Manganism is also described in several nonoccupational settings. Manganese chloride and manganese sulfate are employed as nutritional supplements,<sup>11</sup> and manganese toxicity is well documented in patients receiving excessive doses in total parenteral nutrition.<sup>28,61,67</sup> Infants, young children, and patients with impaired clearance from chronic liver disease are particularly at risk. More recently, epidemic manganese toxicity was reported from the use of intravenous psychostimulant drugs such as methcathinone and a "Russian cocktail" prepared from pseudoephedrine-containing cough and cold products in the presence of potassium permanganate as a strong oxidizer.<sup>49,86,91</sup>

Environmental exposure to excessive manganese in drinking water is linked to neurodevelopmental deficiencies in children, including effects on cognition, behavior, memory, and motor function.<sup>15,21,45</sup> Concerns are also raised about the potential environmental health risks of methylcyclopentadienyl manganese tricarbonyl (MMT), an antiknock agent added to gasoline as an alternative to lead.<sup>26,35</sup> Methylcyclopentadienyl manganese tricarbonyl was allowed in Canada since 1976 and in the United States since 1995; however, more research is needed to understand its contribution to the environmental burden of manganese and to human health.<sup>87</sup>

Permanganates were first discovered to be strong oxidizers in the 18th century. Weak solutions of potassium permanganate (0.01%) are still used in medicine as topical drying and antiseptic skin preparations. Potassium, sodium, and barium permanganate also have uses in the pharmaceutical, chemical, and photographic industries. The toxicity of permanganates is mostly related to their oxidizing effects and is not discussed here.

### CHEMISTRY

Manganese is a transition metal with atomic number 25, located between chromium and iron in the periodic table. It is dark-gray, brittle paramagnetic, and occurs in several mineral forms. Most manganese in the environment is found complexed to oxygen, carbon, or chloride. The most economically important ore is pyrolusite, or manganese dioxide (MnO<sub>2</sub>), from which metallic manganese was first isolated in 1774.

Manganese can exist in oxidation states from -3 to +7. Divalent manganese (Mn<sup>2+</sup>) is the most common, the most bioavailable, and the most physiologically important form. Trivalent manganese ion (Mn<sup>3+</sup>) is also biologically important and is, for example, the form of manganese in superoxide dismutase. Elemental Mn<sup>0</sup> is benign and ionized manganese exists in diverse states.

### PHARMACOLOGY AND PHYSIOLOGY

Manganese is an essential dietary element found in nuts, grains, legumes, fruits, and vegetables. Most people consume 2 to 9 mg of manganese compounds per day, but vegetarians often consume more. Manganese salts in well water also contribute to dietary intake.<sup>83</sup> Manganese is present in human breast milk in its trivalent form bound to lactoferrin, which is readily absorbed via receptors in the small intestine. Manganese salts—usually manganese sulfate or manganese chloride—are typically added to infant formulas, processed foods, and dietary supplements, although these are less well absorbed.

Manganese is considered an essential dietary element because it is a cofactor in many human enzyme systems, including superoxide dismutase, hexokinase, xanthine oxidase, arginase, 3-hydroxymethylglutaryl-CoA (HMG) CoA reductase, and glutamine synthase. It is also present in several metalloproteins involved in the metabolism of amino acids, carbohydrates, and lipids.<sup>11</sup> Although deficiency in humans is not reported, experimental manganese restriction produced a scaling, erythematous, pruritic rash; alterations in calcium homeostasis (eg, hypercalcemia, hyperphosphatemia); and increased alkaline phosphatase in healthy volunteers.<sup>31</sup>

Normally, less than 5% of dietary manganese is absorbed throughout the length of the small intestine. However, enteral manganese absorption is altered depending on the dietary needs of the host and the presence of similarly charged compounds in the diet. For example, divalent manganese ion (Mn<sup>2+</sup>) forms complexes with a variety of ligands in the body and substitutes for Mg<sup>2+</sup>, Ca<sup>2+</sup>, and Fe<sup>2+</sup> in complexes with proteins and enzymes.<sup>63</sup> Because manganese ions compete with iron for binding sites on transferrin, the absorption of manganese is dependent on iron status, increasing in the presence of iron deficiency and decreasing when iron stores are adequate. Radioisotope studies demonstrate that absorption of dietary manganese is doubled in individuals with anemia.<sup>11,30</sup> Manganese absorption from the gastrointestinal tract is also inversely proportional to the amount of calcium in the diet, most likely because of competition between divalent cations for transport.<sup>11</sup>

About 85% of manganese in whole blood is bound to hemoglobin in erythrocytes, and normal measured whole blood concentrations are as much as 5 times higher than those measured in serum.<sup>74</sup> The remaining manganese in plasma is mostly bound to transferrin,  $\beta_1$ -globulin, and albumin.<sup>5</sup>

Manganese is widely distributed to all tissues, and crosses both the placental<sup>11</sup> and the blood–brain barriers.<sup>16</sup> Transport in the body is facilitated by transport proteins and for  $Mn^{2+}$  by the divalent metal transporter.<sup>11</sup>

Manganese is primarily eliminated via the bile in feces, which requires normal hepatic function for healthy manganese homeostasis. It accumulates in bile against a concentration gradient, which suggests an active transport mechanism, possibly by hepatic metal ion ZIP transporter protein.<sup>8,55</sup> Renal excretion is negligible, whereas 67% of a radio-labeled manganese dose injected intravenously is recovered in feces within 48 hours, and less than 0.1% appears in the urine within 5 days of administration.<sup>48</sup>

The elimination half-life of manganese from the body is approximately 40 days,<sup>60</sup> with high variability among individuals. Elimination of manganese is prolonged in young women with high ferritin stores<sup>30</sup> or after the initiation of oral iron therapy for anemia.<sup>60</sup> This effect is most likely due to increased hepatic sequestration from increased production of iron transport and storage proteins. High concentrations of manganese are found in patients with hemochromatosis, supporting the idea that increased or abnormal iron storage proteins will also lead to increased hepatic manganese stores.<sup>1</sup>

### PATHOPHYSIOLOGY

Manganese toxicity typically results from either overexposure or impaired elimination. Because of its low enteral absorption, excessive dietary ingestion of manganese is unlikely to cause toxicity in adults with normal elimination. However, parenteral administration of either nutritional supplements or xenobiotics containing manganese presents a greater toxicologic risk. The major occupational route of exposure is inhalation of manganese dusts or fumes. Inhalation acutely elevates blood concentrations, and possibly creates pulmonary manganese deposits that effectively prolong the exposure and absorption even following patient removal from the environmental source.<sup>68</sup> Whereas normal liver function protects against accumulation of manganese in soft tissue, patients with hepatic disease are at risk for manganese bioaccumulation and toxicity from normal dietary intake.<sup>81,84</sup>

Although manganese is widely distributed in the body, major clinical features of manganese toxicity are primarily related to its accumulation in brain, where it concentrates in the basal ganglia and, to a lesser extent, in the caudate and putamen. People with hereditary mutations in the cell membrane manganese exporter protein SLC30A10 develop manganism in the absence of elevated environmental or occupational exposure, as a result of a relative deficit in manganese efflux from cells.<sup>73,95</sup> The exact mechanisms of manganese uptake into and efflux from neurons, and its transport within the brain, are still being elucidated, but involve multiple transport mechanisms. Transferrin receptor–mediated endocytosis of transferrin-bound manganese is thought to be the major route of entry under normal conditions.<sup>6</sup> However, for unclear reasons, nonprotein-bound manganese crosses the blood–brain barrier more quickly than protein-bound manganese.<sup>66,78</sup> Therefore, exposure to manganese in excess of blood ligand-binding capacity promotes its distribution to the brain. Transferrin also plays an important part in manganese accumulation in the basal ganglia, specifically, because these are areas of high transferrin-receptor density.<sup>5,27</sup> The divalent-metal transporter is most likely also important, but more research is needed to understand its role.

The specific mechanisms of ionized manganese neurotoxicity are also not well established, although oxidative stress, mitochondrial dysfunction, neuroinflammation, and alterations in neurotransmitter metabolism are all likely implicated. Ionized manganese ( $Mn^{2+}$ ) concentrates in mitochondria and inhibits both mitochondrial F1-ATPase and complex I in the electron transport chain, thereby disrupting oxidative phosphorylation and contributing to energy failure and cytotoxicity.<sup>19,32,33,99,100</sup> Like other transition metals, manganese causes local damage by generating reactive oxygen species during redox cycling between the divalent ( $Mn^{2+}$ ) and trivalent ( $Mn^{3+}$ ) forms. The participation of manganese in Fenton reactions also occurs and results in oxidative tissue damage (Chap. 10). Manganese also promotes sustained inflammatory neuronal injury by activating microglia and astrocytes, potentiating the release of nitric oxide, prostaglandin E1, tumor necrosis factor

alpha (TNF- $\alpha$ ), nuclear factor  $\kappa$ B (NF- $\kappa$ B), and other inflammatory mediators from activated glial cells.<sup>29,47,56,65</sup>

The clinical features of manganism share many similarities with idiopathic Parkinson disease. However, neuroimaging and neurochemical studies suggest that the neurodegenerative patterns are different. Degeneration of nigrostriatal dopaminergic neurons is clearly implicated in Parkinson disease, and single-photon emission computed tomography (SPECT) and positron emission tomography (PET) studies in patients with Parkinson disease show decreased presynaptic dopamine terminal markers in the striatum and reduced dopa decarboxylase activity. By contrast, newer evidence indicates a lack of degeneration among midbrain dopaminergic neurons, with normal dopamine synthesis and transporters, and a marked degeneration of basal ganglia structures, in particular the globus pallidus, in patients with manganese-related motor dysfunction.<sup>34</sup> Although neuroimaging and neurochemical studies in patients with manganism are limited, the hypothesis that manganese does not cause presynaptic nigrostriatal neurodegeneration but rather a more widespread pattern of subcortical damage bears further exploration.<sup>44</sup>

### CLINICAL MANIFESTATIONS

Early reports of manganism in German manganese workers<sup>11</sup> and Chilean miners<sup>85</sup> described an acute phase characterized by psychiatric symptoms known as “manganese madness” and included visual hallucinations, behavioral changes, anxiety, impotence, and decreased libido.<sup>11</sup> Currently accumulated evidence indicates that psychiatric and/or cognitive abnormalities such as deficits in attention and memory are common. However, classic manganism is best typified by a late-presenting syndrome of extrapyramidal movement abnormalities, including marked bradykinesia, rigidity, postural instability, loss of facial expression, impaired speech, and pronounced gait disturbance.<sup>10</sup> Signs and symptoms vary with duration and level of exposure, are often insidious in onset, and do not become apparent for several years (Table 94–1). Neurodevelopmental deficits are reported in children with chronic manganese exposure, and numerous studies correlate elevated home water manganese concentrations with poor academic performance and lower IQ scores.<sup>13,15,21,45,72</sup> More work is needed to describe how these clinical features evolve, as well as to understand the relevance of subtle pre-clinical neuropsychological signs for predicting sequelae.

In a longitudinal study of 14 former chronic Ephedrone abusers, the first symptom developed 6 to 12 months after intravenous drug abuse. Dysarthria was the initial symptom in 31% of patients, with 1 patient presenting with manganese madness. Dystonia, tremor, and postural instability began later, but all symptoms demonstrated progression.<sup>86</sup>

**TABLE 94–1** Typical Features of Chronic Manganism

System	Early Manifestations	Late Manifestations
Constitutional	Asthenia, lethargy	—
Gastrointestinal	Anorexia	—
Neurologic	Fine intention tremor Headaches	Coarse intention tremor Visual hallucinations Cognitive impairment Loss of facial expression Dysphagia Micrographia Gait instability <sup>a</sup> Low-volume speech
Psychiatric	Apathy Irritability Emotional lability	Decreased libido or impotence Anxiety Additional behavioral changes
Musculoskeletal	Arthralgias	Muscle rigidity

<sup>a</sup>Decreased arm swing, toe walking, and inability to turn or walk backward without falling.

Although the movement disorder that typically occurs in patients with manganism is similar to that which occurs in cases of idiopathic Parkinson disease, including a typical “cock walk” on the balls of the feet, there are several distinguishing clinical features, including the lack of a typical tremor, a particular tendency to fall backward, and an absence of severe progressive dementia.<sup>34,43</sup> Oculomotor abnormalities are also similar to those that occur in idiopathic Parkinson disease but have distinctive features.<sup>14</sup> Unlike Parkinson disease, the histologic hallmark Lewy bodies are absent in manganism.<sup>17,57</sup> In addition, an absent or transient clinical response to levodopa therapy is considered a criterion for establishing a diagnosis of probable manganism.<sup>70</sup> Although symptomatic improvement with levodopa therapy was reported in some patients,<sup>22,62,79</sup> most evidence indicates that dopamine supplementation does not improve signs and symptoms of parkinsonian in patients with manganese-associated neurotoxicity.<sup>34,50,59,91</sup>

Acute inhalational exposure to high concentrations of manganese oxides can cause metal fume fever (Chaps. 100 and 121), with characteristic fever, chills, nausea, headache, myalgias, and arthralgias.<sup>11</sup> Chronic occupational exposure to manganese oxide fumes is associated with chemical pneumonitis and increased rates of bronchitis and pneumonia, but it does not cause pulmonary fibrosis.<sup>58,80</sup> Manganese exposure is also associated with hypertension.<sup>53</sup>

## DIAGNOSTIC TESTING

Manganism is often difficult to differentiate from other neurodegenerative disorders. Several tests help establish the diagnosis, but each has important limitations. Careful evaluation of plausible sources of exposure, findings on neurologic and neuropsychologic examinations, and determining hepatic function and iron reserve status are important. If movement abnormalities are present, then failure of sustained response to levodopa therapy is highly suggestive of manganism. Because genetic mutations in the manganese transporter SLC30A10 are linked to a neurodegenerative syndrome, a family history should also be explored.<sup>77,95</sup>

Normal reference values for manganese in blood and urine are published (see above) and measurements are helpful, but concentrations are poorly correlated with total body manganese burden. Whole blood manganese concentrations are the most reliable values for biomonitoring purposes, although they only correlate with group and not with individual exposures.<sup>9,11</sup> Additionally, manganese concentrations vary with age, gender, and during pregnancy. Neonates have concentrations up to 3 times the traditional upper limit of normal, probably because of concomitant iron status and erythropoiesis.<sup>71,89</sup> Manganese concentrations are most commonly determined by flame or furnace atomic absorption spectrophotometry. Manganese concentrations should be elevated after acute overexposure, but abnormal concentrations are neither sensitive nor specific for chronic manganese toxicity because manganese is rapidly cleared from the blood.<sup>98</sup> Signs and symptoms of manganism are insidious and typically occur long after concentrations in urine or blood have normalized.

Urine manganese concentrations are not well correlated with either symptoms or extent of exposure.<sup>9</sup> Increased urinary elimination of manganese after chelation challenge with calcium disodium ethylenediaminetetraacetic acid (CaNa<sub>2</sub>EDTA) occurs but cannot be interpreted. In most situations, it is unclear whether the increased excretion signifies mobilization of physiologic manganese, an increased body burden of manganese, or toxicity. The utility of hair, nail clippings, and saliva as biomarkers of chronic manganese exposure is not clearly established.<sup>9,52,90,96</sup>

Patients with manganese-associated movement disorders often have a characteristic pattern of abnormalities on magnetic resonance imaging (MRI) that includes a bilateral, symmetric, hyperintense signal in the basal ganglia, particularly in the globus pallidus, on T1-weighted images.<sup>4,42,43,69,91</sup> The paramagnetic quality of manganese directly affects the MRI spin state in regions of deposition causing T1-hyperintensity.<sup>46</sup> This pattern is also reported in patients with iatrogenic manganism from long-term parenteral nutrition,<sup>12,28,41,64,93</sup> is sometimes seen in cirrhotic patients with impaired dietary manganese elimination,<sup>36,76,88</sup> and in chronic methathionone abusers.<sup>44,86</sup> Magnetic resonance imaging studies in patients receiving

total parenteral nutrition (TPN) have shown a positive correlation between the concentration of manganese in TPN mixtures and the intensity of increased basal ganglia signal on T1-weighted MRI images.<sup>12,93</sup> An increased T1-weighted MRI signal throughout the basal ganglia was demonstrated in welders and correlates with the length of welding exposure.<sup>24</sup> These changes on MRI are reversible with TPN discontinuation in patients without neurologic symptoms.<sup>64,93</sup> Although highly suggestive of manganism in the correct clinical context, an increased T1-weighted signal in the basal ganglia is a nonspecific finding that may also reflect iron, copper, or lipid deposition; hemorrhage; or neurofibromatosis.<sup>11</sup>

By contrast to these radiographic abnormalities, MRI findings in Parkinson disease typically demonstrate a hypointense signal in the substantia nigra on T2-weighted images.<sup>7,51</sup> SPECT and PET facilitate differentiating Parkinson disease from chronic manganese exposure. For example, molecular imaging studies of patients with chronic manganese exposure and extrapyramidal symptoms have largely failed to demonstrate abnormal nigrostriatal dopaminergic activity and projections, although these are clearly abnormal in patients with Parkinson disease.<sup>34,69,97</sup>

## TREATMENT

Treatment for manganese toxicity is primarily supportive. Discovery and removal from the source of exposure is paramount, although clinical manifestations often progress as manganese body stores fall.<sup>40</sup> Antiparkinsonian therapy is generally ineffective or has limited benefit in relieving motor symptoms. Antioxidant therapy is proposed by some authors, based on the hypothesis that oxidant stress and mitochondrial dysfunction contribute to manganese-induced cellular damage,<sup>19,20,37</sup> but because human data are lacking, these therapies are reasonable but not recommended at this time.

The clinical utility of chelation therapy in patients with manganese toxicity is not well studied and remains controversial. Treatment with CaNa<sub>2</sub>EDTA was reportedly useful in some cases (Antidotes in Depth: A30).<sup>38</sup> More often, chelation improves urinary excretion of manganese and decreases concentrations in blood without affecting neurologic manifestations of toxicity.<sup>17,25,91</sup> It is a nonetheless reasonable therapy, particularly in acutely poisoned patients or those with elevated whole blood concentrations. Chelation with succimer had no effect on either manganese concentrations in blood and urine or on clinical signs of manganism in 2 patients.<sup>2</sup>

Iron supplementation is another therapy proposed to reduce manganese concentrations in blood and lower total body burden. Iron supplementation in addition to chelation therapy improved neurologic symptoms in one patient,<sup>95</sup> and is reasonable in patients with iron deficiency or acute exposures. Conversely, treatment with the iron chelator deferoxamine is theoretically counterproductive since iron and manganese tend to compete for ligands, and iron sequestration might leave more ion transporters available for manganese uptake. In vitro studies demonstrate increased rates of cellular apoptosis after co-incubation with manganese and deferoxamine compared to incubation with manganese alone.<sup>82</sup> Human data are lacking but treatment with deferoxamine is not recommended.

Additionally, hemodialysis did not prove beneficial in a case of massive intravenous manganese salt overdose. There was no evidence of enhancement of manganese elimination by analysis of extraction ratio or dialysate concentration, and the patient had a rapid fall in whole blood concentration, suggesting tissue distribution. This hypothesis was supported by positive basal ganglia MRI findings on day 2.<sup>39</sup> Hemodialysis is therefore also not recommended.

## SUMMARY

- Accumulation of manganese in the brain produces a characteristic neurologic disorder, manganism, with cognitive, psychiatric, and movement abnormalities.
- The movement disorder has many features in common with Parkinson disease, including bradykinesia, rigidity, postural instability, gait abnormalities, and hypophonia, but neither tremor nor dementia are characteristically present, and patients with manganism do not typically respond to levodopa therapy.

- An increased signal in the globus pallidus on T1-weighted MRI is typically but not invariably seen.
- Elevated whole blood manganese concentrations help differentiate the cause, but rapid clearance of manganese from the blood makes this a less sensitive test in cases where exposure is remote from the onset of symptoms.
- Treatment is primarily supportive because neither any chelation regimen nor hemodialysis is shown to alter the clinical course.

## MERCURY

Young-Jin Sue

### Mercury (Hg)

Atomic number	=	80
Atomic weight	=	200.59 Da
Normal concentrations		
Whole blood	<	10 mcg/L (50 nmol/L)
Urine	<	20 mcg/L (100 nmol/L)

### HISTORY AND EPIDEMIOLOGY

Mercury is a metal that is widely toxic to multiple organ systems. Its toxicologic manifestations are well known as a result of thousands of years of medicinal applications, industrial use, and environmental disasters.<sup>69,112</sup> Mercury occurs naturally in small amounts as the elemental (Hg<sup>0</sup>) silver-colored liquid (quicksilver); as inorganic compounds such as mercuric (Hg<sup>2+</sup>) sulfide (cinnabar), mercurous (Hg<sup>+</sup>) chloride (calomel), mercuric chloride (corrosive sublimate), and mercuric oxide; and as organic compounds (methylmercury and dimethylmercury). Mercury's gastroenteric irritant effects led to its use as a therapy for constipation. In recent (16th–19th), centuries, mercury-containing preparations, advocated for their potent diuretic and sialogogic properties, were widely used to treat syphilis to “flush” the “virus” out.<sup>81</sup> The musician Paganini was one of several famous persons whose gingivitis, dental decay, ptyalism (excessive salivation), and erethism (pathologic irritability and emotional instability) were attributed to mercury therapy.<sup>80</sup> In the 1800s, the United States witnessed an epidemic of “hatters’ shakes” or “Danbury shakes” and “mercurial salivation” in hat industry workers.<sup>123</sup> Danbury, Connecticut, was a US center of felt hat manufacturing in which mercuric nitrate was used to mat animal furs into felt.<sup>112,123</sup>

In the early 1900s, acrodynia, a painful dusky pink discoloration of the hands and feet, or “pink disease,” was described in children who received calomel for ascariasis or teething discomfort.<sup>16</sup> Vividly described in a series of 41 children, the development of acrodynia was more common in younger children, did not seem to correlate with mercury dose, and was not necessarily related to urine concentrations of mercury.<sup>122</sup>

One of the most devastating epidemics of mercury poisoning occurred as the result of a decade of contamination of Minamata Bay in Japan by a nearby vinyl chloride plant during the 1940s. Methylmercury accumulated in the bay's marine life and poisoned the inhabitants of the local fishing community. Although officially only 121 victims were reported, thousands more are believed to have been affected by what has subsequently been named Minamata disease.<sup>88,113</sup> The largest outbreak of methylmercury poisoning to date occurred in Iraq in late 1971. Approximately 95,000 tons of seed grain intended for planting and treated with methylmercury as a fungicide were baked into bread for direct consumption, resulting in widespread neurologic symptoms, 6,530 hospital admissions, and more than 400 deaths.<sup>5,23,96</sup>

In 1990, the US Environmental Protection Agency (EPA) banned mercury-containing compounds from interior paints.<sup>3</sup> However, mercury-containing paints manufactured before that ruling may still be on interior walls, and mercury-containing paint can still be sold for outdoor use. In 1997, a scientist succumbed to delayed, progressive neurologic deterioration after a minute dermal exposure to dimethylmercury.<sup>77</sup> Contemporary exposures occur in the form of mercury-tainted seafood, mercury-based preservatives (thimerosal), and artisanal gold mining.<sup>36</sup>

However, a once widely feared source of potential poisoning, mercury-containing dental amalgam does not result in clinical poisoning.<sup>14</sup> Occasionally, exposure to mercury from broken thermometers leads to poisoning in the home, but such thermometers are becoming less common because of

recent efforts to replace mercury with digital thermometers and other electronic devices.<sup>78</sup>

More recently, the ongoing movement to replace incandescent light bulbs with compact fluorescent bulbs has once again raised the concern of exposure to mercury in the home and environment. Promoted to reduce greenhouse gas emissions, each bulb contains about 4 mg of elemental mercury.<sup>2</sup>

Table 95–1 lists some potential sources of mercury exposure.

### FORMS OF MERCURY AND TOXICOKINETICS

The 3 clinically important forms of mercury—elemental, inorganic, and organic—differ with respect to their toxicodynamics and toxicokinetics (Table 95–2). Each produces distinct clinical patterns of poisoning

**TABLE 95–2** Classes of Mercury Compounds

	<i>Nomenclature</i>	<i>Example</i>
<b>Elemental</b>	Hg <sup>0</sup>	Quicksilver
<b>Inorganic</b>	Hg <sup>+</sup>	Mercurous ion
	HgCl	Calomel, mercurous chloride
	Hg <sup>2+</sup>	Mercuric ion
	HgCl <sub>2</sub>	Mercuric chloride
<b>Organic</b>	Short-chain alkyl–mercury compounds	Methylmercury
	Long-chain mercury compounds	Ethylmercury Dimethylmercury Methoxyethylmercury
	Aryl mercury compounds	Phenylmercury

**TABLE 95–3** Differential Characteristics of Mercury Exposure

	<i>Elemental</i>	<i>Inorganic</i>	<i>Organic</i>
Primary route of exposure	Inhalation	Oral	Oral
Primary tissue distribution	CNS, kidney	Blood (transient, acute) Kidney CNS (delayed)	CNS, kidney, liver, blood, hair
Clearance	Kidney, GI	Kidney, GI	Methyl: GI Aryl: kidney, GI
<i>Clinical effects</i>			
CNS	Tremor	Tremor, erethism	Paresthesias, ataxia, tremor, tunnel vision, dysarthria
Pulmonary	+++	–	–
Gastrointestinal	+	+++ (caustic)	+
Renal	+	+++ (ATN)	+
Acrodynia	+	++	–
Therapy	BAL, succimer	BAL, succimer	Succimer (early)

ATN = acute tubular necrosis; BAL = British anti-Lewisite; CNS = central nervous system; GI = gastrointestinal; + to +++ = present with increasing importance; – = absent.

stemming in part from their unique kinetic features (Table 95–3). For each form, the specific manifestations are determined by the route of exposure, rate of exposure, distribution, biotransformation of mercury within the body, and relative accumulation or elimination of mercury by the target organ systems. Whereas elemental mercury produces pulmonary toxicity, inorganic mercury initially causes gastrointestinal (GI) symptoms followed by nephrotoxicity. A nearly pure neurologic toxicity results from organic (methylmercury) exposure.

## ABSORPTION

### Elemental Mercury

Elemental mercury ( $Hg^0$ ) is absorbed primarily via inhalation of vapor, although slow absorption after aspiration, subcutaneous deposition, and direct intravenous (IV) embolization occurs.<sup>60,74,121</sup> Volatility, moderate at room temperature, increases significantly with heating or aerosolization, both of which occur with vacuuming.<sup>44,102</sup> When inhaled by human volunteers, 75% to 80% of mercury vapor is absorbed.<sup>44</sup> However, elemental mercury is negligibly absorbed from an anatomically and functionally normal GI tract, and it is usually considered nontoxic when ingested. Abnormal GI motility prolongs mucosal exposure to elemental mercury, and massive ingestion increases subsequent ionization to more readily absorbed forms. Similarly, anatomic GI abnormalities such as fistulae or perforation are associated with extravasation of mercury into the peritoneal in which where elemental mercury is oxidized to more readily absorbed inorganic forms.

### Inorganic Mercury

The principal route of absorption for inorganic mercury is the GI tract. Approximately 10% of soluble divalent ( $Hg^{2+}$ ) mercuric salts such as mercuric chloride ( $HgCl_2$ ) are absorbed following ingestion and dissociation.<sup>66</sup> Absorption of a relatively insoluble monovalent ( $Hg^+$ ) mercurous compound, such as mercurous chloride (calomel;  $HgCl$ ), is dependent on its oxidation to the divalent form.<sup>79</sup> Inorganic mercury is also absorbed across the skin and mucous membranes, as evidenced by urinary excretion of mercury after dermal application of skin-lightening mercurial ointments and powders containing  $HgCl$ .<sup>106,122</sup>

The degree of dermal absorption varies by the concentration of mercury, skin integrity, and lipid solubility of the vehicle. With substantial dermal exposures to mercury salts, skin absorption may be difficult to distinguish from concomitant absorption via other routes, such as ingestion.

### Organic Mercury

As in the case of inorganic mercury, organic mercury is primarily absorbed from the GI tract. Methylmercury, considered the prototype of the short-chain alkyl compounds, is approximately 90% absorbed from the gut. Aryl and long-chain alkyl compounds have more than 50% GI absorption.<sup>79</sup> Although both dermal and inhalational absorption of organic mercury is reported, precise quantitation and exclusion of concomitant absorption by ingestion are difficult to determine.

## DISTRIBUTION AND BIOTRANSFORMATION

After absorption, mercury distributes widely to all tissues, predominantly the kidneys, liver, spleen, and central nervous system (CNS). The initial distributive pattern into nervous tissue of elemental and organic mercury differs from that of the inorganic compounds because of their greater lipid solubility.

### Elemental Mercury

Although peak concentrations of elemental mercury are delayed in the CNS as compared with other organs (2–3 days versus 1 day),<sup>44</sup> significant accumulation in the CNS occurs after an acute, intense exposure to elemental mercury vapor. Conversion of elemental mercury to the charged mercuric ( $Hg^{2+}$ ) cation within the CNS favors retention and local accumulation. Because elemental mercury does not covalently bind to other compounds, its toxicity depends on its oxidation initially to the mercurous ion ( $Hg^+$ ) and then to the mercuric ion ( $Hg^{2+}$ ) by the enzyme catalase.<sup>66</sup> Because this oxidation–reduction reaction favors the mercuric cation at steady state, the distribution and late manifestations of metallic mercury toxicity eventually resemble those of inorganic mercury poisoning. Conversely, and to a lesser extent, inorganic mercuric ions are reduced to the elemental state ( $Hg^0$ ), although the site and mechanism of this reaction are not well understood.<sup>79</sup>

### Inorganic Mercury

The greatest concentration of mercuric ions is found in the kidneys, particularly within the renal tubules. At least in animal studies, administration of mercury induces the renal synthesis of metallothionein, a compound that binds to and detoxifies mercuric ions.<sup>12</sup> Very little mercury is found as free mercuric ions. In blood, mercuric ions are found both within the red blood cells (RBCs) and bound to plasma proteins in approximately equal proportions. Blood concentrations are greatest immediately after inorganic mercury exposure, with rapid waning as distribution to other tissues occurs. Although penetration of the blood–brain barrier is poor because of low lipid solubility, slow elimination and prolonged exposure contribute to significant CNS accumulation of mercuric ions. Within the CNS, mercuric ions concentrate in the cerebellum and hippocampus, and to a lesser degree, the cerebral cortex.<sup>35</sup> Although inorganic mercurials undergo organification in marine life, as in the Minamata Bay disaster,<sup>9,85</sup> the importance of this conversion in humans is unknown. Animal studies demonstrate that the placenta functions as an effective barrier to mercuric ions.<sup>79</sup>

### Organic Mercury

Once absorbed, aryl (phenyl mercury) and long-chain alkyl mercury compounds differ from the short-chain organic mercury compounds (methylmercury) in an important way—the former possess a labile carbon–mercury bond, which is subsequently cleaved, releasing the inorganic mercuric ion. Thus, the distribution pattern and toxicologic manifestations produced by the aryl and long-chain alkyl compounds that occur beyond the immediate postabsorptive phase are comparable to those of inorganic mercury, but organification has facilitated absorption and reduced the local caustic effects.<sup>79</sup> In contrast, short-chain alkyl mercury compounds possess relatively stable carbon–mercury bonds that survive the absorptive phase, although

conversion to the inorganic mercuric cation at a rate of less than 1% per day occurs after absorption.<sup>124</sup> Because it is lipophilic, methylmercury readily distributes across all tissues, including the blood–brain barrier and placenta.<sup>46</sup> An important consequence of this property is the devastating neurologic degeneration that develops in prenatally exposed infants with Minamata disease. The rapid decline of blood mercury concentrations in both suckling rats and breastfeeding human infants is attributed to rapid growth of body volume combined with limited transport of mercury by milk.<sup>76,97,98</sup>

After methylmercury is distributed to brain tissue, its fate is uncertain. Animal evidence indicates that methylmercury is converted to inorganic mercury in brain tissue.<sup>63</sup> Primates fed oral methylmercury daily for periods exceeding 1 year and then killed within days of the last exposure demonstrated an average brain inorganic mercury fraction of only 19%. By contrast, when the postexposure period was extended to between 150 and 650 days, the inorganic mercury fraction increased to 88%. Similarly, long-term survivors of methylmercury poisoning had a higher ratio of inorganic mercury to total mercury in their brains.<sup>29</sup> In one patient who survived 22 years after methylmercury ingestion, autopsy revealed that the brain mercury was nearly completely in the inorganic form.

Methylmercury concentrates in RBCs to a much greater degree than do mercuric ions, with an RBC-to-plasma ratio of about 10:1 (in contrast to 1:1 RBC-to-plasma ratio for inorganic mercury).<sup>124</sup> However, despite this apparent affinity for nervous tissue and RBCs, the greatest methylmercury concentrations are found in the kidneys and liver. In addition, because of the extensive sulfhydryl bonds in hair, methylmercury deposits in hair at concentrations approximately 250 times that found in whole blood.<sup>55</sup>

## ELIMINATION

### Elemental Mercury and Inorganic Mercury

Mercuric ions are excreted through the kidney by both glomerular filtration and tubular secretion and in the GI tract by transfer across gut mesenteric vessels into feces. Small amounts are reduced to elemental mercury vapor and volatilized from skin and lungs. The total-body half-life of elemental mercury and inorganic mercury was previously estimated at approximately 30 to 60 days.<sup>22,66</sup> However, a recent review of case studies indicates that the half-life of inorganic mercury in human brains is on the order of several years to several decades.<sup>92</sup>

### Organic Mercury

In contrast to elemental mercury and inorganic mercury, the elimination of short-chain alkyl mercury compounds (such as methylmercury) is predominantly fecal. Enterohepatic recirculation contributes to its somewhat longer total body half-life of about 70 days. Less than 10% of methylmercury is excreted in urine and feces as the mercuric cation.<sup>124</sup>

## PATHOPHYSIOLOGY

The pervasive disruption of normal cell physiology by mercury arises from its avid covalent binding to sulfur, replacing the hydrogen ion in the body's ubiquitous sulfhydryl groups. Mercury also reacts with phosphoryl, carboxyl, and amide groups, resulting in widespread dysfunction of enzymes, transport mechanisms, membranes, and structural proteins.

Because mercury deposits in all tissues, the clinical manifestations of mercury toxicity involve multiple organ systems with variable features and intensity. Necrosis of the GI mucosa and proximal renal tubules, which occurs shortly after mercury salt poisoning, is thought to result from the direct oxidative effect of mercuric ions. An immune mechanism is attributed to membranous glomerulonephritis and acro-dynia associated with the use of mercurial ointments.<sup>13</sup>

Neurologic manifestations of methylmercury poisoning correlate with pathologic findings in the brains of both adults and children who were prenatally exposed.<sup>68,113</sup> Grossly, atrophy of the brain is more severe in children who had prenatally or postnatally acquired methylmercury compared with the brains of those exposed as adults. In the adult brain, neuronal necrosis and glial proliferation are most prominent in the calcarine cortex of the cerebrum

and in the cerebellar cortex. In fetal Minamata disease, similar lesions are present but in a more diffuse and severe form. Atrophy of the cerebellar hemispheres, postcentral gyri, and calcarine area of the brain demonstrated on magnetic resonance images in organic mercury–poisoned patients correlates with clinical findings of ataxia, sensory neuropathy, and visual field constriction, respectively.<sup>58</sup> Neuropathologic examination of the brain of a scientist who died after unintentional dermal exposure to dimethylmercury revealed lesions in the cerebellum, temporal lobe, and visual cortex.<sup>105</sup>

In rats, neuronal cytotoxicity of methylmercury may result partly from muscarinic receptor–mediated calcium release from smooth endoplasmic reticulum of cerebellar granule cells.<sup>62</sup> There is animal evidence that methylmercury may trigger reactive oxygen species production. In addition, methylmercury inhibits astrocyte uptake of cysteine, the rate-limiting step in the production of glutathione, a major antioxidant in mammalian cell systems.<sup>104</sup> Cultured astrocytes accumulated methylmercury and exhibited increased mitochondrial permeability and oxidative injury.<sup>125</sup> Complexing of methylmercury with L-cysteine may enhance brain uptake by mimicry of methionine, a substrate of the endogenous L amino acid transport system. Uptake of the L-isomer significantly exceeds that of methylmercury–D-cysteine. Careful selection of stereospecific thiol complexing agents may lead to strategies to limit brain uptake of methylmercury.<sup>56,70</sup>

## CLINICAL MANIFESTATIONS

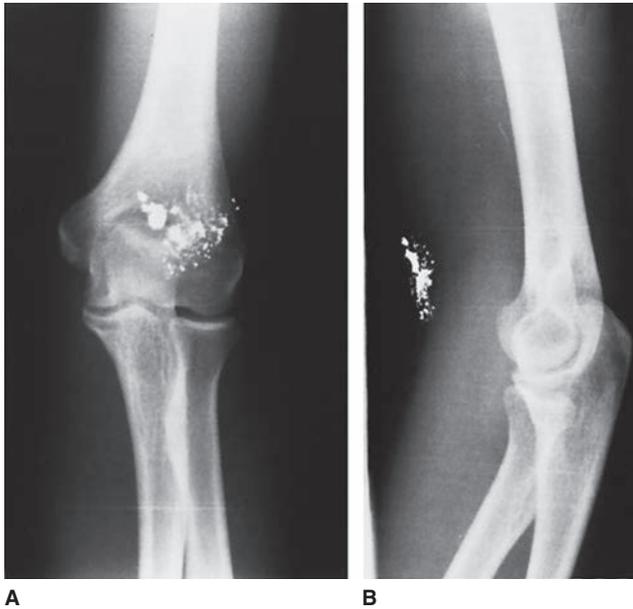

### Elemental Mercury

Symptoms of acute elemental mercury inhalation occur within hours of exposure and consist of cough, chills, fever, and shortness of breath. Gastrointestinal complaints include nausea, vomiting, and diarrhea accompanied by a metallic taste, dysphagia, salivation, weakness, headaches, and visual disturbances. Chest radiography during the acute phase reveals interstitial pneumonitis and both patchy atelectasis and emphysema. Symptoms either resolve with lesser exposures or progress to acute respiratory distress syndrome (ARDS) with respiratory failure and death. Some survivors of severe pulmonary toxicity develop interstitial fibrosis and residual restrictive pulmonary disease. The acute respiratory symptoms occur concomitantly with or precede the development of subacute inorganic mercury poisoning manifested by tremor, kidney dysfunction, and gingivostomatitis.<sup>17,54,94</sup> Thrombocytopenia is also reported to occur during the acute phase.<sup>38</sup>

Although acute exposure to elemental mercury vapor occurs most commonly in the occupational setting, poisonings caused by mishandling of the metal in the home are well reported.<sup>19,29,50,72,108</sup> In fact, attempts at home metallurgy using metallic mercury have resulted in fatalities with ambient air concentrations of mercury as high as 0.9 mg/m<sup>3</sup>. The current US Occupational Safety and Health Administration permissible exposure limit (PEL) for mercury vapor is 0.1 mg/m<sup>3</sup> of air as a ceiling limit.<sup>82</sup>

As with other inhaled toxins, children are likely to be more sensitive to the pulmonary toxicity of mercury vapor because of their ratio of minute ventilation volume to body size.<sup>72</sup> Although pulmonary toxicity from elemental mercury usually results from inhalation of vapor, massive endobronchial hemorrhage followed by death has occurred secondary to direct *aspiration of metallic mercury* into the tracheobronchial tree.<sup>127</sup> Gradual volatilization of elemental mercury results in chronic toxicity from improper handling, such as vacuuming spilled mercury.<sup>102</sup>

The clinical importance of volatilized metallic mercury from dental amalgams for both the dentist and patient is controversial. The preponderance of evidence refutes the idea that dental amalgam causes mercury poisoning. Several comprehensive reviews of the subject conclude that (1) occupational exposure to mercury from dental amalgam is acceptably low, provided that recommended preventive measures such as adequate ventilation are adhered to; (2) the quantity of mercury vaporized from dental amalgam by mechanical forces, such as chewing, is clinically insignificant; and (3) only in exceedingly rare cases will immunologic hypersensitivity to mercury amalgam (manifested as cutaneous signs and symptoms and confirmed by patch testing) necessitate removal of the amalgam.<sup>33,34,37,61,107</sup>

**FIGURE 95-1.** Anteroposterior (A) and lateral (B) views of the elbow after an unsuccessful suicidal gesture involving an attempted intravenous injection of elemental mercury in the antecubital fossa. Note the extensive subcutaneous mercury deposition, which was partially removed by surgical intervention. (Used with permission from Diane Sauter, MD.)

Unusual cases of chronic toxicity have resulted from intentional subcutaneous or IV injection of elemental mercury (Figs. 8–6 and 95–1).<sup>49,74</sup> Aside from management of systemic mercury toxicity, local wound care and excision of deposits of mercury are additional therapeutic challenges presented by these cases. Serial or repeat radiographs are useful in guiding the removal of the radiopaque deposits.

### Inorganic Mercury

Acute ingestion of mercuric salts produces a characteristic spectrum from severe irritant to caustic gastroenteritis. Immediately after the ingestion, a grayish discoloration of mucous membranes and metallic taste typically accompany local oropharyngeal pain, nausea, vomiting, and diarrhea followed by abdominal pain, hematemesis, and hematochezia. The lethal dose of mercuric chloride is estimated to be 30 to 50 mg/kg.<sup>116</sup> The life-threatening manifestations of severe acute mercuric salt ingestion are hemorrhagic gastroenteritis, massive fluid loss resulting in shock, and acute kidney failure.<sup>100</sup>

Oropharyngeal injury, nausea, hematemesis, hematochezia, and abdominal pain were the most prominent symptoms in a series of 54 patients who presented after ingesting up to 4 g of mercuric chloride.<sup>116</sup> In this series, fatality was associated with the early development of oliguria (within 3 days) likely due in large part to lack of routinely available hemodialysis at that time. The development of anuria appeared to be related to the dose of mercuric chloride ingested. The histopathologic finding of proximal tubular necrosis after mercuric salt poisoning results both from direct toxicity to renal tubules and from renal hypoperfusion caused by shock. Consequently, aggressive fluid therapy to maintain perfusion is recommended.<sup>101</sup>

Acute ingestion of mercuric salts is usually intentional, but unintentional ingestion occurs sporadically in both children and adults.<sup>51</sup> Although ingestion of older button batteries containing mercuric oxide was associated with a greater incidence of fragmentation than with other batteries, clinically significant systemic mercury toxicity by this route was not reported.<sup>64,67</sup> Mercuric chloride-containing stool preservatives are another potential source of unintentional inorganic mercury poisoning. Ingestion of 10 to 20 mL of a polyvinyl alcohol preservative that contained 4.5% mercuric chloride resulted in bloody gastroenteritis and proteinuria.<sup>103</sup> Nonprescription<sup>49</sup> and Ayurvedic<sup>99</sup> medicines are also associated with unintentional inorganic mercury poisoning (Chap. 43).<sup>53</sup> These xenobiotics are not subject to US Food

and Drug Administration (FDA) regulation, available without prescription, of variable composition, and are often inadequately labeled (Chap. 43).

Subacute or chronic mercury poisoning occurs after inhalation, aspiration, or injection of elemental mercury; ingestion or application of mercury salts; or ingestion of aryl or long-chain alkyl mercury compounds. Slow in vivo oxidation of elemental mercury and dissociation of the carbon–mercury bond of aryl or long-chain alkyl mercury compounds result in the production of the inorganic mercurous and mercuric ions.

The predominant manifestations of subacute or chronic mercury toxicity include GI symptoms, neurologic abnormalities, and renal dysfunction. Gastrointestinal symptoms consist of a metallic taste and burning sensation in the mouth, loose teeth and gingivostomatitis, excessive salivation (ptyalism), and nausea.<sup>122</sup> The neurologic manifestations of chronic inorganic mercurialism include tremor, as well as the syndromes of neurasthenia and erethism. Neurasthenia is a symptom complex that includes fatigue, depression, headaches, hypersensitivity to stimuli, psychosomatic complaints, weakness, and loss of concentrating ability. Erithism, derived from the Greek word *red*, describes the easy blushing and extreme shyness of affected individuals. Other symptoms of erethism include anxiety, emotional lability, irritability, insomnia, anorexia, weight loss, and delirium. Mercury produces a characteristic central intention tremor (Chap. 22) that is abolished during sleep. In the most severe forms of mercury-associated tremor, choreoathetosis and spasmodic ballismus are also reported. Other neurologic manifestations of inorganic mercurialism include a mixed sensorimotor neuropathy, ataxia, concentric constriction of visual fields (“tunnel vision”), and anosmia.

Chronic poisoning with mercuric ions is associated with renal dysfunction, which ranges from asymptomatic, reversible proteinuria to nephrotic syndrome with edema and hypoproteinemia. An idiosyncratic hypersensitivity to mercury ions is thought to be responsible for acrodynia, or “pink disease,” which is an erythematous, edematous, and hyperkeratotic induration of the palms, soles, and face, and a pink papular rash that was first described in a subset of children exposed to mercurous chloride powders.<sup>122</sup> The rash is described as morbilliform, urticarial, vesicular, and hemorrhagic. This symptom complex also includes excessive sweating, tachycardia, irritability, anorexia, photophobia, insomnia, tremors, paresthesias, decreased deep tendon reflexes, and weakness. The acral rash frequently progresses to desquamation and ulceration. The prognosis is favorable after withdrawal from mercury exposure. Childhood acrodynia has become uncommon since the abandonment of mercurial teething powders and diaper rinses. Occasional case reports still implicate improperly disposed fluorescent light bulbs and phenylmercuric acetate-containing paint.<sup>3,117</sup>

Thimerosal is an example of an aryl mercury compound that results in chronic inorganic mercury toxicity. It is a compound that was widely used as a preservative in the pharmaceutical industry (Chap. 46). Although initial kinetics suggested a stable ethyl–mercury bond, the later elimination phase more closely resembles that of the inorganic mercury compounds. Thimerosal is approximately 50% mercury by weight. Although generally considered safe, toxicity and death can occur after both intentional overdose and excessive therapeutic application of merthiolate (0.1% thimerosal or 600 mcg/mL mercury).<sup>87,95</sup>

Concern that the cumulative dose of thimerosal in childhood immunizations exceeded federally recommended maximum mercury doses (EPA, 0.1 mcg/kg/day; Agency for Toxic Substances and Disease Registry, 0.3 mcg/kg/day; FDA, 0.4 mcg/kg/day) led to a call by the American Academy of Pediatrics to reduce or eliminate thimerosal from vaccines.<sup>4</sup> Thimerosal continues to be used in medically underserved nations as a preservative in multidose vials in areas with inadequate refrigeration.<sup>31</sup> Nevertheless, since 2001, routinely administered childhood vaccines in the United States no longer contain thimerosal.<sup>4,47</sup>

Although sensitization after use in vaccinations has been reported in atopic children,<sup>86</sup> clinical mercury toxicity has not been reported in appropriately immunized children. The claim that thimerosal-containing vaccines causes autism has been refuted by numerous studies and meta-analyses.<sup>8,65,84,109</sup> No causal association with early thimerosal exposure

and adverse neuropsychological outcomes was shown in children tested at 7 to 10 years of age.<sup>115</sup> Clearly, the risk to child health from the diseases targeted for prevention by vaccines far exceeds the risk from thimerosal preservative in vaccines.<sup>39,114,119</sup> In 2010, US courts rejected a causal relationship between thimerosal and autism.<sup>32</sup>

### Organic Mercury Compounds

In contrast to the inorganic mercurials, methylmercury produces an almost purely neurologic disease that is usually permanent except in the mildest of cases. Although the predominant syndrome associated with methylmercury is that of a delayed neurotoxicity, acute GI symptoms, tremor, respiratory distress, and dermatitis are also reported.<sup>124</sup> In addition, ST segment changes on electrocardiography and renal tubular dysfunction are associated with this poisoning.<sup>45</sup> However, no increase in cardiovascular disease risk was reported with mercury exposure in a large cohort of US adults.<sup>73</sup>

The lipophilic property and slower elimination of methylmercury likely contribute to its profound neurologic effects. Characteristically, clinical manifestations occur after the initial poisoning by a latent period of weeks to months. Consequently, the lethal dose of methylmercury is difficult to determine. As noted previously, infants exposed prenatally to methylmercury were the most severely affected individuals in Minamata. Often born to mothers with little or no manifestation of methylmercury toxicity themselves, exposed infants exhibited decreased birth weight and muscle tone, profound developmental delay, seizure disorders, deafness, blindness, and severe spasticity.

Several weeks after methylmercury contaminated grain was ingested in Iraq, patients began to appear with paresthesias involving the lips, nose, and distal extremities. Symptomatic patients also noted headaches, fatigue, and tremor. More serious cases progressed to ataxia, dysarthria, visual field constriction, and blindness. Other neurologic deficits included hyperreflexia, hearing disturbances, movement disorders, salivation, and dementia. The most severely affected patients lay in a mute, rigid posture punctuated only by spontaneous crying, primitive reflexive movements, or feeding efforts.<sup>96</sup>

Although the outlook for methylmercury neurotoxicity is generally considered dismal, observations over the subsequent 2 years in 49 Iraqi children poisoned during the 1971 outbreak revealed complete resolution or partial improvement in all but the most severely affected.<sup>5</sup> Of the 40 symptomatic children, 33 mildly to severely affected children showed partial to complete resolution of symptoms, but the 7 children classified as “very severely poisoned” remained dysarthric, ataxic, blind, and bedridden.

An important route of organic mercury exposure is through seafood consumption. The safe amount of methylmercury in seafood remains controversial. The FDA action concentration of 1 ppm for methylmercury in fish was set to limit consumption of methylmercury to less than 1/10th of amounts found in cases of symptomatic poisoning. The EPA established a reference dose for methylmercury of 0.1 mcg/kg/day.<sup>90,118</sup> Although elevated blood concentrations (19–53 mcg/L) of mercury were found in one group of self-reported high consumers of seafood, increased incidence of cognitive and GI complaints were not.<sup>52</sup> Even so, concentrations at which fetuses experience adverse effects are unknown. Longitudinal studies of fish-eating populations are conflicting. No effect of a high prenatal fish diet was found on developmental markers in children followed to 19 years of age in the Seychelles Islands.<sup>27,28,120</sup>

However, in the studies done in the Faroe Islands and New Zealand, a subtle but significant effect on neuropsychological development was reported.<sup>25,42,110</sup> In the Faroe Islands, this effect persisted when children were retested at 22 years of age.<sup>30,31</sup>

One reason for the discrepancy that occurs between the 2 populations may be the different patterns of seafood consumption and concentrations of methylmercury in the seafood consumed by each. The Faroese consume low level mercury-containing fish 1 to 3 times a week with episodic feasts of highly contaminated pilot whale, whereas the Seychellois consume a more steady diet of low level-contaminated fish on average 12 times per week. The pilot whales consumed in the Faroe Islands are also contaminated with

neurotoxic polychlorinated biphenyls (PCBs), although these compounds were measured and considered a potential confounding variable. The mean concentration of methylmercury in the whale meat consumed in the Faroe Islands was 1.6 mcg/g, and the mean concentration of mercury found in New Zealand shark was 2.2 mcg/g. By contrast, the mean methylmercury content of Seychellois fish was 0.3 mcg/g.<sup>75</sup> The threshold concentration for neuropsychological effects may lie between these concentrations.

The development of neurologic symptoms in infants exclusively breast-fed by women exposed to methylmercury after delivery and the detection of mercury in the milk of lactating women implies a risk for mercury poisoning via breast milk.<sup>57</sup> In one series of lactating women, mercury concentrations in milk were approximately 30% of the concentrations found in blood.<sup>83</sup> Perhaps because of high levels of PCBs in pilot whale meat, 7-year-old children from the Faroe Islands, who have a diet traditionally high in the mercury-containing sea mammals and were breast-fed as infants, exhibited a diminished benefit (but not deficit) on neuropsychological testing when compared with their counterparts fed formula.<sup>48</sup>

Further complicating findings in a cohort of Faroese children, the neurobehavioral deficits from methylmercury may be underestimated unless the protective effects of long-chain n-3 polyunsaturated fatty acids (n-3 PUFA, also found in fish) are included in the analysis.<sup>21</sup> Likewise, the Seychelles Child Development Study Nutrition Cohort 2 found no overall adverse association between prenatal methylmercury exposure and neurodevelopmental outcomes in children with high maternal n-3 PUFA concentrations.<sup>111</sup> The net neuropsychological effects of prenatal and dietary methylmercury result from dose and timing of fish in the diet as well as the concentrations of methylmercury, neurotoxic PCBs, and neuroprotective PUFA in the consumed fish.<sup>111</sup>

The FDA recommends that at-risk populations (pregnant women and women who may become pregnant, nursing mothers, and young children) avoid large predator fish (shark, swordfish, tilefish, and king mackerel) that contain concentrations of methylmercury approaching 1 ppm (1 mcg/g). The 2004 FDA/EPA consumer advisory emphasizes the health benefits of eating fish and allow for up to 12 ounces per week of fish and shellfish lower in mercury such as shrimp, canned light tuna, salmon, pollock and catfish and up to 6 ounces of albacore tuna per week. Given the beneficial effects of seafood, efforts should be aimed at decreasing anthropogenic release of mercury rather than elimination of dietary exposure.<sup>91</sup>

Although methylmercury has greater importance worldwide, the extreme toxicity of another organic mercurial, dimethylmercury, was tragically demonstrated by the delayed fatal neurotoxicity that developed in a chemist who inadvertently spilled dimethylmercury on a break in the gloves on her hands.<sup>77</sup> Over a period of several days, she developed progressive difficulty with speech, vision, and gait. Despite chelation and exchange transfusion, she died of mercury neurotoxicity within several months of the exposure.

### DIAGNOSTIC TESTING

The dual findings of unexplained neuropsychiatric and kidney abnormalities in an individual should alert the clinician to the possibility of mercurialism, as should an at-risk occupation or access by the patient to a mercurial product (Table 95–1). Occupational or environmental exposure and a consistent clinical scenario are suggestive of mercury poisoning, but demonstration of mercury in blood, urine, or tissues is necessary for confirmation of exposure. Of the many methods available to measure mercury, cold atomic absorption spectrometry is rapid, sensitive, and accurate but cannot distinguish the various forms of mercury. Thin-layer and gas chromatographic techniques are recommended to distinguish organic from inorganic mercury. Whole blood should be collected into a trace element collection tube obtained from the laboratory performing the assay. Urine should be collected for 24 hours into an acid-washed container obtained from a laboratory. Spot collections must be adjusted for creatinine concentration. Attempts to measure or otherwise handle the specimen should be avoided to prevent external contamination (Table 95–4).

There is considerable overlap among concentrations of mercury found in the normal population, asymptomatic exposed individuals, and patients

TABLE 95-4 Diagnostic Testing for Mercury

	Whole Blood	24-hour Urine	Hair	Clinical
<b>Elemental/ Inorganic</b>	(+)	(++)	(+)	(+)
	Acute, transient	Confirm exposure	Reflects past exposure and external adsorption	Poor correlation to TBB
		Monitor chelation		Early detection
		Poor correlation to TBB		
<b>Organic</b>	(++)	(-)	(+)	(+)
	Best reflects TBB	Fecal elimination	Reflects past exposure and external adsorption	Poor correlation to TBB
				Reflects irreversible CNS toxicity
				Early detection

CNS = central nervous system; TBB = total body burden; + to ++ = useful testing specimen; - = lack of utility.

with clinical evidence of poisoning. There is no definitive correlation between either whole blood or urine mercury concentration and mercury toxicity. However, mercury serves no useful role in human physiology, and concentrations of 1.0 mcg/L or less for whole blood and 0.5 mcg/L for urine are generally considered to reflect background exposure in nonpoisoned individuals. The inconsistencies of the values found in the literature for mercury exposure are a recurrent issue in metal testing. A credible and qualified laboratory should be employed and their reference ranges accepted when testing is desired.<sup>20</sup>

For inorganic mercury poisoning, urine mercury concentrations correlate roughly with exposure severity and neuropsychiatric symptoms,<sup>93</sup> but the relationship to total body burden is probably poor. Urine mercury determinations have their greatest usefulness in confirming exposure and monitoring the efficacy of chelation therapy. Whole blood mercury concentrations reflect intense, acute inorganic mercury exposure but become less reliable as redistribution to tissues takes place.

Because organic mercury is eliminated via the fecal route, urine mercury concentrations are not useful in methylmercury poisoning. Because methylmercury concentrates in RBCs, the total-body methylmercury burden is best reflected acutely by whole-blood concentrations. As methylmercury distributes to and accumulates in brain, the severity of clinical manifestations probably more closely reflects the degree of the irreversible neuronal destruction that has taken place rather than the current body burden of mercury. Correlation of increasing whole-blood mercury concentrations with prevalence of paresthesias was suggested in a population of Iraqis studied early in the course of methylmercury poisoning.<sup>24</sup> However, in another group of patients, whole-blood concentrations did not correlate with severity of methylmercury poisoning.<sup>96</sup> This apparent discrepancy may have resulted from the finding that paresthesias are among the earliest reported symptoms of methylmercury poisoning.

Because mercury accumulates in the hair, hair analysis has been used as a tool for measuring mercury burden. However, because metal incorporation reflects past exposure and hair avidly binds to noningested environmental mercury, the reliability of this method is questionable and is not recommended.<sup>89</sup> In addition to mercury assays, neuropsychiatric testing, nerve conduction studies, and urine assays for *N*-acetyl- $\beta$ -D-glucosaminidase and  $\beta_2$ -microglobulin are advocated for early detection of subclinical inorganic and organic mercury toxicity.<sup>34,45,93</sup>

## GENERAL MANAGEMENT

After the initial assessment and stabilization, the early toxicologic management of a patient with mercury poisoning includes termination of exposure by removal from vapors, washing exposed skin, GI decontamination, supportive measures (eg, hydration, humidified oxygen), baseline diagnostic studies (eg, complete blood count, serum chemistries, venous blood gas, radiography, ECG), specific analysis of whole blood and urine for mercury, evaluation of possible cointoxicants, and meticulous monitoring.

### Elemental Mercury

Inhalation of mercury vapors or aspiration of metallic mercury may result in life-threatening respiratory failure; in this situation, stabilization of cardiorespiratory function is the initial priority. Postural drainage and endotracheal suction are a reasonable technique to attempt to remove aspirated metallic mercury. Parenteral deposition of subcutaneous or intramuscular (IM) mercury is amenable to surgical excision, if well localized (Fig. 95-1).

An adjunct to the initial management of patients with mercury poisoning is environmental decontamination. Elemental mercury that spills onto solid surfaces should be adsorbed to sand and the resulting mixture then swept into tightly sealed containers. Ideally, a mercury decontamination kit should be used. The kit consists of calcium polysulfide, which contains excess sulfur to convert mercury to water-insoluble mercuric sulfide. Absorbent surfaces, such as carpets, should be removed. Spilled mercury compounds should not be vacuumed because vacuuming could volatilize the mercury.<sup>18</sup> Broken compact fluorescent light bulbs should be handled and disposed of according to EPA guidelines and local requirements.<sup>2</sup>

Recommendations for decontamination after breakage include opening windows to release vapor, using adhesive tape to pick up visible fragments, and discarding contaminated material in double-wrapped bags. Guidance for decontamination of major spills and disposal of materials can be provided by local and federal hazardous materials agencies.

### Inorganic Mercury

Because ingestion of inorganic mercuric may lead to cardiovascular collapse caused by severe gastroenteritis and third-space fluid loss, fluid resuscitation is a priority. Gastrointestinal decontamination of ingested inorganic mercury is particularly problematic because of its causticity and risk for perforating injury. Nevertheless, one series of patients with mercuric chloride ingestion of up to 4 g reported recovery without long-term GI sequelae in patients who did not succumb to kidney failure.<sup>116</sup> Therefore, unless there is high suspicion for penetrating GI mucosal injury, removal of mercury from absorptive surfaces should take priority over endoscopic evaluation. The prominence of vomiting makes gastric lavage unnecessary for most patients with inorganic mercury poisoning.

Metals are among the substances that are often considered to be poorly adsorbed to activated charcoal. Nevertheless, the serious nature of late sequelae after mercury absorption, the typically small quantities of mercury ingested, and evidence that inorganic mercuric salts actually have substantial adsorption to activated charcoal (800 mg mercuric chloride can be adsorbed to 1 g activated charcoal) justify the routine administration of activated charcoal.<sup>6</sup> Whole-bowel irrigation with polyethylene glycol solution is a reasonable adjunct to remove residual mercury, and its progress can be followed with serial radiographs.

### Organic Mercury

Organic mercury exposures do not typically present as single acute ingestions but rather as chronic or subacute ingestion of contaminated food. Therefore, GI decontamination is generally moot with respect to organic mercury poisoning. Nevertheless, its irreversible toxicity coupled with unsatisfactory treatments calls for aggressive decontamination when acute ingestions or dermal exposures occur.

## CHELATION

After initial stabilization and decontamination, early institution of chelators minimizes or prevents the widespread effects of poisoning. Dimercaprol was developed during World War II as an antidote against lewisite, an arsenical warfare agent. The water-soluble analogs DMPS and succimer were developed in the 1950s, and the 3 chelators have remained the mainstay of therapy for mercury poisoning.<sup>59</sup> A high degree of protein binding and distribution to the brain are responsible for the lack of efficacy of other measures to increase mercury clearance, such as peritoneal dialysis and hemodialysis.<sup>100</sup> In one report of the use of continuous venovenous hemodiafiltration in combination with a chelator in a patient with severe inorganic mercury poisoning, 12.7% of the ingested dose was recovered in the ultrafiltrate.<sup>26</sup> Hemodialysis may nevertheless ultimately be necessary because of the acute kidney failure that often occurs after mercuric chloride poisoning.

Chelators have thiol groups that compete with endogenous sulfhydryl groups for the binding of mercury, thereby preventing inactivation of sulfhydryl-containing enzymes and other essential proteins (Antidotes in Depth: A28 and A29). A history of significant mercury exposure combined with the presence of typical symptoms of mercury poisoning is an appropriate indication for the institution of chelation therapy. Elevated whole-blood and urine mercury concentrations help support the decision to begin chelation therapy in unclear cases and can also be used to guide the duration of therapy. Provocative chelation, in which urinary mercury excretion before and after a chelating dose is compared to determine the degree of mercury poisoning, is of no value.<sup>52</sup> Chelation tends to increase urinary elimination of mercury, regardless of exposure history and baseline excretion.

### Elemental Mercury and Inorganic Mercury Salts

For patients with symptomatic acute inorganic mercury poisoning, dimercaprol should be administered for 10 days in dosages of 5 mg/kg/dose every 4 hours IM for 48 hours, then 2.5 mg/kg every 6 hours for 48 hours, followed by 2.5 mg/kg every 12 hours for 7 days. It is reasonable to adjust this dosing regimen, which was derived from lead poisoning, according to clinical response and the occurrence of adverse reactions.

When a patient can take oral medications, we recommend that dimercaprol be replaced with succimer at 10 mg/kg orally 3 times a day for 5 days, then twice a day for 14 days if the GI tract is clear. Because headache, nausea, vomiting, abdominal pain, and diaphoresis are common reactions during dimercaprol chelation therapy, oral succimer is recommended in patients who are not acutely ill or who have been chronically poisoned.

Either dimercaprol or succimer is considered the treatment of choice for inorganic mercury poisoning in the United States, but a few other chelators deserve mention. 2,3-Dimercapto-1-propanesulfonic acid (DMPS) is a water-soluble dimercaprol derivative that is used in Europe. It is administered both IV and orally. D-Penicillamine is an orally administered monothiol. Its adverse events—GI distress, rashes, leukopenia, thrombocytopenia, and proteinuria—although uncommon in therapeutic doses, seriously limit the usefulness of the drug. N-acetyl-D,L-penicillamine (NAP), an investigational analog of D-penicillamine, is thought to be a more effective chelator of mercury than is D-penicillamine, perhaps because of its greater stability.<sup>11,40,43</sup>

### Organic Mercury Compounds

The neurotoxicity of methylmercury and other organic mercury compounds is resistant to treatment, and therapeutic options are less than satisfactory. In rats, both dimercaprol and D-penicillamine effectively reduced tissue mercury and prevented neurologic toxicity if administered within the first day of a methylmercury injection.<sup>126</sup> Neither treatment reversed neurologic toxicity when administered 12 days after methylmercury injection. 2,3-Dimercapto-1-propanesulfonate, D-penicillamine, NAP, and a thiolated resin all led to a marked reduction of blood half-life of mercury (ie, 10, 24, 23, and 19 days, respectively, versus 60 days) during the outbreak of methylmercury poisoning in Iraq in 1971.<sup>24</sup> Clinical improvement was not observed in any treatment group, but it is reasonable to postulate that reducing the total-body burden of methylmercury may prevent or limit the progression of disease.

When studied in mice poisoned with methylmercury,<sup>1</sup> succimer was superior to NAP, DMPS, and a thiolated resin in decreasing brain mercury and increasing urinary excretion. Brain mercury was decreased to 35% of control, and the total-body burden fell to 19%. Some animal evidence suggests that dimercaprol increases mercury mobilization into the brain.<sup>7,10,15</sup> For this reason, and the lack of serious GI symptoms necessitating parenteral chelation, We recommend against the use of dimercaprol the treatment of patients with organic mercury poisoning.

Because the neurologic impairment associated with methylmercury is both profound and essentially irreversible, early recognition of poisoning and prevention of neurotoxicity are essential to a successful outcome. At this time, succimer is the most reasonable treatment for methylmercury poisoning because of its apparently low toxicity and reported efficacy in animal trials.

## SUMMARY

- Mercury poisoning by any of the 3 major forms—elemental, inorganic, and organic—presents a complex toxicologic problem associated with a large variety of clinical presentations.
- An ever present awareness of the signs and symptoms coupled with the knowledge of the differing clinical forms is essential for both early recognition and effective treatment.
- Although some chelators show promise in the treatment of mercury poisoning, neurologic sequelae, particularly those resulting from organic mercury exposures, remain largely irreversible.
- Dietary fish remains an important source of mercury exposure and mercurial neuropsychologic illness.
- There is no evidence for the role of mercury in the pathogenesis of autism.
- Promotion of public education regarding the dangers of mercury, its avoidance, and proper disposal may aid in the prevention of mercury poisoning.

# NICKEL

John A. Curtis

<b>Nickel (Ni)</b>	
Atomic number	= 28
Atomic weight	= 58.7 Da
Normal concentrations	
Serum	< 1.1 mcg/L (17 nmol/L)
Urine	< 6 mcg/L (102 nmol/L)

## HISTORY AND EPIDEMIOLOGY

Nickel is a ubiquitous metal commonly found in both home and industry. It exists in a variety of chemical forms, from naturally occurring ores to synthetically produced nickel carbonyl. Elemental nickel is a white, lustrous metal, the name being derived from the German word “kupfernickel” or “devil’s copper.” Swedish chemist Baron Axel Fredrik Cronstedt first identified kupfernickel in 1751 in a mineral known as niccolite, and named it nickel in 1754. The fifth most abundant element on Earth, Nickel comprises 0.008% of the Earth’s crust and is found in diverse locations, ranging from meteorites and soil to bodies of fresh- and saltwater.

First produced by the Chinese, nickel has been used as a component in a variety of metal alloys for more than 1,700 years. The first malleable nickel was produced by Joseph Wharton following the American Civil War. Wharton went on to sell bulk quantities of nickel to the United States government for the minting of 3-cent coins, and later donated the equivalent of 3.3 million of these coins to help fund what is known today as the Wharton School of Business.<sup>44</sup> The modern United States 5 cent piece, the “nickel,” is actually only approximately 25% nickel by weight, and all currently United States coins except the penny are made of nickel-containing alloys.<sup>7</sup>

Nickel ores typically consist of accumulations of nickel sulfide minerals of relatively low nickel content. Although there are a variety of technical methods for extracting nickel from ore, one method of special note was developed in 1890 by Ludwig Mond, who is credited with the discovery of nickel carbonyl (also called nickel tetracarbonyl). The Mond process for the extraction of nickel involves passing carbon monoxide over smelted ore. This creates nickel carbonyl, which then decomposes at high temperatures to produce purified nickel and carbon monoxide.<sup>44</sup>

There have been 2 notable occupational disasters associated with exposure to nickel carbonyl. The Gulf Oil Company refinery incident in Port Austin, Texas, in 1953 resulted in more than 100 workers’ being exposed, with 31 hospitalizations and 2 deaths. The Toa Gosei Chemical company incident in Nagoya, Japan, in 1969, resulted in 156 male workers’ being exposed to nickel carbonyl, with 137 developing signs and symptoms but no fatalities reported.<sup>44</sup>

Currently, most nickel is imported into the United States from other nickel-rich countries, such as Canada, Russia, and Australia. After a more than 30-year period in which there was no domestic nickel mining in the United States, there is now one active US nickel mine: the Eagle Mine opened in Michigan in 2014, and produced 25,000 metric tons of nickel in 2016.<sup>53</sup>

Nickel is a siderophoric material that forms naturally occurring alloys with iron, a property that has made it useful for many centuries in the production of coins, tools, and weapons. Today, most nickel is used in the production of stainless steel, a highly corrosion-resistant alloy containing 8% to 15% nickel by weight.

Occupational exposure to nickel and nickel-containing compounds occurs in a variety of industries, including nickel mining, refining, reclaiming, and smelting. Chemists, magnet makers, jewelry makers, oil hydrogenator workers, battery manufacturers, petroleum refinery workers, electroplaters, stainless steel and alloy workers, and welders are at increased risk for exposure to nickel and nickel-containing compounds. Most nonindustrial human

exposures to nickel are from dietary and environmental sources, although cigarette smoking is an important source of nickel exposure and elevates urinary nickel concentrations.<sup>41</sup> In the occupational setting, nickel carbonyl is responsible for the majority of acute nickel toxicity, whereas in clinical practice, the most common health issue related to nickel is the development of allergic dermatitis from jewelry and clothing, as well as cosmetics and complementary and alternative medicines. It is estimated that 10% to 15% of people have a metal allergy, with nickel being the most frequent, affecting about 10% to 15% of women and 2% to 3% of men. The incidence of metal allergy is increased in those with autoimmune diseases.<sup>35</sup>

## TOXICOKINETICS

### Exposure

Nickel occurs naturally in soil, volcanic dust, and fresh and saltwater, but it also enters the environment from the combustion of fuel oil, municipal incineration, nickel-refining processes, and the production of steel and other nickel alloys that allow aerosolized nickel to be disseminated into the environment.

The specific form of nickel emitted to the atmosphere depends on the source. Complex nickel oxides, nickel sulfate, and metallic nickel are associated with combustion incineration, smelting, and refining processes. Consequently, ambient air concentrations of these forms of nickel tend to be higher in urban areas, and concentrations of nickel in urban household dust is elevated under certain circumstances and thus poses variable exposure risk for young children who crawl or sit on floors.

Nickel carbonyl, Ni(CO)<sub>4</sub>, deserves special mention. This colorless, highly volatile and potentially dangerous liquid nickel compound is a product of the reaction of nickel and carbon monoxide and is commonly used in nickel refining and petroleum processing, and as a chemical reagent. Its high vapor pressure and high lipid solubility lead to rapid systemic absorption through the lungs. In the air and in the body, it decomposes into metallic nickel and carbon monoxide and its toxicity is often compared with hydrogen cyanide.<sup>35</sup> Even at potentially harmful concentrations, nickel carbonyl has only a mild “sooty” or “musty” odor, and therefore environmental monitoring is necessary.<sup>43</sup> Previously mentioned disasters, such as the Gulf Oil Company refinery and the Toa Gosei Chemical company incidents, illustrate that clinical effects associated with serious toxicity were often delayed, again highlighting the need for monitoring.<sup>44</sup>

However, nonoccupational exposures to nickel are usually environmental and dietary. Ambient air nickel concentrations are typically around 2.2 ng/m<sup>3</sup>, whereas soil usually has nickel concentrations of 4 to 80 parts per million, with some regional variations based on both geography and man-made inputs, and local concentrations in some areas being as high as 5,000 ppm in soils derived from serpentine rock and up to 24,000 ppm near metal refineries.<sup>17,18</sup> Concentrations of metallic nickel in drinking water in the United States average 2 to 4 parts per billion, but higher concentrations of nickel in household and other potable and nonpotable water sources results from corrosion and leaching of nickel alloys present in various plumbing fixtures, including valves and faucets.<sup>18</sup> It is reported that the first water drawn from a hot-water tap plated with nickel may contain 1 to 1.3 mg/L of nickel.<sup>3</sup> Further, it is demonstrated that hot water contains more nickel than cold tap water, and the first 250 mL drawn from the tap contain more nickel than after pipes are flushed for 5 minutes.<sup>1</sup> Although many water suppliers in the United States monitor nickel concentrations in their water, there is currently no US Environmental Protection Agency (EPA) regulation regarding how much nickel is permissible in drinking water.

Dietary intake is a recognized source of nickel exposure for humans. Foods high in nickel include nuts, legumes, cereals, licorice, and chocolate. In addition, certain homeopathic medications, ginseng products, Indian herbal teas, Nigerian herbal remedies, and Chinese herbal plants are high in nickel content.<sup>13</sup> Nickel is not definitively an essential element for human health and dietary recommendations for nickel are not established. Normal consumption is between 0.3 and 0.6 mg/day. A Danish meta-analysis of 17 studies suggested that up to 1% of individuals develop allergic contact dermatitis at the low concentration of oral nickel exposure represented by dietary and drinking water sources.<sup>22</sup> Although estimates vary widely, the total body burden for a 70-kg reference human is about 10 mg of nickel, giving an average body concentration of 0.14 ppm.<sup>18</sup>

### Absorption

Nickel enters the body through the skin, lungs, and gastrointestinal tract. The amount and rate of absorption are dependent on the water solubility of the nickel compound. Once in the body, nickel exists primarily as the divalent cation (Ni<sup>2+</sup>). Independent of the particular nickel compound involved in the exposure, it is nickel ion (Ni<sup>2+</sup>) that is typically measured in the serum or urine.

Following inhalational exposure, nickel accumulates in the lungs, but only 20% to 35% of nickel deposited in the human lung is systemically absorbed.<sup>18</sup> The remainder of the inhaled material is swallowed, expectorated, or deposited in the upper respiratory tract. Subsequent systemic absorption from the respiratory tract is dependent on the solubility of the specific nickel compound in question. Soluble nickel salts (nickel sulfate and nickel chloride) are more easily absorbed, whereas the less-soluble oxides and sulfides of nickel are absorbed to a lesser extent.

Because water-soluble nickel compounds tend to be more readily absorbed from the respiratory tract when compared with poorly soluble nickel compounds, exposure to the soluble nickel chloride or nickel sulfate results in higher urinary nickel concentrations than does exposure to less-soluble nickel oxide or nickel subsulfide, whereas the less soluble compounds have longer apparent half-lives. This likely at least partially represents a longer absorption phase.

