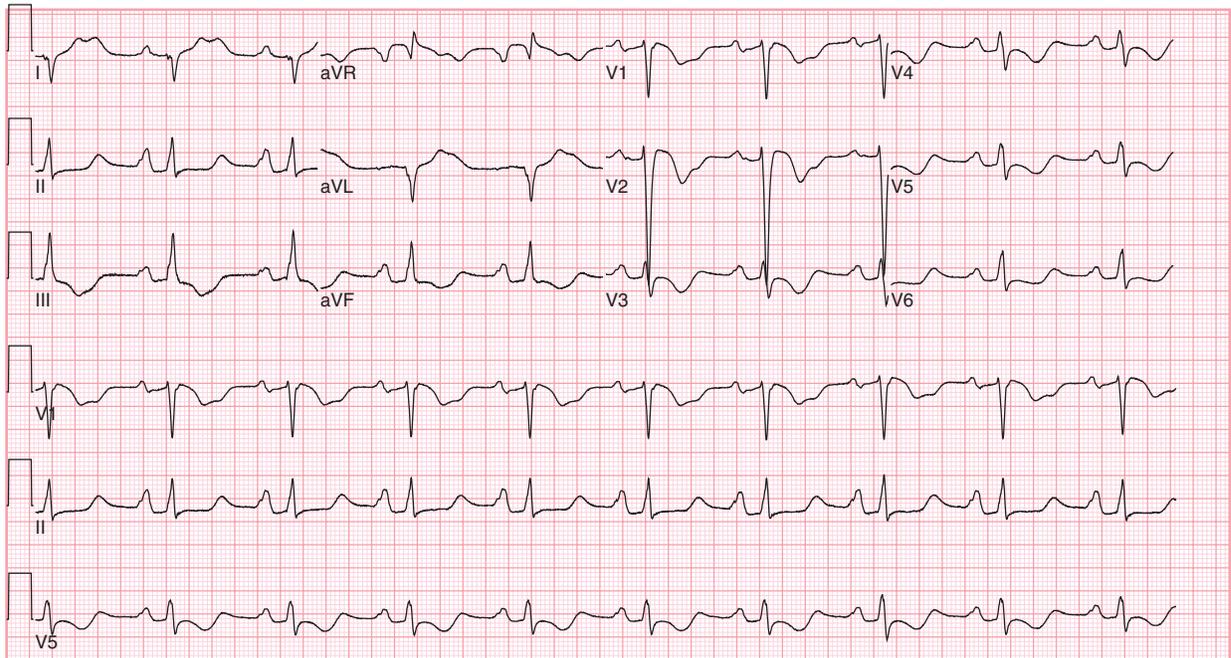

Bradycardia, heart block, and asystole are the terminal events following fatal ingestions of many xenobiotics, but some xenobiotics tend to cause sinus bradycardia (Table 16-2) and conduction abnormalities (Table 15-4) early in the course of toxicity. Sinus bradycardia with an otherwise normal electrocardiogram is characteristic of xenobiotics that reduce central nervous system outflow (Chap. 16). Xenobiotics that cause CNS sedation, such as the sedative-hypnotics, most opioids, and α<sub>2</sub>-adrenergic receptor agonist ("centrally acting") antihypertensives, and imidazolines will usually decrease sympathetic outflow to the heart and produce a heart rate in the range of 40 to 60 beats/min. Xenobiotics that directly affect ion flux across myocardial cell membranes cause abnormalities in AV nodal conduction. β-adrenergic antagonists, calcium channel blockers, and cardioactive steroids (Chaps. 59, 60, and 62) are the leading causes of sinus bradycardia and conduction disturbances. Indirect metabolic effects are also contributory, such as severe hyperkalemia (which may accompany any acidosis), causing a wide complex, sinusoidal bradycardic rhythm.

Xenobiotics with direct depressant effects on the cardiac pacemaker are most likely to produce bradycardia. The ECG manifestations of calcium channel blocker and  $\beta$ -adrenergic antagonist overdoses are challenging to distinguish. In general, both decrease dromotropy (conduction), although the specific pharmacologic actions of the drugs differ even within the class. For example, most members of the dihydropyridine subclass of calcium channel blockers do not have any antidromotropic effect, whereas verapamil and diltiazem routinely produce PR prolongation. Similarly, although most  $\beta$ -adrenergic antagonists produce sinus bradycardia and first-degree heart block, certain members of this group, such as propranolol, prolong the QRS complex through their  $\text{Na}^+$  channel–blocking abilities (Chap. 59). Others, such as sotalol, which has properties of the class III antidysrhythmics, block myocardial potassium channels and prolong the QT interval duration. Bradycardia associated with cardioactive steroids is typically accompanied by electrocardiographic signs of “digitalis effect,” including PR prolongation and ST segment depression (Chap. 62).

### CONDUCTION ABNORMALITIES AND AV NODAL BLOCK

The cardiac toxicity of some xenobiotics results from their effects on the propagation of the electrical impulse through the conduction system of the heart. The ECG abnormalities produced are a result of effects on the AV node, producing first-, second-, or third-degree (complete) heart block, or on the His-Purkinje system, producing intraventricular conduction delays such as bundle-branch blocks. The effects of xenobiotics on myocardial conduction are often mediated through interactions with the sodium or potassium membrane channels. For example, xenobiotics that affect the fast inward  $\text{I}_{\text{Na}}$  currents (such as the type I antidysrhythmics and cyclic antidepressants)

prolong the action potential duration, slow ventricular myocyte depolarization, and slow intraventricular conduction. This produces widening of the QRS complex and prolongation of the QT interval on the ECG. Table 15–4 lists some of the xenobiotics that cause conduction abnormalities. Many of the antidysrhythmics derive their clinical benefit from their ability to alter sodium and potassium channel function and slow conduction through the myocardium. Xenobiotics that depress phase 0 (the inward  $\text{I}_{\text{Na}}$  currents) produce slowing of conduction and widening of the QRS complex. Xenobiotics that prolong depolarization and repolarization (phase 2 or 3 of the action potential) produce prolongation of the QT interval on the ECG. The classes of the antidysrhythmics, their effects on the ion channels and on the action potential, and the resulting ECG abnormalities, are shown in Table 57–1 and discussed in detail in Chapters 16 and 57.

## PEDIATRIC ECG

### Normal Pediatric ECG

The normal pediatric ECG differs in many ways from the normal adult ECG. The resting heart rate of infants and children is substantially faster than that of adults and, in general, conduction is faster. In a term infant, the right ventricle is substantially larger than the left, and the ECG demonstrates prominent R waves in the right precordium and deep S waves in the left lateral precordium.<sup>46</sup> This can be misinterpreted as cyclic antidepressant toxicity.<sup>11</sup> An adult ratio of left to right ventricular size is usually reached by the age of 6 months. In infants, Q waves commonly exist in the inferior and lateral precordial leads, but are abnormal in leads I and  $\text{aV}_1$ . The T waves are the most notable difference between pediatric and adult ECGs. The T waves in the right precordial leads in children are deeply inverted until 7 years and sometimes older, in which case it is called a persistent juvenile T-wave pattern.

### Abnormal Pediatric ECG

Although congenital heart disease is the most common cause of ECG abnormalities in children, electrolyte disorders and xenobiotics also cause changes in electrophysiology that are reflected on the ECG. Abnormalities that are useful markers on the adult ECG are not always as useful in children. For example, in older children, a retrospective chart review of 37 children diagnosed with tricyclic antidepressant overdose and 35 controls (<11 years) found interpatient variability, unrelated to age, so great that a rightward deviation of the terminal 40-ms QRS axis could not distinguish between poisoned and healthy children.<sup>11</sup>

## SUMMARY

- Electrocardiography is one of the few widely available diagnostic procedures that reveals immediate, useful clinical information.
- A thorough mechanistic understanding of the etiologies of the various waves and intervals will help provide an early clue to the etiology of a patient’s toxicity.
- QRS prolongation is characteristic of sodium channel blockade.
- QT prolongation is characteristic of potassium channel blockade.

## CARDIOLOGIC PRINCIPLES II: HEMODYNAMICS

Rachel S. Wightman and Robert A. Hessler

Adequate tissue perfusion depends on maintenance of volume status, vascular resistance, cardiac contractility, and cardiac rhythm. All of these components of the hemodynamic system are vulnerable to the effects of xenobiotics. Cardiovascular toxicity is manifested by the development of hemodynamic instability, heart failure, cardiac conduction abnormalities, or dysrhythmias. The presence of a specific pattern of cardiovascular anomalies (toxicologic syndrome or “toxidrome”) often suggests a particular class or type of xenobiotic.

In addition, an alteration in hemodynamic functioning is frequently the indirect result of metabolic abnormalities. Poisoning with a xenobiotic often leads to development of acid–base disturbances, hypoxia, or electrolyte abnormalities with secondary hemodynamic changes. In these patients, supportive care with ventilation, oxygenation, and fluid and electrolyte repletion can dramatically improve the cardiovascular status.

### PHYSIOLOGY OF THE CARDIOVASCULAR SYSTEM

Maintaining cardiac contractility, heart rate and rhythm, and vascular resistance requires complex modulation of the cardiac and vascular systems. Xenobiotics cause hemodynamic abnormalities as a result of direct effects on the myocardial cells, the cardiac conduction system, or on the arteriolar smooth muscle cells. These effects are frequently mediated by interactions with cellular ion channels or cell membrane neurohormonal receptors. These complex cellular systems provide multiple sites for xenobiotics to demonstrate their toxicologic effects. Xenobiotics and xenobiotic metabolites interact with the cellular receptors, intracellular signal mechanisms, effector enzymes, or intracellular organelles.

Toxic effects of xenobiotics can be due to direct poisoning from excessive amounts of a xenobiotic that follow an overdose. Slower accumulation of the xenobiotic or active metabolites (due to alterations in metabolism) also leads to adverse effects. Additionally, the toxic effects of a xenobiotic can be altered by the characteristics of the host subject. Underlying medical conditions, presence of other xenobiotics, electrolyte abnormalities, concurrent acid–base, and hydration status contribute to the potential adverse hemodynamic effects of a xenobiotic. Even with a small concentration of a xenobiotic, hemodynamic toxicity may occur due entirely to underlying genetic differences in the cellular receptors or the intracellular signal transducers in the particular patient.

This complex interaction between the xenobiotic and patient’s physiology and genetic diversity is exemplified by the Brugada syndrome. This congenital cardiac channelopathy (Chaps. 15 and 57) predisposes to sudden cardiac death due to polymorphic ventricular tachycardia or ventricular fibrillation. Brugada syndrome is characterized by an atypical right bundle branch pattern with a characteristic cove-shaped ST segment elevation in leads V1 to V3 of the electrocardiogram (ECG) in the absence or structural heart disease, ischemia, or electrolyte disturbances).<sup>10,83</sup> This typical type 1 Brugada ECG pattern is shown in Fig. 15-12. However, this distinctive ECG pattern can be covert<sup>30</sup> and only unmasked by sleep, fever, bradycardia, or by xenobiotics such as vagotonic medications or class I antidysrhythmics (sodium channel blockers).<sup>4,59</sup> The reason for this variable and dynamic response to xenobiotics is the heterogeneous genetic basis of the disorder. Mutations in each of 10 different genes have been linked to the Brugada syndrome; more than 300 different mutations have been identified in the *SCN5A* gene alone which encodes the  $\alpha$  subunit of the cardiac sodium channel. Brugada syndrome is also associated with mutations in other cardiac ion channels and with mutations of the glycerol-3-phosphate 1-like (GDP1L) gene, which interacts with the cardiac sodium channel subunits at the cell membrane.<sup>5</sup> The complexity

of the potential xenobiotic interactions and variable potential for toxicity has led to the establishment of a Web page ([www.brugadadrugs.org](http://www.brugadadrugs.org)) to provide up-to-date classification of xenobiotics into those to avoid, those to preferably avoid, and those to potentially use for treatment.<sup>11,59</sup>

### AUTONOMIC NERVOUS SYSTEM AND HEMODYNAMICS

In addition to the voltage-dependent ion channels, the cell membrane contains channels that open in response to receptor binding of neurotransmitters or neurohormones.<sup>60,61</sup> The hemodynamic effects of many xenobiotics are mediated by interactions with membrane receptors and by changes in the autonomic nervous system. The autonomic nervous system is functionally divided into the sympathetic (ie, adrenergic) and parasympathetic (ie, cholinergic) systems. The 2 systems, which share certain common features, function semi-independently of each other. The sympathetic nervous system is primarily responsible for the maintenance of arteriolar tone and cardiac inotropy and chronotropy through the release of norepinephrine and epinephrine. The parasympathetic nervous system opposes the sympathetic nervous system and reduces overall cardiovascular response such as through vagal nerve innervation of the heart, resulting in reduced heart rate. Through complex feedback, the 2 systems provide the balance needed for existence under changing external conditions.

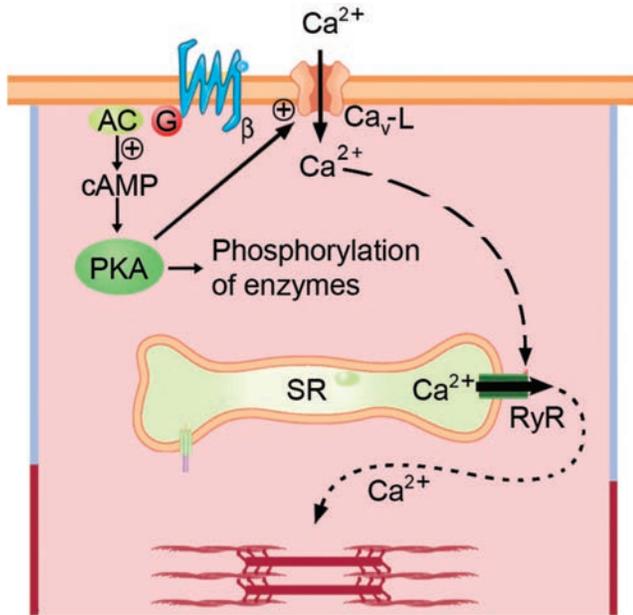

#### Adrenergic Receptors

##### Cellular Physiology of Adrenergic Receptors

The effects of adrenergic xenobiotics on the cell are primarily mediated through a secondary messenger system of cyclic adenosine monophosphate (cAMP). The intracellular cAMP concentration is regulated by the membrane interaction of 3 components: the adrenergic receptor, a G-protein complex, and adenylate cyclase, the (enzyme that synthesizes cAMP in the cell).<sup>13,27,76,77</sup> These receptors are described in detail in Chapter 13.

The G proteins serve as “signal transducers” between the receptor molecule in the cell membrane and the effector enzyme, adenylate cyclase, in the cytosol. The G proteins consist of 3 subunits:  $\alpha$ ,  $\beta$ , and  $\gamma$ .<sup>17,54,55</sup> The  $\alpha$  subunit of a G protein complex binds to the adrenergic receptor in the cell membrane and to the adenylate cyclase enzyme. The G protein complex exists in several isomeric forms, depending on their interactions with adenylate cyclase. These forms,  $G_s$ ,  $G_i$ , and  $G_q$  have different functions in the regulation of cellular activity. The  $G_s$  protein complexes contain  $\alpha_s$  subunits that stimulate adenylate cyclase when “activated” by adrenergic receptor interaction. These  $G_s$  complexes are primarily responsible for the stimulatory activity of  $\beta$ -adrenergic agonist agents.  $\beta_1$ - and  $\beta_2$ -adrenergic receptors interact primarily with  $\beta_s$  subunits in stimulatory  $G_s$  protein complexes. The  $\alpha_i$  subunits of  $G_i$  proteins inhibit the activity of adenylate cyclase. Some  $\beta_2$ -adrenergic receptors and the  $\alpha_2$ -adrenergic receptors interact with inhibitory  $G_i$  proteins to decrease the activity of adenylate cyclase. A third form,  $G_q$  interacts with the  $\alpha_1$ -adrenergic receptors but does not interact directly with adenylate cyclase. Instead, the  $G_q$  interacts with phospholipase C to mediate the cell response to  $\alpha_1$ -adrenergic stimulation.

The G protein complex is composed of the cellular receptor and the 3 subunits,  $\alpha$ ,  $\beta$ , and  $\gamma$ , which are involved in the cellular response to catecholamines. In the absence of a catecholamine at the receptor site, the receptor protein is bound to the  $\beta$  and  $\beta$ - $\gamma$ -dimer of the G protein, and guanosine diphosphate (GDP) is bound to the  $\alpha$  subunit. Catecholamine binding to the receptor causes a conformational change in the  $\alpha$  subunit; GDP dissociates and guanosine triphosphate (GTP) binds to the  $\alpha$  subunit. The  $\alpha$  subunit (with GTP bound) then dissociates from the receptor and from

**FIGURE 16-1.** Binding of the  $\beta$ -adrenergic agonist to the  $\beta$  receptor of a myocardial cell causes the  $G_s$  protein to activate AC to produce cAMP. The cAMP interacts with and activates PKA. Subsequent phosphorylation by PKA changes the activity of multiple other various cellular proteins, including phospholamban, calcium channels, and troponin, all of which increase the activity of the myocardial cell. Refer to the text for more details. AC = adenylyl cyclase; cAMP = cyclic adenosine monophosphate;  $Ca_v-L$  = L-type voltage-dependent calcium channel; PKA = protein kinase A; RyR = ryanodine receptor; SR = sarcoplasmic reticulum.

the  $\beta$ - $\gamma$ -dimer. This “activated”  $\alpha$  subunit then interacts with adenylyl cyclase or other effector enzymes. Interaction of the  $\alpha_s$  subunit with adenylyl cyclase increases the activity of the enzyme, resulting in a rapid increase in the intracellular cAMP (Fig. 16-1).<sup>13,17,45,54</sup>

Cyclic AMP acts as a secondary messenger in the cell. Cyclic AMP interacts with protein kinase A (PKA) and other cAMP-dependent protein kinases to increase their protein phosphorylating activity.<sup>44</sup> In the absence of cAMP, PKA is a tetramer of 2 regulatory and 2 catalytic subunits. Cyclic AMP binds to the regulatory subunits to release the active enzymatic units from the tetramer (Fig. 16-1). The activated protein kinases then transfer phosphate groups from ATP to serine (as well as to threonine and tyrosine amino acid groups) on enzymes that are involved in intracellular regulation and activities. Phosphorylation increases or decreases the activity of specific enzymes, and specific protein kinases are highly selective in the proteins that they phosphorylate.<sup>73,74</sup>

Protein kinase A phosphorylates a variety of cellular proteins involved in  $Ca^{2+}$  regulation, including the voltage-sensitive  $Ca^{2+}$  channel, phospholamban, and troponin,<sup>31,32,72</sup> which are involved in the regulation and control of cellular muscle fiber contraction. Phosphorylation of the L-type calcium channel increases the entry of  $Ca^{2+}$  ions into the cell during membrane depolarization.<sup>58</sup> Phosphorylation of phospholamban decreases its ability to inhibit the calcium ATPase pump on the sarcoplasmic reticulum (SR). Decreased inhibition of the calcium ATPase pump on the SR increases the efficiency of  $Ca^{2+}$  storage in the SR, which enhances both the cellular contractility as the  $Ca^{2+}$  is released into the cell cytosol and the relaxation of muscle fibers as the  $Ca^{2+}$  is pumped back into the SR.<sup>58</sup>

### Physiologic Effects of Adrenergic Receptor Subclasses

The existence of 2 types of adrenergic receptors,  $\alpha$  and  $\beta$ , was first proposed in 1948 to explain both the excitatory and the inhibitory effects of catecholamines on different smooth muscle tissue.<sup>1</sup> The  $\alpha$  receptor was subsequently subdivided into  $\alpha_1$  and  $\alpha_2$  when norepinephrine and other  $\alpha$ -adrenergic agonists were found to inhibit the release of additional norepinephrine from neurons into the synapse. The  $\alpha_1$ -adrenergic receptors are

located on postsynaptic cells outside the central nervous system, primarily on blood vessels, and mediate arteriolar constriction. The “autoregulatory”  $\alpha_2$ -adrenergic receptors are primarily located on the presynaptic neuronal membrane and, when stimulated, decrease release of additional norepinephrine into the synapse. Additionally, some  $\alpha_2$ -adrenergic receptors are also found on the postsynaptic membrane in the central nervous system. Activation of these postsynaptic  $\alpha_2$ -receptors in the cardiovascular control center in the medulla and elsewhere in the central nervous system decreases sympathetic outflow from the brain. Thus,  $\alpha_2$ -adrenergic agonists generally decrease peripheral vascular resistance, decrease heart rate, and decrease blood pressure. The  $\alpha_1$ - and  $\alpha_2$ -adrenergic receptors also interact with circulating catecholamines and other sympathomimetics. The effects of sympathomimetics vary in the different organ systems as a result of differences in the adrenergic receptors and in the cellular responses to the receptor interactions.

The  $\beta$ -adrenergic receptors are subclassified into 3 subtypes:  $\beta_1$ ,  $\beta_2$ , and  $\beta_3$  (Table 16-1). The most prevalent  $\beta$ -adrenergic subtype in the heart is  $\beta_1$  (80%), although  $\beta_2$  (20%) and  $\beta_3$  (few) receptors are also present.<sup>9,20,26,60</sup> Stimulation of the  $\beta_1$ -adrenergic receptors increases heart rate, contractility, conduction velocity, and automaticity. The  $\beta_2$ -adrenergic receptors primarily cause relaxation of smooth muscle with resulting bronchodilation and arteriolar dilation. The  $\beta_3$  receptors are located primarily on adipocytes, where they play a role in lipolysis and thermogenesis.<sup>14</sup> With normal aging and in the setting of heart failure, a decline in  $\beta$ -adrenergic responsiveness referred to as “ $\beta$ -adrenergic desensitization” occurs. This process is believed to be due to a decrease in  $\beta_1$ -adrenergic receptor density in cardiac myocytes, alterations in signaling of G-proteins and kinase activity, and an increase in baseline circulating plasma norepinephrine and epinephrine levels.<sup>22,81</sup>

The  $\beta_1$ - and  $\beta_2$ -receptors interact with  $G_s$  proteins and stimulate the adenylyl cyclase enzyme. Differences in the resultant clinical effects are primarily related to the location and number of the different receptors in different tissues and to differences in the specificity of the tissue protein kinases activated by cAMP. Stimulation of the  $\beta_1$ -adrenergic receptor results in increased heart rate and increased contractility.  $\beta_2$ -Adrenergic receptor stimulation causes relaxation, as opposed to contraction, of smooth muscle. Because both  $\beta$ -adrenergic receptor subtypes interact with stimulatory  $G_s$  proteins, their clinical effects would appear to be paradoxical. However, there are 2 primary reasons for their different effects when  $G_s$  complexes are stimulated by  $\beta_1$ - or  $\beta_2$ -adrenergic agonists. First, PKA is

**TABLE 16-1** Types and Function of the  $\beta$ -Adrenergic Receptors

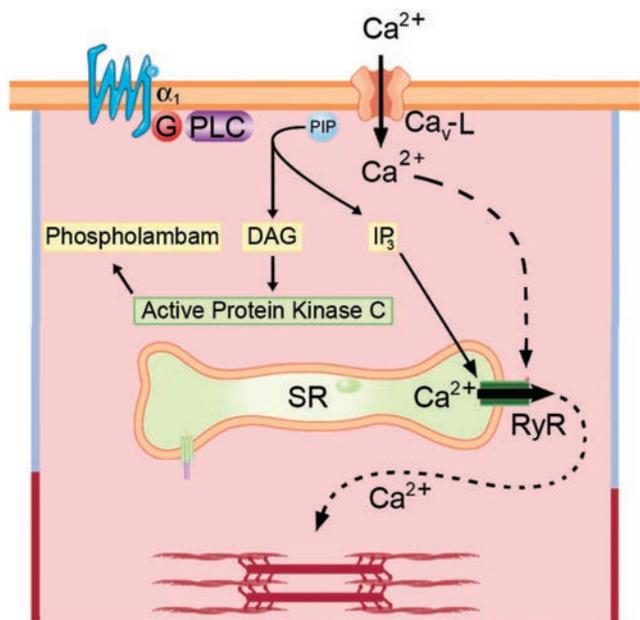

TYPE	Location	Function
$\beta_1$	Heart	Increase rate Increase inotropy Increase sinoatrial and atrioventricular node conduction
	Kidney	Increase renin
	Eye	Increase aqueous humor
	Adipose tissue	Increase lipolysis
$\beta_2$	Heart	Increase rate Increase inotropy
	Liver	Increase glycogenolysis Increase gluconeogenesis
	Skeletal muscle	Increase glycogenolysis
	Smooth muscle (bronchi, arterioles, gastrointestinal tract, uterus)	Relaxation
$\beta_3$	Adipose tissue	Increase lipolysis and thermogenesis
	Bladder	Increases relaxation
	Heart	Decrease inotropy

not a single enzyme, but a group of related enzymes variably expressed in different tissues.<sup>8,35,56</sup> The actions and the substrates of the varied protein kinase enzymes differs between  $\beta_1$ - and  $\beta_2$ -adrenergic responsive tissues. Second, whereas  $\beta_1$ -adrenergic stimulation results in cAMP-mediated effects throughout the cytoplasm,  $\beta_2$ -adrenergic stimulation is compartmentalized within the cell. The effect of  $\beta_2$ -adrenergic stimulation of  $G_s$ -type receptors is primarily localized phosphorylation of the L-type calcium channels, increasing their activity.<sup>16,39,84,85</sup> Additionally, some  $\beta_2$ -adrenergic receptors are also coupled to  $G_i$ -type receptors that inhibit adenylate cyclase and prevent the diffuse cytoplasmic increases in cAMP.<sup>69,70,85</sup> Also,  $\beta_2$ -adrenergic receptor stimulation does not result in phosphorylation of phospholamban<sup>42</sup> or troponins.<sup>16</sup>

The  $\alpha_2$ -adrenergic receptor interacts with a  $G_i$  protein that has an inhibitory interaction with adenylate cyclase. Binding of  $\alpha_2$ -adrenergic agonists to the receptor inhibits (not stimulates) adenylate cyclase and decreases intracellular cAMP.

The  $\alpha_1$ -adrenergic receptors also are associated with G proteins. However, rather than being associated with  $G_s$  proteins and adenylate cyclase, the  $\alpha_1$ -adrenergic receptors are associated with  $G_q$  proteins that are linked to phospholipase C.<sup>75</sup> Agonist binding to the receptor activates the hydrolysis of phosphatidyl inositol 4,5-bisphosphate ( $PIP_2$ ) to 1,2-diacylglycerol (DAG) and inositol triphosphate ( $IP_3$ ).<sup>29</sup> The  $IP_3$  acts as an intracellular messenger, binds to receptors on the SR, and initiates the release of calcium ion.<sup>6</sup> 1,2-Diacylglycerol activates protein kinase C, which phosphorylates slow  $Ca^{2+}$  channels and other intracellular proteins, and increases the influx of  $Ca^{2+}$  ion into the cell (Fig. 16-2).<sup>62,68,87</sup>

Many xenobiotics interact with G-protein membrane receptors and alter the intracellular cAMP or  $Ca^{2+}$  concentration.  $\beta$ -Adrenergic antagonist overdose results in decreased stimulation of adenylate cyclase by  $G_s$  proteins, decreased production of cAMP, decreased activation of the cAMP-dependent kinases, and decreased  $Ca^{2+}$  release (Chap. 59). Similarly, by different mechanisms,  $Ca^{2+}$  channel blocker overdose results in decreased cytoplasmic [ $Ca^{2+}$ ] concentration (Chap. 60).

**FIGURE 16-2.** Binding of the  $\alpha$ -adrenergic agonist to the  $\alpha_1$ -adrenergic receptor causes the  $G_q$  protein to activate PLC. PLC catalyzes the hydrolysis of  $PIP_2$  to produce DAG and  $IP_3$ .  $IP_3$  interacts with the RyR on the sarcoplasmic reticulum to enhance release of  $Ca^{2+}$  from this cellular store. The  $Ca^{2+}$  and DAG activate protein kinase C, which phosphorylates and changes the activity of various cellular proteins, including phospholamban. Refer to the text for more details.  $Ca_V-L$  = L-type voltage-dependent  $Ca^{2+}$  channel; DAG = 1,2-diacylglycerol;  $IP_3$  = inositol triphosphate;  $PIP_2$  = 4,5-bisphosphate; PLC = phospholipase C; RyR = ryanodine receptor.

Glucagon receptors, which resemble  $\beta$ -adrenergic receptors, are coupled to the same  $G_s$  proteins as  $\beta$ -adrenergic receptors and thus stimulate adenylate cyclase activity.<sup>28,86</sup> The ability of glucagon to increase cAMP is further enhanced by its inhibitory activity on phosphodiesterase (preventing cAMP breakdown).<sup>21,51</sup> Phosphodiesterase inhibitors, such as amrinone, milrinone, and enoximone, exert at least some of their inotropic activity by preventing the degradation of cAMP and enhancing calcium cycling.<sup>46,79,82</sup> In a canine model of propranolol poisoning, amrinone significantly increased inotropy, stroke volume, and cardiac output.<sup>46</sup>

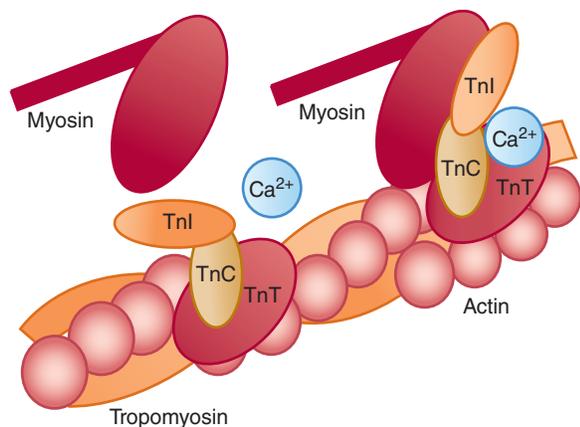

### INTRACELLULAR CALCIUM, CALCIUM CHANNELS, AND MYOCYTE CONTRACTILITY

The contraction and relaxation cycle of the myocyte is controlled by the flux of  $Ca^{2+}$  into and out of the SR into the cytoplasm of the cell.<sup>18,43,63</sup> Only a small proportion of the  $Ca^{2+}$  involved in myofibril contraction actually enters the cell through the exterior cell membrane during the action potential and membrane depolarization. Most of the  $Ca^{2+}$  is actually released from the SR of the cell invaginations of the myocyte membrane known as T-tubules, which place L-type  $Ca^{2+}$  channels in close approximation to calcium-release channels (ryanodine receptors {RyR}) on the sarcoplasmic reticulum. The local increase in  $Ca^{2+}$  concentration that follows the opening of a single L-type calcium channel triggers the opening of the associated RyR channels, resulting in a large release of  $Ca^{2+}$  from the SR.<sup>15</sup> Myocytes contain tens of thousands of *couplons*, clusters of L-type calcium channels and RyR channels. The  $Ca^{2+}$  released from one couplon is not sufficient to trigger firing of neighboring couplons. Therefore, myocyte contraction requires synchronized release of  $Ca^{2+}$  from numerous couplons throughout the myocyte. The cell membrane depolarization synchronizes opening of L-type channels and subsequent  $Ca^{2+}$  release from the sarcoplasmic reticulum.<sup>19,58</sup> This phenomenon of  $Ca^{2+}$ -induced  $Ca^{2+}$  release results in a rapid increase in the intracellular [ $Ca^{2+}$ ] and initiates a rapid myosin and actin interaction.<sup>18</sup>

At the conclusion of cellular contraction, SR-associated  $Ca^{2+}$ -adenosine triphosphatase (ATPase) pumps return the cytosolic  $Ca^{2+}$ -ATPase into the SR. This SR-associated  $Ca^{2+}$ -ATPase pump is regulated by phospholamban, a cellular protein. When phospholamban is bound to the  $Ca^{2+}$ -ATPase pump, the activity of the pump is decreased and less  $Ca^{2+}$ -ATPase is stored in the SR. Phosphorylation of phospholamban decreases its affinity for binding to the  $Ca^{2+}$ -ATPase pump. Dissociation of the phosphorylated phospholamban increases the activity of the  $Ca^{2+}$ -ATPase pump.  $\beta$ -Adrenergic stimulation increases protein kinase activity and leads to phosphorylation of phospholamban, dissociation of the phosphorylated phospholamban from the pump, and an increase in the total SR  $Ca^{2+}$  stores.<sup>24,25</sup> The increased activity of the SR associated  $Ca^{2+}$ -ATPase pump enhances the contractility and increases the rate of relaxation of the myocytes.