The gastrointestinal absorption of nickel compounds varies with the particular nickel compound as well as coingestants. For example, approximately 27% of the total nickel in nickel sulfate given to humans in drinking water is absorbed, whereas only approximately 1% is absorbed when given in food. Serum nickel concentrations peak between 1.5 and 3 hours following ingestion.<sup>46</sup> As noted above, the presence of food in the gastrointestinal tract appears to reduce the absorption of nickel, and most ingested nickel remains in the gut and is excreted in the feces.

Although some systemic absorption of nickel occurs through skin contact, much of the applied nickel remains in the keratinized skin, with limited absorption by keratinocytes.<sup>25</sup>

### Distribution

In human serum, the exchangeable pool of primarily divalent nickel is bound to albumin, L-histidine, and  $\alpha_2$ -macroglobulin. A nonexchangeable pool of nickel that is tightly bound to a transport protein known as nickeloplasmin also exists in the serum. Nickel crosses the placenta and is present in breast milk.

Nickel is also concentrated in various solid organs. An autopsy study of individuals not occupationally exposed to nickel reported the highest concentrations of nickel in the lungs, followed by the thyroid, adrenals, kidneys, heart, liver, brain, spleen, and pancreas.<sup>34</sup> Nickel concentrations in the nasal mucosa are higher in workers exposed to less-soluble nickel compounds relative to soluble nickel compounds,<sup>51</sup> indicating that, following inhalation exposure, less-soluble nickel compounds remain deposited on the nasal mucosa.

### Elimination

In humans, most ingested nickel is excreted in the feces; however, because more than 90% of ingested nickel does not leave the gut, most of the nickel found in feces represents the unabsorbed fraction rather than the elimination of body nickel.<sup>46</sup> Absorbed nickel is primarily excreted in the urine and, to a lesser degree, other bodily fluids.

Regardless of the route of exposure, workers occupationally exposed to nickel have increased urinary concentrations of nickel.<sup>19</sup> In nickel refinery workers, urinary excretion increased from the beginning to the end of the shift, indicating that a fraction of absorbed nickel is rapidly eliminated.<sup>51</sup> Similarly, urinary excretion increased as the work week progressed, indicating the presence of a fraction that is excreted more slowly. In fact, after a massive inhalational welding exposure, the apparent half-life of nickel in urine and blood followed a biphasic exponential decay pattern of excretion, and was 25 and 610 days in urine, and 30 and 240 days in blood, indicating potential saturation of elimination pathways and delayed absorption and redistribution of nickel.<sup>36</sup>

Studies of workers who unintentionally ingested water contaminated with nickel sulfate and nickel chloride reported a mean apparent serum half-life of 60 hours, but this decreased substantially ( $\leq 27$  hours) when the workers were treated with intravenous fluids.<sup>45</sup>

The available literature supports the view that systemically absorbed nickel is excreted through the kidneys, with some excretion of insoluble compounds in the feces. Because of the previously mentioned factors affecting absorption, the apparent half-life following exposure likely reflects continuing absorption and will therefore depend on the route of exposure and the particular nickel species involved.

## CLINICAL MANIFESTATIONS

### Acute

The clinical manifestations associated with acute exposure to nickel depend on the particular compound and route of exposure. Inhalation of nickel-containing aerosolized particles tends to affect the lungs and upper airways directly, whereas ingestion and intravenous administration results in systemic toxicity, usually involving the nervous system (Table 96-1).

The most common disorder associated with exposure to nickel, by far, is an allergic dermatitis. Although acute toxicity is reported following various routes of exposure, the most important source of acute nickel toxicity is inhalational exposure to nickel carbonyl, which is associated with pulmonary, neurologic, and hepatic dysfunction.<sup>44</sup>

### Nickel Allergy and Dermatitis

Nickel dermatitis was first reported in the late 1800s in nickel-plating workers and was recognized as an allergic reaction in 1925. Since then, nickel has been recognized as a common cause of allergic contact dermatitis. Divalent nickel is not itself antigenic but acts as a hapten, binding larger proteins and inducing conformational changes such that these become recognized as non-self antigens.<sup>21</sup>

TABLE 96-1 Symptoms and Signs of Nickel Carbonyl Poisoning<sup>39</sup>

Symptoms and Signs in 179 Cases	Frequency, %
Chest pain/tightness	67
Dizziness	66
Nausea	64
Weakness	54.8
Headache	54
Cough	43.6
Dyspnea	8.9
Vomiting	7.3
Fever	6.7
Somnolence	5.1
Abdominal pain	1.7

**TABLE 96-2 Findings Suggestive of Nickel Dermatitis**

Previous history of allergic response to jewelry
Multiple body piercings
Eruptions at the site of metal contact, or flexor areas if generalized
Eruptions following placement of orthodontic appliances containing high concentrations of nickel (unusual)
Seasonal dermatitis in warm months (increased metal–skin contact and increased sweating)
Facial dermatitis in mobile phone users

The allergic reaction caused by contact with nickel is a type IV delayed hypersensitivity immune response that typically occurs in 2 phases. In the first phase, sensitization occurs when nickel enters the body. The second phase occurs when the body is re-exposed to nickel, at which time allergy manifests. The diagnosis of nickel allergy is suggested by specific historical findings listed in [Table 96-2](#) (Chap. 17).

The North American Contact Dermatitis Group reports that nickel has been the most frequently positive of the 65 tested allergens in patch-testing since 1992.<sup>26</sup> The 5-fold greater prevalence of nickel allergy in women is presumably a consequence of their higher rates of body piercing and more frequent wearing of jewelry, both of which are risk factors for nickel sensitization. Denmark in 2001 and later the European Union as a whole initiated nickel regulations. These laws forbade the use of nickel in piercings during the period of epithelialization, in accessories such as watches and jewelry to be in prolonged contact with skin, and even limited use of nickel when plated with another metal unless liberation of nickel was less than 0.5 mcg/cm<sup>2</sup>/week.<sup>14</sup> It is unclear if these regulations succeeded in reducing rates of nickel sensitivity although this is suggested in several studies.<sup>50</sup>

Nickel dermatitis is classified into 2 types: primary and secondary. The more common primary dermatitis presents as a typical eczematous reaction in the area of skin that is in contact with nickel. It is characterized initially by erythematous papules that progress to lichenification because of pruritus and scratching. These eruptions reportedly mimic basal cell carcinoma.<sup>25</sup> Areas typically involved are the wrists, as a result of wearing watches and bracelets, the ears from earrings, and the periumbilical area at the site of contact with jewelry, nickel-containing buttons on jeans, or nickel-containing belt buckles ([Fig. 96-1](#)). Approximately 50% of all belt buckles and 10% of buttons on blue jeans contain nickel.<sup>10</sup> The most common cause for nickel dermatitis in women is direct contact from jewelry, garments, wristwatches, cosmetics, and occupational contact in the metal, hairdressing, tailoring, hotel, and restaurant industries. In men, nickel dermatitis is often occupational but in some individuals, is also related to jewelry, body piercing, garments, or even metal guitar strings.

The secondary form involves a more widespread dermatitis as a result of other exposures, such as ingestion or inhalation of nickel compounds, and implantation of metal medical devices, and is regarded as a systemic contact

**FIGURE 96-1.** Nickel dermatitis from jewelry. (Used with permission from Brian Wexler.)

dermatitis elicited by nickel. Secondary eruptions are typically symmetrically distributed and localized in the elbow flexure, on the eyelids, on the sides of the neck, and face and can become widespread.

Nickel in foods, excessive skin contact, and certain orthodontic appliances with high nickel content are all linked to this eczematous eruption. Nonetheless, orthodontic exposure to nickel-containing alloys is unlikely to induce hypersensitivity reactions in patients without prior sensitization, and such reactions are still infrequent even in those sensitized.<sup>33</sup>

Other types of medical devices containing nickel have the potential to induce either primary or local nickel dermatitis. Occlusion of a biliary stent was reported as related to nickel allergy, and increased rates of restenosis of bare metal and cobalt-chromium cardiac stents are linked to nickel sensitization, although other studies have found no such correlation, and drug-eluting stents may mitigate any effect of metal allergy.<sup>29</sup>

One study showed that following skin application, nickel salts are retained in the skin for an extended period of time,<sup>25</sup> which could lead to prolonged antigen processing and consequent immune responses in dermal tissue. There may also be a genetic basis for nickel sensitization.<sup>35,49</sup> Development of an allergy, like most of toxicology, is probably dose and duration dependent, and this is the basis of the recent EU regulations to limit consumer exposure to nickel.

## INHALATIONAL EXPOSURE

### Nickel Carbonyl

Nickel carbonyl is the most harmful form of nickel and the majority of acute occupational nickel exposures involve nickel carbonyl. Nickel carbonyl is described as having a “musty” or “sooty” odor, although thresholds for detection vary considerably and potentially harmful exposures cannot be excluded simply by a reported lack of odor. Exposure to concentrations of 100 mg/m<sup>3</sup> is fatal in rats after 20 minutes.<sup>23,47</sup> Once dissociated, nickel carbonyl is oxidized in tissues to Ni<sup>2+</sup>.

Nickel carbonyl exposure causes both immediate and delayed symptoms. In a series of 179 exposures, approximately 40% of patients reported symptoms within 1 hour of exposure; however, it is important to note that symptoms were delayed for approximately 1 week in 20% of patients, and even some patients with mild initial symptoms developed severe delayed symptoms, although usually within the next 2 days.<sup>39</sup> In patients who developed symptoms shortly following exposure, the initial manifestations involved nonspecific complaints, including respiratory tract irritation, chest pain, cough, dyspnea, frontal headache, dizziness, weakness, and nausea. Patients manifesting only these initial signs are categorized as mildly toxic.

Manifestations of severe acute nickel carbonyl poisoning generally develop over the course of several hours to days and are associated with acute respiratory distress syndrome and interstitial pneumonitis. Myocarditis, marked by persistent (time) changes on electrocardiography, including ST- and T-wave changes, as well as QT interval prolongation, are reported.<sup>39</sup> Neurologic symptoms associated with severe poisoning include altered mental status, seizures, and extreme weakness that sometimes necessitate mechanical ventilation. A moderate leukocytosis (10,000–15,000 white blood cells/mm<sup>3</sup>), nonspecific opacities on chest radiography, and elevation of aminotransferase concentrations also occur, but these tend to resolve over the course of several weeks. Deaths from nickel carbonyl are typically caused by interstitial pneumonitis and cerebral edema occurring within 2 weeks of initial exposure.<sup>47</sup> Autopsy studies of those dying after nickel carbonyl exposure demonstrate diffuse pulmonary consolidation, organizing fibrosis, cerebral edema or hemorrhage, and cardiac dilation.<sup>37</sup> Survivors usually recover completely, although in some cases the development of a prolonged neurasthenic syndrome occurs which lasts for months.<sup>39</sup> Clinical features of nickel carbonyl poisoning are found in [Table 96-1](#).

### Noncarbonyl Nickel

There are few human cases of inhalational nickel poisoning. However, from the available data, the primary concerns appear to be pulmonary, neurologic, and, perhaps, renal.

A case report described seizure activity in 2 patients following occupational inhalational exposure to noncarbonyl nickel. Both patients exhibited elevated urinary nickel concentrations, with no recurrence of seizure activity upon removal from exposure.<sup>15</sup> Seizures were previously documented in animal studies, although the mechanisms are unclear and are hypothesized to involve inhibition of the glutamate transporter.<sup>27</sup> Interstitial pneumonia is also associated with inhalational exposure while spray painting high-temperature nickel-chromium alloys.<sup>20</sup> As previously mentioned, inhalational exposure to metallic nickel particles/nanoparticles can induce acute respiratory distress syndrome as well as acute tubular necrosis.<sup>32</sup>

### Parenteral Administration

Acute parenteral toxicity from nickel-containing compounds occurred following the use of water for hemodialysis that was heated in a nickel-plated tank.<sup>55</sup> The concentration of nickel in the delivered water was 0.25 mg/L, and measured serum concentrations exceeded 3 mg/L. Through back-extrapolation, peak serum concentrations were estimated to be as high as 9 mg/L. These patients developed nonspecific effects, including headache, nausea, and vomiting, similar to nickel carbonyl poisoning, although no respiratory complaints were reported. The effects resolved after several hours, and the patients recovered without sequelae.

### Ingestion

Acute ingestions of contaminated water containing 1.63 g Ni<sup>2+</sup>/L caused nausea, vomiting, diarrhea, weakness, and headache, as well as pulmonary findings, including cough and dyspnea, lasting up to 48 hours.<sup>45</sup> Estimated ingested doses of nickel (as Ni<sup>2+</sup>) were 0.5 to 2.5 g, and serum concentrations as high as 13.4 mcg/L were reported.

### Dermal Absorption

Although transdermal absorption is typically of minor clinical significance, disruption of the normal integument likely allows for more efficient systemic absorption. A metal refinery worker suffered a 40% body surface area partial-thickness chemical injury resulting from exposure to a chemical mixture that included nickel carbonate and nickel sulfate.<sup>30</sup> Prior to the incident, this individual's measured serum nickel concentration was 0.023 μmol/L (1.35 mcg/L). On the sixth day following the injury, the serum concentration was 0.490 μmol/L (28.8 mcg/L). Two 5-day courses of chelation with edetate calcium disodium (CaNa<sub>2</sub>EDTA) were begun for concomitant cobalt poisoning, and the patient's serum and urine nickel concentrations were within normal limits by 21 days postexposure. He subsequently recovered without manifesting signs of nickel toxicity.

### Chronic Nickel Exposure

Chronic inhalational exposure to nickel is associated with injury characterized by specific histologic changes in the nasopharynx and upper respiratory tract, including atrophy of the olfactory epithelium, rhinitis, sinusitis, nasal polyps, and nasal septal damage.<sup>8</sup> Pulmonary effects include asthma<sup>28</sup> and pulmonary fibrosis.<sup>6</sup>

The International Agency for Research on Cancer classifies nickel compounds as a group 1 carcinogen (carcinogenic to humans). The potential for and mechanisms of carcinogenesis of nickel depend heavily on the specific compounds studied. Although nickel-induced carcinogenesis is fairly well established for nickel compounds, the role of metallic nickel is less clear.

In Taiwan, an increased incidence of oral cancer is associated with geographic areas containing higher concentrations of nickel in farming soil.<sup>42</sup> Although earlier studies of occupationally exposed workers, primarily electroplaters and refinery workers, also showed increased rates of nasal and pulmonary tumors, more recent studies of nickel-exposed workers in more modern environments with lower permissible limits of nickel exposure do not show a significantly increased risk of cancer or any cause of mortality.<sup>40</sup>

Although the exact mechanism of any possible carcinogenesis remains to be firmly elucidated, studies indicate several potential mechanisms. Animal studies show a threshold dose–response curve for inflammation with soluble

compounds (nickel sulfate), and similar curves describe the risks of pulmonary cancers with the less-soluble nickel oxides and nickel subsulfide.<sup>38</sup>

Depending on the particular nickel compounds studied, carcinogenesis is hypothesized to be due to genetic, epigenetic, or inflammatory mechanisms. The more potent carcinogenic effects of insoluble nickel compounds are suggested to be a consequence of their increased cellular uptake.<sup>12</sup>

Based on concerns about long-term health effects, exposure limits for various nickel compounds were proposed (Table 96–3).

## DIAGNOSTIC TESTING

Although nickel is widely distributed to many body fluids and tissues, urine and blood are the most commonly analyzed samples. Urine collection should ideally use acid-washed, metal-free containers. Some authors recommend correcting urinary nickel concentration per gram of urine creatinine, but it is not clear that this offers any particular advantage in clinical decision making. The average nickel concentration in serum is less than 1.1 mcg/L (17 nmol/L), whereas the value in urine ranges from 1 to 3 mcg/L (102 nmol/L),<sup>48</sup> although substantially higher values are reported even in non-occupationally exposed populations. Concentrations in serum and urine of workers occupationally exposed to nickel are substantially higher, but do not directly correlate with adverse health effects.

Nickel concentrations rise in urine, serum, and whole blood following oral administration. In these studies, serum concentrations were slightly higher than whole blood. Urine and blood concentrations primarily reflect exposure occurring within the previous 48 hours,<sup>11</sup> which is roughly the biologic half-life calculated from various field studies.<sup>52</sup>

Urine nickel concentrations are used more commonly than blood for monitoring of workplace exposures and for prognostic and therapeutic decision making in nickel carbonyl exposures. An 8-hour collection is typically performed, and the average urinary excretion of nickel (in these nickel workers) is 2 mcg/L, with an upper limit of normal of 5 mcg/L. In cases of nickel carbonyl poisoning, concentrations of less than 100 mcg/L in the initial-8-hour specimen implies mild toxicity. Concentrations of 100 to 500 mcg/L are classified as moderate, whereas concentrations higher than 500 mcg/L are categorized as severe poisonings.<sup>47</sup> These classifications are used in guiding treatment decisions. Urine nickel concentrations rise prior to the onset of symptoms in nickel carbonyl poisoning, making this determination a potentially useful screening tool for both workforce surveillance and the management of acute exposures.

Testing for allergic contact dermatitis due to nickel is performed using patch testing, as for other types of contact dermatitis. “Strip” patch testing, in which the stratum corneum is thinned by repeated application and removal

of adhesive tape prior to application of the test substance, is more sensitive than standard patch testing by 16%.<sup>16</sup> Testing metal surfaces for free nickel is possible and sometimes necessary in the evaluation and treatment of nickel dermatitis. Patients with clinically important sensitivity or suspect medical histories can order an inexpensive, commercially packaged dimethylglyoxime spot test, allowing them to test metal objects for the presence of free nickel.<sup>10</sup>

## TREATMENT

The first step in treatment of nickel-related medical problems is eliminating the exposure, which includes detection and removal of the source. In the case of acute exposures to nickel carbonyl, removal of clothing to prevent continued exposure and thorough skin decontamination is recommended.

Symptomatic treatment for pulmonary symptoms associated with hypoxia includes the administration of supplemental oxygen. The use of bronchodilators and corticosteroids are reasonable interventions for the treatment of concomitant bronchospasm. Mechanical ventilation will be required in the most severe cases. Extracorporeal membrane oxygenation is not reported for nickel poisoning, but would be reasonable if needed for oxygenation or hemodynamic support.

The administration of intravenous fluids to promote diuresis reduces the half-life of orally ingested nickel chloride by approximately 50%.<sup>45</sup> Because of high levels of protein binding, hemodialysis does not effectively remove nickel from the serum.<sup>55</sup>

## Chelation

Because there are no controlled human trials, specific recommendations for the use of chelation to treat nickel toxicity are not currently supported by the literature. As a result, extrapolation from animal studies and case reports form the basis for most treatment regimens. Most studies and reports involving treatment focused on workers exposed to nickel carbonyl.

Several drugs are proposed as potential treatments for nickel carbonyl exposures. Studies in rats with various chelators show some protection by administration of dimercaprol and D-penicillamine,<sup>57</sup> whereas CaNa<sub>2</sub>EDTA had no protective effect.<sup>56</sup> Although dimercaprol was being used in the past,<sup>47</sup> the most recent literature has focused on the use of diethyldithiocarbamate (DDC) (Chaps. 78 and 99).

Diethyldithiocarbamate is a chelator formerly used as the color reagent for urine nickel measurements. Rats exposed to several times the LD<sub>50</sub> (median lethal dose for 50% of subjects) for nickel carbonyl had dramatically reduced mortality when pretreated with DDC; however, the antidotal efficacy decreased with increasing delay to treatment.<sup>5</sup> A proposed treatment regimen for exposed workers focuses on analysis both of the exposure and of the initial 8-hour urine collection.<sup>47</sup> Patients with suspected severe poisonings are typically given the first gram of DDC in divided oral doses. When less-severe exposures are suspected, treatment decisions are based on the urinary nickel concentration. At urinary concentrations lower than 100 mcg/L, no initial therapy is recommended as delayed symptoms are unlikely to develop. At urinary concentrations between 100 and 500 mcg/L, an oral regimen consisting of 1 g DDC initially, 0.8 g at 4 hours, 0.6 g at 8 hours, and 0.4 g at 16 hours is used. Diethyldithiocarbamate is continued at a dose of 0.4 g every 8 hours until there is symptomatic improvement and urine nickel concentration is normal. Severe exposures with urinary nickel concentrations more than 500 mcg/L are treated using the same regimen, although these patients frequently require closer monitoring. Critically ill patients should be given parenteral DDC starting at a dose of 12.5 mg/kg. However, given the animal data that the route and timing of administration are important to survival, if available, parenteral DDC should be given as soon as possible following nickel carbonyl poisoning.<sup>9</sup> Although typically well-tolerated, DDC induces a disulfiram reaction (Chap. 78) if taken with ethanol, and there are concerns about using DDC when there is concurrent cadmium exposure, at least by the oral route.<sup>2</sup> As in the case of many chelators, there is also debate about whether the redistribution of nickel by chelators is detrimental by increasing brain and organ concentrations.<sup>31</sup>

Disulfiram is metabolized into 2 molecules of DDC. Given that DDC is not pharmaceutically available in the United States, there is some interest in the

use of disulfiram as an antidote for nickel carbonyl. Although case reports describe successful treatment of nickel carbonyl toxicity with disulfiram,<sup>35</sup> concern exists because animal studies show that disulfiram increased nickel concentration in brain tissue.<sup>4</sup> Disulfiram cannot be considered a standard of care, because of the lack of convincing evidence, but would be reasonable because of its theoretical efficacy. One suggested treatment regimen is 750 mg given orally every 8 hours for 24 hours, followed by 250 mg every 8 hours.<sup>24</sup>

Considering most of the literature and almost all human case reports of nickel carbonyl refer to the use of DDC, it is considered the treatment of choice for nickel toxicity. Although commonly available as a reagent, pharmaceutical-grade DDC is not produced commercially. Although based on less robust evidence, given the fact that disulfiram is essentially a prodrug for the unavailable DDC, treatment of nickel carbonyl poisonings with disulfiram would be reasonable.

Contact dermatitis from nickel is treated with avoidance, topical corticosteroids, and oral antihistamines. Some patients also benefit from dietary reduction of nickel intake, including running hot water faucets to flush pipes before using water for human consumption. Although sometimes advised, there does not appear to be a role for avoiding stainless steel cookware to reduce the nickel content of food.

## SUMMARY

- Nickel is a ubiquitous metal, found in jewelry, electronics, stainless steel, and currencies, as well as in food and water.
- Allergic dermatitis due to hypersensitivity is the most common type of nickel-related disease.
- Acute nickel toxicity is rare and most often related to nickel carbonyl.
- Diethyldithiocarbamate (DDC) is the most studied chelator of nickel for nickel carbonyl exposures, but is currently not pharmaceutically available. It is reasonable to treat with disulfiram, a prodrug of DDC, in the setting of serious nickel carbonyl exposures.
- Chronic, excessive exposures to nickel compounds, particularly subsulfide nickel, increases the risk of sinonasal and lung cancers.

# SELENIUM

Diane P. Calello

## Selenium (Se)

Atomic number	= 34
Atomic weight	= 78.96 Da
Normal concentrations	
Whole blood	= 0.1–0.34 mg/L (1.27–4.32 μmol/L)
Serum	= 0.04–0.6 mg/L (0.51–7.6 μmol/L)
Urine	<0.03 mg/L (0.38 μmol/L)
Hair	= 5.1–17.7 nmol/g

## INTRODUCTION

Selenium was discovered by Jöns Berzelius in 1817 as a contaminant in sulfuric acid vats that caused illness in Swedish factory workers. He originally believed it to be the element tellurium (from the Latin *tellus*, meaning “earth”); however, on finding it to be an entirely new, yet similar, element, he named it from the Greek *selene*, meaning “moon.” Selenium has unusual light-sensitive electrical conductive properties, leading to its widespread use in industry. The long-term health benefits and risks of selenium are the subject of much recent investigation. It is both an essential component of the human diet and a poison.

In the 1970s, the role of selenium as an essential cofactor of the enzyme glutathione peroxidase was discovered. Keshan disease, an endemic cardiomyopathy, was described in 1979 in Chinese women and children who chronically consumed a selenium-poor diet.<sup>15</sup> Kashin-Beck disease, a disease causing shortened stature from chondrocyte necrosis, is described in young children in Russia, China, and Korea; although other etiologies are also likely responsible, selenium supplementation results in partial improvement.<sup>4,23</sup> Selenium was investigated for the prevention and treatment of a myriad of conditions, including autoimmune thyroiditis, cancer, Alzheimer disease, and tropical leishmaniasis.<sup>43</sup> However, it is now clear that selenium supplementation increases the risk of diabetes, amyotrophic lateral sclerosis, depression, and some forms of malignancy.<sup>2,12,25,51</sup>

The recommended daily allowance (RDA) in the United States of selenium for adults was established in 1980 and remains today at 55 mcg/day.<sup>22</sup> This was determined based on the degree of supplementation required to achieve optimal glutathione peroxidase activity in selenium-deficient study populations, and the amounts required to cause overt toxicity. Deficiency occurs when daily intake falls below 20 mcg/day.<sup>15</sup>

Chronic selenium toxicity, or selenosis, was first described in animals. It manifested as the acute syndrome of “blind staggers,” and the more chronic “alkali disease” affected livestock eating plants grown in highly seleniferous soil. Findings included blindness, walking in circles, anorexia, weight loss, ataxia, and dystrophic hooves. Humans in seleniferous areas of China and Venezuela develop similar integumentary symptoms (dermatitis, hair loss, and nail changes) at an intake of approximately 6,000 mcg/day.<sup>7,46</sup> Several outbreaks of chronic selenium toxicity were related to improperly formulated dietary supplements.<sup>3,10,52</sup>

Selenium is widely distributed throughout the Earth’s crust, usually substituting for sulfur in sulfide ores such as marcasite (FeS<sub>2</sub>), arsenopyrite (FeAsS), and chalcopyrite (CuFeS<sub>2</sub>). It is found in the soil, where it has leached from bedrock, in groundwater, and in volcanic gas. The highest soil concentrations of selenium in the United States are in the Midwest and the West, specifically areas of the Dakotas, Wyoming, Nebraska, Kansas, Utah, Colorado, Arizona, and New Mexico.<sup>4</sup> Dietary selenium is easily obtained through meats, grains, and cereals. Brazil nuts, grown in the foothills of the highly seleniferous

Andes Mountains, contain the highest concentration measured in food, but chronic selenium toxicity from Brazil nuts is not reported.<sup>4,27</sup>

In industry, selenium is generated primarily as a by-product of electrolytic copper refining and in the combustion of rubber, paper, municipal waste, and fossil fuels. Selenium compounds are used in glass manufacture and coloring, photography, xerography, rubber vulcanization, and as insecticides and fungicides. Selenium sulfide is the active ingredient in many antidandruff shampoos. Gun bluing solution, used in the care of firearms to restore the natural color to the gun barrel, is composed of selenious acid in combination with cupric sulfate in hydrochloric acid, nitric acid, copper nitrate, or methanol. Tables 97–1 and 97–2 list features and regulatory standards of common selenium compounds.

## CHEMICAL PRINCIPLES

Selenium is a nonmetal element of group 16/VIA of the periodic table along with oxygen, sulfur, tellurium, and polonium. Selenium exists in elemental, organic, and inorganic forms, with 4 important oxidation states: selenide (Se<sup>2-</sup>), elemental (Se<sup>0</sup>), selenite (Se<sup>4+</sup>), and selenate (Se<sup>6+</sup>). Water solubility generally increases with oxidation state. Selenium behaves similarly to sulfur in its tendency to form compounds and to participate extensively in biologic systems<sup>4</sup> and is both photovoltaic (able to convert light to electricity) and photoconductive (conducts electricity faster in bright light), which has led to its use in photography, xerography, and solar cells.

At least 3 solid allotropes of elemental selenium are described, including “gray selenium,” which is predominant at room temperature, red crystalline selenium, and a red amorphous powder.<sup>4</sup> In general, toxicity from elemental selenium is rare and only occurs from long-term exposure. Hydrogen selenide (H<sub>2</sub>Se) is formed from the reaction of water or acids with metal selenides or from the reaction of hydrogen with soluble selenium compounds; at room

TABLE 97–1 Selenium Compounds

Name	Chemical Formula	Oxidation State	Uses
Selenium (elemental)	Se	0	Photography, catalyst, dietary supplement, xerography
Selenium sulfide	SeS <sub>2</sub>	2 <sup>-</sup>	Antidandruff shampoo, fungicide
Hydrogen selenide	H <sub>2</sub> Se	2 <sup>-</sup>	A by-product of metal selenides reaction with water; no commercial use
Dimethylselenide	CH <sub>3</sub> SeCH <sub>3</sub>	2 <sup>-</sup>	Metabolite, garlic odor
Selenium dioxide	SeO <sub>2</sub>	4 <sup>+</sup>	Catalyst, photography, glass decolorizer, vulcanization of rubber, xerography
Selenium oxychloride	SeOCl <sub>2</sub>	4 <sup>+</sup>	Solvent, plasticizer
Selenious acid	H <sub>2</sub> SeO <sub>3</sub>	4 <sup>+</sup>	Gun bluing solution
Sodium selenite	Na <sub>2</sub> SeO <sub>3</sub>	4 <sup>+</sup>	Glass and porcelain manufacture
Selenium hexafluoride	SeF <sub>6</sub>	6 <sup>+</sup>	Gaseous electrical insulator
Sodium selenate	Na <sub>2</sub> SeO <sub>4</sub>	6 <sup>+</sup>	Glass manufacture, insecticide

TABLE 97-2 Selenium Regulations and Advisories

Oral—Recommended Intake and Exposure Limits		
RDA (2000)		55 mcg/day <sup>a</sup> (0.8 mcg/kg/day)
NAS-TUL		400 mcg/day (5.7 mcg/kg/day)
ATSDR-chronic oral		5 mcg/kg/day
MRL <sup>b</sup>		
Water—Limits		
WHO	Drinking water	0.01 mg/L
FDA	Bottled water	0.05 mg/L

temperature, it exists in gaseous form, which results in industrial inhalation exposures. The organic alkyl selenides (dimethylselenide, trimethylselenide) are the least toxic and are by-products of endogenous selenium detoxification (methylation). Inorganic salts and acids are responsible for all cases of acute toxicity. Selenious acid (H<sub>2</sub>SeO<sub>3</sub>), generated from the reaction of selenium dioxide with water, is the most toxic form of selenium; ingestion of selenious acid is often fatal.<sup>21,35,40,49</sup>

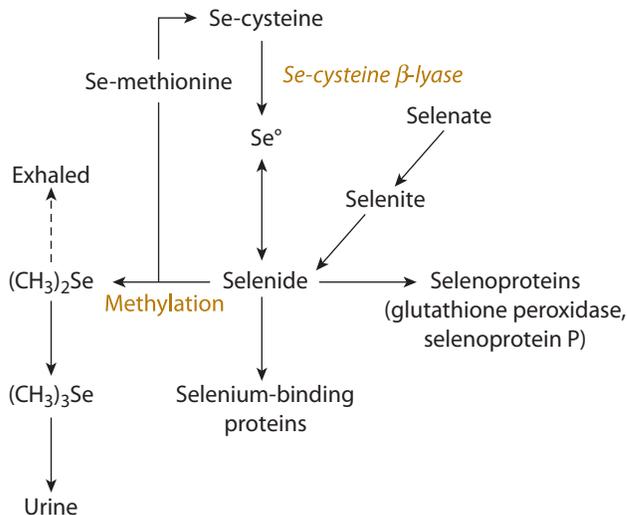

## PHARMACOLOGY

Selenium exists in one of 3 forms in the body. First, *selenoproteins* contain selenocysteine residues and have specific selenium-dependent roles primarily in oxidation–reduction reactions.<sup>8</sup> Second, nonspecific plasma proteins bind and aid in transport of selenium, either by directly binding selenium (albumin, globulins) or incorporating it as selenocysteine or selenomethionine in place of cysteine and methionine, respectively.<sup>8</sup> Third, there are several inorganic forms of selenium in transit throughout the body, such as selenate, alkyl selenides, and elemental selenium (Se<sup>0</sup>).<sup>8</sup>

There are at least 25 selenoproteins—which include glutathione peroxidases, iodothyronine 5-deiodinases, and thioredoxin reductase—each of which contain a selenocysteine or selenomethionine residue at the active site.<sup>43</sup> The most studied of these is glutathione peroxidase I, which is responsible for detoxification of reactive oxygen species. Using reduced glutathione (GSH) as a substrate, glutathione peroxidase catalyzes the reduction of hydrogen peroxide to water and oxidized glutathione (GSSG, or glutathione disulfide); the reaction occurs by concomitant oxidation of the selenocysteine unit on the enzyme.<sup>5</sup> Other selenocysteine-containing proteins, such as thioredoxin reductase, have antioxidant properties. The selenocysteine-containing thyroid hormone deiodinases are responsible for the conversion of thyroxine (T<sub>4</sub>) to the active triiodothyronine (T<sub>3</sub>) form (Chap. 53).

## PHARMACOKINETICS AND TOXICOKINETICS

Gastrointestinal (GI) absorption varies with the type of selenium, and human data are limited. Elemental selenium is the least bioavailable ( $\leq$ 50%), followed by inorganic selenite and selenate salts (75%).<sup>33</sup> Selenious acid is well absorbed from the lungs and GI tract ( $\sim$ 85%) in animal studies.<sup>13</sup> Organic

**FIGURE 97-1.** Metabolism of selenium. The selenide anion is central in selenium metabolism. Organic selenocysteine is converted via the β-lyase enzyme to elemental selenium and then to selenide. Selenomethionine either undergoes transsulfuration to selenocysteine or methylation to excretable metabolites. The selenate and selenite salts are reduced to selenide. Selenide then undergoes one of 3 processes: methylation, incorporation into selenoproteins, or binding by nonspecific plasma proteins.<sup>1</sup>

selenium compounds are the best absorbed ( $\sim$ 90%) as determined by isotope tracers in human studies.<sup>4,29</sup> A breastfed infant developed selenosis exclusively from maternal overexposure, suggesting transmission through breast milk.<sup>53</sup>

Inhalational absorption was reported in a group of workers exposed to selenium dioxide and hydrogen selenide gas,<sup>4,19</sup> but quantitative inhalation studies in humans are not available. Dermal absorption is limited. Selenium disulfide shampoos are not systemically absorbed as measured by urinary selenium concentrations<sup>13</sup> except in cases of repeated use on excoriated skin.<sup>41</sup>

The toxic dose of selenium varies widely among selenium compounds, as demonstrated by LD<sub>50</sub> (median lethal dose for test subjects: 50%) animal studies,<sup>46</sup> making milligram per kilogram exposure estimates difficult to interpret. Elemental selenium has no reported adverse effects in acute overdose, although long-term overexposure is harmful. The selenium salts, particularly selenite, are more acutely toxic, as is selenium oxide (SeO<sub>2</sub>) through its conversion to selenious acid in the presence of water. Selenious acid was lethal in children following ingestion of as little as a tablespoon of 4% solution.<sup>35</sup>

Metabolic conversion of all forms of selenium to the selenide anion occurs through various means (Fig. 97-1), after which the selenide ion undergoes one of 3 fates: (1) incorporation into selenoproteins such as glutathione peroxidase and triiodothyronine, (2) binding by nonspecific plasma proteins such as albumin or globulins, or (3) hepatic methylation into nontoxic, excretable metabolites. Trimethylselenide is the primary metabolite and is excreted by the kidneys, the major elimination pathway for selenium. Fecal elimination also occurs. Dimethylselenide production is usually minor but increases with exposure; this compound is volatilized through exhalation and sweat and is responsible for the garlic odor of patients exposed to excess selenium. The remaining selenium in the body is greater than 95% protein bound within 24 hours.<sup>1,46</sup> Toxicokinetic data are limited and vary by compound.

## PATHOPHYSIOLOGY

In selenium deficiency, glutathione peroxidase activity is decreased, and GSH and glutathione S-transferases are increased.<sup>9</sup> Consequently, selenium-deficient rats are more resistant to substances detoxified by glutathione S-transferase, such as acetaminophen and aflatoxin B, and less resistant to other prooxidants, such as nitrofurantoin, diquat, and paraquat.<sup>9</sup> In animal studies of metal toxicity, selenium also appears to modify the effects of silver, cadmium, arsenic, copper, zinc, mercury, and fluoride; conversely, vanadium, tellurium, and arsenic modify the effects of selenium deficiency or excess.<sup>6,20,24,46</sup> Although it is proposed

that this is accomplished through the formation of insoluble selenium–metal complexes, these relationships are not entirely understood.<sup>18</sup>

Less is known about the biochemical mechanism of selenium toxicity, and what is known is generally from *in vitro* data. Paradoxically, excess selenium causes oxidative stress, presumably as a result of prooxidant selenide (R-Se<sup>-</sup>) anions. In addition, the replacement of sulfur by selenium in enzymes of cellular respiration causes mitochondrial disruption, and the substitution of selenomethionine in place of methionine interferes with protein synthesis. Integumentary effects are also most likely a result of selenium interpolation into disulfide bridges of structural proteins such as keratin.<sup>50</sup>

## CLINICAL MANIFESTATIONS

### Acute

#### Dermal and Ophthalmic Exposure

Dermal exposure to selenious acid or to selenium dioxide (which is converted to selenious acid) and to selenium oxychloride (a vesicant hydrolyzed to hydrochloric acid) causes painful caustic burns.<sup>16</sup> Excruciating pain results from accumulation under fingernails. Corneal injury with severe pain, lacrimation, and conjunctival edema are reported after exposure to selenium dioxide sprayed unintentionally into the face.<sup>34</sup> In chronic exposures, “rose eye,” a red discoloration of eyelids with palpebral conjunctivitis, is also described.

#### Inhalational Exposure

When inhaled, all selenium compounds have the potential to be respiratory irritants, although inhaled elemental selenium dusts are less injurious than those compounds that are converted to selenious acid.<sup>1</sup> Toxicity from hydrogen selenide inhalation is reported throughout the industrial literature.<sup>11,17</sup> Hydrogen selenide is oxidized to elemental selenium, so acute toxic exposures are limited to confined spaces where the hazardous gas accumulates; however, similar to hydrogen sulfide (H<sub>2</sub>S), its ability to cause olfactory fatigue, rendering the exposed persons anosmic to the toxic fumes, poses a significant hazard (Chap. 25).<sup>11</sup> Acute exposure to high concentrations of hydrogen selenide gas produces respiratory and mucosal irritation, which in some cases persists for years as residual restrictive and obstructive disease.<sup>44</sup>

By contrast, selenium dioxide and selenium oxide fumes cause more injury through conversion to selenious acid in the presence of water in the respiratory tract. Upper respiratory irritation, bronchospasm, and transient hemodynamic instability developed in 28 workers in a selenium rectifier plant who were inadvertently exposed to smoke and high concentrations of selenium oxide in an enclosed area.<sup>54</sup> Some developed chemical pneumonitis, fever, chills, headache, vomiting, and diarrhea. Five patients required hospitalization for respiratory support, with fever, leukocytosis, and bilateral infiltrates. All patients recovered without sequelae.

Selenium hexafluoride is a caustic gas used in industrial settings as an electrical insulator. Its caustic properties are derived from its conversion to elemental selenium and hydrofluoric acid in the presence of water. Severe pain and burning of the eyes, skin, and respiratory tract similar to that seen with hydrofluoric acid exposure can occur after inhalation of selenium hexafluoride (Chap. 104).<sup>36</sup>

#### Oral Exposure

Acute fulminant selenium toxicity occurs after ingestion of inorganic selenium compounds, the most toxic of which is selenious acid in the form of gun bluing solution. Similar toxicity results from selenium oxide and dioxide, which are converted to selenious acid as well as sodium selenite and selenate. The underlying mechanism for this often fatal syndrome is not well understood, but may stem from a multifocal disruption of cellular oxidative processes and antioxidant defense mechanisms. Elemental selenium and organic selenium compounds do not cause acute toxicity.

Some authors have proposed a “triphasic” course of acute inorganic selenium toxicity, with GI, skeletal muscle, and circulatory symptoms as the toxic effects progress.<sup>49</sup> In reality, acute inorganic selenium poisoning is often rapid and fulminant, with onset of symptoms within minutes and, in some cases, death within one hour of ingestion. Gastrointestinal symptoms are the most

commonly described and the first to occur and include abdominal pain, diarrhea, nausea, and vomiting. Caustic esophageal and gastric burns are sometimes the cause of these symptoms but not in all cases. Patients frequently have a garlic odor. Skeletal muscle involvement is characterized by weakness, hyporeflexia, myoclonus, fasciculations, and elevated creatine phosphokinase concentrations with normal myocardial band (MB) fraction. Acute kidney injury is also reported and presumably results from myoglobinuria and hemolysis. More severely poisoned patients exhibit lethargy, delirium, and coma.

Circulatory failure is the hallmark of serious inorganic selenium toxicity. Patients present with dyspnea, chest pain, tachycardia, and hypotension. Reported initial electrocardiographic (ECG) abnormalities include ST segment elevation, a prolonged QT interval, and T-wave inversions. Refractory hypotension occurs both as a result of decreased myocardial contractility from toxic cardiomyopathy and decreased peripheral vascular resistance. Pulmonary edema, ventricular dysrhythmias, myocardial and mesenteric infarction, and metabolic acidosis all contribute to poor outcome in these patients.<sup>35,39,54</sup> Death results from circulatory collapse in the setting of pump failure, hypotension, and ventricular dysrhythmias, often within 4 hours of ingestion.<sup>21,26,40,48</sup> Other less frequent abnormalities include hypokalemia, hyperkalemia, coagulopathy, leukocytosis, hemolysis, thrombocytopenia, and metabolic acidosis with an elevated lactate concentration.<sup>45,49</sup>

### Chronic

Chronic elemental selenium toxicity, or selenosis, is most commonly reported in the present day as a result of improperly formulated selenium-containing dietary supplements. In 2008, at least 200 people developed painful skin lesions, diarrhea, alopecia, fever, fatigue, memory loss, and nail deformities after use of the supplement.<sup>3,32,52</sup> The manufacturer voluntarily recalled the product, and a US Food and Drug Administration investigation revealed that the liquid supplement contained approximately 200 times the concentration stated on the packaging.<sup>14</sup> The patients consumed approximately 40,000 mcg/d while taking the supplement, or 1,000 times the US RDA.<sup>3</sup> A similar outbreak occurred from a super-potent supplement in 1983, affecting at least 13 patients, all of whom recovered after discontinuation of the supplement.<sup>10</sup>

Selenosis is similar to arsenic toxicity, with the most consistent manifestations being nail and hair abnormalities. As in the case of arsenic toxicity, nail or hair findings alone are unlikely to be the sole evidence of selenosis, but their absence makes the diagnosis unlikely. The hair becomes very brittle, breaking off easily at the scalp, with regrowth of discolored hair and the development of an exfoliative pruritic scalp eruption with acneiform papules.<sup>31</sup> The nails also break easily, with white or red ridges that can be either transverse or longitudinal; the thumb is usually involved first, and paronychia and nail loss often develops.<sup>31,38</sup> The skin becomes erythematous, swollen, and blistered, as well as slow to heal and has a persistent red discoloration. Increased dental caries are described.<sup>31</sup> Neurologic manifestations include hyperreflexia, peripheral paresthesia, anesthesia, and hemiplegia. Although cardiotoxicity is described with both selenium deficiency and acute poisoning, no such cases are reported with human selenosis from chronic exposure. Aside from one case described in which there was insufficient postmortem data, there are no reported deaths from chronic exposure.<sup>55</sup>

Selenosis is implicated in a number of long-term environmental exposures. Many descriptions come from inhabitants of the Hubei province of China from 1961 to 1964, the majority of whom developed clinical signs after an estimated average consumption of 5,000 mcg/d of selenium (but as little as 910 mcg/d) derived from local crops and vegetation.<sup>55</sup> Inhabitants of a seleniferous area of Venezuela, consuming approximately 300 to 400 mcg/d of selenium, also developed symptoms of selenium excess; however, the low socioeconomic and poor dietary status of the subjects is a confounding factor.<sup>7</sup> In contrast, US residents in a seleniferous area with a high selenium intake (724 mcg/d) over 2 years who were compared with a control population and monitored for symptoms and laboratory abnormalities remained asymptomatic, with only a clinically insignificant elevation of hepatic aminotransferases in the high-selenium group.<sup>30</sup> Average selenium concentrations

were serum, 0.215 mg/L; whole blood, 0.322 mg/L; and urine, 0.17 mg/L. A similar cohort with comparable blood concentrations was also reported in the Brazilian Amazon.<sup>27</sup>

Selenosis is also reported in the industrial setting. Copper refinery workers develop garlic odor and GI and respiratory symptoms coincident with exposure to selenium dust and fumes.<sup>19</sup> Long before workplace biologic monitoring took place, intense garlic odor of the breath and secretions was recognized as a reason to remove a worker from selenium exposure until the odor subsided. Neuropsychiatric findings such as fatigue, irritability, and depression are reported throughout the industrial literature and are difficult to quantify. Early reports describe the selenium factory worker who “could not stand his children about him” at the end of the day.<sup>16</sup>

Although carcinogenicity is suggested by a number of animal studies, the available human data suggest, if anything, an inverse correlation between selenium intake and cancer risk. The International Agency for Research on Cancer does not list selenium as a known or suspected carcinogen.<sup>4</sup> Animal studies also suggest that selenium has embryotoxic and teratogenic properties.<sup>18</sup> A recent large randomized controlled trial of selenium supplementation reported an increased risk of diabetes mellitus with the ingestion of 200 mcg/d of elemental selenium-fed baker's yeast compared with placebo.<sup>2,25,51</sup>

## DIAGNOSTIC TESTING

Over time, selenium is incorporated into blood and erythrocyte proteins, making serum the best measure of acute toxicity and whole blood preferable for the assessment of patients with chronic exposure. Patients with acute poisoning generally have an initial serum concentration greater than 2 mg/L, which falls below 1 mg/L within 24 hours, reflecting redistribution.<sup>38</sup> Patients with long-term elemental exposures are reported to have serum concentrations of 0.5 to 1.0 mg/L. However, there is no predictable relationship between selenium concentrations and exposure, toxicity, or time course. Population-based studies suggest an average serum concentration of 0.126 mg/L in the United States.<sup>37</sup>

Urine concentrations reflect very recent exposure because urinary excretion of selenium is maximal within the first 4 hours. In addition, urine concentrations are an imperfect measure because they can be affected by the most recent meal and hydration status. However, in general, a normal urinary concentration is less than 0.03 mg/L.<sup>42</sup> Freezing of urine specimens after collection is recommended to retard the enzymatic formation of volatile metabolites.<sup>38</sup>

Hair concentrations of selenium were measured in the Hubei Chinese populations of interest and during the contaminated supplement outbreak in 2008 and may be a useful qualitative measure of chronic exposure.<sup>31,47,55</sup> However, the usefulness of hair selenium is limited in countries such as the United States where the use of selenium sulfide shampoos is widespread.

Other ancillary tests to assess selenium toxicity include ECG, thyroid function, platelet counts, aminotransferases, creatinine, and creatine phosphokinase concentrations. These are abnormal in some patients (eg, patients with selenious acid poisoning) and are not indicated in patients not expected to develop systemic toxicity.

## MANAGEMENT

### Pain

Aside from standard pain management strategies, a number of topical remedies for selenium burns are reported historically with little evidence supporting their use. For example, a 10% sodium thiosulfate solution or ointment to reduce selenium dioxide to elemental selenium is mentioned as a potential therapy for painful skin, nail bed, or ocular burns.<sup>16</sup> In one series, workers exposed to selenium dioxide fumes reported similar relief from inhalation of vapor from ammonium hydroxide-soaked sponges.<sup>54</sup> However, the mechanism and efficacy of these therapies are unproven, and we recommend they not be administered.

For workers exposed to selenium hexafluoride gas, it is reasonable to apply calcium gluconate gel to the affected areas. This is the same treatment as in hydrofluoric acid exposures, which is discussed in Chap. 104.

## Decontamination

As in the case of any toxic exposure, prompt removal from the source is required if possible. Patients with dermal exposure should have their skin irrigated immediately. There are limited data to support the use of aggressive GI decontamination after the ingestion of most elemental selenium-containing xenobiotics because little expected acute toxicity is present. However, in xenobiotics with the potential for producing systemic toxicity, such as the selenite salts, decontamination with orogastric lavage and activated charcoal is reasonable.

Special mention should be made of the ingestion of selenious acid. Given its toxicity, the judicious use of small nasogastric lavage would be reasonable based on the time since ingestion, the amount and concentration ingested, the presence or absence of spontaneous emesis, the likelihood of caustic esophageal injury, and the clinical condition of the patient.

## Chelation and Antidotal Therapy

There are no proven antidotes for selenium toxicity. Animal studies and scant human data suggest that chelation with dimercaprol (BAL), edetate calcium disodium (CaNa<sub>2</sub>EDTA), or succimer is not advised because they form nephrotoxic complexes with selenium, do not speed clinical recovery, and in fact, worsen toxicity.<sup>28,29</sup> Arsenical compounds appear to ameliorate selenium toxicity through enhanced biliary excretion,<sup>11,18,19,28</sup> but in light of their inherent toxicity and unproven efficacy, they are not indicated.

Extracorporeal removal techniques such as hemodialysis or hemofiltration decrease selenium concentrations in patients undergoing the procedure regularly for chronic kidney disease, so theoretically, this could be effective in lowering toxic serum selenium concentrations. However, because of extensive protein binding, this benefit is likely minor and only relevant to patients undergoing frequent dialysis. Nonetheless, although there are only scant reports of hemodialysis in acute selenium poisoning, it would be reasonable in patients with severe toxicity.<sup>24,26</sup>

## Supportive Care

This is the mainstay of therapy in selenium poisoning. In particular, patients with selenious acid toxicity require intensive monitoring and multisystem support to survive.

## SUMMARY

- Selenium is an essential trace element and is required in the diet of both animals and humans.
- Ingestion of selenious acid is often fatal.
- Other selenium compounds cause variable toxicity, usually in the setting of occupational exposure. Topical and inhalational exposure causes burns and pulmonary irritation, respectively. Acute systemic exposure results in gastrointestinal, muscular, and circulatory toxicity.
- Long-term exposure to elemental selenium leads to selenosis, of which alopecia is the most consistent finding.
- Although it is possible to obtain blood, urine, and hair selenium concentrations to confirm exposure, no clear relationship exists between concentration and clinical outcome.
- Supportive therapy remains the standard of care.

# SILVER

Melisa W. Lai-Becker and Michele M. Burns

## Silver (Ag)

Atomic number	=	47
Atomic weight	=	107.9
Normal concentrations		
Serum	<	0.5 mcg/L (<10 nmol/L)
Urine (24-hour)	<	1 mcg/L (<20 nmol/L)

## HISTORY

Although the symbol of silver, Ag, is derived from the Latin and Greek words for silver—*argentum* and *argyros*—the word we use in English is derived from Slavic and Germanic *Silubr* and *Sirebro*, as well as Old English *Seolfor*. The alchemy symbol of silver (a crescent moon) and dalton symbol (a coinlike circumscribed letter S) convey the impression of silver as a valued and precious element.

In Asia Minor and on islands in the Aegean Sea, dumps of slag (scum formed by molten metal surface oxidation) demonstrate that silver was likely separated from lead circa 4000 B.C. The use of silver as a precious metal with trade value appears to have begun around 600 B.C., when weighed pieces of silver were exchanged for goods. Silver coinage debuted circa 550 B.C. in the Mediterranean, and was adopted by various empires, dynasties, and nation-states thereafter. Today, only Mexico uses silver in circulating coinage.

The Phoenicians and early Greeks knew to store water, wine, and vinegar in silver-lined vessels during long sea voyages, just as later American pioneers added silver coins to water barrels and jugs of milk to keep them fresh.<sup>56</sup> The phrase “born with a silver spoon in his mouth” referred originally to health and not wealth, as silver pacifiers and baby spoons were used to help ward off childhood illnesses.

A traded commodity on the world’s markets, silver was used as an abstract financial standard for various economies throughout modern banking history until the late 19th century. Although the United States incorporates silver purely in commemorative and proof coins, the state of Utah passed the “Legal Tender Act of 2011” to allow its residents to use silver and gold coins produced by the US Mint as cash with value based on weight rather than minted face value.<sup>71,85</sup>

Beyond the economic role of silver, the electrical and thermal conductive properties of the element make it an invaluable material for scientific instrument manufacture and engineering. Because silver contacts neither corrode nor overheat, silver is commonly used in electronic devices and appliances. Silver was a key component of early telecommunications—it was the choice for Morse’s first telegraph contacts in 1844—and made the jet age possible, as only silver-plated bearings have the adequate dry lubricity necessary for safe engine shutdown without volatile oil lubricants. Today, washing machines, cars, smartphones, and many types of consumer electronics—from televisions to toaster ovens—use small amounts of silver throughout their mechanical and electronic parts. Silver also remains relevant in advancing technologies of the Information Age. Silver nanoparticles (AgNPs) decorated on graphene layers combined in a pencil-like tool provide the ability to literally draw conducting lines on new portable, foldable, and disposable “paper” circuit boards.<sup>52</sup> Likewise, integrating silver nanowire (AgNW) with conducting films polymerized to cloth is allowing for development of wearable electronics that can maintain thermal, chemical, and mechanical stability.<sup>65,86</sup>

Silver is also used to “make rain”: silver iodide crystals, whose lattice structure is similar to ice, are released into “supercooled” (7°F–25°F) clouds, causing water droplets in clouds to attach and form ice crystals that become

large and heavy enough to drop from the clouds and melt into raindrops en route to earth.

The medicinal value of silver has been greatly exaggerated and is suggested by some to be a “cure-all.” In the late 19th and early 20th century, claims were made that oral administration of colloidal silver proteins (CSPs) (gelatinous suspensions of finely divided elemental silver) would successfully treat diverse diseases, mostly without evidence.<sup>21,81</sup> However, in 1960, the United States Dispensary stated that “there is no justification for this internal use, either theoretically or practically,” and silver was banned in all nonprescription drugs.<sup>19</sup> In 1999, the US Food and Drug Administration (FDA) issued a Final Rule declaring that all nonprescription (over-the-counter {OTC}) drugs containing colloidal silver or silver salts are “not recognized as safe and effective and are misbranded.”<sup>20</sup> However, CSPs and other silver-containing “natural” products were reintroduced for use as health and dietary supplements and as such are not subject to FDA regulation under the Dietary Supplement Health and Education Act of 1994 (DSHEA) as long as they make no claim to treat or prevent any disease.<sup>21</sup> After the anthrax terrorist acts of 2001, the mayor of Tampa, Florida, called for CSPs to be mixed into the town’s water supply as a protective “elixir” without scientific justification.<sup>4</sup> Throughout the late 20th century, companies even tried to market silver acetate—containing products such as lozenges, gums, and sprays for use as smoking-cessation aids due to production of an unpleasant taste when combined with tobacco.<sup>36</sup> Since the turn of the 21st century, there has been a small resurgence of case reports of argyria—a permanent bluish-gray discoloration of the skin from chronic silver overexposure—due to silver-containing products continuing to be marketed and sold online as “natural” health supplements, with few warnings about the possible development of argyria.<sup>24</sup>

## EPIDEMIOLOGY

Humans are exposed to minute amounts of silver in various occupations. Silver is released into the environment during silver nitrate manufacture for use in photography (diminishing), mirrors, plating, inks and dyes, and porcelain; as well as for germicides, antiseptics, caustics, and analytical reagents. Silver-salt catalysts, used for oxidation–reduction and polymerization reactions, are another source of silver exposure, as are silver powder pigments and paints.<sup>43</sup> Workplace exposure is often via transdermal, transmucosal, or inhalational routes as silver particles are liberated during various mining, refining, and manufacturing processes.

Both the National Institute for Occupational Safety and Health (NIOSH) and the Occupational and Safety Health Administration (OSHA) established the safe occupational exposure limit to silver metal and soluble compounds as 10 mcg/m<sup>3</sup> air per 8-hour work shift. The estimated oral intake of silver from average environmental exposure for humans not working in silver-related industries ranges from 10 to 88 mcg/d.<sup>18</sup>

Additionally, industrial exposure of workers involved in silver mining and manufacturing increases the workplace risk of generalized argyria, although development of signs of argyria from uninterrupted occupational exposure reportedly takes up to 24 years.<sup>14</sup> Employees are susceptible to localized argyria and corneal argyrosis (permanent ashen-gray discoloration of the conjunctiva) following repeated topical exposure from working with smaller amounts of silver in specific applications. These localized forms of argyria occur in workers who coat metallic films on glass and china, manufacture electroplating and photographic processing solutions, prepare artificial pearls, and even those who simply primarily cut and polish silver.

## PHARMACOLOGY

Following absorption, silver is transported by globulins in blood and stored mainly in skin and liver, with average daily excretion via bile and elimination in the feces (up to 30–80 mcg/day), with a smaller amount excreted in the urine (up to 10 mcg/day).<sup>19</sup> Silver elimination through the feces occurs in 2 phases: the initial phase has a relatively short  $t_{1/2}$  ranging from 1 to 2.4 days, varying with route of administration (apparent  $t_{1/2}$  is: oral, 1 day; inhalational, 1.7 days; and intravenous, 2.4 days),<sup>19,22,54</sup> and second has an elimination  $t_{1/2}$  of 48 to 52 days, which is thought to represent liver deposition and clearance.<sup>47,55</sup>

Although study of a single human showed 18% of an orally administered silver acetate salt was retained after 30 weeks, animal studies show little silver absorption from gastrointestinal (GI) tract, with 90% of ingested silver excreted within 2 days of ingestion.<sup>18</sup> Humans retain only 0% to 10% of their daily silver exposure of 10 to 88 mcg/day.<sup>83</sup> Minute amounts of silver accumulate in humans throughout life, with a possible estimated lifetime accumulation of 230 to 480 mg by 50 years of age.<sup>18</sup> Silver has a  $1^+$ ( $Ag^+$ ) valence when bonding with other elements and compounds to form complex ions and salts. Because of the antimicrobial effects of silver cations at low concentrations,<sup>70</sup> silver is used for potential medicinal and bactericidal effects.

The antimicrobial activity of silver is related to both direct binding to biologic molecules and disruption of hydrogen ions and, thus, pH balance. Silver ions bind to electron donor groups of proteins (sulfhydryl, amine, carboxyl, phosphate, and imidazole) to inhibit enzymatic activities and provoke protein denaturation and precipitation.<sup>21</sup> Silver also intercalates with DNA without destroying the double helix, thereby inhibiting fungal DNase.<sup>19a</sup> Silver ions induce proton leakage through a bacterial (*Vibrio cholerae*) membrane, leading to loss of the proton motor force in oxidative phosphorylation, with subsequent energy loss and cell death.<sup>13</sup> Bacterial resistance to silver was not reported until the mid-1970s, followed shortly thereafter by the identification of the genes for silver resistance in bacteria.<sup>70</sup>

Although banned from routine administration via intravenous, intramuscular, and oral routes in the United States, silver salts are approved for use in topical medications, either as a caustic styptic (hemostatic) or as an antimicrobial for burn care. Approved medicinal uses for silver in the United States apply only to silver salts and specifically preclude use of elemental silver (Table 98–1).

Today silver is used in water filtration cartridges and supermarket products for washing vegetables. It is also used as a low cost nonfiltration point-of-use-water-treatment (PoUWT) technology by embedding silver in ceramic tablets that can be placed in a water storage container to release low steady concentrations of disinfecting silver ions.<sup>16</sup> Incorporation of silver is also used as a means of preventing biofilm formation in dental unit water lines.<sup>27</sup> Silver was also used to sterilize recycled drinking water on the Russian MIR space station and NASA space shuttle.<sup>70</sup> Silver dressings used on burns speed healing and reduce scarring,<sup>46</sup> perhaps because of hormesis of epithelial cells;<sup>72</sup> and silver sulfadiazine added to burn dressings is bacteriocidal and increases the rate of reepithelialization across partial-thickness wounds.<sup>12</sup> However, more recent animal model research demonstrates that these findings may not be applicable to nonburn excisional wounds.<sup>57</sup>

Central venous catheters impregnated with silver sulfadiazine and silver-impregnated Foley catheters are used to lower rates of infection.<sup>29,48</sup> For example, extraventricular drains (EVDs) impregnated with silver have had half the CSF infection risk as plain catheters.<sup>35</sup> Also, silver-lined endotracheal tubes reduce the risk of ventilator-assisted pneumonia (VAP) by up to 51%, including specifically drug-resistant pathogens such as methicillin-resistant *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Acinetobacter baumannii*.<sup>66</sup>

Multiple new antibacterial applications are under investigation, ranging from applying a silver-containing coating to prevent biofilm formation on titanium orthopedic implants, to the use of silver to treat osteomyelitis.<sup>42,74</sup> Additionally, in the realm of oral and dental health, silver nanoparticles eliminate *Enterococcus faecalis* following root canal surgery and are effective

TABLE 98–1 Medicinal Silver Containing Products

Product Name/Device	Route of Administration/ Exposure	Applications
Silver nitrate (1% $AgNO_3$ )	Ophthalmic	Prevention of gonorrheal ophthalmia neonatorum.
Silver nitrate (10% $AgNO_3$ )	Cutaneous	Chemical cautery of nasal mucosa and exuberant granulations (eg, in podiatry for corns, calluses, impetigo vulgaris, plantar warts, and papillomatous growths).
Silver sulfadiazine (0.2% or 1% micronized silver sulfadiazine)	Cutaneous	Antimicrobial adjunct for prevention and treatment of wound infection for patients with second- and third-degree burns.
Silver-impregnated catheters and tubes	Nanoparticle coating	Antimicrobial adjunct for use in catheters (Foley catheters, central venous catheters, extra ventricular drains, and endotracheal tubes).
Silver acetate	Mucocutaneous (oral)	Used in gum, sprays, and lozenges as smoking cessation adjunct. Silver combined with smoke creates an unpleasant metallic taste in the user's mouth. <sup>36</sup>

in preventing dental caries in children when infused as pit and fissure sealants.<sup>2,61</sup> However, in spite of the disinfectant characteristics of silver, concerns persist with regard to the long-term toxicity of silver.<sup>10,78</sup>

## PATHOPHYSIOLOGY

In great enough quantities, silver manifests cardiovascular, hepatic, and hematopoietic toxicity. Acutely, administration of 50 mg or more of particulate metallic (colloidal) silver intravenously in humans is fatal, leading to pulmonary edema, acute respiratory distress syndrome (ARDS), hemorrhage, and necrosis of bone marrow, liver, and kidneys.<sup>19</sup> The mechanism for this acute toxicity was studied only in the water flea (*Daphnia magna*) where silver blocks  $Na^+, K^+$ -ATPase activity.<sup>6</sup> A summary of silver toxicity manifested in animals and humans is described in Table 98–2.

Silver is not classified with regard to human carcinogenicity. It has not been found to be mutagenic, and no current data link therapeutic use of silver to human cancer.<sup>18</sup> Although animal studies show that silver implanted subcutaneously leads to local sarcoma formation, the EPA has deemed this reaction questionable with regard to human carcinogenicity, as implantation of other insoluble solids—such as plastic and smooth ivory—in animals produces similar results.<sup>18</sup> Colloidal silver injected into rats induces growths at injection sites, but intramuscular injections of silver powder have not induced cancer.<sup>23</sup>

Local inflammatory responses notwithstanding, silver is considered an inert substance and not a human carcinogen. In fact, silver nanoparticles (AgNPs) (Chap. 125) are increasingly being shown to possess antitumor properties through inhibition of transcription factors that promote cancer cell growth and angiogenesis.<sup>11</sup> Continued research of the antimicrobial properties of silver has led to further inquiry into its apparent specific cytotoxicity against ovarian cancer cells<sup>3</sup> and ovarian cancer stem cells<sup>84</sup> as well as a chemotherapeutic adjunct by providing a delivery scaffold for chemotherapeutics.<sup>38</sup> As a result of these new insights into AgNP cytotoxicity, more research is being conducted to assess the effects of silver nanoparticles on reproductive toxicity<sup>17,33,39</sup> and the formation of neural tube defects.

TABLE 98–2 Silver Toxicity: Systemic Manifestations	
Cardiovascular	Rats given 0.1% silver nitrate in drinking water for 218 days developed ventricular hypertrophy that was not attributable to silver deposition in the heart despite advanced pigmentation in other body organs. <sup>51</sup>
Dermatologic	Generalized argyria, localized argyria, and argyrosis (silver deposition in the eyes) developed after chronic administration of silver.
Hematologic	Topical application of silver (human) correlated with bone marrow depression with subsequent leukopenia or aplastic anemia. <sup>9</sup>
Hepatic	Vitamin E and selenium-deficient rats developed hepatic necrosis with ultrastructural changes after administration of silver salts. <sup>9,13,77</sup> Silver can induce selenium deficiency that consequently inhibits synthesis of the selenoenzyme glutathione peroxidase.
Neurologic	Silver deposits in peripheral nerves, basal membranes, macrophages, and elastic fibers were found in one reported case of a 55-year-old woman with progressive vertigo, cutaneous hypoesthesia, and weakness after self-administration of silver salts to treat oral mycosis for 9 years. <sup>80</sup> Seizures were reported in a schizophrenic patient who ingested >20 mg silver daily for 40 years. Serum silver concentrations were elevated (12 mcg/L). Seizures resolved concurrently with discontinuation of silver ingestion and a subsequent decrease in silver serum concentration. <sup>50</sup>
Renal	Tubular lesions are demonstrated in animals, and acute tubular necrosis is rarely reported in humans. <sup>44</sup>

In vitro, silver nanoparticles are effective in inhibiting islet amyloid polypeptide (IAPP) aggregation associated with type 2 diabetes, perhaps opening a promising new application for nanotechnologies aimed at mitigating such an amyloid-mediated pathology.<sup>79</sup> However, although this IAPP inhibition may be extrapolated to other amyloid-mediated diseases like Alzheimer dementia in vitro,<sup>33</sup> in vivo exposure in murine models has instead demonstrated potential neurodegenerative progression.<sup>40</sup>

### Argyria

The most significant effect of silver overexposure in humans is argyria, a permanent bluish-gray discoloration of skin resulting from silver throughout the integument (Figs. 98–1 and 98–2).

**FIGURE 98–1.** Argyria, the slate or silver discoloration of the skin that results from silver overexposure is demonstrated in this image of Rosemary Jacobs, who developed the condition after use of colloidal silver nasal drops for 3 years as a teenager. (Used with permission from Rosemary Jacobs. We thank Ms. Rosemary Jacobs for her support and her permission to use the featured photographs.)

**FIGURE 98–2.** Long-term exposure to  $\text{AgNO}_3$  in the workplace led to this patient's characteristic pigment changes of argyria. A normally pigmented arm is across the patient's chest. (Used with permission from the New York University Department of Dermatology.)

Generalized argyria develops in stages, beginning with an initial gray-brown staining of gingiva, progressing to hyperpigmentation and bluish-gray discoloration in sun-exposed areas. Later, nail beds, sclerae and mucous membranes become hyperpigmented; on autopsy, viscera are noted to be blue.

Cases of argyria have been reported in the medical literature since at least the early 19th century. One of the most famous cases of argyria is that of the Barnum and Bailey Circus' "Blue Man" who died at New York's Bellevue hospital in 1923 and was described on autopsy as follows: "The color of the skin was of an unusually deep blue and from a distance appeared almost black. This deep color was almost uniform throughout the entire body, although it was more intense over the exposed skin areas."<sup>26</sup> An American woman who developed argyria as a teenager during the 1950s from the use of a nasal CSP for allergies described her story on the Internet to warn others of the effects of prolonged contact with, or ingestion of, silver salts.<sup>31</sup> Her appearance was documented as an Image in Clinical Medicine in the *New England Journal of Medicine*.<sup>8</sup> In 2002, libertarian party Montana legislator Stan Jones became known as the "blue" lawmaker who promoted the use of colloidal silver health supplements and developed argyria after manufacturing his own colloidal silver at home out of fears that the Y2K (year 2000) problem might cause a shortage of antibiotics.<sup>5,59</sup>

Generalized argyria can result from either simple mechanical impregnation of skin by silver particles or inhalational and oral absorption of particulate silver. Local routes of silver absorption are through the conjunctiva or oral mucous membranes after long-term topical treatment with silver salts.

Argyria occurs at doses much lower than those associated with acutely toxic effects of silver; the degree of discoloration is directly proportional to the amount of silver absorbed or ingested.<sup>25</sup> The threshold dose for silver accumulation and retention resulting in generalized argyria varies considerably. Discoloration is reported from as little as a cumulative 1 g of metallic silver administered intravenously (from 4 g of silver arspenamine used to

treat syphilis over a 2-year period in the early 1900s), whereas others tolerated infusions containing up to 5 g of elemental silver over 9 months before clinical change was noted.<sup>25</sup>

In 2002, a 42-year-old European man developed argyria after just 4 years of weekly application of a topical nasal vasoconstrictor (Coldargan, manufactured by Siegfried, Sweden) available in Austria. The patient used this product to treat his rhinitis medicamentosa (rebound nasal congestion brought on by extended use of topical decongestants); each drop of medication contained 0.85 mg silver protein—considerably more than expected in chronic occupational exposure.<sup>75</sup> More directly, colloidal silver protein ingestion for “health supplementation” leads to body burdens of silver that can produce argyria. In 1933, argyria was reported in a 33-year-old woman who ingested 48 mg/day of elemental silver (from silver nitrate capsules) during alternating 2-week periods (2 weeks on—2 weeks off) over 1 year to treat chronic gastrointestinal symptoms.<sup>7</sup> Her serum silver concentrations remained at 500 mcg/L for 3 months after discontinuation of the capsules, indicating significant silver deposition in tissues.

Mechanical impregnation of silver produces localized argyria following repeated contact with metallic silver or silver salts.<sup>34</sup> Localized argyria is reported from both implanted acupuncture needles and short-contact acupuncture, when particle deposition occurs from silver needles used repeatedly during brief therapeutic sessions.<sup>37</sup> Silver sulfadiazine use produces localized argyria in and around wound scars.<sup>22,78</sup> Localized argyria of the tongue and gingiva is described in patients with silver dental amalgams.<sup>32,60</sup> Some of these patients also have elevated tissue concentrations of silver, but there are no known cases of significant absorption resulting in generalized argyria.<sup>15</sup> Even long-standing wearing of silver earrings has resulted in local contact argyria.<sup>45,73,76</sup> Corneal argyrosis was frequently reported from prolonged use of colloidal silver disinfectant eyedrops, but as these drops are no longer used, the condition has become an occupational disease caused by both inadequate eye personal protection and worker self-contamination of their eyes with hands contaminated by silver particles.<sup>62,64,87</sup>

### Histopathology of Argyria

There are no inflammatory reactions noted because of silver deposition or impregnation. Rather, the skin discoloration of argyria comes from the silver itself and from the induction of increased melanin production. Silver granules are initially found within fibroblasts and macrophages, then extracellularly along the basement membrane of blood vessels, sweat glands, dermoepidermal junction, and beside erector pili muscles (Chap. 17). Patients with argyria commonly manifest increased pigmentation over sun-exposed skin. Although the mechanism for this process is not yet fully understood, it is proposed that silver-complexed proteins are reduced to their elemental form via photoactivation from sunlight, similar to photographic image development. Silver and light then further stimulate melanogenesis, increasing melanin in light-exposed areas and enhancing this cycle.

Evidence demonstrates how silver is deposited in the skin. Ingested silver nanoparticles dissolve in the acidic environment of the stomach, forming silver ions that are transported by glutathione and other biomolecules to the dermis. These ions are reduced by sunlight and sulfur. Subsequently, selenium ions align or collocate alongside silver atoms creating blue discoloration.<sup>41</sup> Skin biopsy can confirm the diagnosis of argyria, showing brown-black clusters of silver granules in the dermis.

### Diagnostic Testing

Urine and serum concentrations of silver are measured as indices of silver exposure. Hair is also tested for silver, but airborne silver particles bind to hair and contaminate samples, potentially invalidating the results.

In individuals without a history of medicinal silver ingestion or occupational exposure, the normal serum silver concentration is less than or equal to 0.5 nmol/L, normal urinary silver concentration is less than or equal to 21 nmol/L and normal fecal silver concentration less than or equal to 1.5 mcg/g.<sup>14</sup> These values are in contrast to workers who smelt and refine

silver and who prepare silver salts for use in the photographic industry, who have mean serum concentrations measured of 234 nmol/L, urine silver concentrations of less than 0.005 mcg/g, and fecal silver concentrations of 15 mcg/g.<sup>14</sup>

### Treatment of Argyria

Chelators are ineffective in treating both silver toxicity and argyria.<sup>19</sup> Dermatologic conventional wisdom has suggested that topical hydroquinone 5% reduces the number of silver granules in the dermis and around sweat glands, as well as diminishes the number of melanocytes.<sup>9</sup> Sunscreens and opaque cosmetics prevent further pigmentation darkening from sun exposure. Successful treatment of argyria using laser technology is also reported and appears promising with one case report of a full cure.<sup>28,58</sup>

As oxidant deficiencies enhance silver toxicity, antioxidants, such as selenium and vitamin E, limit the effects of silver exposure. Selenium-dependent glutathione peroxidase synthesis is diminished when silver binds to selenium and thus reduces intracellular selenium.<sup>9,77</sup> Supplemental vitamin E and selenium increase tolerance for silver in rats and chickens.<sup>10</sup>

Selenium has been considered a potentially effective treatment for argyria. Although collocation of selenium with silver nanoparticles promotes argyria, paradoxically it to precipitates or chelates silver by forming silver selenide complexes. Furthermore, silver selenide is insoluble in vivo and should reduce the availability of monovalent silver to interfere with normal enzymatic activities.<sup>1,49,63</sup> Hence, increased selenium intake is theorized to bind silver for excretion rather than skin deposition. Similarly, sulfur has been investigated for effects comparable to those of selenium, although the silver—sulfur complex is not as stable.<sup>63</sup> At this time, there are no recommendations for dosages or duration of treatment with vitamin E, selenium or sulfur for reversing argyria.

### EMERGENCY MANAGEMENT

Although systemic toxicity of silver is predominantly a result of chronic exposure, clinicians rarely encounter a patient who has ingested a colloidal silver product, a silver-containing medicinal product, or a silver salt. Emergency management should take into consideration the type of silver ingested.

Cutaneous burns from silver salt cautery should be managed as thermal burns; ingested cautery should be treated as a caustic. Patients who ingest elemental silver should be managed supportively, as elemental silver should pass through the GI tract unchanged. Silver salt ingestion (such as silver nitrate) should be treated as a caustic ingestion (Chap. 103). There is no evidence to support gastric lavage or administration of activated charcoal as a decontamination method, so neither of these decontamination methods is recommended.

### SUMMARY

- Silver toxicity—primarily argyria and burns—is still occasionally encountered.<sup>30,74,81,82</sup> The workplace environment and health and nutritional supplements are the main sources of exposure.
- Despite frequent therapeutic use of elemental silver and silver salts, there is no evidence of silver mutagenicity or carcinogenicity in humans.
- Significant toxicity is very rare, although when argyria results from chronic silver use, it is invariably permanent.
- There are no proven effective means for removing accumulated silver and reversing argyria.