Cellular contraction occurs when myosin filaments interact with the actin-tropomyosin helix. A complex of troponins T, I, and C binds to the actin helix near the myosin-binding site and act as regulators of the interaction. Troponin T binds the regulatory complex to the actin helix, troponin I prevents myosin from accessing its binding site on the actin helix, and troponin C acts as a  $Ca^{2+}$  trigger to initiate contraction. When the intracellular [ $Ca^{2+}$ ] increases, 4 molecules of  $Ca^{2+}$  bind to troponin C and a conformational shift occurs in the troponin complex. Troponin I shifts away and the myosin-binding site is exposed. Myosin then binds to the exposed site and myofibril contraction occurs (Fig. 16-3).<sup>36,37,64,65</sup>

Calcium transport through the cellular membrane ion channels is critical for normal cardiac muscle function and contractility and for maintenance of vascular smooth muscle tone. The physiologic response to  $Ca^{2+}$  channel blockers and to xenobiotics that interact with the  $\alpha$ - or  $\beta$ -adrenergic receptors is mediated through changes in the intracellular  $Ca^{2+}$  concentration. Calcium channel blockers in current clinical use primarily block the L-type  $Ca^{2+}$  channel, although their specificity differs for the  $Ca^{2+}$  channels on the vascular smooth muscle cells versus on the myocardial cells. Dihydropyridine  $Ca^{2+}$  channel blockers preferentially act on peripheral vascular smooth muscle cells, whereas non-dihydropyridine  $Ca^{2+}$  channel blockers exert

**FIGURE 16-3.** Troponin regulation of actin and myosin interaction. On the left, TnI blocks the binding site for myosin on the tropomyosin-actin helix. On the right,  $\text{Ca}^{2+}$  binding to TnC causes a conformational shift in the troponin molecules, and myosin binds to the actin helix and initiates myofibril contraction. TnC = troponin C; TnI = troponin I; TnT = troponin T.

stronger central effects. This results in variable effects of the different  $\text{Ca}^{2+}$  channel blockers on the vascular tone and peripheral vascular resistance, and on the contractility and electrical activity of the myocardial cells.

Patients poisoned by  $\text{Ca}^{2+}$  channel blockers have less  $\text{Ca}^{2+}$  entry into the cell during cardiac membrane depolarization. Administration of exogenous  $\text{Ca}^{2+}$  increases the concentration gradient across the cell membrane, enhances flow through available  $\text{Ca}^{2+}$  channels, and restores the triggered response of the RyR-2 channels to release  $\text{Ca}^{2+}$  from the sarcoplasmic reticulum (Antidotes in Depth: A32). Because  $\beta$ -adrenergic antagonists have negative effects on  $\text{Ca}^{2+}$  handling by the SR, similar effects occur in the myocyte affected by  $\beta$ -adrenergic antagonists.

In the vascular smooth muscle, the cytosolic  $[\text{Ca}^{2+}]$  maintains the basal contraction of the vascular muscle. Any decrease of  $\text{Ca}^{2+}$  influx results in relaxation and arterial vasodilation.<sup>55</sup> Any influx of  $\text{Ca}^{2+}$  binds calmodulin, and the resulting complex stimulates myosin light-chain kinase activity.<sup>47</sup> The myosin light-chain kinase phosphorylates myosin. The phosphorylated myosin has increased activity for binding to actin, which causes contraction (Fig. 60-1).<sup>7,37</sup>

## CARDIOVASCULAR EFFECTS OF XENOBIOTICS

Certain xenobiotics produce adverse effects on the cardiovascular system by acting on the myocardial cells or the autonomic nervous system to directly affect the heart rate, blood pressure, or cardiac contractility. Because metabolic abnormalities (especially acidemia, hypotension, hypoxia, and electrolyte abnormalities) can further exacerbate toxicity, or can be the sole cause of the cardiovascular abnormalities, correction of metabolic abnormalities must be a high priority in the treatment of patients with cardiovascular manifestations of poisoning. The terminal phase of any serious poisoning includes nonspecific hemodynamic abnormalities and cardiac dysrhythmias.

### Heart Rate Abnormalities

Xenobiotics that directly cause dysrhythmias or cardiac conduction abnormalities usually affect the myocardial cell membrane. These abnormal rhythms, cardiac conduction abnormalities, and heart blocks are discussed in Chap. 15.

### Bradycardia

Sinus bradycardia is probably the most common xenobiotic-induced bradycardia. Xenobiotics (Table 16-2) produce bradycardia through different mechanisms. The xenobiotic influences the central or peripheral nervous systems affecting rhythm generation or conduction in the heart. Most xenobiotics that cause central nervous system depression, such as the sedative-hypnotics, opioids, and  $\alpha_2$ -adrenergic receptor agonist (“centrally acting”) antihypertensives, usually decrease sympathetic outflow to the heart and

**TABLE 16-2** Common Xenobiotics Causing Bradycardia

$\alpha_1$ -Adrenergic agonists (reflex bradycardia)	Cholinergics
Phenylephrine	Carbamates or organic phosphorus compounds
Phenylpropanolamine	Edrophonium
$\alpha_2$ -Adrenergic agonists (centrally acting)	Neostigmine
Clonidine	Physostigmine
Imidazolines	Opioids
Methyldopa	Sedative hypnotics
$\beta$ -Adrenergic antagonists	Sodium channel openers
Antidysrhythmics	Aconitine
Amiodarone	Ciguatoxin
Sotalol	Grayanotoxin
Calcium channel blockers	Veratridine
Cardioactive steroids	Synthetic cannabinoids

produce sinus bradycardia in the range of 40 to 60 beats/min. Digoxin, certain cholinergics, and  $\alpha_1$  agonists produce bradycardia and heart block through the enhancement of vagal tone. Sodium channel activators, such as aconitine, cause bradycardia due to intracellular  $\text{Na}^+$  overload with a resultant alteration in  $\text{Ca}^{2+}$  handling. The most profound bradycardia results from overdoses of xenobiotics that have direct depressant effects on the cardiac pacemakers.<sup>71</sup> The inability to propagate an impulse within the cardiac conducting system produces bradycardia or even asystole. Examples of xenobiotics that produce pacemaker or conduction effects include  $\text{Ca}^{2+}$  channel blockers and  $\beta$ -adrenergic antagonists.

Bradycardia, heart block, and asystole frequently are terminal events in patients with massive overdose of many noncardiotoxic xenobiotics. These dysrhythmias occur as a result of direct effects on the myocardium or of indirect metabolic effects. For example, severe hyperkalemia or metabolic acidosis results in a wide complex, sinusoidal bradycardic rhythm.

### Tachycardia

Sinus tachycardia is the most common xenobiotic induced tachycardia. Parasympatholytic drugs, such as atropine, raise the heart rate by elimination of the inhibitory vagal influence. However, more rapid rates result from direct myocardial stimulatory effects, generally mediated by  $\beta$ -adrenergic agonism. For example, catecholamine excess (eg, cocaine, psychomotor agitation, methylxanthines, sedative-hypnotic withdrawal) causes sinus tachycardia with rates faster than 150 beats/min. Tachycardia is also an indirect effect in response to hypotension, hypoxia, acidemia, fever, electrolyte abnormalities, and other metabolic derangements that present in poisoned patients (Table 16-3).

### Decreased Cardiac Contractility and Congestive Heart Failure

Xenobiotics reduce cardiac contractility, with a resulting decrease in cardiac ejection fraction and cardiac output, a decrease in blood pressure, and development of congestive heart failure (CHF). Cardiogenic pulmonary edema generally occurs as a result of the direct negative effects of the xenobiotic on the contractility, or inotropy, of the heart, or through increases in the preload or afterload. Acute cardiogenic pulmonary edema, resulting from impaired left heart filling, which often results from decreased cardiac output, occurs in patients poisoned by a nondihydropyridine calcium channel blocker or  $\beta$ -adrenergic receptor antagonist. Other xenobiotics that exert direct depressant effects on cardiac contractility, generally through sodium channel blockade, include antihistamines, phenothiazines, antidysrhythmics, and local anesthetics. By slowing intraventricular conduction these xenobiotics reduce the ability of the heart to contract efficiently. Pulmonary edema can result from the fluid overload accompanying infusion of large quantities of sodium-containing xenobiotics (eg, sodium penicillin), the renal effects of medications such as nonsteroidal antiinflammatory drugs, or as a late consequence of xenobiotics that cause kidney failure (Chap. 27).

**TABLE 16–3** Common Xenobiotics Causing Sinus Tachycardia and/or Tachydysrhythmias

Amantadine	Pentamidine
Antidysrhythmics	Phenothiazines
Anticholinergics	Phosphodiesterase inhibitors
Antihistamines	Amrinone
Botanicals and plants (Chaps. 43 and 118)	Methylxanthines
Bupropion	Sedative–hypnotics
Carbamazepine	Chloral hydrate
Cardioactive steroids	Ethanol
Chloroquine and quinine	Sympathomimetics
Cyclic antidepressants	Amphetamines
Cyclobenzaprine	Catecholamines
Hydrocarbons and solvents	Cocaine
Halogenated hydrocarbons	Thyroid hormone preparations
Inhalational anesthetics	
Jellyfish venom ( <i>Chironex fleckeri</i> )	
Loperamide	
Metal salts	
Arsenic	
Iron	
Lithium	
Magnesium	
Potassium	

Xenobiotics can cause cardiomyopathy through chronic toxic effects directly on the myocardium or indirectly through effects on blood pressure or cardiac vasculature (Table 16–4). In most cases, the exact mechanism of toxicity is not known. However, free radical generation, nitric oxide formation, acetaldehyde production, myocardial ischemia, mechanical overload, nutritional deficiency, and persistent tachycardia are each implicated in the cellular toxicity of the various xenobiotics and development of cardiomyopathy.<sup>23,38,57,67,80</sup>

### Blood Pressure Abnormalities

Blood pressure is dependent upon cardiac and vascular function. (The blood pressure is directly related to the heart rate (HR), the stroke volume (SV), and the systemic vascular resistance (SVR): Blood pressure = HR × SV × SVR.) The systolic component of the blood pressure measurement is a reflection of the inotropic state of the myocardium, whereas the diastolic component reflects the vascular tone. Blood pressure is also expressed as the mean arterial pressure (MAP) during a single cardiac cycle. Because at normal heart rates the duration of diastole is approximately twice that of systole, the MAP is calculated as  $\{(2 \times \text{diastolic}) + (\text{systolic})\}/3$ .

Systemic vascular resistance depends on vascular tone, vessel diameter, and flow properties of blood. Arteries are twice the thickness of veins and thus a higher resistance to flow and the ability to handle higher shear stress. The viscoelastic properties of large arteries dampen the pulsatile pressure and flow from cardiac output, which enables the microvasculature to steadily

**TABLE 16–4** Xenobiotics Associated with Cardiomyopathy

Amphetamines	Clozapine
Anabolic steroids	Cobalt
Anthracyclines (e.g. dactinomycin, doxorubicin)	Cocaine
Antimony	Ethanol
Catecholamines	HMG-CoA reductase inhibitors
Checkpoint inhibitors	Phenylpropanolamine, Zidovudine

HMG-CoA =  $\beta$ -hydroxy- $\beta$ -methylglutarylcoenzyme A.

deliver nutrients and oxygen to tissues. Most of the pressure change in the vascular system occurs in precapillary arterioles. To maintain blood flow to vital organs over a wide range of pressures, the smooth muscle tone of these arterioles is directly linked to changes in blood pressure. Arteriolar resistance is also affected by vasoactive humoral and tissue factors such as bradykinin, vasopressin, circulating catecholamines, angiotensin II, and natriuretic peptides as well as metabolic effects such as blood oxygen and carbon dioxide content, pH, osmolarity, and  $K^+$ . Additionally, release of nitric oxide and prostaglandin  $I_2$  triggered by metabolic factors and/or shear stress on the endothelial surface of arterioles leads to local vasodilation and liberation of nitric oxide downstream, furthering vessel dilatation. Arterioles vary by territory and, given their different structure, function and react variably in different locations in the body.<sup>34</sup>

Capillaries have very thin walls and are highly permeable to fluid. The low capillary pressure is important for maintenance of tissue fluid balance and nutrient and oxygen delivery to cells. The hydrostatic pressure within the early capillary section drives diffusion and filtration across the capillary beds, which is counterbalanced by the oncotic pressure. In the setting of circulatory shock, increased release of catecholamines causes reduced microvascular perfusion to nonessential organ systems in an attempt to maintain perfusion to vital organs. Tissue hypoxia and release of inflammatory mediators increase vascular permeability and ultimately decrease venous return and cardiac output. When blood pressure falls below the limits of autoregulation, cardiovascular instability occurs, leading first to decreased oxygen delivery and, if left uncorrected, to activation of an inflammatory cascade leading to cellular apoptosis and organ failure.<sup>2,34,66</sup>

### Hypertension Caused by Xenobiotics

Hypertension can be the result of an increase in either inotropy or vascular resistance or both. For example, stimulation of the  $\alpha_1$ -adrenergic receptor causes hypertension through vasoconstriction, and stimulation of the  $\beta_1$ -adrenergic receptor causes hypertension through enhanced myocardial contractility (Table 16–5).

The hemodynamic results of a xenobiotic overdose depend on the specific xenobiotic ingested and the relative action on the various types of receptors. This suggests that, among  $\beta$ -adrenergic agonists, only those with a predominant  $\beta_1$ -adrenergic effect cause hypertension. Nonselective  $\beta$ -adrenergic agonists (those that agonize at both  $\beta_1$  and  $\beta_2$ ) produce  $\beta_1$ -mediated systolic hypertension (through inotropic effects) with  $\beta_2$ -mediated vascular vasodilation and diastolic hypotension. This results in a widened pulse pressure, which is the numerical difference between the systolic and diastolic pressures. Exposure to selective  $\beta_2$ -adrenergic agonists such as albuterol result in tachycardia and enhanced inotropy with a widened pulse pressure in a manner analogous to nonselective  $\beta$ -adrenergic agonists. The resulting blood pressure depends on the relative physiologic balance between inotropy and vasodilation.

Xenobiotics that interact only with the  $\alpha_1$ -adrenergic receptor (such as phenylephrine) cause vasoconstriction and hypertension. Baroreceptors detect the increased blood pressure and signal the parasympathetic nervous system neurons of the vagus nerve to fire and slow the heart rate. In the absence of  $\beta$ -adrenergic stimulation, a “reflex” bradycardia results. Norepinephrine is an  $\alpha_1$ -adrenergic agonist with additional  $\beta$ -adrenergic activity. Profound hypertension is the primary hemodynamic toxic effect due to the activity of norepinephrine as both a positive inotrope ( $\beta_1$ ) and a vasoconstrictor ( $\alpha_1$ ). Reflex bradycardia does not occur as a result of stimulation of the cardiac  $\beta_1$ -adrenergic receptors.

### Hypotension Caused by Xenobiotics

Typically, hypotension in adults is arbitrarily defined as a systolic blood pressure of less than 90 mm Hg or a MAP of less than 70 mm Hg. However, this is not an adequate clinical parameter. Young children and adults with a small body habitus often have a normal systolic pressure less than 90 mm Hg (Chap. 3). Patients with hypothermia have decreased metabolic demands, and a lower blood pressure is often “normal” for these patients. Most importantly, patients with long-standing hypertension often have inadequate tissue

**TABLE 16-5** Xenobiotics That Commonly Cause Hypertension

<i>Hypertensive Effects Mediated by <math>\alpha</math>-Adrenergic Receptor Interaction</i>	<i>Hypertensive Effects Not Mediated by <math>\alpha</math>-Adrenergic Receptor Interaction</i>
Direct $\alpha$ -adrenergic receptor agonists	$\beta$ -Adrenergic receptor agonists <sup>b</sup>

Pseudoephedrine	

<sup>a</sup>These cause transient hypertension followed by hypotension.

<sup>b</sup>These cause hypotension.

perfusion even with a MAP of more than 70 mm Hg. The cerebral arterioles normally constrict or dilate to maintain a relatively constant cerebrovascular blood flow despite changes in the peripheral blood pressure. Chronically hypertensive patients lose this autoregulatory response as a consequence of atherosclerotic disease, arteriolar hypertrophy, or arteriolar smooth muscle constriction. These narrowed arterioles typically require a higher peripheral blood pressure to properly perfuse the brain.

Clinically, hypotension is defined as blood pressure that is inadequate to perfuse tissues. The clinical assessment of tissue perfusion is based on the vital signs, skin color, capillary refill, mental status, urine output and concentration, and acid–base balance (eg, serum lactate concentration). However, if a xenobiotic directly affects one or more of these parameters, the clinical assessment of volume and hemodynamic status may be difficult.

Poor tissue perfusion results from hypovolemia, decreased peripheral vascular resistance, myocardial depression, or a dysrhythmia that reduces cardiac output. A single xenobiotic can exert several effects on the hemodynamic system, such as diltiazem, a calcium channel blocker that causes negative inotropy and vasodilation. Appropriate treatment of the hypotension requires an understanding of the pathophysiologic consequences of the xenobiotic and the resultant hemodynamic derangement (Table 16-6).

Hypotension in a poisoned patient also results from intravascular volume depletion. Intravascular volume decreases as a result of gastrointestinal, urinary, or insensible losses; or fluid may redistribute from the intravascular space into the intracellular, interstitial, pleural, or peritoneal spaces. Xenobiotics cause significant intravascular volume depletion through all of these mechanisms.

Hypotension is also caused by xenobiotics that affect venous tone. These xenobiotics increase venous capacitance, decrease the central venous pressure, and result in relative hypovolemia. The effects are mediated via central effects on the sympathetic nervous system or direct effects on the peripheral vasculature. Sedative hypnotics and central  $\alpha_2$ -adrenergic agonists

**TABLE 16-6** Heart Rate and ECG Abnormalities of Xenobiotics That Commonly Cause Hypotension

<i>Characteristic ECG Abnormalities</i>

(eg, clonidine) decrease the central sympathetic outflow and result in hypotension. Other xenobiotics directly block peripheral  $\alpha_1$ -adrenergic receptors or stimulate  $\beta_2$ -adrenergic receptors on the blood vessels to produce vascular smooth muscle relaxation, venodilation, and hypotension. A large number of xenobiotics are reported to cause hypotension; however, the hypotension often is not a direct action of the xenobiotic. Rather, the cause of hypotension is coexisting hypoxia, acidemia, anaphylaxis, volume depletion, or dysrhythmias.

Identification of the specific xenobiotic causing hypotension requires the integration of a detailed history, complete physical examination, and laboratory studies. Often the identification of the specific xenobiotic responsible for hypotension is based on other physical findings associated with the xenobiotic or recognition of a specific toxic syndrome.

## ASSESSMENT OF HEMODYNAMIC STATUS IN THE POISONED PATIENT

Assessment of volume status can be particularly difficult in the poisoned patient because of functional alterations in the patient's autonomic nervous system and the pharmacologic effects of the xenobiotic. For example, the usual signs of salt and water depletion, such as dry mucous membranes, dry skin, low blood pressure, tachycardia, narrowed pulse pressure, altered sensorium, and decreased urine output, can be mimicked by a number of xenobiotics, including cyclic antidepressants. Additionally, hypovolemic patients present with diaphoresis, flushed skin, hypertension, bradycardia, or increased urine output following exposure to a cholinergic xenobiotic such as an organic phosphorus compound.

The most accurate immediate assessment of volume status in a patient is the demonstration of increased cardiac output after a fluid challenge. If concern about providing a fluid bolus exists, providers can perform the passive leg-raising test to functionally give the patient a fluid bolus to assess the

adequacy of fluid resuscitation without adding to whole-body volume status. The test is performed by having the patient sit upright in a semi-recumbent position at about 45 degrees. The head is then lowered to the recumbent position and the legs are raised to about 45 degrees. This transiently increases the circulatory volume by approximately 130 to 300 mL, and it results in changes in the arterial pressure and heart rate.<sup>33,53</sup> Several studies demonstrate that this simple maneuver is a good predictor of hemodynamic response to a fluid bolus especially in intensive care patients.<sup>12,40,41,47,49,50,52,78</sup>

Other modes of hemodynamic monitoring have been proposed, including CVP, ultrasonography of the inferior vena (IVC), neck vein distension, and orthostatic vital sign monitoring. However, none of these modes have proven to be reliable or accurate markers of volume status and should not be relied upon when managing a critically ill poisoned patient. The only truly

reliable means to assess the volume status of a patient and how a patient will respond to fluid is a trial bolus.

Lactate is a widely accepted diagnostic and prognostic marker of shock in medical and surgical patients due to trauma, sepsis, and cardiogenic shock. In circulatory failure, lactate is elevated as a result of a combination of increased production from tissue hypoxia, increased glucose metabolism/metabolic demands, and/or decreased clearance.<sup>3</sup> In a retrospective case-control study serum lactate concentration had excellent prognostic utility to predict drug-overdose fatality.<sup>48</sup> However lactate as a marker of adequate microcirculatory perfusion and overall hemodynamic status is nonspecific. Elevated lactate can occur due to factors outside hemodynamics including seizure (eg, methylxanthine or cocaine toxicity), mitochondrial DNA changes (eg, nucleoside inhibitors), increased production (eg, propylene glycol), or decreased clearance (eg, metformin).

If hypoperfusion and hypotension do not resolve after initial fluid resuscitation, an echocardiogram to assess cardiac output is a useful adjunct to guide further management. For example, a patient with a decreased ejection fraction and normal volume status, which occurs in a  $\beta$ -adrenergic antagonist overdose, can benefit from an inotrope such as dobutamine, whereas an  $\alpha_1$ -adrenergic agonist such as phenylephrine is indicated for a patient with hypotension despite good cardiac contractility and adequate fluid resuscitation. Definitive care of the poisoned patient with hemodynamic compromise or a dysrhythmia begins with the recognition that a possible xenobiotic ingestion occurred. Infections, cardiovascular disease, and other metabolic disorders must always be considered; however, the toxic effects of xenobiotics must be included in the differential diagnosis. A variety of clinical clues, when present, should heighten the clinician's suspicion that a xenobiotic effect is responsible for the hemodynamic or dysrhythmic problem (Table 16-7).

**TABLE 16-7** Clues That an Unanticipated Xenobiotic Might Be Causing Hemodynamic Compromise or Dysrhythmia

#### History

- Concomitant seizure
- Gastrointestinal disturbances (colicky pain, nausea, vomiting, diarrhea)
- Prior ingestion of medications (consider possibility that the container is mislabeled or misidentified)
- Depression (even if patient denies ingestion)
- Suspected myocardial ischemia in patient < 35 years old
- Treatment with any cardiac medications (especially antidysrhythmics or cardioactive steroids)
- History of psychiatric illness, asthma, or hypertension
- History of drug use or abuse

#### Physical Examination and Vital Signs

- Heart rate
  - Sinus tachycardia with rate > 130 beats/min
  - Sinus tachycardia without apparent identified cause
  - Sinus bradycardia
- Respiratory rate
  - Any unexplained depression or elevation in rate
- Temperature
  - Hyperthermia especially if > 106°F (> 41.1°C)
  - Hypothermia if < 86°F (< 30°C)
- Dissociation between typically paired changes, for example:
  - Hypotension and bradycardia (tachycardia expected)
  - Fever and dry skin (diaphoresis expected)
  - Hypertension and tachycardia (reflex bradycardia anticipated)
  - Depressed mental status and tachypnea (decreased respirations common)
- Relatively rapid changes in vital signs
- Initial hypertension becomes hypotension
- Increasing sinus tachycardia or hypertension

#### General

- Alteration in consciousness, such as depressed mental status, confusion, or agitation
- Findings usually not associated with cardiovascular diseases
- Ataxia, bullae, dry mucous membranes, lacrimation, miosis or mydriasis, nystagmus, unusual odor, flushed skin, salivation, tinnitus, tremor, visual disturbances
- Findings consistent with a toxic syndrome
  - Especially findings consistent with anticholinergics, sympathomimetics, or sedative hypnotics

#### Laboratory Tests

- Any unexpected or unexplained laboratory result, especially:
  - Metabolic acidosis
  - Respiratory alkalosis
  - Electrolyte abnormalities

## SUMMARY

- Xenobiotics interact with the heart or blood vessels to produce hypotension or hypertension, congestive heart failure, dysrhythmias (including bradycardias and tachycardias), or cardiac conduction delays.
- These toxic effects often occur through interactions with specific receptors or with the ion channels in the cell membrane.
- Disruption of the normal cellular regulation of metabolic processes or of the cellular ionic status leads to the cardiovascular and hemodynamic compromise.
- The occurrence of these abnormalities, individually or in combination, might suggest a particular xenobiotic or class of xenobiotics as etiologic (toxic syndrome) and might dictate initial treatment.
- By understanding both the pharmacology of the xenobiotic and the physiology of the heart vasculature autonomic nervous system appropriately tailored treatment can be delivered.

## CASE STUDY 4

**History** A 32-year-old woman with no significant past medical history presented to the emergency department with a 2-day history of a painless, rapidly expanding lesion on her back. She reported subjective fever and malaise. She first noticed the lesion 2 days prior but did not recall any trauma or other inciting factors. The woman denied headache, shortness of breath, chest pain, nausea, vomiting, diarrhea or dysuria. She was not taking any medications, she drank alcohol socially, and she denied injection drug use. She worked as an accountant in New York City and traveled frequently to a vacation home in Montauk, Long Island.

**Physical Examination** On presentation to the emergency department, the patient was well appearing and in no apparent distress. Vital signs were: blood pressure, 102/52 mm Hg; pulse, 92 beats/min; respiratory rate, 16 breaths/min; tympanic temperature, 98.7°F (37.1°C); and oxygen saturation, 100% on room air. A complete physical examination was within normal limits, except for her skin examination. This was notable for a solitary 9-cm annular plaque on the upper back with central hemorrhagic crust overlying a 5-cm violaceous plaque surrounded by a ring of erythema with a dermatonecrotic lesion (Fig. CS4-1). The lesion was only mildly tender to palpation, and there was no underlying fluctuance.

**Initial Management** A more detailed history failed to reveal any clues. The woman specifically denied knowledge of tick or spider bites, and she neither worked, lived, nor vacationed in an area known to be inhabited by brown recluse spiders. However, she frequented an area of Long Island where ticks are endemic. An intravenous line was inserted and a complete blood count, basic metabolic panel, and liver function tests were sent; all were within normal limits. The patient was started on vancomycin to provide methicillin-susceptible *Staphylococcus aureus* as well as methicillin-resistant *S. aureus* coverage for a presumed bacterial infection or necrotizing soft tissue infection.

**What Is the Differential Diagnosis?** The only remarkable finding in this patient is the 2-day-old skin lesion, associated with subjective fever and malaise. The differential diagnosis includes infectious diseases such as cellulitis or a bacterially superinfected cyst or arthropod bite, sporotrichosis, Lyme disease, and anthrax (Chap. 127); drug reactions such as a fixed-drug eruption, or given the necrotic appearance of the lesion, necrosis due to warfarin or heparin therapy (Chaps. 17 and 58); and necrotic spider bites (Chap. 115).

Cases such as these require an immediate assessment for potential public health

implications. Once a diagnosis of cutaneous anthrax is considered, the possibility of malicious exposure mandates a coordinated effort to establish a definitive diagnosis. It is important to recall that one of the cases of cutaneous anthrax that occurred following the malicious letters in New York in 2001 involved the case of a small child who was initially diagnosed with brown recluse spider envenomation. Additionally, although spider envenomation may occur outside of regions considered to be endemic as movement of spiders in suitcases, packages, or vehicles may occasionally occur, a new pattern of envenomation may represent a local infestation or the expansion of an endemic area resulting from climate changes. All of these scenarios may require public health interventions.

### What Clinical and Laboratory Analyses Help Exclude Life-Threatening Causes of This Patient's Presentation?

A dermatology consult was called, and a biopsy was taken for histologic evaluation of a permanent section as well as Gram stain. An acid-fast bacillus stain was also done on the tissue for mycobacterial infection and was negative. Extensive laboratory testing was ordered to help exclude uncommon etiologies for the skin lesion. The biopsy demonstrated epidermal necrosis and dermal abscess, which are nonspecific findings. A wound Gram stain and culture failed to show white blood cells or microorganisms.

### Further Diagnosis and Treatment

Serologic studies including a Lyme Western blot, Rocky Mountain spotted fever antibodies, and *Francisella tularensis* were all negative. The vancomycin was stopped, and the woman was discharged on a 21-day course of oral doxycycline for presumed Lyme disease given the history and morphology of the lesion. The lesion began to regress on oral doxycycline. Although a final diagnosis was never established, the working diagnosis was that of either Lyme disease or a necrotic spider envenomation, and the patient's Lyme Western blot was to be repeated in 3 to 4 weeks in order to further clarify between the two leading diagnoses: Lyme disease or necrotic spider envenomation.

**Figure CS4-1.** The lesion on the woman's back, reproduced with her permission.

# DERMATOLOGIC PRINCIPLES

Jesse M. Lewin, Neal A. Lewin, and Lewis S. Nelson

## INTRODUCTION

Dermatology is a specialty in which visual inspection allows for rapid diagnosis. A brief physical examination prior to a lengthy history is valuable because some of the classic skin diseases with obvious morphologies allow a “doorway diagnosis” to be established. The tools the physician needs are readily available: magnifying glass, glass slide (for diascopy to determine if a lesion is blanchable), adequate lighting, a flashlight, alcohol pad to remove scale or makeup, scalpel, and at times a Wood lamp. Universal precautions should always be used.

The ability to describe lesions accurately is an important skill, as is the ability to recognize specific patterns. These abilities aid clinicians in their approach to the patient with a cutaneous eruption both in developing a differential diagnosis and while communicating with other physicians. The classic dermatologic lesions are defined in [Table 17-1](#).

The skin shields the internal organs from harmful xenobiotics in the environment and maintains internal organ integrity. The adult skin covers an average surface area of 2 m<sup>2</sup>. Despite its outwardly simple structure and function, the skin is extraordinarily complex. The skin is affected by xenobiotic exposures that occur through many routes. Dermal exposures themselves are important as they account for approximately 7% of all human exposures reported to the American Association of Poison Control Centers (Chap. 130). The clinician must obtain essential information as to the dose, timing, route, and location of exposure. Knowledge of the physical and chemical properties of the xenobiotic can be used to make relevant predictions of adverse cutaneous reactions and whether the response will be local or systemic. The location of xenobiotic exposure determines the histologic morphology, the severity of the reaction pattern, and the overall clinical findings. It should

be noted, however, that different xenobiotics produce clinically similar skin changes and conversely that an individual xenobiotic produces diverse cutaneous lesions.