# THALLIUM

Maria Mercurio-Zappala and Robert S. Hoffman

<b>Thallium (Tl)</b>	
Atomic number	= 81
Atomic weight	= 204.37 Da
Normal concentrations	
Whole blood	< 2 mcg/L (9.78 nmol/L)
Urine (24 hour)	< 5 mcg/L (24.5 nmol/L)

## HISTORY AND EPIDEMIOLOGY

Thallium ( $Tl^0$ ), a metal with atomic number 81, is located between mercury and lead on the periodic table. Elemental thallium is a soft, pliable metal that melts at 572°F (300°C), boils at 2699.6°F (1,482°C), and is essentially nontoxic. Thallium forms univalent thallos ( $Tl^+$ ) and trivalent thallic ( $Tl^{3+}$ ) salts, which are highly toxic. Thallium is a commonly found constituent of granite, shale, volcanic rock, and pyrites used to make sulfuric acid and is also recovered as flue dust from iron, lead, cadmium, and copper smelters.<sup>28</sup>

In the early 1900s, thallium salts were used medicinally to treat syphilis, gonorrhea, tuberculosis, and as a depilatory for ringworm of the scalp.<sup>7,73</sup> Although the usual oral dose given for ringworm was 7 to 8 mg/kg, fatal doses ranged from 6 to 40 mg/kg.<sup>16,62</sup> Many cases of severe thallium poisoning (thallotoxicosis) resulted from this treatment, with one author summarizing nearly 700 cases and 46 deaths.<sup>75</sup>

Because thallium sulfate is odorless, tasteless, and highly toxic it became commercially available as a rodenticide and was sold as Thalgrain, Echol's Roach Powder, Mo-Go, Martin's Rat Stop liquid, and Senco Corn Mix. As a consequence of numerous case reports of unintentional poisonings,<sup>75,87</sup> the use of thallium salts as a household rodenticide was restricted in the United States in 1965. Ultimately, even the commercial use of thallium salts as a rodenticide was banned in the United States in 1972 because of continued reports of human toxicity.

Life-threatening unintentional poisoning continues to occur in other countries, especially where thallium salts are still commonly used as rodenticides.<sup>2,15,58,85,89,94,104,113</sup> Additional cases of thallium poisoning are reported in the United States and other countries as a result of the use of thallium for suicide,<sup>101</sup> homicide,<sup>23,57,66,71,79,81,91,100</sup> through contamination of herbal products,<sup>18,97</sup> and illicit drugs such as heroin, opium,<sup>1,34,84</sup> and cocaine.<sup>48</sup> Although occupational exposures to consequential amounts of thallium salts are uncommon, occupational toxicity is well described.<sup>42</sup> Additionally, although small amounts of thallium salts (<1 mcg) are used as radioactive contrast to image tumors and to permit the visualization of cardiac function, the doses used are insignificant and pose no risk for thallium toxicity.<sup>73</sup>

The following discussion of thallium toxicity is based on exposures to inorganic thallium salts, which represents virtually the entire literature on thallium poisoning. Although exceedingly rare, exposures to organic thallium compounds are reported<sup>4</sup> and should be assessed and managed in a fashion similar to that used for patients with inorganic exposures.

## TOXICOKINETICS

Exposures usually occur via one of 3 routes: inhalation, ingestion, and absorption through intact skin. Thallium is rapidly absorbed following all routes of exposure. Bioavailability is greatest after ingestion and exceeds 90%.<sup>44</sup> Distribution follows 3-compartment toxicokinetics (Chap. 9),<sup>86</sup> achieving a final volume of distribution that is estimated to be about 3.6 L/kg.<sup>21</sup> Thallium toxicity is manifested in virtually all organs; however, it is distributed unevenly, with the highest concentrations found in the large and small intestine, liver,

kidney, heart, brain, and muscle.<sup>8,56</sup> In animals, the highest concentrations of thallium are found in the kidney.<sup>3,56</sup>

The toxicokinetics of thallium is described in the following 3-phase model. The first phase occurs within 4 hours after oral exposure, during which time thallium is distributed to the central compartment and to well-perfused peripheral organs such as the kidney, liver, and muscle. In the second phase, which lasts between 4 and 48 hours, thallium is distributed into the central nervous system (CNS).<sup>86</sup> Whereas some literature suggests that this distribution phase is generally completed within 24 hours of ingestion,<sup>86</sup> one human case suggests slower distribution into the CNS as evidenced by increasing cerebrospinal fluid (CSF) concentrations in the days after exposure when blood concentrations were declining, which likely excludes ongoing absorption.<sup>100</sup> The third or elimination phase usually begins within 24 hours after ingestion. The primary mechanism of thallium elimination is secretion into the intestine, but enteral reabsorption of thallium that is present in the bile subsequently reduces the fecal elimination.<sup>21,71</sup> Thallium is excreted primarily via the feces (51.4%) and the urine (26.4%).<sup>61</sup> It is filtered by the glomerulus, with approximately 50% being reabsorbed in the tubules. Thallium is also secreted into the tubular lumen in a manner similar to potassium.<sup>7</sup> The duration of the elimination phase depends on the route of exposure, dose, and treatment. Unlike many other metals, thallium does not have a major anatomic reservoir. For this reason, reported elimination half-lives are as short as 1.7 days in humans with thallium poisoning.<sup>46</sup>

## PATHOPHYSIOLOGY

The mechanism of thallium toxicity is not well established. Thallium behaves biologically in a manner similar to potassium because both have similar ionic radii (1.47 Å for thallium and 1.33 Å for potassium). Because cell membranes cannot differentiate between thallos ( $Tl^+$ ) and potassium ( $K^+$ ) ions, thallos ions accumulate in areas with high potassium concentrations, such as the central and peripheral nervous system, liver, and muscle.<sup>67,113</sup> This accumulation is the fundamental principle that governs the use of radioactive thallium in cardiac imaging studies. Thallium replaces potassium in the activation of potassium-dependent enzymes.<sup>67</sup> In low concentrations, thallium stimulates these enzyme systems, but in high concentrations, inhibition occurs.<sup>9,69</sup> Pyruvate kinase, a magnesium-dependent glycolytic enzyme that requires potassium to achieve maximum activity, has 50 times greater affinity for thallos ions than potassium ions.<sup>52</sup> Succinate dehydrogenase, a citric acid cycle enzyme, is inhibited by small doses of thallium in rats.<sup>41</sup> Sodium-potassium adenosine triphosphatase ( $Na^+,K^+$ -ATPase), which is responsible for active transport of monovalent ions across cell membranes, can use thallos ions at extremely low concentrations because of an affinity that is 10-fold greater than that for potassium, ions,<sup>10,33</sup> but is inhibited by thallium at higher concentrations.<sup>49</sup>

Thallium also impairs depolarization of muscle fibers.<sup>73</sup> Mitochondrial energy is decreased as a result of the inhibition of pyruvate kinase and succinate dehydrogenase, resulting in a decrease of adenosine triphosphate (ATP) generation via oxidative phosphorylation. Oxidative stress results in opening of the mitochondrial permeability transition pore.<sup>27</sup> This results in swelling and vacuolization of the mitochondria.<sup>57,102</sup> At low concentrations, thallium activates other potassium-dependent enzymes such as phosphatase, homoserine dehydrogenase, vitamin B<sub>12</sub>-dependent diol dehydrogenase, L-threonine dehydrogenase, and adenosine monophosphate (AMP) deaminase.<sup>73</sup> The net result of these processes is a failure of energy production. In the central nervous system, there is evidence that damage is also caused by activation of

glutamatergic transmission by the *N*-methyl-D-aspartate (NMDA) receptor, because as an antagonist, dizocilpine (MK-801), limits injury in rats by preventing this transmission.<sup>78</sup>

Thallos ions are used to isolate riboflavin from milk in the form of a reversible precipitate. Thallos ions may also form insoluble complexes and cause intracellular sequestration of riboflavin *in vivo*.<sup>14</sup> Riboflavin is the vitamin precursor of the flavin coenzyme flavin adenine dinucleotide (FAD). Because of a decrease in riboflavin, metabolic reactions dependent on flavoproteins decrease, causing disruption of the electron transport chain and a subsequent further decrease or impairment in the generation of cellular energy.<sup>14</sup> This decrease in cellular energy may lead to a decrease in mitotic activity and cessation of hair follicle formation, resulting in the clinical sign of alopecia. Subsequent hair loss is the result of combined arrested formation and local destruction of hair shaft cells in the hair bulb and is known as anagen effluvium (Chap. 17).<sup>12,14,18,87</sup> Unfortunately, riboflavin supplementation was not beneficial in one animal model of thallium poisoning.<sup>6</sup> Data also demonstrate that the dermatologic, neurologic, and cardiovascular effects of thallium toxicity mirror the manifestations of thiamine deficiency (beriberi), highlighting the inhibitory effect of thallium on glycolytic enzymes.<sup>14,73</sup> It is unclear whether thiamine administration has any beneficial effect in patients with thallium poisoning.

Thallium has a high affinity for the sulfhydryl groups present in many other enzymes and proteins. Keratin, a structural protein, consists of many cysteine residues that crosslink and form disulfide bonds. These disulfide bonds add strength to keratin. Thallium interferes with the formation of disulfide bonds, which likely contributes to the development of alopecia and defects in nail growth, resulting in Mees lines (Fig. 86–4).<sup>37,73,79,93,94</sup> Additionally, the complexation of sulfhydryl groups with thallium results in a decrease in both the production of glutathione and the reduction of oxidized glutathione.<sup>39,114</sup> This results in oxidative damage<sup>31</sup> and the accumulation of lipid peroxides in the brain (which is most prominent in the cerebellum) and appears as dark, pigmented areas.<sup>40</sup> The complexity and presumable multifactorial nature of thallium poisoning are further demonstrated by the inability of *N*-acetylcysteine (NAC)—induced augmentation of glutathione stores to protect against toxicity in an animal model.<sup>6</sup>

Thallium also adversely affects protein synthesis in animals by damaging ribosomes, particularly the 60S subunit.<sup>47</sup> Although ribosomes are primarily dependent on potassium and magnesium, thallium is substituted if present. In an experimental model, low concentrations of thallium are protective against hypokalemia-induced ribosomal inactivation. As thallium concentrations increase, the protective effects diminish, resulting in progressive destabilization and destruction of the ribosomes.

Pathologic studies of the CNS in patients with thallium poisoning reveal localized areas of edema in the cerebrum and brain stem. Chromatolytic changes are prominent in neurons of the motor cortex, third nerve nuclei, substantia nigra, and pyramidal cells of the globus pallidus. In chronic exposures, there are signs of edema of the pial and arachnoid membranes and chromatolysis, swelling, and fatty degeneration in the ganglion cells of the ventral and dorsal horns of the spinal cord.<sup>8,87</sup>

The peripheral nervous system, which is usually clinically affected before the CNS, develops a diffuse axonopathy in a classic dying back or Wallerian degeneration pattern (Chap. 22).<sup>7,8,19,25,68</sup> Fragmentation and degeneration of associated myelin sheaths are accompanied by activation of Schwann cells.<sup>8,13,14</sup> Because thallium affects the longer peripheral fibers—first sensory, then motor, and finally the shorter fibers—toxic effects occur initially in the lower extremities.<sup>60,77,120</sup>

## CLINICAL MANIFESTATIONS

Many of the effects of thallium poisoning are nonspecific and occur throughout the acute and chronic phases of an exposure.<sup>59</sup> When combined, however, a clear toxic syndrome is defined (Table 99–1). Alopecia and a painful ascending peripheral neuropathy are the most characteristic findings.<sup>7,30,71,77</sup> Because of the delayed development of alopecia, the diagnosis of thallos toxicosis is often delayed. In fact, with acute exposures, a dose-dependent latent period of hours to days may precede initial symptoms.<sup>59,73</sup> When death

occurs, it is usually the result of coma with loss of airway protective reflexes, respiratory paralysis, and cardiac arrest.

Unlike most other metal salt poisonings, diarrhea is often modest or even absent following thallium exposure.<sup>16</sup> The most common symptom is abdominal pain, which is often accompanied by vomiting and either diarrhea or constipation.<sup>23,54,59,69,93,115,116</sup> Constipation is presumed to be a result of decreased intestinal motility and peristalsis caused by direct involvement of the vagus nerve.<sup>16,73</sup> Rarely, severe manifestations occur, such as hematemesis, bloody diarrhea, or ulceration of the mucosal lining.

Pleuritic chest pain was described in a small series of poisoned patients.<sup>66</sup> Another patient was reported to have developed chest tightness shortly after drinking thallium-poisoned tea.<sup>71</sup> Although the etiology for this finding is uncertain, a more recent case report describing the development of pleural and pericardial effusions in an otherwise healthy young man with a suicidal ingestion of thallium monobromide may shed light on one possible etiology of this symptom.<sup>101</sup>

Tachycardia and hypertension frequently occur in patients with thallos toxicosis and usually develop during the first or second week after acute ingestion. A persistent and pronounced tachycardia is associated with a poor prognosis. No exact mechanism has been determined for these cardiovascular effects of thallium toxicity. Some authors theorize that they result from autonomic neuropathic dysfunction directly related to involvement of the vagus nerve,<sup>77</sup> but others have noted early electrocardiographic (ECG) changes, such as prolongation of the QT interval, T wave flattening or inversion, and nonspecific ST segment abnormalities, which might suggest direct myocardial injury.<sup>8,13,69,73,90</sup> Another theory suggests that the direct stimulation of ATPase in the chromaffin cells by thallium leads to increased output of catecholamines, resulting in sinus tachycardia.<sup>5,71</sup>

Neurologic effects usually appear 2 to 5 days after exposure. Patients develop severely painful, rapidly progressive, ascending peripheral neuropathies.<sup>7,8,25,66</sup> Pain and paresthesias are present in the lower extremities (especially the soles of the feet), and although numbness is present in the fingers and toes, there is also decreased sensation to pinprick, touch, temperature, vibration, and proprioception.<sup>7,97</sup> The weight of bedsheets on the lower extremities is sometimes sufficient to cause excruciating pain.<sup>66</sup> Motor weakness is always distal in distribution, with the lower limbs more affected than the upper limbs.<sup>13,73</sup>

Confusion, delirium, psychosis, hallucinations, seizures, headache, insomnia, anxiety, tremor, ataxia, and choreoathetosis are common. The onset of these clinical findings is variable and most likely dependent on dose. Insomnia occurs in most patients and progresses to total reversal of sleep rhythms. Coma occurs following large exposures.<sup>13,59,73,93</sup> All cranial nerves can probably be affected by thallium, although abnormalities of cranial nerves I, V, and VIII have not been reported. Cranial nerve III involvement, as evidenced by ptosis, is common and may be asymmetric.<sup>13</sup> Nystagmus, another common finding, demonstrates involvement of cranial nerves IV and VI.<sup>13</sup> Cognitive abnormalities often persist for months after exposure.<sup>64</sup>

Thallium is toxic to both the retinal fibers and the neural retina.<sup>98</sup> In cases of a large, single ingestion of thallium, approximately 25% of patients develop severe lesions of the optic nerve.<sup>73,93</sup> Optic neuropathy can progress to optic atrophy and a permanent decrease in visual acuity. In the early stages, the optic disk shows signs of neuritis, which is red and poorly defined, and later develops pallor from resultant optic nerve atrophy. In patients exposed to multiple small doses, nearly 100% suffer optic nerve injury.<sup>69</sup> Visual complaints are often significantly delayed in comparison to other neurologic findings,<sup>98</sup> typically include decreased acuity and central scotomata, and sometimes are not noted until after recovery from coma. Other described ophthalmic effects are noninflammatory keratitis, cataracts, and the color vision defect of tritanomaly (blue color defect).<sup>106,107</sup>

Kidney function remains normal in mild cases of thallium poisoning, even though the kidney has greater bioaccumulation than any other organ. Proteinuria is often the earliest or only finding of kidney injury. Changes in kidney function in patients with severe thallos toxicosis include oliguria, diminished creatinine clearance, elevated blood urea nitrogen,

TABLE 99-1 Clinical Manifestations of Thallium Poisoning

Organ System	Onset of Effects			
	Immediate (<6 hours)	Intermediate (Rarely in the first few days; within 2 weeks)	Late (>2 weeks)	Residual Effects‡

† = Typical onset of clinical effects. The predicted time course is often accelerated with extremely large doses. When † appears in 2 adjacent columns, the time course is highly variable and likely dose dependent. With small ingestions, many of the effects listed above are evident. ‡ = Effects that persist long after exposure, possibly permanently.

and proteinuria.<sup>5,66,69,73</sup> These findings correlate with morphologic studies in thallium poisoned rats, demonstrating abnormalities in the renal medulla, mainly in the thick ascending limb of the loop of Henle, that occur by the second day after exposure and resolve by the 10th day.<sup>5</sup>

Alopecia is the most characteristic manifestation of thallium toxicity.<sup>71,110</sup> In patients with chronic exposure, hair loss is often the first recognizable symptom and typically is present at approximately 10 days and is maximal within 1 month.<sup>30,71,75</sup> With acute or massive exposure, hair loss can occur earlier. Facial and axillary hair, especially the inner third of the eyebrows, is often spared, but in some cases, full beards, as well as all scalp hair, are lost.<sup>87</sup> Microscopic inspection of the hair reveals a diagnostic pattern of black pigmentation of the hair roots of the scalp in approximately 95% of poisoned patients,<sup>11,18,71,93,110</sup> which can be found within 3 to 5 days of initial exposure<sup>11,69</sup> (Fig. 99-1). In patients with recurrent exposures, several bands are noted on the hair shaft, demonstrating multiple exposures. Initial hair regrowth is very fine and unpigmented but usually returns to normal after mild exposures.<sup>69</sup> In some patients with severe exposures, alopecia is permanent. Other dermatologic effects that are observed include acne, palmar erythema, and dry scaly skin that results from sebaceous gland damage.<sup>110</sup> Mees lines appear within 2 to 4 weeks after exposure<sup>71,79,93</sup> (Fig. 86-4).

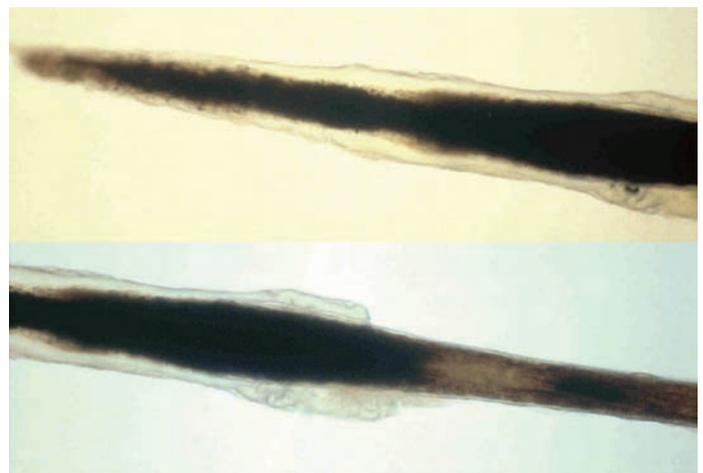

FIGURE 99-1. Hair from a patient with severe thallium poisoning (top) compared to a normal (bottom). Note the dark pigmented granules around the root of the poisoned patient. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

Other less common findings include hepatotoxicity,<sup>48</sup> hyperchloremic metabolic acidosis,<sup>93</sup> anemia, and thrombocytopenia.<sup>60,93</sup>

### Teratogenicity

In animal models, thallium is teratogenic.<sup>36,38</sup> In humans, one study evaluated 297 children born in a region in which the population's urine thallium concentrations were higher than normal because of industrial contamination of their environment.<sup>24</sup> Urine thallium concentrations in the exposed children were as high as 76.5 mcg/L. Although these children had a slightly higher than expected incidence of congenital abnormalities, no causal relation could be established with regard to thallium exposure.<sup>24</sup> More recently, a case-control study evaluating more than 1,000 infants born in a region of China with high environmental concentrations of thallium demonstrated an association between thallium exposure and low birth weight.<sup>119</sup>

There are few human reports of acute thallium poisoning during pregnancy. A comprehensive literature review demonstrated 25 cases, which included acute and chronic exposures that occurred during all trimesters.<sup>43</sup> Thallium slowly traverses the placenta and is able to cause characteristic fetal toxicity,<sup>26,76</sup> which manifests initially as decreased fetal movement, possibly as a consequence of fetal paralysis. Findings consistent with thallium poisoning are described both in the fetus after abortion and in the neonate after viable delivery.<sup>26,69,76,85</sup> However, normal infants are also reported despite being born to mothers with significant maternal toxicity.<sup>26,50</sup> The only consistent finding is a trend toward prematurity and low birth weight, especially in children exposed during the first trimester.<sup>43</sup> One author recommends continuing the pregnancy as long as the mother is clinically improving.<sup>26</sup>

These few case reports and animal studies provide confusing and sometimes contradictory results. It seems that fetal outcome is determined by both the trimester of pregnancy and the extent of maternal toxicity. It is reasonable to conclude that a fetus exposed to thallium during organogenesis has the potential for permanent injury. Those exposed later in pregnancy may recover without deficit if their exposures are limited and the mother recovers. If the exposure occurs closer to term, some children will be born with overt toxicity such as alopecia, dermatitis, nail growth disturbances, and permanent CNS injury.<sup>69</sup> However, because there are insufficient data to predict the outcome of pregnancy complicated by maternal thallium poisoning, no specific course of action can be recommended other than extensive fetal monitoring and aggressive treatment for the mother. When a viable child is delivered, it is important to note that thallium is eliminated in breast milk, and that ongoing evaluation of maternal toxicity is essential because nursing will result in continued exposure for the child.<sup>43</sup>

### ASSESSMENT

Most patients with acute thallium toxicity seek health care soon after exposure because of either alterations in their gastrointestinal (GI), cardiovascular, and neurologic function. Establishing the correct diagnosis at this early stage is essential to maximize the likelihood of for a satisfactory outcome. Unfortunately, many patients with either smaller acute exposures or chronic thallium poisoning first present days to weeks after their initial exposure and diagnosis is often further delayed. In these instances, many valuable epidemiologic aspects of the exposure history become difficult to obtain. Gastrointestinal findings may not have occurred or their consequence or etiology unrecognized because of their nonspecific, mild, and transient nature. Many patients with small acute or chronic exposures usually seek care because of alopecia or neuropathy.

The differential diagnosis of the neuropathy includes poisoning by arsenic, colchicine, vinca alkaloids, and disorders such as botulism, thiamine deficiency, and Guillain-Barré syndrome. Both the sensory neuropathy and the preservation of reflexes help differentiate thallium-induced neuropathy from Guillain-Barré syndrome and most other causes of acute neuropathy.<sup>13</sup> When GI manifestations are present in addition to a neuropathy and other end-organ manifestations, possible poisoning with metal salts such as arsenic and mercury should be evaluated (Chaps. 86 and 95). The differential diagnosis of rapid-onset alopecia is more restricted and includes arsenic,

selenium, colchicine, and vinca alkaloid poisoning as well as radiation injury (Chap. 17). When present, Mees lines indicate past exposure to metals, mitotic inhibitors, or antimetabolites and as such are nonspecific for thallium poisoning (Chaps. 17, 86, and 95).

### Diagnostic Testing

Radiographs of tampered food products<sup>66</sup> or of the abdomen<sup>37</sup> can document the presence of a metal such as thallium, which is radiopaque. Although abdominal radiography has potential utility shortly after a suspected exposure, the sensitivity and specificity of this test is unknown. Similarly, the yield from other routine studies, such as the complete blood count, electrolytes, urinalysis, and ECG, is limited in that these other studies are often normal or at most, merely demonstrate nonspecific abnormalities. Although microscopic inspection of the hair is intriguing, this test is unlikely to be conclusive for inexperienced observers.

The definitive clinical diagnosis of thallium poisoning can only be established by demonstrating elevated thallium concentrations in various body fluids or organs. Thallium can be recovered in the hair, nails, feces, saliva, CSF, blood, and urine, and standard assays and normal concentrations for most of these sources are published.<sup>73</sup> Qualitative point of care urine spot tests notoriously give false negative results and require the use of dangerous chemicals that are not routinely available (20% nitric acid) and therefore should be avoided.<sup>93</sup> The standard toxicologic testing method is to assay a 24-hour urine sample for thallium by atomic absorption spectroscopy.<sup>17,117</sup> Normal urine concentrations are lower than 5 mcg/L. Some authors suggest a potassium mobilization test to enhance urinary elimination (similar to the edetate calcium disodium mobilization test), to assist in the diagnosis of thallium exposure.<sup>11,48,93</sup> We recommend against this practice because of its lack of proven usefulness and its potential to exacerbate neurologic toxicity (see Potassium below).

### MANAGEMENT

The treatment goals for a patient with thallium poisoning are initial stabilization, prevention of absorption, and enhanced elimination. After the initial assessment and stabilization of the patient's airway, breathing, and circulatory status, GI decontamination is recommended in all patients with suspected thallium ingestions because of the morbidity and mortality associated with a significant exposure.

### Decontamination

Orogastic or nasogastric lavage is recommended for patients who have not had spontaneous emesis and present within 1 to 2 hours after ingestion (Chap. 5). If the patient presents more than 2 hours after ingestion or has had considerable spontaneous emesis, gastric emptying is unnecessary unless the ingestion is known to be massive.

Thallium salts are substantially adsorbed to activated charcoal (AC) in vitro.<sup>45,54</sup> Additionally, because thallium undergoes enterohepatic recirculation, AC will be useful both to prevent absorption after a recent ingestion and also to enhance elimination of thallium in patients who present in the postabsorptive phase.<sup>109</sup> In fact, a rat model of thallium poisoning demonstrated that multiple-dose AC (given as 0.5 g/kg twice daily for 5 days) increased the fecal elimination of thallium by 82% and substantially improved survival.<sup>61</sup> Other data demonstrate that AC alone is superior to either forced diuresis or potassium chloride therapy.<sup>55</sup>

In some patients with severe thallium toxicity, constipation will be prominent, so the addition of oral mannitol<sup>93,103,115</sup> or another cathartic to the first dose of AC is reasonable. Although no studies address the efficacy of whole-bowel irrigation with polyethylene glycol electrolyte lavage solution, we recommend this technique when radiopaque material is demonstrated in the GI tract (Antidotes in Depth: A2).

### Potassium

The similarities between the cellular handling of potassium ions and thallium ions led to the investigation of a possible role for potassium in the treatment of thallium poisoning. In humans, parenteral potassium administration is associated with an increase in urinary thallium elimination.<sup>16,32,80</sup> The

magnitude of this increase is on the order of 2- to 3-fold.<sup>80</sup> This is supported by animal models that demonstrate some benefit in terms of either enhanced thallium elimination or animal survival.<sup>33,55,61</sup> Potassium administration is believed to both block tubular reabsorption of thallium and mobilize thallium from tissue stores, thereby increasing thallium concentrations available for glomerular filtration.<sup>74,93</sup> However, the mobilization of the thallium is of concern. Many authors report either the development of acute neurologic symptoms or the significant exacerbation of neurologic manifestations during potassium administration.<sup>7,32,66,80,90,111</sup> Others cite data demonstrating that the augmentation of thallium elimination by potassium administration in humans is quite limited.<sup>83</sup> Additionally, animal models demonstrate that potassium loading enhances lethality and permits thallium redistribution into the CNS.<sup>40</sup> For these reasons, we recommend against the use of potassium loading. Some authors recommend forced diuresis, especially in conjunction with potassium chloride.<sup>22,108</sup> However, no convincing experimental or clinical evidence can support the use of forced diuresis with or without potassium at this time.

Likewise, the similarities between thallium and potassium might suggest a role for administration of sodium polystyrene sulfonate (SPS) as a sodium–thallium exchange resin. Despite excellent *in vitro* binding of thallium by SPS, it is unlikely to be clinically useful because of preferential binding between potassium and SPS and a comparatively large reservoir of potassium in the body and SPS is therefore not recommended.<sup>45</sup>

### Prussian Blue

Prussian blue is approved by the US Food and Drug Administration for thallium toxicity (Antidotes in Depth: A31).<sup>109</sup> When given orally, Prussian blue acts as an ion exchanger for univalent cations, with its affinity increasing as the ionic radius of the cation increases. As such, Prussian blue interferes with the enterohepatic recirculation of thallium by exchanging potassium ions from its lattice for thallium ions in the GI tract. This results in the formation of a concentration gradient, causing an increased movement of thallium into the GI tract.

Humans with thallium exposure are routinely given Prussian blue, with apparent clinical benefits, enhanced fecal elimination, and decreasing thallium concentrations.<sup>17,20,66,83,103,111,112,115,116</sup> One series of 11 thallium-poisoned patients demonstrated both tolerability of Prussian blue and substantially increased fecal thallium elimination.<sup>103</sup> Unfortunately, because there have been no controlled trials in humans that compare Prussian blue with other drugs and because many of the patients reported above received multiple therapies, the actual efficacy of Prussian blue is unknown.

The dose of Prussian blue is 250 mg/kg/day orally via a nasogastric tube in 2 to 4 divided doses.<sup>103</sup> For patients who are constipated, the Prussian blue may have greater benefit if dissolved in 50 mL of 15% mannitol.<sup>108</sup> Although any cathartic is theoretically useful, most authors have used mannitol, possibly because of concerns regarding repeated use of magnesium-containing cathartics in patients with neurologic findings and the use of sorbitol in patients with poor GI mobility (Antidotes in Depth: A31).

### Extracorporeal Drug Removal

Extracorporeal drug removal has at most a limited beneficial role in patients with thallium exposure, especially if initiated shortly after the initial exposure while serum concentrations remain high before effective tissue distribution. Because a frequently quoted review attests to the benefits of hemodialysis,<sup>69</sup> many patients still receive this therapy.<sup>68</sup> The actual data, however, show that hemodialysis, at various stages of poisoning, is no better than forced diuresis.<sup>20,82</sup> Reported thallium removal rates by hemodialysis are trivial: 143 mg of thallium was removed by 120 hours,<sup>83</sup> 222.8 mg was removed by 121 hours,<sup>20</sup> and 128 mg was removed by 54 hours of hemodialysis.<sup>20</sup> These quantities are placed in perspective knowing that the minimum lethal adult dose of thallium is estimated to be on the order of 1 g,<sup>73</sup> and that many reported doses exceed that by a factor of 10. Data from one hemodialysis case suggests that by using high blood flow rates (300 mL/min), clearances as high as 90 to 150 mL/min could be obtained.<sup>63</sup> Although these clearances seem encouraging, they should be interpreted with an appreciation of the large volume of distribution that thallium achieves in the postabsorptive phase. With lower

blood flow rates, charcoal hemoperfusion is 2 to 3 times more efficient than hemodialysis, providing clearance rates as high as 139 mL/min.<sup>20</sup> Combined hemoperfusion and hemodialysis were used in several cases<sup>4,20,22</sup> and were reported to remove as much as 93 mg of thallium within 3 hours of therapy.<sup>4</sup> Although extracorporeal therapy alone is probably insufficient for patients with significant poisoning and unnecessary in those with small exposures, some benefit seems likely when used in combination with other therapies, especially in patients with either underlying chronic kidney disease or acute kidney injury from thallium poisoning, and those with early massive, and presumed lethal, exposures. As is the case with other xenobiotics, thallium is probably not effectively removed by peritoneal dialysis.<sup>53</sup> A multidisciplinary consensus work group recently supported extracorporeal (HD + HP) therapy in patients with acute exposure when blood thallium concentrations are greater than 400 mcg/L (if rapidly available) or, if in the absence of laboratory support, severe signs and symptoms are present and treatment can be initiated within 24 to 48 hours of ingestion.<sup>35</sup> Table 99–2 summarizes the suggested therapy for thallium-exposed patients.

### Chelation

Patients with thallium toxicity do not respond to traditional chelation therapy. Studies demonstrate that the use of EDTA and diethylenetriamine pentaacetic acid are without benefit.<sup>70,93</sup> Dimercaprol (British anti-Lewisite {BAL}) and D-penicillamine also fail to enhance thallium excretion in experimental models.<sup>70,93</sup> In one model in which D-penicillamine was able to enhance thallium elimination, the resultant substantial thallium redistribution into vital organs was a significant disadvantage.<sup>88</sup> A rodent model of combined use of Prussian blue with DL-penicillamine not only suggested a survival advantage for combined therapy but demonstrated reduced thallium concentrations in vital organs, including the brain.<sup>70</sup> Sulfur-containing compounds such as cysteine and NAC are not beneficial.<sup>61,65</sup> Another chelator, diphenylthiocarbazon (dithizone), forms a minimally toxic complex with thallium, resulting in a 33% increase in fecal elimination of thallium in rats.<sup>99</sup> Unfortunately, dithizone is goitrogenic and diabetogenic in animal studies.<sup>61,73,108</sup> Dithiocarb (sodium diethyldithiocarbamate), an intermediate metabolite of tetraethylthiuram disulfide (disulfiram, or Antabuse) (Chap. 78), also increases the urinary excretion of thallium.<sup>99,105</sup> Before thallium is eliminated, however, the formation of a lipophilic thallium–diethyldithiocarbamate complex likely results in the redistribution

**TABLE 99–2 Treatment for Thallium Exposure**

#### Early (patients who present in the first 1–2 hours postexposure)

- Stabilize airway, breathing, and circulation if necessary.
- Perform orogastric or nasogastric lavage if the patient has not vomited.
- Perform whole-bowel irrigation with polyethylene glycol electrolyte lavage solution for large ingestions or the presence of radiopaque material on abdominal radiographs.
- Begin multiple-dose activated charcoal (MDAC) therapy; add a cathartic (preferably oral mannitol) to the first dose if no recent bowel movements. Discontinue MDAC when Prussian blue can be administered.
- Give 250 mg/kg/d of Prussian blue orally in 2 or 4 divided doses dissolved in water or 50 mL of 15% mannitol if no recent bowel movements.
- Add simultaneous charcoal hemoperfusion and hemodialysis or hemodialysis alone, especially if in the presence of chronic kidney disease or acute kidney injury.

#### Delayed (patients who present more than 2–4 hours after acute exposure or with chronic toxicity)

- Stabilize airway, breathing, and circulation if necessary.
- Begin MDAC therapy; add a cathartic (preferably oral mannitol) to the first dose if no recent bowel movement. Discontinue MDAC when Prussian blue can be administered.
- Give 250 mg/kg/day of Prussian blue orally in 2 or 4 divided doses dissolved in water or 50 mL of 15% mannitol if no recent bowel movements.
- Add simultaneous charcoal hemoperfusion and hemodialysis or hemodialysis alone if in the presence of chronic kidney disease or acute kidney injury or life-threatening clinical manifestations or a thallium concentration 400 mcg/L.

of thallium into the CNS.<sup>51,105</sup> After decomposition of the chelate complex, thallium remains in the CNS, potentially exacerbating neurologic manifestations.<sup>51,92</sup> Because of the significant adverse effects of dithizone and the redistribution of thallium after dithiocarb use, neither chelator is recommended in the treatment of patients with thallium poisoning.

There is some interest in the water-soluble analogs of dimercaprol (DMPS (2,3-dimercapto-1-propanesulfonic acid) and succimer) for the treatment of thallium toxicity. However, in an animal model, DMPS failed to decrease tissue concentrations of thallium.<sup>72</sup> Similarly, in another animal model, although succimer improved survival over control subjects, the benefit was less than that achieved for Prussian blue and was at the cost of an increase in brain thallium concentrations.<sup>92</sup> Preliminary animal investigations demonstrate reduction in serum thallium concentrations after administration of the iron chelators deferoxamine and deferasirox.<sup>29,95,96</sup> Although worthy of additional study, these results are too preliminary to recommend either drug antidotes in thallium-poisoned patients. Similarly, experimental evidence from combined use of Zn-DTPA and Prussian blue is insufficient to recommend use in humans.<sup>118</sup>

## SUMMARY

- Thallium is a multiorgan system toxin whose effects result from cellular mimicry for potassium and avid binding to sulfhydryl groups.
- The removal of thallium salts from depilatories and rodenticides has substantially reduced the incidence of both intentional and unintentional thallium toxicity in the United States.
- Cases of significant poisoning still occur in countries where thallium-containing rodenticides remain in use, as well as in this country, from suicide, attempted homicide, and by personal injury from contamination of foods and illicit xenobiotics.
- Early recognition of the characteristic signs and symptoms of thallium poisoning, such as a painful ascending sensory neuropathy and alopecia, followed by prompt initiation of safe and appropriate therapy will substantially improve the prognosis.
- Orogastric or nasogastric lavage is recommended for patients with acute oral poisonings if they present early and have not had significant emesis and/or at least one dose of oral AC followed by either multiple-dose activated charcoal (MDAC) or Prussian blue, if available. Oral mannitol can be added to either MDAC or Prussian blue when constipation is present.
- In severe acute poisoning, the addition of hemodialysis or combined hemodialysis and hemoperfusion in series is reasonable and offers a limited additional benefit.

## PRUSSIAN BLUE

Robert S. Hoffman

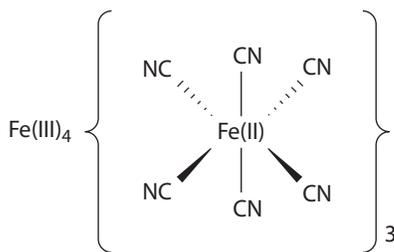

## INTRODUCTION

Poisoning with salts of thallium or cesium are uncommon causes of life-threatening toxicity in which supportive care is often insufficient to alter outcome. Radioactive cesium is either released as part of a nuclear incident<sup>13,22,68</sup> or dispersed as a “dirty bomb,”<sup>4,16</sup> producing radiation exposure with sub-toxic cesium doses. Prussian blue is an orally available cation exchange resin that enhances elimination of thallium and cesium in humans and animals and improves survivability in animals.

## HISTORY

Prussian blue, the first artificially synthesized pigment, was discovered unintentionally by Diesbach in 1704 while attempting to make another pigment, cochineal red lake. Although immediately popular in art and later in printing, it took approximately 250 years to recognize that Prussian blue attracted monovalent alkali metals into its crystal lattice. Subsequently, in 1963, Nigrovic demonstrated that Prussian blue enhanced cesium elimination from the gastrointestinal tract of rats given either oral or intraperitoneal cesium.<sup>44</sup> In 2003, the US Food and Drug Administration (FDA) approved Prussian blue (as Radiogardase) for the treatment of thallium and radioactive cesium poisoning.

The Prussian blue literature is complicated by many confusing chemical and physical terms. The product synthesized by Diesbach,  $\text{Fe}_4\{\text{Fe}(\text{CN})_6\}_3$ , iron(III) hexacyanoferrate(II), commonly known as insoluble Prussian blue, is assigned the Chemical Abstracts Service (CAS) number 14038-43-8 and is the FDA-approved product Radiogardase (Fig. A31-1). Synonyms for Prussian blue include Berlin blue, Hamburg blue, mineral blue, Paris blue, Turnbull’s blue, and Pigment blue 27, among others.<sup>66</sup> These names are often used interchangeably to refer to both insoluble Prussian blue and a soluble (colloidal) Prussian blue that either has the molecular formula  $\text{KFe}\{\text{Fe}(\text{CN})_6\}_3$  or  $\text{K}_3\text{Fe}\{\text{Fe}(\text{CN})_6\}_3$ . Thus “Prussian blue” also carries 2 additional CAS numbers: 25869-98-1 and 12240-15-2.<sup>45</sup> Compounds containing the same basic core structure, such as  $\text{NH}_4\text{Fe}\{\text{Fe}(\text{CN})_6\}_3$  (ammonium ferric ferrocyanide or Chinese blue) and sodium ferric ferrocyanide, may have similar efficacy in binding monovalent cations and are also sometimes incorrectly called Prussian blue. For the purpose of clarity, general statements that follow use the term “Prussian blue.” In many instances, the terms “insoluble” and “soluble” are chosen to highlight differences between the compounds. Unfortunately,

**FIGURE A31-1.** The chemical structure of insoluble Prussian blue. The Roman numerals II and III denote the valence state of iron. Although in most current nomenclature this would be expressed as  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$ , the figure is drawn this way for consistency with most available references, which employ the older nomenclature.

because many studies do not specify which Prussian blue is used, some inherent ambiguity persists in the literature. Radiogardase, the currently available pharmaceutical preparation, is the insoluble form of Prussian blue, possibly selected preferentially for its efficacy in cesium poisoning.

## PHARMACOLOGY

The crystal lattice of Prussian blue typically binds cationic potassium ions from the surrounding environment. However, because its affinity increases as the ionic radius of the monovalent cation increases, Prussian blue preferentially binds cesium (ionic radius: 1.69 Å) and thallium (ionic radius: 1.47 Å) over potassium (ionic radius: 1.33 Å).<sup>10,23</sup> Additionally, strong binding for rubidium (ionic radius: 1.48 Å) is demonstrated.<sup>55</sup> Thus, when given orally, Prussian blue binds unabsorbed thallium or cesium in the gastrointestinal tract, preventing absorption and reversing the concentration gradient to enhance elimination through enteroenteric circulation (gastrointestinal dialysis). Prussian blue also interferes with enterohepatic circulation, causing a further reduction in tissue stores.

Insoluble Prussian blue remains almost exclusively in the gastrointestinal tract and is eliminated nearly entirely in feces at a rate determined by gastrointestinal (GI) transit time. In a radiolabeled study of healthy pigs, 99% of a single ingested dose was recovered unchanged in the stool.<sup>42</sup> In contrast, soluble Prussian blue is slightly absorbed based on the clinical finding of a blue discoloration that develops in the sweat and tears of patients undergoing prolonged therapy.<sup>18</sup> This discoloration appears to be without clinical significance and resolves within days when therapy ceases. No significant food or drug interactions are known to exist.

## THALLIUM

## In Vitro Adsorption

The chemical formulation of Prussian blue influences the in vitro and, presumably, the in vivo adsorption of thallium ions. An early investigation demonstrated that the soluble form more effectively adsorbs thallium than the insoluble form.<sup>12</sup> In a more rigorous study, the in vitro adsorptions of both forms were similar when thallium concentrations remained low.<sup>21</sup> However, as thallium concentrations increased, the colloidal (soluble) form demonstrated far greater adsorptive capacity. Although not proven, this difference may occur because the soluble form contains more potassium and can therefore exchange proportionally more cation. Furthermore, the actual size of the crystal lattice alters its efficacy. When laboratory-synthesized Prussian blue (with a crystal size of 176.8 Å) was compared with a commercial preparation (with a crystal size of 311.9 Å), the laboratory-synthesized product adsorbed more thallium in vitro because its smaller size increased its surface area.<sup>23</sup> In vitro analysis of the FDA-approved antidote demonstrated that pH and hydration state greatly influenced adsorption, with the maximal adsorptive capacity (MAC) predicted to be as high as 1,400 mg of thallium/g at pH 7.5.<sup>78</sup>

## In Vitro Comparison of Prussian Blue and Activated Charcoal

In one in vitro study, thallium was well adsorbed to Norit brand activated charcoal.<sup>21</sup> Although numerical data are not supplied in the body of the paper, the 10% to 20% adsorption to activated charcoal demonstrated in a figure was far less than the results achieved with several different forms of Prussian blue tested simultaneously.<sup>21</sup> Two other binding studies showed results different from the Norit activated charcoal study. One investigation determined

that the MAC of activated charcoal was 124 mg of thallium/g, whereas the MAC for Prussian blue was only 72 mg of thallium/g.<sup>24</sup> In another study, a MAC of only 59.7 mg of thallium/g was calculated for CharcoAid activated charcoal, compared with a higher MAC for insoluble Prussian blue of 72.7 mg of thallium/g.<sup>19</sup> Although the MACs for Prussian blue in these 2 studies are nearly identical, they differ significantly from the MAC reported above for the FDA-approved formulation, possibly as a result of different experimental conditions.<sup>78</sup> Similarly, the variable results for activated charcoal may also be a function of the study pH or the different types of activated charcoal used.

### Animal Data: Kinetics, Tissue Concentrations, and Survival

#### Thallium

Sublethal doses of thallium were used to evaluate the effects of various antidotes in rats over an 8-day period.<sup>24</sup> Although the control group only eliminated 53% of the administered dose of thallium, 93% of the dose was eliminated in the activated charcoal, and 82% was eliminated in the insoluble Prussian blue groups. In contrast, other investigators demonstrated only a modest increase in thallium elimination in rats treated with oral activated charcoal while demonstrating a consistent benefit of Prussian blue.<sup>25</sup>

Multiple studies demonstrate that Prussian blue not only decreases the half-life of thallium in animals but also lowers thallium content in critical organs such as the brain and the heart.<sup>17,38,39,54,56</sup> Half-lives are typically reduced by approximately 50% when Prussian blue is given with or without a cathartic. The rationale for the cathartic is that constipation is invariably present in humans and animals with severe thallium poisoning.

Only a few studies evaluated the effects of Prussian blue on survival. In these studies, a statistically significant survival advantage is shown in thallium-poisoned rats<sup>23,56</sup> and mice<sup>29</sup> treated with Prussian blue. The experimental benefit was a 31% increase in the LD<sub>50</sub> (median lethal dose for 50% of poisoned animals).<sup>57</sup> Although most chelators have a limited or detrimental effect in thallium poisoning (Chap. 99) and DL-penicillamine has no demonstrable benefit as a single antidote, in an animal model the combined use of Prussian blue and DL-penicillamine not only decreased thallium concentration in critical tissues such as the brain but also enhanced survival.<sup>2,36</sup> Although interesting, these data are too preliminary to recommend the routine use of combined DL-penicillamine and Prussian blue in poisoned humans.

#### Radioactive Thallium

There is no published experience describing human poisoning with radioactive thallium. Prussian blue has demonstrable efficacy in an animal model of radioactive thallium poisoning, as would be expected because the ionic radii of isotopes are generally similar. In one small study, insoluble Prussian blue decreased the biologic half-life of radioactive thallium in rats by approximately 40%.<sup>5</sup> Many humans receive radioactive thallium (<sup>201</sup>Tl) chloride as part of myocardial scintigraphy, with a typical adult dose of 110 megabecquerels (MBq). Concerns about excess radiation exposure following the termination of diagnostic testing have led to the evaluation of Prussian blue to enhance post-imaging elimination. In vitro evidence suggests a MAC of 5,000 MBq/g.<sup>3</sup> In a controlled trial, in which Prussian blue was given to a patient post myocardial scintigraphy, radioactivity was reduced 18% and 30% after 24 and 48 hours, respectively.<sup>3</sup>

#### Thallium Poisoning in Humans

A thorough analysis of the efficacy of Prussian blue in thallium poisoning is severely hampered by many factors. First, and most importantly, there are no controlled human trials. Second, although multiple patients have received Prussian blue in the setting of thallium poisoning, many were simultaneously treated with a variety of therapies, including forced potassium diuresis, single- or multiple-dose activated charcoal, and either hemodialysis or hemoperfusion. Thus, it is impossible to determine the specific effects of Prussian blue on morbidity or mortality, and even toxicokinetic data must be interpreted with caution. Third, many reports fail to specify the exact type of Prussian blue used. Those investigations that do specify the type of Prussian blue typically used the soluble form, which is presently unavailable as a

pharmaceutical preparation in the United States. Discussions of the available data in the following sections are limited by these considerations.

Three patients, in 1971, were the first to receive Prussian blue as a treatment for thallium poisoning.<sup>21</sup> Although daily fecal thallium concentrations were not determined in 2 of the 3 patients because of severe constipation, an approximately 7-fold increase in fecal thallium elimination over baseline was attributed to Prussian blue therapy in the third patient. Subsequently, many humans with thallium poisoning have received Prussian blue, with or without a cathartic, as part of their therapy.<sup>1,7,9,10,15,21,48,51,52,58,61,63,70,71,75</sup> Unfortunately, other components of therapy that may have confounded the effects of Prussian blue in these cases include single- or multiple-dose activated charcoal and the use of D-penicillamine, dimercaprol, ethylenediaminetetraacetic acid (EDTA), succimer, 2,3-dimercaptopropane-1-sulfate (DMPS), forced potassium diuresis, and either hemodialysis or hemoperfusion. There are no controlled human trials of any of these modalities alone or in combination, and most of the data presented are based on single case reports or small case series.

One of the largest series was composed of 11 thallium-poisoned patients who were treated with soluble Prussian blue.<sup>63</sup> This report not only demonstrated the tolerability of Prussian blue, but also was the first to systematically evaluate its fecal elimination. In all individuals studied, fecal elimination remained high, even when urinary elimination fell, suggesting selective redistribution of thallium into the gut.<sup>63</sup> Although the authors commented on clinical improvement in these patients, the lack of controlled data makes these subjective observations difficult to interpret. Similarly, a substantial reduction in thallium half-life was demonstrated when Prussian blue was compared with no therapy at all in patients with thallium poisoning.<sup>10</sup> Another series of 14 patients with delayed presentation (9–19 days) were reported. These patients were treated with DMPS, followed by Prussian blue and hemodialysis, and 13 survived. Data are insufficient to make inferences about the effects of Prussian blue alone or as part of this treatment regimen.<sup>64</sup>

#### Dosage and Administration

The dosage of Prussian blue has never been investigated systematically in either humans or animals. In most of the case reports and series mentioned above, a total dose of 150 to 250 mg/kg/day was administered orally or via a nasogastric tube in 2 to 4 divided doses.<sup>63</sup> Because constipation or obstipation is often present or expected, Prussian blue is generally administered dissolved in 50 mL of 15% mannitol.<sup>65</sup> Although any cathartic may be appropriate, mannitol is used most frequently, possibly because of concerns over the risks associated with repeated doses of magnesium or sorbitol (Antidotes in Depth: A2). The manufacturer of Radiogardase recommends that adults and adolescents with thallium poisoning receive a total dose of 9 g divided daily (3 g every 8 hours) and that children receive a total dose of 3 g divided daily (1 g every 8 hours). Although the manufacturer does not recommend using a cathartic, a high fiber diet is advocated when constipation is present. Because Prussian blue is well tolerated, the editors of this text continue to favor the 150- to 250-mg/kg/day dosing because it provides more antidote with limited adverse consequence and most of the published experience has used this dose with essentially no adverse effects. In addition, because many severely poisoned patients cannot tolerate swallowing large numbers of capsules, it is recommended to open the capsules and mix them with food or liquids when needed. This will often result in a benign blue discoloration of the mouth and teeth. The use of a cathartic is reasonable when constipation is consequential.

The end point of therapy is similarly poorly defined. By convention, Prussian blue is usually continued until total urinary thallium concentrations fall below 0.5 mg/day. Although this end point is not a perfect measurement of total body thallium burden, as small amounts of fecal elimination continue, even when urinary elimination has diminished,<sup>63</sup> most laboratories are not equipped to measure fecal thallium concentrations. In patients who remain significantly symptomatic, it is reasonable to continue Prussian blue therapy for a short period past the 0.5-mg/day endpoint on an individual basis.

## CESIUM

The radioactive isotope of cesium ( $^{137}\text{Cs}$ ), a common byproduct of nuclear fission reactions, is a strong  $\beta$  and  $\gamma$  emitter with a physical half-life of more than 30 years and a biologic half-life of about 110 days. Another isotope ( $^{134}\text{Cs}$ ) is only produced by neutron activation of the stable isotope ( $^{133}\text{Cs}$ ) and has a physical half-life of about 2 years and a biologic half-life comparable to  $^{137}\text{Cs}$ . Cesium is absorbed in the small bowel, distributes like potassium, and undergoes enteric recirculation in a manner comparable to thallium.<sup>37</sup> Approximately 80% of a given dose of cesium is eliminated in the urine, with 20% cleared in the feces.

The isotope  $^{137}\text{Cs}$  is used clinically as a radiotherapy source in nuclear medicine and to irradiate banked blood. Although uncommon, radiologic disasters such as Fukushima, Chernobyl, and Goiânia (see human data below) have resulted in lethal incorporation exposures. Additionally, concerns over the use of  $^{137}\text{Cs}$  in “dirty bombs” have increased the potential need to treat patients with radioactive cesium poisoning. Toxicity from nonradioactive cesium is also reported. Cases of QT interval prolongation, torsade de pointes, and death are reported in patients taking cesium chloride either as a dietary supplement or for its alleged antineoplastic effects.<sup>6,8,27,47,53,59,67</sup>

### In Vitro Adsorption

Standard binding studies compared the ability of activated charcoal, sodium polystyrene sulfonate (SPS), and both soluble and insoluble Prussian blue to adsorb  $^{137}\text{Cs}$  over a range of gastrointestinal pHs.<sup>73</sup> Unlike thallium, the adsorption of cesium to activated charcoal was negligible. Comparable to thallium, SPS offered no benefit, likely because of preferential effects on potassium. Although both forms of Prussian blue adsorbed cesium, the insoluble form was consistently superior. A pH of 7.5 was selected to represent the pH of the small bowel lumen, the location where most adsorption would occur. At this pH, a MAC of 238 mg of  $^{137}\text{Cs}$ /g of insoluble Prussian blue was determined. In an interesting extension, when the same authors bound insoluble Prussian blue to a hemoperfusion column, they demonstrated a clearance of approximately 100 mL/min of  $^{137}\text{Cs}$  from plasma and projected that a 4-hour treatment would adsorb about 0.3 terabecquerel (TBq) of radioactive cesium.<sup>74</sup> When the FDA-approved antidote was analyzed, like thallium, pH and hydration introduced significant variations in binding, with a MAC of 715 mg of cesium/g noted at pH 7.5.<sup>14</sup>

### Animal Data: Kinetics, Tissue Concentrations, and Survival

Small animal investigations with either  $^{134}\text{Cs}$  or  $^{137}\text{Cs}$  consistently demonstrate that Prussian blue therapy reverses the urine-to-stool elimination ratio from 8:1 to 0.3:1 and reduces the biologic half-life and the total body area under the curve by as much as 60%.<sup>40,43,44,55,62</sup> For example, rats given oral  $^{134}\text{Cs}$  retained 84.7% of the ingested dose at 7 days. Treatment with insoluble or soluble Prussian blue, as well as Chinese blue, produced significant reductions in retained cesium (only 6.36%, 2.63%, and 2.43% of the dose was retained at 7 days, respectively).<sup>11</sup>

In addition to human toxicity, concern over radioactive cesium incorporation into cattle milk and meat resulted in a number of large animal model investigations. Daily Prussian blue therapy reduced radioactive cesium concentrations in sheep by as much as 42%.<sup>20,50</sup> Likewise, radioactive cesium transfer to milk was reduced by 85% in cows.<sup>69</sup> When dogs were contaminated with  $^{137}\text{Cs}$ , Prussian blue reduced the total body burden by as much as 51%.<sup>32</sup> Similar efficacy in reducing the amount of cesium was demonstrated in meat from pigs fed  $^{134}\text{Cs}$ -contaminated whey, with insoluble Prussian blue reducing activity from 359 to 11 Bq/kg over 27 days.<sup>11</sup>

### Human Volunteer Studies

Two human volunteers ingested meals contaminated with  $^{134}\text{Cs}$  to compare the efficacy of both the soluble and insoluble forms of Prussian blue with controls.<sup>11</sup> At 14 days after exposure and without therapy, the volunteers retained 94.7% of the ingested dose, compared with retention of only 5.1% following therapy with insoluble Prussian blue and 4.9% following soluble

Prussian blue. In another study, 2 volunteers demonstrated that Prussian blue decreased the biologic half-life of ingested radioactive cesium by approximately 33%.<sup>28</sup> Finally, in 2 volunteers, the effects of pretreatment were compared with simultaneous posttreatment Prussian blue. When a single dose of Prussian blue was administered 10 minutes before  $^{134}\text{Cs}$ , absorption decreased from 100% (without therapy) to 3% to 10%. However, simultaneous administration of 0.5 or 1 g of Prussian blue with  $^{134}\text{Cs}$  resulted in 38% to 63% absorption. Finally, when Prussian blue was given daily at a dose of 0.5 g every 8 hours in the postabsorptive phase, the biologic half-life of  $^{134}\text{Cs}$  was reduced from 106 to 44 days.<sup>42</sup>

### Radioactive Cesium Poisoning in Humans

There are no controlled trials of Prussian blue in radioactive cesium poisoning. Experience is derived exclusively from treating disaster victims. In 1987, a number of people in Goiânia, Brazil, were incorporated with radioactive cesium from a discarded radiotherapy unit.<sup>46</sup> Although the reported total number of individuals treated is uncertain because of multiple reports that probably include the same patient several times, one group describes 37 patients who were given insoluble Prussian blue in doses ranging from 3 g/d in children up to 10 g/d in adults. Untreated, elimination kinetics were first order, and half-lives varied extensively from 39 to 106 days in adults (mean: 65.5 days in women and 83 days in men). Half-lives were shorter in children. Therapy with insoluble Prussian blue reduced half-lives by a mean of 32%,<sup>26</sup> and reduced the retained cesium dose from between 51% and 84% of the total dose.<sup>30</sup>

The nuclear disaster at Chernobyl, Ukraine, resulted in many cases of acute radiation exposure as well as incorporation into the population of radioactive iodine, cesium, and strontium. In one trial, insoluble Prussian blue was given to 3 victims of radioactive cesium incorporation many weeks after their exposure. The reported reduction in biologic half-life ranged from 12% to 52%.<sup>33</sup> The authors of this paper include data from the Chinese literature describing another 6 patients who demonstrated a similar reduction in the biologic half-life of cesium following Prussian blue therapy. Kinetic modeling based on all available data suggest that although Prussian blue is most effective if given nearly immediately post exposure. However, administration as late as 30 days post exposure, and perhaps even one year post exposure will substantially reduce the biological half-life of  $^{137}\text{Cs}$ .

### Nonradioactive Cesium Poisoning in Humans

Three cases describe the use of Prussian blue for patients with nonradioactive cesium poisoning. A 58-year-old woman presented with syncope, polymorphic ventricular tachycardia, hypokalemia, and a QT interval of 590 ms after taking cesium chloride as an alternative therapy for cancer. The apparent half-life of cesium was reported as 7.9 days during Prussian blue therapy in comparison to 86.6 days after therapy. The authors state that there were no adverse effects of therapy.<sup>67</sup> Similarly, a 65-year-old woman presented with syncope and was found to have multiple episodes of torsade de pointes, hypokalemia, and a QT interval of 620 ms after taking cesium chloride for 6 weeks. Therapy with insoluble Prussian blue (3 g/d) was associated with a reduction in the apparent half-life for cesium from 61.7 to 29.4 days.<sup>6</sup> The final case describes a 61-year-old woman who injected cesium chloride subcutaneously around a mass and suffered a cardiac arrest. She was resuscitated, found to have a prolonged QT interval (>700 ms) and a very high blood cesium concentration. She received Prussian blue but the regimen and effect on cesium elimination are not clearly defined.<sup>60</sup>

### Dosage and Administration

We agree with the manufacturer of Radiogardase recommendation that for radioactive cesium poisoning, adults and adolescents 13 years or older receive a total daily dose of 9 g divided into 3 g, 3 times per day. Children aged 2 through 12 years should receive a total daily dose of 3 g divided into 1 g, 3 times per day. Although the manufacturer offers no recommendation in children under the age of 2 years, administering 150 to 250 mg/kg/day in divided doses

are appropriate. Although these are the same doses used for thallium poisoning, therapy for cesium poisoning should be continued for at least 30 days. Even though there are no recommendations of other criteria to determine the end point of therapy, quantitative and radiologic evaluations of cesium elimination should be performed. Capsules can be opened and mixed in liquids and given via nasogastric tube for patients unable to swallow. Since constipation does not commonly occur with either radioactive or nonradioactive cesium poisoning, neither routine cathartic administration nor the use of a high-fiber diet is recommended.

### ADVERSE EFFECTS AND SAFETY ISSUES

Animal studies show no adverse effects of therapeutic doses.<sup>49</sup> Oral lethal doses are not known or projected for humans, but are likely to be astronomical given that there is no or minimal absorption of Prussian blue and the absence of local toxicity in the GI tract. The only significant adverse effects reported in humans receiving therapeutic doses are constipation and hypokalemia,<sup>65</sup> and the constipation is likely to be related more to the thallium toxicity than to Prussian blue.

Although there is some concern regarding the potential for cyanide liberation from Prussian blue, this release appears to be quantitatively minimal. Cyanide release from soluble Prussian blue was less than 3 mg/24 h in simulated gastric fluid.<sup>72</sup> When 3 human volunteers were given 500 mg of soluble Prussian blue (radiolabeled with <sup>59</sup>Fe, either in the ferric or ferrous position and with <sup>14</sup>C on the CN), only 2 mg of cyanide were absorbed.<sup>41</sup> Over the physiological range of potential gastrointestinal pH, the maximal cyanide release from insoluble Prussian blue is only 135 mcg/g at pH 1.<sup>76,77</sup> When extrapolated even for repeated therapeutic doses, only a trivial amount of cyanide would be liberated.

### PREGNANCY AND LACTATION

Insoluble Prussian blue is listed as pregnancy category C. Because of the severe consequences of poisoning from radioactive cesium and thallium, both of which cross the placenta, and the lack of systemic absorption of insoluble Prussian blue, a risk-to-benefit analysis would favor the use of the antidote in all poisoned pregnant patients. Both cesium and thallium are excreted in breast milk. Prussian blue's confinement in the GI tract would make excretion in breast milk unlikely. In any event, women contaminated with cesium or thallium should not breastfeed.

### FORMULATION AND ACQUISITION

Insoluble Prussian blue (Radiogardase) is available as a 0.5-g blue powder in gelatin capsules for oral administration manufactured from Haupt Pharma Berlin GmbH for distribution by HEYL Chemisch-pharmazeutische Fabrik GmbH & Co. KG, Berlin (281-395-7040; fax 281-395-2320; see information at www.heytext.com). Prussian blue is part of the US Strategic National Stockpile, which can be accessed at CDC emergency response hotline: 770-488-7100; and is also stored at REAC/TS, Oak Ridge; emergency number 865-576-1005. Thirty capsules retail for about \$100 and have a listed 5-year shelf-life. Although data suggest that Prussian blue is stable well beyond the 5-year label,<sup>34,35</sup> recommendations for use after longer storage periods cannot be made without formal evaluation by the shelf-life extension program.

### SUMMARY

- Prussian blue is a crystalline lattice that adsorbs radioactive and nonradioactive isotopes of thallium and cesium.
- Animal data demonstrate the ability of Prussian blue to prevent absorption, enhance elimination, and improve survival following thallium or cesium administration.
- Although human data are limited, the use of Prussian blue appears beneficial in case reports and small case series.
- Because Prussian blue is essentially nontoxic, it should be used whenever severe thallium or cesium poisoning is suspected.
- If Prussian blue is unavailable, activated charcoal can be substituted for thallium poisoning, but not for cesium poisoning.

<b>Zinc (Zn)</b>	
Atomic number	= 30
Atomic weight	= 65.37 Da
Normal concentrations	
Blood	= 600–1,000 mcg/dL (91.8–153 mmol/L)
Serum	= 109–130 mcg/dL (16.7–19.9 mmol/L)
Urine (24-hour)	= <500 mcg/d (<7.65 mmol/d)

## HISTORY AND EPIDEMIOLOGY

The Babylonians used zinc alloys more than 5,000 years ago,<sup>2</sup> and references to zinc oxide as a lotion to heal lesions around the eye can be found in the Ebers papyrus, written in 1500 BC.<sup>18</sup> Zinc oxide and zinc sulfate were used in Western Europe during the late 1700s and early 1800s for gleet (urethral discharge), vaginal exudates, and convulsions. In the late 1800s, brass workers who inhaled zinc oxide fumes were noted to develop “zinc fever,” “brass founders’ ague,” and “smelter shakes,” all of which are now identified as metal fume fever (Chap. 121).<sup>70</sup>

Throughout history, humans have contaminated the environment with zinc. For example, release of zinc from mines such as those in southern China and the former Soviet Union elevated concentrations in the water supply and vegetation, which lead to elevated tissue zinc concentrations and clinical effects in the population.<sup>54,64</sup>

The antiinflammatory effects of zinc sulfate were studied in the late 1970s for acne vulgaris with mixed results. However, a double-blinded controlled study found no difference between zinc and placebo.<sup>75</sup> The more recent use of zinc supplementation as an alternative preventive and treatment strategy for upper respiratory infections exposes large numbers of patients to undefined risks for unclear benefits.

An epidemic of hematologic and, more importantly, neurologic impairment resulting from large unintentional exposures to zinc denture creams occurred. This syndrome, sometimes referred to as “Zinc swayback,” is described below.<sup>3,11,42,58</sup>

The nanotoxicology associated with zinc will not be discussed here (Chap. 125).

## CHEMISTRY

Zinc, a transition metal, has 2 common oxidation states, Zn<sup>0</sup> (elemental or metallic) and Zn<sup>2+</sup>. The pure element exists as a blue to white shiny metal. Zinc combines with other elements to form many compounds such as zinc chloride (ZnCl<sub>2</sub>), zinc oxide (ZnO), zinc sulfate (ZnSO<sub>4</sub>), and zinc sulfide (ZnS). Once metallic zinc is exposed to moisture, it becomes coated with zinc oxide or carbonate (ZnCO<sub>3</sub>).<sup>85</sup>

Like the other transition metals iron (Chap. 45) and copper (Chap. 92), zinc ions participate in reactions that result in the generation of reactive oxygen species such as superoxide radicals or hydroxyl radicals that damage both local and remote tissues (Chap. 10).

## PHARMACOLOGY AND PHYSIOLOGY

Zinc is an essential nutrient and found in more than 200 metalloenzymes, including acid phosphatase, alkaline phosphatase, alcohol dehydrogenase, carbonic anhydrase, superoxide dismutase, and DNA and RNA polymerases.<sup>85</sup> The average daily intake of zinc in the United States is 5.2 to 16.2 mg; foods that contain zinc include leafy vegetables (2 ppm), meats, fish, and poultry (29 ppm).<sup>85</sup> The recommended daily allowance is 11 mg/day for men and

8 mg/day for women. Pregnant and nursing women require 12 mg/day. Zinc accumulates in erythrocytes resulting in whole blood concentrations 6- to 7-fold higher than those in the serum.<sup>72</sup> Zinc and copper concentrations generally have an inverse relationship in the serum with elevated zinc concentrations resulting in decreased copper concentrations (Chap. 92).

Zinc contributes to gene expression and chelates with either cysteine or histidine in a tetrahedral configuration, forming looped structures known as “zinc fingers,” which bind to specific DNA regions.<sup>12,105</sup> Other functions of zinc include membrane stabilization, vitamin A metabolism, and the development and maintenance of the nervous system. Zinc is important for fetal growth. When 29 pregnant mothers who were at risk for small for gestational age babies were given zinc citrate, zinc sulfate, or zinc aspartate, no intrauterine growth retardation was observed.<sup>91</sup> Subsequent studies demonstrated that zinc supplementation in women with low serum zinc concentrations in early pregnancy is associated with greater infant birth weights and head circumferences.<sup>37</sup>

Zinc is important in maintaining olfactory and gustatory function (Chap. 25). Serum, urine, and salivary zinc concentrations are lower in patients with dysfunctional senses of smell or taste. This is thought to be related to an abnormality in a salivary growth factor known as gustin/carbonic anhydrase VI.<sup>43</sup> Because this enzyme is zinc dependent, oral zinc produced subjective improvement in taste and smell in patients with a known decrease in parotid gustin/carbonic anhydrase VI complex.<sup>44</sup> Oral zinc sulfate also improved subjective findings in a group of 25 patients with post-traumatic olfactory disorders.<sup>6</sup>

Zinc gluconate supplementation, when added to corticosteroid therapy, was beneficial in patients with sudden sensorineural hearing loss when compared to corticosteroid treatment alone. The antioxidant and antiinflammatory effect on the cochlea is thought to be the mechanism for this benefit.<sup>107</sup>

The role of zinc in the immune system is undefined. Zinc therapy remains controversial for nonspecific infectious diarrhea.<sup>80</sup> However, it appears to be beneficial specifically in the management of *Shigella* spp by improving the shigellacidal antibody response and increasing circulating B lymphocytes and plasma cells.<sup>82,83</sup>

Zinc gluconate and zinc acetate containing lozenges are sold as dietary supplements with conflicting evidence that they shorten the duration of the “common cold.”<sup>50,66</sup> One placebo-controlled study found that zinc nasal gel shortened the duration of viral syndromes when applied within 24 hours of the onset of symptoms.<sup>45</sup> A subsequent systematic review concluded that zinc administration within 24 hours of onset of symptoms reduces the duration and severity of the common cold in healthy people. In addition, when supplemented for at least 5 months, it reduces cold incidence, school absenteeism, and prescription of antibiotics in children.<sup>92</sup>

Zinc deficiency, or hypozincemia, is a well described clinical entity. It is either inherited as an autosomal recessive pattern known as acrodermatitis enteropathica, or develops due to a defect in zinc absorption in the gastrointestinal (GI) tract.<sup>77</sup> Additional patients at risk for acquiring the disorder include patients who receive total parenteral nutrition without adequate zinc supplementation, patients who have undergone intestinal bypass procedures, those with Crohn’s disease, and premature infants with low zinc stores. A nationwide shortage of injectable zinc resulted in the development of dermatitis in the diaper region, perioral erosions, and bullae on the dorsal surfaces of the hands and feet in premature infants requiring parenteral nutrition due to severe cholestasis.<sup>1</sup> Excessive ingestion of phytates (the primary storage of phosphates) in whole grains, legumes, nuts, and seeds also decreases zinc absorption.<sup>40</sup> Physical findings that suggest the diagnosis of zinc deficiency, regardless of etiology, include the triad of dermatitis

(acral and perioral), diarrhea, and alopecia. Zinc salts, in initial doses of 5 to 10 mg/kg/day of elemental zinc followed by maintenance doses of 1 to 2 mg/kg/day, are highly effective as a treatment regimen. In fact, skin lesions typically heal within 2 to 4 weeks, and hair growth is also reestablished during this time frame.

The US Food and Drug Administration (FDA) approved zinc acetate in 1997 for maintenance therapy of Wilson disease, a disorder associated with copper overload.<sup>13,63</sup> Its use in this disorder is related to the ability of zinc to induce the formation of metallothionein, which assists in the elimination of copper from the blood and body tissues (Chap. 92).<sup>7</sup>

## TOXICOKINETICS AND PATHOPHYSIOLOGY

Following ingestion, the main site of zinc absorption is the jejunum, although absorption occurs throughout the intestine. Binding to metallothionein, which is a zinc protein complex found in the luminal cells, facilitates this absorption.<sup>104</sup> Metallothioneins are family of specific metal binding proteins with diverse and complex functions considered essential to metal homeostasis. Metallothioneins are relatively low molecular weight (3,500–14,000 Da) and are rich in thiol ligands; it is these ligands that allow high affinity binding to metals such as zinc, copper, cadmium, mercury, and silver. Metallothioneins regulate the peripheral utilization of zinc and copper once they are bound.<sup>33</sup> Excess zinc absorption leads to upregulation of metallothioneins as a counterregulatory mechanism to prevent excess plasma absorption. However, the affinity of other metals, especially copper, is higher for metallothioneins, resulting in excessive copper elimination and hence decreased absorption. The primary route of excretion of the copper and zinc metallothioneins complexes is fecal. In addition, sequestration of copper in the absorptive cells of the enterocytes also plays a role in the decreased peripheral utilization of copper.<sup>24</sup> Very little metallothionein is bound to zinc or copper in the blood as it is primarily an intracellular cytosolic molecule.<sup>8</sup> Albumin binds about two-thirds of zinc in the plasma, and the remainder is bound to  $\alpha_2$ -globulins.<sup>85</sup> Zinc concentrations in the body show a great variability by organ, with the prostate having the highest concentration because of the presence of the zinc-containing enzyme acid phosphatase.<sup>9</sup>

Zinc salts are used to enhance the solubility of pharmaceuticals such as insulin. Certain salts, such as zinc oxide, are used in baby powder, sun blocks, and topical burn preparations, and are also used on both latex and latex-free gloves. In contrast, the use of oral zinc salts within 3 hours of cephalexin administration decreased peak serum concentrations, which is suggested to result from its inhibitory effects on intestinal transport peptides. This finding may imply that the absorption of all orally administered  $\beta$ -lactam antibiotics are altered as they are all dependent on these intestinal transport peptides.<sup>26</sup>

## CLINICAL MANIFESTATIONS

The toxicity of zinc is dependent on the route of exposure. Each zinc compound has similar toxic manifestations following oral and dermal exposure. However, they have unique inhalational toxicities. The metallic form of zinc is not toxic per se, and only the salt forms are considered here unless otherwise specifically mentioned. The acute and chronic toxic doses of each compound and route of exposure are difficult to define because of a lack of human studies.