## SKIN ANATOMY AND PHYSIOLOGY

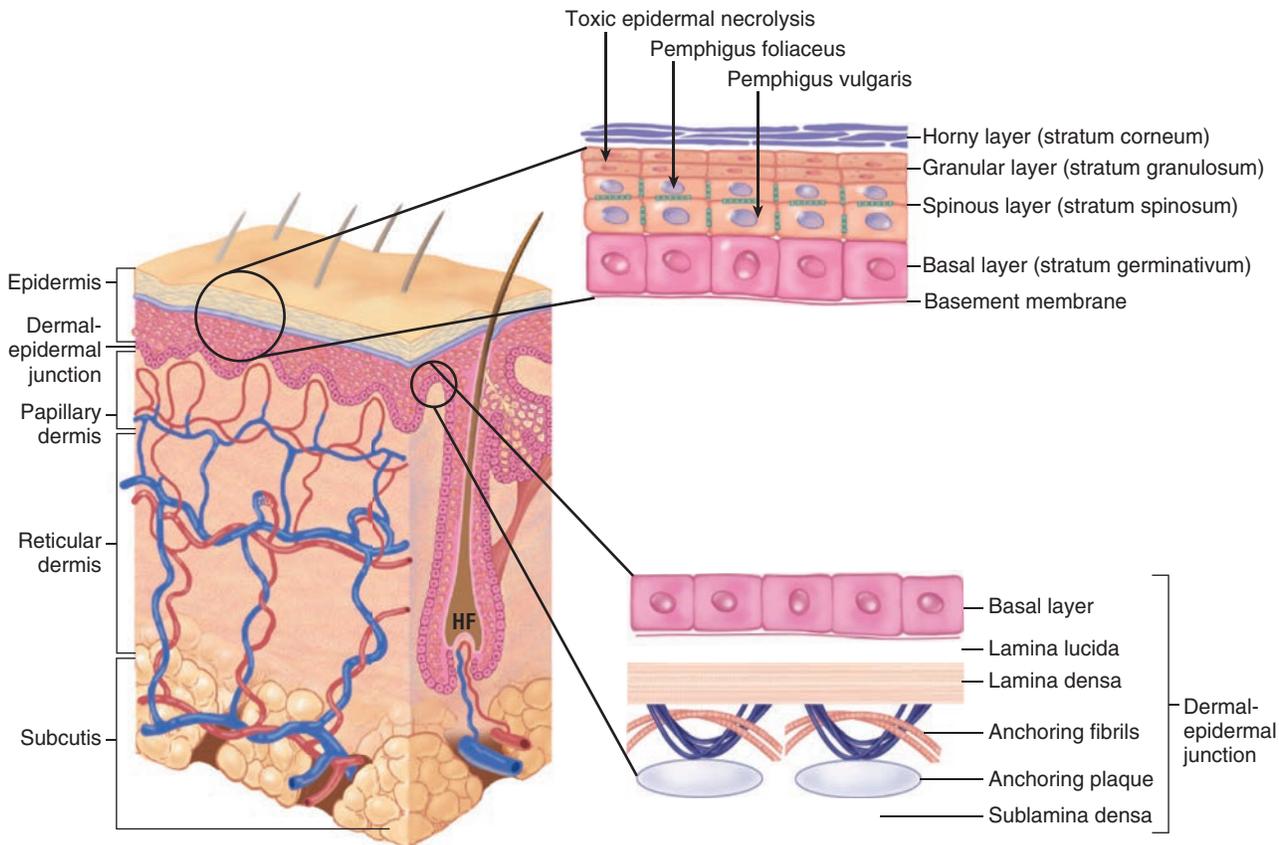

The skin has 3 main components that interconnect anatomically and interact functionally: the epidermis, the dermis, and the subcutis or hypodermis ([Fig. 17-1](#)). Some experts further categorize the components of the skin into 3 reactive units: The superficial reactive unit, which is composed of the epidermis, the dermal-epidermal junction, and the superficial or papillary dermis with its vascular system; the dermal reactive unit, which is composed of the reticular layer of the dermis and the dermal microvascular plexus; and the subcutaneous reactive unit, which consists of fat lobules and septae.<sup>38</sup> The primary physiologic role of the epidermis, the outermost layer of the skin, is to serve as a barrier, maintain fluid balance, and prevent infection. The degree of barrier function of the epidermis varies with the thickness of the epidermis, which ranges from 1.5 mm on the palms and soles to 0.1 mm on the eyelids. The epidermis is composed of 4 layers: the horny layer (stratum corneum), the granular layer (stratum granulosum), the spinous layer (stratum spinosum), and the basal layer (stratum germinativum), which overlies the basement membrane zone ([Fig. 17-1](#)). The keratinocyte, or squamous cell, which is an ectodermal derivative, comprises the majority of cells in the epidermis.

The stratum corneum, a semipermeable surface composed of differentiated keratinocytes, is predominantly responsible for the physical barrier function of the skin. Disruption or abnormal formation of the stratum corneum leads to inadequate function of this barrier, whether by disorders of proliferation or desquamation. For example, accelerated cornification leads to retained nuclei in the stratum corneum (parakeratosis) causing gaps in the stratum corneum, as in psoriasis, which impedes barrier function.<sup>38</sup> Alternatively, in some forms of ichthyosis there is decreased desquamation leading to epidermal retention that influences the barrier function of the stratum corneum.<sup>4</sup> Barrier function is also partly maintained by the upper spinous and granular layers. In this layer, there are Odland bodies, also known as membrane-coating granules, lamellar granules, and keratinosomes. The contents of these organelles provide a barrier to water loss while mediating stratum corneum cell cohesion.<sup>19</sup> The stratum corneum is covered by a surface film composed of sebum emulsified with sweat and breakdown products of keratinocytes.<sup>33</sup> This surface film functions as an external barrier to protect from the entry of bacteria, viruses, and fungi. The role of the surface film, however, is limited with regard to percutaneous absorption. The major barrier molecules to percutaneous absorption in the skin are lipids called ceramides.<sup>33</sup> Diseases characterized by dry skin, such as atopic dermatitis and psoriasis, are in part caused by decreased concentrations of ceramide in the stratum corneum, which allows increased xenobiotic penetration because of barrier degradation.<sup>33</sup> Similarly, hydrocarbon solvents, including alcohols, or detergents, commonly produce a “defatting dermatitis” by keratolysis or the dissolution of these surface lipids.

The cells of the basal layer control the renewal of the epidermis. The basal layer contains stem cells and transient amplifying cells, which are the proliferative cells resulting in new epidermal formation that occurs approximately every 28 days.<sup>38</sup> As the basal cells migrate toward the skin surface they flatten, lose their nuclei, develop keratohyalin granules, and eventually develop into keratinocytes of the stratum corneum. The basal layer of the epidermis is just above the basement membrane zone and is also populated by melanocytes and Langerhans cells in addition to basal keratinocytes. Melanocytes

**TABLE 17-1** Dermatologic Diagnostic Descriptions of Lesions of the Skin

Primary Cutaneous Lesions	Secondary Cutaneous Lesions
<b>Comedone:</b> open and closed dilated pores (blackheads and whiteheads, respectively)	<b>Erosion:</b> a loss of the epidermis up to the full thickness of the epidermis but not through the basement membrane
<b>Macule:</b> a circumscribed flat variation of color that is brown, blue, yellow, red, or hyper- or hypopigmented, <1 cm	<b>Ulcer:</b> a loss of full-thickness epidermis and papillary dermis, reticular dermis, or subcutis
<b>Patch:</b> a circumscribed flat variation of color that is brown, blue, yellow, red, or hyper- or hypopigmented, >1 cm	<b>Lichenification:</b> thickening of the epidermis and accentuation of natural skin lines
<b>Papule:</b> a circumscribed elevation of <1 cm in diameter	<b>Atrophy:</b> thinning of the epidermis
<b>Plaque:</b> a circumscribed elevation of >1 cm in diameter	<b>Scale:</b> flaking caused by accumulation of stratum corneum (hyperkeratosis) or delayed desquamation
<b>Nodule:</b> a circumscribed elevation often >2 cm in diameter, involves the dermis and at times subcutis	<b>Scar:</b> a thickened, often discolored surface
<b>Pustule:</b> a circumscribed collection of purulent fluid that varies in size	
<b>Tumor:</b> an elevation of >0.5 cm in diameter	
<b>Vesicle:</b> a circumscribed collection of clear fluid <1 cm in diameter	
<b>Bulla:</b> a circumscribed collection of clear fluid >1 cm in diameter	
<b>Wheal:</b> a firm edematous plaque resulting from infiltration of the dermis with fluid	

**FIGURE 17-1.** Skin histology and pathology. Intraepidermal cleavage sites in various xenobiotic-induced blistering diseases. In pemphigus foliaceus, the cleavage is below or within the granular layer, whereas in pemphigus vulgaris, it is suprabasilar. This accounts for the differing types of blisters found in the 2 diseases. HF = hair follicle.

contain melanin, which is the major chromophore in the skin that protects the skin from ultraviolet radiation. Melanocytes are primarily responsible for producing skin pigmentation. Langerhans cells are bone marrow–derived dendritic cells with a primary role in immunosurveillance. These cells function in the recognition, uptake, processing, and presentation of antigens to previously sensitized T lymphocytes. In addition, Langerhans cells also carry antigens via dermal lymphatics to regional lymph nodes.

The basement membrane zone (BMZ) consists of 3 layers—the lamina lucida, the lamina densa, and the sublamina densa (which is composed of anchoring fibrils) — and separates the epidermis from the dermis (Fig. 17-1). It provides a site of attachment for basal keratinocytes and permits epidermal–dermal interaction. The BMZ is also of clinical significance as it is the target of genetic defects and autoimmune attack, leading to a variety of inherited and acquired cutaneous diseases.

The dermal–epidermal junction (DEJ) provides resistance against trauma, gives support to the overlying structures, organizes the cytoskeleton in the basal cells, and serves as a semipermeable barrier. The dermis, below the DEJ, contains the adnexal structures, blood vessels, and nerves. It is arranged into 2 major regions, the upper papillary dermis and the deeper reticular dermis. The dermis provides structural integrity and contains many important appendageal structures. The structural support is provided by both collagen and elastin fibers embedded in glycosaminoglycans, such as chondroitin A and hyaluronic acid. Collagen accounts for 70% of the dry weight of the skin, whereas elastic fibers comprise 1% to 2% of the skin's dry weight. Several important cells, including fibroblasts, macrophages, and mast cells, are residents of the dermis, each with their own unique function. Traversing the dermis are venules, capillaries, arterioles, nerves, and glandular structures.

The arteriovenous framework of the skin is derived from a deep plexus of perforating vessels within the skeletal muscle and subcutaneous fat. From this deep plexus, smaller arterioles transverse upward to the junction of

the reticular and papillary dermis, where they form the superficial plexus. Capillary venules form superficial vascular loops that ascend into and descend from the dermal papillae (Fig. 17-1). The communicating blood vessels provide channels through which xenobiotics exposed on the skin surface can be transported internally. This circulatory network provides nutrition for the tissue and is involved in temperature and blood pressure regulation, wound repair, and numerous immunologic events.<sup>12</sup> Parallel to the vasculature are cutaneous nerves, which serve the dual function of receiving sensory input and carrying sympathetically mediated autonomic stimuli that induce piloerection and sweating.<sup>22</sup>

The apocrine glands consist of secretory coils and intradermal ducts ending in the follicular canal. The secretory coil is located in the subcutis and consists of a large lumen surrounded by columnar to cuboidal cells with eosinophilic cytoplasm.<sup>22</sup> Apocrine glands, which are concentrated in select areas of the body such as the axillae, eyelids, external auditory meatus, areolae, and anogenital region, produce secretions that are rendered odoriferous by cutaneous bacterial flora.

The eccrine glands, in contrast, produce an isotonic to hypotonic secretion that is modified by the ducts and emerges on the skin surface as sweat. The eccrine unit consists of a secretory gland as well as intradermal and intraepidermal ducts. The coiled secretory gland is located in the area of the deep dermis and subcutis. These glands are innervated by postganglionic sympathetic fibers that use acetylcholine neurotransmission, explaining the clinical effects of anticholinergic xenobiotics. Xenobiotics that are concentrated in the sweat increase the intensity of the local skin reactions. Certain chemotherapeutics, such as cytarabine or bleomycin, directly damage the eccrine sweat glands, resulting in neutrophilic eccrine hidradenitis.<sup>65</sup>

Sebaceous glands also reside in the dermis. They produce an oily, lipid-rich secretion that functions as an emollient for the hair and skin, and can be a reservoir of noxious environmental xenobiotics. Pilosebaceous follicles, which are present all over the body, consist of a hair shaft, hair follicle,

**FIGURE 17-2.** Chloracne due to dioxin intoxication. Comedones and papulopustular lesions, nodules, and cyst have led to a gross deformity of the nose. (Used with permission from Dr. Alexandra Geusau.)

sebaceous gland, sensory end organ, and erector pili. Certain halogenated aromatic chemicals, such as polychlorinated biphenyls (PCBs), dioxin, and 2,4-dichlorophenoxyacetic acid, are excreted in the sebum and cause hyperkeratosis of the follicular canal. This produces the syndrome, chloracne, which appears clinically like severe acne vulgaris but predominates in the malar, retroauricular, and mandibular regions of the head and neck and typically develops after several weeks of exposure (Fig. 17-2). Similar syndromes result from exposure to brominated and iodinated compounds, and are known as bromoderma and ioderma, respectively.<sup>70</sup>

The subcutis serves to insulate, cushion, and allow for mobility of the overlying skin structures. Adipocytes represent the majority of cells found in this layer. Leptin, an adipose-derived hormone responsible for feedback of appetite and satiety signaling, is synthesized and regulates fat mass (adiposity) in this layer.

The hair follicle is divided into 3 portions, the hair bulb, infundibulum, and isthmus.<sup>57</sup> The deepest portion of the hair follicle contains the bulb with matrix cells. The matrix cells are highly mitotically active and often are the target of cytotoxic xenobiotics. The rate of growth and the type of hair are unique for different body sites. Hair growth proceeds through 3 distinct phases: the active prolonged growth phase (anagen phase) during which matrix cell mitotic activity is high; a short involutinal phase (catagen phase), and a resting phase (telogen phase). The length of the anagen phase determines the final length of the hair and varies depending on site of the body. For example, hair on the scalp has the longest anagen phase ranging from 2 to 8 years with hair growth at a rate of 0.37 to 0.44 mm/day.<sup>38</sup> Understanding the phases of hair growth is important because hair growth can be used to identify clues regarding the timing of exposure and the mechanism of action of a particular xenobiotic.

The nail plate, which is often considered analogous to the hair, is also a continuously growing structure. Fingernails grow at average of 2 to 3 mm per month and toenails grow approximately 1 mm per month. The mitotically active cells of the nail matrix that produce the nail plate are subject to both traumatic and xenobiotic injury, which in turn affects the appearance and growth of the nail plate. Because nail growth is relatively stable, location of an abnormality in the plate can predict the timing of exposure, such as Mees lines (transverse white lines).

## TOPICAL TOXICITY

### Transdermal Xenobiotic Absorption

Although there is no active cutaneous uptake mechanism for xenobiotics, many undergo percutaneous absorption by passive diffusion. Lipid solubility, concentration gradient, molecular weight, and certain specific skin

characteristics are important determinants of dermal absorption.<sup>23,24,50,54</sup> Absorption is determined to a great extent by the lipid solubility of the specific xenobiotic.<sup>15,39</sup> The pharmacokinetic profile of transdermally administered xenobiotics is markedly different than by the enteral or other parenteral routes.<sup>17</sup> As with any other routes of administration, adverse effects are caused by excessive absorption following application or even with therapeutic use of a transdermal patch. Other xenobiotics, topically applied without a specific delivery device, including podophyllin, camphor, phenol, organic phosphorus compounds, ethanol, organochlorines, nitrates, and hexachlorophene, can lead to systemic morbidity and mortality (Special Considerations: SC3).

### Direct Dermal Toxicity

Exposure to any of a myriad of industrial and environmental xenobiotics results in dermal “burns.” Although the majority of these xenobiotics injure the skin through chemical reactivity rather than thermal damage, the clinical appearances of the two are often identical. Injurious xenobiotics act as oxidizing or reducing agents, corrosives, protoplasmic poisons, desiccants, or vesicants. Often an injury initially appears to be mild or superficial with minimal erythema, blanching, or discoloration of the skin. Over the subsequent 24 to 36 hours, the injury progresses to extensive necrosis of the skin and subcutaneous tissue.

Both inorganic and organic acids are capable of penetrating and damaging the epidermis via protein denaturation and cytotoxicity; however, organic acids tend to be less irritating. The damaged tissue coagulates and forms a thick eschar, which limits the spread of the xenobiotic. The histopathologic finding following acid injury is termed coagulative necrosis.<sup>10</sup> Inorganic acids that are frequently used in industry include hydrochloric and sulfuric acids which lead to the severe injury. The weakly acidic hydrofluoric (HF) acid, is used for the etching of glass, metal and stone. Hydrofluoric acid, because of its limited dissociation constant, is able to penetrate intact skin with subsequent penetration into deeper tissues. The fluoride ion is extremely cytotoxic, causing severe tissue damage, including bone destruction, by interfering with cellular enzymes. Severe pain is due to the capacity of fluoride ions to bind tissue calcium, thus affecting nerve conduction.<sup>61</sup> Once in the dermis, the proton (H<sup>+</sup>) and fluoride ions (F<sup>-</sup>) cause both acid-induced tissue necrosis and fluoride-induced toxicity (Chap. 104).<sup>5</sup>

Alkali exposures characteristically produce a liquefactive necrosis, which allows continued penetration of the corrosive. Consequently, cutaneous and subcutaneous injury following alkali exposure is typically more severe than after an acid exposure, with the exception of hydrofluoric acid. With alkali burns there are generally no vesicles, but rather necrotic skin due to the disruption of barrier lipids, including denaturation of proteins with subsequent fatty acid saponification. Common strong alkalis include sodium, ammonium, and potassium hydroxide; sodium and potassium carbonate; and calcium oxide. These are used primarily in the manufacture of bleaches, dyes, vitamins, pulp, paper, plastics, and soaps, and detergents. Alkali burns from wet cement, which has an initial pH of 10 to 12 that rises to 12 to 14 as the cement sets,<sup>37</sup> result from the liberation of calcium hydroxide.