### Acute

The hallmark of acute oral zinc salt ( $Zn^{2+}$ ) toxicity is GI distress, including nausea, vomiting, abdominal pain, and gastrointestinal hemorrhage.<sup>9</sup> In initial studies that evaluated the oral use of zinc sulfate ( $ZnSO_4$ ) as an acne therapy, epigastric distress occurred in 33% of patients.<sup>28,36</sup> Zinc chloride solutions in concentrations greater than 20% are particularly corrosive when ingested. Partial- and full-thickness burns to the oral mucosa, pharynx, esophagus, and stomach, as well as to the laryngo-tracheal tree, occur even following small unintentional ingestions of zinc chloride by children.<sup>22,56,71</sup> Delayed gastric stricture is reported after acute<sup>71</sup> or chronic zinc chloride consumption.<sup>20,98</sup> Pancreatitis was noted in a piglet model<sup>34</sup> and also in a 24-year-old man who inadvertently ingested liquid zinc chloride.<sup>22</sup>

Hyperamylasemia, acute respiratory distress syndrome (ARDS), hypotension, vomiting, diarrhea, jaundice, anemia, thrombocytopenia, and subsequent death occurred following an unintentional 60-hour intravenous infusion of 7.4 g of zinc sulfate in a total parenteral nutrition formula. The patient's serum zinc concentration was 4,184 mcg/dL.<sup>13</sup> A 14-week premature neonate received a 1,000-fold error increase in the concentration of zinc in her total parenteral nutrition. Rather than 330 mcg/dL, she received 330 mg/dL, which resulted in hypotension, respiratory failure, and death despite the administration of edetate calcium disodium ( $CaNa_2EDTA$ ).<sup>38</sup>

The degree of inhalational toxicity is dependent on the type of zinc salt involved in an exposure. The water solubility of the various zinc salts plays an important role in the extent and time to onset of pulmonary toxicity. The solubility of zinc chloride in water at 77°F (25°C) is 432 g/100 mL, whereas that of zinc oxide at 84°F (29°C) is 0.00016 g/100 mL.<sup>85</sup> Acute inhalation of zinc chloride from smoke bombs produces lacrimation, rhinitis, dyspnea, stridor, and retrosternal chest pain. Upper respiratory tract inflammation and ARDS occur, generally without renal or hepatic manifestations of systemic absorption.<sup>35,47,48,68</sup> Morbidity and mortality increase when the exposure to a zinc chloride smoke bomb occurs in an enclosed space.<sup>88</sup> Of 70 individuals exposed to a zinc chloride smoke bomb in a tunnel during World War II, 10 died within 4 days. Ambient zinc concentrations in the tunnel were measured at 33,000 mg/m<sup>3</sup>.<sup>30</sup> Inhalation of zinc oxide, a far less water-soluble zinc salt, is associated with metal fume fever and not pneumonitis or ARDS despite similar ambient zinc concentrations (Chap. 121).<sup>9</sup>

Despite the importance of zinc in gustatory function, there is an association of intranasal zinc use and anosmia.<sup>93</sup> Animal research suggests that intranasal zinc sulfate use causes transient or persistent anosmia as a consequence of anatomic disruption of functional connections between the olfactory bulb and the olfactory epithelium.<sup>69</sup> Topical zinc sulfate is used experimentally in murine models to induce anosmia.<sup>102</sup> Multiple patients, ages 31 to 55 years, who developed a burning sensation after intranasal zinc gluconate application to the olfactory epithelium for therapeutic purposes later developed either a long-lasting or permanent anosmia and olfactory dysfunction.<sup>53</sup> The mechanism of zinc-induced hyposmia and anosmia is thought to be a direct result of proteolytic destruction of the olfactory receptor cells.<sup>25</sup>

United States pennies (97.5% Zn and 2.5% Cu) lodged in the distal esophagus release zinc ions following exposure to gastric acids and can damage the local esophageal tissue.<sup>17</sup> The phenomenon of acid dissolution is demonstrated in animal<sup>4</sup> and in vitro models.<sup>74</sup>

Rare reports of renal complications exist. Hematuria was observed in a 24-year-old man who ingested liquid zinc chloride, but kidney function remained otherwise normal.<sup>22</sup> Intravenous zinc sulfate administration can result in acute tubular necrosis and acute kidney injury.<sup>13</sup>

Certain zinc salts, such as zinc oxide, found in baby powders and calamine lotion, are usually nonirritating for intact skin.<sup>5</sup> Although older studies suggested the possibility of pruritic, pustular rashes in workers who are exposed to zinc oxide, other causative factors, including personal hygiene, were not considered.<sup>100</sup> One case report describes urticaria and angioedema in a 34-year-old welder following contact with zinc oxide fumes at a smelting plant.<sup>31</sup> The patient was asymptomatic once he was removed from the environment and had no further difficulty during the welding process when appropriate personal protective equipment was employed.

### Chronic

Several individual case reports demonstrate the significant implications of chronic zinc exposure. Chronic zinc toxicity following nutritional supplements and the ingestion of coins produces a reversible sideroblastic anemia manifested by anemia and granulocytopenia associated with bone marrow demonstrating vacuolated myeloid and erythroid precursors and ringed sideroblasts.<sup>14</sup> The mechanism for this reversible sideroblastic anemia appears to be a zinc-induced copper deficiency.<sup>32</sup>

A 55-year-old schizophrenic patient with a 15-year history of pica typically of metal objects and frequently zinc-containing pennies, presented with

pancytopenia, including a hemoglobin of 3 g/dL and a white blood cell count of 1,300/mm<sup>3</sup>. He had a serum zinc concentration of 280 mcg/mL and low serum copper concentration of less than 0.05 mcg/mL.<sup>57</sup> The patient refused surgery to remove the coins, which formed a massive bezoar in his GI tract. The patient continued to ingest coins and ultimately died of sepsis and multiorgan failure. An autopsy revealed a coin mass, almost all of which were pennies, weighing 1,870 g in his stomach and another bezoar at the site of a sigmoid volvulus.

Over a 6- to 7-month period, a 17-year-old boy used significant doses of oral vitamins and mineral supplements containing zinc to treat acne and developed copper deficiency and anemia, leukopenia, and neutropenia.<sup>87</sup> A 28-month-old boy developed anemia, neutropenia, and developmental delay after 11 months of parental administration of 314 mg/day of oral zinc gluconate (3.6 mg/kg/day of elemental zinc).<sup>96</sup> Hyperzincemia and hypocupremia were present and improved after discontinuation of zinc without copper supplementation.

It is suggested that zinc and other transition metals are important in the pathogenesis of demyelinating diseases.<sup>59,81</sup> Clusters of cases of multiple sclerosis (MS) were described in northern New York in a factory where zinc was the primary occupational exposure. One hypothesis is that the allele frequency for transferrin (an iron- and zinc-binding protein) differs in these MS subjects.<sup>89,95</sup> Another cluster was found in Canada where excess metals, including zinc, were found in the soil and water.<sup>39,51,52</sup> A conclusive link to MS, however, has not been established.

Because the prostate contains the highest concentration of zinc in the human body, the role of zinc in the development of prostate cancer has been investigated. Specifically, American men participating in the Health Professionals Follow-Up Study were followed for 14 years, from 1986 to 2000. Of the 46,974 in the cohort, 2,901 new cases of prostatic cancer were diagnosed, with 434 of them considered to be in an advanced stage.<sup>63</sup> Men who used zinc supplementation at a dose greater than 100 mg/day had a relative risk of 2.29 for advanced prostate cancer, and those using zinc for longer than 10 years had a relative risk of 2.37. Neither the International Agency for Research on Cancer (IARC) nor the Environmental Protection Agency (EPA) currently classify zinc as a carcinogen.

The Third National Health and Nutrition Examination Survey examined the association of higher dietary zinc intake on the risk of kidney stone disease. Dietary zinc intake of greater than 15 mg/day was associated with a significantly increased risk of kidney stones compared to those with a dietary zinc intake less than 7 mg/day. More rigorous studies are required to determine causality and a potential underlying mechanism for this association.<sup>97</sup>

A neurologic syndrome of progressive myeloneuropathy called “sway-back” is defined by a spastic gait, usually a prominent sensory ataxia, and hematologic manifestations.<sup>58,59,61,62</sup> These cases involve patients with copper deficiency and typically elevated serum zinc concentrations. A history of excess zinc exposure is obtained in some but not all patients. The potential of an inherited zinc overload syndrome was considered.<sup>41</sup> A 46-year-old man presented with evidence of bone marrow suppression followed by sensory ataxia and a progressive myelopathy. His neuroimaging evaluation was normal. His only remarkable laboratory studies included an elevated serum zinc concentration of 184 mcg/dL (28.1 μmol/L) and a low copper concentration of less than 10 mcg/dL (<1.57 μmol/L). There was no known occupational exposure or supplementation of zinc by history. Although his copper deficit improved with copper therapy, hyperzincemia persisted for more than the 3 years that he was followed. More recently, an unusual source of high zinc concentrations was related to denture creams, which contained as much as 34 g of zinc per gram of cream. Four patients with chronic exposure to excess denture cream developed neurologic abnormalities in the setting of hyperzincemia with associated hypocupremia.<sup>73</sup> Multiple other reports have confirmed the relationship between denture cream, hyperzincemia, hypocupremia, and the development of this progressive myeloneuropathy. The history in these patients often reveals poor fitting dentures as well as use of dentures during sleep.<sup>3,11,42,94</sup>

Patients with underlying Wilson disease are also at risk for chronic zinc overload syndromes due to treatment. Reports express concern

over increased use of zinc in the treatment of Wilson disease, with recommendations for more frequent monitoring of zinc and copper blood concentrations.<sup>49,84,106</sup>

Chronic inhalation of zinc oxide lowers blood copper and serum calcium concentrations. However, no long-term effect on ventilatory function or chest radiography is reported.<sup>29</sup>

### Occupational Exposures

Since 1983, the US penny is composed of 97.5% zinc and 2.5% copper.<sup>101</sup> Zinc is widely used in industry because it enhances the durability of iron and steel alloys; it also is commonly used in construction. Galvanization involves coating an iron product with metallic zinc to prevent it from oxidizing (rusting). Electroplaters, smelters, jewelers, artists working on stained glass or sculpting metal, as well as aircraft manufacturing workers, are routinely exposed to zinc. Zinc chloride is an essential component of flux, which can be used for soldering of galvanized iron.

Zinc is present in drinking water and beverages stored in metal containers or that flow through pipes coated with zinc. Zinc concentrations in air are typically low; average zinc concentrations in the United States are less than 1 mcg/m<sup>3</sup>. Air concentrations near industrial zones can be higher, and are typically substantially greater in certain occupational settings such as mining and smelting. The currently accepted occupational threshold limit value (TLV)-time-weighted average (TWA) is 1 mg/m<sup>3</sup>.<sup>85</sup>

### Metal Fume Fever

Metal fume fever typically occurs within 12 hours after an exposure to metal oxide fumes. Patients develop fever, chills, cough, myalgias, muscle cramping, chest pain, dyspnea, dry throat, and a metallic taste in the mouth. Although exposure to zinc oxide fumes is the commonest zinc etiology, other zinc salts are implicated. Although the chest radiograph is often normal, infiltrates are common finding. Hypoxia and tachycardia are rare, but reported. Overall, however, the syndrome is relatively benign, with tolerance developing within days.<sup>29</sup> An immune mechanism is suggested, and chronic exposure leads to sensitization (Chap. 121).<sup>23</sup>

### DIAGNOSTIC TESTING

Because zinc is ubiquitous in the environment and laboratory, great care must be taken to avoid contamination of any samples intended for investigation.<sup>85</sup> Because elevated zinc concentrations cause copper deficiency, a serum copper and ceruloplasmin concentration should be obtained in patients with suspected zinc poisoning.

Urine zinc concentrations are not well defined. In a cohort of non-occupationally exposed patients, the mean urine concentrations were 450 mcg/L, with a maximum concentration up to 1,300 mcg/L.<sup>72</sup> In the United States, normal urine concentrations are generally accepted as less than 500 mcg/d. The National Institute for Occupational Safety and Health established detection limits in urine and blood or tissue as low as 0.1 mcg per sample and 1 mcg/100 g, respectively. Testing requires extraction of the metals from urine with polydithiocarbamate resin prior to digestion with concentrated acids and analysis.<sup>85</sup>

Errors are caused by incorrect sample collection, equipment malfunction or miscalibration, inadequate reagent purity, and atmospheric deposition. Zinc oxide powder in some gloves can contaminate specimens, as can the rubber stoppers in certain blood collection tubes. Specific tubes are recommended with exceptionally low concentrations of trace elements.<sup>19</sup> During sample analysis, laminar flow is recommended to prevent airborne particles from interfering.

Abdominal radiographs have limited utility in determining the gastrointestinal burden of zinc, except following ingestions of pennies. Findings should be used to guide the decision to continue gastrointestinal decontamination in certain circumstances.<sup>16</sup> (See Management below.)

Neuroimaging in patients with chronic zinc exposure and secondary copper deficiency reveals characteristic findings. The MRI typically reveals increased T2 signal in the dorsal columns of the cervical spinal cord similar to that found in B<sub>12</sub> deficiency.<sup>60</sup> These lesions are thought to represent

Wallerian degeneration and demyelination of white matter. One case showed evidence of bilateral subcortical hyperintense T2 abnormalities on an MRI of the brain.<sup>73</sup> These findings are the result of copper deficiency and not necessarily zinc toxicity.

## MANAGEMENT

Treatment for acute oral zinc salt toxicity is primarily supportive. Efforts should focus on hydration and antiemetic therapy. Histamine<sub>2</sub> receptor antagonists or proton pump inhibitors can relieve abdominal discomfort when given for several days following the zinc salt ingestion and are recommended.<sup>9</sup>

We recommend whole-bowel irrigation (WBI) for gastrointestinal decontamination after zinc salt ingestion. A radiograph in a 16-year-old boy who ingested 50 (500 mg) zinc sulfate tablets noted no change in tablet position 4 hours after gastric emptying with induced emesis followed by orogastric lavage. Within one hour of institution of WBI therapy, zinc tablets were present in the rectal effluent.<sup>16</sup> Zinc-containing penny ingestion can provide a unique challenge. A schizophrenic patient required laparotomy and gastrotomy to remove a total of 275 coins.<sup>76</sup>

The data regarding the efficacy of chelation therapy for zinc is limited in humans. Edetate calcium disodium (CaNa<sub>2</sub>EDTA) was used successfully in several cases, including a child<sup>79</sup> and a 24-year-old man who were exposed to zinc chloride as a component of soldering flux.<sup>22</sup> The combination of CaNa<sub>2</sub>EDTA and dimercaprol (British anti-Lewisite {BAL}) was used successfully in a 16 month-old 74 hours after ingestion.<sup>71</sup> However, the potential of BAL to increase copper elimination should limit its clinical use.

Both DTPA (diethylenetriaminepentaacetic acid) and CaNa<sub>2</sub>EDTA (ethylenediaminetetraacetic acid) were effective in enhancing the urinary excretion of zinc in a rodent model of zinc acetate poisoning.<sup>27</sup> Diethylenetriaminepentaacetic acid had its greatest antidotal efficacy when given within 30 minutes of the intraperitoneal injection of zinc acetate.<sup>65</sup> The urinary excretion of zinc increased 1.6- to 44-fold following a 3-mg/kg intravenous dose of DMPS (2,3-dimercaptopropane-1-sulfonate) in one human study where metal toxicity in patients with dental amalgams was the focus.<sup>99</sup> Two potential zinc-selective chelators, DPESA (4-[[2-(bis-pyridin-2-ylmethylamino)ethylamino]-methyl]phenyl]methanesulfonic acid) sodium salt, as well as TPESA(4-[[2-bis-pyridin-2-ylmethylamino) ethyl]pyridin-2-ylmethylamino]-methyl]phenyl]methanesulfonic acid) sodium salt, rapidly chelate zinc in vitro, but further detailed in vivo studies are needed before their clinical use can be considered.<sup>55</sup> Finally, an iron chelator, deferiprone, was incidentally noted to decrease serum zinc concentrations when it was used to lower iron concentrations in patients with transfusion overload (Antidotes in Depth: A7).<sup>103</sup> A subsequent prospective trial showed enhanced urinary excretion of zinc in children with thalassemia major who had received multiple blood transfusions.<sup>10</sup>

Many of the clinical manifestations and metabolic effects of zinc toxicity are due to its ability to cause copper deficiency. In patients with zinc overload-related copper deficiency, the supplementation of oral copper alone improved the hematopoietic effects and prevented further neurologic deterioration without chelation therapy.<sup>86</sup> The route of copper supplementation may be dependent on tolerability and reliability of gastrointestinal absorption. Initial recommended starting doses are 2 mg intravenously or 6 mg orally of elemental copper once per day. A decrease in dose by 2 mg each week is recommended with the goal of eventually giving 2 mg orally once per day until complete resolution of toxicity and normalization of blood concentrations occur.

Though treatment with copper sulfate alone can be adequate for patients with neurologic sequelae and mild hematopoietic effects, chelation will be required for patients with hemodynamic compromise or other consequential systemic manifestations. Limited experience exists with regard to treatment of these patients; however, 1,000 mg/m<sup>2</sup>/day IV CaNa<sub>2</sub>EDTA divided every 6 hours seems to be the most reasonable choice based on case reports of successful use.

Intravenous *N*-acetylcysteine (NAC) increased the urinary zinc excretion in a patient who had inhaled zinc chloride fumes.<sup>78</sup> Two individuals

with inhalational zinc chloride-induced ARDS had simultaneous transient decreases in serum zinc concentrations and increases in urinary zinc excretion when treated with intravenous and nebulized NAC.<sup>47</sup> However, these individuals succumbed at days 25 and 32 after inhalation. Although an increase in urinary zinc excretion was noted in one rat model, 10 healthy volunteers who were treated with oral NAC for 2 weeks had no significant change in either their serum or urine zinc concentrations.<sup>46</sup> As a result of these findings, NAC therapy cannot be recommended at this time.

Supportive care is used for patients with inhalational zinc exposures, including oxygen therapy and bronchodilators as clinically indicated; however, the seriously ill will necessitate ventilatory support. Exposure to zinc oxide fumes by rescuers is usually minimal, although respiratory protective equipment should be worn.<sup>90</sup> In a case series of 5 soldiers exposed to zinc chloride smoke bombs during military training, the 2 individuals not wearing gas masks developed ARDS;<sup>47</sup> the others remained clinically well. A 23-year-old man developed severe ARDS after inhalation of zinc chloride from a smoke bomb during a military drill. After extensive ventilatory supportive efforts, tube thoracostomy, intravenous antibiotics, and intravenous corticosteroids, the patient continued to deteriorate. The patient was placed on extracorporeal life support (ECLS), weaned off the ventilator by day 30, and survived. If ECLS is available, its use is reasonable based on clinical grounds. More prospective studies are required to determine the extent of the benefit of ECMO.<sup>21</sup>

Metal fume fever is typically self-limited. Nonsteroidal antiinflammatory drugs are usually sufficient to relieve the transient discomfort. Personal protective equipment and or adequate engineering design and strategies may allow the individual to continue to work in the particular occupational site. Personal protective equipment (PPE) is essential in preventing inhalational exposure to zinc chloride. The National Institute of Safety and Health (NIOSH) has recommended the following PPE based upon ambient air concentrations. Up to 10 mg/m<sup>3</sup>, the recommendation is use of N95, R95, or P95 filter particulate respirators. Up to 25 mg/m<sup>3</sup>, a continuous-flow respirator is required. Up to 50 mg/m<sup>3</sup>, an air-purifying full facepiece respirator with N100, R100, or P100 filter is required.

Dermal decontamination is paramount to prevent direct epidermal effects or systemic absorption of zinc salts.<sup>15</sup> However, water should not be used to perform dermal decontamination of patients exposed to metallic zinc because zinc metal ignites when wet. Treatment in these situations includes mechanical removal of any metallic particles with forceps and the application of mineral oil to the affected skin to protect the metal from ambient moisture.

## SUMMARY

- Zinc exposures in humans occur due to diet, medicinal uses, nutritional supplements, and the occupational settings.
- The clinical manifestations of zinc toxicity include acute, life-threatening gastrointestinal and pulmonary effects, which are generally effectively treated with supportive care.
- Chronic zinc toxicity manifests primarily as copper deficiency.
- Copper supplementation alone often corrects systemic manifestations.
- Chelation therapy is reasonable for patients with severe zinc toxicity.

# ANTISEPTICS, DISINFECTANTS, AND STERILANTS

Ashley Haynes and Paul M. Wax

## HISTORY AND EPIDEMIOLOGY

Joseph Lister, often considered the father of modern surgery, revolutionized surgical treatment and dramatically reduced surgical mortality by introducing the concept of antiseptics to the surgical theatre.<sup>50</sup> It was Lister's understanding that microorganisms contributed to infection and sepsis from even the most trivial wounds that led to his search for chemicals that would prevent such infection. Lister demonstrated that phenol, a chemical that was used to treat foul-smelling sewage, could be used to clean dirty wounds of patients with compound fractures and dramatically increase survival rates. Soon thereafter, the use of phenol was expanded to surgical instrument cleaning and as a surgical hand scrub wash, ushering in the modern surgical era.

Antiseptics, disinfectants, and sterilants are a diverse group of germicides used to prevent the transmission of microorganisms to patients (Table 101–1). Although these terms are sometimes used interchangeably and some of these xenobiotics are used for both antiseptics and disinfection, the distinguishing characteristics between the groups are important to emphasize. An *antiseptic* is a chemical that is applied to living tissue to kill or inhibit microorganisms. Iodophors, chlorhexidine, and the alcohols (ethanol and isopropanol) are commonly used antiseptics. A *disinfectant* is a chemical that is applied to inanimate objects to kill microorganisms. Bleach (sodium hypochlorite), phenolic compounds, formaldehyde, hydrogen peroxide liquid, *ortho*-phthalaldehyde, and quaternary ammonium compounds are examples of currently used disinfectants. Neither antiseptics nor disinfectants have complete sporicidal activity. A *sterilant* is a chemical that is applied to inanimate objects to kill all microorganisms as well as spores. Ethylene oxide, glutaraldehyde, hydrogen peroxide gas, and peracetic acid are examples of sterilants. Many of the xenobiotics used to kill microorganisms also demonstrate considerable human toxicity.<sup>18,69,180</sup>

The choice of disinfectant or sterilant depends on the degree of risk for infection involved in use of medical and surgical instruments and patient care items. Surgical instruments and cardiac and urinary catheters that enter the vascular system or other sterile tissues (so-called critical items) must be cleaned with a sterilant while instruments that contact mucous membranes or nonintact skin such as gastrointestinal (GI) endoscopes and laryngoscope blades (semicritical items) are cleaned with a high-level disinfectant such as *ortho*-phthalaldehyde or 7.5% hydrogen peroxide. Noncritical items such as bedpans, blood pressure cuffs, crutches, and computers are those that come in contact with intact skin but not mucous membranes and are cleaned with intermediate-level and low-level disinfectants such as bleach or phenol. Whether a chemical is classified as a sterilant or disinfectant depends on how it is used. Device sterilization with glutaraldehyde 3% requires a 10-hour cleaning cycle whereas high-level disinfection using the same chemical requires a 25-minute cleaning cycle.

The use of these xenobiotics evolved during the 20th century as their toxicity and the principles of microbiology became better understood. Two of the more toxic antiseptics—iodine and phenol—were gradually replaced by the less toxic iodophors and substituted phenols. The use of mercuric chloride was superseded by the organic mercurials such as merbromin and thimerosal, which also proved toxic. In recent years, newer xenobiotics, such as quaternary ammonium compounds, ethylene oxide, glutaraldehyde, and a peracetic acid–hydrogen peroxide mixture, are more extensively used.

## ANTISEPTICS

### Chlorhexidine

This cationic biguanide has had extensive use as an antiseptic since the early 1950s. It is found in a variety of skin cleansers, usually as a 4% emulsion, and is also found in some mouthwash.

### Clinical Effects

Few cases of deliberate ingestion of chlorhexidine are reported. Symptoms are usually mild, and GI irritation is the most likely effect after ingestion.<sup>25</sup> Chlorhexidine has poor enteral absorption. In one case, ingestion of 150 mL of a 20% chlorhexidine gluconate solution resulted in oral cavity edema and significant irritant injury of the esophagus.<sup>130</sup> In the same case, liver enzyme concentrations rose to 30 times normal on the fifth day after ingestion. Liver biopsy showed lobular necrosis and fatty degeneration. In another case, the ingestion of 30 mL of a 4% solution by an 89-year-old woman did not result in any GI injury.<sup>52</sup> An 80-year-old woman with dementia ingested 200 mL of a 5% chlorhexidine solution and subsequently aspirated.<sup>79</sup> She rapidly developed hypotension, respiratory distress, coma, and died 12 hours following ingestion.

Intravenous administration of chlorhexidine is associated with acute respiratory distress syndrome (ARDS)<sup>90</sup> and hemolysis.<sup>28</sup> Inhalation of vaporized chlorhexidine causes methemoglobinemia, likely as a consequence of the conversion of chlorhexidine to *p*-chloraniline.<sup>211</sup> Methemoglobinemia due to this degradation product was also reported after the ingestion of a 0.5% chlorhexidine in 70% ethanol solution.<sup>107</sup> This patient was successfully treated with methylene blue. In one patient, the rectal administration of 4% chlorhexidine resulted in acute colitis with ulcerations.<sup>68</sup>

Topical absorption of chlorhexidine is negligible. Contact dermatitis is reported in up to 8% of patients who received repetitive topical applications of chlorhexidine.<sup>69</sup> More ominously, anaphylactic reactions, including shock, are associated with dermal application.<sup>7,148</sup> Some of these cases of chlorhexidine-related anaphylaxis occurred during surgery, appearing 15 to 45 minutes after application of the antiseptic.<sup>13</sup> Eye exposure results in corneal damage.<sup>205</sup>

### Management

Treatment guidelines for chlorhexidine exposure are similar to those for other potential caustics (Chap. 103). Patients with significant symptoms should undergo endoscopy, but the need for such extensive evaluation is uncommon.

### Hydrogen Peroxide

Hydrogen peroxide, an oxidizer with weak antiseptic properties, has a long history of use as an antiseptic and a disinfectant.<sup>215</sup> This oxidizer is generally available in 2 strengths: dilute, with a concentration of 3% to 9% by weight (usually 3%), sold for home use; and concentrated, with a concentration greater than 10%, used primarily for industrial purposes. Commercial-strength hydrogen peroxide is commonly found in solutions varying from 27.5% to 70%. Home uses for dilute hydrogen peroxide include cerumen removal, mouth gargle, vaginal douche, enema, and hair bleaching. Dilute hydrogen peroxide is also used as a veterinary emetic. Commercial uses of the more concentrated solutions include bleaching and cleansing textiles and wool, and producing foam rubber and rocket fuel.

TABLE 101-1 Antiseptics, Disinfectants, Sterilants, and Related Xenobiotics

<i>Xenobiotic</i>	<i>Commercial Product</i>	<i>Use</i>	<i>Toxic Effects</i>	<i>Therapeutics and Evaluation</i>
<b>Acids</b>				
Boric acid	Borax Sodium perborate Dobell solution	Antiseptic Mouthwash Eyewash Roach powder	Blue-green emesis and diarrhea Boiled lobster appearance of skin Central nervous system (CNS) depression; kidney failure	Orogastric lavage Hemodialysis (rare)
<b>Alcohols</b> (Chaps. 76 and 106)				
Ethanol	Rubbing alcohol (70% ethanol)	Antiseptic Disinfectant	CNS depression Respiratory depression Dermal irritant	Supportive
Isopropanol	Rubbing alcohol (70% isopropanol)	Antiseptic Disinfectant	CNS depression Respiratory depression Ketonemia, ketonuria Gastritis/hemorrhage Hemorrhagic tracheobronchitis	Supportive Hemodialysis (rare)
<b>Aldehydes</b>				
Formaldehyde	Formalin (37% formaldehyde, 12%–15% methanol)	Disinfectant Fixative Urea-formaldehyde insulation	Caustic CNS depression Carcinogen	Orogastric lavage Hemodialysis Sodium bicarbonate Endoscopy Folinic acid
Glutaraldehyde <i>ortho</i> -Phthalaldehyde (OPA)	Cidex (2% glutaraldehyde) Cidex OPA (<1% OPA)	Sterilant Sterilant	Mucosal and dermal irritant Mucosal and dermal irritant	Supportive Supportive
<b>Chlorinated Compounds</b>				
Chlorhexidine	Hibiclens	Antiseptic	GI irritation	Supportive
Chlorates	Sodium chlorate Potassium chlorate	Antiseptic (obsolete) Matches Herbicide	Hemolysis Methemoglobinemia Kidney failure	Exchange transfusion Hemodialysis
Chlorine	Household bleach (5% NaOCl)	Disinfectant	Irritant	Supportive
Chlorophors (sodium hypochlorite)	Dakin solution (1 part 5% NaOCl, 10 parts H <sub>2</sub> O)	Disinfectant Decontaminating solution	Mild GI irritation	Endoscopy (rare)
<b>Ethylene Oxide</b>				
		Sterilant Plasticizer	Irritant CNS depression Peripheral neuropathy Carcinogen, mutagen	Supportive
<b>Mercurials</b>				
Merbromin 2% (Mercurochrome)		Antiseptic (obsolete)	CNS	Orogastric lavage, activated charcoal dimercaprol, succimer
(Chaps. 46 and 95)	Thimerosal (Merthiolate)		Kidney	
<b>Iodinated Compounds</b>				
Iodine	Tincture of iodine (2% iodine, 2% sodium iodide, and 50% ethanol) Lugol solution (5% iodine)	Antiseptic	Caustic	Orogastric lavage Milk, starch, sodium thiosulfate
Iodophors	Povidone-iodine (Betadine) (0.01% iodine)	Antiseptic	Limited	Endoscopy Same as iodine
<b>Oxidants</b>				
Hydrogen peroxide	H <sub>2</sub> O <sub>2</sub> 3%—household H <sub>2</sub> O <sub>2</sub> 30%—industrial	Disinfectant	Oxygen emboli Caustic	Orogastric lavage Radiographic evaluation Endoscopy
Potassium permanganate	Crystals, solution	Antiseptic	Oxidizer, caustic, increased serum manganese	Decontamination Endoscopy
<b>Phenols</b>				
Nonsubstituted	Phenol	Disinfectant	Caustic Dermal burns Cutaneous absorption CNS effects	Decontamination: polyethylene glycol or water Endoscopy
Substituted	Hexachlorophene	Disinfectant	CNS effects	Supportive
<b>Quaternary Ammonium Compounds</b>				
Benzalkonium chloride	Zephiran	Disinfectant	Caustic	Endoscopy as needed

A 35% hydrogen peroxide solution is also available to the general public in health food stores and is sold as “hyperoxygenation therapy” and as an additive to oxygenate health food drinks.<sup>86</sup> This potentially dangerous therapy is suggested as a treatment for a variety of conditions, including AIDS and cancer.

Toxicity from hydrogen peroxide occurs after ingestion, inhalation, injection, wound irrigation, rectal administration, dermal exposure, and ophthalmic exposure.<sup>215</sup> Hydrogen peroxide has 2 main mechanisms of toxicity: local tissue injury and gas formation. The extent of local tissue injury and amount of gas formation are determined by the concentration of the hydrogen peroxide. Dilute hydrogen peroxide is an irritant, and concentrated hydrogen peroxide is a caustic. Gas formation results when hydrogen peroxide interacts with tissue catalase, liberating molecular oxygen, and water. At standard temperature and pressure, 1 mL of 3% hydrogen peroxide liberates 10 mL of oxygen, whereas 1 mL of the more concentrated 35% hydrogen peroxide liberates more than 100 mL of oxygen. Gas formation results in life-threatening embolization. The ingestion of “2 sips” of 33% hydrogen peroxide resulted in cerebral gas embolization and hemiplegia.<sup>173</sup> Gas embolization is a result of dissection of gas under pressure into the tissues or of liberation of gas in the tissue or blood following absorption. The use of hydrogen peroxide in partially closed spaces, such as operative wounds, or its use under pressure during wound irrigation increases the likelihood of embolization.

### Clinical Effects

Airway compromise manifested by stridor, drooling, apnea, and radiographic evidence of subepiglottic narrowing occurs.<sup>44</sup> The combination of local tissue injury and gas formation from the ingestion of concentrated hydrogen peroxide causes abdominal bloating, abdominal pain, vomiting, and hematemesis.<sup>55,123</sup> Endoscopy shows esophageal edema and erythema and significant gastric mucosal erosions.<sup>162,182</sup>

Symptoms consistent with sudden oxygen embolization include rapid deterioration in mental status, cyanosis, respiratory failure, seizures, ischemic ECG changes, and acute paraplegia.<sup>57,119</sup> A 2-year-old boy died after ingesting 120 to 180 mL of 35% hydrogen peroxide.<sup>30</sup> Antemortem chest radiography showed gas in the right ventricle, mediastinum, and portal venous system. Portal vein gas is also a prominent feature in other cases.<sup>55,85,155</sup> Arterialization of oxygen gas embolization results in cerebral infarction.<sup>189</sup> Encephalopathy with cortical visual impairment<sup>23</sup> and bilateral hemispheric infarctions detected by MRI imaging occurred after ingestion of concentrated hydrogen peroxide.<sup>89</sup> In a case of acute paraplegia after the ingestion of 50% hydrogen peroxide, MRI revealed discrete segmental embolic infarctions of the cervical and thoracic spinal cord as well as both cerebral hemispheres and left cerebellar hemisphere.<sup>119</sup>

Death from intravenous injection of 35% hydrogen peroxide is also reported.<sup>112</sup> The application of a concentrated hydrogen peroxide solution to the scalp and hair as part of a hair highlighting procedure resulted in a severe scalp injury, including necrosis of the galea aponeurotica.<sup>183</sup>

Clinical sequelae from the ingestion of dilute hydrogen peroxide are usually much more benign.<sup>44,76</sup> Nausea and vomiting are the most common symptoms.<sup>44</sup> A whitish discoloration is noted in the oral cavity. Gastrointestinal injury is usually limited to superficial mucosal irritation, but multiple gastric and duodenal ulcers, accompanied by hematemesis, and diffuse hemorrhagic gastritis are reported.<sup>76,136</sup> Portal venous gas embolization occurs as a result of the ingestion of 3% hydrogen peroxide.<sup>31,136,166</sup>

The use of 3% hydrogen peroxide for wound irrigation results in significant complications. Extensive subcutaneous emphysema occurred after a dog bite to a human's face was irrigated under pressure with 60 mL of 3% hydrogen peroxide.<sup>192</sup> Systemic oxygen embolism, causing hypotension, cardiac ischemia, and coma, resulted from the intraoperative irrigation of an infected herniorrhaphy wound.<sup>12</sup> Gas embolism, resulting in intestinal gangrene, was reported to occur following colonic lavage with 1% hydrogen peroxide during surgical treatment of meconium ileus.<sup>187</sup> Multiple cases of acute colitis are reported as a complication of administering 3% hydrogen peroxide

enemas.<sup>132</sup> The use of 3% hydrogen peroxide as a mouth rinse is associated with the development of oral ulcerations.<sup>170</sup> Ophthalmic exposures result in conjunctival injection, burning pain, and blurry vision.<sup>44,131</sup> Optic neuropathy including transient blindness (ability to visualize shadows only) and subsequent optic atrophy from possible inhalational of hydrogen peroxide is described.<sup>45</sup> Cough, wheezing, and shortness of breath is associated with occupational exposure to peracetic acid–hydrogen peroxide mixtures used to clean endoscopic equipment.<sup>36</sup>

### Diagnosis

A careful examination should be performed to detect any evidence of gas formation. A chest radiograph is recommended to assess for gas in the cardiac chambers, mediastinum, or pleural space. Likewise, an abdominal radiograph is also recommended to assess for gas in the GI tract or portal system and define the extent of bowel distension. Magnetic resonance imaging and CT imaging are reasonable to detect brain and spinal cord lesions secondary to gas embolism and should be obtained if patient experiences neurologic effects.<sup>5,89,119</sup> For those with clinical presentations consistent with esophageal, gastric or intestinal injury, endoscopic evaluation is recommended.<sup>162</sup>

### Management

The treatment of patients with hydrogen peroxide ingestions depends, to a large degree, on whether the patient has ingested a diluted or concentrated solution. Those with ingestions of concentrated solutions require expeditious evaluation. There is not enough evidence to support the dilution with milk or water. Nasogastric or orogastric aspiration of hydrogen peroxide is reasonable to consider if the patient presents immediately after ingestion. Induced emesis and activated charcoal are contraindicated. Gastric suctioning for patients with abdominal distension from gas formation is recommended. Place patients with clinical or radiographic evidence of gas in the heart in the Trendelenburg position to prevent gas from blocking the right ventricular outflow tract. Careful aspiration of intracardiac air through a central venous line is recommended in patients in extremis.<sup>30</sup> Hyperbaric therapy is recommended in cases of life-threatening gas embolization after hydrogen peroxide ingestion.<sup>55,85,119,138,155,211</sup> We recommend home observation for asymptomatic patients who unintentionally ingest small amounts of 3% hydrogen peroxide.

### Iodine and Iodophors

Iodine is one of the oldest topical antiseptics.<sup>184</sup> Iodine usually refers to molecular iodine, also known as I<sub>2</sub>, free iodine, and elemental iodine, which is the active ingredient of iodine-based antiseptics. The use of ethanol as the solvent, such as in tincture of iodine, allows substantially more concentrated forms of I<sub>2</sub> to be available. Iodine (I<sub>2</sub>) and tincture of iodine ingestions are much less common than in the past as a result of the change in antiseptic use from iodine to iodophor antiseptics.<sup>46</sup>

Iodophors have molecular iodine compounded to a high-molecular-weight carrier or to a solubilizing xenobiotic. Povidone-iodine, a commonly used iodophor, consists of iodine linked to polyvinylpyrrolidone (povidone). Iodophors, which limit the release of molecular iodine and are generally less toxic, are the current standard iodine-based antiseptic preparations. Iodophor preparations are formulated as solutions, ointments, foams, surgical scrubs, wound-packing gauze, and vaginal preparations. The most common preparation is a 10% povidone-iodine solution that contains 1% “available” iodine (referring to all oxidizing iodine species), but only 0.001% free iodine (referring only to molecular iodine).<sup>18,69</sup>

Iodine is used to disinfect medical equipment and drinking water. Iodine is effective against bacteria, viruses, protozoa, and fungi, and is used both prophylactically and therapeutically.<sup>42</sup> Iodine is cytotoxic and also an oxidant. It is thought to work by binding amino and heterocyclic nitrogen groups, oxidizing sulfhydryl groups, and saturating double bonds. Iodine also iodates tyrosine groups.<sup>69</sup> It appears to induce apoptosis through oxidative stress.<sup>95</sup>

Significant systemic absorption of iodine from topical iodine or iodophor preparations is rare.<sup>157</sup> Markedly elevated iodine concentrations occur in

patients who receive topical iodophor treatments to areas of dermal breakdown, such as burn injuries.<sup>109</sup> Significant absorption occurs when iodophors are applied to the vagina, perianal fistulas, umbilical cords, and the skin of low-birth-weight neonates.<sup>212</sup> The mucosal application of povidone-iodine during a hysteroscopy procedure resulted in acute kidney injury (AKI) that transiently required hemodialysis.<sup>14</sup> A fatality following intraoperative irrigation of a hip wound with povidone-iodine was also reported.<sup>37</sup> In this latter case, the postmortem serum iodine concentration was 7,000 mcg/dL (normal: 5–8 mcg/dL).

### Clinical Effects

Problems associated with the use of iodine include unpleasant odor, skin irritation, allergic reactions, and clothes staining. Ingestion of iodine causes abdominal pain, vomiting, diarrhea, GI bleeding, delirium, hypovolemia, anuria, and circulatory collapse. Severe caustic injury of the GI tract occurs. The ingestion of approximately 45 mL of a 10% iodine solution resulted in death from multisystem failure 67 hours after ingestion.<sup>48</sup> In another case, the ingestion of 200 mL of tincture of iodine containing 60 mg/mL iodine and 40 mg/mL potassium iodide in 70% v/v ethanol resulted in AKI and severe hemolysis.<sup>126</sup>

Reports of adverse consequences from iodophor ingestions are rare. In one case report, a 9-week-old infant died within 3 hours of receiving povidone-iodine by mouth.<sup>106</sup> In this unusual case, the child was administered 15 mL of povidone-iodine mixed with 135 mL of polyethylene glycol by nasogastric tube over a 3-hour period for the treatment of infantile colic. Postmortem examination showed an ulcerated and necrotic intestinal tract. A blood iodine concentration of 14,600 mcg/dL was recorded. Significant toxicity from intentional ingestions of iodophors in adults is not documented.

Acid–base disturbances are among the most significant abnormalities associated with iodine and iodophors. Metabolic acidosis occurred in several burn patients after receiving multiple applications of povidone-iodine ointment.<sup>109,158</sup> These patients had elevated serum iodine concentrations and normal lactate concentrations. The exact etiology of the acidosis remains unclear. Postulated mechanisms for the acidosis include the povidone-iodine itself (pH 2.43), bicarbonate consumption from the conversions of I<sub>2</sub> to NaI, and decreased renal elimination of H<sup>+</sup> as a consequence of iodine toxicity.<sup>158</sup> Metabolic acidosis associated with an elevated lactate concentration after iodine ingestion likely reflects tissue destruction.<sup>42</sup>

Electrolyte abnormalities also occur following the absorption of iodine. A patient with decubitus ulcers who received prolonged wound care with povidone-iodine-soaked gauze developed hypernatremia, hyperchloremia, metabolic acidosis, and AKI.<sup>37</sup> The hyperchloremia was thought to be caused by a spurious elevation of measured chloride ions as a consequence of the interference of iodine with the chloride assay. This interference occurs on the Technicon STAT/ION autoanalyzer, but does not occur when the silver halide precipitation assay is used.<sup>42</sup> Spurious hyperchloremia from iodine (or iodide) results in the calculation of a low or negative anion gap (Chaps. 7 and 12).<sup>24,54</sup> The spurious effect of iodide on chloride and anion gap occurs even with very low serum iodide concentrations (<1 mEq/L) and the degree of anion gap deviation does not reliably predict the amount of iodide present.<sup>105</sup>

Other problems associated with topical absorption of iodine-containing preparations are hypothyroidism (particularly in neonates),<sup>24,193</sup> hyperthyroidism,<sup>169,174</sup> elevated liver enzyme concentrations, neutropenia, anaphylaxis,<sup>1</sup> and hypoxemia.<sup>42</sup> Because of the lack of consistency between iodine concentrations and clinical manifestations, and because many of these patients had significant secondary medical problems that contributed to their symptoms, the exact relationship between iodine absorption and the development of a specific clinical syndrome remains speculative. However, a clinical controlled trial that compared preterm infants exposed to either topical iodinated antiseptics or to chlorhexidine-containing antiseptics showed that the infants exposed to topical iodine-containing antiseptics were more likely to have higher TSH concentrations and elevated urine iodine concentrations than were those in the chlorhexidine group.<sup>116</sup>

Contact dermatitis can result from repetitive applications of iodophors.<sup>127</sup> A dermal burn results from the trapping of an iodophor solution under the body of a patient in a pooled dependent position or under a tourniquet.<sup>118,142</sup> Aspiration pneumonitis is rarely described following the intraoperative application of povidone-iodine prior to craniofacial surgeries.<sup>27</sup> These patients generally recover with supportive care.

### Management

The patient who ingests iodine requires expeditious evaluation, stabilization, and decontamination. If signs of perforation are absent, it is reasonable to proceed with careful nasogastric or orogastric aspiration and lavage to limit the caustic effect of the iodine. In symptomatic patients, irrigation with a starch solution is recommended to convert iodine to the much less toxic iodide and, in the process, turn the gastric effluent dark blue-purple. This change in color is a useful guide in determining when lavage can be terminated. If starch is not available, milk or 100 mL of a solution of 1% to 3% sodium thiosulfate is a reasonable alternative to convert any remaining iodine to iodide. We recommend early endoscopy in patients with significant symptoms to help assess the extent of the GI injury. Hemodialysis and continuous venovenous hemodiafiltration were used successfully to enhance elimination of iodine in a patient with CKD with iodine toxicity who developed renal deterioration after undergoing continuous mediastinal irrigation with povidone-iodine.<sup>99</sup> The benefit of hemodialysis or continuous venovenous hemodiafiltration is unknown in patients with normal kidney function and therefore not routinely recommended at this time.

Most patients with iodophor ingestion require only supportive management. The use of starch or sodium thiosulfate is reasonable in symptomatic patients.

### Potassium Permanganate

Potassium permanganate (KMnO<sub>4</sub>) is a violet water-soluble xenobiotic that is usually sold as crystals or tablets or as a 0.01% dilute solution.<sup>96</sup> Historically, it was used as an abortifacient, urethral irrigant, lavage fluid for alkaloid poisoning, and snakebite remedy. Currently, potassium permanganate is most often used in baths and wet bandages as a dermal antiseptic, particularly for patients with eczema.

Potassium permanganate is a strong oxidizer, and poisoning results in local and systemic toxicity.<sup>195</sup> Upon contact with mucous membranes, potassium permanganate reacts with water to form manganese dioxide, potassium hydroxide, and molecular oxygen. Local tissue injury is the result of contact with the nascent oxygen, as well as the caustic effect of potassium hydroxide. A brown-black staining of the tissues occurs from the manganese dioxide. Systemic toxicity occurs from free radicals generated by absorbed permanganate ions.<sup>221</sup>

### Clinical Effects

Dermal contact leads to cutaneous staining. Following ingestion, initial symptoms include nausea and vomiting. Laryngeal edema and ulceration of the mouth, esophagus, and, to a lesser extent, the stomach, result from the caustic effects. Airway obstruction and fatal GI perforation and hemorrhage are reported.<sup>43,133,150</sup> Esophageal strictures and pyloric stenosis are potential late complications.<sup>103</sup>

Although potassium permanganate is not well absorbed from the GI tract, systemic absorption occurs, resulting in life-threatening toxicity. Systemic effects include hepatotoxicity, AKI, methemoglobinemia, hemolysis, hemorrhagic pancreatitis, airway obstruction, ARDS, disseminated intravascular coagulation, and cardiovascular collapse.<sup>114,125,133,150</sup> Elevation in blood and serum manganese concentrations also occurs, confirming systemic absorption.

Chronic ingestion of potassium permanganate results in classic manganese poisoning (manganism) characterized by behavioral changes, hallucinations, and delayed onset of parkinsonian-like symptoms. A 66-year-old man who ingested 10 g of potassium permanganate instead of potassium iodate over a 4-week period (because of medication mislabeling) developed

impaired concentration and autonomic and visual symptoms. He also developed abdominal pain, gastric ulceration, and alopecia. Serum manganese concentration was elevated. Nine months later, the patient had extrapyramidal signs consistent with parkinsonism (Chap. 94).<sup>83</sup>

### Management

Because the consequential effects of potassium permanganate ingestion are a result of the liberation of strong alkalis, immediate assessment for evidence of airway compromise should be performed in such a patient. Dilution with milk or water is reasonable. Patients with symptoms consistent with caustic injury should undergo early upper-GI tract endoscopy.<sup>96</sup> Corticosteroids are recommended if laryngeal edema is present. When systemic toxicity is suspected, of liver enzymes, blood urea nitrogen, creatinine, lipase, serum manganese, and methemoglobin concentrations all will help in the evaluation. We recommend methylene blue for clinically significant methemoglobinemia (Antidotes in Depth: A43). Dermal irrigation with dilute oxalic acid removes cutaneous staining.<sup>195</sup> The administration of *N*-acetylcysteine (Antidotes in Depth: A3) to increase reduced glutathione production, thereby limiting free radical-mediated oxidative injury in cases of systemic potassium permanganate poisoning, is suggested, but there is inadequate evidence to support routine use at this time.<sup>221</sup>

## OTHER ANTISEPTICS

### Alcohols

Ethanol and isopropanol (Chaps. 76 and 106) are commonly used as skin antiseptics. When sold as rubbing alcohol, the standard concentration for these solutions is usually 70%. In recent years, alcohol-based hand sanitizers containing 60% to 95% ethyl or isopropyl alcohol have become ubiquitous throughout patient care units, jails, and some public buildings as a primary infection control measure. Their antiseptic action is a result of their ability to coagulate proteins. Isopropanol is slightly more germicidal than ethanol.<sup>69</sup> The alcohols have limited efficacy against viruses or spores. Isopropanol tends to be more irritating than ethanol and causes more pronounced central nervous system depression.<sup>213</sup> Unfortunately, readily available alcohol-based sanitizers are a tempting source for patients admitted with alcohol abuse disorders.<sup>51,217</sup> In one report, a patient was admitted to the hospital with chest pain. While in the hospital the patient became hypotensive and delirious. He was later found in the bathroom drinking an alcohol-based hand wash that contained 63% isopropanol.<sup>51</sup> The clinical effects and treatment for alcohol poisoning are discussed in Chaps. 76 and 106.

### Chlorine and Chlorophors

Chlorine, one of the first antiseptics, is still used in the treatment of the community water supply and in swimming pools. Chlorine is a potent pulmonary irritant that can cause severe bronchospasm and ARDS. Chapter 121 contains a further discussion of chlorine.

Sodium hypochlorite (NaClO), found in household bleaches and in Dakin solution, remains a commonly used disinfectant. First used in the late 1700s to bleach clothes, its usefulness arises from its oxidizing capability, measured as "available chlorine," and its ability to release hypochlorous acid (HClO) slowly. It is used to clean blood spills and to sterilize certain medical instruments. A 0.5% hypochlorite solution is sometimes recommended for dermal and soft-tissue wound decontamination after exposure to biologic and chemical warfare agents (Chaps. 126 and 127).<sup>86</sup> Toxicity from hypochlorite is mainly a result of its irritant effects. The ingestion of large amounts of household liquid bleach (5% sodium hypochlorite) on rare occasions can result in esophageal burns with subsequent stricture formation.<sup>56</sup> In a cat model of bleach ingestion, a high incidence of mucosal injury and stricture formation was noted.<sup>216</sup> However, the vast majority of household bleach ingestions in humans do not cause significant GI injuries.<sup>159</sup> Accordingly, we recommend not performing routine endoscopic evaluation when assessing asymptomatic patients with household liquid bleach ingestions. Endoscopy is reasonable in symptomatic patients. Endoscopy is recommended in symptomatic

patients who ingest a more concentrated "industrial strength" bleach preparation such as 35% sodium hypochlorite, because of the increased likelihood of local tissue injury (Chap. 103).

### Mercurials

Both inorganic mercurials, such as mercuric bichloride (HgCl<sub>2</sub>), and organic mercurials, such as merbromin (C<sub>20</sub>H<sub>8</sub>Br<sub>2</sub>HgNa<sub>2</sub>O<sub>6</sub>) (mercuochrome) and thimerosal (C<sub>9</sub>H<sub>9</sub>HgNaO<sub>2</sub>S) (merthiolate), which both contain 49% mercury, were previously used as topical antiseptics. The usefulness of mercurials is significantly limited because of their relatively weak bacteriostatic properties and the many concerns associated with mercury toxicity (Chap. 95). Repeated application of topical mercurial causes significant absorption and systemic toxicity.<sup>139,176</sup> The use of high-dose hepatitis B immunoglobulin (HBIG) causes mercury toxicity because of the use of thimerosal as a preservative in the HBIG preparation.<sup>121</sup> In one case, a 44-year-old man received 250 mL of HBIG (containing about 30 mg of thimerosal) over 9 days following liver transplantation.<sup>121</sup> He developed speech difficulties, tremor, and chorea. His whole blood mercury concentration was 104 mcg/L (normal <10 mcg/L).

## DISINFECTANTS

### Formaldehyde

Formaldehyde is a water-soluble, highly reactive gas at room temperature. Formalin consists of an aqueous solution of formaldehyde, usually containing approximately 37% formaldehyde and 12% to 15% methanol. Formaldehyde is irritating to the upper airways, and its odor is readily detectable at low concentrations. Lethality in adults follows ingestion of as little as 30 to 60 mL of formalin.<sup>49</sup>

Formerly used as a disinfectant and fumigant, its role as a disinfectant is now largely confined to the maintenance of hemodialysis machines. Nonetheless, formaldehyde has many other applications. Formaldehyde is widely used in construction including wood processing and the manufacturing of furniture, textiles, and carpeting.<sup>101</sup> Health care workers are probably most familiar with the use of formaldehyde as a tissue fixative and embalming agent. Medical students are routinely exposed to formalin in the anatomy laboratory.<sup>167</sup>

Exposure to formaldehyde, a potent tissue fixative results in both local and systemic symptoms, causing coagulation necrosis, protein precipitation, and tissue fixation. Ingestions of formalin results in significant gastric injury, including hemorrhage, diffuse necrosis, perforation, and stricture.<sup>3,11</sup> The most extensive damage appears in the stomach, with only occasional involvement of the small intestine and colon.<sup>220</sup> Chemical fixation of the stomach occurs. Esophageal involvement is not very prominent and, if present, is usually limited to its distal segment.

The most striking and rapid systemic manifestation of formaldehyde poisoning is anion gap metabolic acidosis, resulting both from tissue injury and from the conversion of formaldehyde to formic acid. Although the methanol component of the formalin solution is readily absorbed and produces methanol concentrations reportedly as high as 40 mg/dL,<sup>22,49</sup> the rapid metabolism of formaldehyde to formic acid is responsible for much of the metabolic acidosis (Chap. 106).

### Clinical Effects

Patients presenting after formalin ingestions complain of the rapid onset of severe abdominal pain, vomiting, and diarrhea. Altered mental status and coma usually follow rapidly. Physical examination demonstrates epigastric tenderness, hematemesis, cyanosis, hypotension, and tachypnea. Profound hypotension is due to decreased myocardial contractility, as well as hypovolemic shock.<sup>78,203</sup> Early endoscopic findings include ulceration, necrosis, perforation, and hemorrhage of the stomach, with infrequent esophageal involvement. Chemical pneumonitis occurs after significant inhalational exposure.<sup>161</sup> Intravascular hemolysis is described in hemodialysis patients whose dialysis equipment contained residual formaldehyde after undergoing routine cleaning.<sup>152,165</sup>

Occupational and environmental exposure to formaldehyde receives considerable attention. In particular, there is concern over the potential off-gassing of formaldehyde from the widely used urea formaldehyde building insulation and particle board.<sup>149</sup> Headache, nausea, skin rash, sore throat, nasal congestion, and eye irritation are associated with the use of these polymers.<sup>39</sup> Formaldehyde, at concentrations as low as 1 ppm, causes significant irritation to mucous membranes of the upper respiratory tract and conjunctivae.<sup>82,120</sup> Formaldehyde is also a potential sensitizer for immune-mediated reversible bronchospasm.<sup>75</sup> The exact immunologic mechanism is not yet elucidated, although it is likely that formaldehyde acts as a hapten. In addition, formaldehyde is a dermal sensitizer.<sup>194</sup>

Concerns about the health effects from the off-gassing of formaldehyde in trailers used by the Federal Emergency Management Agency (FEMA) after Hurricane Katrina illustrates the potential public health issues related to low-level formaldehyde exposure.<sup>124</sup> A Centers for Disease Control and Prevention (CDC) investigation revealed that air formaldehyde concentrations in closed, unventilated trailers are, in fact, high enough to cause acute symptoms in some people.<sup>4</sup> Long-term effects after these exposures remain undefined.

Formaldehyde exposure is associated with an increased incidence of nasopharyngeal carcinoma.<sup>2,71,156,177</sup> Although its role in the pathogenesis of cancer in humans is the subject of much debate,<sup>33,128</sup> formaldehyde is classified as a Group 1, *known*, carcinogen by the International Agency for Research on Cancer (IARC).

### Management

Dilution with water is reasonable for the immediate management of a patient who has ingested formalin. Gastric aspiration with a small-bore nasogastric or orogastric tube is also reasonable to limit systemic absorption. Activated charcoal should not be used. Significant acidemia is treated with sodium bicarbonate and folinic acid (Chap. 106). Immediate hemodialysis removes the accumulating formic acid as well as the parent molecules formaldehyde and methanol and is reasonable in refractory acidemia (Antidotes in Depth: A33 and A34).<sup>6,49</sup> Early endoscopy is recommended for all patients with significant GI manifestations to assess the degree of burn injury. Surgical intervention is required for those with suspected severe burns, tissue necrosis and/or perforation.<sup>220</sup> Emergent gastrectomy, as well as late surgical intervention to relieve formaldehyde-induced gastric outlet obstruction, is rarely required.<sup>72,104</sup>

### Phenol

Phenol is one of the oldest antiseptics. It is rarely used as an antiseptic today, because of its toxicity, and is replaced by the many phenolic derivatives. Currently, phenol is used as a disinfectant and chemical intermediary. The concentration of phenol in consumer products can vary significantly, from 0.1% to 4.7% in various lotions, ointments, gels, gargles, lozenges, and throat sprays and up to 89% in nail cauterizer solution.<sup>69</sup> Although many cases of phenol poisoning were reported in the past, acute oral overdoses of phenol-containing solutions are uncommon today.<sup>62</sup>

Phenol acts as a caustic causing cell wall disruption, protein denaturation, and coagulation necrosis. It also acts as a central nervous system (CNS) stimulant. Intentional ingestion of concentrated phenol, ingestion of phenol-containing water, occupational exposure to aerosolized phenol, dermal contact, and parenteral administration result in symptomatic phenol poisoning. Phenol demonstrates excellent skin penetrance and causes severe dermal burns, resulting in potentially fatal systemic toxicity within minutes to hours.<sup>16,113</sup> Deaths from parenteral administration of phenol are reported. The lethal oral dose is as little as 1 g.<sup>84</sup>

### Clinical Effects

Clinical manifestations can be divided into local and systemic symptoms. Systemic symptoms from GI or dermal absorption of phenol are usually more dangerous than the local effects. Manifestations of systemic toxicity include CNS and cardiac manifestations. Central nervous system effects include central stimulation, seizures, lethargy, and coma.<sup>65</sup> In a study of patients who

had ingested Creolin (26% phenol), CNS toxicity predominated.<sup>196</sup> Of the 52 patients who were evaluated at the hospital, 9 developed lethargy and 2 developed coma. Seizures were not reported. Cardiac signs and symptoms from phenol include tachycardia, bradycardia, and hypotension.<sup>65</sup> Parenteral absorption of 10 mL concentrated 89% phenol resulted in hypoxemia, ARDS, pulmonary nodular opacities, and AKI requiring intubation and hemodialysis.<sup>64</sup> This last case was associated with a phenol concentration of 87 mg/dL (normal <2 mg/dL).

Other systemic effects include hypothermia, metabolic acidosis, methemoglobinemia, and rabbit syndrome.<sup>84,97</sup> Rabbit syndrome is most commonly observed as a distinctive extrapyramidal effect from antipsychotics and is characterized by fine rapid repetitive movements of the perioral musculature resembling a rabbit's chewing movements. Increased acetylcholine release and a relative dopaminergic hypofunction explain the development of rabbit syndrome after phenol exposure.<sup>97</sup>

Local toxicity to the GI tract from the ingestion of phenol results in nausea, painful oral lesions, vomiting, severe abdominal pain, bloody diarrhea, and dark urine.<sup>8,94</sup> Serious GI burns are uncommon, and strictures are rare. White patches in the oral cavity occur. In the Creolin study cited above, only 1 of 17 patients who underwent endoscopy had a significant esophageal burn.<sup>196</sup> Dermal exposures to phenol usually result in a light-brown staining of the skin. Excessive dermal absorption of phenol during chemical peeling procedures is associated with dysrhythmias and many of the other toxic manifestations.<sup>208,214</sup>

Markedly elevated blood and urine concentrations of phenol are detected after ingestion, or dermal absorption, of phenol and phenol-containing compounds.<sup>16,84</sup>

### Management

When phenol is mixed with water, a bilayer with unique properties is created that makes it difficult to remove from tissues. A variety of treatments are suggested for dermal and gastric decontamination of phenol. A study using a rat model showed that cutaneous decontamination with a low-molecular-weight polyethylene glycol solution decreased mortality, systemic effects, and dermal burns.<sup>21</sup> Although this study suggested that polyethylene glycol (PEG) was superior to water as a decontamination, a subsequent study using a swine model could not demonstrate a difference between these 2 therapies.<sup>164</sup> In another swine model, PEG 400 and 70% isopropanol were both superior to water washes and equally effective in decreasing dermal burn.<sup>135</sup> Given the lack of definitive efficacy data, either low-molecular-weight PEG, for example, PEG 300 or 400 (not to be confused with high-molecular-weight PEG that is used for whole-bowel irrigation), or high-flow water are reasonable for dermal irrigation and careful gastric decontamination. Endoscopic evaluation, for symptomatic patients to determine the extent of GI injury is recommended.

### Substituted Phenols and Other Related Compounds

Hexachlorophene, a trichlorinated *bis*-phenol, is considered generally less tissue-toxic than phenol. During the 1970s, an association was observed between repetitive whole-body washing of premature infants with 3% hexachlorophene and the development of vacuolar encephalopathy and cerebral edema.<sup>129</sup> There are also multiple reports of significant neurologic toxicity and death in children who became toxic after ingesting hexachlorophene.<sup>77</sup> In addition, fatalities also occurred after patients absorbed substantial amounts of hexachlorophene during the treatment of burns.<sup>29</sup> The use of hexachlorophene has declined significantly. Currently used substituted phenols include a sodium solution of octylphenoxyethoxyethyl ether sulfonate, chloroxyleneol and cresol.

### Clinical Effects

A sodium solution of octylphenoxyethoxyethyl ether sulfonate and lanolin is a safe antiseptic. Irritative effects such as nausea, vomiting, and diarrhea are the main adverse effects following ingestion.

In a study of poisoning admissions to Hong Kong hospitals, the ingestion of a household disinfectant that contained 4.8% chloroxyleneol, 9% pine

oil, and 12% isopropanol accounted for 10% of admissions.<sup>26</sup> Aspiration (perhaps, in part, because of the pine oil) occurred in 8% of these patients, resulting in upper airway obstruction, pneumonia, and ARDS. More common symptoms included nausea, vomiting, sore mouth, sore throat, drowsiness, abdominal pain, and fever. Dermal contact with Dettol results in full-thickness chemical burns.<sup>40</sup>

Cresol, a mixture of 3 isomers of methylphenol, has better antiseptic activity than phenol and is a commonly used disinfectant. Exposure to concentrated cresol results in significant local tissue injury, hemolysis, AKI, hepatic injury, and CNS and respiratory depression.<sup>40,70,98,219</sup> Phenol concentrations, as well as cresol concentrations, serve as markers of exposure.<sup>219</sup>

### Management

Treatment is supportive care emphasizing decontamination.

### Quaternary Ammonium Compounds

Quaternary ammonium compounds, positively charged compounds where 4 organic groups are linked to a nitrogen atom ( $\text{NR}_4^+$ ), are cationic surfactants (surface-active agent) that are used as disinfectants, detergents, and sanitizers. Chemically, the quaternary ammonium compounds are synthetic derivatives of ammonium chloride, and structurally similar to other quaternary ammonium derivatives, such as carbamate cholinesterase inhibitors and neuromuscular blockers. Other cationic surfactants include the pyridinium compounds and the quinolinium compounds. Benzalkonium chloride was one of the most commonly employed quaternary ammonium compounds in the past. Many newer quaternary ammonium compounds have supplanted its use. However, nebulized solutions used for the treatment of asthma, including albuterol and ipratropium bromide, contain small amounts of benzalkonium chloride.

### Clinical

Quaternary ammonium compounds are usually less toxic than phenol or formaldehyde. Most of the infrequent complications that are described result from ingestions of benzalkonium chloride. Complications of these ingestions include burns to the mouth and esophagus, CNS depression, elevated liver enzyme concentrations, metabolic acidosis, and hypotension.<sup>80,147,210</sup> Paralysis is also occasionally described as a complication of these ingestions and is presumably a result of cholinesterase inhibition at the neuromuscular junction.<sup>62</sup> Chronic inhalational exposure is associated with occupational asthma.<sup>17</sup> Topical use of the quaternary ammonium compounds causes contact dermatitis.<sup>190</sup> Ingestion of a 2.25% ammonium chloride solution, marketed as a bacteriostatic for algae and odor humidifier treatment, results in serious GI and pulmonary injury.<sup>67</sup>

Ingestions of other cationic surfactants, such as the pyridinium-derived cetrimeronium bromide are associated with corrosive burns to the mouth, lips, and tongue.<sup>137</sup> Peritoneal irrigation with cetrimeronium bromide produces metabolic abnormalities, hypotension, and methemoglobinemia.<sup>9,134</sup> Intravenous administration of cetrimeronium bromide leads to hemolysis, muscle paralysis, and cardiac arrest.<sup>58</sup>

### Management

Treatment recommendations following the ingestion of the quaternary ammonium compounds and other cationic surfactants are similar to those for other potentially caustic ingestions. Emergency department evaluation is recommended for all patients who ingest more than a taste of a dilute (<1%) solution. Therapy is mainly supportive care. Endoscopy is indicated if signs and symptoms suggest the possibility of a burn.

## STERILANTS

### Ethylene Oxide

Ethylene oxide ( $\text{C}_2\text{H}_4\text{O}$ ) is a gas that is commonly used to sterilize heat-sensitive material in health care facilities. Unlike antiseptics and disinfectants, which generally do not exhibit full sporicidal activity, sterilants, such as ethylene oxide, inactivate all organisms. Ethylene oxide is also used in the synthesis of many chemicals, including ethylene glycol, surfactants, rocket

propellants, and petroleum demulsifiers, and is used as a fumigant. Ethylene oxide has a cyclic ester structure that acts as an alkylating agent, reacting with most cellular components, including DNA and RNA.

Medical attention regarding ethylene oxide toxicity has centered on its mutagenic and possible carcinogenic effects.<sup>108</sup> Approximately 270,000 workers (including 96,000 hospital workers) in the United States are at risk for occupational exposure to ethylene oxide.<sup>199</sup> Retrospective studies suggest a possible excess incidence of leukemia and gastric cancer in ethylene oxide exposed workers.<sup>81,199</sup> The 2008 IARC updated monographs concluded that there was limited evidence for carcinogenicity in humans, with an association with lymphatic, hematopoietic, and breast cancers. However, sufficient evidence for the carcinogenicity of ethylene oxide was found in experimental animals. Evidence suggests direct-acting alkylating effects leading to genotoxicity. Ethylene oxide was subsequently placed in IARC group I—carcinogenic to humans.<sup>87</sup> An increased incidence of spontaneous abortions is associated with occupational exposure to ethylene oxide.<sup>74</sup>

### Clinical Effects

The acute toxicity of ethylene oxide is mainly the result of its irritant effects, including conjunctival, upper respiratory tract, GI, and dermal irritation. Dermal burns from acute exposure to ethylene oxide are reported. Acute exposure to a broken ethylene oxide ampule (17 g) by a 43-year-old recovery room nurse resulted in nausea, lightheadedness, malaise, syncope, and recurrent seizures.<sup>181</sup> There were no long-term complications. In another case of acute exposure, coma was followed by an irreversible parkinsonism.<sup>10</sup>

Chronic exposure to high concentrations of ethylene oxide causes mild cognitive impairment and motor and sensory neuropathies.<sup>20,63,146</sup> Hazard studies of occupational exposure have demonstrated no increased incidence of cancer in exposed populations over the expected occurrence rate.<sup>32,198,204</sup>

### Management

Treatment for patients with ethylene oxide exposure is supportive.

### Glutaraldehyde

Glutaraldehyde is a liquid solution used in the cold sterilization of nonautoclavable endoscopic, surgical, and dental equipment. It is also employed as a tissue fixative, embalming fluid, preservative, and tanning agent, in radiographic solutions, and in the treatment of warts.<sup>60</sup> Glutaraldehyde ( $\text{C}_5\text{H}_8\text{O}_2$ ) is a dialdehyde with 2 active carbonyl groups that is less volatile than formaldehyde. It kills all microorganisms, including viruses and spores. The sterilant ability of glutaraldehyde results from the alkylation of sulfhydryl, hydroxyl, carboxyl, and amino groups, within microbes interfering with RNA, DNA, and protein synthesis.<sup>179</sup> It is prepared as a 2% alkaline solution in 70% isopropanol. Health care workers are exposed to glutaraldehyde vapors when equipment is processed in poorly ventilated areas, or in open immersion baths or after spills. Under these circumstances, the evaporation of glutaraldehyde results in the increase in ambient air concentrations that exceeds recommended limits. Approximately 35,000 workers are occupationally exposed to glutaraldehyde annually.<sup>160</sup> To prevent exposure, OSHA recommends the use of personal protective equipment with elbow-length gloves of butyl rubber or nitrile, gowns and eye protection. Local exhaust ventilation at the point of release should include either a local exhaust hood or ductless hood. Enclosed processing is also recommended when available. Respirators should be available in the event that ventilation fails for any reason.<sup>153</sup> Patients are exposed when diagnostic instruments are inadequately rinsed following cold sterilization with glutaraldehyde.

### Clinical

Clinical signs and symptoms are comparable to those of formaldehyde exposure, although human toxicity data are limited. Animal studies show that the inhalational and dermal toxicity of glutaraldehyde are similar to those of formaldehyde at equivalent doses.<sup>202</sup>

Glutaraldehyde is a mucosal irritant. Coryza, epistaxis, headache, asthma, chest tightness, palpitations, tachycardia, and nausea are all associated with glutaraldehyde vapor exposure.<sup>15,34,143,154</sup> Occupational asthma, contact

dermatitis, and ocular inflammation also occur.<sup>38,151,186</sup> Colitis is reported following the use of endoscopes contaminated with residual glutaraldehyde solution.<sup>188</sup> Patients with glutaraldehyde-induced colitis typically present with fever, chills, severe abdominal pain, bloody diarrhea, and an elevated white blood cell count within 48 hours after colonoscopy or sigmoidoscopy.

The IARC has not ranked the carcinogenic potential of glutaraldehyde.

### Management

Treatment recommendations are similar to those for patients with formaldehyde exposure. Prompt removal from the exposure is essential. Copious irrigation with water is recommended for dermal decontamination. Severe inhalational exposures require hospital admission for observation, supportive care, and treatment of bronchospasm.

In recent years, some hospitals have started using *ortho*-phthalaldehyde (OPA) or a mixture of hydrogen peroxide and peracetic acid as alternatives to glutaraldehyde for high-level disinfection.<sup>172</sup> These alternative disinfectants do not appear to have the pulmonary or dermal sensitizing properties associated with glutaraldehyde, although they do cause some irritation to skin and mucous membranes.<sup>172</sup> A single case of occupational asthma related to OPA exposure was reported in 2014, proven with a specific inhalation challenge, and represents the only reported case in the literature.<sup>175</sup> Oropharyngeal and laryngeal burns are also reported in a patient exposed to residual OPA during transesophageal echocardiography.<sup>185</sup>

## OTHER PRODUCTS

### Boric Acid

Boric acid is an odorless, transparent crystal, although it is most commonly available as a finely ground white powder. It is also available as a 2.5% to 5% aqueous solution. Boric acid ( $H_3BO_3$ ), prepared from borax (sodium borate;  $Na_2B_4O_7 \cdot 10 H_2O$ ), was first used as an antiseptic by Lister in the late 19th century. Although used extensively over the years for antiseptics and irrigation, boric acid is only weakly bacteriostatic. As a result of its germicidal limitations and its inherent toxicity, boric acid is nearly obsolete in modern antiseptic therapy. Nonetheless, it continues to be used as an antimicrobial to treat such conditions as vulvovaginal candidiasis.<sup>88,100,163</sup> Boric acid is also employed in the treatment of cockroach infestation and as a soap, contact lens solution, toothpaste, and food preservative.<sup>66</sup> Recently, do-it-yourself recipes for children's slime, a squishy colorful play material, include boric acid as a major ingredient.<sup>47</sup>

Boric acid is readily absorbed through the GI tract, wounds, abraded skin, and serous cavities. Absorption does not occur through intact skin. Boric acid is predominantly eliminated unchanged by the kidney. Small amounts are also excreted into sweat, saliva, and feces.<sup>59</sup> Boric acid is concentrated in the brain and liver.

The exact mechanism of action of toxicity remains unclear. Although it is an inorganic acid, it is not a caustic. Local effects are limited to tissue irritation.

Over the years, boric acid developed a reputation as an exceptionally potent toxin. This reputation derived in great part from a series of reports involving neonatal exposures to boric acid resulting in high morbidity and mortality. Life-threatening toxicity resulted from the repetitive topical application of boric acid for the treatment of diaper rash or the use of infant formulas unintentionally contaminated with boric acid.<sup>59,218</sup> Fatality rates greater than 50% were reported in some series.<sup>218</sup> Although infants appear to be the most sensitive to the toxic effects of boric acid, many cases of significant toxicity are also reported in adults. These cases date predominantly from the first half of the 20th century when boric acid was widely used as an irrigant. Routes of exposure to boric acid, resulting in fatalities, include wound irrigation, pleural irrigation, rectal washing, bladder irrigation, and vaginal packing.<sup>209</sup>

### Clinical Effects

Boric acid poisoning usually involves multiple exposures over a period of days. Gastrointestinal, dermal, CNS, and renal manifestations predominate.

The initial effects—nausea, vomiting, diarrhea, and occasionally crampy abdominal pain—are frequently confused with an acute gastroenteritis. At times, the emesis and diarrhea are greenish blue.<sup>218</sup> Following the onset of GI signs and symptoms, the majority of patients develop a characteristic intense generalized erythroderma.<sup>218</sup> This rash, described as producing a “boiled lobster” appearance, appears indistinguishable from toxic epidermal necrolysis or staphylococcal scalded skin syndrome in the neonate.<sup>122,178</sup> The rash is especially noticeable on the palms, soles, and buttocks.<sup>59</sup> Typically, extensive desquamation takes place within 1 to 2 days. On occasion, prominent mucous membrane involvement of the oral cavity and conjunctivae is also apparent.<sup>218</sup> At the time of development of the erythroderma, patients, particularly young infants, develop prominent signs of CNS irritability, resembling meningeal irritation. Seizures, delirium, and coma occur.<sup>59</sup> Acute kidney injury is common, both as a result of the renal elimination of this compound and prerenal azotemia from GI losses.<sup>59</sup> Other complications of boric acid poisoning include hepatic injury, hyperthermia, and cardiovascular collapse. A marked decrease in the incidence of significant boric acid poisoning is attributed to the abandonment of boric acid as an irrigant and particularly its removal from the nursery setting.

Two retrospective studies on boric acid ingestions suggest that a single acute ingestion of boric acid is generally quite benign.<sup>115,117</sup> In these studies, 79% to 88% of patients remained asymptomatic. Symptoms, when present, primarily consist of nausea and vomiting. None of the 1,184 patients in these 2 studies manifested the generalized erythroderma so commonly described in previous reports. Central nervous system manifestations of acute overdose were infrequent and limited to occasional lethargy and headache. Kidney injury did not occur following single acute ingestions.

Fatalities from massive acute ingestion of boric acid are reported in both unintentional ingestions in children and intentional ingestions in adults.<sup>66,171</sup> Fatality resulted from a single ingestion of 2 cups (280 g) of boric acid crystals dissolved in water by a 45-year-old man. Signs and symptoms on presentation (2 days after ingestion) included nausea, vomiting, green diarrhea, lethargy, hypotension, AKI, and a prominent “boiled lobster” rash on his trunk and extremities. In another case, the ingestion of 30 g of boric acid by a 77-year-old man resulted in similar symptoms and death 63 hours postingestion, despite hemodialysis.<sup>91</sup>

Long-term chronic exposure to boric acid results in alopecia in adults and seizures in children.<sup>145</sup> A 32-year-old woman who over a 7-month period ingested commercial mouthwash products containing boric acid developed progressive hair loss.<sup>201</sup> The chronic application of a commercial preparation of borax and honey mixture to pacifiers resulted in the development of recurrent seizures in 9 infants, which resolved after the mixture was withheld.<sup>61,145</sup>

### Management

Treatment of boric acid toxicity is supportive care. Activated charcoal is not recommended because of its relatively poor adsorptive capacity for boric acid.<sup>41</sup> Because boric acid has a low molecular weight and relatively small volume of distribution, in cases of massive oral overdose or AKI, hemodialysis, or perhaps exchange transfusion in infants, is reasonable in shortening the half-life of boric acid.<sup>35,117,141,206</sup> Although forced diuresis is suggested by others to enhance renal elimination, this is highly unlikely to be successful and is not recommended.<sup>207</sup>

### Chlorates

Sodium chlorate is a strong oxidizer. At one time, the chlorate salts sodium chlorate and potassium chlorate were used as medicinals to treat inflammatory and ulcerative lesions of the oral cavity and could be found in various mouthwash, toothpaste, and gargle preparations.<sup>197</sup> Although their use as local antiseptics is obsolete, chlorates are used as herbicides and in the manufacture of matches, explosives, and dyestuffs.<sup>92</sup> Historically, cases have included dispensing errors that confused sodium chlorate with sodium sulfate or sodium chloride.<sup>92</sup> Sodium chlorate in the form of white crystals was mistaken for table sugar in one case.<sup>73</sup> A case of significant toxicity from

the inhalation of atomized chlorates is also reported.<sup>92</sup> More recent cases of chlorate poisoning continue to result from the ingestion of sodium chlorate-containing weed killers<sup>168,197</sup> and industrial chemicals.<sup>111</sup>

Sodium chlorate is rapidly absorbed from the GI tract and eliminated predominantly unchanged from the kidneys.<sup>93</sup> Its systemic effects are chiefly hematologic and renal. The major mechanism of toxicity of chlorate is its ability to oxidize hemoglobin and increase red blood cell membrane rigidity.<sup>191</sup> Consequently, significant methemoglobinemia and hemolysis result. Methemoglobinemia occurs prior to or after the development of hemolysis.<sup>144,200</sup> The hemolysis and the resultant hemoglobinuria secondarily causes disseminated intravascular coagulation and potential renal toxicity. Chlorates are also directly toxic to the proximal renal tubule.<sup>110</sup> The worsening kidney function is especially problematic because of its adverse effect on chlorate elimination. Chlorates also act locally as a GI irritant and cause mild CNS depression after absorption (Chap. 124).<sup>62</sup>

### Clinical

Clinical signs and symptoms of chlorate poisoning usually begin 1 to 4 hours after ingestion.<sup>102</sup> The earliest manifestations are nausea, vomiting, diarrhea, and crampy abdominal pain. Subsequently, the patient exhibits cyanosis from the methemoglobinemia and black-brown urine from the hemoglobinuria. Obtundation and anuria ensue. Laboratory studies demonstrate methemoglobinemia, anemia, Heinz bodies, ghost cells, fragmented spherocytes, metabolic acidosis, thrombocytopenia, and abnormal coagulation.<sup>53</sup> Hyperkalemia is particularly problematic if the patient ingests potassium chlorate preparations.<sup>140</sup> In a case of chlorate poisoning from the ingestion of 120 potassium chlorate-containing matchsticks, an MRI revealed symmetric abnormal signal intensity within the deep gray matter and medial temporal lobes.<sup>140</sup> This finding can be explained by the increased vulnerability to oxygen deprivation of the basal ganglia. Follow-up MRI 2 months later was normal.