Thermal damage also results from xenobiotic exposure. For example, the exothermic reaction generated by the wetting of elemental phosphorus or sodium results in a thermal burn.<sup>18</sup> In these circumstances, the products of reactivity, phosphoric acid and sodium hydroxide, respectively, produce secondary chemical injury. Alternatively, skin exposure to a rapidly expanding gas, such as nitrous oxide from a whipped cream cartridge or compressed liquefied nitrogen, or to frozen substances, such as dry ice (CO<sub>2</sub>), produce a freezing injury, or frostbite. Dermatologists routinely use liquid nitrogen to induce a cold injury that destroys precancerous lesions such as actinic keratoses.

Hydrocarbon-based solvents are liquids that are capable of dissolving non-water-soluble solutes.<sup>10</sup> Although the most prominent effect is dermatitis due to loss of ceramides from the stratum corneum of the epidermis, prolonged exposure results in deeper dermal injury.

## PRINCIPLES OF DERMAL DECONTAMINATION

On contact with xenobiotics, the skin should be thoroughly cleansed to prevent direct effects and systemic absorption. In general, water in copious amounts is the decontaminant of choice for skin irrigation. Soap should be used when adherent xenobiotics are involved. Following exposures to airborne xenobiotics, the mouth, nasal cavities, eyes, and ear canals should be irrigated with appropriate solutions such as water or a 0.9% NaCl solution. For nonambulatory patients, the decontamination process is conducted using special collection stretchers if available.<sup>9</sup>

There are a few situations in which water should not be used for skin decontamination. These situations include contamination with the reactive metallic forms of the alkali metals, sodium, potassium, lithium, cesium, and rubidium, which react with water to form strong bases. The dusts of pure magnesium, sulfur, strontium, titanium, uranium, yttrium, zinc, and zirconium will ignite or explode on contact with water. Following exposure to these metals, any residual metal should be removed mechanically with forceps, gauze, or towels and stored in mineral oil. Phenol, a colorless xenobiotic used in the manufacturing of plastics, paints, rubber, adhesives, and soap, has a tendency to thicken and become difficult to remove following exposure to water. Suggestions for phenol decontamination include alternating washing with water and polyethylene glycol (PEG 400) or 70% isopropanol for 1 minute each for a total of 15 minutes.<sup>40</sup> Our conclusions are that inexpensive readily available tepid water should be utilized (Special Considerations: SC2). Calcium oxide (quicklime) thickens and forms  $\text{Ca}(\text{OH})_2$  following exposure to water, which releases heat and causes cutaneous ulcerations, suggesting that mechanical removal as above is advised.

## DERMATOLOGIC SIGNS OF SYSTEMIC DISEASES

### Cyanosis

Normal cutaneous and mucosal pigmentation is caused by several factors, one of which is the visualization of the capillary beds through the translucent epidermis and dermis. Cyanosis manifests as a blue or violaceous appearance of the skin, mucous membranes, and nailbeds. It occurs when excessive concentrations of reduced hemoglobin (>5 g/dL) are present, as in hypoxia or polycythemia, or when oxidation of the iron moiety of heme to the ferric state ( $\text{Fe}^{3+}$ ) forms methemoglobin, which is deeply pigmented (Chap. 124). The presence of the more deeply colored hemoglobin moiety within the dermis results in cyanosis that is most pronounced on areas of thin skin such as the mucous membranes or underneath fingernails. In the differential diagnosis of skin discoloration is pseudochromhidrosis, also termed extrinsic apocrine chromhidrosis. The discoloration is a product of staining of the sweat by chromogenic bacteria including *Corynebacterium*, *Malassezia furfur*, and *Bacillus* spp; the latter 2 species have been known to cause blue discoloration of the skin. Several cases of blue pseudochromhidrosis due to topiramate are reported in the literature, and diagnosis is established by the ability of the clinician to wipe off the discoloration with a damp cotton swab (Fig. 17-3).<sup>11</sup>

### Xanthoderma

Xanthoderma is a yellow to yellow-orange macular discoloration of skin.<sup>26</sup> Xanthoderma is caused by xenobiotics such as carotenoids, which deposit in the stratum corneum, and causes carotenoderma. Carotenoids are lipid soluble and consist of  $\alpha$ -carotene,  $\beta$ -carotene,  $\beta$ -cryptoxanthin, lycopene, lutein, and zeaxanthin, and serve as precursors of vitamin A (retinol). The carotenoids are excreted via sweat, sebum, urine, and GI secretions. Jaundice is typically a sign of hepatocellular failure or hemolysis and is caused by hyperbilirubinemia, either conjugated or unconjugated, deposits in the subcutaneous fat. Jaundice due to hyperbilirubinemia is often accompanied by other cutaneous stigmata including spider angiomas, telangiectasias, palmar erythema, and dilated superficial abdominal veins (caput medusae). True hyperbilirubinemia is differentiated from hypercarotenemia by the presence of scleral icterus in patients with hyperbilirubinemia. In addition, the cutaneous discoloration seen in hypercarotenemia can be removed by wiping the skin with an alcohol swab. Hypercarotenemia is reported among

**FIGURE 17-3.** Pseudochromhidrosis. Blue discoloration on the elbow in a 28-year-old woman as a result of topiramate treatment for epilepsy. This entity is postulated to be a result of a decrease in sweat gland activity and a change in the skin's pH induced by topiramate, leading to the growth of chromogenic bacteria. (Reproduced with permission from Castela E, Thomas P, Bronsard V, et al. Blue pseudochromhidrosis secondary to topiramate treatment. *Acta Derm Venereol.* 2009;89(5):538-539.)

people who take carotene nutrient supplements (Fig. 17-4).<sup>59</sup> Lycopopenia, an entity similar to carotenemia, is caused by the excessive consumption of tomatoes, which contain lycopene. Additionally, topical exposure to dinitrophenol, picric acid, or stains from cigarette use produces localized yellow discoloration of the skin.

**FIGURE 17-4.** Carotenemia. Yellow-orange discoloration on the palm (left) as compared with that of a normal control (right). In the presence of excessive blood carotene concentrations, this yellow component is increased, and is most conspicuously accentuated where the skin is thick on the palms and soles. (Reproduced with permission from Takita Y, Ichimiya M, Hamamoto Y, et al. A case of carotenemia associated with ingestion of nutrient supplements. *J Dermatol.* 2006 Feb;33(2):132-134.)

## Pruritus

Pruritus is the poorly localized, unpleasant sensation that elicits a desire to scratch. The biologic purpose of pruritus is to provoke the removal of a pruritogen, a response likely to have originated when most pruritogens were parasites. Pruritus is a common manifestation of urticarial reactions, but at times it is of nonimmunologic origin. Pruritus is the most common dermatologic symptom and can arise from a primary dermatologic condition or is a symptom of an underlying systemic disease in an estimated 10% to 50% of patients.<sup>29</sup> Pruritus is also caused by topical exposure to the urticating hairs of *Tarantula* spiders, spines of the stinging nettle plant (*Urtica* spp), or via stimulation of substance P by capsaicin.<sup>25</sup> Virtually any xenobiotic can cause a cutaneous reaction that can be associated with pruritus, whether by inducing hepatotoxicity, cholestasis, phototoxicity, or histamine release (ie, neurologically mediated). Xenobiotics commonly implicated in neurally mediated itch include tramadol, codeine, cocaine, morphine, butorphanol, and methamphetamine.<sup>29</sup>

## Flushing

Vasodilation of the dermal arterioles leads to flushing, or transient reddening of the skin, commonly of the face, neck, and chest. Flushing occurs following autonomously mediated vasodilation, as occurs with stress, anger, or exposure to heat, or it can be induced by vasoactive xenobiotics. Xenobiotics that cause histamine release through a type I hypersensitivity reaction are the most frequent cause of xenobiotic-induced flush. Histamine poisoning produces flushing from the consumption of scombrototoxic fish (Chap. 39). Flushing after the consumption of ethanol is common in patients of Asian and Inuit descent and is similar to the reaction following ethanol consumption in patients exposed to disulfiram or similar xenobiotics (Chap. 78). The inability to efficiently metabolize acetaldehyde, the initial metabolite of ethanol, results in the characteristic syndrome of vomiting, headache, and flushing. Niacin causes flushing through an arachidonic acid–mediated pathway that is generally prevented by aspirin.<sup>7,66</sup> Vancomycin, if too rapidly infused, causes a transient bright red flushing, mediated by histamine and at times can be accompanied by hypotension. This reaction typically occurs during and immediately after the infusion, and is termed “red man syndrome.” Idiopathic flushing is managed with nonselective beta-adrenergic antagonists (nadolol, propranolol) or clonidine, while anxiolytics are beneficial if emotional distress or anxiety is determined to be causative. Other nontoxicologic causes of flushing including carcinoid syndrome, pheochromocytoma, mastocytosis, anaphylaxis, medullary carcinoma of the thyroid, pancreatic cancer, menopausal flushing, and renal carcinoma, are in the differential diagnosis of the flushed patient.<sup>28</sup>

## Sweating

Xenobiotic-induced diaphoresis is either part of a physiologic response to heat generation or is pharmacologically mediated following parasympathetic or sympathomimetic xenobiotic use. Because the postsynaptic receptor on the eccrine glands is muscarinic, most muscarinic agonists stimulate sweat production. Sweating occurs following exposure to cholinesterase inhibitors, such as organic phosphorus compounds, but also occurs with direct-acting muscarinic agonists such as pilocarpine. Alternatively, antimuscarinics, such as belladonna alkaloids or antihistamines, reduce sweating and produce dry skin. Certain xenobiotics have proven useful for the treatment of hyperhidrosis including the anticholinergics glycopyrrolate, propantheline bromide, and botulinum toxin. Botulinum toxin-A derived from *Clostridium botulinum*, which is FDA approved for the treatment of primary focal axillary hyperhidrosis, temporarily chemodenervates eccrine sweat glands at the neuroglandular junction via inhibition of presynaptic acetylcholine release.<sup>1</sup>

## Xenobiotic-Induced Dyspigmentation

Cutaneous pigmentary changes can result from the deposition of xenobiotics that are ingested and carried to the skin by the blood or that permeate the skin from topical applications. Many heavy metals are associated with dyspigmentation. Argyria, a slate-colored discoloration of the skin resulting from the systemic deposition of silver particles in the skin after excessive ingestion of colloidal silver, can be localized or widespread. The discoloration tends to be most prominent in areas exposed to sunlight, probably because silver

stimulates melanocyte proliferation. Histologically, fine black granules are found in the basement membrane zone of the sweat glands, blood vessel walls, the dermoepidermal junction, and along the erector pili muscles (Chap. 98). Gold, which was historically used parenterally in the treatment of rheumatoid arthritis, caused a blue or slate-gray pigmentation, often periorbitally, known as chrysiasis. The pigmentation is also accentuated in sun-exposed areas but, unlike argyria, sun-protected areas do not histologically demonstrate gold. Also, melanin is not increased in the areas of hyperpigmentation. The hyperpigmentation is probably caused by the gold itself, but the cause of its distribution pattern remains unknown. Histologically, the gold is found within lysosomes of dermal macrophages and distributed in a perivascular and perieccrine pattern in the dermis. Bismuth produces a characteristic oral finding of the metallic deposition in the gums and tongue known as bismuth lines, as well as a blue-gray discoloration of the face, neck, and dorsal hands. Chronic arsenic exposure occurs following exposure to pesticides or contaminated well-water, which can cause cutaneous hyperpigmentation with a bronze hue, with areas of scattered hypopigmentation occurring between 1 and 20 years following exposure. Lead also deposits in the gums, causing the characteristic “lead lines,” which are the result of subepithelial deposition of lead granules. Intramuscular injection of iron stains the skin, resulting in pigmentation similar to that seen in tattoos, and iron storage disorders, known as hemochromatosis, and results in a bronze appearance of the skin.<sup>21</sup>

Medications are also often implicated in dyspigmentation. The tetracycline-class antibiotic minocycline is a highly lipid-soluble, yellow crystalline xenobiotic that turns black with oxidation. Minocycline-induced discoloration of the skin is at times accompanied by darkening of the nails, sclerae, oral mucosa, thyroid, bones, and teeth. Hyperpigmentation from minocycline is divided into 3 types depending on the color, anatomic distribution, and whether iron- or melanin-containing granules are found within the skin. Other medications associated with hyperpigmentation include amiodarone, zidovudine, bleomycin, and other chemotherapeutics, antimalarials, and psychotropics (chlorpromazine, thioridazine, imipramine, desipramine, amitriptyline).<sup>30</sup> Although not true dyspigmentation, as noted above topiramate is linked to blue pseudochromhidrosis.<sup>11</sup>

## XENOBIOTIC-INDUCED CUTANEOUS REACTIONS (DRUG REACTIONS)

The skin is one of the most common targets for adverse drug reactions.<sup>3</sup> Drug eruptions occur in approximately 2% to 5% of inpatients and in greater than 1% of outpatients. Several cutaneous reaction patterns account for the majority of clinical presentations of xenobiotic-induced dermatotoxicity (Table 17–2). The following drug reactions will be discussed in detail: urticaria, erythema multiforme, Steven-Johnson syndrome and toxic epidermal necrolysis, fixed eruptions, and drug-induced hypersensitivity syndrome (formerly called “DRESS” syndrome).

### Urticarial Drug Reactions

Urticarial drug reactions are characterized by transient, pruritic, edematous, pink papules, or wheals that arise in the dermis, which blanch on palpation and are frequently associated with central clearing. At times, the urticarial lesions are targetoid and mimic erythema multiforme. Approximately 40% of patients with urticaria experience angioedema and anaphylactoid reactions as well.<sup>2</sup> The reaction pattern is representative of a type I, or IgE-dependent, immune reaction and commonly occurs as part of clinical anaphylaxis or anaphylactoid (non-IgE-mediated) reactions. Widespread urticaria occurs following systemic absorption of an allergen or following a minimal localized exposure in patients highly sensitized to the allergen. Regardless of whether the eruption is localized or widespread, it occurs as a result of immunologic recognition of a putative antigen by IgE antibodies, thus triggering the immediate degranulation of mast cells, which are distributed along the dermal blood vessels and nerves. The release of histamine, complements C3a and C5a, and other vasoactive mediators results in extravasation of fluid from dermal capillaries as their endothelial cells contract. This produces the characteristic urticarial lesions described above. Activation of the nearby sensory neurons produces pruritus.

TABLE 17-2 Xenobiotics Commonly Associated with Various Cutaneous Reaction Patterns

<b>Acneiform</b>	Cimetidine	Oral contraceptives	Hydrochlorothiazide	Minocycline
ACTH	Codeine	D-Penicillamine	Hematoporphyrin (Porphyria)	NSAIDs
Amoxapine	Gold	Salicylates	Levofloxacin	Oral contraceptives
Androgens	Ethinyl estradiol		NSAIDs	Penicillamine
Azathioprine	Furosemide	<b>Hair Loss</b>	Oxybenzone	Penicillin
Bromides	Ketoconazole	<b>Telogen Effluvium</b>	Piroxicam	Phenytoin
Corticosteroids	NSAIDs	β-Adrenergic antagonists (eg, timolol, propranolol)	Psoralen	Propylthiouracil
Dantrolene	Nitrogen mustard	Albendazole	Sulfanilamide	Quinolones
Halogenated hydrocarbons	Phenolphthalein	Anticoagulants (heparin, warfarin)	Tetracyclines	Serum (antithymocyte globulin)
Iodides	Phenothiazines	Antiepileptics (phenytoin, valproic acid, carbamazepine)	Tolbutamide	Sulfonamides
Isoniazid	Thiazides	Antithyroid (propylthiouracil, methimazole)		<b>Phototoxic Dermatitis</b>
Lithium		Heavy metals	<b>Phototoxic Dermatitis</b>	<b>Vesiculobullous</b>
Oral contraceptives	<b>Erythroderma</b>	Interferon-α	Celery	Amoxapine
Phenytoin	Allopurinol	Oral contraceptives (discontinuation)	Dispense blue 35	Barbiturates
<b>Allergic Contact Dermatitis</b>	Antimicrobials (aminopenicillins, sulfonamides, vancomycin)	Vitamin A excess	Eosin	Captopril
Bacitracin	Antiepileptics		Fig	Carbon monoxide
Balsam of Peru	Antimuscarinics	<b>Anagen Effluvium</b>	Fragrance materials	Chemotherapeutics
Benzocaine	Boric acid	Alkylating agents: cyclophosphamide, ifosfamide, mechlorethamine	Lime	Dipyridamole
Carba mix	Calcium channel blockers	Anthracyclines: daunorubicin, doxorubicin, idarubicin	Parsnip	Furosemide
Catechol	Cimetidine	Arsenic	Tar	Griseofulvin
Cobalt	Dapsone	Bismuth	<b>Toxic Epidermal Necrolysis</b>	Penicillamine
Diazolidinyl urea	Gold	Chemotherapeutics (taxanes: paclitaxel, docetaxel, topoisomerase-1 inhibitors: topotecan, irinotecan, etoposide, vincristine, vinblastine, busulfan, actinomycin D, gemcitabine)	Allopurinol	Penicillin
Ethylenediamine dihydrochloride	Lithium	Gold	L-Asparaginase	Rifampin
Formaldehyde	Niacin	Thallium	Amoxapine	Sulfonamides
Fragrance mix	Quinidine		Mithramycin	<b>Xanthoderma</b>
Imidazolidinyl urea	Scombroid		Nitrofurantoin	<b>Generalized</b>
Lanolin			NSAIDs	Carotenoderma
Methylchlorisothiazolinone or methylisothiazolinone	<b>Fixed Drug Eruptions</b>		Penicillin	Canthaxanthin (tanning pills)
Neomycin sulfate	Acetaminophen		Phenytoin	Dipyridamole (yellow compound)
Nickel	Allopurinol		Prazosin	Hepatic jaundice (acetaminophen, isoniazid)
<i>p</i> - <i>tert</i> -Butylphenol formaldehyde resin	Barbiturates		Pyrimethamine-sulfadoxine	Hemolytic jaundice
<i>p</i> -Phenylenediamine	Captopril		Streptomycin	Quinacrine
Quaternium-15	Carbamazepine		Sulfonamides	<b>Localized</b>
Rosin (colophony)	Chloral hydrate	<b>Maculopapular or Exanthematous Drug Eruptions</b>	Sulfasalazine	Dihydroxyacetone (spray tanning)
Sesquiterpene lactones	Chlordiazepoxide	Antimicrobials (cephalosporins, sulfonamides and aminopenicillins)	Trimethoprim-sulfamethoxazole	Picric acid
Thimerosal	Chlorpromazine	Antiepileptics	<b>Vasculitis</b>	Methylenedianiline
Urushiol	Erythromycin		Allopurinol	Phenol, topical
<b>Erythema Multiforme</b>	Fiorinal	<b>Photosensitivity Reactions</b>	Bortezomib	<b>Nail Changes: Beau Lines and Mees Lines (Leukonychia)</b>
Allopurinol	Gold	Amiodarone	Cephalosporins (commonly cefaclor)	Arsenic
Antiepileptics (phenytoin, carbamazepine)	Griseofulvin	Benoxaprofen	Cimetidine	Cyclophosphamide
Antimicrobial (sulfonamides, aminopenicillins)	Lithium	Chlorpromazine	G-CSF	Doxorubicin
Barbiturates	Phenolphthalein	Ciprofloxacin	Gold	Hydroxyurea
	Metronidazole	Dacarbazine	Hydralazine	Paclitaxel
	Minocycline	5-Fluorouracil	Levamisole	Thallium
	Naproxen	Furosemide	Methotrexate	
	NSAIDs	Griseofulvin		

ACTH = adrenocorticotropic hormone; G-CSF = granulocyte colony-stimulating factor; NSAIDs = nonsteroidal antiinflammatory drugs.

Nonimmunologically mediated mast cell degranulation producing an identical urticarial syndrome also occurs following exposure to any xenobiotic.<sup>14</sup>

### Erythema Multiforme

Historically, it was believed that erythema multiforme existed on a spectrum with Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) given overlapping clinical features and morphology. However, these entities were reclassified on the basis that most cases of erythema multiforme are believed to be triggered by viral infection (herpes simplex virus most

commonly) and most cases of SJS/TEN are triggered by xenobiotics.<sup>51</sup> Erythema multiforme is an acute self-limited disease characterized by target-shaped, erythematous macules and patches on the palms and soles, as well as the trunk and extremities (Fig. 17-5). The Nikolsky sign, defined as sloughing of the epidermis when direct pressure is exerted on the skin, is absent. Mucosal involvement is absent or mild in erythema multiforme minor and severe in erythema multiforme major. While less common than viral-induced erythema multiforme, xenobiotics such as sulfonamides, phenytoin, antihistamines, many antibiotics, rosewood, and urushiol also elicit erythema multiforme.

**FIGURE 17-5.** Erythema multiforme. Typical targetoid macules on the palm. (Reproduced with permission from Wolff K, Goldsmith LA, Katz SI, et al. *Fitzpatrick's Dermatology in General Medicine*, 7th ed. New York, NY: McGraw-Hill; 2008.)

Differentiating erythema multiforme from SJS/TEN, which can also present with targetoid lesions, can be difficult, especially in the case of bullous erythema multiforme. A skin biopsy revealing partial or full-thickness epidermal necrosis would favor a diagnosis of SJS/TEN rather than erythema multiforme.

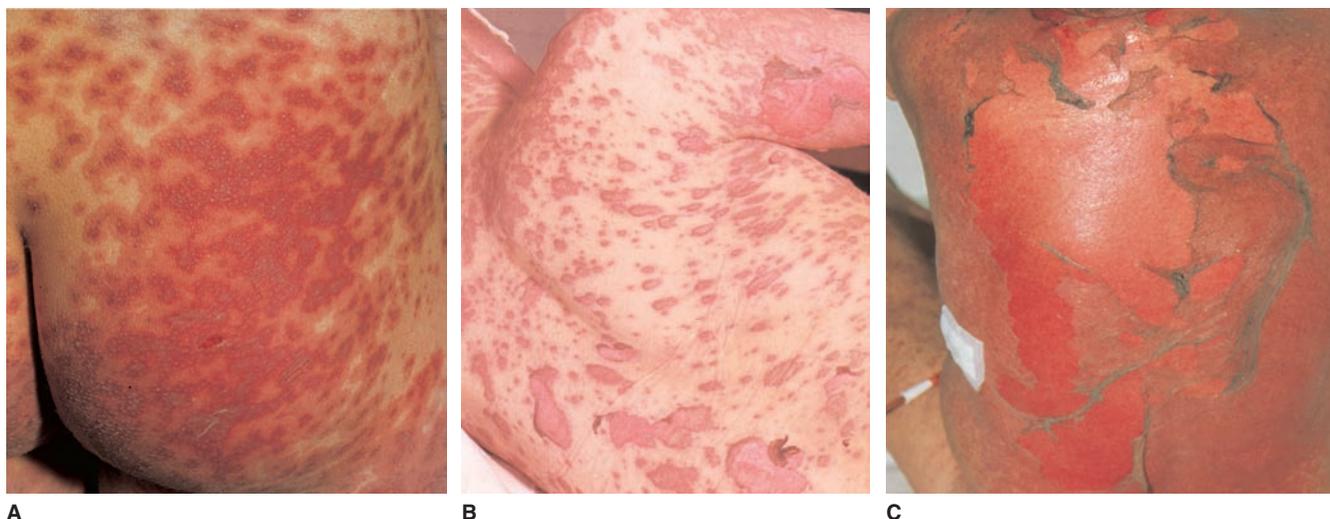

### Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis

Toxic epidermal necrolysis (TEN) and Stevens-Johnson syndrome (SJS) (Fig. 17-6) are considered to be related disorders that belong to a spectrum of increasingly severe skin eruptions.<sup>45</sup> Stevens-Johnson syndrome is defined by lesser than 10% body surface area epidermal detachment, SJS-TEN overlap

10% to 30% involvement, and TEN greater than 30% epidermal sloughing. Although on a spectrum, SJS has a mortality rate of 5%, which is far lower than the approximate 25% to 50% mortality rate for patients with TEN.<sup>49,52</sup> However, a more recent series of 40 patients with TEN cared for at academic burn units revealed a 10% mortality rate.<sup>35</sup> Toxic epidermal necrolysis is a rare, life-threatening dermatologic emergency whose incidence is estimated at 0.4 to 1.2 cases per 1 million persons. More than 220 xenobiotics are causally implicated in 80% to 95% of the TEN cases. The largest study examining medication triggers of TEN divided these medications into long-term (used for months to years) and short-term. Short-term xenobiotics most commonly implicated in the development of TEN included trimethoprim-sulfamethoxazole and other sulfonamide antibiotics, followed by cephalosporins, quinolones, and aminopenicillins.<sup>53</sup> With chronic medication use, the increased risk largely occurred during the first 2 months of treatment and was greatest for carbamazepine, phenobarbital, phenytoin, valproic acid, the oxicam NSAIDs, allopurinol, and corticosteroids.

Classically, the eruption of TEN is painful and occurs within 1 to 3 weeks after the exposure to the implicated xenobiotic(s). The eruption is preceded by malaise, headache, abrupt onset of fever, myalgia, arthralgia, nausea, vomiting, diarrhea, chest pain, or cough. One to 3 days later, signs begin in the mucous membranes including the eyes, mouth, nose, and genitals in 90% of cases.<sup>49</sup> A macular erythema then develops that subsequently becomes raised and morbilliform on the face, neck, and central trunk and finally the extremities. Individual lesions can appear targetoid because of their dusky centers and progress to bullae in the following 3 to 5 days involving the entire thickness of the epidermis. This necrosis and sloughing can also lead to loss of the fingernails. A Nikolsky sign, or sloughing of the epidermis with gentle manual pressure, is suggestive of TEN but not pathognomonic. A Nikolsky sign occurs in a variety of other dermatoses, including pemphigus vulgaris. If the diagnosis is suspected, a punch biopsy should be performed for immediate frozen section and the suspected triggering xenobiotic discontinued immediately. The histopathology typically shows partial- or full-thickness epidermal necrosis, with subepidermal bullae with a sparse infiltrate, and vacuolization with numerous dyskeratotic keratinocytes along the dermoepidermal junction adjacent to the necrotic epidermis.

The incidence of TEN is higher in patients with advanced HIV disease.<sup>45,62</sup> There is general agreement that the keratinocyte cell death in TEN is the result of apoptosis, which is suggested based on electronic microscopic studies with DNA fragmentation analysis.<sup>45</sup> Cytotoxic T lymphocytes are the main effector cells and experimental evidence points to involvement of the Fas-ligand (FasL) and perforin/granzyme pathways.

**FIGURE 17-6.** Toxic epidermal necrolysis. (A) Early eruption. Erythematous dusky red macules (flat atypical target lesions) that progressively coalesce and show epidermal detachment. (B) Advanced eruption. Blisters and epidermal detachment have led to large confluent erosions. (C) Full-blown epidermal necrolysis characterized by large erosive areas reminiscent of scalding. (Reproduced with permission from Wolff K, Goldsmith LA, Katz SI, et al. *Fitzpatrick's Dermatology in General Medicine*, 7th ed. New York, NY: McGraw-Hill; 2008.)

There are several theories as to the pathogenesis of SJS/TEN. These include that a xenobiotic could induce upregulation of Fas Ligand leading to a death receptor-mediated apoptotic pathway. A xenobiotic might interact with MHC class I-expressing cells and cause drug-specific CD8<sup>+</sup> cytotoxic T lymphocytes to accumulate within epidermal blisters, releasing perforin and granzyme B that kills keratinocytes. Finally it has been proposed that the xenobiotic triggers the activation of CD8<sup>+</sup> T lymphocytes, NK cells and NKT cells to secrete granulysin, with keratinocyte death not requiring cell contact.<sup>44</sup> Serum Fas ligand concentrations are elevated up to 4 days prior to mucosal involvement in patients with SJS/TEN and have the potential to be useful clinically as an early predictor of these severe dermatologic diseases.<sup>43</sup> Serum granulysin, a proinflammatory cytolytic enzyme released by CD8<sup>+</sup> T lymphocytes found in the blisters of TEN was demonstrated to be a potential early predictive marker of SJS/TEN.<sup>20</sup> A rapid immunochromatographic test that detects elevated serum granulysin (>10 ng/mL) in 15 minutes demonstrates promise in a small study in which its sensitivity was noted to be 80% and specificity 95.8% for differentiating SJS/TEN from ordinary exanthematous drug eruptions.<sup>20</sup> However, this test is not yet commercially available.

Because immediate removal of the inciting xenobiotic is critical to survival, patients with TEN related to a xenobiotic with a long half-life have a poorer prognosis, and these patients should be transferred to a burn or other specialized center for sterile wound care. Risk factors for mortality include older patient age, higher total surface area of involvement, and more pre-existing comorbidities.<sup>35</sup> In a recent study, only serum bicarbonate less than 20 mmol/L was found to portend hospital mortality in patients with TEN.<sup>68</sup> Porcine xenografts or human skin allografts including amniotic membrane transplantation are used and are widely accepted therapy.<sup>48</sup> A meta-analysis of 17 studies revealed a trend toward improved mortality with high-dose IVIG in adults and good prognosis in children; however, there is insufficient evidence to support a clinical benefit.<sup>27</sup> Patients with TEN develop metabolic abnormalities, sepsis, multiorgan failure, pulmonary emboli, and gastrointestinal hemorrhages and should be closely monitored. The major microbes leading to sepsis are *Staphylococcus aureus* and *Pseudomonas aeruginosa*. In a patient with SJS/TEN with ophthalmic involvement, early ophthalmologic consultation is necessary because blindness is a potential complication.

Mimickers of TEN include SJS, staphylococcal scalded skin syndrome, severe exanthematous drug eruptions, erythema multiforme-major, linear

IgA dermatosis, paraneoplastic pemphigus, acute graft versus host disease, drug-induced pemphigoid and pemphigus vulgaris, and acute generalized exanthematous pustulosis. Discussion of some of these entities is beyond the scope of this chapter (Table 17-3).

### Bullous Reactions (Blistering Reactions)

In addition to SJS and TEN, other bullous cutaneous reactions include drug-induced pseudoporphyria, fixed drug eruption, acute generalized exanthematous pustulosis, phototoxic drug eruptions, and drug-induced autoimmune blistering diseases. Xenobiotic-related cutaneous blistering reactions are clinically indistinguishable from autoimmune blistering diseases such as pemphigus vulgaris or bullous pemphigoid (Fig. 17-7). Certain topically applied xenobiotics such as the vesicant cantharidin derived from “blister beetles” in the Coleoptera order and Meloidae family are used in the treatment of molluscum and viral warts. In high concentrations, xenobiotics lead to necrosis of both skin and mucous membranes. Other systemic xenobiotics cause a similar reaction pattern mediated by the production of antibody directed against the cells at the dermal-epidermal junction (Table 17-3).

A number of medications, many of which contain a “thiol group” such as penicillamine and captopril, induce either pemphigus resembling pemphigus foliaceus, a superficial blistering disorder in which the blister is at the level of the stratum granulosum, or pemphigus vulgaris, in which blistering occurs above the basal layer of the epidermis (Fig. 17-1). Other xenobiotics, such as furosemide, penicillin, and sulfasalazine produce tense bullae that resemble bullous pemphigoid. Direct immunofluorescence studies demonstrate epidermal intracellular immunoglobulin deposits at the dermal-epidermal junction. The offending xenobiotic should be discontinued and the patient should be referred to a dermatologist to determine treatment. The reaction may persist for up to 6 months after the offending xenobiotic is withdrawn.