### Management

In symptomatic patients with chlorate ingestions, it is reasonable to pursue GI decontamination.<sup>73</sup> The utility of methylene blue in the treatment of symptomatic chlorate-induced methemoglobinemia has been questioned as a consequence of the inactivation by chlorates of glucose-6-phosphate dehydrogenase, an enzyme that is required for methylene blue to effectively reduce methemoglobin.<sup>191,200</sup> Nevertheless, more recent experience suggests that early use of methylene blue prior to the onset of hemolysis is beneficial due to the necessity of the intact erythrocyte for methylene blue to be efficacious and thus a reasonable treatment.<sup>191,111</sup> Exchange transfusion and hemodialysis are reasonable in the treatment of patients with severe chlorate poisoning.<sup>144,200</sup> Because the chlorate ion is easily dialyzable, hemodialysis will be effective in removal of chlorate as well as in treating concomitant AKI.<sup>92,102,110</sup>

### SUMMARY

- Many of the more toxic xenobiotics, such as iodine, phenol, and chlorates, are no longer commonly used as cleansers but are still available in some health care and occupational settings.
- Formaldehyde exposures, though also uncommon, cause significant respiratory toxicity and is potentially carcinogenic.
- Frequently employed antiseptics, are chlorhexidine, octylphenoxethoxyethyl ether sulfonate, and many of the currently used quaternary ammonium compounds. Iodine, phenol, and quaternary ammonium compounds are caustic when ingested.
- Ingestions of the iodophors do not usually cause significant toxicity, but absorption through other routes produces significant adverse effects.
- Ingestion of concentrated hydrogen peroxide results in life-threatening injuries. Boric acid causes a dermatitis.

Camphor

Naphthalene

Paradichlorobenzene

Many different products have been used as moth repellents. In the United States, paradichlorobenzene has largely replaced both camphor and naphthalene as the most common active component of moth repellent and moth flakes because of its lower toxicity. However, life-threatening camphor and naphthalene toxicity still occurs, especially in immigrant communities, from exposures to imported camphor or naphthalene-containing products.<sup>3,48,65,80</sup> Therefore, toxicity of camphor, naphthalene, and paradichlorobenzene all remain possible following exposure to moth repellents.

## CAMPHOR

### History and Epidemiology

Camphor (2-bormanone, 2-camphonone), a cyclic ketone of the terpene group, is an essential oil originally distilled from the bark of the camphor tree, *Cinnamomum camphora*. Today, camphor is synthesized from the hydrocarbon pinene, a derivative of turpentine oil. Camphor has been used for centuries as an aphrodisiac, fumigant, contraceptive, abortifacient, suppressor of lactation, analeptic, cardiac stimulant and antiseptic.<sup>1,56,72,96,108</sup> Camphor is a commonly used ingredient found in many nonprescription remedies for cold symptoms, cold sores, and in muscle liniments.<sup>2,75,77,93</sup> Camphor is also rarely abused as a stimulant (Chap. 42).<sup>70</sup>

Camphorated oil and camphorated spirits contain varying concentrations of camphor. Historically, most camphorated oil was prepared as a 20% weight (of solute) per weight (of solvent) (w/w) solution of camphor with cottonseed oil, and most camphorated spirits contained 10% w/w camphor with isopropyl alcohol. Toxicity and death following ingestion of camphorated oil, which was confused with castor oil and cod liver oil, prompted the FDA to ban the nonprescription sale of camphorated oil in the United States in 1980.<sup>76,123,126</sup> The FDA ban of camphorated oil was followed in 1983 by a restriction on camphor concentration to less than 11% in nonprescription camphor-containing products.<sup>126</sup> However, camphorated oil is still used as a herbal remedy and muscle liniment, and products containing greater than 11% camphor can be purchased in local stores of various ethnic communities in the United States and in other countries.<sup>48,65,118</sup>

Common camphor-containing products include ointments used for herpes simplex on the lips (usually <1% camphor), muscle liniments, rubefacients (usually 4%–7% camphor), and camphor spirits (usually 10% camphor). Paregoric, camphorated tincture of opium, contains a combination of anhydrous morphine (0.4 mg/mL), ethanol (46%), benzoic acid (4 mg/mL), and a small amount of camphor.<sup>69</sup> For industrial uses, strengths up to 100% camphor are sold legally in the United States. Occupational exposures to camphor occur during the manufacture of plastic, celluloid, lacquer, varnish, explosives, embalming fluids, numerous pharmaceuticals and cosmetics.<sup>69</sup>

Although products containing lower concentrations of camphor are implicitly safer, life-threatening toxicity and death still result from misuse or intentional overdose. Most reported cases of acute camphor poisoning are unintentional ingestions of camphor-containing products mistaken for other medications or therapeutic misadventures from nonprescription products, including home remedies.<sup>3,50,65,99,119</sup> According to data obtained by the

American Association of Poison Control Centers (AAPCC), there are approximately 13,000 exposures to camphor-containing products each year, with a majority of the exposure, approximately 80%, occurring in children under the age of 5 years (Chap. 130).

Prior to the FDA ban of camphorated oil and restriction on camphor content in nonprescription products, there was a high incidence of systemic manifestations such as vertigo, confusion, delirium, seizures and coma reported in children younger than 5 years.<sup>131</sup> In a group of 530 patients with camphor exposures, 15% presented with systemic effects and 4% had seizures.<sup>41,93</sup> Unfortunately, limited data are available with regard to the true incidence of symptoms associated with camphor toxicity since the FDA ruling in 1983. According to AAPCC data, 8 reported deaths (1 child and 7 adults) were attributable to camphor over the past 25 years. Although a majority of the patients with unintentional exposures remain asymptomatic and do not present to a health care facility, significant morbidity from unintentional camphor exposures continue to occur in children.<sup>3,48,65,118</sup> The public health implication of camphor exposure in children is of great concern because of the simultaneous lack of therapeutic value of their products and their potential life-threatening toxicity.

### Pharmacology

Camphor is a colorless glassy solid. Its pharmacologic activity is not well studied, and its mechanism of action remains unclear. Therapeutic use of camphor as an expectorant is limited, and its anti-infective property is being explored. Camphor, a major component in the essential oil of many plant species, demonstrates bacteriostatic and fungistatic activities against select microorganisms (eg, *Enterococcus hirae*, *Staphylococcus aureus*, and *Candida albicans*) in several in vitro studies.<sup>64,105,120,132</sup> Imine derivatives of camphor under investigation have antiviral effects against influenza virus (A and H1N1 subtypes) through inhibition of viral hemagglutinin.<sup>113–115</sup> No therapeutic benefit of camphor is proven in any well-controlled clinical trials although camphor provides limited local analgesic and antipruritic effects, much safer alternatives are available for these indications.

### Pharmacokinetics and Toxicokinetics

There are limited pharmacokinetic and toxicokinetic data for camphor. Ingestion is the most common route of exposure that results in significant camphor toxicity.<sup>3,65,70,80</sup> However, toxicity also occurs following inhalation, intranasal instillation, intraperitoneal administration, dermal, and from transplacental transfer, resulting in fetal death.<sup>48,65,97,110</sup> Camphor is a highly lipophilic compound that is rapidly absorbed from the gastrointestinal tract and is detected in the blood within 15 to 20 minutes following ingestion.<sup>93,101</sup> Because of the lack of experimental data, the bioavailability from each route of exposure is unknown. A peak blood camphor concentration was achieved in 90 minutes when rats were administered an oral dose of 1 g/kg.<sup>33</sup> A significant amount of camphor is absorbed through normal skin. Dermal absorption of camphor is slow, but can produce systemic toxicity up to 72 hours following exposure.<sup>48,65</sup> The volume of distribution is estimated at 2 to 4 L/kg with protein binding of approximately 61%.<sup>69,70</sup>

Camphor is predominantly metabolized in the liver and eliminated by the kidneys. Up to 59% of the camphor is eliminated in urine as glucuronides, but unchanged camphor (<1%) and other oxidative metabolites are also found in the urine.<sup>70,103,108</sup> Five inactive metabolites are produced by hydroxylation of a methylene group (the predominant pathway) and reduction of the oxo group.<sup>103</sup> Inactive metabolites, 3-hydroxycamphor, 5-hydroxycamphor (major metabolite), 8-hydroxycamphor, 9-hydroxycamphor, and borneol, are either conjugated with glucuronic acid or further oxidized and eliminated

by the kidneys.<sup>70,103</sup> The exact site of camphor metabolism is unknown, but CYP 2A6 and NADPH-P450 reductase are known to be involved.<sup>49,84</sup> A volunteer study in which 200 mg of camphor with Tween 80 as a solvent (10 mL) or without the solvent was ingested demonstrated, in humans, plasma elimination half-lives of 93 minutes and 167 minutes, respectively following oral administration.<sup>69</sup> A comparable elimination half-life of 144 minutes was found in an animal model.<sup>35</sup> Small amounts of camphor are eliminated by exhalation, as noted by characteristic breath odor but no studies have assessed the significance of this route of elimination.<sup>70,75</sup>

The reported toxic dose of camphor is highly variable.<sup>50,112</sup> A potential lethal dose of 50 to 500 mg/kg of camphor is often cited for humans.<sup>41,80,93</sup> Yet, as little as 1 g of camphor resulted in death in a 19-month-old infant, whereas up to 42 g of camphor was ingested by an adult who recovered.<sup>2,112</sup> There are insufficient data to suggest a clear toxic dose range of camphor. However, there is evidence to suggest that camphor causes life-threatening toxicity at low doses (estimated exposure of 700–1,500 mg) based on a series of case reports in both adults and children.<sup>75,93,112,118</sup>

Workplace standards determined by the Occupational Safety and Health Administration (OSHA) has set the permissible exposure limit (PEL) at 2 mg/m<sup>3</sup>.<sup>125</sup> The American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit value (TLV) is 12 mg/m<sup>3</sup> (2 ppm), whereas the short-term exposure limit (STEL) is 19 mg/m<sup>3</sup> (3 ppm). The National Institute for Occupational Safety and Health (NIOSH) Immediately Dangerous To Life or Health Concentration (IDLH) is 200 mg/m<sup>3</sup>.<sup>124</sup>

### Pathophysiology

The mechanism of toxicity of camphor is unknown. Camphor is an irritant. Pathologic changes following ingestion include cerebral edema, neuronal degeneration, fatty changes in the liver, centrilobular congestion of the liver, and hemorrhagic lesions in the skin, gastrointestinal tract, and kidneys.<sup>62,112,139</sup>

### Clinical Manifestations

Exposure to camphor can often be detected by its characteristic aromatic odor (Chap. 25). Ingestion of camphor typically produces oropharyngeal irritation, nausea, vomiting, and abdominal pain. Generalized tonic-clonic seizures usually occur within 1 to 2 hours of ingestion.<sup>13,17</sup> The onset of systemic toxicity, particularly CNS toxicity, occurs as early as 5 minutes after ingestion.<sup>30,33,75,112</sup> Most seizures are brief and self-limited, although some patients experience multiple seizures, including status epilepticus.<sup>43,48,68,111</sup> Delayed seizures are reported occurring up to 9 hours following ingestion and up to 72 hours following dermal exposure.<sup>49,105</sup> Central nervous system (CNS) depression is common, but camphor rarely compromises respiratory function.<sup>29,68</sup> Other neurologic manifestations include headache, lightheadedness, transient visual changes, confusion, myoclonus, and hyperreflexia.<sup>55,102</sup> Psychiatric manifestations include agitation, anxiety, and hallucinations.<sup>51,65,68</sup> Dermal effects include flushing and petechiae.<sup>29,55</sup> Camphor does not typically cause life-threatening cardiovascular effects, although a case of myocarditis is reported.<sup>19</sup> Deaths are reported secondary to status epilepticus.<sup>16,29,77,110</sup> Transient elevation of hepatic aminotransferases concentrations were observed in acute ingestion of camphor.<sup>62,101,110</sup> Chronic administration of camphor to a child caused altered mental status and elevated hepatic aminotransferase concentrations suggestive of Reye syndrome.<sup>62</sup> When hepatotoxicity occurs, however, camphor does not typically produce morphologic changes in the liver characteristic of Reye syndrome. Albuminuria was also reported.<sup>112</sup>

Camphor crosses the placenta. Both fetal demise and delivery of healthy neonates are reported in mothers following intentional and unintentional ingestion.<sup>19,101,139</sup> Specific dose-related toxicity cannot be determined from these case reports.

Inhalational and dermal exposures to camphor typically result in mucous membrane and dermal irritation, respectively.<sup>47</sup>

### Diagnostic Testing

No specific diagnostic test is available or indicated when managing patients with camphor toxicity. Camphor and its metabolites can be identified in blood and urine,<sup>70,103</sup> but these tests are not clinically useful.<sup>53,70,103</sup>

### Management

Gastric decontamination is not well studied in patients with acute camphor ingestion. Camphor is rapidly absorbed from the gastrointestinal tract because of its high lipophilicity and vomiting is common. The benefit of gastrointestinal decontamination rapidly diminishes with time following acute ingestion. Gastric lavage was commonly performed in patients with acute camphor ingestions, but it is no longer routinely performed or recommended.<sup>41,93</sup> The utility of activated charcoal in acute camphor ingestion is unknown. One animal study showed the administration of activated charcoal (2 g/kg; 2:1 activated charcoal to toxin ratio) immediately following camphor ingestion did not alter the gastrointestinal absorption of camphor.<sup>35</sup> There are no human data in support of the use of activated charcoal in camphor ingestions. It remains reasonable to administer activated charcoal following a large recent ingestion if no contraindications exist.

Patients who should be evaluated in a health care facility after an acute ingestion include those who have signs or symptoms consistent with camphor toxicity, those who ingest more than 30 mg/kg of camphor, suicidal patients, and any patient with a significant occupational exposure.<sup>77</sup>

There is no antidote for camphor. Most patients survive with supportive care. Although the management of camphor-induced seizures is not well studied, the first-line therapy recommended for camphor-induced seizures are benzodiazepines. Repeat doses of benzodiazepines are often needed to control seizures. If benzodiazepines fail to control seizures, other sedative-hypnotics, including propofol or pentobarbital, should be administered. Case reports suggest that most patients who develop life-threatening camphor toxicity develop symptoms within a few hours postexposure. Based on this, an observation period of at least 4 hours is reasonable following a potentially toxic ingestion. In case reports, hemodialysis with a lipid dialysate and either hemoperfusion using an Amberlite resin or charcoal hemoperfusion successfully removed camphor.<sup>42,68,69,78</sup> However, isolated lipid hemodialysis or lipid dialysis in combination with hemoperfusion is neither routinely recommended nor widely available.

## NAPHTHALENE

### History and Epidemiology

Naphthalene, an aromatic bicyclic hydrocarbon, is commonly found in products such as moth repellents, toilet-bowl and diaper-pail deodorizers, and soil fumigants.<sup>116</sup> It is the single most abundant component of coal tar, approximately 11% by weight, and is used in the manufacture of numerous commercial and industrial products.<sup>25,116</sup> Both crude oil and refined products such as gasoline and diesel fuels contain naphthalene.

Historically, naphthalene toxicity resulted from its use as an antihelminthic and an antiseptic.<sup>111</sup> In more recent years, unintentional and intentional ingestions of mothballs containing naphthalene became the major etiology of naphthalene toxicity.<sup>73,108,117,138</sup> A single naphthalene mothball can contain between 0.5 and 5 g of naphthalene depending on its size.<sup>4</sup> Toilet-bowl and diaper-pail deodorizers containing naphthalene also cause toxicity.<sup>29,148</sup> Chronic exposure to naphthalene occurs in occupational setting with variable amounts of exposure depending on the industry. The most common use of naphthalene is in the production of phthalic anhydride, a compound used in chemical feedstock.<sup>46</sup> Other industrial uses of naphthalene include carbamate insecticides, dye intermediates, synthetic resins, bathroom (urinal) air fresheners, fuel additives, plasticizers, and the manufacture of other chemicals.<sup>46,116</sup> Naphthalene is also generated as a by-product of combustion and is present in ambient air at low concentrations.<sup>46</sup>

Most unintentional exposures to naphthalene-containing moth repellents occur in children and do not cause life-threatening toxicity. According to data from the AAPCC, there are 1,200 to 1,900 naphthalene exposures annually. During the past 25 years, one death occurred from suicide whereas reports of “major toxicity” occurred rarely (Chap. 130). Mothball vapors are also intentionally inhaled as a form of “recreational” inhalant abuse.<sup>71,138</sup>

### Pharmacology, Pharmacokinetics, and Toxicokinetics

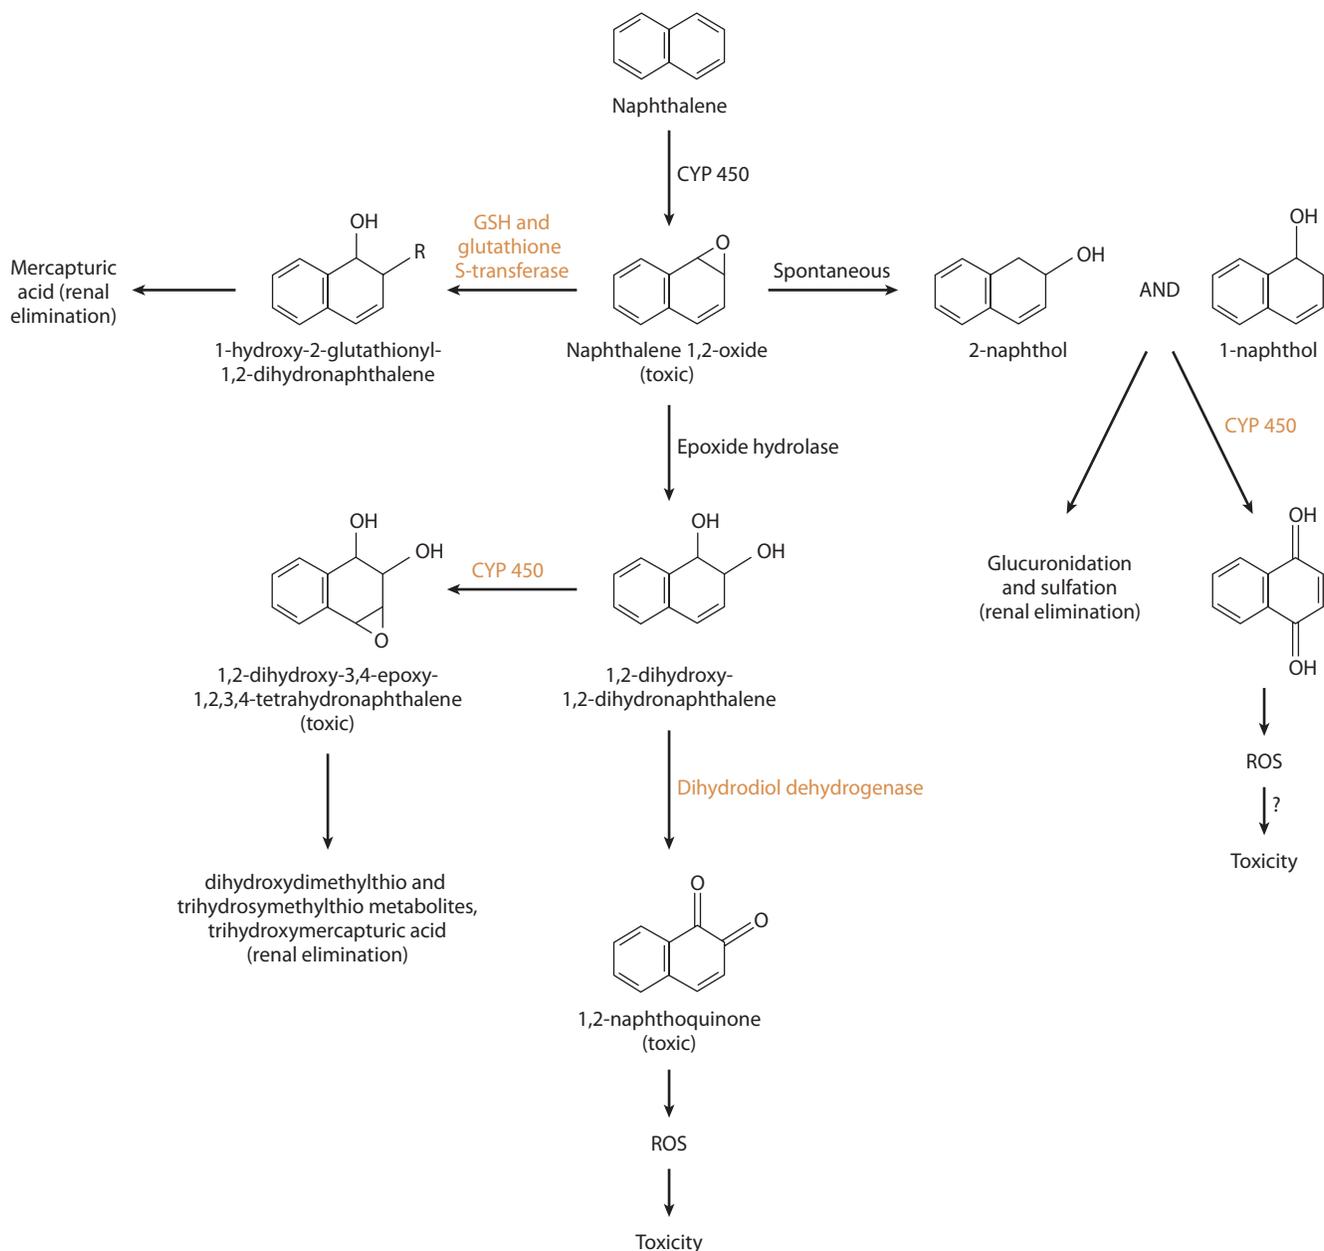

Naphthalene is a white, flakey crystalline solid with a noxious odor. Synonyms include white tar and tar camphor. Naphthalene toxicity is reported following ingestion, dermal application, and inhalation.<sup>34,106,129</sup> The absorption of naphthalene is not well studied. Naphthalene metabolism is complex and varies considerably among species and different anatomical regions.<sup>21</sup> For instance, an *in vitro* study using human liver microsomes showed that multiple CYP450 enzymes are involved in naphthalene metabolism: 1A1, 1A2, 1B1, 2A6, 2B6, 2C19, 2D6, 2E1, and 3A4.<sup>27</sup> Metabolic pathways involve several intermediates and generate multiple reactive metabolites: 1,2-naphthalene oxide, 1,4-naphthoquinone, 1,2-naphthoquinone, and 1,2-dihydroxy-3,4-epoxy-1,2,3,4-tetrahydronaphthalene<sup>4,21,22</sup> (Fig. 102–1).

Naphthalene is initially metabolized to an unstable epoxide intermediate, naphthalene 1,2-oxide, in both human and animals.<sup>4,22,116</sup> 1,2-Naphthalene oxide reacts with cellular components such as DNA and protein to form covalent adducts or can be spontaneously converted to 1-naphthol and 2-naphthol, which undergo glucuronidation or sulfation to form conjugates

that are subsequently eliminated in urine.<sup>4,21,22</sup> Glutathione-*S*-transferase and glutathione play an important role in detoxification of 1,2-naphthalene oxide by converting the reactive epoxide to nonreactive mercapturic acid metabolites.<sup>21,22,76</sup> The depletion of glutathione prior to naphthalene exposure increases acute injury in lung Clara cells, one of the target organs of naphthalene toxicity in mice.<sup>94,95</sup>

Reactive hepatic metabolites, 1-naphthol ( $\alpha$ -naphthol), 1,2-naphthoquinone, and 1,4-naphthoquinone, are cytotoxins that deplete intracellular glutathione stores and generate reactive oxygen species.<sup>4,116,147</sup> They are responsible for the oxidative stress leading to naphthalene-induced hemolysis and methemoglobinemia.

The toxic amount of naphthalene reported is highly variable. As little as one naphthalene mothball resulted in hemolysis in an infant.<sup>40,148</sup> Workplace standards include the OSHA PEL, which is 50 mg/m<sup>3</sup> (10 ppm), ACGIH TLV, which is 52 mg/m<sup>3</sup> (10 ppm), and the ACGIH STEL, which is 79 mg/m<sup>3</sup> (15 ppm); NIOSH IDLH is 250 ppm (US Department of Labor OSHA).<sup>125</sup>

**FIGURE 102–1.** Hepatic metabolism of naphthalene and its respective metabolites. GSH = reduced glutathione; ROS = reactive oxygen species; R=2-glutathionyl. (Data from Buckpitt, et al 2002; Bogen, et al 2008; Agency for Toxic Substances and Disease Registry 2005.)

## Pathophysiology

Naphthalene-induced (via oxidative metabolites: 1-naphthol, 1,2-naphthoquinone, and 1,4-naphthoquinone) hemolysis and methemoglobinemia result when physiologic compensatory mechanisms to oxidative stress are overwhelmed. It is important to understand how oxidant stress affects erythrocytes and the normal mechanisms that erythrocytes use to prevent and reverse the effects of oxidant stress.

Oxidant stressors cause methemoglobinemia and/or hemolysis. When oxidant stress causes an iron atom from any of the 4 globin chains of hemoglobin to be oxidized from the ferrous state ( $\text{Fe}^{2+}$ ) to the ferric state ( $\text{Fe}^{3+}$ ), methemoglobin is formed (Chap. 124). When oxidant stress causes hemoglobin denaturation, the heme groups and the globin chains dissociate and precipitate in the erythrocyte, forming Heinz bodies. An erythrocyte with denatured hemoglobin is more susceptible to hemolysis (Chap. 20).

Hemolysis and methemoglobinemia can occur independently or simultaneously in patients with either normal or deficient glucose-6-phosphate dehydrogenase (G6PD) activity.<sup>58,129,148</sup> Patients with G6PD deficiency are at much greater risk of hemolysis rather than methemoglobinemia because of their decreased glutathione stores.<sup>79,129,147</sup> Glucose-6-phosphate dehydrogenase affects all races, but is most prevalent in patients of African, Mediterranean, and Asian descent. The gene that codes for G6PD is X-linked; consequently, men are affected more often than women.

Infants are also at increased risk of methemoglobinemia because fetal hemoglobin is more susceptible to the formation of methemoglobin. Moreover, cytochrome-b<sub>5</sub> reductase (a nicotinamide adenine dinucleotide {NADH}-dependent enzyme) activity in infants is approximately 50% lower than adults, impairing the reduction of methemoglobin to hemoglobin.<sup>45,54,63</sup>

Injuries to other organs, that is, eyes, lungs, and liver, occurred in animals after exposure to naphthalene.<sup>39,89,98,116,130</sup> However, there is a significant interspecies variation in the degree of toxicity. Human data on organ toxicity beyond hematologic effects of naphthalene are limited. A few case reports link the development of cataracts to occupational exposure; however, the causal relationship remains questionable.<sup>89</sup> Oxidative destruction of lens proteins is theorized to result in cataract formation.<sup>116</sup> Animal studies show that oxidative stress from naphthalene results in pulmonary epithelial necrosis and hepatic injury by lipid peroxidation.<sup>39,98,116</sup> However, there is no report of hepatotoxicity or pulmonary toxicity in humans following naphthalene exposure.

## Clinical Manifestations

Clinically significant toxicity from naphthalene exposure occurs rarely. However, if present, both acute and chronic exposures to naphthalene result in similar toxicity.<sup>29,86,147</sup> Ingestion and inhalational exposures to naphthalene commonly cause headache, nausea, vomiting, diarrhea, abdominal pain, fever, and altered mental status.<sup>29,74,91</sup> Dermal exposure results in dermatitis.<sup>44</sup>

Hemolysis and methemoglobinemia, caused by naphthalene metabolite 1-naphthol, occurs infrequently as a result of naphthalene exposure. They become clinically evident as early as 24 to 48 hours postexposure, but more typically on the third day postexposure because of the time necessary for the hepatic metabolism of naphthalene.<sup>34,73</sup> Anemia secondary to hemolysis often does not reach its nadir until 3 to 5 days postexposure.<sup>9,121</sup>

Signs and symptoms of hemolysis and methemoglobinemia include tachycardia, tachypnea, shortness of breath, cyanosis, jaundice, dark urine, generalized weakness, decreased exercise tolerance, and altered mental status (Chap. 124). Acute kidney injury is reported as a complication of naphthalene-induced hemolysis and hemoglobinuria. Naphthalene and its metabolites cross the placenta.<sup>11</sup> Naphthalene pica during pregnancy causes both maternal and fetal toxicity. Hemolytic anemia in children born to mothers who had naphthalene toxicity at the time of delivery is believed to be related to the maternal naphthalene exposure.<sup>147</sup> Data on the development of cataracts following naphthalene exposure in human are inconclusive.<sup>82</sup>

Based on animal data on carcinogenicity, naphthalene is classified by the International Agency for Research on Cancer (IARC) as a Group 2B carcinogen (possibly carcinogenic to humans) and by the EPA as a Group C possible

human carcinogen.<sup>46,60</sup> The data supporting human carcinogenicity of naphthalene are limited. There are several case reports that associate exposure with laryngeal cancer in East Germany and colorectal cancer in Nigeria, but causal relationship cannot be determined.<sup>7,46</sup>

## Diagnostic Testing

No specific diagnostic testing is indicated, although both naphthalene and its metabolites are identifiable in blood and urine. Identification of 1-naphthol and 2-naphthol in the urine confirms exposure to naphthalene. Qualitative or quantitative testing for naphthalene or its metabolites is not clinically indicated when managing a patient with an acute overdose.<sup>92</sup>

The presentation of naphthalene-induced hemolysis is similar to that of hemolysis from other causes. Hyperbilirubinemia from hemolysis is characterized by an elevation of the unconjugated (indirect) bilirubin and a relatively normal conjugated (direct) fraction. Serum haptoglobin is usually low because the haptoglobin-hemoglobin complex is cleared by the kidneys. Both the direct and indirect Coombs tests are negative in naphthalene-induced hemolytic anemia. Lactate dehydrogenase is elevated due to its release from hemolyzed red blood cells. Hemoglobinuria is suggested by a urine dipstick that reacts strongly positive for hemoglobin with a paucity or absence of red blood cells on microscopic examination of the urine sediment. Hemoglobinemia is differentiated from myoglobinuria, which has a comparable urine sediment, by measuring the serum creatine phosphokinase and myoglobin which will be elevated in patients with rhabdomyolysis and myoglobinuria but not in those with hemolysis and hemoglobinuria.

Examination of a peripheral blood smear is useful in identifying hemolysis before a patient develops clinical or laboratory evidence of anemia. Hemolysis is present when red blood cell (RBC) abnormalities are present including schistocytes, anisocytosis, microspherocytosis, reticulocytosis, nucleated RBCs, Blister cells, and Heinz body (Chap. 20). Peripheral smear abnormalities and anemia often occurs within the first 24 hours following ingestion.<sup>29,107,147,148</sup> Testing for G6PD activity is not recommended during an acute episode of hemolysis. Reticulocytes have higher G6PD activity than do older RBCs. If G6PD activity is measured during an episode of hemolysis when many of the older RBCs have already been destroyed, false elevation or normal G6PD activity is observed. It is best to delay testing for G6PD activity for a few months following an episode of hemolysis. Family members of patients with life-threatening G6PD deficiency should also be tested.

Naphthalene-induced methemoglobinemia is similar in presentation to methemoglobinemia from other xenobiotics. The percentage of methemoglobin is rapidly determined using a cooximeter (Chap. 124).

## Management

Most patients with an unintentional exposure to no more than one naphthalene-containing mothball do not require medical evaluation. Patients who should be evaluated in a health care facility following an acute ingestion include those who recently ingested more than one naphthalene-containing mothball equivalent, those with signs or symptoms of toxicity, especially hemolysis and/or methemoglobinemia, those with known or suspected G6PD deficiency, all intentional ingestions, and those patients with substantial inhalational exposures, particularly those occurring in an occupational setting.

Gastrointestinal decontamination is not well studied in patients who have ingested naphthalene. Most patients with unintentional exposures do not require gastrointestinal decontamination. Administration of activated charcoal, 1 g/kg, although not of proven efficacy, is reasonable because it is considered safe. Repeat doses of activated charcoal 0.5 g/kg and/or whole-bowel irrigation with polyethylene glycol electrolyte lavage solution would only be reasonable for patients with large ingestions of naphthalene who are expected to have significant ongoing gastrointestinal absorption.

Diagnostic testing within the first 24 to 48 hours postexposure will detect the onset of methemoglobinemia and/or hemolysis before a patient becomes symptomatic. Most low-risk patients who are asymptomatic within the first 24 to 48 hours postexposure and who have no laboratory evidence of hemolysis or methemoglobinemia should be managed as outpatients if

reevaluation within 24 to 48 hours can be arranged. Patients who are discharged should be instructed to return if they become symptomatic. Admission recommended for high-risk patients, those with laboratory evidence of hemolysis and/or methemoglobinemia, and those who cannot be reliably managed as outpatients.

Patients with life-threatening hemolysis and anemia should be transfused with packed red blood cells. However, most healthy patients will be able to compensate for the hemolysis and will not require a transfusion. For patients with symptomatic methemoglobinemia methylene blue 1 to 2 mg/kg (0.1–0.2 mL/kg of a 1% solution) is recommended intravenously. Repeat doses may be necessary (Antidotes in Depth: A43).

## PARADICHLOROBENZENE

### History and Epidemiology

Paradichlorobenzene (1,4-dichlorobenzene) is widely used as a deodorizer, disinfectant, repellent, fumigant, insecticide, fungicide, and industrial solvent. Today, paradichlorobenzene is the most common component of moth repellents and deodorants for restrooms in the United States. Low-level exposure to paradichlorobenzene in the United States is extremely common as a result of environmental contamination from release of paradichlorobenzene to air by industrial facilities.<sup>90</sup> The primary route of human exposure is inhalation in either an occupational setting or from indoor air where paradichlorobenzene is used as a deodorizer or moth repellent.<sup>90</sup> Paradichlorobenzene is also found in both water and numerous food items, including pork and fresh vegetables, from environmental contamination.<sup>90,102,133</sup> Consequently, approximately 96% to 98.3% of the US population, including children as young as 2 years old, have detectable 2,5-dichlorophenol, a metabolite of paradichlorobenzene, in the urine.<sup>57,58,144</sup> Analysis of urine samples from the participants of National Health and Nutrition Examination Survey (NHANES) showed that urinary 2,5-dichlorobenzene concentrations decreased between the 2003–2004 and 2009–2010 survey periods. However, highest urinary concentrations were noted among 6- to 11-year-old children and adults older than 60 years.<sup>144</sup> The health effects of the low-level paradichlorobenzene exposure from environmental contamination are unclear. Recent population-based (NHANES) studies suggest a dose-dependent increase in the prevalence of diabetes, thyroid dysfunction, metabolic syndrome, obesity, earlier age of menarche, and food allergies.<sup>22,23,61,123,134–137</sup> These findings do not establish a clear causal relationship, but further research is warranted to investigate the relationship between environmental paradichlorobenzene exposure and its potential adverse health effects.

Approximately 150 paradichlorobenzene exposures are reported annually. The majority of the cases are unintentional exposures to paradichlorobenzene-containing moth repellents, predominantly occurring in children (<5 years old), which do not cause toxicity. According to the AAPCC data, no deaths or major toxicity were reported between 1995 and 2015, and only 15 cases of paradichlorobenzene exposures experienced moderate toxicity during the same period (Chap. 130).

### Pharmacology, Pharmacokinetics, Toxicokinetics, and Pathophysiology

Paradichlorobenzene is a colorless solid with a noxious odor. It is available as pure white crystals, as a solid in combination with other chemicals, or as a liquid dissolved in volatile solvents or oil.<sup>10</sup> Paradichlorobenzene is well absorbed via ingestion, inhalation, and dermal exposure. Inhalation toxicokinetics show that there is rapid distribution and accumulation in tissues, specifically in adipose tissue.<sup>14,27,55,146</sup> This contributes to sustained serum paradichlorobenzene concentrations and clinical toxicity after cessation of chronic exposure, a phenomenon known as “coasting.”<sup>56,36</sup> Starvation increases paradichlorobenzene release owing to utilization of adipose tissues.<sup>13,52</sup> Paradichlorobenzene undergoes hepatic metabolism by several CYP450 enzymes including 1A1, 1A2, 2B1, 2E1 (primary isoenzyme), and 3A1 and 3A4 to its primary metabolite, 2,5-dichlorophenol.<sup>20,36,52,56</sup> With several other minor metabolites (2,5-dichlorohydroquinone, 2,5-dichlorophenylmethyl sulfide, 2,5-dichlorophenylmethyl sulfone), 2,5-dichlorophenol is

eliminated primarily via urinary excretion as either sulfated or glucuronidated conjugates.<sup>14,36,52,146</sup>

The mechanism of the toxicologic effect of paradichlorobenzene has not been studied to date. Although rare, paradichlorobenzene toxicity is reported following ingestion and inhalation.<sup>59,81</sup>

Workplace standards include the OSHA PEL, which is 450 mg/m<sup>3</sup> (75 ppm) time-weighted average (TWA), ACGIH TLV, which is 60 mg/m<sup>3</sup> (10 ppm) TWA, and the ACGIH STEL, which is 675 mg/m<sup>3</sup> (110 ppm); NIOSH IDLH is 150 ppm.<sup>126</sup>

### Clinical Manifestations

Paradichlorobenzene is considered to have less toxicity than camphor and naphthalene. However, cases of clinical toxicity from paradichlorobenzene are reported ranging from hemolytic anemia to toxic leukoencephalopathy following acute and/or chronic exposure.<sup>13,27,37,38,56</sup> Although paradichlorobenzene is absorbed following inhalation, ingestion and cutaneous exposures, ingestion, and inhalation are the routes of exposure that lead to toxicity.<sup>37,38,56,83</sup> Acute unintentional exposure to paradichlorobenzene typically causes limited transient clinical effects such as nausea and vomiting, headache, and mucous membrane irritation.<sup>32,59</sup> However, significant neuropsychiatric dysfunction, specifically cerebellar dysfunction, motor weakness, behavioral changes, and cognitive decline, is reported following chronic intentional and occupational exposure.<sup>37,38,56</sup> In most cases, neurologic and cognitive deficits associated with paradichlorobenzene developed after several months of exposure and seldom had complete resolution after cessation of paradichlorobenzene exposure.<sup>13,36,56,83</sup> Other clinical signs and symptoms from chronic exposure include pulmonary granulomatosis, hepatotoxicity, acute kidney injury, an ichthyosislike dermatosis, aplastic anemia, and dyspnea.<sup>37,38,85,140</sup>

Hemolytic and aplastic anemias are reported, as well as methemoglobinemia, following acute paradichlorobenzene ingestion.<sup>53,109</sup>

Paradichlorobenzene is classified by IARC as a Group 2B, possibly carcinogenic to humans, based on evidence of carcinogenicity from experimental animal studies. In mice and rats, chronic exposure was associated with the development of both hepatocellular carcinomas and adenomas in male and female mice, and renal tubular cell adenocarcinoma and mononuclear cell leukemia developed in male mice.<sup>5,6,16,87,88,143</sup> Evidence for carcinogenicity in humans from paradichlorobenzene exposure is limited. One case series reported 5 cases of leukemia that were associated with paradichlorobenzene exposure.<sup>88,142</sup> No additional epidemiologic data on human carcinogenesis from paradichlorobenzene exposure is available.

### Diagnostic Testing

Both paradichlorobenzene and its primary metabolite, 2,5-dichlorophenol, can be identified in blood and urine following exposure.<sup>14,59</sup> However, detectable serum or urine concentrations of paradichlorobenzene or 2,5-dichlorobenzene are difficult to interpret as they are universally present in healthy adults and children as a common environmental contaminant.<sup>56,57,146</sup> In one study, a sample of 1,000 adults in the United States had detectable concentrations of 2,5-dichlorophenol and paradichlorobenzene in their urine and blood, 98% and 96%, respectively, without evidence of clinical toxicity. The mean 2,5-dichlorophenol and paradichlorobenzene concentrations in urine and blood were 200 and 2.1 mcg/L, respectively. A similar frequency of detectable 2,5-dichlorophenol concentrations in urine was also detected in healthy children.<sup>57</sup> Quantifying the amount of paradichlorobenzene in the urine of workers is useful for monitoring occupational exposures.<sup>40</sup> Overall, qualitative or quantitative testing for paradichlorobenzene or its metabolites is not generally indicated when managing a patient with an acute overdose. Structural CNS abnormalities, including toxic leukoencephalopathy, are occasionally noted on imaging studies such as MRI.<sup>13</sup> Hyperintense signals are seen in specific anatomic locations including periventricular white matter, corpus callosum, deep cerebellar nuclei, the parieto-occipital region and internal capsule.<sup>13,27,56</sup>

## Management

Most unintentional exposures to paradichlorobenzene do not cause severe or life-threatening toxicity. It is reasonable to manage asymptomatic patients with unintentional exposures as outpatients. Patients who should be evaluated in a health care facility include those with clinical signs or symptoms, suicidal patients, and patients who have had a large exposure.

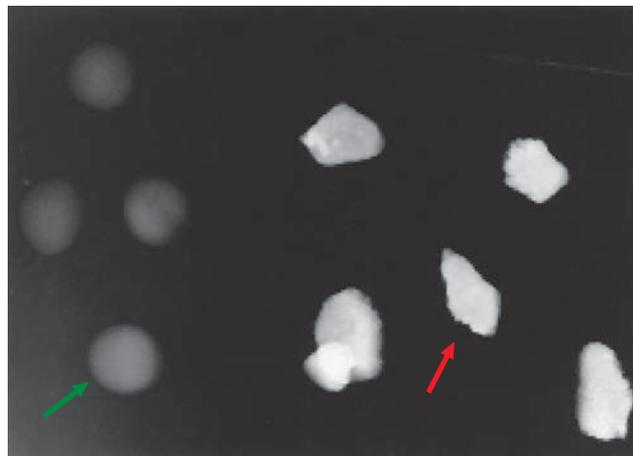

Gastrointestinal decontamination has not been studied in patients who ingest paradichlorobenzene. Most patients with unintentional exposures do not require gastrointestinal decontamination. However, administration of activated charcoal, 1 g/kg, is reasonable for patients with large, intentional ingestions. If present, gastrointestinal effects such as nausea and vomiting should be managed with supportive care, including fluid resuscitation and antiemetics. Laboratory testing is generally not helpful in the acute setting unless there is clinical evidence for hemolysis or methemoglobinemia. Transfusion of packed RBCs is recommended for symptomatic anemia resulting from acute hemolysis. Methylene blue is recommended for symptomatic methemoglobinemia.

It is reasonable for asymptomatic patients to follow up as outpatients for reevaluation in 24 to 48 hours postexposure as delayed development of hemolysis or methemoglobinemia is possible, but rare. Careful discharge instructions should be provided to patients should they become symptomatic.

Management of paradichlorobenzene-induced neurotoxicity such as encephalopathy, cerebellar dysfunction, psychomotor retardation and cognitive decline from chronic exposure is mainly supportive. Improvement of neuropsychiatric symptoms is variable; complete recovery is possible, although infrequent, after cessation of exposure, but residual neurotoxic effects are frequently present.<sup>36,56,83</sup>

## MOTH REPELLENT RECOGNITION

Health care providers occasionally must determine whether a mothball is made of naphthalene, paradichlorobenzene, or camphor because management and prognosis for each is different. When the container is unavailable, as is often the case, mothballs are difficult to distinguish based on appearance, odor, texture, or size. Most mothballs are white, crystalline, and have a noxious odor.<sup>141</sup> Camphor moth repellents are more oily than both naphthalene and paradichlorobenzene mothballs. If controls are available, moth repellents are frequently differentiated based on their odor and texture.<sup>8</sup> Although most new paradichlorobenzene moth repellents are slightly larger than most new naphthalene moth repellents, all moth repellents shrink over time when exposed to air, making size an unreliable differentiating characteristic. Identifying a moth repellent as paradichlorobenzene often permits outpatient management, saving both hospital resources and unnecessary concern. The tests described in Table 102–1 and shown in Fig. 102–2 might

**FIGURE 102–2.** Radiograph of mothballs. Paradichlorobenzene (→) is densely radiopaque, whereas naphthalene (→) is faintly radiopaque.

allow rapid identification of the component of an unknown moth repellent. When performing these tests, it is most helpful to have camphor, naphthalene, and paradichlorobenzene controls available for comparison.

## SUMMARY

- Paradichlorobenzene has largely replaced both camphor and naphthalene as a moth repellent in the United States, but exposures to all 3 compounds occur, especially in immigrant communities.
- It is reasonable to administer activated charcoal in patients with large ingestions if no contraindications are present, such as CNS depression, active vomiting, or seizures.
- Seizures commonly occur after camphor ingestion, and deaths due to status epilepticus are reported. Camphor-induced seizures are responsive to benzodiazepines, propofol, and barbiturates.
- Hemolytic anemia and methemoglobinemia occur after naphthalene and, less frequently, following paradichlorobenzene ingestions. Appropriate supportive care, packed red blood cell transfusions, and methylene blue administration are recommended for symptomatic patients.
- Simple radiography and buoyance tests are helpful in identifying the unknown moth repellent.

## HISTORY AND EPIDEMIOLOGY

A caustic is a xenobiotic that causes both functional and histologic damage on contact with tissue surfaces. As early as 1927, legislation in the United States governing the packaging of alkali- and acid-containing products mandated that warning labels be placed on these products. In response to the recognition that caustic exposures were more frequent in children, the Federal Hazardous Substances Act and Poison Prevention Packaging Act were passed in 1970. These acts mandated that all caustics with a concentration greater than 10% be sold in child-resistant containers. By 1973, the household concentration triggering mandatory child-resistant packaging was lowered to 2%. In addition, the subsequent development of poison prevention education dramatically decreased the incidence of unintentional caustic injuries in children in the United States. The positive impact of both regulatory legislation and public health intervention is evident when observing the decreasing number of significant exposures in the United States compared to the number of exposures in developing nations that lack these policies.

In the United States, even though legislation limiting the concentration of caustics has existed since the early 20th century, exposures to both acids and alkalis continue to be significant. Data collected from the 5 most recent years of the American Association of Poison Control Centers Annual Reports of the National Poison Data System revealed 37,272 acid exposures and 18,801 alkali exposures. Of these, 4,405 (12%) of acid and 3,153 (17%) of alkali exposures resulted in moderate to major outcomes and a total of 26 deaths occurred (Chap. 130).

Caustic exposures follow a bimodal age distribution pattern with peak occurrences in the pediatric population age 1 to 5 years and again in adulthood. In children, exposures usually consist of household products and occur most often in an unsupervised setting. In adults, exposures to household or industrial products result from occupational exposure, suicide attempts, and assaults. Although less frequent, intentional exposures by adults are invariably more significant. One study noted that although children comprised 39% of admissions for caustic ingestions, adults comprised 81% of patients requiring treatment.<sup>38</sup>

Exposure to caustics occurs via the dermal, ocular, respiratory, and gastrointestinal route. Caustics cause diverse histologic and functional damage on contact with tissues depending on the tissue and caustic involved. [Table 103-1](#) lists common caustics and the products that contain them. Many are available for home use, in both solid and liquid forms, with variations in viscosity, concentration, and pH.

The severity of a caustic injury is often not immediately evident in patients who present shortly after exposure. Predicting which patients will require rapid interventions to prevent morbidity and mortality requires the determination and evaluation of multiple clinical and laboratory parameters. This chapter reviews the pathophysiology and approach to patients with potentially serious exposures.

## PATHOPHYSIOLOGY

Although there are many ways to categorize caustics, they are most typically classified as acids or alkalis. An acid is a proton donor and causes significant injury, generally at a pH below 3. An alkali is a proton acceptor and causes significant injury, generally when the pH is above 11. Chapter 10 contains a more detailed discussion of the chemistry of acids and bases. The extent of injury is modulated by duration of contact; ability of the caustic to penetrate tissues; volume, pH, and concentration; the presence or absence of food in the stomach; and a property known as titratable

acid/alkaline reserve (TAR). Titratable acid/alkaline reserve quantifies the amount of neutralization needed to bring the pH of a caustic to that of physiologic tissues. Neutralization of caustics takes place at the expense of the tissues, resulting in the release of thermal energy, producing burns. Generally, as the TAR of a caustic increases, so does the ability to produce tissue damage.<sup>5,42</sup> Some caustics, such as zinc chloride and phenol, have a high TAR and are capable of producing severe burns even though their pH is near physiologic. Beyond tissue damage, some caustics have the potential to cause systemic toxicity.

**TABLE 103-1** Sources of Common Caustics

Caustic	Common Applications
Acetic acid	Permanent wave neutralizers, photographic stop bath, concentrated solution for food purposes
Ammonia (ammonium hydroxide)	Toilet bowl cleaners, metal cleaners and polishes, hair dyes and tints, antirust products, jewelry cleaners, floor strippers, glass cleaners, wax removers
Benzalkonium chloride	Detergents
Boric acid	Roach powders, water softeners, germicides
Formaldehyde, formic acid	Deodorizing tablets, plastic menders, fumigants, embalmers
Hydrochloric acid (muriatic acid)	Metal and toilet bowl cleaners
Hydrofluoric acid	Antirust products, glass etching, microchip etching
Iodine	Antiseptics
Mercuric chloride (HgCl <sub>2</sub> )	Preservatives
Methylethyl ketone peroxide	Industrial synthetic
Oxalic acid	Disinfectants, household bleaches, metal polishes, antirust products, furniture refinishers
Phenol (creosol, creosote)	Antiseptics, preservatives
Phosphoric acid	Toilet bowl cleaners
Phosphorus	Matches, fireworks, rodenticides, methamphetamine synthesis
Potassium permanganate	Illicit abortifacients, antiseptic solutions
Potassium hydroxide	Oven cleaners, hair products, manufacture of biodiesel, soaps
Selenious acid	Gun bluing agents
Sodium hydroxide (lye)	Detergents, paint removers, drain cleaners and openers, oven cleaners
Sodium borates, carbonates, phosphates, and silicates	Detergents, electric dishwasher preparations, water softeners
Sodium hypochlorite	Bleaches, cleansers
Sulfuric acid	Automobile batteries, drain cleaners
Zinc chloride	Soldering flux

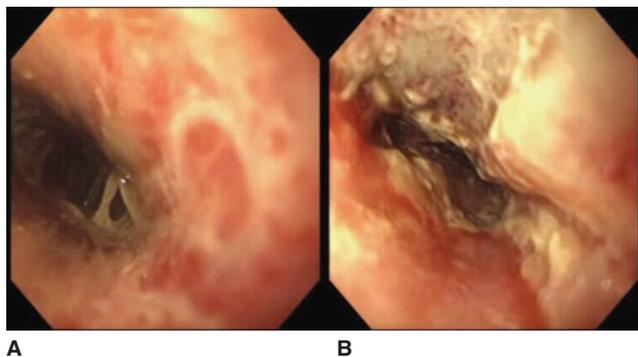

**FIGURE 103-1.** Photograph demonstrating burns to the lips and tongue of a 20-year-old man following ingestion of sodium hydroxide. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

### Alkalis

Following exposure to an alkaline xenobiotic, dissociated hydroxide ( $\text{OH}^-$ ) ions penetrate tissue surfaces, producing a histologic pattern of liquefactive necrosis (Figs. 103-1 and 103-2). This process includes protein dissolution, collagen destruction, fat saponification, cell membrane emulsification, transmural thrombosis, and cell death.<sup>5</sup> Animal studies of alkali exposure to the eye<sup>41</sup> demonstrate rapid formation of corneal epithelial defects with eventual deep penetration that may lead to perforation. Similarly, animal studies of the esophagus demonstrate that erythema and edema of the mucosa occur within seconds followed by an inflammatory reaction extending to the submucosa and muscular layers. The alkali, such as sodium hydroxide (“lye”), continues to penetrate until the  $\text{OH}^-$  concentration is sufficiently neutralized by the tissues.<sup>5,55</sup>

Although federal regulations have lowered the maximal available household concentration of many caustics, 2 industrial-strength products seem to be readily available and therefore warrant special mention: ammonium hydroxide and sodium hypochlorite. Ammonia (ammonium hydroxide) products are weak bases—partially dissociated in water—that cause significant esophageal burns, depending on the concentration and volume ingested.<sup>38</sup> Household ammonium hydroxide ranges in concentration from 3% to 10%. Strictures are reported in patients who ingested 28% solutions.<sup>71</sup> Sodium hypochlorite is the major component in most industrial and household bleaches. Severe injuries typically only occur in patients with large-volume ingestions of concentrated products and most other patients do well with supportive care.<sup>15,38</sup> A series of 393 patients with household bleach ingestions demonstrated no stricture

**FIGURE 103-2.** Endoscopic images of a 20-year-old man following ingestion of sodium hydroxide. (A) Grade IIa noncircumferential burn of the midesophagus. (B) Grade IIb circumferential burn of the distal esophagus. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

formation.<sup>5</sup> Likewise, a canine model found that although vomiting was commonly associated with bleach ingestion, no esophageal lesions were noted, and perforation occurred only following prolonged contact.<sup>54</sup>

Ingestion of button batteries were once considered a unique caustic exposure. Composed of metal salts and a variety of alkaline xenobiotics, such as sodium and potassium hydroxide, leakage of battery contents was a legitimate concern. In recent years, however, new techniques used in the production of button batteries that effectively prevent leakage have shifted the concern following their ingestion from that of a caustic to a foreign body exposure with the significant potential for electrical injury.

Household detergents, such as laundry powders, laundry detergent pods (LDPs),<sup>83</sup> and dishwasher detergents, contain silicates, carbonates, and phosphates and have the potential to induce caustic burns and strictures, even when ingested unintentionally.<sup>16</sup> Although airway compromise rarely occurs after ingestion of traditional detergents,<sup>16,23,59</sup> the majority of exposures to traditional products result in only minor toxicity and usually do not require hospitalization. Compared to children with traditional non-LDP exposures, LDP exposures are associated with a higher incidence of adverse health effects, including mental status depression and respiratory compromise.<sup>10,26,49</sup> At this time it is unclear if the adverse health effects observed with LDP versus non-LDP exposures are due to unique contents or differences in pH, concentration, tensile strength, or the delivery vehicle.

Cationic detergents include quinolinium compounds, pyridinium compounds, and quaternary ammonium salts. These are frequently found in products developed for industrial use, as well as household fabric softeners. A concentration greater than 7.5% can cause severe burns.<sup>58</sup>

### Acids

In contrast to alkaline exposures, following exposure to an acid, hydrogen ( $\text{H}^+$ ) ions desiccate epithelial cells, producing an eschar and resulting in a histologic pattern of coagulation necrosis. This process leads to edema, erythema, mucosal sloughing, ulceration, and necrosis of tissues. Dissociated anions of the acid ( $\text{Cl}^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{PO}_4^{3-}$ ) also act as reducing agents, further injuring tissue. Ophthalmic exposure to acid results in coagulative necrosis that tends to prevent further penetration into deeper layers of the eye.

In most series, following an acid ingestion, both the gastric and esophageal mucosa are equally affected.<sup>21,103</sup> On occasion, the esophagus is spared damage while severe injury is noted in the stomach<sup>29,38</sup> (Fig. 103-3). This result tends to be a rarer finding than concomitant injury to both stomach and esophagus and is probably related to the rapid transit time of liquid acids through the upper gastrointestinal tract. Skip lesions from acid ingestions are reported and presumed to be a function of viscosity and contact

**FIGURE 103-3.** Postmortem specimen from a man with an intentional ingestion of a mixture of phosphoric and hydrochloric acid that was used as a brick cleaner. Note the relative sparing of the esophagus in contrast to full-thickness injury with perforation of the stomach. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

**TABLE 103–2** Evaluation of Caustic Injuries and Their Management<sup>3,19,38,93,103</sup>

Grading of Injury by Endoscopic Visualization	Tissue Findings	Likelihood of Stricture Formation	Suggested Nutritional Support	Indication for Corticosteroids	Indications for Antibiotics	Indication for Stenting
I	Hyperemia or edema of mucosa without ulcer formation	None	Resume diet as tolerated	None (unless airway edema mandates short course)	None	None No stricture risk
Ila	Submucosal lesions, ulcers, exudates that are not circumferential	Low	Soft diet as tolerated or tube feeds (following nasogastric tube placement under direct visualization)	None (unless airway edema mandates short course)	Identified infection	None No stricture risk
Ilb	Submucosal lesions, ulcers, exudates that are near-circumferential	High, 75%	Because of risk of perforation, feeding via gastrostomy, jejunostomy, or total parenteral nutrition are recommended as rapidly as possible	Short course	Identified infection	Intraluminal stents, nasogastric tubes are reasonable interventions to prevent strictures
III	Deep ulcers and necrosis into periesophageal tissues	High, near 100%	Because of risk of perforation, feeding via gastrostomy, jejunostomy, or total parenteral nutrition are recommended as rapidly as possible	Contraindicated (unless airway edema mandates short course)	Identified infection	Intraluminal stents, nasogastric tubes are reasonable interventions to prevent inevitable strictures

time.<sup>38</sup> Additionally, acid-induced pylorospasm is reported to lead to gastric outlet obstruction, antral pooling, and perforation.<sup>21,102</sup> A cat model of the effects of sulfuric acid on the esophagus revealed a coagulative necrosis of the mucosa with whitish discoloration of the tissues and underlying smooth muscle spasm.<sup>5</sup> Other animal models demonstrate chronic generalized esophageal motility dysfunction and shortening.<sup>86,88</sup>

Chapters 95, 101, and 104 contain a more detailed discussion of mercury, phenol, and hydrofluoric acid, respectively, each a unique caustic.

### Classification and Progression of Caustic Injury

Esophageal burns, secondary to both alkali and acid exposures, are classified based on endoscopic visualization that employs a grading system similar to that used with dermal burns (Table 103–2).<sup>19,28,33,102</sup> Human case reports, postmortem studies, histologic inspection of surgical specimens, and experimental animal models reveal a consistent pattern of injury and repair following caustic injury.<sup>80</sup> As wound healing of gastrointestinal tract tissue occurs, neovascularization and fibroblast proliferation take place, laying down new collagen and replacing the damaged tissue with granulation tissue. A similar pattern of repair occurs following caustic injuries of the eye.

Burns of the esophagus typically persist for up to 8 weeks as remodeling takes place and is often followed by esophageal shortening. If the initial injury penetrates deeply, there is progressive narrowing of the esophageal lumen. The dense scar formation presents clinically as a stricture. Strictures can evolve over a period of weeks to months, leading to dysphagia and significant nutritional deficits.

### CLINICAL MANIFESTATIONS

The gastrointestinal tract, respiratory tract, eyes, and skin of the patient are potential sites of caustic injury. Caustics produce severe pain on contact with any of these tissues. By far, the majority of long-term morbidity and mortality from caustic exposure results from ingestion.

In general, despite variation in the mechanism of injury, patients who have ingested either alkalis or acids present and are managed in a similar manner. Depending on the type, amount, and formulation (solid vs liquid) as well as the percentage of tissue exposed, ingestion has the potential to produce severe pain of the lips, mouth, throat, chest, or abdomen. Oropharyngeal edema and burns lead to drooling and rapid airway compromise. Symptoms and findings of esophageal involvement include dysphagia and odynophagia, whereas epigastric pain and hematemesis are typical of gastric involvement.

Respiratory tract damage occurs through direct inhalation or aspiration of vomitus, leading to the clinical manifestations of hoarseness, stridor, and

respiratory distress. Injury results in epiglottitis, laryngeal edema and ulceration, pneumonitis, and impaired gas exchange. Tachypnea or hyperpnea results from either direct injury or as a compensatory response to a metabolic acidosis, which often is associated with elevated lactate concentrations from necrotic tissue or hemodynamic compromise.

Visual changes, eye pain, redness, burns, or ulceration of the eyes suggest ophthalmic exposure. Skin contact with caustics can result in pain, burns, and/or ulceration.

### Predictors of Injury

The severity of injury following a caustic ingestion varies from mild with complete recovery to severe with associated morbidity and mortality. Many attempts have been made to define a method for clinical identification of patients with severe esophageal injuries based on signs and symptoms at presentation in an effort to avoid unnecessary procedures and admission for patients with less severe injury, while identifying patients at risk for severe complications. Various studies, mostly involving alkaline xenobiotics, examine the predictive value of stridor, oropharyngeal burns, drooling, vomiting, and abdominal pain.

One prospective study of 79 children evaluated for vomiting, drooling, and stridor found that a combination of 2 or more of these signs was predictive of significant esophageal injury as visualized on endoscopy.<sup>19</sup> Another study found that drooling, buccal mucosal burns, and an elevated white blood cell count elevation were significant independent predictors of severe gastrointestinal tract injury following acid ingestions.<sup>37</sup> Two additional retrospective studies found that all children with clinically significant injury had symptoms on presentation, but that no single symptom or combination of symptoms could identify all patients with esophageal injury.<sup>15,35</sup> A prospective study of alkali ingestions in both adults and children found that stridor was 100% specific for significant esophageal injury, but this was based on only 3 patients with this finding.<sup>33</sup> However, other authors have found signs or symptoms at presentation to lack prognostic utility in caustic ingestions. A retrospective study of 378 children admitted for a caustic injury found that signs or symptoms could not be used to predict significant esophageal injury.<sup>28</sup> A prospective evaluation of 41 patients after caustic ingestion found that signs and symptoms were unreliable in predicting the extent and severity of injury.<sup>103</sup>

Variation in findings between studies may be due to the population studied (pediatric vs adult), differences in the type of caustic ingested (acid vs alkali), and/or the circumstances associated with the ingestion (intentional vs unintentional). Additionally, studies evaluating the presence or absence of oropharyngeal burns as a predictor of distal esophago-gastric

injury repeatedly found this finding to be poorly predictive.<sup>1,19,28,33,76,90</sup> In one study, esophageal injury was present 51.5% of the time in the absence of oropharyngeal lesions, and 22.2% of these were second- and third-degree burns.<sup>76</sup>

Based on these findings, endoscopy, a standard diagnostic tool used in the management of caustic ingestions, is recommended in all patients with intentional ingestions. Endoscopy is also recommended in any patient with an unintentional ingestion in the presence of stridor and in any patient with 2 or more of the following findings: pain, vomiting, and drooling.<sup>19,77</sup> Children with unintentional caustic ingestions who remain completely asymptomatic and tolerate liquids after a few hours of observation probably require no further medical care.

The abdominal examination is likewise an unreliable indicator of the severity of injury. The presence of abdominal pain suggests tissue injury, but the absence of pain or findings on abdominal examination does not preclude life-threatening gastrointestinal damage.<sup>24,99,103</sup> Esophageal perforations result in mediastinitis and are commonly associated with fever, dyspnea, chest pain, and subcutaneous emphysema of the neck and chest. Although indicative of viscus perforation, abdominal peritoneal signs are late findings.

In addition to the direct effects that occur with tissue contact, systemic absorption and/or direct contact after perforation of acids results in damage to the spleen, liver, biliary tract, pancreas, and kidneys. This also produces a metabolic acidosis, hemolysis, and, ultimately, death.<sup>44</sup> Significant complications occur at various stages of wound recovery. Most importantly, these include airway compromise, hemodynamic instability secondary to hemorrhage from vascular erosion or septic shock, perforations of the gastrointestinal tract with the development of mediastinitis or peritonitis, and other overwhelming infections from bacteria residing in the oropharynx. A patient who survives acute injury with an acid or an alkali is at risk to subsequently develop stricture formation, gastric atony, decreased acid secretion, pseudo-diverticula, and gastric outlet obstruction.<sup>31,103</sup>

Other complications include dysmotility of the pharynx and esophagus,<sup>20</sup> formation of aorto- and tracheo-esophageal fistulas resulting in delayed massive hemorrhage from erosion into a great vessel, and pulmonary thrombosis.<sup>9,38,68,85</sup> Those patients surviving a few weeks after a grade IIb or III injury who subsequently form strictures present with dysphagia and vomiting. Some strictures result in esophageal motility disorders caused by impaired smooth muscle reactivity. Manometric studies of the esophagus help with the early assessment and long-term prognosis by providing precise information about the severity of the initial injury.<sup>30</sup>

Long-term survivors of moderate and severe caustic injury of the esophagus have a risk of esophageal carcinoma that is estimated to be 1,000 times higher than that of the general population and appears to present with a latency of up to 40 years.<sup>4</sup>

## DIAGNOSTIC TESTING

### Laboratory

Laboratory assessment in patients with caustic ingestion has limited clinical utility, but can aid in management planning and evaluation of systemic toxicity and hemorrhage. Thus, all patients with presumed serious caustic ingestion should have an evaluation of serum pH, blood type and cross-match, complete blood count, coagulation parameters, and electrolytes. Elevated coagulation markers,<sup>44</sup> as well as a venous or arterial pH lower than 7.22,<sup>13</sup> are associated with severe caustic injury, but these findings are neither sensitive nor specific. One study evaluating 32 children with caustic ingestion found no difference in the mean leukocyte count or CRP between children with mild versus severe esophageal injury.<sup>12</sup>

Absorption of nonionized acid from the stomach mucosa results in acidemia. Following ingestion of hydrochloric acid, hydrogen and chloride ions (both of which are accounted for in the measurement of the anion gap) dissociate in the serum, resulting in a hyperchloremic (normal anion gap) metabolic acidosis. Other acids, such as sulfuric acid, result in an elevated anion gap metabolic acidosis because the sulfate anion ( $\text{SO}_4^{2-}$ ) is not measured in the calculation of the anion gap. Although alkalis are not absorbed

systemically, significant necrosis of tissue results in a metabolic acidosis with an elevated lactate concentration.

A gastric pH greater than 7.30 correlated retrospectively with severe alkaline injury. The prospective usefulness of this information is limited, as obtaining gastric secretions without direct visualization is dangerous. One prospective study in children also found an increase in uric acid and decreases in phosphate and alkaline phosphatase concentrations to be useful in predicting the presence of esophageal injuries.<sup>73</sup>

### Radiology

Chest and abdominal radiographs are useful in the initial stages of assessment to detect gross signs of esophageal or gastric perforation. Signs of alimentary tract perforation visualized on plain radiographs include pneumomediastinum, pneumoperitoneum, and pleural effusion. However, these studies have a limited sensitivity, and an absence of findings does not preclude perforation.<sup>99</sup> Free intraperitoneal air is best visualized on an upright chest radiograph. Occasionally, free air is only visible on the lateral view. In patients too ill to obtain an upright chest radiograph, an abdominal radiograph obtained with the patient in a left-side-down position is useful to evaluate free intraperitoneal air adjacent to the liver. Additionally, bedside ultrasound has potential utility in the diagnosis of free air and is based entirely on the lack of visualization of the usual intraperitoneal structures.<sup>11,70</sup> Computed tomography (CT) scanning is considerably more sensitive than both radiography and ultrasound for detecting viscus perforation and is recommended for patients if endoscopy is unavailable or if the patient is critically ill.<sup>25,97</sup> In settings in which CT scan is not readily available, a contrast esophagram can be performed if endoscopy is unavailable.

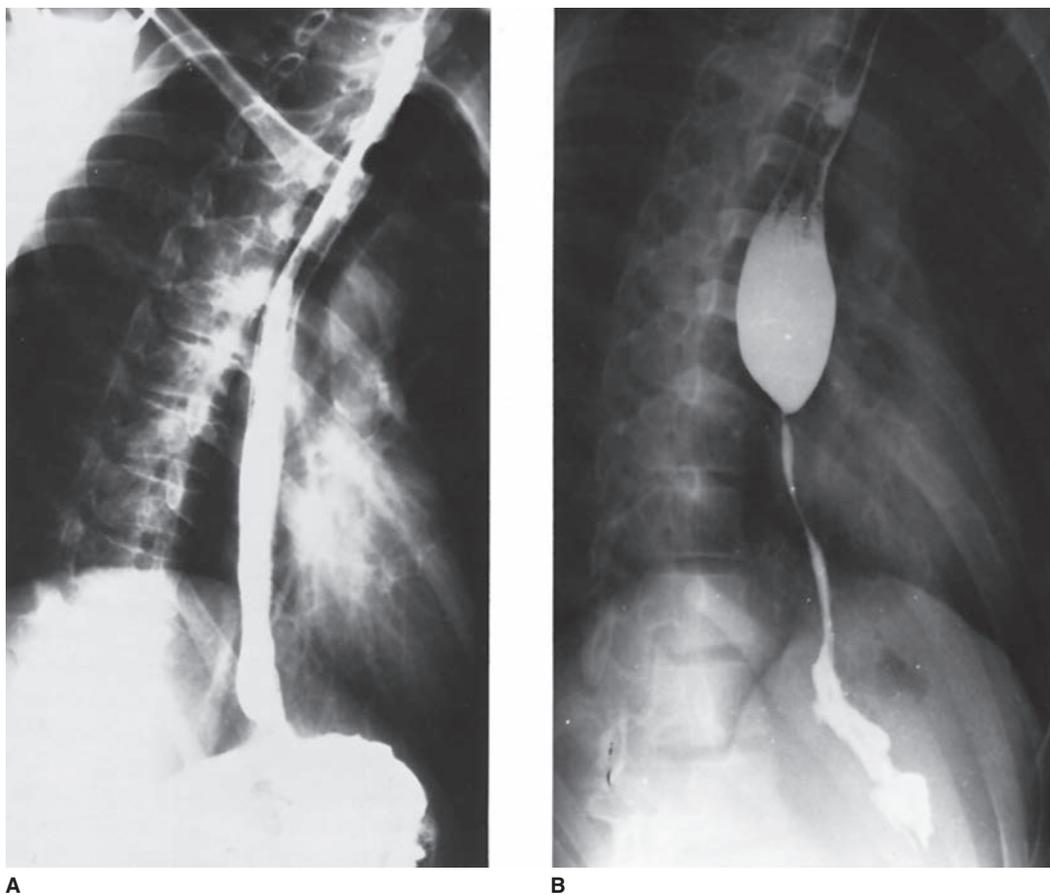

The role for CT scans in caustic ingestions has not been prospectively investigated. In the acute stage, CT has great sensitivity at detecting extraluminal air in the mediastinum or peritoneal cavity as a sign of perforation. In addition, CT visualizes the esophagus and stomach distal to severe caustic burns that cannot be safely visualized using endoscopy, one retrospective study suggests that CT grading of esophageal injuries is superior to endoscopy for prediction of the degree of esophageal damage and the development of stricture formation.<sup>82</sup> These results suggest a promising future role for this noninvasive study following caustic ingestions. Other imaging modalities are proposed for assessing esophageal injury after ingestion of a caustic, including technetium 99m-labeled sucralfate swallow for the presence of injury<sup>65</sup> and esophageal ultrasonography for determining the depth of injury.<sup>67</sup>

Another use of radiographic imaging is to noninvasively follow the patient after initial evaluation and stabilization. For example, contrast radiography is routinely used in the weeks or months following a caustic ingestion to detect esophageal narrowing representing stricture formation (Fig. 103–4).<sup>87,91</sup>

### Endoscopy

Endoscopy is recommended for all patients with intentional ingestions, regardless of symptoms, as well as in patients with unintentional ingestions who demonstrate stridor, or 2 or more of the findings of pain, vomiting, and drooling.<sup>19,33</sup> Early endoscopy serves multiple purposes. It offers a rapid means of obtaining diagnostic and prognostic information while shortening the period of time that patients forego nutritional support, permitting more precise treatment regimens. Patients found to have minimal or no evidence of gastroesophageal injury can be discharged. A nasogastric tube may be passed under direct visualization in appropriate patients to facilitate caloric intake. Endoscopy is ideally performed within 12 hours and generally not later than 24 hours postingestion. Numerous case series demonstrate that the procedure is safe during this period.<sup>15,24,28,57,64,77,84,95,102</sup> We recommend against the use of endoscopic assessment after 24 hours and it should be avoided between 48 hours and 2 weeks postingestion; at this time, tissue strength is most compromised and the risk of perforation is greatest.

The choice of rigid versus flexible endoscopy is dependent on the comfort and experience of the endoscopist. The flexible endoscope has a smaller diameter but requires gentle insufflation of air to achieve or enhance visualization. We agree with a prospective evaluation of the role of fiberoptic endoscopy in the management of caustic ingestions that recommended

**FIGURE 103-4.** (A) Barium swallow several days after ingestion of liquid lye shows the esophagus to be atonic. There is poor coating of the esophagus, suggesting edema and intramural penetration. Note that the initial evaluation immediately following a caustic ingestion to assess the extent of injury is esophagoscopy, rather than a contrast esophagram. (B) Four months later, a repeat barium esophagram shows a severe stricture below the middle third of the esophagus. The barium barely passes the stricture, and the remainder of the esophagus is pencil thin. (Used with permission from Emil J. Balthazar, MD, Professor of Radiology, New York University.)

the following guidelines: (a) direct visualization of the esophagus prior to advancing the instrument, (b) minimal insufflation of air, (c) passage into the stomach unless there is a severe (particularly circumferential) esophageal burn, and (d) avoidance of retroversion or retroflexion of the instrument within the esophagus. Provided that the patient is hemodynamically stable and endoscopy is indicated, every attempt should be made to visualize the esophagus, stomach, and proximal duodenum as soon as possible after a caustic ingestion.<sup>103</sup> The absence of burns in the esophagus does not imply that severe necrosis and ulcerations do not exist in the stomach<sup>65,96,102</sup> and duodenum. In the case of termination of endoscopy because of grade IIb or grade III esophageal burns, we recommend water-soluble contrast studies,<sup>77</sup> CT scan, or surgical exploration to visualize remaining structures.

Endoscopy permits limited evaluation of gastrointestinal injury. For example, the endoscopist is able to appreciate only the mucosal surface of tissues, not the serosal side. This is especially evident in stomach ulcerations, which often appear black and necrotic from a true burn through the layers of the stomach or from the effect of stomach acid on the blood exposed from a shallow lesion. As mentioned above, in these cases, endoscopic ultrasonography or CT scan improves assessment of injury depth.<sup>8,52</sup> Often, however, only direct visualization of serosal and mucosal tissues with laparoscopy or laparotomy allows for definitive evaluation.

Most cases of perforation clearly linked to endoscopy have occurred when the endoscope was advanced through an esophagus with severe grade IIb or III lesions—a violation of current endoscopic standards.<sup>97</sup> In addition, perforations are also more likely to occur when rigid instruments are used in children or in uncooperative patients. Thus, the use of the flexible endoscope and adequate procedural sedation has decreased the complications

from endoscopic evaluation.<sup>77</sup> Some authors advocate the presence of a surgeon during endoscopy to assist in the assessment for potential surgical intervention.

## MANAGEMENT

### Acute Management

As in the case of any patient presenting with a toxicologic emergency, the health care provider must first adhere to universal precautions using early decontamination. Decontamination should include removal of clothing isolating it in a plastic bag for appropriate disposal and careful, copious irrigation of the patient's skin and eyes when indicated to remove any residual caustic and to prevent contamination of other patients, staff, and equipment. Concurrently, initial stabilization should include airway inspection and protection if indicated as well as basic resuscitation principles. Examination of the oropharynx should look for signs of injury, drooling, and vomitus, as well as careful auscultation of the neck and chest for stridor. Careful and constant attention to signs and symptoms of respiratory distress and airway edema, such as a change in voice, are essential and should prompt early intubation as airway edema characteristically rapidly progress over minutes to hours. Although not studied, dexamethasone 10 mg (intravenous) in adults and 0.6 mg/kg up to a total dose of 10 mg in children is reasonable for patients with these or other signs of caustic-induced airway compromise.

If airway involvement is significant enough to warrant intubation, it is best to mobilize a team of the most skilled physicians early in case of unforeseen complications. A delay in prophylactic airway protection often makes subsequent attempts at intubation or bag-valve-mask ventilation difficult or impossible. Direct visual inspection of the vocal cords with a fiberoptic

laryngoscope, nasopharyngoscope, or intubating scope can be used to evaluate impending airway compromise when clinical signs and symptoms are unclear. Patients necessitating intubation are best served by direct visualization of the airway either via direct laryngoscopy or fiberoptic endoscopy, as perforation of edematous tissues of the pharynx and larynx is a grave complication that may occur during blind nasotracheal intubation attempts.

Nonsurgical airway placement is recommended whenever possible as both cricothyrotomy and tracheostomy interfere with the surgical field if esophageal repair is required.<sup>58</sup> Some patients with significant ingestions, however, require emergent surgical airway intervention. The decision to perform a surgical airway is dependent on the status of the patient, the ability to orotracheally or nasotracheally intubate via a fiberoptic endoscope, and operator skill.

Following definitive airway management, large-bore intravenous access should be secured and volume resuscitation initiated. Both acid and alkali ingestions cause “third spacing” of intravascular fluid to the interstitial space, which can result in hypotension. Empiric volume resuscitation with clinical assessment should be used to guide individual fluid requirements. In addition to third spacing hypotension can also result from gastrointestinal tract perforation leading to peritonitis, or mediastinitis, infection, or hemorrhagic shock from vascular erosion. In patients with caustic ingestions, significant complications can occur acutely on presentation or in a delayed fashion on admission. Serial physical examinations and constant monitoring of the vital signs, acid–base status, and urine output to assess the severity of the exposure and the progression in clinical status throughout the ED and/or hospital admission are imperative in patients with suspected serious caustic ingestion.

### Gastrointestinal Decontamination, Dilution, and Neutralization

Gastrointestinal decontamination is usually limited in patients with a caustic ingestion with rare exceptions discussed below. Induced emesis is contraindicated, as it may cause reintroduction of the caustic to the upper gastrointestinal tract and airway. Activated charcoal is also not recommended, as it will interfere with tissue evaluation by endoscopy and preclude a subsequent management plan. Most caustics are not adsorbed to activated charcoal. Exceptions, such as cationic detergents, that do bind well to activated charcoal<sup>58</sup> have not been evaluated with a large series. For this reason, therapy with activated charcoal following any caustic ingestion cannot be recommended, with rare exceptions discussed below. Gastric emptying via cautious placement of a narrow nasogastric tube with gentle suction is reasonable to remove the remaining acid in the stomach only in patients with large, life-threatening, intentional ingestions of acid who present within 30 minutes. Although this technique has never been studied and carries the risk of perforation, the outcome for this particular group of patients with massive exposure is often grave, and options for treatment are limited. Therefore, preventing absorption of some portion of the ingested acid has the potential benefit in reducing systemic toxicity. Although the procedure also has the potential to induce injury, a risk-to-benefit analysis favors gastric emptying following a presumed lethal ingestion. In contrast, gastric emptying is contraindicated with alkaline and unknown caustic ingestions as blind passage of a nasogastric tube carries the risk of perforation of damaged tissues, a risk that outweighs the benefit.

Exceptions to the general rules of gastrointestinal decontamination of caustics exist in the management of zinc chloride (ZnCl<sub>2</sub>) and mercuric chloride (HgCl<sub>2</sub>). Both are caustics with severe systemic toxicity in the form of cationic metal injury.<sup>14,32,53,62,63,69,89,101</sup> The local caustic effects, though of great concern, are less consequential than the manifestations of systemic absorption. Therefore, prevention of systemic absorption should be addressed primarily, followed by the direct assessment and management of the local effects of these xenobiotics. Initial management to prevent systemic absorption includes aggressive decontamination with gentle nasogastric tube aspiration and administration of activated charcoal. In vitro data exist to suggest adequate activated charcoal adsorption of ionic mercury.<sup>2</sup>

The use of dilutional therapy was examined using in vitro, ex vivo, and in vivo models in an attempt to assess its efficacy in caustic ingestions. An

early in vitro model demonstrated a dramatic increase in temperature when either water or milk was added to a lye-containing crystal drain opener (NaOH).<sup>61</sup> Another in vitro model found less consequential increases in temperature despite large volumes of diluent. Results of both studies suggested that dilutional therapy was of limited benefit.<sup>61</sup> Dilutional therapy was also associated with an increase in temperature in an ex vivo study of harvested rat esophagi that examined the histopathologic effects of saline dilution after an alkali injury. Additionally, the usefulness of dilution appeared to be inversely related to the length of time from exposure, with minimal efficacy when delay to initiation was as short as 30 minutes.<sup>44,46</sup> In contrast, an in vivo canine model of alkaline injury demonstrated that water dilution did not cause an increase in either temperature or intraluminal pressures.<sup>47</sup>

The extrapolation of these variable results to humans with caustic ingestions is limited and suggests that histologic damage can only be attenuated by milk or water when administered within the first seconds to minutes following ingestion.<sup>5,43,44,46,47,55</sup> For solid, as opposed to liquid, substances (eg, crystal lye), there is a theoretical value for delayed dilutional therapy, as tissue contact time is increased with solids and their concentration is distributed over a small surface area. However, dilutional therapy is limited in its ability to change pH, risks the spread of the caustic, and adds concerns of producing an exothermic reaction. Experimentally, milk is the best diluent with regard to an ability to attenuate the heat generated by a caustic. Caution should be used in advising patients or family members about the use of diluents. A child who refuses to swallow or take oral liquids should never be forced to do so. In general, dilutional therapy should be limited to the first few minutes after ingestion in patients without airway signs or compromise; are not complaining of significant pharyngeal, chest, or abdominal pain; are not vomiting; and are alert. Dilutional therapy should be avoided in patients with nausea, drooling, stridor, or abdominal distention as it stimulates vomiting and results in reintroduction of the caustic into the upper gastrointestinal tract.<sup>81</sup>

Attempts at neutralization of ingested caustics are contraindicated. This technique has the potential to worsen tissue damage by forming gas and generating an exothermic reaction. In vitro and ex vivo models demonstrate that neutralization of caustics generates heat, requires a large volume to attain physiologic pH, and had limited usefulness in preventing histologic damage if delayed beyond the first several minutes following caustic exposure.<sup>45,61</sup> In one in vivo canine model, orange juice was used to neutralize sodium hydroxide–induced gastric injury and demonstrated no change in temperature or intraluminal pressure.<sup>47</sup> Despite this study, neutralization is contraindicated; there are no other data demonstrating that clinical outcome is improved.

### Surgical Management

The decision to perform surgery in patients with caustic ingestions is generally clear in the presence of either endoscopic or diagnostic imaging evidence of perforation,<sup>99</sup> severe abdominal rigidity, or persistent hypotension. Hypotension is a grave finding and often indicates perforation or significant blood loss. Additionally, elevated PT and PTT,<sup>99</sup> as well as acidemia,<sup>13,50,100</sup> are correlated with severe caustic injury.

Many patients will not have an obvious indication for surgical intervention despite impending perforation, necrosis, sepsis, or delayed hemorrhage. Although more challenging to diagnose, all these sequelae are potentially avoidable if surgery is performed early<sup>58</sup> as morbidity and mortality increase in patients whose surgery is delayed.<sup>20,40,63</sup> Multiple studies have attempted to codify the signs and symptoms necessary or sufficient to rapidly identify patients who would benefit from surgery but who lack clear clinical indications. Several retrospective and prospective series of caustic ingestions found that patients with large ingestions (>150 mL), shock, acidemia, or coagulation disorders tended to have severe findings on surgical exploration. These studies also reinforce that the abdominal examination was frequently unreliable in predicting the need for surgery.<sup>21,99,103</sup> It should be noted, again, that patients with severe acid injuries often lack abdominal pain, but generally have positive findings on diagnostic imaging.<sup>21,103</sup>

It is recommended to consult with a surgeon who is familiar with caustic ingestions for patients with grade IIb and III esophageal burns identified on endoscopy in case of progression of injury and surgery is required.<sup>24,64</sup>

## Adjunctive Therapies

### Steroids

The recommendations for steroid use in patients with caustic injury vary according to the grade of caustic injury. Although corticosteroid therapy is theorized to arrest the process of inflammatory repair and potentially prevent stricture formation, there is evidence that patients with grade III burns, in particular, will progress to stricture formation regardless of therapy.<sup>3,38,96</sup> Additionally, the use of corticosteroids in the management of patients with grade III burns has the potential to mask infection and make the friable, necrotic esophageal tissue more prone to perforation.<sup>75</sup> No study has found benefit for routine use of steroid therapy in grade I or IIa caustic injury. For these reasons, corticosteroid therapy is contraindicated for grade I, IIa, and III esophageal burns. When required in these patients for other indications such as caustic-induced airway inflammation, short-term corticosteroids are recommended.

Currently, some controversy exists regarding the use of corticosteroid therapy in the management of grade IIb circumferential esophageal burns. A recent prospective study of 83 children with grade IIb esophageal burns compared a short (3 day) course of high-dose methylprednisolone to placebo and found a statistically significant decrease in stricture formation in the group that received a short course of high-dose steroids.<sup>93</sup> Prior to this study, the medical literature suggested no benefit of steroids and occasionally harm for patients with grade IIb caustic injury. Two prospective studies to evaluate the efficacy of corticosteroid therapy for caustic injuries to the esophagus failed to show a benefit of corticosteroid therapy, and one even suggested harm.<sup>3,51</sup> A meta-analysis of studies completed from 1956 to 1991, with a total of 361 patients, evaluated the efficacy of corticosteroid therapy and found that in patients with grade II and III esophageal burns, strictures formed in 19% of the corticosteroid-treated group and in 41% of the untreated group.<sup>48</sup> Another meta-analysis of studies from 1991 to 2003, with a total of 211 patients, was unable to find a benefit in treating patients with corticosteroids with grade II and III esophageal burns.<sup>75</sup> A systematic pooled analysis of studies from 1956 to 2006, with a total of 328 patients, attempted to reevaluate the usefulness of corticosteroid therapy in grade II esophageal burns. Although methodologically limited, this study found no benefit in treating patients with steroids with grade II esophageal burns.<sup>75</sup> In addition, a multitude of case series failed to clearly differentiate between grade IIa, IIb, and III lesions, making clinical application of their results difficult.<sup>3,17,96</sup> However, prior to the more recent study noted above, all preceding studies were either retrospective or failed to differentiate between grades of lesions, making interpretation of the data difficult. Despite the imbalance of the quantity of studies demonstrating no benefit (or even harm) versus benefit for the use of steroids in the treatment of grade IIb lesions, the quality of the single prospective study supports our recommendation of a short course of methylprednisolone (1g/1.73 m<sup>2</sup>/day for 3 days) and ranitidine, ceftriaxone, and total parenteral nutrition in these patients.<sup>93</sup>

### Antibiotics

No major outcome studies have investigated the use of antibiotics alone as prophylactic treatment for stricture prevention, but it is reasonable to reserve antibiotics for patients with an identified source of infection.

### H<sub>2</sub> Antagonists/Proton Pump Inhibitors

Histamine<sub>2</sub> antagonists or proton pumps inhibitors theoretically help reduce acid production and injury after caustic ingestion and are thus reasonable as adjunctive therapy in discussion with a gastroenterologist despite a lack of studies to demonstrate their efficacy.

### Stents and Feeding Tubes

A variety of other management strategies have been used in an attempt to prevent strictures and esophageal obstruction. In both animal models<sup>79</sup> and in human case series,<sup>24,66,78</sup> intraluminal stents and nasogastric tubes<sup>66</sup> made

of silicone rubber tubing successfully maintain the patency of the esophageal lumen. For nutritional support, the stents are usually attached to a feeding tube secured in the nasopharynx through which the patient can receive feedings without interfering with esophageal repair. These tubes are left in place for 3 weeks<sup>78,79</sup> and are often used with concomitant corticosteroid and antibiotic therapy. In animal models, the use of a stent for 3 weeks is superior in maintaining esophageal patency when compared to corticosteroids and antibiotics alone.<sup>79</sup> Potential disadvantages of esophageal stents include mechanical trauma at the site and increased reflux, both of which may inhibit healing.<sup>87</sup> A feline model of esophageal exposure to sodium hydroxide used stents but reported deaths from aspiration and mediastinitis.<sup>79</sup> One series of 251 humans exposed to caustics who were managed with silicone rubber stents found that the procedure was successful in preventing stricture formation.<sup>7</sup> Stents and feeding tubes provide the benefit of enteral nutrition and potential to prevent stricture formation and are reasonable on a case-by-case basis in discussion with surgery and gastroenterology consultants.

### Additional Considerations

Additionally, a plethora of animal models have attempted to identify therapies that attenuate oxidative damage, inhibit synthesis, or stimulate breakdown of collagen and thereby prevent stricture formation. β-Amino propionitrile,<sup>60</sup> penicillamine,<sup>29</sup> N-acetylcysteine,<sup>56</sup> halofuginone,<sup>34,74</sup> vitamin E, sphingosylphosphorylcholine, colchicine, erythropoietin,<sup>6</sup> mitomycin C,<sup>92</sup> ozone,<sup>36</sup> fibroblast growth factor,<sup>72</sup> 5-fluorouracil,<sup>22</sup> ibuprofen,<sup>39</sup> and retinoic acid<sup>18</sup> are some of these xenobiotics. These treatments are inadequately studied in humans and cannot be routinely recommended at this time.

### Disposition

The extent of tissue injury dictates the subsequent management and disposition of patients with caustic ingestions.

### Grade I Esophageal Injuries

Patients with isolated grade I injuries of the esophagus do not develop strictures and are not at increased risk of carcinoma. Their diet can be resumed as tolerated. No further therapy is required. These patients can be discharged from the emergency department as long as they are able to eat and drink and their psychiatric status is stable.

### Grade IIa Esophageal Injuries

If endoscopy reveals grade IIa lesions of the esophagus and sparing of the stomach, a soft diet can be resumed as tolerated or a nasogastric tube can be passed under direct visualization. If oral intake or feeding via a nasogastric tube is not feasible, feeding via gastrostomy, jejunostomy, or total parenteral nutrition is recommended as rapidly as possible. Providing interim enteral support is imperative as metabolic demands are increased in any patient with a significant caustic injury.

### Grades IIb and III Esophageal Injuries

Patients with grades IIb and III lesions must be followed for the complications of perforation, infection, and stricture development. Strictures are a debilitating complication of both acid and alkali ingestions that evolve over a period of weeks or months. Strictures form as a result of the natural process by which the body repairs injured tissue through the production of collagen with resultant scar formation. In addition to stricture formation, patients with grade III burns are also at high risk for other complications, including fistula formation, infection, and perforation with associated mediastinitis and peritonitis.

### Chronic Treatment of Strictures

Commonly, the management of patients with esophageal strictures includes endoscopic dilation, for which a variety of types of dilators are available. Contrast CT can be used to determine maximal esophageal wall thickness, which can then be used to predict response, as well as the number of sessions required to achieve adequate dilation. Multiple dilations are often necessary. In one study, patients with a maximal esophageal wall thickness of 9 mm or greater required more than 7 sessions to achieve adequate dilation.

This was significantly higher than in patients with a lesser maximal wall thickness. Measurement of maximal wall thickness is useful in determining long-term follow-up, type of nutritional support, and the potential need for surgical repair as an alternative to dilation. It also provides an indication for those who should undergo dilation under fluoroscopy to limit the risk of perforation.

The risk of perforation from esophageal dilation is decreased if the initial procedure is delayed beyond 4 weeks postingestion, when healing, remodeling, and potential stricture formation in the esophagus have already taken place. Several series report perforation secondary to esophageal dilation.<sup>38,97</sup> Following perforation, patients develop dyspnea or chest pain in the setting of associated subcutaneous emphysema or pneumomediastinum. Diagnostic imaging is recommended to identify the perforation and provide information for emergent surgical repair if the diagnosis is unclear. Patients with stricture formation require long-term endoscopic follow-up for the presence of neoplastic changes of the esophagus that may occur with a delay of several decades.<sup>4,94</sup>

### Management of Ophthalmic Exposures

Ophthalmic exposures occur from splash injuries and malicious events as well as from the alkaline by-products of sodium azide released in automobile air bag deployment and rupture.<sup>98</sup> The mainstay of therapy for these patients is immediate irrigation of the eye for a minimum of 15 minutes with 0.9% sodium chloride, lactated Ringer solution, or tap water, if it is the only therapy immediately available. Several liters of irrigation fluid are recommended. The normal pH of ophthalmic secretions is approximately 6.5 to 7.6. This can be tested colorimetrically by using a urine dipstick, which can test a range of pH from 5 to 9.6; litmus paper can be used in the same fashion. Another useful option in acid exposures is Nitrazine (phenolphthazine) paper, which changes color from yellow to dark blue at a pH above 6.5.<sup>25</sup> These different test strips should be applied to the ophthalmic secretions to test the baseline pH and followed with intermittent evaluations after 15 minutes of lavage to determine the adequacy of irrigation. If these testing materials are not readily available, irrigation should not be delayed, as the depth of penetration of the caustic will determine outcome. If anterior chamber irrigation is required it should be performed emergently by an ophthalmologist. A thorough eye examination should be completed, and follow-up should be arranged. Chapter 24 and Special Considerations: SC2 contain a more detailed description of the evaluation and management of caustic injuries of the eye.

### SUMMARY

- Initial management of all patients with caustic exposures begins with universal precautions in an effort to prevent further contamination of staff, other patients, and equipment.
- In patients with caustic ingestions, airway assessment and stabilization are of primary importance.
- It is recommended to not perform induced emesis, lavage, activated charcoal, neutralization, or dilutional therapy in patients with caustic ingestions with rare exceptions.
- Significant caustic injury should be suspected in all patients with intentional ingestions and in patients with unintentional ingestions presenting with stridor or 2 or more of the following: vomiting, drooling, and pain in the oropharynx, chest, or abdomen.
- All patients with suspected significant ingestions should undergo endoscopy or CT emergently so that effective treatment strategies are initiated expeditiously.
- Surgeons should be involved in the initial assessment of all patients with suspected significant ingestions and those who have an acute abdomen or hypotension so that any surgical intervention deemed necessary is performed promptly.

## HISTORY AND EPIDEMIOLOGY

Hydrofluoric acid has been known for centuries for its ability to dissolve silica. The Nuremberg artist Schwanhard is given credit for the first attempt in 1670 to use HF vapors to etch glass.<sup>47</sup> Today, hydrofluoric acid (HF) is widely used throughout industry. In addition to glass etching, HF is used in brick cleaning, etching microchips in the semiconductor industry, electroplating, leather tanning, rust removal, and the cleaning of porcelain.<sup>47</sup> From 2011 to 2015, the American Association of Poison Control Centers (AAPCC) reported 2,761 single-substance exposures to HF and 6 deaths (Chap. 130). The hands are the commonest part of the body injured. Exposures to HF often occur as unintentional occupational hazards. The actual number of work-related poisonings from HF appears difficult to quantitate because of limitations in International Classification of Diseases (ICD) medical coding and the lack of notification of regional poison control centers by worksites.<sup>10</sup>

Hydrofluoric acid is also the commonest cause of fluoride poisoning, although other forms of fluoride, including sodium fluoride (NaF), ammonium bifluoride ( $\text{NH}_4\text{HF}_2$ ), and sodium or zinc fluorosilicate, also produce significant toxicity. Historically, NaF was used as an insecticide, rodenticide, an antihelminthic for swine, and a delousing powder for poultry and cattle. Ammonium bifluoride is mainly used in industrial inorganic chemistry, especially in the processing of alloys and in glass etching. Other fluoride salts are widely used in, for example, the steel industry, drinking water, toothpaste additives, electroplating, lumber treatment, and the glass and enamel industries.

The widespread use of HF and fluoride-containing compounds results in significant toxicity. In 1988, an oil refinery in Texas released a cloud of hydrogen fluoride gas that resulted in 939 people seeking hospital treatment and 94 of these patients requiring admission.<sup>100</sup> The petroleum industry has since been plagued by similar HF incidents.<sup>100</sup> In 2015, Washington State reported one death and 48 occupational HF burns associated with car and truck washing between 2001 and 2013.<sup>78</sup> Sodium fluoride was responsible for the poisoning of 263 people and 47 fatalities when it was mistaken for powdered milk and unintentionally combined with scrambled eggs.<sup>55</sup> Following ingestion, this and other fluoride salts are converted to HF in vivo, resulting in significant fluoride toxicity.

## CHEMISTRY

Hydrofluoric acid is synthesized as the product of gaseous sulfuric acid and calcium fluoride, which is subsequently cooled to a liquid.<sup>56</sup> Aqueous HF is a weak acid, with a  $\text{pK}_a$  of 3.17; as such, it is approximately 1,000 times less dissociated than equimolar hydrochloric acid, a strong acid. Hydrofluoric acid generally ranges in concentrations from 3% to 40%, for use in both industry and the home. Anhydrous HF is highly concentrated (>70%) and used almost exclusively for industrial purposes. Hydrofluoric acid has unique properties that can cause life-threatening complications following seemingly trivial exposure.

Sodium fluoride is commonly synthesized by the reaction of sodium hydroxide (NaOH) with HF, with subsequent purification by recrystallization. Sodium fluoride is highly water soluble and readily dissociates.<sup>4</sup>

To synthesize ammonium bifluoride ( $\text{NH}_4\text{HF}_2$ ), ammonium fluoride ( $\text{NH}_4\text{F}$ ) is first formed by the reaction of ammonium hydroxide ( $\text{NH}_4\text{OH}$ ) with HF. Ammonium fluoride is then converted to bifluoride by dehydrating the aqueous solution.

Fluorine is the most electronegative element in the Periodic Table of the Elements owing to its relatively large number of protons in the nucleus compared to its molecular size, and the minimal amount of screening or shielding

by inner electrons. Other halides possess lesser electronegative properties. Consequently, the corresponding anion of fluorine, the fluoride ion ( $\text{F}^-$ ), is a weak base because it possesses only a limited ability to donate its electrons. Liberation of the fluoride ion from the previously mentioned compounds is believed to be the major determinant of toxicity.

## PATHOPHYSIOLOGY

Exposures to HF occur via dermal, ophthalmic, inhalation, oral, and rectal routes.<sup>18</sup> A permeability coefficient of  $1.4 \times 10^{-4}$  cm/sec allows HF to penetrate deeply into tissues prior to dissociating into hydrogen ions and highly electronegative fluoride ions.<sup>34</sup> These fluoride ions avidly bind to extracellular and intracellular stores of calcium ( $\text{Ca}^{2+}$ ) and magnesium ( $\text{Mg}^{2+}$ ), depleting them, and ultimately leading to cellular dysfunction and cell death.<sup>11,54,64</sup> The alteration in local calcium homeostasis causes neuroexcitation and accounts for the development of neuropathic pain. Furthermore, ischemia related to calcium dysregulation-mediated localized vasospasm is likely an additional contributory factor to the development of pain.<sup>42,91</sup>

Formation of insoluble calcium fluoride ( $\text{CaF}_2$ ) is proposed as the etiology for both the precipitous fall in serum calcium concentration and the severe pain associated with tissue toxicity. There are several theories regarding the actual fate of calcium and fluoride ions in tissues. In vitro evidence suggests that fluorapatite is formed in the presence of phosphate and hydroxyapatite, which is a more likely pathway for disposition of the fluoride ion.<sup>11</sup> Fluorapatite, like calcium fluoride, is insoluble and its formation contributes to the clinical findings recognized following HF toxicity.

Fluoride also binds magnesium and manganese ions and there is in vitro evidence that this interferes with many enzyme systems. In the anhydrous form, the high concentration of hydrogen ions in HF also produces a caustic burn similar to that caused by strong acids (Chap. 103). The minimal lethal oral dose in humans is approximately 5 to 10 g of NaF.<sup>5</sup>

## CLINICAL EFFECTS

### Local Effects

#### Dermal

The extent of tissue injury following dermal exposure is determined by the volume, concentration, and contact time with the tissues. Following dermal exposure, the concentration of HF is directly related to the onset of pain at the contact site.<sup>31,56,90</sup> High concentrations (>20%) cause immediate pain with visible tissue damage.<sup>84</sup> Exposure to household rust-removal products (6% and 12% HF) is often associated with a typical latency of several hours, before pain develops.<sup>31,85,95,96</sup> The initial site of injury typically appears relatively benign despite significant subjective complaints of pain. Over time, the tissue becomes hyperemic, with subsequent blanching and coagulative necrosis. As calcium complexes precipitate, a white discoloration of the affected area appears<sup>74</sup> (Fig. 104-1). Ulceration is dependent on the concentration and duration of contact.<sup>27,48,57</sup> If more than 2.5% of the body surface area (BSA) is burned with highly concentrated HF, life-threatening systemic toxicity should be expected.<sup>20,71,73,84,90</sup> Small body surface area exposures to low concentrations (<20%) typically do not result in life-threatening systemic toxicity, although fatalities have resulted with dermal exposures to concentrated HF covering less than 5% body surface area.<sup>89</sup>

#### Gastrointestinal

Intentional ingestion of concentrated HF (or other fluoride salts) causes significant gastritis yet often spares the remainder of the gastrointestinal tract. Patients promptly develop vomiting and abdominal pain. Although systemic

**FIGURE 104-1.** Severe injury to the fingers resulted from exposure to hydrofluoric acid. Note the arterial line in place for administration of calcium. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

absorption is rapid and almost invariably fatal, there is at least one report of a patient who ingested a low concentration (8%) of HF and suffered multiple episodes of ventricular fibrillation but was successfully resuscitated.<sup>87</sup> Following HF ingestion, patients often present with altered mental status, airway compromise, and dysrhythmias.<sup>13,55,59,87</sup>

### Ophthalmic

Hydrofluoric acid results in more extensive injury to the eye than most other acids.<sup>65</sup> Ophthalmic exposures from liquid splashes or hydrogen fluoride gas rapidly denudes the corneal and conjunctival epithelium, and lead to stromal corneal edema, conjunctival ischemia, sloughing, and chemosis.<sup>47</sup> Fluoride ions penetrate deeply to affect anterior chamber structures.<sup>47</sup> The effects are usually noted within one day.<sup>47</sup> Other possible findings include corneal revascularization, recurrent epithelial erosions, and, sometimes, keratoconjunctivitis sicca (dry eye) develops as a long-term complication with subsequent corneal ulcers.<sup>7,65,80</sup>

### Pulmonary

Patients with inhalational exposures present with a variety of signs and symptoms depending on the concentration and exposure time. Thirteen oil refinery workers exposed to a low-concentration HF mist experienced minor upper respiratory tract irritation.<sup>52</sup> By contrast, in a mass inhalational exposure to HF, throat burning and shortness of breath were among the more common chief complaints.<sup>100</sup> Some of these patients developed hypoxemia and hypocalcemia and had altered pulmonary function tests. Stridor, wheezing, rhonchi, and erythema and ulcers of the upper respiratory tract were described. Eye pain was also noted, reinforcing the fact that ophthalmic injury often accompanies inhalational and/or dermal exposures.<sup>52,62,79,100</sup>

## ASSESSING SEVERITY OF SYSTEMIC EFFECTS

Significant systemic toxicity occurs via any route of exposure because of the ability of HF to penetrate tissues. The potential for systemic toxicity is an important consideration in management necessitating rapid decontamination and treatment.<sup>12,16,33,83,84,92,93</sup> Fatal exposures to HF by any route share the similar features of hypocalcemia, hypomagnesemia, and, in many cases, hyperkalemia as preterminal events.<sup>4,13,19,23,33,56,59,66,67,90</sup> In some circumstances, the hypocalcemia severely disrupts the coagulation cascade, resulting in significant anticoagulation, even on postmortem examination.<sup>59,69,70</sup>

Fatalities from HF occur as a result of either sudden-onset myocardial conduction failure or ventricular fibrillation. Although the evidence regarding the mechanism of myocardial irritability is inconclusive, electrolyte disturbances that lead to ventricular dysrhythmias including ventricular fibrillation are the most likely primary cause of death in patients with severe

systemic fluoride poisoning.<sup>20,72,84,90,104</sup> Although one postmortem human case reveals significant structural myocardial injury,<sup>63</sup> interestingly, histologic abnormalities of the myocardium do not occur in canine models of HF poisoning.<sup>25,69</sup>

Systemic fluoride toxicity results in hypocalcemia, by mechanisms not fully elucidated. Fluoride causes calcium ions to accumulate intracellularly, leading to an efflux of potassium ions into the extracellular space.<sup>25,54,69</sup> One in vitro study performed with human erythrocytes demonstrated that fluoride inhibition of  $\text{Na}^+, \text{K}^+$ -ATPase and  $\text{Na}^+, \text{Ca}^{2+}$  exchange leads to an increase in intracellular calcium.<sup>68</sup> The subsequent hyperkalemia alters the automaticity and resting potential of the heart, leading to fatal dysrhythmias (Chap. 15).<sup>66</sup> Dogs treated with quinidine, a potassium efflux blocker, are protected from lethal doses of intravenous  $\text{NaF}$ .<sup>25</sup> Likewise, amiodarone, which also blocks potassium efflux has demonstrable efficacy in both in vitro and in vivo models of fluoride toxicity.<sup>88</sup> However, efficacy in humans has not been studied. Furthermore, the mechanism of toxicity is likely much more complicated.<sup>106</sup> A child with systemic fluoride toxicity, who was appropriately replenished with calcium, and had normal electrolytes still experienced nonfatal ventricular fibrillation.<sup>12,106</sup> Perhaps this is because serum potassium, calcium, and magnesium concentrations only partly represent tissue concentrations.<sup>11,12,25,66,67</sup> Furthermore, HF directly impairs myocardial function. Rabbits exposed to topical HF over 2% of their total body surface area developed focal necrosis of myocardial fibers, as well as significant elevations in cardiac enzymes that persisted for almost 5 days after injury.<sup>105</sup>

*Assessing Severity of Clinical Exposures.* Historical and clinical features of an exposure usually determine which HF exposures are life-threatening. All oral and inhalational exposures are potentially fatal, as should burns of the face and neck, regardless of HF concentration. Inhalational exposure should be assumed for all patients with skin burns of greater than 5% body surface area, any exposure to HF concentrations greater than 20%, and head and neck burns.<sup>46</sup> Patients presenting with altered mental status directly related to HF are critically ill and necessitate rapid therapy.

Hydrofluoric acid concentrations greater than 20% have potential for significant toxicity in any patient, even if only a small surface area is exposed.<sup>61</sup> As a general rule, patients who experience severe pain within minutes of contact are most likely exposed to a very high concentration of HF and their condition should be expected to rapidly deteriorate. Some otherwise well-appearing patients have a precipitous demise without any clinical manifestations of hypocalcemia. Furthermore, it is possible that systemic toxicity will occur following seemingly minimal exposure. A 36-year-old man was exposed to 20% HF over a 3% BSA and subsequently developed hypocalcemia, hypomagnesemia, and cardiac arrest 16 hours later.<sup>102</sup> A 2-year-old girl ingested some “fingers full” of an ammonium bifluoride glass etching cream and had prolonged hypocalcemia refractory to calcium gluconate up to 24 hours after ingestion.<sup>58</sup> Consequently, patients will require prolonged electrolyte and cardiac monitoring following significant fluoride exposures.

## DIAGNOSTIC TESTING

No monitoring or testing is required for uncomplicated small BSA exposures to low concentrations of HF. Diagnostic testing for systemic fluoride poisoning is currently based on monitoring of serum electrolytes. Calcium, magnesium and potassium concentrations should be serially monitored.<sup>33</sup> As systemic toxicity progresses, a metabolic acidosis will likely develop necessitating a venous or arterial blood gas analysis.<sup>11</sup> Serum fluoride concentrations are not readily available in a clinically relevant time frame. Although a serum fluoride concentration of 0.3 mg/dL was reported as fatal, one patient survived with a serum fluoride concentration of 1.4 mg/dL.<sup>90,106</sup>

Electrocardiographic findings of both hypocalcemia (prolonged QT interval) and hyperkalemia (peaked T waves, etc) are often reliable indicators of toxicity (Chap. 15).<sup>4,16,33,36,41,70,90</sup> In fact, ECG findings of peaked T waves from hyperkalemia preceded the onset of ventricular dysrhythmias in reported cases, thus potentially serving as a marker of severe fluoride toxicity.<sup>12,67</sup> It should be noted that in some cases of HF poisoning, hypokalemia is

reported<sup>26,32,102</sup> and for unclear reasons, are specifically related to sodium fluoride toxicity.<sup>97</sup>

## MANAGEMENT

### General

For patients with more than localized exposure to low concentration (<20%) HF or any exposures to high concentration (>50%) HF, the mainstay of management is to prevent or limit systemic absorption, assess for systemic toxicity, and rapidly correct any electrolyte imbalances. Intravenous access should be obtained. An ECG should be obtained and examined for dysrhythmias and signs of hypocalcemia, hypomagnesemia, and hyperkalemia. The patient should be attached to continuous cardiac monitoring and have a rapid assessment of serum electrolyte concentrations.

Rapid airway assessment and protection should occur early in patients with inhalation or ingestion, respiratory distress, ingestion with vomiting, or burns significant enough to cause a change in mental status or phonation. If an unstable patient requires intubation, the depolarizing neuromuscular blocking agent, succinylcholine, should not be used because of potential hyperkalemia.

For patients with less significant dermal exposures, studies have focused on alternatives to irrigation with water or saline as decontamination techniques. The compound “hexafluorine” is promoted for dermal and ophthalmic decontamination of HF splashes.<sup>60,86</sup> Hexafluorine is a proprietary name whose chemical formula is not disclosed and papers that report success have strong ties to the manufacturer. In a controlled and blinded experimental study, Hexafluorine treatment was less effective than irrigation with water followed by the application of topical calcium.<sup>40</sup> In a follow-up animal study, water irrigation was as effective as Hexafluorine in preventing systemic toxicity from HF.<sup>43</sup> At this time, until further objective data are available, we do not recommend the use Hexafluorine for initial decontamination of patients with HF exposures.

An iodine-containing preparation was evaluated in a guinea pig model of HF-induced burns and found to be associated with significant reductions in ulceration area.<sup>101</sup> Iodine is hypothesized to inhibit apoptosis and has protective effects against burns from various alkylating agents, including mustard gas.<sup>101</sup> Because experience with iodine treatment of human HF burns is lacking, it cannot be recommended at this time.

The most important therapy for skin exposures is the rapid removal of clothing and irrigation of the affected area with copious amounts of water or saline, whichever is more readily available.<sup>2,51,53,57</sup>

One report describes a woman who was dying from severe HF toxicity who was treated by amputation of the affected limb, and survived. Although this may be an alternative measure for patients who are critically ill and demonstrate an inadequate response to all other therapeutic modalities, we do not recommend such aggressive measures.<sup>15,49</sup>

### Dermal Toxicity

Several therapeutic options have been studied in animal models for treatment of topical HF burns. Unfortunately, many study designs use histologic or subjective wound inspection as outcome parameters,<sup>17,75</sup> some with unblinded inspection.<sup>14,29,49,51,72</sup> These animal models do not address the clinically important parameters of pain reduction, cosmesis, and functionality (Antidotes in Depth: A32).

We recommend that a topical calcium gel be applied to the affected area. A commercial gel is available in the United States but an acceptable substitute is reasonable and easily prepared. This is accomplished by mixing 3.5 g of calcium gluconate powder in 150 mL of sterile water-soluble lubricant, or 25 mL of 10% calcium gluconate in 75 mL of sterile water-soluble lubricant.<sup>2,17,46</sup> If calcium gluconate is unavailable, it is reasonable to use calcium chloride or calcium carbonate in a similar formulation.<sup>21</sup> This topical therapy for severe and non-life-threatening toxicity scavenges fluoride ions. After irrigation, we recommend a gel solution of calcium carbonate or gluconate be applied directly to the affected area or mixed directly into a sterile surgical glove and then placed on the patient's burned hand for 30 minutes.

Two case series report limited success with this therapy.<sup>2,21</sup> Some patients describe prompt and dramatic relief of pain. Alternatively or simultaneously, analgesics are recommended orally or parenterally as needed, but preferably not to the point of sedation, because local pain response is used to guide therapy. Digital nerve blocks with subcutaneous lidocaine or bupivacaine is also reasonable for patients with significant pain presenting 12 to 24 hours after the injury from a low concentration of HF and with no systemic signs of toxicity since that time topical calcium salts are unlikely to be effective.<sup>28</sup> An animal study examining the efficacy and mechanism of topical calcium gel therapy found that the fluoride ion concentration in the calcium gel was significantly higher than non-calcium-containing gel controls. Although this was a limited study, these animals also had a decrease in urinary fluoride ion concentration as compared to controls, suggesting less overall tissue absorption of the HF.<sup>51</sup> Delivery of calcium transcutaneously is enhanced by various means. In a rodent study of HF burns, iontophoretic (facilitated transport using an electromotive force) delivery of calcium ions appeared to increase calcium concentrations in vitro and improve pathologic changes in vivo.<sup>103</sup> Significant limitations to this study are time to administration of therapy and feasibility in patients with complex burns.<sup>81</sup> Human data are lacking. Dimethyl sulfoxide (DMSO) mixed with topical calcium salts facilitates the transport of calcium ions through the skin to penetrate deeply into the tissues. Dimethyl sulfoxide also is able to act as a scavenger of free radicals, thus limiting inflammation and ongoing injury.<sup>36</sup> Although one group of authors advocates for the combined use of DMSO and calcium,<sup>36</sup> concerns remain over reported adverse effects of DMSO.<sup>47</sup> There are currently inadequate data to support the routine use of DMSO in the treatment of HF burns.

Three other therapies have had variable success in human exposures: the application of calcium via intradermal, intravenous, and intraarterial routes. If topical gel therapy fails within the first few minutes of application, intradermal therapy with dilute calcium gluconate is a reasonable next step. Unfortunately, this treatment has limited usefulness and is not recommended in nondistensible spaces such as fingertips. Histologic studies in animal models demonstrate that 10% calcium chloride solution is damaging to the tissues and is not recommended.<sup>28,35</sup> The preferred method is to approach the wound from a distal point of injury and inject intradermally no more than 0.5 mL/cm<sup>2</sup> of 5% calcium gluconate. Although one author recommends a palmar fasciotomy whenever this method of treatment is used in the hand,<sup>2</sup> this practice is not recommended unless a compartment syndrome is present. The potential for iatrogenic injury exceeds the potential benefit of injections in the hand. The limits of intradermal injection include the potential to increase soft-tissue damage without adequate relief, infection, and inadequate space to safely inject without causing a compartment syndrome.

Effective pain relief is especially problematic for nailed involvement, leading some authors to suggest removal of the nail. This approach has some advantages in accessing the affected area; however, it is a painful procedure that is often cosmetically undesirable and the outcome is not always significantly improved. We therefore do not routinely recommend this procedure.

If the wound is large or on a section of the fingerpad or an area that is not amenable to intradermal injections, intraarterial calcium gluconate is the next most reasonable step.<sup>95</sup> This procedure delivers calcium directly to the affected tissue from a proximal artery. Placement should be ipsilateral and proximal to the affected area, usually in the radial or brachial artery. The method of obtaining access is debated. Because of the potential to damage the endothelial lining of the artery, and because extravasation can have potentially devastating consequences, angiographic confirmation or direct visualization of the vessel was formerly recommended. This practice is still prudent if cannulation of the artery is expected to be difficult because of prior surgery or if an anatomic deformity is suspected. If the arterial line is carefully placed in a single attempt, and a good confirmatory arterial tracing is obtained, the infusion can be started. We recommend adding 10 mL of 10% calcium gluconate to either 40 mL of D<sub>5</sub>W (dextrose 5% in water) or 0.9% sodium chloride solution infused continuously over 4 hours.<sup>1,2,76,85,94,95</sup> This results in a 2% calcium gluconate solution. An animal model examined the effect of undiluted 10% calcium gluconate intraarterially. Although the

model did not involve exposure to HF, there was significant tissue injury in the vessel wall as compared to a 2% calcium gluconate solution.<sup>28</sup> Calcium chloride has also been used successfully, although the potential for vessel injury and extravasation are significant and there is no defined benefit over calcium gluconate.<sup>94,107</sup> The complications associated with the use of intra-arterial calcium infusion in several case series were relatively benign, and include transient radial artery spasm, hematoma, inflammation at the puncture site, and a fall in serum magnesium concentration.<sup>82,95</sup> After the infusion is initiated, patients typically experience significant pain relief. Patients requiring an arterial line for treatment should be admitted to the hospital, as the majority will require more than one treatment, and some patients require as many as 5 separate infusions of calcium gluconate. Although wounds may require débridement,<sup>2</sup> some authors suggest that following intraarterial calcium infusion, tissue can be salvaged that initially would not have been considered viable.<sup>96</sup> There are no reported cases of clinically significant hypercalcemia following infusion as the total dose infused is quite low, although serum calcium concentrations were not routinely recorded in some cases.

Magnesium salts are an alternative or adjunctive therapy to the administration of calcium salts for patients with dermal HF burns. Application of magnesium hydroxide and magnesium gluconate gel show histologic evidence of efficacy in rabbit models of dermal HF burns.<sup>17</sup> Two other animal models of intravenous magnesium for dermal HF burns also suggest efficacy in terms of wound healing.<sup>24,99</sup> Magnesium was suggested as an antidote for fluoride poisoning because magnesium fluoride is more water soluble than calcium fluoride and magnesium is readily excreted by the kidneys.<sup>100</sup> However, these magnesium models inadequately address the disadvantage of magnesium salt solubility, and both topical and intravenous magnesium therapy remain incompletely evaluated in humans and therefore is not routinely recommended.

Another reported therapy for localized HF poisoning is an intravenous Bier block technique that uses 25 mL of 2.5% calcium gluconate. In one case, the effects lasted 5 hours and there were no adverse events.<sup>39</sup> In 2 other cases of patients exposed to HF, a 6% calcium gluconate solution administered using this procedure resulted in rapid and complete analgesia with minimal tissue necrosis.<sup>82</sup> Although the intravenous Bier block technique is not reported as being used in a substantial number of patients, it is reasonable, particularly when intraarterial infusion is problematic.<sup>82</sup> Further data are required before this therapy is routinely recommended.

We routinely observe all patients with digital exposures to HF over 4 to 6 hours, as the pain often recurs and reapplication of the gel or an alternative therapy will be necessary. Even if successful pain control is achieved, the patient will require specialized follow-up and wound care.

### Inhalational Toxicity

Patients exposed to a low concentration of HF and treated with 4 mL of a 2.5% nebulized calcium gluconate solution demonstrated a subjective decrease in irritation with no adverse effects.<sup>52</sup> Another report demonstrated a good outcome following nebulization of a 5% calcium gluconate solution in a patient with an inhalational exposure.<sup>50</sup> Because nebulized calcium gluconate is a relatively benign therapy, we recommend that all patients with symptomatic inhalational exposures to any concentration of HF be administered a dilute solution of calcium gluconate.<sup>30</sup>

### Ingestions

In patients with intentional ingestions of HF, gastrointestinal decontamination poses a dilemma. Induction of emesis is potentially harmful and therefore contraindicated. Because aqueous HF is a weak acid, the risk of perforation by passage of a small nasogastric tube may be lower than the risk of death from systemic absorption.<sup>4,59</sup> In the acidic environment of the stomach, more of the weak acid solution remains nonionized, thus penetrating the gastric mucosa and causing rapid systemic poisoning. Moreover, activated charcoal is unlikely to adsorb the relatively small fluoride ions. Although placement of a nasogastric tube to perform gastric lavage is

clearly associated with risks to the patient, insertion of a nasogastric tube is beneficial under specific circumstances if done safely and in a timely manner. Consequently, gastric emptying via a nasogastric tube is reasonable in the absence of significant spontaneous emesis because these exposures are almost universally fatal.<sup>4,13,59,70</sup> Health care providers should exercise extreme caution during this procedure because secondary dermal or inhalational exposures to the provider is possible in the absence of appropriate personal protective equipment. If there is a possibility of inhalation by the provider, the area should be well ventilated. Acceptable forms of hand protection include gloves made of nitrile, butyl rubber, polyvinyl chloride, or Neoprene. Latex gloves should not be used.

Following ingestion, we recommend a solution of a calcium or magnesium salt be administered orally as soon as possible to prevent HF penetration into the stomach and to provide an alternative source of cations for the damaging electronegative fluoride ions.

When comparing the efficacy of calcium to magnesium salts, calcium is better than magnesium in reducing the bioavailability of fluoride as described in a murine model.<sup>38</sup> Magnesium citrate in a standard cathartic dose, magnesium sulfate, or any of the calcium solutions can be administered orally to prevent absorption (Antidotes in Depth: A16). Although intuitive, evidence for the benefit of oral calcium or magnesium salts is limited. In a mouse model of oral HF toxicity, administration of calcium- or magnesium-containing solutions did not change average survival time.<sup>37</sup> The study results, however, were limited because the calcium and magnesium salts were premixed together with the HF during administration, thus being an inadequate model for the study of HF ingestion. In another study, the survival rate of mice poisoned with NaF was significantly greater when treated with either high doses of oral CaCl<sub>2</sub> or MgSO<sub>4</sub>.<sup>45</sup> Given the current information, we recommend oral calcium salts for oral ingestion; however, if calcium salts are unavailable, magnesium salts are reasonable should be given.

### Ophthalmic Toxicity

Patients with ophthalmic exposures should have each eye irrigated with 1 L of 0.9% sodium chloride solution, lactated Ringer solution, or water.<sup>65</sup> Although there are limited data, repetitive or prolonged irrigation appears to worsen outcome.<sup>65</sup> A complete ophthalmic examination should be performed after the patient is deemed stable, and an ophthalmology consultation should be obtained (Chap. 24). One case report demonstrated a good outcome following ocular HF exposure with the use of 1% calcium gluconate eye drops.<sup>7</sup> Although 2 reviews also recommend the use of 1% calcium gluconate for this purpose,<sup>30,36</sup> calcium salts tend to be irritating to the eye and this therapy is not adequately studied; consequently, use is not recommended at this time. There is no role for gel therapy or ophthalmic injection for these patients, because most calcium and magnesium salts are potentially toxic to ophthalmic tissues and may actually worsen outcome.<sup>6,65</sup>

### Systemic Toxicity

If there is a clinical suspicion of severe toxicity, the immediate intravenous administration of both calcium and magnesium salts is recommended. Calcium gluconate is preferred over calcium chloride because of the risks associated with extravasation (Antidotes in Depth: A32). Patients often require several grams of calcium to treat severe HF toxicity.<sup>33</sup> We recommend that intravenous magnesium be administered to adults as 20 mL of a 20% magnesium sulfate solution (4 g) over 20 to 30 minutes. An approach that uses intravenous calcium or magnesium, and local calcium or magnesium gels to limit absorption protects against life-threatening hypocalcemia and hyperkalemia. Because of the numerous adverse effects of systemic fluoride poisoning, administration of calcium and magnesium salts alone is often insufficient in improving survival from systemic fluoride poisoning.<sup>22</sup> Furthermore, an animal model of hydrogen fluoride toxicity found that maintaining a normal acid–base balance was protective against HF toxicity.<sup>98</sup> Moreover, in a study of patients receiving enflurane, an inhalational anesthetic metabolized by the liver to fluoride ions, urine alkalinization improved

the excretion of fluoride.<sup>77</sup> Thus, it is beneficial to correct any significant acidemia with hydration and IV sodium bicarbonate (calcium salts and sodium bicarbonate cannot be mixed). Because standard treatment for systemic fluoride toxicity includes administration of calcium salts and sodium bicarbonate, hyperkalemia is simultaneously addressed.

Treatment with large quantities of calcium and magnesium do not generally result in significant hypercalcemia or hypermagnesemia.<sup>30</sup> Several explanations are proposed. First, in systemically HF-poisoned patients, total body calcium and magnesium stores are severely decreased so that large doses are required for adequate repletion. In addition, most patients who are exposed to HF are young and healthy, with intact kidney function.<sup>30</sup> Administration of calcium also results in antidiuretic hormone antagonism on renal tubular reabsorption resulting in polyuria which facilitates the urinary excretion of calcium and magnesium.<sup>30</sup>

Because most of the fluoride ions are eliminated renally,<sup>8,44,51,83</sup> hemodialysis is reasonable in patients with severe HF poisoning and acute kidney injury. There are several reported cases of successful clearance of fluoride ions via hemodialysis, with one case also using continuous venovenous hemodialysis.<sup>3,8,9</sup> Because the reported clearance rate did not differ significantly from normally functioning kidneys, it is unclear whether hemodialysis alters outcome in patients with normal kidney function. Furthermore, prolonged hemodialysis, beyond the standard 4-hour course, is unnecessary for most patients unless they have kidney failure.<sup>3</sup>

Although the use of quinidine, a potassium channel blocker, is protective in dogs,<sup>69</sup> it has not been studied or used in humans, and at this time cannot be recommended, but in the presence of life-threatening ventricular dysrhythmias, quinidine (or any other class III antidysrhythmic) is reasonable.

## SUMMARY

- Although HF has a pKa of 3.17 and is considered a weak acid, it causes local and systemic toxicity because of fluoride binding to cations.
- Dermal exposure to HF causes severe pain, often before any physical manifestations are evident.
- In patients with greater than 2.5% BSA HF burns we recommend periodic assessment of serum calcium, magnesium, and potassium concentrations. Admission is required for prolonged electrolyte and cardiac monitoring.
- Therapy for local toxicity includes topical calcium and magnesium salts and systemic analgesia. In some cases, intradermal or intraarterial administration of calcium is required.
- Therapy for systemic toxicity includes all treatments for local toxicity plus intravenous calcium and magnesium salts, sodium bicarbonate, and potentially hemodialysis.

## CALCIUM

Silas W. Smith and Mary Ann Howland

**INTRODUCTION**

Calcium is a divalent cation that is essential to maintain the normal function of the heart, vascular smooth muscle, the skeletal system, the nervous system, and intracellular signaling. It is vital in enzymatic reactions, neurohormonal transmission, blood coagulation, and the maintenance of cellular integrity.<sup>12</sup> The endocrine system maintains calcium homeostasis. Hypercalcemia raises the threshold for nerve and muscle excitation, resulting in muscle weakness, lethargy, cardiac conduction disturbances, and coma. Hypocalcemia can result in hyperreflexia, muscle spasms, tetany, seizures, and QT interval prolongation (Chaps. 12 and 15).<sup>12</sup>

**HISTORY**

Sir Humphry Davy used his pioneering work in electrolysis to isolate potassium and sodium from their hydroxides in 1807. In 1808, using slightly moistened lime,  $\text{Ca(OH)}_2$ , Davy succeeded again, in a series of experiments using electrolysis, to isolate calcium.<sup>25</sup> Ringer performed controlled animal experiments in the 1880s demonstrating the importance of calcium in sustaining and resuscitating cardiac ventricular contraction.<sup>96,97</sup> As the clinical use of calcium chloride antedated 1938, it was “grandfathered” under the Food, Drug, and Cosmetic Act; calcium gluconate was approved in 1941.<sup>37,115</sup>

**PHARMACOLOGY****Chemistry/Preparation**

Calcium has an atomic number of 20, a molecular weight of 40.08 Da, and a valence of 2. For clinical use, calcium is prepared typically in combination with gluconate or chloride. Calcium as calcium chloride ( $\text{CaCl}_2$ ) is used in its dihydrate form  $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$ , with a molecular weight of 147.02 Da when accounting for water. It is a white odorless fragments or granules that are freely soluble in water.<sup>1</sup> Calcium as calcium gluconate is provided as calcium D-gluconate (1:2) monohydrate,  $\text{C}_{12}\text{H}_{22}\text{CaO}_{14} \cdot \text{H}_2\text{O}$ , with a molecular weight of 448.39 Da.<sup>37</sup> It is a clear and colorless to slightly yellow solution.

**Related Agents**

Calcium as calcium chloride or gluconate is a component of electrolyte, parenteral nutrition, dialysis, and cardioplegic solutions.<sup>115</sup> Calcium acetate is used orally to treat hyperphosphatemia, particularly in patients with end-stage kidney disease.<sup>10</sup> Other oral calcium salts such as calcium carbonate, citrate, lactate, gluconate, glycerophosphate, and polycarbophil are variously used as cariostatics, food additives, mineral supplements, and stool stabilizers.

**Pharmacokinetics**

Calcium is the fifth most abundant element and the most abundant mineral in the body, and the third most common plasma cation after sodium and potassium.<sup>131</sup> More than 99% of the 1 to 2 kg of calcium in the adult human is located in bone.<sup>12</sup> Calcium is variously reported in units of mg/dL, mmol/L (mM), and mEq/L, as well as both in total and ionized values. To convert mg/dL to mM, multiply by 0.25; to convert mg/dL to mEq/L, multiply by 0.5. Antidotal calcium is also variously reported as grams of the salt or mEq (mM) of calcium. One gram of calcium chloride contains 13.6 mEq (6.8 mM, 272.5 mg) of elemental calcium; one gram of calcium gluconate contains 4.64 mEq (2.32 mM, 93 mg) of calcium. In blood, the total calcium

concentration is normally 8.5 to 10.6 mg/dL (2.13–2.65 mM, 4.25–5.3 mEq/L), of which approximately half is ionized and active, that is, 4.65 to 5.30 mg/dL (1.16–1.33 mM, 2.33–2.65 mEq/L).<sup>39</sup> The remaining calcium is bound to negatively charged proteins (such as albumin and immunoglobulins) or loosely associated with anions such as phosphate, citrate, sulfate, lactate, and bicarbonate.<sup>12</sup> Because of this calcium binding to albumin, the total calcium is typically corrected or adjusted as follows:

$$\text{Calcium (mg/dL) corrected} = \text{Serum calcium (mg/dL) measured} + [\kappa \times (\text{normal albumin} - \text{measured albumin})]$$

where  $\kappa$  is typically ascribed a value of 0.8 and a “normal” albumin is arbitrarily 4 g/dL.<sup>88</sup> However, this formula underestimates calcium for albumin values greater than 4 g/dL, limiting its utility in cases of hyperalbuminemia.<sup>86</sup> Calcium concentrations are also affected by pH, with increases in pH causing a decrease in ionized calcium and vice versa.<sup>103</sup> Intracellular cytosolic free calcium concentrations are many orders of magnitude (~10,000-fold) lower than ionized calcium concentrations in the blood and extracellular fluid, creating a significant gradient.<sup>12</sup> Calcium is excreted fecally as insoluble salts (80%) and renally (20%).<sup>1</sup> Non-albumin-bound calcium is filterable at the glomerulus and is reabsorbed in the proximal tubule (60%–70%), in the thick ascending limb of Henle (20%–30%), and in the distal convoluted tubule (10%).<sup>35</sup>

Following establishment of the principle that ionized calcium was critical for myocardial inotropy and conduction, calcium preparations were evaluated for their kinetics and effects. In a placebo-controlled trial of 30 consecutive adults receiving cardiopulmonary bypass and citrated blood products, calcium chloride via intermittent IV bolus (5 mg/kg) or as a constant infusion (0.5 mg/kg/min) raised ionized calcium concentrations from  $1.48 \pm 0.30$  to  $1.79 \pm 0.28$  mEq/L ( $0.74 \pm 0.15$  to  $0.89 \pm 0.14$  mM), but did not produce a detectable hemodynamic effect.<sup>4</sup> In a prospective, randomized, double-blind trial of calcium chloride in 36 cardiac surgery patients emerging from cardiopulmonary bypass, calcium chloride (200 mg/dose) increased serum ionized calcium by 6% to 8%.<sup>57</sup> In a prospective, randomized, blinded, crossover designed study of 12 postoperative aortocoronary bypass surgery patients, calcium chloride (10 mg/kg bolus followed by 2 mg/kg/h infusion) raised ionized calcium concentrations from  $2.12 \pm 0.06$  to  $2.88 \pm 0.1$  mEq/L ( $1.06 \pm 0.03$  to  $1.44 \pm 0.05$  mM), and raised arterial pressure without elevating cardiac index.<sup>126</sup> In a single-arm, placebo-controlled study of 43 preterm infants, calcium gluconate (100 mg/kg over 30–60 minutes) raised total and ionized serum calcium concentrations 3 to 6 hours after infusion from  $3.16 \pm 0.06$  to  $3.4 \pm 0.1$  mEq/L ( $1.58 \pm 0.03$  to  $1.70 \pm 0.05$  mM) and  $1.34 \pm 0.06$  to  $1.6 \pm 0.04$  mEq/L ( $0.67 \pm 0.03$  to  $0.80 \pm 0.02$  mM), respectively.<sup>93</sup>

The issue of interchangeability arose because calcium gluconate was thought to both have a lower bioavailability and to require gluconate metabolism for ionized calcium release.<sup>123</sup> In 49 hypocalcemic critically ill children, calcium chloride produced slightly larger increases in ionic calcium than infusions of calcium gluconate in central venous infusions (not controlled for rate of administration), with no survival difference.<sup>13</sup> Other studies challenged the notion of calcium gluconate metabolism. In 15 adults undergoing extracorporeal perfusion with a citrated priming solution, there were no significant differences in ionized calcium between calcium chloride or calcium gluconate.<sup>123</sup> In animals instrumented with a calcium-selective catheter electrode in the aorta, there was no significant difference in plasma calcium ion

concentrations between calcium gluconate and calcium chloride administered intravenously.<sup>48</sup> Similar results were found in human in vitro experiments, in which calcium gluconate and calcium chloride added to blood samples produced identical rises in plasma calcium ion concentrations.<sup>48</sup> In 10 children undergoing burn excision and grafting, calcium chloride and calcium gluconate produced identical ionized calcium changes at 0, 0.5, 1, 3, 5, and 10 minutes when injected over the same period of time.<sup>23</sup> Animal studies with calcium chloride (4, 8, 12 mg/kg) and calcium gluconate (14, 28, 42 mg/kg) produced similar ionized calcium concentrations when measured as early as 30 seconds to 45 minutes.<sup>23</sup> In a pivotal human trial during the intraoperative period in liver transplant patients in which no liver was present, administration of equivalent molar doses of calcium found in calcium chloride (1 g CaCl<sub>2</sub> 10%) and calcium gluconate (3 g Ca gluconate 10%) produced similar serum ionized calcium concentrations, with both peaks occurring within 30 seconds.<sup>77</sup> These results support the concept that simple dissociation of calcium from gluconate is responsible for releasing calcium, rather than hepatic metabolism.<sup>37</sup>

### Pharmacodynamics and Mechanisms of Action

The roles and functions of calcium are more completely reviewed in Chaps. 12, 13, 15, 16, and 20. Calcium is fundamental to neurotransmission, cardiovascular physiology, muscle performance, bone maintenance, coagulation, cellular exocytosis, and signaling. Cardiac excitation-contraction coupling is accomplished via sodium-triggered calcium influx through voltage-activated L-type calcium channels (Ca<sub>v</sub>1.2), which triggers ryanodine receptor type-2 (RyR2) calcium release, calcium binding to and activation of cardiac troponin C, and initiation of myofilament contraction.<sup>66</sup> Calcium is labeled for use in children and adults for the treatment of acute symptomatic hypocalcemia and conditions requiring a prompt increase in plasma calcium.<sup>1,37</sup>

### ROLE IN CALCIUM CHANNEL BLOCKER TOXICITY

Calcium enters cells in numerous ways. In cardiac and smooth muscles the voltage-dependent L-type channels are inhibited by the calcium channel blockers (CCBs) available in the United States.<sup>7,106</sup> Patients with CCB overdose (Chap. 60) typically develop nausea, vomiting, hypotension, bradycardia, myocardial depression, sinus arrest, atrioventricular (AV) block, cardiovascular collapse, and metabolic acidosis, hyperglycemia, shock, pulmonary edema, altered mental status, and seizures.<sup>59,89</sup> Because CCBs do not alter either receptor-operated channels or the release of calcium from intracellular stores,<sup>113</sup> the serum calcium concentration remains normal in overdose.

Intravenous administration of calcium to dogs poisoned with verapamil or diltiazem improved cardiac output secondary to increased inotropy.<sup>44</sup> The heart rate and cardiac conduction were affected minimally, if at all.<sup>38,44</sup> Case reports and reviews of the literature suggest similar minimal or variable findings in human calcium channel blocker overdose, although some cases report benefit in severe bradycardia or asystole.<sup>2,3,14,21,27,34,36,45,59,74,94,95,108</sup> Pretreatment with 10 mL of 10% calcium chloride prevented hypotension associated with intravenous verapamil (average verapamil dose 6.25 ± 1.52 mg) administered for supraventricular tachycardia.<sup>43</sup> Calcium gluconate provided prior to or following intravenous verapamil demonstrated similar efficacy.<sup>122</sup> Several other clinical trials validated the efficacy of calcium salts to preclude verapamil-induced hypotension.<sup>6,63,80,101</sup> A statistically significant benefit in preventing hypotension was not observed with calcium pretreatment in diltiazem administration.<sup>61</sup>

As a relatively simple intervention, calcium is recommended for symptomatic patients with CCB overdoses.<sup>53,65,73</sup> Unfortunately, the most seriously ill patients respond inadequately, and other measures are often required. The dose of calcium needed to treat patients with CCB overdose is unknown. In animal experiments, there appears to be a dose-related improvement.<sup>14</sup> Several authors have successfully treated patients with a total of 18–30 g of calcium gluconate or 13 g of calcium chloride over 0.5–12 hours, either by intermittent bolus dose or infusion, without apparent adverse

effects.<sup>14,53,65,73,74</sup> However, following the use of large doses of calcium, hypercalcemia is expected, which is associated with potentially severe consequences including altered mental status, gut atony, myocardial depression, and intense vasoconstriction leading to multiorgan ischemia and death.<sup>105</sup> Introduction of high-dose insulin (Antidotes in Depth: A21) in the treatment of CCB overdose has diminished the need for extensive calcium administration. The provision of massive calcium doses should therefore be limited, and if used, meticulous monitoring of ionized calcium is advised to avoid hypercalcemia (Table A32–1).

Because calcium chloride is extremely irritating to small vessels, subcutaneous tissue, and muscle, and causes necrosis following extravasation, it is usually only administered through a central venous line. The customary approach is to administer an initial IV dose of 3 g of calcium gluconate (30 mL of 10% calcium gluconate) or 1 g of calcium chloride (10 mL of 10% calcium chloride) to adults.<sup>89</sup> Based on case reports, it is reasonable to repeat this dose every 10–20 minutes for up to 3–4 doses as necessary. The hypothesis is that sufficient calcium must be present to compete with the CCB for binding to the L-type calcium channel. This approach is reportedly beneficial even in moribund cases. One author used a total of 10 g of calcium gluconate as 1 g boluses over 12 minutes after diltiazem induced asystole and another 2.5 g of calcium gluconate minutes later for a second asystolic event, with a resultant serum calcium concentration of 3.36 mM (6.72 mEq/L) approximately 1 hour after administration of the calcium gluconate.<sup>55</sup> Other authors reported smaller dose requirements (eg, 2 g calcium gluconate) in diltiazem-induced asystole.<sup>21</sup> Table A32–1 provides recommended dosing.

The administration of calcium to a patient with toxicity from cardioactive steroids such as digoxin is potentially harmful.<sup>42,120</sup> In the event of concurrent overdose with both a cardioactive steroid and a CCB, the early use of digoxin-specific antibody fragments (Antidotes in Depth: A22) will permit the subsequent safe use of calcium (Chap. 62).

Therapy in children poisoned by CCBs is based on more limited data. The American Heart Association pediatric guidelines did not review calcium administration in calcium channel blocker exposure in the 2015 update to the 2010 guidelines.<sup>26</sup> The 2010 guidelines preferentially suggested calcium chloride based on a single study mentioned above that compared the chloride to the gluconate salt in critically ill children with hypocalcemia.<sup>13</sup> The 2015 guidelines comment that calcium administration is of variable efficacy.<sup>26</sup> It is reasonable to administer calcium gluconate in pediatric CCB toxicity, particularly if only peripheral venous access is available.<sup>60</sup>

**TABLE A32–1 Calcium Salts for Intravenous Use**

	Calcium Gluconate <sup>a</sup>	Calcium Chloride (CaCl <sub>2</sub> ) <sup>a,b</sup>
10% solution	10 mL = 1 g of Ca <sup>2+</sup> gluconate 10 mL = 4.64 mEq = 93 mg = 2.32 mmol of elemental Ca <sup>2+</sup> or 1 mL = 0.465 mEq = 9.3 mg = 0.23 mmol of elemental Ca <sup>2+</sup>	10 mL = 1 g of CaCl <sub>2</sub> 10 mL = 13.6 mEq = 273 mg = 6.8 mmol of elemental Ca <sup>2+</sup> or 1 mL = 1.36 mEq = 27.3 mg = 0.68 mmol of elemental Ca <sup>2+</sup>
Adult dose	3 g (30 mL of 10% solution) over 10 minutes (unless in extremis—deliver over 60 seconds) Repeat every 10–20 minutes up to 3–4 doses as necessary	1 g (10 mL of 10% solution) over 10 minutes (unless in extremis—deliver over 60 seconds) Repeat every 10–20 minutes up to 3–4 doses as necessary
Pediatric dose (not to exceed the adult dose)	60 mg/kg (0.6 mL/kg) of 10% solution infused over 5–10 minutes (unless in extremis—deliver over 60 seconds) Repeat every 10–20 minutes up to 3–4 doses as necessary	20 mg/kg (0.2 mL/kg) infused over 5–10 minutes (unless in extremis—deliver over 60 seconds) Repeat every 10–20 minutes up to 3–4 doses as necessary

<sup>a</sup>Monitor calcium concentration after several doses. <sup>b</sup>Use of a central venous line is recommended to avoid extravasation.

## ROLE IN $\beta$ -ADRENERGIC ANTAGONIST TOXICITY

In vitro studies suggest that the negative inotropic action of  $\beta$ -adrenergic antagonists are related to interference with both the forward and reverse transport of calcium in the sarcoplasmic reticulum and the inhibition of microsomal and mitochondrial calcium uptake (Chap. 59).<sup>28,67,84</sup> In isolated rat hearts, higher calcium concentrations blunted the adverse effects of  $\beta$ -adrenergic antagonists.<sup>29,67</sup> In a canine model of propranolol poisoning, the administration of calcium chloride improved mean arterial pressure, the change in maximal left ventricular pressure over time, and peripheral vascular resistance, but it had no significant effect on bradycardia or QRS complex prolongation.<sup>72</sup> With a dose of both propranolol and verapamil that produced death in all controls, calcium chloride pretreatment in mice and post-treatment in rabbits and swine led to survival of all animals.<sup>118</sup> Several case reports attest to the beneficial effects of intravenous calcium in  $\beta$ -adrenergic antagonist overdose alone or in combination with CCBs.<sup>11,50,58,92,102</sup> Because distinguishing an overdose of a CCB from that of a  $\beta$ -adrenergic antagonist is often clinically difficult and the 2 classes are sometimes ingested simultaneously, a trial of IV calcium is reasonable for a presumed  $\beta$ -adrenergic antagonist overdose if cardioactive steroid toxicity is excluded.

## ROLE IN HYPOCALCEMIA SECONDARY TO ETHYLENE GLYCOL

Following ethylene glycol poisoning (Chap. 106), metabolism of the parent molecule generates oxalic acid, which complexes with calcium and subsequently precipitates in the kidneys, brain, and elsewhere, resulting in hypocalcemia.<sup>54,87,106,110</sup> Although one more recent study found hypocalcemia to be uncommon and to correlate poorly with changes in serum pH, it may yet be severe enough to warrant treatment.<sup>51</sup> After exposure to ethylene glycol, it is reasonable to monitor the ionized calcium concentration in addition to repeated examinations for signs of hypocalcemia such as QT interval prolongation, hyperreflexia, muscle spasms, tetany, and seizures (Chap. 12). Intravenous calcium is recommended in the customary doses (as above) to patients with these findings.

## ROLE IN HYPOCALCEMIA SECONDARY TO HYDROFLUORIC ACID AND FLUORIDE-RELEASING XENOBIOTICS

Deaths from dermal, gastrointestinal, and inhalational hydrofluoric acid (HF) exposures are well documented in the literature.<sup>17,41,119</sup> In these cases, hypocalcemia is invariably present. Any body contact with HF (Chap. 104) can result in severe burns and death, depending on concentration, area exposed, and duration of exposure. The toxicity results from (a) release of free hydrogen ions; (b) complexation of fluoride with calcium and magnesium to interfere with many enzyme systems and to form insoluble salts, which cause cellular necrosis; (c) liberation of potassium ions and permeability of cell membranes for potassium ions, and other mechanism.<sup>16,33,75,78,121</sup> Soluble salts of fluoride and bifluoride (eg, sodium, potassium, and ammonium) have all the toxicity associated with HF and should be managed accordingly.

Following HF exposure, calcium gluconate is recommended topically and subcutaneously to manage minor to moderate cutaneous burns, intravenously to treat systemic hypocalcemia, and intraarterially to manage significant burns.<sup>2,16,17,18,22,33,41,75,78,83,90,98,104,117,119,125</sup> Experimental studies demonstrate that when concentrated HF burns are immediately flushed with water and then treated with topical calcium, burn size, severity, and depth are significantly reduced.<sup>9,15</sup> A 2.5% topical calcium gluconate topical gel is marketed. In the event that the commercial preparation is inaccessible, a topical calcium gel can be prepared from calcium carbonate tablets, calcium gluconate powder or solution, and a water-soluble jelly or surgical lubricant (mix 3.5 g calcium gluconate powder or 35 mL of a 10% calcium gluconate solution or 10 g of calcium carbonate tablets or seven 500-mg crushed calcium gluconate tablets with 5 oz of water-soluble jelly). The chloride salt is also acceptable for topical therapy. However, calcium chloride should never be injected into tissues (subcutaneously, intramuscularly), because severe tissue necrosis can result. While an experimental study in rats demonstrated that iontophoretic delivery of calcium chloride enhanced the delivery of calcium and

significantly reduced the burn area if applied within 30 minutes,<sup>100,124</sup> practical considerations have limited use.

Repeated intrabrachial arterial perfusion of calcium gluconate was described in 1979.<sup>56</sup> Use of intravenous regional analgesia (the “Bier’s method” or “Bier block”) for hydrofluoric acid poisoning was reported in 1992.<sup>49</sup> In patients with severe topical HF exposures, aggressive administration of regional IV calcium using a Bier block technique (10 mL of 10% calcium gluconate in a total volume of 40 mL) or intraarterial calcium (10 mL of 10% calcium gluconate in 50 mL in a total volume of 5% dextrose solution over 4 hours) is reasonable (Chap. 104).<sup>46,71,111</sup> One patient who was massively exposed to HF required 211 mEq (4.2 g) of calcium (equivalent to 15.5 g of calcium chloride) infused within the first 5 hours, with an additional 55.8 mEq (1.1 g) of calcium gluconate injected below the burn eschar.<sup>41</sup> For moderate to severe burns (generally from HF concentrations >20%) of the fingers and hands or other areas such as the face, an intraarterial calcium infusion is reasonable and more effective than local or IV therapy, although it is more invasive and more hazardous.<sup>83,90,104,111,117,119</sup> In a series of 7 cases who failed topical therapy, 4 patients had complete pain relief with Bier’s technique and one patient had partial relief, with 3 patients requiring intraarterial therapy.<sup>40</sup> A calcium gluconate solution (10 mL of 10%) mixed in 40 to 50 mL of 5% dextrose solution creates a reasonable concentration to be infused intraarterially over 4 hours, followed by subsequent 40 to 50 mL intraarterial infusions after 4 hours when pain persists.<sup>116</sup>

In patients with life-threatening poisoning and particularly HF inhalation, it is reasonable to simultaneously administer IV, oral, and nebulized 2.5% calcium gluconate<sup>68</sup> to facilitate the availability of the maximum amount of calcium. To prepare nebulized calcium gluconate, mix 1.5 mL of 10% calcium gluconate solution with 4.5 mL of sterile water or 0.9% sodium chloride to make a 2.5% solution. Serum calcium, potassium, and magnesium concentrations should be carefully monitored in all severely poisoned patients, as well as coagulation parameters, which are disrupted by calcium depletion.<sup>121</sup>

Hypocalcemia from the ingestion of household fluoride-containing dental products such as dental fluoride rinses and sodium fluoride tablets rarely occurs and is dose dependent. Hypocalcemia and significant morbidity and mortality occur with ingestion of industrial-strength fluoride cleaners or fluoride releasers such as ammonium bifluoride used for cleaning white wall tiles. Patients with these exposures should be treated with calcium in a manner similar to the hypocalcemia from other causes.