### Fixed Drug Eruptions

Fixed drug eruption is another bullous drug eruption and is characterized by well-circumscribed erythematous to dusky violaceous patches which with central bullae or erosions and develops 1 to 2 weeks after first exposure to the drug. This reaction pattern is so named because re-exposures to the xenobiotic cause lesions in the same area, typically within 24 hours of exposure (Fig. 17-8). Typical locations include acral extremities, genitals,

**TABLE 17-3** Differential Diagnosis of Xenobiotic-Induced Blistering (Vesiculobullous) Disorders

Disease	Fever	Mucositis	Morphology	Onset	Miscellaneous
Acute graft-versus-host disease	Yes	Present	Morbilloform rash, bullae and erosions	Acute	Closely resembles toxic epidermal necrolysis
Acute generalized exanthematous pustulosis	Yes	Rare	Superficial pustules	Acute	Self-limiting on discontinuation of drug
Linear IgA bullous dermatitis	No	Rare	Tense, subepidermal bullae	Acute	Vancomycin is most commonly implicated
Pemphigus	No	Usually absent	Erosions, crusts, patchy erythema (resembles pemphigus foliaceus)	Gradual	Commonly caused by penicillamine and other “thiol” drugs; often resolves after the inciting xenobiotic is discontinued
Pemphigoid	No	Rare	Tense bullae (sometimes hemorrhagic)	Acute	Diuretics a common cause, especially furosemide, spironolactone; often pruritic
Paraneoplastic pemphigus	No	Present (usually severe)	Polymorphous skin lesions, flaccid bullae	Gradual	Resistant to treatment; associated with malignancy, especially lymphoma
Staphylococcal scalded skin syndrome	Yes	Absent	Erythema, skin tenderness, periorificial crusting	Acute	Affects children younger than 5 years, adults on dialysis, and those on immunosuppressive therapy
Xenobiotic-triggered Pemphigus	No	Present	Mucosal erosions, flaccid bullae	Gradual	Caused by “nonthiol” xenobiotics which are more likely to persist after discontinuation of xenobiotic; may require long-term immunosuppressive therapy

A

B

**FIGURE 17-7.** Pemphigus vulgaris. (A) Flaccid blisters. (B) Oral erosions. (Part A, Used with permission from Lawrence Lieblich, MD. Part B, Reproduced with permission from Wolff K, Goldsmith LA, Katz SI, et al. *Fitzpatrick's Dermatology in General Medicine*, 7th ed. New York, NY: McGraw-Hill; 2008.)

and intertriginous sites, and this process is confused with TEN if widely confluent as in a “generalized fixed drug eruption.” This reaction pattern is generally not life threatening and heals with residual postinflammatory hyperpigmentation. Bullous fixed-drug reactions result from exposure to diverse xenobiotics such as angiotensin-converting enzyme inhibitors and a multitude of antibiotics. As mentioned above, EM can have a bullous variant that can also be confused with SJS/TEN.

### Coma Bullae

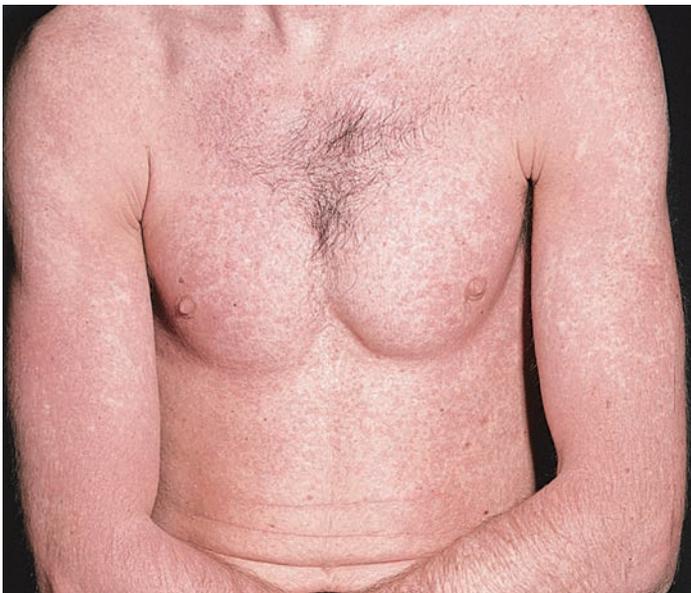

“Coma bullae” are tense bullae on normal-appearing skin that occur within 48 to 72 hours in comatose patients with sedative–hypnotic overdoses, particularly phenobarbital, or carbon monoxide poisoning. They also occur in patients in coma from infectious, neurologic, or metabolic causes. Although these blisters are thought to result predominantly from pressure-induced epidermal necrosis, they occasionally occur in non–pressure-dependent areas, suggesting a systemic mechanism. Histologically, an intraepidermal or subepidermal blister is observed. There is accompanying eccrine duct and gland necrosis.

### Drug-Induced Hypersensitivity Syndrome

The skin is linked with systemic immunologic diseases such that an alteration in the metabolism of certain xenobiotics leads to a hypersensitivity syndrome. The drug-induced hypersensitivity syndrome, formerly called Drug Reaction with Eosinophilia and Systemic Symptoms (DRESS), can be severe and potentially life threatening. The hypersensitivity syndrome is characterized by the triad of fever, skin eruption, and internal organ involvement.<sup>32</sup> The frequency is estimated between 1 in 1,000 to 1 in 10,000 with antiepileptic or sulfonamide antibiotic exposures and usually presents within 2 to 6 weeks of the initial exposure. For antiepileptics, the inability to detoxify arene oxide metabolites is suggested to be a key factor; once a patient has a documented drug-induced hypersensitivity syndrome to one antiepileptic, it is important to note that cross-reactivity between phenytoin, carbamazepine, and phenobarbital is well documented, both in vivo and in vitro.<sup>47</sup> In the case of sulfonamides, acetylator phenotype and lymphocytes’ susceptibility to the metabolite hydroxylamine are risk factors for developing drug hypersensitivity syndrome. Further support for the role of genetic predisposition comes from data in Northern European populations in which the presence of the HLA-A\*3101 allele significantly increases the risk of developing carbamazepine-induced hypersensitivity syndrome.<sup>34</sup> Fever and a cutaneous eruption are the most common symptoms. Accompanying malaise, pharyngitis, and cervical lymphadenopathy are frequently present. Atypical lymphocytes and eosinophilia occur initially. The exanthem is initially generalized and morbilliform, and conjunctivitis and angioedema occur (Fig. 17-9). Later the eruption becomes edematous, and facial edema, which is often present, is a hallmark of this syndrome. One-half of patients with drug induced hypersensitivity syndrome will have hepatitis, interstitial nephritis, vasculitis, CNS manifestations (including encephalitis, aseptic meningitis), interstitial pneumonitis, acute respiratory distress

**FIGURE 17-8.** Fixed drug eruption due to tetracycline. A well-defined plaque on the knee, merging with 3 satellite lesions. The large plaque exhibits epidermal wrinkling, a sign of incipient blister formation. This was the second such episode after ingestion of a tetracycline. No other lesions were present. (Reproduced with permission from Wolff K, Goldsmith LA, Katz SI, et al. *Fitzpatrick's Dermatology in General Medicine*, 7th ed. New York, NY: McGraw-Hill; 2008.)

**FIGURE 17-9.** A patient with a hypersensitivity syndrome associated with phenytoin. He has a symmetric, bright red, and exanthematous eruption, confluent in some sites. The patient had associated lymphadenopathy. (Reproduced with permission from Wolff K, Johnson RA. *Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology*, 6th ed. New York, NY: McGraw-Hill; 2009.)

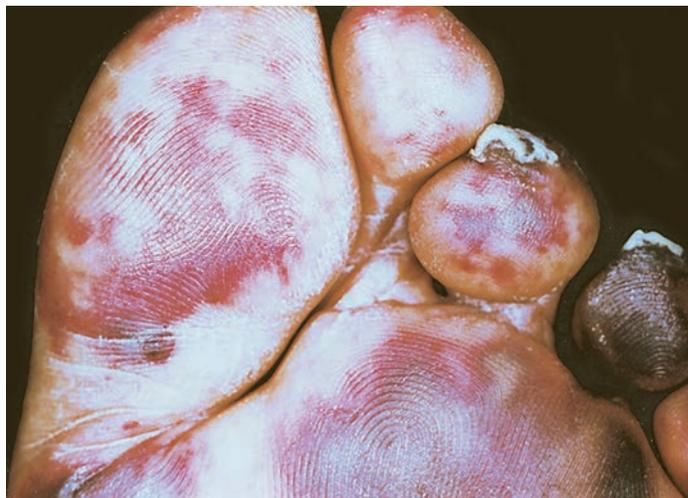

syndrome, and autoimmune hypothyroidism. Hepatic involvement can be fulminant and is the most common cause of deaths associated with this syndrome. Colitis with bloody diarrhea and abdominal pain are associated. In addition to the aromatic antiepileptics (phenobarbital, carbamazepine, and phenytoin), lamotrigine, allopurinol, sulfonamide antibiotics, dapsone and the protease inhibitor abacavir are implicated. Early withdrawal of the offending xenobiotic is crucial and treatment is generally supportive.<sup>42,67</sup> If cardiac or pulmonary involvement is present, systemic corticosteroids should be initiated. However, their benefit on outcome has not been demonstrated, and relapse may occur during tapering, necessitating long-term (several month) courses of therapy. The authors recommend that patients with drug-induced hypersensitivity syndrome be managed in conjunction with a dermatologist and that adequate follow-up is ensured.

### Erythroderma

Erythroderma, also known as exfoliative dermatitis, is defined as a generalized redness and scaling of the skin. However, it does not represent one disease entity, but rather it is a severe clinical presentation of a variety of skin diseases including psoriasis, atopic dermatitis, drug reactions, or cutaneous T-cell lymphoma (CTCL). At times, the underlying etiology of erythroderma is never discovered and this is termed “idiopathic erythroderma.” The importance of this presentation is its association with systemic complications such as hypothermia, peripheral edema, and loss of fluid, electrolytes and albumin with subsequent tachycardia and cardiac failure. Many xenobiotics produce erythroderma (Table 17-2). Boric acid, when ingested, can cause systemic toxicity in addition to a bright red eruption (“lobster skin”), followed usually within 1 to 3 days by a generalized exfoliation.<sup>55</sup>

### Vasculitis

Xenobiotic-induced vasculitis (Fig. 17-10) comprises 10% to 15% of secondary cutaneous vasculitis. It generally occurs from 7 to 21 days after initial exposure to the xenobiotic or 3 days after rechallenge and is considered to be a secondary cause of cutaneous small vessel vasculitis (typically involving dermal post-capillary venules). Many xenobiotics are implicated as triggers of cutaneous vasculitis (Table 17-2).<sup>60</sup> Cutaneous vasculitis is characterized by purpuric, nonblanching macules that usually become raised and palpable. The purpura tends to occur predominantly on gravity-dependent areas, including the lower

**FIGURE 17-10.** Leukocytoclastic vasculitis in a patient with mixed cryoglobulinemia manifested as palpable purpura and acrocyanosis. Patient with tuberculosis, positive antinuclear antibody, and hepatitis. (Reproduced with permission from Wolff K, Goldsmith LA, Katz SI, et al. *Fitzpatrick's Dermatology in General Medicine*, 7th ed. New York, NY: McGraw-Hill; 2008.)

extremities, particularly the feet, ankles, and buttocks (Fig. 17-11). Sometimes the reaction pattern has edematous purpuric wheals (urticarial vasculitis), hemorrhagic bullae, or ulcerations. Histologic examination of affected skin shows a leukocytoclastic vasculitis, which is characterized by fibrin deposition in the vessel walls. There is a perivascular infiltrate with intact and fragmented neutrophils that appear as black dots, known as “nuclear dust” and extravasated red blood cells. Vasculitis can be limited to the skin, or can involve other organ systems, particularly the kidneys, joints, liver, lungs, and brain.

**FIGURE 17-11.** Purpura. Nonblanching red erythematous papules and plaques (palpable purpura) on the legs, representing leukocytoclastic vasculitis. (Reproduced with permission from Wolff K, Goldsmith LA, Katz SI, et al. *Fitzpatrick's Dermatology in General Medicine*, 7th ed. New York, NY: McGraw-Hill; 2008.)

**FIGURE 17-12.** Levamisole-induced purpura: violaceous patches on the ear, neck, and thigh of 46-year-old woman exposed to levamisole-adulterated cocaine. (Reproduced with permission from Chung C, Tumei PC, Birnbaum R, et al. Characteristic purpura of the ears, vasculitis, and neutropenia—a potential public health epidemic associated with levamisole-adulterated cocaine. *J Am Acad Dermatol.* 2011 Oct;65(4):722-725.)

The purpura results from the deposition of circulating immune complexes, which form as a result of hypersensitivity to a xenobiotic. Treatment consists of withdrawing the putative xenobiotic and initiating systemic corticosteroid therapy if systemic involvement is present. A syndrome of vasculitis, neutropenia, and retiform purpura occurs as a result of levamisole-adulterated cocaine (Fig. 17-12).<sup>13</sup> The earlobe is a common site of purpuric lesions from levamisole, and it was estimated that up to 70% of the cocaine sold in some areas during an epidemic in the United States contained levamisole.<sup>6,63,64</sup>

### Purpura

Purpura is the multifocal extravasation of blood into the skin or mucous membranes (Fig. 17-12). Ecchymoses, therefore, are considered to be purpuric lesions. Chemotherapeutics that either diffusely suppress the bone marrow or specifically depress platelet counts below 30,000/mm<sup>3</sup>, predispose to purpuric macules. Xenobiotics that interfere with platelet aggregation, such as aspirin, clopidogrel, ticlopidine, valproic acid, and thrombolytics, cause purpura. Anticoagulants, such as heparin and warfarin, may also result in purpura (Chaps. 20 and 58).

### Anticoagulant-Induced Skin Necrosis

Skin necrosis from warfarin, low-molecular-weight heparin, or unfractionated heparin usually begins 3 to 5 days after the initiation of treatment, which corresponds with the expected early decline of protein C function with warfarin (Fig. 17-13). The estimated risk is one in 10,000 persons. It is 4 times higher in women, especially if obese, with peaks in sixth to seventh decades of life. The necrosis is secondary to thrombus formation in vessels of the dermis and subcutaneous fat. Heparin-induced cutaneous necrosis results from antibodies that bind to complexes of heparin and platelet factor 4 and induce platelet aggregation and consumption. This causes bullae, ecchymosis, ulcers, and massive subcutaneous necrosis, usually in areas of abundant subcutaneous fat, such as the breasts, buttocks, abdomen, thighs, and calves. Heparin-induced necrosis is associated with protein C or S deficiency, anticardiolipin antibody syndrome, as well as factor V Leiden mutations.<sup>46</sup>

### Contact Dermatitis

When a xenobiotic comes in contact with the skin, it can result in either an allergic contact dermatitis (20% of cases) or more commonly an irritant contact dermatitis (80% of cases). Contact dermatitis is characterized by inflammation of the skin with spongiosis (intercellular edema) of the epidermis that results from the interaction of a xenobiotic with the skin. Well-demarcated erythematous vesicular or scaly patches or plaques, and at times bullae, are noted on areas in direct contact with the xenobiotic, whereas the remaining areas are spared.

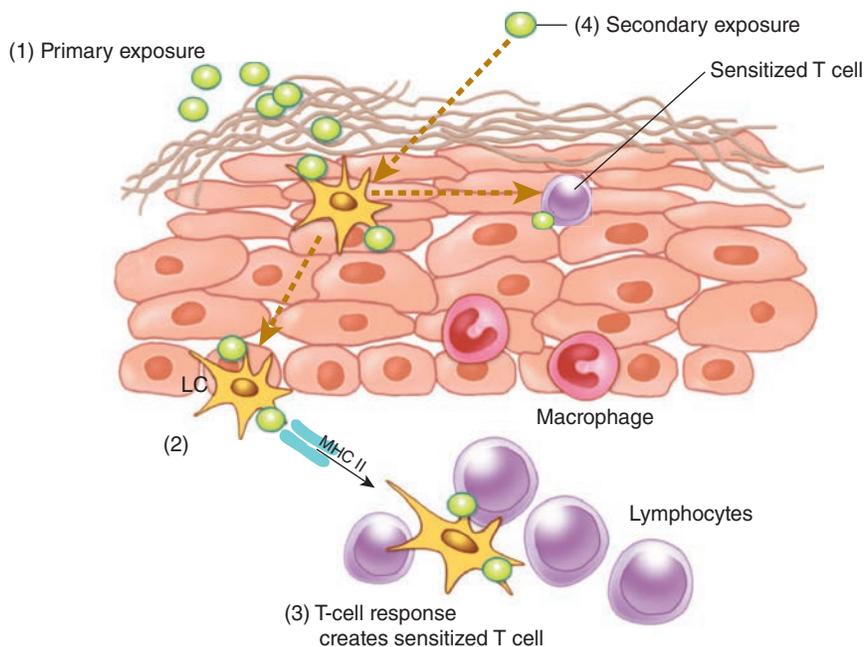

Allergic contact dermatitis fits into the classic delayed hypersensitivity, or type IV, immunologic reaction. The development of this reaction requires prior sensitization to an allergen, which, in most cases, acts as a hapten by

binding with an endogenous molecule that is then presented to an appropriate immunologic T cell. Upon reexposure, the hapten diffuses to the Langerhans cell, is chemically altered, bound to an HLA-DR, and the complex is expressed on the Langerhans cell surface. This complex interacts with primed T cells either in the skin or lymph nodes, causing the Langerhans cells to make interleukin-1 and the activated T cells to make interleukin-2 and interferon. This subsequently activates the keratinocytes to produce cytokines and eicosanoids that activate mast cells and macrophages, leading to an inflammatory response (Fig. 17-14).<sup>31</sup>