## ROLE IN HYPOCALCEMIA SECONDARY TO PHOSPHATE EXPOSURES

Inappropriate use of oral and rectal phosphates as a laxative can result in hypocalcemia, hyperphosphatemia, and hyperkalemia with resultant morbidity and mortality.<sup>5,30</sup> Furthermore, even routine high phosphorus supplementation (1 g/day) in healthy adults adversely affects calcium metabolism.<sup>112</sup> Intravenous calcium is recommended for life-threatening hypocalcemia. However, because administration of calcium in the presence of hyperphosphatemia risks precipitation of calcium phosphate throughout the body (most commonly in cases of chronic phosphate exposure),<sup>30</sup> in non-life-threatening cases, the risks and benefits of calcium administration versus hemodialysis and other therapies should be weighed in consultation with a nephrologist.

## ROLE IN HYPERMAGNESEMIA

Hypermagnesemia causes both direct and indirect depression of skeletal muscle, resulting in neuromuscular blockade, loss of reflexes, and profound muscular paralysis, with attendant ventilatory failure (Chap. 12 and Antidotes in Depth: A16).<sup>31,64,81</sup> Excess magnesium also causes prolongation of the PR interval and QRS complex on electrocardiography (ECG) and depression of the sinoatrial node, leading to a bradycardic arrest. Intravenous calcium serves as a physiologic competitive antagonist to these adverse effects of magnesium and is recommended as indicated in [Table A32-1](#).

## ROLE IN HYPERKALEMIA

Hyperkalemia causes significant myocardial depression. The resultant ECG changes are well defined. The height of the T wave increases, and lengthening of the PR interval and QRS complex develop; ultimately, a sine wave pattern precipitating cardiac arrest occurs (Chaps. 12 and 15).<sup>79,99</sup> Calcium makes the membrane threshold potential less negative, restoring the resting and threshold potential difference so that a larger stimulus is required to depolarize the cell from the resting potential. This stabilization antagonizes the hyperexcitability caused by modest hyperkalemia.<sup>79</sup> However, when severe hyperkalemia exists, voltage-gated sodium channels are inactivated and cannot be depolarized, regardless of the strength of the impulse. Calcium transforms the voltage sensor of the sodium channel from inactive to closed, thus allowing the sodium channel to be opened with depolarization.<sup>52</sup> The typical initial dose is 1 g (10 mL) of IV calcium gluconate. The onset of action is within minutes, but the duration of action is only 30–60 minutes. Data do not support any definitive recommendations for repeat calcium administration; experts recommend up to 2 additional doses.<sup>99</sup> If hyperkalemia is secondary to the toxic effects of cardioactive steroids on the Na<sup>+</sup>,K<sup>+</sup>-adenosine triphosphatase (ATPase) pump, IV calcium can potentially exacerbate an already excessive intracellular calcium concentration, making IV calcium potentially harmful (Chap. 62). Although the consequences of inadvertent administration have been somewhat mitigated by animal and clinical experience, digoxin-specific antibody fragments (Antidotes in Depth: A22) should be given for cardioactive steroid-induced hyperkalemia.<sup>42,69,120</sup>

## ROLE IN CITRATE TOXICITY

Citrate binds divalent cations. This property is useful therapeutically (eg, to mitigate renal calcium stone disease) and analytically (eg, to facilitate laboratory anticoagulation studies). Citrate is hepatically metabolized via the citric acid cycle and participates in many other pathways, including conversion to glucose via gluconeogenesis.<sup>32,82</sup> In a process dating back to 1914–1915, blood products contain citrate to prevent coagulation, and thus citrate is transfused into the patient.<sup>32</sup> In massive transfusions, with citrate use in extracorporeal circuits, and in patients with liver disease (who metabolize citrate more slowly), excess citrate causes toxicity (hypocalcemia and more rarely, hypomagnesemia).<sup>4,32,82,91</sup> Signs and symptoms range from mild perioral paresthesias and digital numbness to tetany, myocardial depression, and cardiac dysrhythmias.<sup>24,47</sup> Calcium correction should be guided by clinical signs and ionized calcium determinations. Calcium should not be directly added to blood products, as this can cause clotting, but rather provided via a separate infusion line.

## ADVERSE EFFECTS AND SAFETY ISSUES

Severe hypercalcemia is defined by a serum calcium concentration greater than 14.0 mg/dL (3.5 mmol/L) in a patient with a normal albumin concentration.<sup>19</sup> The adverse effects of hypercalcemia (independent of the rate of administration) include nausea, vomiting, constipation, ileus, polyuria, polydipsia, nephrolithiasis, cognitive alterations, hyporeflexia, coma, vascular alterations, and dysrhythmias.<sup>114</sup> Excessively aggressive calcium infusions in a patient with channel blocker overdose have led to death.<sup>105</sup> Neither calcium chloride nor calcium gluconate should be combined and administered intravenously with sodium bicarbonate because calcium carbonate, a precipitate, is formed. Calcium gluconate is not physically compatible with fluids containing phosphate and will result in precipitation if mixed with solutions of these compounds.<sup>37</sup> Calcium gluconate should not be mixed with ceftriaxone, because of formation of ceftriaxone-calcium precipitates that may act as emboli.<sup>37</sup> Calcium should not be given concurrently with minocycline, as it complexes with minocycline, rendering it inactive.<sup>37</sup> Calcium chloride is an acidifying salt, and it is extremely irritating to tissue. It should never be given intramuscularly, subcutaneously, or perivascularly, and is typically administered via central venous access. In a series of 96 patients receiving IV calcium chloride solution peripherally for symptomatic hypocalcemia after parathyroidectomy, 3 suffered skin necrosis.<sup>70</sup> Calcium gluconate is less irritating, but care should also be taken to avoid

extravasation. Calcinosis cutis—dermal deposits of calcium salts—which can lead to tissue necrosis, ulceration, and secondary infection is reported with calcium gluconate.<sup>37</sup> The best reason for choosing calcium gluconate in almost all clinical situations is that the risk of tissue injury is far less. If extravasation occurs, subcutaneous injection of aliquots of hyaluronidase is reasonable to inject around the site to diminish tissue injury (Special Considerations: SC8). In pediatric patients intraosseous calcium chloride administration along with other vasopressors is rarely associated with acute limb ischemia, presumably due to calcium extravasation, which resulted in amputation.<sup>85,109</sup>

## PREGNANCY AND LACTATION

Calcium injection is U.S. Food and Drug Administration pregnancy category C. Animal reproductive studies have not been conducted. Benefit is expected to outweigh risk when indicated as life-saving therapy for the mother. The World Health Organization guidelines recommend calcium supplementation as part of antenatal care to reduce maternal mortality.<sup>76</sup> Calcium is excreted as a natural component in human breast milk, but no definitive evaluations have been performed on potential adverse effects in the breastfed child following maternal intravenous calcium administration.

## DOSING AND ADMINISTRATION

Intravenous calcium must be administered slowly, at a rate not exceeding 0.7 to 1.8 mEq (14–36.1 mg) per minute, which equates to approximately one-half to one 10-mL vial of calcium chloride or one-and-one-half to three 10-mL vials of calcium gluconate over 10 minutes in adults, unless the patient is in extremis. The package label recommends not to exceed 200 mg/min calcium gluconate in adult patients or 100 mg/min in pediatric patients.<sup>37</sup> More rapid administration can lead to vasodilation, hypotension, bradycardia, dysrhythmias, syncope, and cardiac arrest.<sup>8,20,62,107</sup> In cases of life-threatening hypocalcemia or for a patient in extremis, a slow IV push is reasonable. Repeat doses are administered every 10 to 20 minutes up to 3 to 4 doses as clinically indicated. Total and ionized calcium should be frequently monitored, particularly in light of the acid–base disturbances that occur in poisoned patients. Topical, nebulized, and intraarterial administration is specifically addressed in the section on the role of calcium in the management of HF. If time permits, calcium solutions should be warmed to body temperature to minimize pain. Although intraosseous administration of calcium was used for vascular collapse, ensuring correct needle placement and the gluconate formulation are recommended, given the previous reports of limb ischemia.<sup>85,109</sup> Pediatric dosing is provided in [Table A32–1](#).

## FORMULATION AND ACQUISITION

A variety of calcium salts are available for parenteral administration. The 2 most commonly used are calcium chloride (10%) and calcium gluconate (10%) ([Table A32–1](#)). Calcium chloride 10% injection contains 100 mg of calcium chloride per mL, which contains 27.3 mg (1.36 mEq) of elemental calcium per mL.<sup>115</sup> Calcium gluconate 10% injection contains 100 mg of calcium gluconate per mL, which contains 9.3 mg (0.464 mEq) of elemental calcium per mL.<sup>37</sup> Calcium chloride 10% injection has a pH of 6.3 (5.5–7.5); calcium gluconate 10% injection has a pH of 6.0 to 8.2.

A topical calcium gluconate gel (2.5%) 25 g is available. Topical preparations can be made extemporaneously as described in the section above on hydrofluoric acid. A commercially prepared emergency eyewash calcium gluconate 1% solution is available in 120-mL squirt bottles.

## SUMMARY

- Calcium serves as a physiologic antagonist to the cardiac and/or neurologic effects of hypermagnesemia and hyperkalemia and counteracts some of the effects of CCB overdoses.
- Calcium is beneficial in the treatment of some β-adrenergic antagonist overdoses, and since coingestion with CCBs occurs, is reasonable to administer.
- Intravenous calcium infusion is an effective antidote for the hypocalcemia induced by ethylene glycol, phosphate, HF, and fluoride-releasing xenobiotics.

- Equivalent molar calcium doses found in appropriate volumes of calcium gluconate and calcium chloride deliver equal amounts of ionized calcium.
- Calcium gluconate is preferred for peripheral administration because extravasation of calcium chloride causes tissue necrosis.
- Electrocardiographic monitoring and frequent ionized calcium concentration measurements are required to prevent iatrogenic toxicity.

# HYDROCARBONS

Morgan A. A. Riggan and David D. Gummin

## HISTORY AND EPIDEMIOLOGY

The modern world could not exist without hydrocarbons. Virtually everything we touch is either coated with or made up primarily of hydrocarbon products. Organic chemistry originated during the Industrial Revolution, largely as a result of advances in coal tar technology. In the coking process, bituminous (soft) coal is heated to liberate coal gas. This gas contains volatile hydrocarbons that are captured and separated into a variety of natural gases. The viscous residue left over from the coking process forms coal tar, which is distilled into kerosene and other hydrocarbon mixtures. Over the years, petroleum replaced coal tar as the principal source of commercial organic compounds.

Crude oil processing involves heating to a set temperature within processors that separate (distill) hydrocarbon fractions by vapor (or boiling) point. Because of the relationship between boiling point and molecular weight, distillation roughly divides hydrocarbons into like-sized molecules. The most volatile fractions come off early as gases, and these are used primarily as heating fuels. The least volatile fractions (larger than about 10 or 12 carbons) are used chiefly for lubricants or as paraffins, petroleum jelly, or asphalt. The remaining midsized fractions (5 to 10 carbons) are those most commonly used in combustion fuels and as solvents. Petroleum distillates are also used as raw materials in the production of finished products.

For decades in the United States, kerosene ingestion in children was a major public health concern.<sup>108</sup> Only through public education, consumer product safety initiatives, and modernization of the use and distribution of cooking and heating fuels has this problem been largely eliminated. However, in the developing world, these same challenges have yet to be resolved, with large numbers of children ingesting kerosene from poorly labeled and poorly secured containers.<sup>1,14,15,40,57,82,97,111,124</sup>

Public attention and debate surround the hydrocarbon exposures following environmental spills. One of the most notable events in recent years was the April 20, 2010, explosion of the BP Deepwater Horizon oil platform in the Gulf of Mexico. This resulted in the release of millions of barrels of oil into the Gulf. The human health consequences of disasters of this nature are categorized as related to worker safety; toxicologic effects in workers, visitors, and community members; mental health effects due to social and economic disruption; and ecosystem effects that have health effects on humans.<sup>52</sup> Even more controversial is the practice of “induced hydraulic fracturing” of rock or shale, commonly called “fracking.” Fracking is performed on up to 60% of oil and gas wells drilled today, to liberate pockets of trapped gas or oil from within the fractured rock.<sup>92,145</sup> The intent is to capture and collect trapped hydrocarbons, but some escape into nearby aquifers, thereby entering water supplies or otherwise contaminating human environments. Critics are concerned about the composition of the hydraulic fluids used, as these often contain methanol, ethylene glycol, benzene, or other hydrocarbons. Components of these fluids are found in area groundwater, with resultant risk of human exposure<sup>56,153</sup> and untoward health effects.<sup>87</sup> In addition to the toxicity associated with direct hydrocarbon exposure, the combustion of hydrocarbons leads to other long-term health effects such as chronic lung disease, coronary artery disease, and malignancy.<sup>33</sup> This is a major concern when massive quantities of oil are burned such as in Kuwait, Nigeria, and Venezuela, and areas of the Middle East plagued by terrorism.<sup>117</sup>

The true epidemiology of hydrocarbon exposure and illness is difficult to ascertain from available data sources. Three populations appear to be at particular risk for hydrocarbon-related illness: children with unsupervised

ingestions that result in pulmonary aspiration; workers with inhalational and dermal occupational exposures; and adolescents or young adults who intentionally abuse solvents by inhalation. High-risk occupations include petrochemical workers, plastics and rubber workers, printers, laboratory workers, painters, and hazardous waste workers. Most hydrocarbon exposures do not involve ingestion, and most do not result in illness. Exposures range from self-pumping gasoline, painting a spare bedroom, or applying or removing fingernail polish. Hydrocarbon solvents are often volatile, making inhalation common in these exposures. Lipid solubility results in dermal absorption when skin is exposed.<sup>59</sup> Data from US poison control centers suggest that about 30% of reported exposures to hydrocarbons are in children younger than 6 years (Chap. 130). Largely not captured in these data is an alarming rate of intentional misuse of volatile solvents by adolescents, which is discussed in more depth in Chap. 81.

Most commonly encountered hydrocarbons are mixtures of compounds, often obtained from a common petroleum distillation fraction. The many applications for these in consumer and household products include paints and thinners, furniture polish, lamp oils, and lubricants. Table 105–1 lists frequently encountered hydrocarbon compounds and their common uses. This chapter focuses principally on toxicity of hydrocarbons present in these commercially available mixtures. Individual hydrocarbons are discussed only when they are commonly available in purified form, or when specific xenobiotics result in unique toxicologic concerns.

**TABLE 105–1** Classification and Viscosity of Common Hydrocarbons

Compound	Common Uses	Viscosity (SUS) <sup>a</sup>
<b>Aliphatics</b>		
Gasoline	Motor vehicle fuel	30
Naphtha	Charcoal lighter fluid	29
Kerosene	Heating fuel	35
Turpentine	Paint thinner	33
Mineral spirits	Paint and varnish thinner	30–35
Mineral seal oil	Furniture polish	30–35
Heavy fuel oil	Heating oil	>450
<b>Aromatics</b>		
Benzene	Solvent, reagent, gasoline additive	31
Toluene	Solvent, spray paint solvent	28
Xylene	Solvent, paint thinner, reagent	28
<b>Halogenated</b>		
Methylene chloride	Solvent, paint stripper, propellant	27
Carbon tetrachloride	Solvent, propellant refrigerant	30
Trichloroethylene	Degreaser, spot remover	27
Tetrachloroethylene	Dry cleaning solvent, chemical intermediate	28

<sup>a</sup>Direct values for kinematic viscosity in Saybolt Universal seconds (SUS) were not available for the following compounds: naphtha, xylene, methylene chloride, carbon tetrachloride, trichloroethylene, perchloroethylene, and toluene. Saybolt universal seconds was calculated for these hydrocarbons by converting from available measurements in centipoise viscosity and/or centistokes viscosity using the following conversions: the value in centistokes is estimated by dividing centipoise by density at 68°F (20°C); SUS (Y) is approximated from centistokes (X) using  $y = 3.2533x + 26.08$  ( $R^2 = 0.9998$ ). Centipoise viscosity for naphtha was estimated from the value for butylbenzene. Centipoise viscosity for xylene is the average of *o*-, *m*-, and *p*-xylene.

## CHEMISTRY

A *hydrocarbon* is an organic compound made up primarily of carbon and hydrogen atoms, typically ranging from 1 to 60 carbon atoms in length. This definition includes products derived from plants (terpenes such as pine oil and triglyceresin vegetable oil), animal fats (cod liver oil), natural gas, petroleum, or coal tar. There are 2 basic types of hydrocarbon molecules, *aliphatic* (straight or branched chains) and *cyclic* (closed ring), each with its own subclasses. The aliphatic compounds include the *paraffins* (*alkanes*, with a generic formula  $C_nH_{2n+2}$ ); the *olefins* (*alkenes* have one double bond and *alkadienes* have 2 double bonds); *acetylenes* (alkynes) with at least one triple bond; and the *acyclic terpenes* (polymers of isoprene,  $C_5H_8$ ). Some aliphatic compounds have branches with carbon atoms in the subchain; both the chain and branches are essentially straight.

The cyclic hydrocarbons include *alicyclic* (3 or more carbon atoms in a ring structure, with properties similar to the aliphatics), and *aromatic* compounds, as well as the *cyclic terpenes*. The alicyclics are further divided into *cycloparaffins* (*naphthenes*) such as cyclohexane, and the *cycloolefins* (2 or more double bonds) such as cyclopentadiene. Aromatic hydrocarbons are divided into the *benzene* group (one ring), *naphthalene* group (2 rings), and the *anthracene* group (3 rings). *Polycyclic aromatic hydrocarbons* (polynuclear aromatic hydrocarbons) have multiple, fused benzenelike rings. Aromatic organic compounds may also be *heterocyclic* (in which oxygen or nitrogen substitutes for carbon in the ring). The *cyclic terpenes* are the principal components of the variety of plant-derived essential oils (Chap. 43), often providing color, odor, and flavor. *Limonene* in lemon oil, *menthol* in mint oil, *pinene* in turpentine, and *camphor* are terpenes.

*Saturated* hydrocarbons contain carbon atoms that exist only in their most reduced state. This means that each carbon is bound to either hydrogen or to another carbon, with no double or triple bonds. Conversely, *unsaturated* compounds are those with hydrogens removed, in which double or triple bonds exist.

*Solvents* are a heterogeneous class of xenobiotics used to dissolve and provide a vehicle for delivery of other xenobiotics. The most common industrial solvent is water. The solvents most familiar to toxicologists are *organic solvents* (containing one or more carbon atoms), and most of these are composed of hydrocarbons. Most are liquids in the conditions under which they are used. Specifically named solvents (Stoddard solvent, white naphtha, ligroin) represent mixtures of hydrocarbons emanating from a common petroleum distillation fraction.

Physical properties of hydrocarbons vary by the number of carbon atoms and by molecular structure. Unsubstituted, aliphatic hydrocarbons that contain up to 4 carbons are gaseous at room temperature, 5 to 19 carbon molecules are liquids, and longer-chain molecules tend to be tars or solids. Branching of chains tends to destabilize intermolecular forces, so that less energy is required to separate the molecules. The result is that for a given molecular size, highly branched molecules have lower melting and boiling points and tend to be more volatile.

The various definitions of paraffin warrant discussion. In chemistry, *paraffin* is a general term for any alkane. In North American common use, *paraffin* describes either medicinal paraffin or paraffin wax. *Medicinal paraffin* is the same as mineral oil, a viscous mixture of longer-chained alkanes (typically 15–50 carbon atoms per molecule) derived from a petroleum source. The molecules in *medicinal paraffin* are considerably branched, making it a viscous liquid at room temperature and pressure. *Paraffin wax* molecules are nearly identical in size to *medicinal paraffin*, but due to less branching it forms a waxy solid at room temperature. Outside North America, the term *paraffin* often refers to kerosene—a mixture of medium-chain alkanes typically used for lighting and heating.

Gasoline is a mixture of alkanes, alkenes, naphthenes, and aromatic hydrocarbons, predominantly 5 to 10 carbon atoms in size. Gasoline is separated from crude oil in particular distillation fractions and then blended with several other fractions in refinery processors. More than 1,500 individual molecular species are present in commercial gasoline grades, but most

analytical methods isolate only 150 to 180 constituent compounds. Notably, *n*-hexane is present at up to 6%, and benzene is present between 1% and 6%, depending on the origin and processing technique. A number of additives may go into the final formulation: alkyl leads, ethylene dichloride, and ethylene dibromide in leaded gasoline, and oxygenates such as methyl *t*-butyl ether (MTBE), as well as methanol, ethanol, and detergents.

*Organic halides* contain one or more halogen atoms (fluorine, chlorine, bromine, iodine) substituted for a hydrogen atom in the parent structure. Examples include chloroform, trichloroethylene, and the freons.

Oxygenated hydrocarbons demonstrate toxicity specific to the oxidation state of the carbon, as well as to the atoms adjacent to it (the “R” groups). The *alcohols* are widely used as solvents in industry and in household products. Their toxicity is discussed in Chaps. 76 and 106. *Ethers* contain an oxygen atom bound on either side by a carbon atom. Acute toxicity from ethers tends to mirror that of the corresponding alcohols. *Aldehydes* and *ketones* contain one carbon–oxygen double bond (C=O), the former at a terminal carbon, the latter on a nonterminal carbon. *Organic acids*, *esters*, *amides*, and *acyl halides* represent more oxidized states of carbon; human toxicity is xenobiotic specific.

*Phenols* consist of benzene rings with an attached hydroxyl (alcohol) group. The parent compound, phenol, has only one hydroxyl group attached to benzene. The toxicity of phenol is dramatically altered by addition of other functional groups to the benzene ring (Chap. 101). Cresols, catechols, and salicylate are examples of substituted phenols.

A variety of amines, amides, nitroso and nitro compounds, as well as phosphates, sulfites, and sulfates are used commercially and industrially. The addition of these functional groups to hydrocarbons dramatically alters the characteristics, including the toxicity of the compound.

## PHARMACOLOGY

The effects of hydrocarbons on humans are chiefly related to interactions with lipid bilayers in cellular membranes. Acute central nervous system (CNS) toxicity from inhalational occupational overexposure or recreational abuse parallels the effect of administering an inhaled general anesthetic. Inhaled solvent vapor produces unconsciousness in 50% of subjects, when the partial pressure in the lung reaches its median effective dose ( $ED_{50}$ ). The  $ED_{50}$  in occupational terms is effectively the same as the MAC in anesthesiology terms (Chap. 65).

The physical property of an inhaled anesthetic that correlates most closely with its ability to extinguish nociception is its lipid solubility. The Meyer-Overton lipid solubility theory implies that the potency of an anesthetic correlates directly with its lipid solubility (Chap. 65).

Unfortunately, this theory is too simplistic. Numerous protein receptor interactions also occur. Halothane, isoflurane, sevoflurane, enflurane, and desflurane inhibit fast sodium channels.<sup>104</sup> Toluene, trichloroethylene, perchloroethylene, and others inhibit neuronal calcium currents.<sup>101,122</sup> The halogenated hydrocarbons increase the outward potassium rectifying current<sup>123</sup> and decrease exocytosis of neuronal synaptic vesicles.<sup>62</sup> Specific ligand-receptor interactions also occur,<sup>36</sup> such as the inhibition of receptor function at nicotinic,<sup>146</sup> and at glutamate receptors,<sup>35</sup> as well as enhancement of type-A  $\gamma$ -aminobutyric acid (GABA<sub>A</sub>) and glycine receptor currents.<sup>13</sup>

Pharmacodynamic properties of inhaled hydrocarbons and other volatile xenobiotics (Chap. 65) suggest some receptor–ligand interaction, and a growing body of evidence suggests that the Meyer-Overton lipid solubility theory cannot explain the many neurochemical activities demonstrated by this broad class of xenobiotics.<sup>64</sup> Perhaps a more elegant approach to the lipid bilayer interaction is termed the “modern lipid hypothesis.” The hypothesis is thermodynamically derived, purporting an increase in lateral pressure on protein receptors within the neuronal bilayer. Lateral pressure leads to conformational changes in membrane ion channels, modulating the capacity for activation.<sup>27</sup> Although this hypothesis is mechanistically plausible, no in vitro or in vivo work has yet substantiated it. Thus, no single mechanism fully explains the pharmacologic and toxicologic activity of volatile hydrocarbons on neuronal tissues.

## TOXICOKINETICS

Hydrocarbons are variably absorbed by ingestion, inhalation, or by dermal routes. Human toxicokinetic data are lacking for most of these xenobiotics, so much of our understanding derives from *in vitro* studies and animal research. Partition coefficients are useful predictors of the rate and extent of the absorption and distribution of hydrocarbons into tissues. A partition coefficient for a given chemical species is the ratio of concentrations achieved between 2 different media at equilibrium. The blood-to-air, tissue-to-air, and tissue-to-blood coefficients directly relate to the pulmonary uptake and distribution of hydrocarbons. The tissue-to-blood partition coefficient is commonly derived by dividing the tissue-to-air coefficient by the blood-to-air coefficient.<sup>107</sup> The higher the value, the greater the potential for distribution into tissue. Table 105–2 lists partition coefficients for commonly encountered hydrocarbons. Where human data are limited, rat data are presented in the table, because human and rat data often correlate.<sup>107</sup>

Inhalation is a major route of exposure for volatile hydrocarbons. Most cross the alveolar membrane by passive diffusion. The driving force is the difference in vapor concentration between the alveolus and the blood. The absorbed dose is determined by the air concentration, duration of exposure, minute ventilation, and the blood-to-air partition coefficient. Hydrocarbons that are highly soluble in blood and tissues are readily absorbed, and blood concentrations rise rapidly following inhalation exposure. Although aromatic species are generally well absorbed, absorption of aliphatic hydrocarbons varies by molecular weight: aliphatic hydrocarbons with between 5 and 16 carbons are readily absorbed through inhalation, whereas those with more than 16 carbons are less extensively absorbed.

Absorption of aliphatic hydrocarbons through the digestive tract is inversely related to molecular weight, ranging from complete absorption at lower molecular weights, to approximately 60% for C-14 hydrocarbons, 5% for C-28 hydrocarbons, and essentially no absorption for aliphatic hydrocarbons with more than 32 carbons. Oral absorption of aromatic hydrocarbons with between 5 and 9 carbons ranges from 80% to 97%. Oral absorption of aromatics with more than 9 carbons is poorly characterized.

Although the skin is a common area of contact with solvents, the dose of dermally absorbed hydrocarbons is small compared to other routes such as

inhalation. The skin is composed of both hydrophilic (proteinaceous portion of cells) and lipophilic (cell membranes) regions (Chap. 17). Although many hydrocarbons can remove lipids from the stratum corneum, permeability is not simply the result of lipid removal; permeability also increases with hydration of the skin. The rate of skin absorption is highest when xenobiotics have a water-to-lipid partition coefficient near one. Solvents that contain both hydrophobic and hydrophilic moieties (eg, glycol ethers, dimethylformamide, dimethylsulfoxide) are particularly well absorbed through skin. Other factors that determine penetration across the skin include the thickness of the skin layer, the difference in concentration of the solvent on either side of the epithelium, the diffusion constant, and skin integrity (ie, normal versus cut or abraded).

The dose absorbed through skin is proportional to the exposed surface area and the duration of contact. Although highly volatile compounds typically have a short duration of skin contact because of evaporation, skin absorption also occurs from contact with hydrocarbon vapor. In studies with human volunteers exposed to varying concentrations of hydrocarbon vapors, the dermal dose accounted for 0.1% to 2% of the inhalation dose. With massive exposure (eg, whole-body immersion), dermal absorption contributes significantly to toxicity. Significant dermal absorption with resultant toxicity is described with carbon tetrachloride,<sup>68</sup> tetrachloroethylene,<sup>59</sup> and phenol.<sup>80</sup>

Once absorbed into the central compartment, hydrocarbons are distributed to target and storage organs based on their tissue-to-blood partition coefficients and on the rate of perfusion of the tissue with blood. During the onset of systemic exposure, hydrocarbons accumulate in tissues that have tissue-to-blood coefficients greater than 1 (eg, for toluene, the fat-to-blood partition coefficient is 60). Table 105–2 lists the distribution half-lives of selected hydrocarbons.

Hydrocarbons can be eliminated from the body unchanged, for example, through expired air, or can be metabolized to more polar compounds, which are then excreted in urine or bile. Table 105–2 lists the blood elimination half-lives (for first-order elimination processes) and metabolites of selected hydrocarbons. Some hydrocarbons are metabolized to toxic compounds (eg, methylene chloride, carbon tetrachloride, *n*-hexane, methyl-*n*-butyl ketone). The specific toxicities of these metabolites are discussed later in this chapter.

**TABLE 105–2** Kinetic Parameters of Selected Hydrocarbons

	Partition Coefficients <sup>a</sup>		$t_{1/2}$		Elimination	Relevant Metabolites
	Blood-to-Air	Fat-to-Air	$\alpha$	$\beta$		
<b>Aliphatics</b>						
<i>n</i> -Hexane	2	159	0.17 hours	1.7 hours	10%–20% exhaled; liver metabolism by CYP2E1	2-Hexanol, 2,5-hexanedione, $\gamma$ -valerolactone
Paraffin/tar	Not absorbed or metabolized		—		—	—
<b>Aromatics</b>						
Benzene	8.19	499	8 hours	90 hours	12% exhaled; liver metabolism to phenol	Phenol, catechol, hydroquinone, and conjugates
Toluene	8–16	1021	4–5 hours	15–72 hours	Extensive liver extraction and metabolism	80% metabolized to benzyl alcohol; 70% renally excreted as hippuric acid
<i>o</i> -Xylene	34.9	1877	0.5–1 hour	20–30 hours	Liver CYP2E1 oxidation	Toluic acid, methyl hippuric acid
<b>Halogenated</b>						
Methylene chloride	5–10	120	Apparent $t_{1/2}$ of COHb 13 hours	0.7 hours	92% exhaled unchanged Low doses metabolized; high doses exhaled Two liver metabolic pathways	(a) CYP2E1 to CO and CO <sub>2</sub> (b) Glutathione transferase to CO <sub>2</sub> , formaldehyde, formic acid
Carbon tetrachloride	1.6	359	~1.5 hours	1.5–8 hours	Liver CYP2E1, some lung exhalation (dose-dependent)	Trichloromethyl radical, trichloromethyl peroxy radical, phosgene
Trichloroethylene	9	554	3 hours	30 hours	Liver CYP2E1—epoxide intermediate; trichloroethanol is glucuronidated and excreted	Chloral hydrate, trichloroethanol, trichloroacetic acid
1,1,1-Trichloroethane	1–3	263	0.7 hours	53 hours	91% exhaled; liver CYP2E1	Trichloroacetic acid, trichloroethanol
Tetrachloroethylene	10.3	1638	2.7 hours	33 hours	80% exhaled; liver CYP2E1	Trichloroacetic acid, trichloroethanol

<sup>a</sup>Fat-to-blood partition coefficient is obtained by dividing the fat-to-air coefficient by the blood-to-air coefficient, as determined in rat models. All coefficients are determined at 98.6°F (37°C).

## PATHOPHYSIOLOGY AND CLINICAL FINDINGS

### Respiratory

Several factors are associated with pulmonary toxicity after hydrocarbon ingestion. These include specific physical properties of the xenobiotics ingested, the volume ingested, and the occurrence of vomiting. Physical properties of viscosity, surface tension, and volatility are primary determinants of aspiration potential.

*Dynamic (or absolute) viscosity* is the measurement of the ability of a fluid to resist flow. This property is measured with a rheometer and is typically given in units of pascal-seconds. More frequently, engineers work with *kinematic viscosity*, measured in square millimeters per second, or centistokes. Dynamic viscosity is converted to kinematic viscosity by dividing the dynamic viscosity by the density of the fluid. An older system for measuring viscosity was initially popularized by the petroleum industry and expresses kinematic viscosity in units of Saybolt Universal seconds (SUS). Unfortunately, many policy statements were developed in an era when SUS units were popular, and many still describe viscosity in SUS units. Various tables and calculators are available to convert kinematic viscosity to SUS units. **Table 105-1** shows kinematic viscosity of common hydrocarbons, measured in SUS. An approximate unit conversion is given in the footnote of tables.

Hydrocarbons with low viscosities (<60 SUS; eg, turpentine, gasoline, naphtha) have a higher tendency for aspiration in animal models. The US Consumer Products Safety Commission issued a rule in 2001, requiring child-resistant packaging for products that contain 10% or more hydrocarbon by weight and have a viscosity less than 100 SUS.

*Surface tension* is a cohesive force generated by attraction due to the Van der Waals forces between molecules. This influences adherence of a liquid along a surface ("its ability to creep"). The lower the surface tension, the more effectively the liquid will creep, leading to a higher aspiration risk.<sup>49</sup>

*Volatility* is the tendency for a liquid to become a gas. Hydrocarbons with high volatility tend to vaporize, displace oxygen, and potentially lead to transient hypoxia.

Early reports conflicted in their attempts to relate risk of pulmonary toxicity<sup>1</sup> to the amount of hydrocarbon ingested<sup>12</sup> or to the presence or absence of vomiting. One prospective study addressed both these variables. The cooperative kerosene poisoning (COKP) study was a multicenter study that enrolled 760 patients with hydrocarbon ingestion. Of these, 409 individuals could provide an estimate of the amount ingested. Patients who reportedly ingested more than 30 mL had a 52% chance of developing pulmonary complications, compared with 39% of those who ingested less than 10 mL. The risk of central nervous complications was 41%, compared with 24% using the same criterion. There was a 53% incidence of pulmonary toxicity when vomiting occurred, compared with 37% when there was no history of vomiting.<sup>108</sup> Although this knowledge may help modify the index of suspicion regarding possible pulmonary toxicity, none of these parameters is completely predictive. Severe hydrocarbon pneumonitis sometimes occurs after ingestion of "low-risk" hydrocarbons.<sup>118</sup> Some patients develop severe lung injury after low-volume (<5 mL) ingestions, as well as after ingestions with no history of coughing, gagging, or vomiting.<sup>5</sup>

It is widely held that aspiration is the main route of injury from ingested simple hydrocarbons. The mechanism of pulmonary injury, however, is not fully understood. Intratracheal instillation of 0.2 mL/kg of kerosene causes physiologic abnormalities in lung mechanics (decreased compliance and total lung capacity) and pathologic changes such as interstitial inflammation, polymorphonuclear exudates, intraalveolar edema and hemorrhage, hyperemia, bronchial and bronchiolar necrosis, and vascular thrombosis.<sup>56</sup> These changes most likely reflect both direct toxicity to pulmonary tissue and disruption of the lipid surfactant layer.<sup>149</sup>

Most patients who develop pulmonary toxicity following hydrocarbon ingestion will have an initial episode of coughing, gagging, or choking. This usually occurs within 30 minutes after ingestion and is presumptive evidence of aspiration. The majority of patients who have respiratory signs and symptoms in addition to the initial history of gagging, choking, and coughing

develop radiographic evidence of pneumonitis. Pulmonary toxicity manifests as crackles, rhonchi, bronchospasm, tachypnea, hypoxemia, hemoptysis, acute respiratory distress syndrome (hemorrhagic or nonhemorrhagic), or respiratory distress. Cyanosis develops in approximately 2% to 3% of patients. The etiology of cyanosis is multifactorial and includes the simple asphyxiant effects of volatilized hydrocarbons, ventilation-perfusion mismatch, or, rarely, from methemoglobinemia (aniline, nitrobenzene, or nitrite-containing hydrocarbons). Clinical findings often worsen over the first several days but typically resolve within a week. Death is distinctly uncommon and typically occurs after a severe, progressive respiratory insult marked by hypoxia, ventilation-perfusion mismatch, and barotrauma.<sup>69,81,157</sup>

Intravenous (IV), subcutaneous, and even intrapleural injection of hydrocarbons are reported.<sup>39,115,144</sup> Severe hydrocarbon pneumonitis occurs following IV exposure. Animal experiments show that intravascular hydrocarbons injure the first capillary bed encountered.<sup>113,151</sup> The clinical course after IV hydrocarbon injection is comparable to that of aspiration injury.

Radiographic evidence of pneumonitis develops in 40% to 88% of patients admitted following aspiration.<sup>12,38,102</sup> Findings develop as early as 15 minutes or as late as 24 hours after exposure (**Fig. 105-1**).<sup>18,47,108</sup> Chest radiographs performed immediately on initial presentation are not useful in predicting infiltrates in either symptomatic or asymptomatic patients.<sup>5</sup> Ninety percent of patients who develop radiographic abnormalities do so by 4 hours postingestion.<sup>18</sup> Clinical signs of pneumonia (eg, crackles, rhonchi) are evident in 40% to 50% of patients.<sup>38</sup> A small percentage (<5%) are completely asymptomatic after a period of observation, yet go on to have radiographic findings.<sup>5,102</sup>

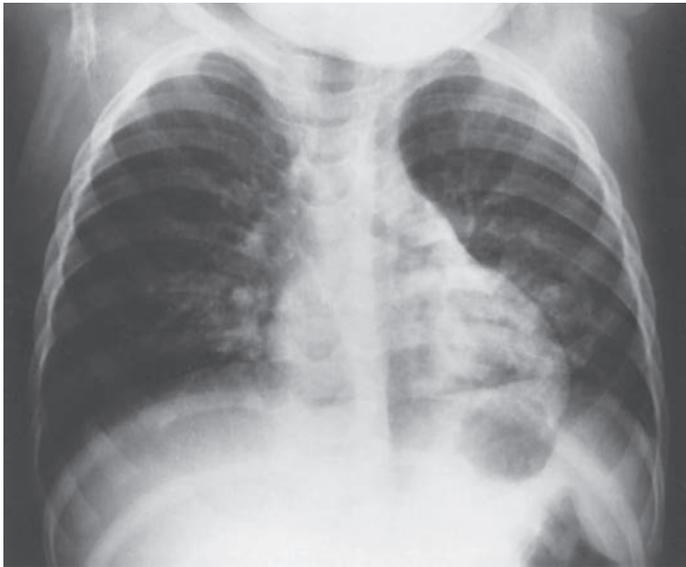

Specific radiologic findings include perihilar densities, bronchovascular markings, bibasilar infiltrates, and pneumonic consolidation.<sup>50</sup> Right-sided involvement occurs in 75% of cases and bilateral involvement in approximately 50%. Upper-lobe involvement is uncommon. Pleural effusions develop in 3% of cases, with one-third appearing within 24 hours.<sup>88</sup> Pneumothorax, pneumomediastinum, and pneumatoceles occur uncommonly.<sup>6,16,72</sup> Initial upright chest radiographs after ingestion rarely reveal 2 liquid densities in the stomach, known as the "double-bubble" sign. This represents an air-fluid (hydrocarbon or water) and a hydrocarbon-water interface, as the hydrocarbon is not miscible with gastric (aqueous) fluid and may have a specific gravity less than that of water.<sup>32</sup>

Radiographic resolution does not correlate with clinical improvement but rather lags behind by several days to weeks. There are few reports of long-term follow-up on patients with hydrocarbon pneumonitis.<sup>58,138</sup> Frequent respiratory tract infections are described after hydrocarbon pneumonitis, but these studies are not well controlled.<sup>47,141</sup> Delayed formation of pneumatoceles occurs in isolated reports.<sup>16,72</sup> Bronchiectasis and pulmonary fibrosis are reported but appear to be uncommon.<sup>54,111</sup> In one study, 82% of patients examined 8 to 14 years after hydrocarbon-induced pneumonitis had asymptomatic minor pulmonary function abnormalities. The abnormalities were consistent with small-airway obstruction and loss of elastic recoil.<sup>58</sup>

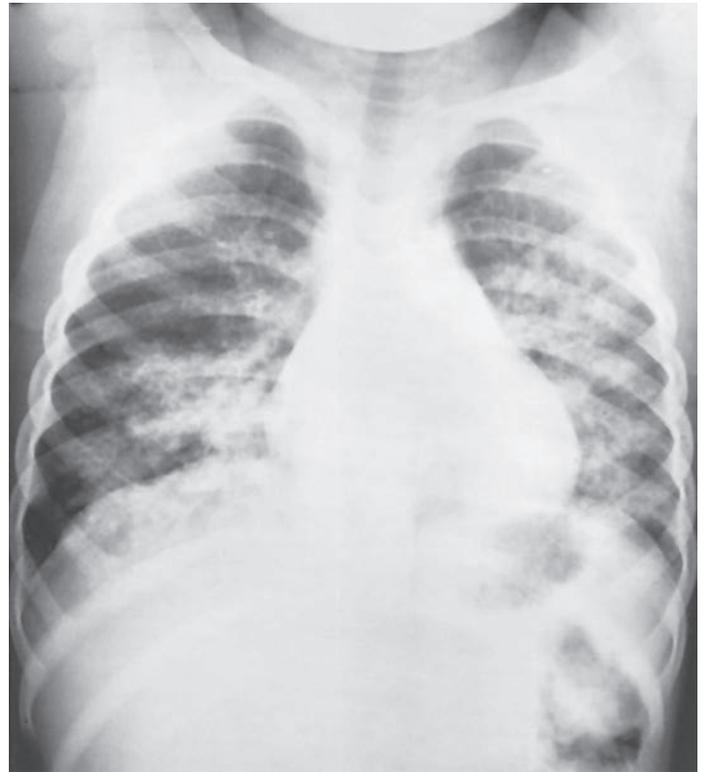

### Cardiac

The most concerning cardiac effect from hydrocarbon exposure is precipitation of dysrhythmias through myocardial sensitization.<sup>98</sup> Malignant dysrhythmias occur after exposure to high concentrations of volatile inhalants or inhaled anesthetics. Such events are described with all classes of hydrocarbons, but halogenated compounds are most frequently implicated, followed by aromatic compounds.<sup>9,112</sup> Atrial fibrillation, ventricular tachycardias, junctional rhythms, ventricular fibrillation, and cardiac arrest are reported.<sup>93,99,112</sup> When this occurs in the context of inhalant abuse, it is termed the "sudden sniffing death syndrome."<sup>10</sup> Prolongation of the QT interval in some cases raises additional concern for the development of torsade de pointes.<sup>10,120</sup>

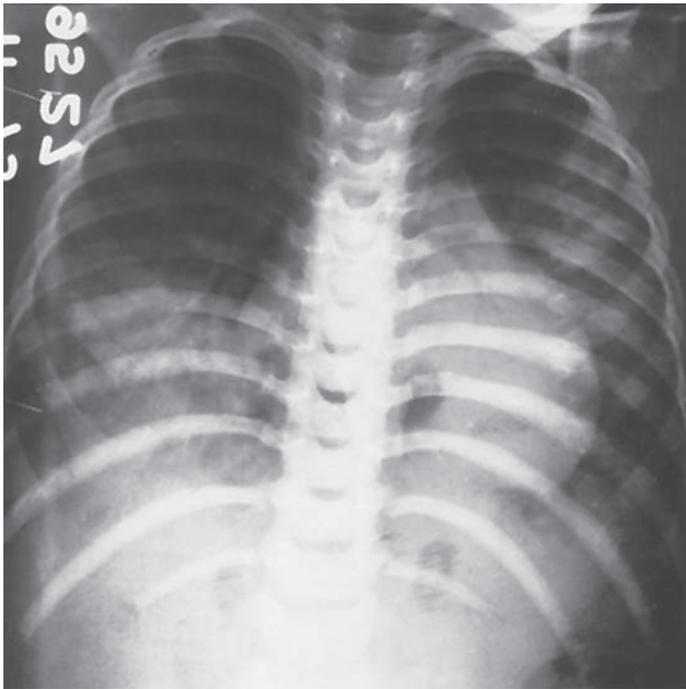

Cardiac sensitization is incompletely understood.<sup>98</sup> Halothane and isoflurane inactivate sodium channels,<sup>129</sup> whereas chloroform and others attenuate potassium efflux through voltage-gated channels.<sup>120</sup> Sensitization is mediated by slowed conduction velocity through membrane gap junctions.<sup>69</sup>

C

**FIGURE 105-1.** Three sequential radiographs of a young girl with severe hydrocarbon aspiration. (A) Initial: Patchy densities appear in the basilar areas of both lung fields with increased interstitial markings and peribronchial thickening. (B) Day 2: More extensive diffuse alveolar infiltrates are apparent. (C) Day 6: Dense consolidation and atelectasis are evident in the right lower lobe. (Used with permission from Nancy Genieser, MD, Professor of Radiology, New York University.)

Gap junction channels are composed of 2 hemichannels (connexons), each composed of 6 subunits (connexins). Halothane modulates gap-junction channels to the closed state in a dose-specific and connexin-specific manner, thus altering conductance.<sup>61</sup> Halocarbons, in the presence of epinephrine, cause dephosphorylation of the gap junction protein connexin-43, thereby increasing resistance and slowing conduction velocity in myocardial tissue.<sup>70,90</sup>

All routes of exposure to hydrocarbons are potentially cardiotoxic. Classically, sudden death follows an episode of sudden exertion, presumably associated with an endogenous catecholamine surge.<sup>10</sup> Tachydysrhythmias, cardiomegaly, and myocardial infarction are rarely reported after ingestion of hydrocarbons.<sup>66</sup> A retrospective follow-up cohort of exposed methylene chloride workers did not find evidence of excess long-term cardiac disease.<sup>103</sup>

### Central Nervous System

Transient CNS excitation occurs after acute hydrocarbon inhalation or ingestion, but more commonly, CNS depression or general anesthesia

occurs.<sup>38</sup> In cases of aspiration, hypoxemia from pulmonary damage may contribute to CNS depression.<sup>81,152</sup> Coma and seizures are reported in 1% to 3% of cases.<sup>102,110,156</sup> Chronic occupational exposure or volatile substance use leads to a chronic neurobehavioral syndrome, the painter syndrome, most notably described after toluene overexposure as toluene leukoencephalopathy which also occurs after inhalational abuse. Clinical features include ataxia, spasticity, dysarthria, and dementia, consistent with leukoencephalopathy.<sup>44,46</sup> Autopsy studies of the brains of chronic toluene abusers show atrophy and mottling of the white matter, as though the lipid-based myelin were dissolved away. Microscopic examination shows a consistent pattern of myelin and oligodendrocyte loss with relative preservation of axons.<sup>75</sup> Animal models of toluene poisoning reveal norepinephrine and dopamine depletion. The severity and reversibility of this syndrome depends on the intensity and duration of toluene exposure.<sup>119</sup> Infrequent exposure rarely produces clinical neurologic signs, whereas severe (daily) use can lead to significant neurologic impairment after as little as 1 year, but more

commonly after 2 to 4 years of continuous exposure. The specific cognitive and neuropsychological findings in toluene-induced dementia are termed a white matter dementia.<sup>44,46</sup>

Initial findings of white matter dementia include behavioral changes, impaired sense of smell, impaired concentration, and mild unsteadiness of hand movements and gait. Further exposure leads to slurred speech, nystagmus, head tremor, poor vision, deafness, stiff-legged and staggering gait, spasticity with hyperreflexia, plantar extension, and subsequent dementia. An abnormal brain stem auditory-evoked response appears to be a sensitive indicator of toluene-induced CNS damage. The electroencephalogram can show mild, diffuse slowing. Computed tomography in severe cases shows mild to moderate cerebellar and cortical atrophy. Magnetic resonance imaging (MRI) findings are consistent with white matter disease. Most cases show clinical improvement after 6 months of abstinence; however, with moderate to severe abuse, the improvement may be incomplete. Although toluene abuse is addicting, a withdrawal or abstinence syndrome is surprisingly uncommon and, when present, appears relatively benign.<sup>44,46</sup>

Exposures in the occupational setting are rarely as extreme as those that occur with intentional volatile substance misuse. Given the significantly lesser exposures, the findings among workers exposed to solvent concentrations above permissible exposure limits are often subclinical and detected primarily through neurobehavioral testing. In the rare case of acute occupational exposure to high solvent concentrations, CNS depression is likely. Repeated, symptomatic overexposures over a protracted period of time have the potential to lead to a chronic encephalopathy, as evident from the experience with solvent abusers.<sup>45</sup>

### Peripheral Nervous System

Peripheral neuropathy is well described following occupational exposure to *n*-hexane or methyl-*n*-butyl ketone (MBK).<sup>20</sup> This axonopathy results from a common metabolic intermediate, 2,5-hexanedione. The mechanism by which this intermediate causes peripheral neuropathy probably relates to decreased phosphorylation of neurofilament proteins, with disruption of the axonal cytoskeleton. Methyl ethyl ketone may exacerbate this neurotoxicity, probably by interfering with metabolic pathways of *n*-hexane and MBK.<sup>4,116</sup> Axonopathy from MBK or *n*-hexane exposure typically begins in the distal extremities and progresses proximally (a classic, “dying-back” neuropathy) (Chap. 22).<sup>53</sup> Exposure to one of these hydrocarbons should be included in the differential diagnosis of the patient with Guillain-Barré syndrome (GBS), although sensory findings are present with MBK and absent in GBS.<sup>127</sup> The longest axons appear to be affected initially, so that the patient manifests a “length-dependent polyneuropathy.” With discontinuation of exposure many of the effects reverse over weeks to months.<sup>65</sup> Alternatively, the phenomenon of “coasting” occurs, in which neuropathy progresses for a time (weeks to months) after discontinuation of the toxic insult.<sup>127</sup> A reversible peripheral neuropathy occurred in 40% of chronic toluene abusers and was characterized by severe motor weakness without sensory deficits or areflexia.<sup>134</sup> However, it is possible that the toluene in this series was contaminated by *n*-hexane or MBK.<sup>4</sup>

Other organic solvents, such as carbon disulfide, acrylamide, and ethylene oxide, are reported to cause a similar peripheral axonopathy.<sup>53</sup> Cranial and peripheral neuropathies occur after acute and chronic exposure to trichloroethylene (TCE).<sup>42,71,79,135</sup> Pathologically, TCE appears to induce a myelinopathy.<sup>42,53</sup> Trichloroethylene exposure is also associated with trigeminal neuralgia.<sup>42,79</sup> Symptoms can develop within 12 hours of a single intense exposure and persist for many years.<sup>42</sup> Trigeminal nerve damage was documented by evoked potentials following 15 minutes of TCE inhalation.<sup>79</sup> Some evidence suggests that decomposition products or impurities in TCE are responsible for cranial neuropathy.<sup>29,41</sup>

### Gastrointestinal

Hydrocarbons irritate gastrointestinal mucous membranes. Nausea and vomiting are common after ingestion. As discussed earlier, vomiting increases the risk of pulmonary toxicity.<sup>100,102</sup> Hematemesis was reported in 5% of cases in one study.<sup>100</sup>

### Hepatic

The chlorinated hydrocarbons (Table 105–1) and their metabolites are hepatotoxic. In most cases, activation occurs via a phase I reaction to form a reactive intermediate (Chap. 11). In the case of carbon tetrachloride, this intermediate is the trichloromethyl radical. This radical forms covalent bonds with hepatic macromolecules and initiates lipid peroxidation.<sup>22</sup> Carbon tetrachloride causes centrilobular necrosis after inhalational, oral, or dermal exposure.<sup>22</sup> Hepatotoxicity in animals is ranked for common hydrocarbons as follows: carbon tetrachloride is greater than benzene, and trichloroethylene is greater than pentane.<sup>150</sup> Vinyl chloride is a liver carcinogen, and trichloroethylene, tetrachloroethylene, and 1,1,1-trichloroethane are less acutely hepatotoxic than vinyl chloride.<sup>89</sup> Hepatotoxicity rarely follows ingestion of petroleum distillates.<sup>67</sup> Hepatic injury, manifested as aminotransferase elevation and hepatomegaly, is usually reversible except in massive exposures.<sup>71</sup>

### Renal

Haloalkanes and haloalkenes are nephrotoxic.<sup>31</sup> Acute kidney injury (AKI) and distal renal tubular acidosis occur in some painters and volatile-substance abusers.<sup>11</sup> Toluene causes a renal tubular acidosislike syndrome (see Toluene later in the chapter). Hydrocarbon exposure is also associated with Goodpasture syndrome (see Immunologic section below).

### Hematologic

Hemolysis is sporadically reported to occur following hydrocarbon ingestion.<sup>3</sup> One retrospective study of 12 patients showed hemolysis in 3 individuals and disseminated intravascular coagulation in another.<sup>3</sup> Although one patient required transfusion, hemolysis is usually mild and typically does not require red blood cell transfusion (also see discussion of the effects of benzene on bone marrow, under Benzene later in the chapter).

### Immunologic

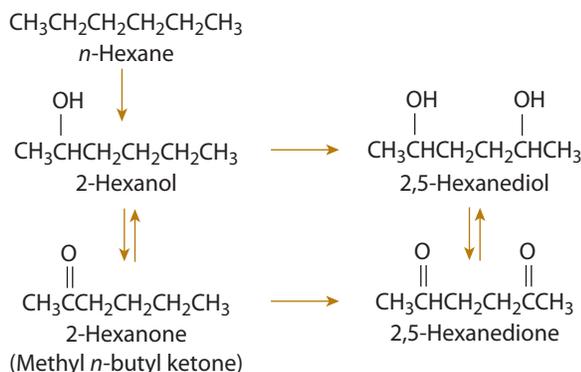

Hydrocarbons disturb the structural and functional integrity of membrane lipid bilayers by accumulating within the membrane and disrupting membrane lipopolysaccharides and proteins. This results in swelling and increased permeability to protons and other ions.<sup>125</sup> Resultant toxicity directly destroys capillary endothelium.<sup>21</sup> Additionally, there appears to be significant basement membrane dysfunction, and this is postulated to underlie both alveolar and glomerular toxicity of hydrocarbons.<sup>131</sup> Immune mechanisms may account for basement membrane dysfunction in chronic exposures. Hydrocarbon exposure is suggested as one possible cause of the Goodpasture syndrome (immune dysfunction causing both pulmonary damage and glomerulonephritis),<sup>19</sup> although the association is not widely accepted. Measurable changes in immune function occur after hydrocarbon exposure;<sup>8</sup> the clinical relevance of this is unknown.

### Dermatologic

Most hydrocarbon solvents cause nonspecific irritation of skin and mucous membranes. Repeated, prolonged contact can dry and crack the skin. The mechanism of dermal injury appears to be defatting of the lipid layer of the stratum corneum. Up to 9% of workers develop contact dermatitis.<sup>154</sup> Solvent abusers demonstrate a classic “glue sniffer’s rash” or “huffer’s eczema.” Limonene and turpentine contain sensitizers that can rarely result in contact allergy (Chap. 17).

Hydrocarbons are irritating to skin. Acute, prolonged exposure causes dermatitis and even full-thickness dermal damage.<sup>60</sup> Severity is proportional to duration of exposure. Chronic dermal exposure to kerosene or diesel fuel causes oil folliculitis.<sup>143</sup> A specific cutaneous lesion called chloracne is associated with exposure to chlorinated aromatic hydrocarbons with highly specific stereochemistry such as dioxins and polychlorobiphenyls.<sup>37</sup>

Soft tissue injection of hydrocarbon is locally toxic, leading to necrosis.<sup>39</sup> Secondary cellulitis, abscess formation, and fasciitis can occur. Infectious complications are treated by meticulous wound care, with surgical debridement as necessary. Particularly destructive lesions result from high-pressure injection gun injury. These injuries typically involve the extremities, with high-pressure

**FIGURE 105–2.** The metabolism of both organic solvents *n*-hexane and methyl *n*-butyl ketone produces the same common metabolite, 2,5-hexanedione.

injection of grease or paint into the fascial planes and tendon sheaths. Emergent surgical débridement is necessary in most of these cases.<sup>43,95</sup>

## HYDROCARBONS WITH SPECIFIC AND UNIQUE TOXICITY

### *n*-Hexane

Hexane is a 6-carbon simple aliphatic hydrocarbon. It is a constituent of some brake-cleaning fluids, rubber cement, glues, spray paints, coatings, and silicones. Outbreaks of *n*-hexane–related neurotoxicity have occurred in printing plants, sandal shops, furniture factories, and automotive repair shops.<sup>30</sup> Human exposure occurs primarily by inhalation. As discussed above, both *n*-hexane and MBK are well-known peripheral neurotoxins because of their common metabolic intermediate: 2,5-hexanedione. Similar 5- and 7-carbon species do not induce a comparable neurotoxicity, except those that are direct precursor intermediates in the metabolic pathway producing 2,5-hexanedione<sup>137</sup> (Fig. 105–2).

### Methylene Chloride

Methylene chloride is commonly found in paint removers, cleansers, degreasers, and aerosol propellants. Like other halogenated hydrocarbons, it can rapidly induce general anesthesia by inhalation or ingestion. Unlike other hydrocarbons, methylene chloride and similar one-carbon halomethanes such as methylene dibromide are metabolized by CYP2E1 mixed-function oxidase to carbon monoxide.<sup>2</sup> Significant delayed and prolonged carboxyhemoglobinemia can occur<sup>109</sup> (Table 105–2 and Chap. 122).

### Carbon Tetrachloride

Carbon tetrachloride (CCl<sub>4</sub>), although not actually a hydrocarbon, has been used as an industrial solvent and reagent. Its use in the United States declined dramatically since recognition of its toxicity caused the Environmental Protection Agency to restrict its commercial use. Absorption occurs by all routes, including dermal. Carbon tetrachloride is an irritant to skin and mucous membranes and gastric mucosa when ingested. As in the case of other halogenated hydrocarbons, aspiration can result in pneumonitis, and systemic absorption may result in ventricular dysrhythmias.

Carbon tetrachloride exposures are hepatotoxic and nephrotoxic. Both occur more commonly with repetitive occupational exposure.<sup>68,139</sup> Toxicity follows phase-I dehalogenation of the parent compound, which produces free radicals and causes lipid peroxidation and the production of protein adducts.<sup>22</sup> Localization of specific phase I hepatic enzymes in the centrilobular area of the liver results in regionalized (zone 3) centrilobular injury after CCl<sub>4</sub> exposure (Chap. 21). Hepatotoxicity is typically manifested as reversible aminotransferase concentration elevations with or without hepatomegaly. Cirrhosis is reported in both animal models and in humans with prolonged excessive exposures. Nephrotoxicity is less studied but may result from a similar mechanism. Carbon tetrachloride is a suspected human carcinogen.<sup>96</sup>

### Trichloroethylene

Trichloroethylene is a commonly used industrial solvent, cleanser, and degreaser. Systemically absorbed TCE, as might occur in the occupational

setting, competitively inhibits aldehyde dehydrogenase. Concomitant ethanol consumption results in a disulfiramlike reaction that is termed “degreaser’s flush”<sup>132</sup> (Chap. 78).

Trichloroethylene was used for years as a general anesthetic, and hundreds of disposal sites in the United States remain sources of ongoing human exposure. The use of TCE as a general anesthetic was abandoned because of associated acute cardiotoxicity.<sup>51</sup> Trichloroethylene is also hepatotoxic, neurotoxic, and nephrotoxic in humans and animals.<sup>51</sup> Trichloroethylene exposure is linked to the development of neurodegenerative diseases, such as parkinsonism.<sup>48</sup> Evidence suggests that TCE is a human carcinogen.<sup>105</sup>

### Benzene

Benzene is hematotoxic and associated with acute hemolysis or with the delayed development of aplastic anemia and acute myelogenous leukemia.<sup>76,106,114</sup> Other aromatic hydrocarbons that are reported to cause similar hematologic effects most likely are contaminated with benzene. Benzene is an IARC group I carcinogen linked to chronic myelocytic leukemia, acute myeloid leukemia, acute nonlymphocytic leukemia, multiple myeloma, myelodysplastic syndromes, and lymphoma.<sup>140</sup> Chromosomal changes are believed to provide a marker for carcinogenicity.<sup>142</sup> Because of the carcinogenic risk, most benzene-based solvents were removed from the US market, and the Occupational Safety and Health Administration has limited the permissible worker exposure concentration to 1 ppm.

### Toluene

Toluene has essentially replaced benzene as the primary organic solvent in many commercial products. Many oil paints and stains primarily contain toluene as solvent. As such, it is readily available and abused as an inhalant. The CNS sequelae of chronic solvent inhalation are most frequently related to chronic toluene exposure.

Chronic toluene abuse can also cause a syndrome that resembles transient distal renal tubular acidosis (RTA).<sup>136</sup> Although the mechanism is incompletely understood, the acidosis results in great part from the urinary excretion of hippuric acid (Table 105–2).<sup>28</sup> Renal potassium loss results in symptomatic hypokalemia.<sup>73</sup> Clinical findings are a hyperchloremic metabolic acidosis, hypokalemia, and aciduria. Transient azotemia, proteinuria, and an active urine sediment are reported.<sup>147</sup> Some also report a proximal RTA, or the Fanconi syndrome.<sup>94</sup> A metabolic acidosis resulting from the metabolism of toluene to benzyl alcohol through alcohol dehydrogenase to benzoic acid may be an adequate explanation for the serum and urine acid-base disturbances.

### Pine Oil and Terpenes

Pine oil is an active ingredient in many household cleaning products. It is a mixture of unsaturated hydrocarbons composed of terpenes, camphenes, and pinenes. The major components are terpenes, which are found in plants and flowers. Wood distillates including pine oil and turpentine are derived from pine trees. Patients who ingest pine oil often emit a strong pine odor. Wood distillates are readily absorbed from the gastrointestinal tract, and ingestion causes CNS and pulmonary toxicity without aspiration.

The clinical features of pine oil ingestion include CNS depression, respiratory failure, and gastrointestinal dysfunction, which are rarely fatal.<sup>74</sup> Aspiration pneumonitis remains the primary clinical concern. Rare reported complications of wood distillate ingestion include turpentine-associated thrombocytopenic purpura, AKI, and hemorrhagic cystitis.<sup>148</sup>

### Lipoid Pneumonia

Ingestion of low-viscosity hydrocarbons poses risk of pulmonary aspiration with subsequent acute pneumonitis. Conversely, viscous hydrocarbons rarely lead to pulmonary aspiration. However, inhalation of aerosolized oil droplets occurs in various occupational settings, resulting in lipoid pneumonia. The most common xenobiotics involved are mineral or vegetable oils.<sup>17</sup>

Initially, inhaled oil droplets are emulsified in the alveoli by surfactant, and then engulfed by alveolar macrophages. Unfortunately, macrophages are unable to readily process the internalized, exogenous oil. Microscopically,

persistent cytoplasmic droplets give a “foamy” appearance to these “lipophages” that may persist for weeks to years. Symptoms of lipoid pneumonia are limited or even subclinical, but once they arise, illness may be prolonged from months to years. Ultimately, irreversible proliferative fibrosis may develop.<sup>128</sup>

Silicone-based polymers share structural similarities and some physical properties with long-chain hydrocarbons. Silicone polymers such as dimethylsiloxane exist as oily, viscous liquids at room temperature and are widely used as lubricants, antifoaming agents, and even as medicine and food additives. Pulmonary aspiration or inhalation of aerosolized silicone droplets causes clinical pneumonitis that is indistinguishable from that caused by their viscous hydrocarbon counterparts. The time course of lung injury is similarly protracted, and complications result.<sup>126</sup>

### Tar and Asphalt Injury

Tar and asphalt injuries are common occupational hazards among construction workers. Asphalt workers are at risk for toxic gas exposure to hydrogen sulfide, carbon monoxide, propane, methane, and volatilized hydrocarbons.<sup>64</sup> In addition, cutaneous exposure to these hot hydrocarbon mixtures causes severe burns. The material quickly hardens and is very difficult to remove. However, immediate cooling with cold water is important to limit further thermal injury. Complete removal is essential to ensure proper burn management and to limit infectious complications. Attempts to remove hardened tar or asphalt mechanically cause further damage. Dissolving the material with mineral oil, petroleum jelly, or antibacterial ointments are met with variable success. Surface-active compounds combined with an ointment (De-Solv-it, Tween-80, Polysorbate 80) are more effective.<sup>34,133</sup>

### DIAGNOSTIC TESTING

Laboratory and ancillary testing for hydrocarbon toxicity should be guided by available information regarding the specific xenobiotic, the route of exposure, and the best attempt at quantifying the exposure. Inhalation or ingestion of hydrocarbons associated with pulmonary aspiration is most likely to result in pulmonary toxicity. The use of pulse oximetry and arterial blood gas testing in this group of patients is warranted in symptomatic patients. Early radiography is indicated in patients who are severely symptomatic; however, radiographs performed immediately after hydrocarbon ingestion have a poor predictive value for the occurrence of aspiration pneumonitis.<sup>5</sup> In the asymptomatic patient, early radiography is not cost effective. Patients observed for 6 hours after an ingestion, who demonstrate adequate oxygenation, are not tachypneic, demonstrate no abnormal pulmonary findings, and have a normal chest radiograph obtained after the 6-hour observation period have a good medical prognosis with very low risk of subsequent deterioration.<sup>5</sup>

The choice of specific diagnostic laboratory tests to assess organ system toxicity or function following exposure to a hydrocarbon depends on the patient's clinical condition, as well as the dose, route, and intent (intentional self-harm versus unintentional). Always exercise caution and assume potentially severe toxicity with any intentional self-harm exposure. Useful clinical tests include pulse oximetry, ECG, arterial blood gas, serum or urine electrolytes, complete blood counts, and creatinine phosphokinase. If a hydrocarbon has specific target organ toxicities (eg, benzene/bone marrow, CCl<sub>4</sub>/liver, or *n*-hexane/peripheral nervous system), evaluating and monitoring target organ system function is indicated.

Specific diagnostic testing for hydrocarbon poisoning can be performed with bioassays for the specific hydrocarbon or its metabolites in blood, breath, or urine. These bioassays are not available in a clinically relevant time frame and should not be used to guide initial management of suspected hydrocarbon poisoning in the emergency setting. Bioassays can be useful to assist with a differential diagnosis (eg, testing for CCl<sub>4</sub> in a comatose patient with unexplained hepatic and renal toxicity or a carboxyhemoglobin determination in a paint stripper with chest pain), in workers compensation situations (eg, testing for urinary trichloroethanol and trichloroacetic acid in a worker exposed to TCE with unexplained bouts of dizziness), or for forensic purposes (eg, sudden death in a huffer).

Chronic overexposures to hydrocarbons, as occurs with volatile substance use, results in persistent damage to the CNS. Damage can be detected and quantified using neuroimaging methods such as MRI or positron emission tomography. Major MRI findings in patients with chronic toluene abuse include atrophy, white matter T2 hyperintensity, and T2 hypointensity involving the basal ganglia and thalamus.<sup>26,155</sup> Neurobehavioral testing can be used to detect subtle central nervous system effects following chronic occupational overexposures.

### MANAGEMENT

Identification of the specific type, route, and amount of hydrocarbon exposure is rarely essential to achieve effective management.

Decontamination is one of the cardinal principles of toxicology, with priority that is second only to stabilization of the cardiopulmonary status. Safe decontamination prevents further absorption and also avoids secondary casualties among those providing care. Protection of rescuers with appropriate personal protective equipment and rescue protocols is paramount, especially in situations in which the victim has lost consciousness. The principle of removing the patient from the exposure (eg, vapor or gaseous hydrocarbon) or the exposure from the patient (eg, hydrocarbon liquid on skin or clothing), while protecting the rescuer, implies that appropriate personal protective equipment be applied at each level of the health care delivery system.

Exposed clothing should be removed and safely discarded as further absorption or inhalation of hydrocarbons from grossly contaminated clothing can worsen systemic toxicity. Decontamination of the skin is a high priority in patients with massive hydrocarbon exposures, particularly those exposures involving highly toxic hydrocarbons. Soap and water should be the initial method of skin decontamination for the majority of hydrocarbons. The exception to this is phenol, for which water is often inadequate and polyethylene glycol 400 (PEG 400) solution is recommended.<sup>91</sup> Note that PEG 400 is not interchangeable with polyethylene glycol with electrolytes (PEG-ELS) used for bowel irrigation. The caregiver should remain aware that certain hydrocarbons are highly flammable posing a fire risk to hospital staff (Chap. 131 and Special Considerations: SC2).

Several studies have attempted to evaluate the role of gastric emptying with gastric lavage or syrup of ipecac after hydrocarbon ingestion. Results were largely inconclusive and in some instances showed a trend toward harm.<sup>12,25,69,108</sup> Because of the high incidence of spontaneous emesis and the risk of aspiration in hydrocarbon ingestion, we recommend against routine attempts at gastric emptying.

Activated charcoal (AC) has limited ability to decrease gastrointestinal absorption of hydrocarbons and may distend the stomach and predispose patients to vomiting and aspiration.<sup>77</sup> Given the risk of spontaneous emesis and aspiration, we likewise recommend against the routine use of activated charcoal.

Antibiotics were once frequently administered in the setting of hydrocarbon pneumonitis to treat possible bacterial superinfection,<sup>25</sup> and they are still occasionally used today as fever and infiltrates are common. Although animal models rapidly demonstrate superinfection, prophylactic antibiotics only appear to alter pulmonary flora.<sup>23</sup> Prophylactic antibiotics did not affect length of stay or otherwise impact the outcome of 48 pediatric patients admitted for respiratory distress from hydrocarbon poisoning.<sup>69</sup> A randomized controlled study of pediatric patients with mild respiratory symptoms (history of cough or dyspnea, age-specific tachypnea, chest indrawing, stridor, or wheeze) due to kerosene-induced pneumonitis did not show any benefit of prophylactic amoxicillin in reducing the rate of clinical deterioration (treatment failure), duration of hospitalizations or signs and symptoms at follow-up.<sup>7</sup> However, this study excluded all patients judged to be too ill to withhold antibiotics, as determined by requiring more than 2 L/min of oxygen by nasal prongs, intermittent or continuous positive-pressure ventilation, or those with a fever greater than 40°C. Given the available evidence, we recommend against routine antibiotic use in the management of patients with mild hydrocarbon pneumonitis.

Corticosteroids, like antibiotics, have been prophylactically administered in the setting of hydrocarbon pulmonary toxicity.<sup>54,138</sup> The rationale for their use is prevention and limitation of the pulmonary inflammatory response

after hydrocarbon injury. Animal models do not show any benefit of corticosteroid administration,<sup>130</sup> and corticosteroids may increase the risk of bacterial superinfection. Furthermore, a controlled human trial failed to show a benefit from corticosteroid administration.<sup>84</sup> It is clear that corticosteroid use does not improve the acute course of hydrocarbon pulmonary toxicity, although some authors suggest improved outcome with delayed corticosteroid therapy despite little supporting evidence.<sup>72</sup> Coupled with the possible increased risk of bacterial superinfection, we recommend against the routine use of corticosteroids for hydrocarbon pulmonary toxicity.

Patients with severe hydrocarbon toxicity pose unique problems for management. Respiratory distress requiring mechanical ventilation in this setting may be associated with a large ventilation–perfusion mismatch. The use of positive end-expiratory pressure (PEEP) in this setting is often beneficial. However, when very high levels of PEEP are required there is an increased risk of barotrauma.<sup>119</sup> High-frequency jet ventilation (HFJV), using very high respiratory rates (220–260) with small tidal volumes, has helped to decrease the need for PEEP.<sup>24</sup> Patients who continue to have severe ventilation–perfusion mismatch despite PEEP and HFJV have benefited from extracorporeal membrane oxygenation (ECMO).<sup>118</sup> Extracorporeal membrane oxygenation appears to be a useful option in severe pulmonary toxicity after other treatments have failed. Although there are case reports of clinical improvement of hydrocarbon pneumonitis with early administration of surfactant therapy, the evidence is poor and we do not recommend routine use of surfactant.<sup>86</sup>

Cyanosis is uncommon after hydrocarbon toxicity. Although this is most often caused by severe hypoxia, methemoglobinemia associated with hydrocarbon exposure is reported.<sup>78</sup> The potential for methemoglobinemia should be investigated in patients who remain cyanotic following normalization of arterial oxygen tension (Chap. 124).

Hypotension in severe hydrocarbon toxicity raises additional concerns. The etiology of hypotension in this setting is often due to compromise of cardiac output because of high levels of PEEP. Hydrocarbons do not have significant direct cardiovascular effects, and decreasing the PEEP may improve hemodynamics. The use of  $\beta$ -adrenergic agonists such as dopamine, epinephrine, isoproterenol, and norepinephrine should be avoided if possible, as certain hydrocarbons predispose to dysrhythmias.<sup>98,112</sup> The recommended first-line treatments for hypotension is fluid resuscitation and minimizing PEEP, with phenylephrine used for refractory hypotension.

Management of dysrhythmias associated with hydrocarbon toxicity includes evaluation and correction of electrolyte and acid–base abnormalities such as hypokalemia and acidosis resulting from toluene, hypoxemia, hypotension, and hypothermia. Ventricular fibrillation poses a specific concern, as common resuscitation algorithms recommend epinephrine administration to treat this rhythm. If it is ascertained that the dysrhythmia emanates from myocardial sensitization by a hydrocarbon solvent, catecholamines should be avoided. In this setting, we recommend short-acting  $\beta$ -adrenergic antagonists such as esmolol as the treatment of choice for hydrocarbon induced dysrhythmias.<sup>93</sup>

Hyperbaric oxygen (HBO) was studied in a rat model of severe kerosene-induced pneumonitis.<sup>121</sup> Hyperbaric oxygen at 4 ATA showed some benefit in 24-hour survival rates; however, no follow-up studies were performed. Hyperbaric oxygen also decreased  $\text{CCl}_4$ -induced hepatic necrosis in a rat model when given within 6 hours, after which HBO augmented necrosis.<sup>85</sup> Given the lack of human studies and the risks associated with hyperoxia, we do not routinely recommend HBO for the treatment of  $\text{CCl}_4$  poisoning.

In the past, hospital admission was routinely recommended for patients who ingested hydrocarbons, because of concern over possible delayed symptom onset and progression of toxicity. Several reports documented patients with relatively asymptomatic presentations who rapidly decompensated with respiratory compromise. However, progressive symptoms after hydrocarbon ingestion are rare,<sup>5,83</sup> and these recommendations predate noninvasive assessments of gas exchange. In a retrospective study of 950 patients,<sup>5</sup> 800 patients were asymptomatic on initial evaluation with normal chest radiographs, remained asymptomatic after 6 to 8 hours of observation, and had a normal repeat radiograph. No patient in this group of 800 had progressive symptoms,

and all were discharged from the emergency department (ED) without clinical deterioration. A total of 150 patients were diagnosed with hydrocarbon pneumonitis based on a history of hydrocarbon ingestion and either abnormalities on physical examination or an abnormal chest radiograph, and these patients were admitted to hospital for observation. Seventy-nine of the 150 hospitalized patients (53%) were symptomatic on presentation to the ED, and 71 patients (47%) were asymptomatic at the time of their ED evaluation. All were reported to have had symptoms prior to ED arrival. Furthermore, 36 of the 71 had an abnormal chest radiograph, and 35 were admitted because of the history of prehospital respiratory symptoms. Of the 36 patients with abnormal chest radiographs, 2 (6%) developed progression of pulmonary symptoms during the 6-hour observation period. Of the 35 who had a normal radiograph, 2 (6%) developed pulmonary symptoms and radiographic pneumonitis during the 6-hour observation period. The 4 patients who were hospitalized for progression of symptoms became asymptomatic over the next 24 hours and had no complications. Overall, 136 patients (91%) had no progression of their pulmonary disease and uneventful hospitalizations. Only 14 of the 150 hospitalized patients (9.3%) had progression of pulmonary toxicity.<sup>5</sup> Of these 14 patients, 7 had persistence of symptoms for less than 24 hours. Overall, 1.5% of all patients presenting with a history of hydrocarbon exposure had progression of their pulmonary symptoms.

A separate poison control center–based study evaluated 120 asymptomatic patients over an 18-hour telephone follow-up period.<sup>83</sup> Sixty-two patients had initial pulmonary symptoms that quickly resolved. One of the 62 patients (1.6%) developed progressive pulmonary toxicity. This patient was hospitalized and had resolution of symptoms within 24 hours without complications.

A number of investigators offer protocols for determining which patients can be safely discharged.<sup>5,83</sup> None of these protocols are prospectively validated. However, rational guidelines for hospitalization can be recommended. We recommend hospitalization for those patients who have clinical evidence of toxicity, and most individuals with intentional ingestions. Patients who do not have any initial symptoms, have normal chest radiographs obtained at least 6 hours after ingestion, and who do not develop symptoms during the 6-hour observation period can be safely discharged. Patients who are asymptomatic on initial assessment but who have radiographic evidence of hydrocarbon pneumonitis can be safely discharged if they remain asymptomatic after a 6-hour observation period and able to be reassessed in 24 hours. Patients who have initial respiratory symptoms but quickly become asymptomatic during medical evaluation and remain so after a 6-hour observation period who have a normal 6-hour chest radiograph can be discharged home.

## SUMMARY

- Hydrocarbons are a diverse group of xenobiotics that cause toxicity by inhalation, ingestion, or dermal absorption.
- Populations at particular risk for toxicity include unsupervised children who ingest hydrocarbon compounds, workers who are occupationally exposed by inhalation or dermal absorption, and youths who intentionally inhale volatile hydrocarbons.
- Aspiration pneumonitis is the primary concern after hydrocarbon ingestion, with the risk of aspiration dependent on many factors, including viscosity, volatility, surface tension, amount ingested, and the history or presence of emesis.
- Many hydrocarbons are poorly absorbed from the gastrointestinal tract and unlikely to produce systemic poisoning. Acute systemic toxicity is unlikely to occur in the absence of CNS effects such as excitation or sedation.
- An exposed child who is asymptomatic after 6 hours of observation and who has a normal chest radiograph taken after 6 hours of observation is most likely safe for discharge.

## CASE STUDY 10

**History** A 38-year-old woman was transported to the hospital by EMS directly from the airport because she complained of shortness of breath immediately after exiting the airplane. She had a history of depression and took amitriptyline and zolpidem and admitted to daily alcohol use. She also had a history of hypertension but did not recall the name of her medication. She reported that she was well prior to getting on the flight and only drank 2 beers about 6 hours apart. During the flight, she noted some abdominal and back pain, followed by difficulty breathing. She denied other ingestions or suicidal ideations.

**Physical Examination** On arrival to the hospital, she was noted to be severely short of breath with the following vital signs: blood pressure, 156/92 mm Hg; pulse, 140 beats/min; respiratory rate, 42 breaths/min; temperature, 98.2°F (36.8°C); oxygen saturation, 100% on a 100% non-rebreather mask. Her head was without signs of trauma, and her pupils were equal, round, and sluggishly reactive to light. Her neck was supple, and her chest was clear. She had a regular tachycardia, no murmurs, rubs, thrills, or gallops. Her abdomen was soft with normal bowel sounds and no organomegaly. She was slightly tender in all 4 quadrants, but without guarding or rebound. Her extremities were without clubbing, cyanosis, or edema, and a neurologic examination was without deficit or focality.

**Initial Management** The patient was immediately intubated, sedated with midazolam, and attached to a mechanical ventilator. A rapid bedside glucose was reported as 50 mg/dL, and she was given 25 g of D<sub>50</sub>W and 100 mg of thiamine intravenously. An arterial blood gas revealed a pH of 6.80, a PCO<sub>2</sub> of 24 mm Hg, and a PO<sub>2</sub> of 106 mm Hg on 21% oxygen. A CT scan of the chest was negative for pulmonary embolus. Standard laboratories are shown in Table CS10-1.

**What Is the Differential Diagnosis?** The laboratory analysis shows a severe

metabolic acidosis with elevated anion gap (40 mEq/L). Of the many mnemonics used to help recall the differential diagnosis, one of the most popular is MUDPILES: (Methanol, Uremia, Diabetic and other ketoacidoses, Phenformin and metformin, Iron and isoniazid, Lactate, Ethylene glycol, Salicylates) (Chap. 12). It should be remembered that this is an imperfect mnemonic in that it is easy to forget cyanide, theophylline, and a number of other xenobiotics that are not directly noted. Instead, a mnemonic that is more comprehensive and helps to guide laboratory analysis is KULTS: (Ketones, Uremia, Lactate, Toxic Alcohols, and Salicylate).

**What Clinical and Laboratory Analyses Can Help Identify the Etiology?** A rapid clinical assessment will help to narrow the differential diagnosis. For example, iron poisoning is almost always associated with vomiting (Chap. 45), and isoniazid rapidly produces seizures (Chap. 56). Uremia is excluded based on the BUN and creatinine. Likewise, the presentation glucose concentration helps diminish the probability of diabetic ketoacidosis.

At this point, additional rapid tests are useful. A urinalysis showing ketones would be helpful in cases of alcoholic ketoacidosis (Chap. 76) or salicylates (Chap. 37) and might show oxalate crystals or fluorescence following ethylene glycol poisoning (Chap. 106). A lactate concentration would be elevated in patients with metformin toxicity (Chap. 47) and might be falsely elevated from glycolate accumulation following ethylene glycol poisoning (Chap. 106). Additionally, most laboratories can determine salicylate concentrations rapidly. An ethanol concentration is exceedingly helpful in that it might be low in those with alcoholic ketoacidosis and if elevated essentially excludes methanol

or ethylene glycol poisoning because it would be protective. Finally, if ethanol and methanol concentrations are not available, an osmol gap can be calculated, although caution is advised when interpreting the results especially in this case (Chap. 12).

**Further Diagnosis and Treatment** Additional studies revealed the following: urine was negative for ketones and crystals; a serum lactate was 6 mmol/L; ethanol and salicylate concentrations were negative. Despite receiving fluids, thiamine, and glucose (empiric treatment for alcoholic ketoacidosis), the patient's metabolic acidosis persisted. Because of the severity of the anion gap acidosis and the lack of alternative diagnoses, a loading dose of fomepizole was administered (Antidotes in Depth: A33) for presumed toxic alcohol (methanol or ethylene glycol) ingestion. Intravenous hypertonic sodium bicarbonate was infused for presumed methanol poisoning (Antidotes in Depth: A5), as a repeat creatinine concentration was slightly improved prior to fomepizole administration, making ethylene glycol poisoning less likely (Chap. 106).

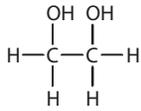

Nephrology was consulted for hemodialysis, and two 4-hour hemodialysis treatments were performed 8 hours apart. A second dose of fomepizole was given in between the hemodialysis treatments. After the second treatment, her anion gap was 8 mEq/L, and sedation was weaned. The patient was extubated easily a few hours later, and her mental status and neurologic examination were normal. The next day her presentation methanol concentration was reported from the reference laboratory as 45 mg/dL. A formal ophthalmology evaluation was unremarkable, and the patient was transferred to psychiatry for what was ultimately decided was her suicidal behavior.

**HISTORY AND EPIDEMIOLOGY**

Methanol was a component of the embalming fluid used in ancient Egypt. Robert Boyle first isolated the molecule in 1661 by distilling boxwood, calling it *spirit of box*.<sup>29</sup> The molecular composition was determined in 1834 by Dumas and Peligot, who coined the term “methylene” from the Greek roots for “wood wine.”<sup>215</sup> Industrial production began in 1923, and today most methanol is used for the synthesis of other chemicals. Methanol-containing consumer products that are commonly encountered include model airplane and model car fuel, windshield washer fluid, solid cooking fuel for camping and chafing dishes, photocopying fluid, colognes and perfumes, and gas line antifreeze (“dry gas”). Methanol is also used as a solvent by itself or as an adulterant in “denatured” alcohol.<sup>141</sup> Most reported cases of methanol poisoning in the United States involve ingestions of one of the above products, with more than 60% involving windshield washer fluid,<sup>58</sup> although most inhalational exposures involve carburetor cleaner.<sup>86</sup> In a Tunisian series, ingested cologne was the most common etiology.<sup>30</sup> In a Turkish series, cologne was also most common, accounting for almost 75% of ingestions.<sup>132</sup> Perfume was one of several exposures in a patient with methanol poisoning in a report from Spain,<sup>183</sup> and methanol poisoning from cologne was also reported in India.<sup>12</sup> There are sporadic epidemics of mass methanol poisoning, most commonly involving tainted fermented beverages.<sup>23,133</sup> These epidemics are a continuing problem in many parts of the world (Table 106–1).<sup>102,216</sup> Abuse of hydraulic fracturing (“fracking”) fluid is another more recent source of methanol poisoning.<sup>50</sup> Methyl acetate in non-acetone nail polish removers is hydrolyzed to methanol in acidic environments, but it is unclear to what extent this occurs in vivo.<sup>184</sup>

Ethylene glycol was first synthesized in 1859 by Charles-Adolphe Wurtz and first widely produced as an engine coolant during World War II, when its precursor ethylene oxide became readily available.<sup>69</sup> Today its primary use remains as an engine coolant (antifreeze) in car radiators. Because of its sweet taste, it is often unintentionally consumed by animals and children. Aversive bittering agents are often added to ethylene glycol-containing antifreeze to try to prevent ingestions by making the antifreeze unpalatable, an approach that manufacturers now voluntarily employ throughout the United States, and that is required by law in many states.<sup>128</sup> However, there is no evidence that this strategy is effective, and comparisons in poison control center data between ethylene glycol ingestions in which bittering agents were required and or not revealed no significant differences in frequency or volume of ingestion, or any other outcome variable (Chap. 129).<sup>128,272,273</sup>

Isopropanol is primarily available as rubbing alcohol. Typical household preparations contain 70% isopropanol. It is also a solvent used in many

household, cosmetic, and topical pharmaceutical products. Perhaps because it is so ubiquitous, inexpensive, and with a common name that contains the word “alcohol,” isopropanol ingestions are by far the most common toxic alcohol exposure reported to poison control centers in the United States every year, typically in cases in which it was used as an ethanol substitute (Chap. 130).

## CHEMISTRY

Alcohols are hydrocarbons that contain a hydroxyl (–OH) group. The term “toxic alcohol” refers to alcohols other than ethanol that are not intended for ingestion. In a sense, this is arbitrary, since all alcohols are toxic, causing inebriation and end-organ effects if taken in excess. The most common clinically relevant toxic alcohols are methanol and ethylene glycol (1,2-ethanediol). Primary alcohols, such as methanol and ethanol, contain a hydroxyl group on the end of the molecule (the terminal carbon), whereas secondary alcohols, such as isopropanol, contain hydroxyl groups bound to middle carbons. Ethylene glycol contains 2 hydroxyl groups; molecules with this characteristic are termed diols or glycols because of their sweet taste. Other common toxic alcohols include isopropanol (isopropyl alcohol or 2-propanol), benzyl alcohol (phenylmethanol), and propylene glycol (1,2-propanediol). Glycol ethers are glycols with a hydrocarbon chain bound to one or more of the hydroxyl groups (forming the basic structure  $R_1O-CH_2-CH_2-OR_2$  or  $R_1O-CH_2-CH_2-CH_2-OR_2$ ). Glycol ethers commonly encountered include ethylene glycol butyl ether (also known as 2-butoxyethanol, ethylene glycol monobutyl ether, or butyl Cellosolve), ethylene glycol methyl ether (2-methoxyethanol), and diethylene glycol (2,2'-dihydroxydiethyl ether). Poisoning with these xenobiotics has some clinical similarities with toxic alcohol poisoning, and diethylene glycol is discussed in detail in Special Considerations: SC9.

## TOXICOKINETICS/TOXICODYNAMICS

### Absorption

#### Ingestion

Alcohols are rapidly absorbed after ingestion,<sup>73,87</sup> but are not completely bioavailable because of metabolism by gastric alcohol dehydrogenase (ADH), as well as by first-pass hepatic metabolism. Occasionally, delayed or prolonged absorption occurs.<sup>66</sup> Ethylene glycol has an oral bioavailability 92% to 100%.<sup>73</sup> The bioavailabilities of methanol and isopropanol are not described, but are likely to be similar.

#### Inhalation

Although methanol is absorbed in significant amounts by inhalation, poisoning by this route is uncommon. In workers exposed to methanol fumes from industrial processes for up to 6 hours at concentrations of 200 ppm (Occupational Health and Safety Administration {OSHA} permissible exposure limit {PEL}), there was no significant accumulation of methanol or its metabolite formate.<sup>152</sup> Another study showed that with methanol use in the semiconductor industry, ambient methanol concentrations generally do not approach this OSHA limit even in a room with poor ventilation and with no local exhaust ventilation.<sup>77</sup> However, a total of 5 patients in 2 case series of smartphone manufacturing workers had chronic exposures and developed permanent visual and neurologic sequelae.<sup>46,219</sup> Surprisingly, concentrations far in excess of the OSHA PEL are present within the passenger compartment of a car when using the windshield wipers with methanol-containing windshield washing fluid.<sup>21</sup> No cases of human poisoning are reported from this type of exposure, probably because these concentrations are not sustained over a long time. Two patients with occupational inhalational exposure aboard a tanker carrying methanol developed toxicity, including the death of one; both patients reportedly used appropriate personal protective equipment.<sup>142</sup> Additionally, cases of inhalational poisoning are reported with intentional inhalation of methanol as a drug of abuse, typically in the form of carburetor-cleaning fluid (“huffing”) (Chap. 81), and with massive exposures of rescue workers responding to the scene of an overturned rail car filled with methanol.<sup>14,74,86,166,262,269</sup> Two case series suggest that patients who present after chronic inhalation of methanol generally do not have severe

poisoning,<sup>20,166</sup> but in another series, patients with inhalational exposure were as likely to require extensive therapy as patients with methanol ingestion,<sup>86</sup> and permanent visual sequelae and death are reported.<sup>142,162,219</sup>

Ethylene glycol has low volatility and is not reported to cause poisoning by inhalation. In one study, human volunteers inhaled vaporized ethylene glycol at a concentration of 1,340 to 1,610 ppm for 4 hours to simulate an industrial exposure. Afterward, the volunteers had detectable but not clinically significant concentrations of ethylene glycol and its metabolites.<sup>261</sup>

#### Transdermal

Most alcohols have some dermal absorption, although isopropanol and methanol penetrate the skin much more effectively than ethylene glycol.<sup>62,158,266</sup> Most reported cases of toxic alcohol poisoning by this route involve infants<sup>57</sup> because of their greater body surface area–volume ratio and differences in permeability of infant skin compared to adults, and likely this also involved simultaneous inhalation. When transdermal methanol exposure is prolonged, severe toxicity is reported.<sup>134</sup> One reported case of transdermal methanol poisoning involved a 51-year-old woman, but details of the exposure were not reported.<sup>245</sup> Another case involved a 52-year-old woman who reportedly frequently massaged with methanol-containing cologne and spirit over the course of 3 days. That patient had significant visual and neurologic sequelae despite aggressive treatment with ethanol and hemodialysis.<sup>2</sup> One methanol fatality was deemed to be caused by transdermal absorption (in addition to blunt trauma) when high tissue methanol concentrations were measured in the absence of detectable methanol in the gastrointestinal tract,<sup>15</sup> but inhalational exposure could have also conceivably contributed. Transdermal methanol absorption is responsible for multiple cases of consequential poisoning in Turkey, where methanol-soaked bandages or clothing are used as a traditional or alternative remedy for musculoskeletal pain.<sup>105,260</sup> When human volunteers were exposed to 100% ethylene glycol applied to a 66 cm<sup>2</sup> area of skin under an occlusive dressing for 6 hours, detectable but not clinically significant amounts were absorbed.<sup>261</sup>

#### Distribution

Once absorbed, alcohols are rapidly distributed to total body water. In human volunteers given an oral dose of methanol on an empty stomach, the measured volume of distribution was 0.77 L/kg, with a distribution half-life of about 8 minutes.<sup>87</sup> This is only slightly longer than the absorption half-life, so serum concentrations often peak soon after ingestion and then begin to fall. However, this is not necessarily the case in patients with large ingestions or with food in their stomachs prior to ingestion. The volume of distribution of ethylene glycol with IV administration in a rat model was 0.60 L/kg.<sup>73</sup> The reported volume of distribution of isopropanol is 0.45 to 0.55 L/kg.<sup>242</sup>

#### Metabolism and Elimination

Without intervention, toxic alcohols are metabolized through successive oxidation by ADH and aldehyde dehydrogenase (ALDH), each of which is coupled to the reduction of NAD<sup>+</sup> to NADH. Methanol is metabolized to formaldehyde, then to formic acid (Fig. 106–1). The formate metabolite is then bound by tetrahydrofolate and undergoes metabolism by 10-formyltetrahydrofolate dehydrogenase to carbon dioxide and water. Ethylene glycol has 2 hydroxyl groups that are serially oxidized by ADH and ALDH, producing, in turn, glycoaldehyde, glycolic acid, glyoxylic acid, and finally oxalic acid (Fig. 106–2). Like ethanol, metabolism follows zero-order kinetics, with a rate of approximately 10 mg/dL/h.<sup>49,120,179</sup> Additionally, this rate is apparently unchanged in chronic ethanol users.<sup>97,98</sup> Alternate minor metabolic pathways such as catalase exist for methanol and ethylene glycol.

Ethylene glycol is also metabolized to ketoacid and glycine using thiamine and pyridoxine as cofactors.<sup>189</sup> Because of the low toxicity of these ethylene glycol metabolites, enhancing these normally minor metabolic pathways is theoretically beneficial in poisoned patients.

Methanol and ethylene glycol are also eliminated from the body as unchanged parent compounds. When kidney function is normal, ethylene glycol is cleared with a half-life of approximately 17 hours.<sup>28,45,240</sup> In patients with renal impairment, the half-life is prolonged (34 ± 13 hours) in the absence

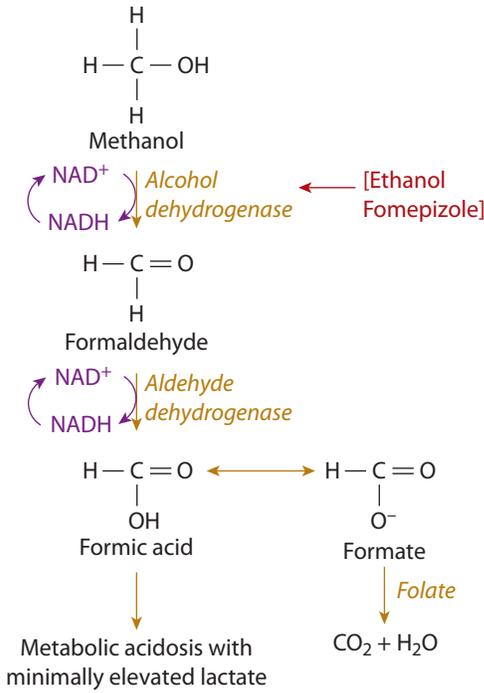

FIGURE 106-1. Major pathway of methanol metabolism.

of renal function) and about 49 h in those with impaired kidney function (Cr>1.2).<sup>240</sup> Methanol does not have significant renal elimination (about 1% of the ingested dose in patients with intact hepatic metabolism) and is cleared much more slowly than is ethylene glycol, presumably as a vapor in expired air (half-life 52 hours, with a longer half-life at very high concentrations).<sup>32,111,147,198</sup>

Isopropanol is metabolized by alcohol dehydrogenase to acetone. Because acetone is a ketone, not an aldehyde, it cannot be further metabolized by ALDH and is eliminated in the urine and in expired air (Fig. 106-3).

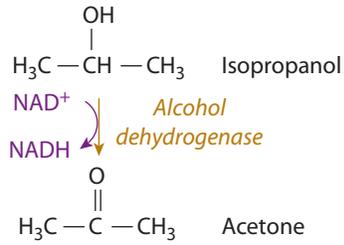

FIGURE 106-3. Isopropanol metabolism.

## PATHOPHYSIOLOGY AND CLINICAL MANIFESTATIONS

### Acute Central Nervous System Effects

All alcohols cause inebriation, depending on the dose. Based on limited animal data, the higher-molecular-weight alcohols are more intoxicating than lower-molecular-weight alcohols on a molar basis (therefore, isopropanol approximates ethylene glycol < which is greater than ethanol < which is greater than methanol).<sup>270</sup> However, the absence of apparent inebriation does not exclude ingestion, particularly if the patient chronically drinks ethanol and is thereby tolerant to its central nervous system (CNS) effects.<sup>250</sup> Additionally, serum methanol concentrations of 25 to 50 mg/dL are associated with toxicity, whereas one may legally drive a car in the US with a blood ethanol concentration of up to 80 mg/dL.

The CNS manifestations of toxic alcohol poisoning are incompletely understood. It is assumed by analogy that inebriation is similar to that of ethanol, in which effects are mediated through increased  $\gamma$ -aminobutyric acid (GABA)-ergic tone both directly and through inhibition of presynaptic GABA, GABA<sub>A</sub> receptors as well as inhibition of the *N*-methyl-D-aspartic acid glutamate receptors.<sup>9,40,89,107,182</sup> Although the CNS effects of other alcohols are clinically similar, there is no direct evidence that they are mechanistically the same.

### Metabolic Acidosis

Metabolic acidosis with an elevated anion gap is a hallmark of toxic alcohol poisoning. This is a consequence of the metabolism of the alcohols to toxic organic acids. The acids have no rapid natural metabolic pathway of elimination, and therefore they accumulate. In methanol poisoning, formic acid is responsible for the acidosis, whereas in ethylene glycol poisoning, glycolic acid is the primary acid responsible for the acidosis, with other metabolites making a minor contribution.<sup>123</sup> An exception to the formation of an acid metabolite is isopropanol, which is metabolized to acetone. Because acetone cannot be metabolized by ALDH, isopropanol has no organic acid metabolite and does not cause metabolic acidosis. In fact, ketosis without acidosis is essentially diagnostic of isopropanol poisoning. Occasionally, a non-anion gap (hyperchloremic) metabolic acidosis is present with ethylene glycol poisoning (almost 18% in one series), often concurrently with anion gap acidosis.<sup>244</sup> The mechanism for this is unclear, but a similar pattern is observed in diabetic ketoacidosis, alcoholic ketoacidosis, and toluene poisoning. Different volumes of distribution of bicarbonate and the anion are a potential explanation for the phenomenon.

### End-Organ Manifestations

Additional end-organ effects depend on which alcohol is involved. Methanol causes visual impairment, ranging from blurry or hazy vision or defects in color vision, to “snowfield vision” or total blindness in severe poisoning. Although it is counterintuitive, vision loss is often asymmetric.<sup>47,169</sup> On physical examination, central scotoma are sometimes present on visual field testing, and both hyperemia and pallor of the optic disc, papilledema, and an afferent papillary defect are described as characteristic findings.<sup>23,194,290</sup> In a retrospective study, optic disk cupping developed in at least one eye in 22 of 50 consecutive patients with vision loss due to methanol poisoning, and 43 of 100 eyes.<sup>79</sup> Scotopic (monochromatic vision in low-light conditions) and photopic (color vision under well-lit conditions) function are both impaired after methanol poisoning in a rat model.<sup>163</sup> Electroretinography demonstrates

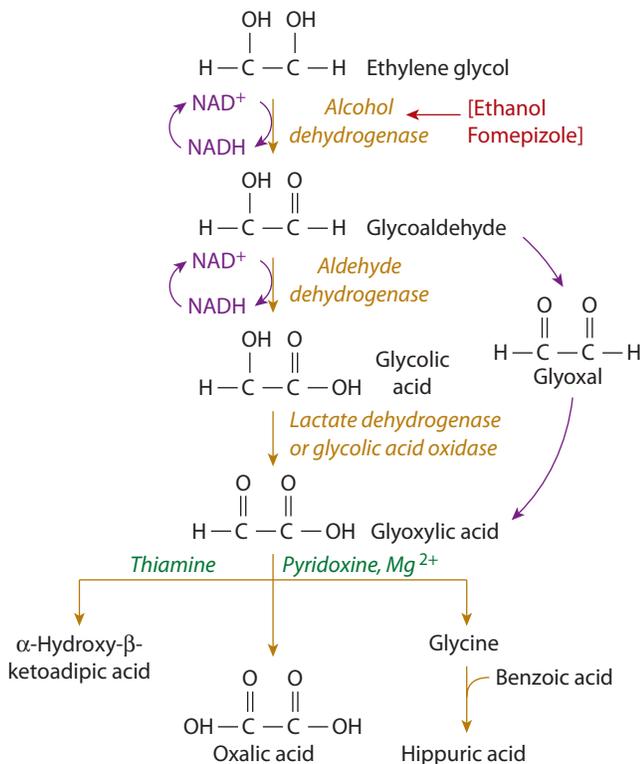

FIGURE 106-2. Pathways of ethylene glycol metabolism. Thiamine and pyridoxine enhance formation of nontoxic metabolites.

a diminished b-wave,<sup>258</sup> a marker of bipolar cell dysfunction, and optical coherence tomography (OCT), similar in principle to ultrasound, but using reflected light waves to image translucent tissues, demonstrates peripapillary nerve fiber swelling and intraretinal fluid accumulation.<sup>76</sup> These OCT changes are best assessed at 2 months after discharge, when retinal edema resolves, to prevent false negative results. Formate is a mitochondrial toxin, inhibiting cytochrome oxidase and it thereby interferes with oxidative phosphorylation.<sup>67,190,191</sup> Although it is unclear why this results in ocular toxicity whereas other tissues are relatively spared, retinal pigmented epithelial cells and optic nerve cells appear to be uniquely susceptible.<sup>64,175,257,258</sup> Proteomic analysis of retinas in rats poisoned by methanol showed that concentrations of 24 proteins were different from baseline (14 increased, 10 decreased),<sup>44</sup> so the underlying pathophysiology of retinal toxicity from methanol is likely more complex than is currently understood. Years after exposure, optic nerve atrophy, disc pallor, and severe cupping often persist, even with normal intraocular pressure.<sup>79,236</sup> In fact, optic nerve axonal degeneration continues to progress over at least 2 years after exposure to methanol.<sup>283</sup>

Interestingly, neurons in the basal ganglia appear to be similarly susceptible to this toxicity. Bilateral basal ganglia lesions, bilateral necrosis of the putamen (with or without hemorrhage), and less commonly, caudate nucleus are characteristically abnormal visualized on cerebral computed tomography (CT) or magnetic resonance imaging (MRI) after methanol poisoning.<sup>134,232,253</sup> Although lesions of this type are nonspecific, and also occur in hypoxia, hypotension, and carbon monoxide poisoning, in methanol poisoning they occur in the absence of hypotension and hypoxia,<sup>177</sup> suggesting a direct toxic mechanism. Some patients develop parkinsonism after poisoning by methanol, a finding consistent with lesions in the basal ganglia.<sup>91,176,209</sup> In one series, typical radiological lesions were present in 6 of 9 cases.<sup>232</sup> Other CNS lesions reported include necrosis of the corpus callosum,<sup>137</sup> infarcts of other areas of the brain,<sup>95</sup> and intracranial hemorrhage.<sup>13,231</sup> Pathologic examination of the brain reveals lesions similar to those found radiologically.<sup>135</sup> Increased glial fibrillary acidic protein and decreased CD34 expression are pathologic markers in affected tissues, although how these relate to the underlying pathophysiology is not yet clear.<sup>259</sup> Serum leukotrienes are also elevated in patients with methanol poisoning, and patients with the worst neurologic outcomes have the least elevated leukotrienes.<sup>279</sup> The role of leukotrienes is incompletely understood, but this could be explained by leukotriene-related inflammation as part of the pathophysiology of neurodegeneration.

Both retinal and neurologic toxicity in patients with methanol poisoning are often permanent. Among 86 survivors of a methanol poisoning outbreak in Estonia in 2001, 26 had died 6 years later (many from ethanol intoxication) and 33 could not be located. Of the 5 patients who could be located of the 20 patients who were discharged with retinal or neurologic sequelae, all had persistent effects. Interestingly, 8 of the 22 patients located who were discharged without sequelae had newly identified neurologic and visual sequelae 6 years later (among 66 initially discharged without sequelae), possibly because they were present initially but missed because of lack of ophthalmologic evaluation, but more likely because they had progressive findings or reexposure to methanol. New neurologic abnormalities were probably due to ongoing ethanol consumption.<sup>197</sup> In another series from Iran, 37 of 50 survivors of methanol poisoning with retinal toxicity were followed 1 year later; 16 patients improved before discharge from the hospital. Seven patients had their visual disturbance resolve within 2 weeks; 5 were blind at discharge but partially recovered within 3 to 4 weeks; 5 were blind at discharge and had no improvement 1 year later; and 4 were blind at discharge, had partial recovery within 1 month, but then had worsening vision within the subsequent 9 months.<sup>225</sup> In a series of patients from a 2012 methanol poisoning outbreak in the Czech Republic, 42 of 101 hospitalized patients presented with visual disturbances. Only 16 of these 42 (38%) survived without sequelae.<sup>289</sup> In a subsequent study of these patients, 8 of 37 who were discharged with no visual complaints after methanol poisoning subsequently had visual damage after additional testing at follow-up.<sup>285</sup> Further testing showed progressive axonal injury over 2 years.<sup>283</sup> In another study of 50 patients from the same outbreak, major neurologic sequelae were uncommon, but cognitive deficits in executive function and verbal memory compared

to controls persisted 2 years later.<sup>25</sup> Clearly, long-term outcomes of retinal and neurologic toxicity are difficult to predict from the initial presentation, especially when complicated by persistent alcoholism and thiamine deficiency.

Injury to other tissues also occurs. Both acute kidney injury (AKI) and pancreatitis are reported after methanol poisoning.<sup>101,143</sup> One case series showed a much higher incidence of pancreatitis (50%)<sup>101</sup> and in another, 11 of 15 patients had pancreatitis,<sup>265</sup> but this is not typical. Of note, all of the patients in the first series and 13 of 15 patients in the second series had been treated with ethanol. Some of the AKI that results from methanol poisoning likely results from myoglobinuria.<sup>90</sup> In one series of methanol-poisoned patients with AKI, about half had associated myoglobinuria, presumably because of atraumatic rhabdomyolysis and prolonged immobilization associated with inebriation, or to seizures. One reported patient with methanol poisoning had rhabdomyolysis severe enough to cause compartment syndrome in both legs, requiring fasciotomies.<sup>70</sup> Patients with AKI were also more likely than a control group of patients to have severe poisoning, as manifested by low initial serum pH, high initial osmolality, and high peak formate concentration.<sup>265</sup> Pathologic abnormalities of the liver, esophagus, and gastric mucosa are also found in some fatal cases of methanol poisoning.<sup>4,42</sup>

The most prominent end-organ effect of ethylene glycol is nephrotoxicity. The oxalic acid metabolite forms a complex with calcium to precipitate as calcium oxalate monohydrate crystals in the renal tubules, leading to AKI.<sup>72,92,93,178,205,249,254</sup> In fact, the diagnosis of ethylene glycol poisoning is sometimes established at autopsy by demonstrating this abnormality;<sup>10,156</sup> in another case, the diagnosis was established by kidney biopsy.<sup>137</sup> Although the intermediate products of ethylene glycol metabolism, and possibly ethylene glycol itself, are directly toxic to the renal tubules in some studies,<sup>48,72,204,207</sup> this appears not to occur at clinically relevant concentrations.<sup>92</sup> Currently no explanation exists for the presence of necrotic lesions to the glomerular basement membrane on some pathology specimens<sup>72</sup> as oxalic acid generally does not cause glomerular injury.<sup>127</sup>

Ethylene glycol can occasionally affect other organ systems. In severe poisoning, the oxalic acid metabolite causes hypocalcemia by precipitation as calcium oxalate. Hypocalcemia results in prolongation of the QT interval on the electrocardiogram and ventricular dysrhythmias.<sup>230</sup> However, a retrospective review of serum calcium concentrations in patients with ethylene glycol poisoning did not find an association with hypocalcemia, even in patients with significant acidemia.<sup>106</sup> This suggests that though hypocalcemia occurs, it is uncommon. Cerebral edema was present on CT scan in 2 patients who died of ethylene glycol poisoning.<sup>75,254</sup> In contrast, reversible osmotic demyelination syndrome (central pontine myelinolysis) occurred in one patient with a massive ethylene glycol ingestion despite normal serum sodium; the patient had full neurologic recovery several weeks later.<sup>3</sup> Two reported patients had delayed neurologic manifestations. One patient developed increased intracranial pressure, with papilledema and an abducens (CN VI) palsy approximately 9 days after recovering from acute ethylene glycol poisoning and without another clear etiology.<sup>59</sup> Another patient developed the same cluster of delayed effects (increased intracranial pressure, papilledema, and an abducens palsy) on day 13 of hospitalization, after fomepizole, thiamine, pyridoxine, and hemodialysis. He subsequently developed a facial (CN VII) palsy, sensory neuropathy, and autonomic neuropathy, including postural hypotension and gastroparesis.<sup>208</sup> Precipitation of calcium oxalate crystals in the brain was found on autopsy after severe ethylene glycol poisoning<sup>7,72,75</sup> and likely accounts for the multiple cranial nerve abnormalities that occasionally develop,<sup>59,68,246</sup> although there is as yet no direct evidence of causation. Peripheral polyradiculoneuropathy was diagnosed by electromyography and nerve conduction studies in cases of ethylene glycol poisoning,<sup>5,16</sup> and intracranial hemorrhage involving the globus pallidus also occurs.<sup>37</sup> A leukemoid reaction is reported in some patients with severe ethylene glycol poisoning, but the mechanism remains unclear.<sup>168,187</sup> One pediatric case of hemophagocytic syndrome and liver failure in the setting of ethylene glycol poisoning resulted in fatality.<sup>150</sup> Similar to methanol poisoning, parkinsonism also occurs.<sup>209</sup> Two severe cases of unintentional ethylene glycol ingestion in the United Kingdom resulted in blindness and

deafness; one with associated cranial neuropathies and one with multiple peripheral neuropathies.<sup>39,61</sup> One patient had a myocardial infarction with ST segment elevation while poisoned with ethylene glycol, but survived after cardiac catheterization and placement of 5 stents, as well as treatment with ethanol and hemodialysis.<sup>252</sup> However, this was most likely due to the stress of poisoning in a patient with underlying cardiovascular disease rather than a direct toxic effect. Finally, death is reported from massive ethylene glycol ingestion with no elevation of its metabolites, suggesting direct toxicity of the alcohol, probably through respiratory depression.<sup>80</sup>

Hemorrhagic gastritis is associated with isopropyl alcohol toxicity. Although this is often assumed to be caused by a local irritant effect, one reported case of hemorrhagic gastritis after percutaneous isopropanol exposure suggests that this is not the only mechanism, and could in fact be a specific end-organ effect.<sup>63</sup> Hemorrhagic tracheobronchitis is reported in fatal cases of isopropanol aspiration.<sup>5</sup> The acetone metabolite of isopropyl alcohol also interferes with some creatinine assays, causing a falsely elevated result,<sup>139</sup> but it does not actually cause AKI.

## DIAGNOSTIC TESTING

### Toxic Alcohol and Metabolite Concentrations

Serum methanol, formate, ethylene glycol, oxalate, and isopropanol concentrations (as appropriate) would be the ideal tests to perform shortly after suspected toxic alcohol poisoning. However, these concentrations are most commonly measured by gas chromatography with or without mass spectrometry confirmation, methodologies that are not available in most hospital laboratories on a 24-hour basis, if at all. In fact, in many hospitals these are only available as “send out” tests, so results arrive too late for meaningful clinical decision making.<sup>136</sup> Enzymatic assays for methanol, formic acid, ethylene glycol, and glycolic acid use newer methodology,<sup>26,99,212,228,247,268</sup> and these may lead to more readily available clinical tests in the future. One commercial assay currently only approved for veterinary use is effective for confirming the qualitative presence of ethylene glycol in human poisoning, although false positives may occur with propylene glycol.<sup>165</sup> At least one medical center has adopted the veterinary product for clinical use. Over 4 years, no false negatives occurred (most negative tests did not have GC performed for confirmation, but chart review did not identify any missed cases).<sup>140,213</sup> There were only 25 false positives out of 222 samples, most due to propylene glycol in lorazepam or in activated charcoal.<sup>214</sup> In a murine model, a commercially available ethanol in saliva point of care test detected the presence of a low concentration of methanol but not ethylene glycol.<sup>96</sup> Unfortunately, it would not distinguish between methanol and ethanol, limiting the clinical utility of this test. A group in Finland described a point of care breath test for methanol, using a portable Fourier transform infrared (FT-IR) analyzer similar to the “breathalyzers” used by law enforcement agents.<sup>151</sup> Although analyzers like this are used to detect methanol as a combustion product in industry, they are not yet approved for medical use in the United States. Once approved, they would be useful for early clinical decision making because they are easy to use and provide a rapid result. They also can provide continuous monitoring of concentrations, a feature that would be very helpful during hemodialysis. Unfortunately, this methodology could not be used to detect ethylene glycol because of its low volatility. A newer dry chemistry “dipstick” technology for formate detection shows promise for rapid detection of cases of methanol poisoning with minimal equipment or skilled laboratory personnel.<sup>112</sup> Patients with significant serum concentrations of ethanol generally do not have measurable formate concentrations even when there are significant serum concentrations of methanol,<sup>170</sup> so serial testing of these patients would be necessary if methanol poisoning is suspected.

Patients presenting late after ingestion have already metabolized all parent compound to toxic metabolites and thus have low or no measurable toxic alcohol concentrations. The enzymatic assay for ethylene glycol is also capable of detecting glycolic acid, although as mentioned, this assay is approved only for veterinary use. Some authors actually advocate for routine testing for glycolic acid in addition to testing for the parent compound when ethylene glycol poisoning is suspected.<sup>207</sup> Serum and urine oxalate concentrations

can also be determined,<sup>248</sup> but they are unlikely to be clinically useful. In a postmortem study, patients who died of ethylene glycol poisoning had similar oxalate concentrations to some negative controls who died of causes unrelated to ethylene glycol, and 2 of 6 patients who died of ethylene glycol poisoning had very low urine oxalate concentrations.<sup>267</sup> By contrast, a formate concentration would be valuable when a patient presents late after methanol ingestion.<sup>117,195</sup> Formate was detected in blood samples from 97% of patients who died of methanol poisoning in one series; all of these patients also had detectable blood or vitreous methanol concentrations.<sup>129</sup> Based on a series of 38 patients from the Czech methanol epidemic, serum formate concentrations greater than 4.0 mmol/L (18 mg/dL) were associated with clinical signs of visual toxicity, and concentrations greater than 11 mmol/L (49.5 mg/dL) were associated with permanent visual and neurologic sequelae. Concentrations greater than 17.5 mmol/L (78.8 mg/dL) were potentially lethal.<sup>280</sup> Newer capillary electrophoresis methodology has the potential to rapidly determine serum formate concentrations with a small sample size and lower cost.<sup>148,149</sup> Clearly, a low or undetectable toxic alcohol concentration must be interpreted within the context of the history and other clinical data, such as the presence of acidosis and end-organ toxicity, with glycolate and formate concentrations as potentially valuable additions.

Samples must be handled correctly for accurate toxic alcohol results. Particularly with the more volatile alcohols methanol and isopropanol, evaporation from sample tubes that are not airtight lowers serum concentrations in those tubes so that they do not accurately reflect the serum concentration in the patient. This results in falsely low results if alcohol concentrations are done as “add on” tests to samples already opened for electrolyte or osmol determinations.

Other alcohols such as benzyl alcohol and propylene glycol are not routinely assayed for by gas chromatography. Thus, these xenobiotics present a much greater diagnostic challenge than methanol and ethylene glycol. Enzymatic assays for methanol or ethylene glycol would also fail to detect these, although false positive ethylene glycol tests may occur if propylene glycol is present. Thus, a high index of suspicion is critical to establishing the diagnosis in these cases. If suspected on the basis of history, specific toxic alcohol testing should be performed.

Once alcohol concentrations are obtained, their interpretation represents a further point of controversy. Traditionally, a methanol or ethylene glycol concentration greater than 25 mg/dL was considered toxic, but the evidence supporting this as a threshold is often questioned. In a case series of methanol-poisoned patients from the 1950s, a methanol concentration of 52 mg/dL was the lowest associated with vision loss.<sup>23</sup> This is the origin of the 25-mg/dL threshold, incorporating a 50% reduction as a margin of safety. However, the patient with the 52-mg/dL concentration presented 24 hours after his initial ingestion, and therefore was much more severely poisoned than suggested by his serum concentration at that point. In fact, almost all reported cases of methanol poisoning involve patients with delayed presentations who already have a metabolic acidosis.<sup>144</sup> A 6-week-old infant, the only reported patient who went untreated after presenting early with an elevated methanol concentration (45.6 mg/dL), never developed acidosis or end-organ toxicity.<sup>31,144</sup> A systematic review found that 126 mg/dL was the lowest methanol concentration resulting in metabolic acidosis in a patient who arrived early after ingestion and met the inclusion criteria. The authors concluded that the available data are currently insufficient to apply a 25-mg/dL treatment threshold in a patient presenting early after ingestion without metabolic acidosis.<sup>144</sup> However, until better data are available demonstrating the safe application of a higher concentration, it seems prudent to use a conservative concentration such as 25 mg/dL as a threshold for treatment.

Because of the problems with obtaining and interpreting actual serum concentrations, many surrogate markers are used to assess the patient with suspected toxic alcohol poisoning. The initial laboratory evaluation should include serum electrolytes, including calcium, blood urea nitrogen, serum creatinine concentrations, urinalysis, measured serum osmolality, and a serum ethanol concentration. Blood gas analysis with a lactate concentration is also helpful in the initial evaluation of ill-appearing patients.

## Anion Gap and Osmol Gap

For a full discussion of the anion gap concept, refer to Chap. 12. As previously discussed, anion gap elevation is a hallmark of toxic alcohol poisoning. In fact, the possibility of methanol or ethylene glycol poisoning is often first considered when patients present with an anion gap metabolic acidosis of unknown etiology, frequently with no history of ingestion. Unless clinical information suggests otherwise, it is important to exclude metabolic acidosis with elevated lactate concentration and ketoacidosis, which are the most common causes of anion gap metabolic acidosis, before pursuing toxic alcohols in these patients. This is because of the extensive evaluation required and expensive, potentially invasive course of therapy to which they are otherwise committed. However, elevated lactate concentrations are often present in the setting of both methanol and ethylene glycol poisoning.<sup>173,180,234</sup>

The unmeasured anions in toxic alcohol poisoning are the dissociated organic acid metabolites discussed above. The metabolic acidosis takes time to develop, sometimes up to 16 to 24 hours for methanol. Thus, the absence of an anion gap elevation early after reported toxic alcohol ingestion does not exclude the diagnosis. If ethanol is present in the body, the development of metabolic acidosis will not begin to occur until enough ethanol has been metabolized that it can no longer effectively inhibit ADH (see Ethanol Concentration, below).

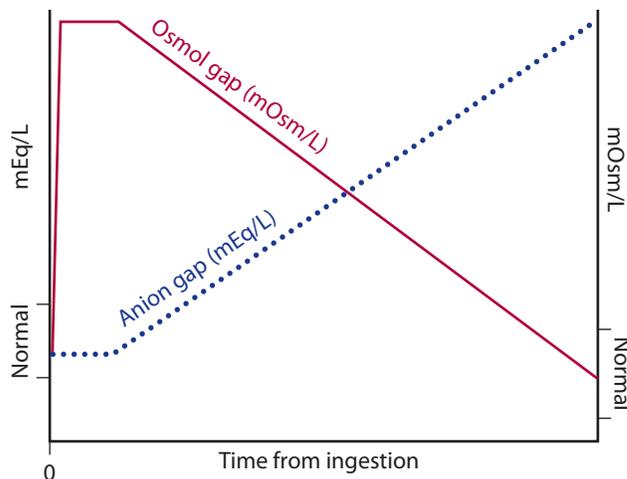

A potential early surrogate marker of toxic alcohol poisoning is an elevated osmol gap (the principles and the calculations are discussed in detail in Chap. 12). However, it is important to recognize that osmol gap elevation is neither sensitive nor specific for toxic alcohol poisoning. Because a baseline osmol gap is generally not available when evaluating a patient (with rare exceptions),<sup>115</sup> and a normal osmol gap ranges from  $-14$  to  $+10$  mOsm/L, so-called “normal” osmol gaps cannot exclude toxic alcohol poisoning.<sup>109</sup> For example, in a patient with a baseline osmol gap of  $-10$ , a current gap of  $+5$  mOsm/L potentially represents a methanol concentration of  $47$  mg/dL or an ethylene glycol concentration of  $93$  mg/dL, values that might require hemodialysis. Inversely, a moderately elevated osmol gap ( $+10$  to  $+20$  mOsm/L) is not necessarily diagnostic of toxic alcohol poisoning because other disorders such as alcoholic ketoacidosis and metabolic acidosis with elevated lactate concentration will raise the osmol gap.<sup>229</sup> Furthermore, mean osmol gaps vary within populations over time, further limiting their utility.<sup>145</sup> However, a markedly elevated osmol gap ( $>50$  mOsm/L) is difficult to explain by anything other than a toxic alcohol.

Further complicating matters, the anion gap and osmol gap have a reciprocal relationship over time. This is because soon after ingestion, the alcohols present in the serum raise the osmol gap but do not affect the anion gap because metabolism to the organic acid anion has not yet occurred. As the alcohols are metabolized to organic acid anions, the anion gap rises while the osmol gap falls, because the metabolites are negatively charged particles that have already been accounted for in the calculated osmolarity by doubling of the sodium. Thus patients who present early after ingestion have a high osmol gap and normal anion gap, whereas those who present later have the reverse.<sup>113,119</sup> Figure 106-4 depicts a more intuitive visual representation of this process.

One retrospective and one prospective study attempted to evaluate the performance characteristic of the osmol gap as a diagnostic test. Although in both cases, the osmol gap performed fairly well, the studies were small, 20 patients with toxic alcohol poisoning in the retrospective study and 28 patients with methanol poisoning in the prospective study, and the prospective study identified 3 patients with significant poisoning and metabolic acidosis but “normal” osmol gaps, defined in the study as less than  $25$  mOsm/L.<sup>113,172</sup> Therefore, these data do not eliminate the concern that a patient with significant poisoning could be missed by relying on the osmol gap alone to exclude poisoning. One reported patient had his diagnosis delayed by 2 days because of false reassurance from a “normal” osmol gap.<sup>11</sup>

## Ethanol Concentration

A serum ethanol concentration is an important part of the assessment of the patient with suspected toxic alcohol poisoning. As discussed in Chap. 12, the ethanol concentration is necessary to calculate osmolarity. In addition,

**FIGURE 106-4.** The reciprocal relationship of anion gap and osmol gap over time (hours). Note that patients presenting early may have a normal anion gap while patients who present late may have a normal osmol gap.

because ethanol is the preferred substrate of ADH (4:1 over methanol and 8:1 over ethylene glycol on a molar basis), a significant concentration would be protective if coingested with a toxic alcohol. In fact, ethanol concentrations near  $100$  mg/dL virtually preclude toxic alcohols as the cause of an unknown anion gap metabolic acidosis because the presence of such a concentration should have prevented metabolism to the organic acid. A possible exception would be ingestion of ethanol several hours after ingestion of a toxic alcohol.<sup>108</sup> If a breath alcohol analyzer is used to determine ethanol concentration, significant methanol concentrations can cause a false positive ethanol, without an indication from the machine that an interfering substance is present (as there is with acetone).<sup>38</sup> Therefore, even if a prehospital breath alcohol analyzer indicates a significant ethanol concentration, this should be confirmed by determining the serum ethanol concentration.

## Lactate Concentration

Both methanol and ethylene glycol poisoning can result in elevated lactate concentrations, for different reasons. Formate, as an inhibitor of oxidative phosphorylation, leads to anaerobic metabolism and resultant lactate elevation. Additionally, metabolism of all alcohols results in an increased NADH/NAD<sup>+</sup> ratio, which favors the conversion of pyruvate to lactate. Furthermore, hypotension and organ failure in severely poisoned patients also produces an elevated lactate concentration. Finally, the fact that these patients are often alcoholics who are nutritionally deprived and thiamine depleted also contributes to the elevated lactate concentration. However, lactate production by these mechanisms is rarely greater than  $5$  mmol/L.

In ethylene glycol poisoning, the glycolate metabolite also causes a false positive lactate elevation when measured by some analyzers, particularly with whole blood arterial blood gas analyzers. The Radiometer ABL series (625, 700, 725, 825, 835) is most widely reported to result in a false positive lactate. Other specific models implicated to varying degrees of false positive lactate results include Beckman LX 20, Siemens Rapidlab series (860, 865), all Roche models, Architect c8000, Vitros Fusion 5.1, IL GEM 4000 Premium, Abbott iSTAT and Hitachi 911 analyzers. The Vitros 950, Vitros 250, Siemens Dimension Vista, Siemens Dimension RxL, Abbott Aeroset, or Abbott Architect C8000 do not produce false positive results. Reports are conflicting on the Beckman Coulter DxC-800 chemistry analyzer.<sup>34,43,52,71,173,180,186,200,206,227,256,276</sup> In such cases, the degree of lactate elevation directly correlates with the concentration of glycolate present,<sup>173,180</sup> and the artifact results from the lack of specificity of the lactate oxidase enzyme used in these machines,<sup>180,186,206,276</sup> although direct oxidation of glycolate at the analyzer anode is also a possible mechanism.<sup>237</sup> In general, assays that use a lactate dehydrogenase enzyme instead of lactate oxidase, or assays that use lactate oxidase with colorimetry instead of amperometry, are less prone to

give a false positive lactate result.<sup>256</sup> This artifact can be exploited, using the presence of a “lactate gap” to diagnose ethylene glycol poisoning in hospitals where lactate assays are available with and without sensitivity to glycolate (eg, the lactate assay using lactate oxidase on the blood gas machine and the plasma lactate assay using lactate dehydrogenase), or 2 lactate assays with different sensitivities to glycolate.<sup>237,264</sup> Ingestion of propylene glycol also results in elevated lactate concentrations, but in this case, it is not a false positive lactate but rather an accurate measurement of lactate, the principal metabolite of propylene glycol.<sup>130,131</sup>

### Other Diagnostics

Serum glucose concentration is generally obtained as part of routine laboratory analysis. Hyperglycemia, defined as serum glucose greater than 140 mg/dL (7.77 mmol/L) in nondiabetic patients, portended a greater risk of death after methanol poisoning, with an odds ratio of 6.5 in one retrospective study.<sup>224</sup> This has not yet been prospectively validated.

The urine provides some information in the assessment of the patient with suspected ethylene glycol poisoning. Calcium oxalate monohydrate (spindle-shaped) and dihydrate (envelope-shaped) crystals are often seen when the urine sediment is examined by microscopy, although this finding is neither sensitive nor specific.<sup>78,120,185</sup> In fact, calcium oxalate crystals were present in the urine of 63% (12 of 19) of patients with proven ethylene glycol ingestion in one series.<sup>33</sup>

Some brands of antifreeze contain fluorescein to facilitate the detection of radiator leaks. If one of these products is ingested and the urine is examined with a Woods lamp within the first 6 hours, there will often be urinary fluorescence.<sup>275</sup> False positive fluorescence also results from examining the urine in glass or plastic containers because of the inherent fluorescence of these materials, so if this test is performed, an aliquot of the urine should be poured onto a piece of white gauze or paper. Unfortunately, the utility of this test is quite limited. In one study, almost all children had urinary fluorescence, and there was poor interrater agreement in determining fluorescence of specimens.<sup>41,199</sup> Gastric aspirate also sometimes demonstrates fluorescence.<sup>55</sup>

The evaluation of patients with known or suspected ethylene glycol poisoning should also include serum calcium and creatinine concentrations. Patients with methanol poisoning and abdominal pain also warrant an assessment of liver function tests and serum lipase because of the possibility of associated hepatitis and pancreatitis. In one study, 4 of 13 patients had an elevation of serum troponin, but no further cardiac testing of these patients was reported.<sup>220</sup> Until more data are available, there is likely little role for serum troponin screening in patients without ischemic symptoms or suggestive ECG findings.

Although characteristic brain CT and MRI abnormalities are frequently reported in the setting of methanol poisoning, it is unclear what role they have in the routine evaluation of these patients. The presence of putaminal hemorrhage or insular subcortex white matter necrosis was associated with a greater odds ratio of death (8 and 10, respectively) in one study of patients with methanol poisoning.<sup>253</sup> However, in the absence of neurologic abnormalities on physical examination, routine CT or MRI is not routinely recommended.

Various electrocardiographic abnormalities are reported in the setting of methanol poisoning (more than 80% had some kind of abnormality in one series), including sinus tachycardia, prolonged QT interval, right bundle branch block, prolonged PR interval, and nonspecific T-wave changes. However, none correlates well with clinical outcomes, and changes generally normalize as patients recover.<sup>99,126</sup>

### Diagnostic Testing and Risk Assessment

Many pediatric patients with toxic alcohol exposures have not actually ingested the product with which they are found. Because of this, pediatric patients tend to do better than adults with similar exposures.<sup>161</sup> However, children who actually do ingest toxic alcohols can be just as sick as adults and smaller-volume ingestions are required to reach consequential serum concentrations, so risk assessment is particularly important for these patients. It can also be important for managing adults, particularly in allocating resources during poisoning epidemics.

If the ingested dose of a toxic alcohol is known, an estimate of the projected maximum serum concentration can be determined using the formula:

$$C = D/V_D$$

where C is the estimated concentration projected, D is the dose in grams, and  $V_D$  is the volume of distribution (typically estimated at 0.6 L/kg, though this may lead to an underestimate of the projected concentration for isopropanol and an overestimate for methanol) multiplied by the patient's weight in kilograms. Care must be taken with units to avoid 10-, 100-, or 1000-fold errors. Once the projected serum concentration is calculated and converted to mg/dL, it can be compared to typical thresholds for treatment (see Management below) to decide whether the ingestion could potentially lead to a concerning serum concentration.

Increases in both anion gap and osmolar gap are useful for risk stratification in methanol poisoning, and a venous or arterial blood gas with lactate is recommended. Formate concentrations should also be obtained, if available. A review of reported toxic alcohol cases attempted to identify risk factors for mortality in adults with methanol or ethylene glycol poisoning. For methanol poisoning, no patient with an anion gap less than 30 mEq/L or an osmolar gap less than 49 mOsm/L died. A pH less than 7.22 was an even better predictor of mortality, as no patient with a pH greater than 7.22 died. For ethylene glycol, the tests were less useful. One patient with an osmolar gap of only 25 mOsm/L died, no patient with an anion gap less than 20 mEq/L died, and pH did not predict mortality with statistical significance.<sup>53</sup> This study was criticized for missing a substantial number of patients,<sup>222</sup> and for selection bias,<sup>171</sup> and it still needs to be validated in another population. A more recent retrospective study of 121 patients with ethylene glycol poisoning suggests pH has more promise. A pH higher than 7.37 predicted survival without prolonged kidney injury with a sensitivity of 95% and a specificity of 76%, whereas a pH less than 7 had a sensitivity of 36% and specificity of 95% for death or prolonged kidney injury. Other markers of poor outcomes in this study were initial creatinine higher than 1.65 mg/dL (sensitivity 41%, specificity 97%), seizure, and coma.<sup>171</sup> Another retrospective study of risk factors for poor outcomes in methanol poisoning only found that pH less than 7 (as well as coma or a greater than 24-hour delay to presentation) was associated with death.<sup>103</sup> In a large series from several epidemics of methanol poisoning, a pH less than 7 and coma were again identified as risk factors associated with death. In patients with a pH less than 7,  $PCO_2$  greater than or equal to 23.3 mm Hg was also a risk factor.<sup>196</sup> In another series, 50% of those who were comatose at presentation died, and no patients who were not comatose died.<sup>281</sup> Another study of 32 methanol-poisoned patients found no statistically significant relationship between pH and mortality, but did find an association between low GCS, hypothermia and elevated serum creatinine with mortality.<sup>153</sup> In methanol-poisoned patients unlikely to die, the pH is of some use in predicting retinal toxicity. A retrospective study examined markers for poor visual outcome after methanol poisoning and again found pH to be the best predictor, with a pH greater than 7.2 associated with a high likelihood of only transient visual sequelae.<sup>60</sup> Formate, as discussed above, was a good predictor of outcome in one series, with concentrations less than 18 mg/dL associated with good outcomes and concentrations higher than 78.8 mg/dL associated with a 90% risk of mortality. The same study showed that lactate greater than 7 mmol/L and/or pH less than 6.87 carried the same 90% risk of mortality.<sup>280</sup> All of these studies, while interesting, are of limited utility in decision making about an individual patient because of wide variability of the studied markers, often with overlapping ranges and wide confidence intervals.<sup>210</sup> Markers are a guide to inform clinical judgment, but decisions about management should be based on the entirety of clinical and laboratory data.

### MANAGEMENT

As always, immediate resuscitation of critically ill patients starts with management of the airway, breathing, and circulation. Because alcohols cause respiratory depression and coma, intubation and mechanical ventilation are commonly necessary for patients with severe poisoning. Alcohol-induced

vasodilation combined with vomiting often leads to hypotension, and many patients will require fluid resuscitation with intravenous crystalloid. Gastrointestinal decontamination is rarely, if ever, indicated for toxic alcohols because of their rapid absorption and limited binding to activated charcoal. However, placement of a nasogastric tube and aspiration of any gastric contents is reasonable in intubated patients, as absorption is sometimes delayed after a large dose.<sup>66</sup>

### Alcohol Dehydrogenase Inhibition

The most important part of the initial management of patients with known or suspected toxic alcohol poisoning (after initial resuscitation) is blockade of ADH. This allows time for the establishment of a definitive diagnosis and arrangement for hemodialysis while preventing the formation of toxic metabolites. Additionally, in some cases ADH blockade will itself serve as definitive therapy.

Teleologically, ADH exists for the purpose of metabolizing ethanol, so it is not surprising that the enzyme has a higher affinity for ethanol than for other alcohols. Alcohol dehydrogenase metabolizes ethanol with a  $K_M$  that is 15 to 20 times lower in vitro than its  $K_M$  for methanol metabolism and 67 times lower than its  $K_M$  for ethylene glycol metabolism.<sup>54,201,202</sup> Thus, significant concentrations of ethanol prevent metabolism of other alcohols to their toxic products. Ethanol is the traditional method of ADH inhibition and is still the only option in most of the world, although it is rarely used in the United States. Orally administered ethanol is effective and may be reasonable when intensive monitoring is unavailable, particularly in rural areas where there is likely a significant delay in getting the patient to a hospital.<sup>84</sup> A 10% solution is administered through a central venous catheter or peripheral vein if a central vein cannulation is not easily accomplished and titrated to maintain a serum concentration of 100 mg/dL (Antidotes in Depth: A34). Complications of the infusion include hypotension, respiratory depression (with supratherapeutic concentrations), CNS depression and inebriation, flushing, hypoglycemia, hyponatremia, pancreatitis, and gastritis, so patients receiving intravenous ethanol require admission to an intensive care unit. The true incidence of these adverse events is unclear. In one study, complications of ethanol infusion in children were uncommon.<sup>217</sup> However, in another review of 49 adults treated with ethanol infusions for toxic alcohol poisoning, 92% of patients had at least one adverse event.<sup>271</sup> In a prospective study from the United Kingdom, 12% of 131 patients treated with ethanol had an adverse event.<sup>255</sup> Both orally and parenterally administered ethanol are effective and generally safe, but it is challenging to maintain the serum concentration in the therapeutic range, and the risk of medication errors is also a concern.<sup>255,282</sup>

Fomepizole is a competitive antagonist of ADH that has many advantages over ethanol. It reliably inhibits ADH when administered as an intravenous bolus diluted and administered over 30 mins every 12 hours, and concentrations do not need to be monitored as with an ethanol infusion.<sup>32,33</sup> It does not cause inebriation and is associated with fewer adverse effects and fewer medication errors, so it does not require intensive care unit monitoring.<sup>18,19,32,33,155,255</sup> For these reasons, it has become the preferred method of ADH blockade in the United States, despite being significantly more expensive than ethanol.<sup>239</sup> In theory, the savings in intensive care unit (ICU) monitoring and laboratory costs probably compensate for the higher drug cost of fomepizole, unless the patient requires intensive monitoring regardless based on the severity of illness.<sup>28</sup> However, one study showed that even after fomepizole was introduced to their hospital, 95% of patients received ICU admission and hemodialysis,<sup>88</sup> so this may not be a large area of savings. Additionally, the cost difference will vary depending on the setting of poisoning and the health care delivery system of the country involved. A series in Belgium found that treating with ethanol and dialysis was much less expensive than fomepizole without dialysis within their system.<sup>8</sup> In the 2012 Czech outbreak of methanol poisoning, the sickest patients were treated with fomepizole, whereas others were treated with ethanol because of limited availability of fomepizole, yet the outcomes in both groups were similar.<sup>281,286</sup>

The dose of fomepizole is 15 mg/kg intravenously as an initial loading dose followed by 10 mg/kg every 12 hours. Fomepizole infusion rarely causes

bradycardia and hypotension, so vital signs should be monitored closely during and after each dose.<sup>154</sup> After 48 hours of therapy, fomepizole induces its own metabolism, so the dose must be increased to 15 mg/kg every 12 hours. Although one review advocates giving doses as high as 20 mg/kg every 12 hours with no adjustment for induced metabolism,<sup>24</sup> this dosing regimen is not supported by the manufacturer or any current clinical guideline. A review of reported cases in which fomepizole was used in children suggests that it is safe and effective with the same weight-based dosing as in adults.<sup>31</sup> When treating chronic alcoholics with fomepizole, it is important to be vigilant of signs of alcohol withdrawal, because unlike ethanol, fomepizole does not prevent withdrawal.<sup>281</sup> Pharmacokinetic data from a human volunteer study show that there is no significant difference in serum concentrations between oral and intravenous fomepizole.<sup>174</sup> However, there is currently no oral preparation of fomepizole on the market in the United States (Antidotes in Depth: A33).

Indications for fomepizole or ethanol therapy are based on the history or on laboratory data. It is reasonable to treat a patient with a history of methanol or ethylene glycol ingestion until concentrations are available because, as previously discussed, early signs and symptoms, and laboratory markers other than serum concentrations are frequently absent. In addition, we recommend treating any patient with an anion gap metabolic acidosis without another explanation or a markedly elevated osmol gap. Once concentrations are available, we recommend continuing therapy until the serum toxic alcohol concentration is predicted or measured to be below 25 mg/dL, although as discussed previously, this value is based more on consensus opinion than on data.

The antiretroviral medication abacavir is a substrate for ADH and seemed to delay metabolism of methanol in one case.<sup>83</sup> It was suggested that abacavir could have potential as an alternative to fomepizole in places where fomepizole is unavailable.<sup>226</sup> Similarly, ranitidine is an inhibitor of gastric and hepatic ADH, and in a rat model, ranitidine improved pH, formate concentrations, and retinal histopathology.<sup>65</sup> Although both of these are intriguing possibilities, there are currently no data to support the use of either abacavir or ranitidine in human poisoning.

### Hemodialysis

The definitive therapy for symptomatic patients poisoned by toxic alcohols is hemodialysis. Hemodialysis clears both the alcohols and their toxic metabolites from the blood and corrects the acid–base disorder. The indications for hemodialysis have become more restricted with the advent of fomepizole because of its effectiveness combined with its low incidence of adverse effects. Particularly for ethylene glycol, which can generally be expected to be cleared within a few days once ADH is blocked, as long as the glomerular filtration rate is normal.<sup>35,157,263</sup> Some have argued that the risks of an invasive and costly procedure such as hemodialysis are not warranted in minimally symptomatic patients with normal kidney function and without metabolic acidosis.<sup>36,81</sup> However, a single treatment of hemodialysis is less expensive than a day in the hospital, and the complication rate is exceedingly low.<sup>27</sup> While fomepizole alone is reasonable for ethylene glycol poisoning in a setting in which a patient might need to be transferred for hemodialysis or in a patient who cannot tolerate vascular access or hemodialysis, hemodialysis remains a reasonable option when available. Even a patient with a moderately elevated serum methanol concentration, 80 mg/dL (2.5 mmol/L), was successfully treated with fomepizole alone,<sup>218</sup> though the 4 days in the hospital and 8 doses of fomepizole would be prohibitively expensive in many settings. Based on toxicokinetic data, some patients with methanol poisoning might be treated without dialysis or with delayed dialysis, particularly in epidemic scenarios, in which the need for hemodialysis exceeds the availability.<sup>114</sup> However, patients with end-organ toxicity or severe acidemia have significant amounts of toxic metabolites (a problem not addressed by ADH blockade) and acidemia is associated with poor prognosis.<sup>164</sup> Additionally, although formate is normally cleared rapidly once ADH is blocked, the apparent half-life increases with higher serum methanol concentrations and varies from 2.5 to 12.5 hours.<sup>100,111</sup> In one very atypical patient with severe poisoning, formate was eliminated at an extremely slow rate with an apparent

half-life of 77 hours until hemodialysis was initiated,<sup>116</sup> underscoring the importance of hemodialysis in patients with significant metabolic acidosis. In addition, patients with AKI will not eliminate the parent compound once ADH is blocked, except very slowly in expired air in the case of methanol. Therefore, the consensus is that metabolic acidosis, signs of end-organ toxicity, including coma and seizures, and AKI are indications for hemodialysis. A “toxic concentration” and possibly a very high osmol gap<sup>203</sup> are more relative indications for hemodialysis, and decisions must be based on the judgment of the clinician for the specific clinical scenario, considering the available resources. Some authors advocate using toxic metabolite concentrations if available as additional criteria for hemodialysis. In data from one case series, an elevated formate concentration appears to be a better predictor of clinically important toxicity than methanol concentrations.<sup>195</sup> Similarly, glycolate concentrations are a better predictor of death and AKI than ethylene glycol concentrations.<sup>207</sup> However, although clearance of formate by hemodialysis is substantial,<sup>124,125,138</sup> the overall clearance in one case series did not appear to increase significantly above endogenous clearance in patients also treated with folate and bicarbonate.<sup>138</sup> Some question the data quality in this series, pointing out that (a) the predialysis clearance in 2 patients was calculated using only 2 data points and in the 3 others was calculated using 3 points, generally considered the minimum; (b) several patients actually had decreased clearance during dialysis, contradicting all previous data; and (c) 2 of the patients had variable blood flow during dialysis.<sup>114,277</sup>

The Extracorporeal Treatments in Poisoning (EXTRIP) group has published interdisciplinary consensus guidelines for dialysis in methanol poisoning (Table 106–2).<sup>211</sup> The AACT guidelines for ethylene glycol actually advise against hemodialysis for a concentration alone without clinical indications such as metabolic acidosis, AKI, end-organ effects, or worsening clinical status,<sup>19</sup> and rates of hemodialysis for early ethylene glycol poisoning have declined in recent years.<sup>84</sup> Still, ethylene glycol remains the second most common xenobiotic to be removed by hemodialysis in the United States,<sup>110</sup> and hemodialysis for ethylene glycol remains a reasonable choice for the treatment of ethylene glycol poisoning depending on local resources. In addition, decisions about treatment should also be informed by the availability of ethanol and fomepizole, the cost of each, the cost of hemodialysis and intensive care, and the turnaround time for serum toxic alcohol concentrations in any given clinical setting, as well as consensus recommendations.<sup>8,56,274</sup>

**Hemodialysis Recommended:**

1. Severe methanol poisoning
  - a) coma
  - b) seizures
  - c) new vision deficit
  - d) metabolic acidosis
    - i) blood pH  $\leq$  7.15
    - ii) persistent metabolic acidosis despite adequate support measures and antidotes
  - e) serum anion gap  $\geq$  24 calculated by serum  $[\text{Na}^+] - ([\text{Cl}^-] + [\text{HCO}_3^-])$
2. Serum methanol concentration
  - a)  $>70$  mg/dL in the context of fomepizole therapy
  - b)  $>60$  mg/dL in the context of ethanol treatment
  - c)  $>50$  mg/dL in the absence of an ADH antagonist
  - d) in the absence of a serum methanol concentration, the osmol gap may be informative
3. In the context of impaired renal function

**To optimize the outcomes of extracorporeal treatment:**

4. Intermittent hemodialysis is the modality of choice in methanol poisoning. Continuous modalities are acceptable alternatives if intermittent hemodialysis is unavailable.
5. Alcohol dehydrogenase inhibitors and folic acid are to be continued during hemodialysis.
6. Extracorporeal treatment can be terminated when the methanol concentration is  $<20$  mg/dL and a clinical improvement is observed.

Modified with permission from Roberts DM, Yates C, Megarbane B, et al. Recommendations for the role of extracorporeal treatments in the management of acute methanol poisoning: a systematic review and consensus statement. *Crit Care Med*. 2015 Feb;43(2):461-472.

Although hemodialysis effectively clears isopropanol and acetone from the blood, it is rarely if ever indicated for this purpose. Because isopropanol does not cause a metabolic acidosis and very rarely results in significant end-organ effects, the risks of hemodialysis likely outweigh the benefits.

Many patients will require multiple courses of hemodialysis to clear the toxic alcohol estimated. The dialysis time required can be calculated using the formula:

$$t = [-V \ln(5/A)]/0.06k$$

where  $t$  is the dialysis time required to reach a 5 mmol/L toxic alcohol concentration,  $V$  is the estimate of total body water (liters),  $A$  is the initial toxic alcohol concentration (mmol/L), and  $k$  is 80% of the manufacturer-specified dialyzer urea clearance (mL/min) at the observed initial blood flow rate.<sup>104,278</sup> The main problem with this formula is that it relies on an initial toxic alcohol concentration, which is often not available when hemodialysis needs to be initiated. If practicing in a setting where rapid determination of toxic alcohol concentrations is available, the need for further hemodialysis should be guided by the posthemodialysis concentration. Normalization of the osmol gap is another strategy to guide the required duration of hemodialysis, and though not validated, seems reasonable.<sup>118</sup> The important point with all of these strategies is that the duration of hemodialysis required is often much longer than a standard 4-hour course that would be used routinely in a patient with kidney failure, necessitating multiple or very long courses of hemodialysis. Regardless of how the duration of dialysis is determined, we recommend continuing ADH blockade during and after hemodialysis until a subsequent concentration of the offending toxic alcohol is below 20 mg/dL. Ethanol infusion rates must be increased during hemodialysis to maintain a therapeutic serum concentration as the ethanol is cleared (Antidotes in Depth: A34). Fomepizole should be redosed every 4 hours during hemodialysis to maintain therapeutic serum concentrations.<sup>18,19</sup>

Continuous renal replacement therapy (CRRT) such as venovenous hemodiafiltration is used in some patients with toxic alcohol poisoning. Hemodialysis is much more efficient at clearing xenobiotics than CRRT and is the modality of choice if available.<sup>211,287,288</sup> However, if there is a contraindication to hemodialysis, such as hemodynamic instability or severe cerebral edema,<sup>85,251</sup> or if hemodialysis is unavailable, continuous modalities are acceptable alternatives.<sup>211</sup> In a pharmacokinetic model, the addition of CRRT to hemodialysis can decrease the treatment time by 40%.<sup>54</sup>

Because methanol poisoning is sometimes complicated by coagulopathy, anticoagulations during hemodialysis is at least a theoretical concern because of the potential risk of bleeding. In patients with laboratory evidence of coagulopathy, it is reasonable to perform hemodialysis or CRRT without systemic anticoagulation.

**Adjunctive Therapy**

There are several therapeutic adjuncts to ADH blockade with or (especially) without hemodialysis that we recommend for these patients. One of the differences invoked to explain the absence of retinal toxicity from methanol in some species is the relative abundance of hepatic folate stores in these species such as the rat. Folate and leucovorin enhance the clearance of formate in animal models.<sup>192,193</sup> Thiamine enhances the metabolism of ethylene glycol to ketoacid, and pyridoxine enhances its metabolism to glycine and ultimately hippuric acid (Fig. 106–2).<sup>189</sup> Although all of these modalities offer theoretical advantages, they have yet to be proven to change outcome in humans. However, there is one human case report showing enhanced formate elimination with folic acid therapy.<sup>122</sup> Additionally, the apparent lack of an increase in formate clearance by hemodialysis in one study could be because it was dwarfed by the effectiveness of folate supplementation in both the study group and the control group.<sup>138</sup> In a study of 79 patients who survived methanol poisoning, patients treated with folate or folic acid had better visual outcomes than those untreated, despite sicker patients in the treated group, but these differences were not statistically significant.<sup>284</sup> For unclear reasons, folate treatment for methanol poisoned patients has declined in recent years.<sup>160</sup> However, because of the safety of vitamin

supplementation and the fact that many of these patients are chronic alcoholics who require folate and thiamine anyway, we recommend the use of folate, thiamine and pyridoxine in toxic alcohol poisoning (Antidotes in Depth: A12, A15, and A27).

Formate is much less toxic than undissociated formic acid, likely because formic acid has a much higher affinity for cytochrome oxidase in the mitochondria, the ultimate target site for toxicity.<sup>159</sup> In addition, the undissociated form is better able to diffuse into target tissues.<sup>125</sup> Alkalinization with a bicarbonate infusion shifts the equilibrium to favor the less toxic, dissociated form, in accordance with the Henderson-Hasselbalch equation. This also enhances formate clearance in the urine by ion trapping.<sup>125</sup> Data from uncontrolled case series demonstrate that patients treated with bicarbonate alone had better than expected outcomes after severe methanol poisoning,<sup>188</sup> but the results are equivocal in patients also treated with ADH blockade and hemodialysis.<sup>32,121,181</sup> Additionally, the severity of the metabolic acidosis after methanol poisoning is a good predictor of severe neurologic effects such as coma and seizures,<sup>164</sup> although it is not proven that alkalinization prevents these effects. However, in the absence of contraindications to a bicarbonate infusion (eg, hypokalemia, volume overload), alkalinization is reasonable in the patient with suspected methanol poisoning and a significant acidemia. A blood pH greater than 7.20 is a reasonable endpoint. Alkalinization is also reasonable for patients with ethylene glycol poisoning and life-threatening metabolic acidosis.

Aluminum citrate has potential promise as an adjunctive therapy for ethylene glycol poisoning. It interacts with the surface of calcium oxalate monohydrate crystals and prevents their aggregation. This decreases tissue damage from calcium oxalate monohydrate crystals in an in vitro model of human proximal tubule cells.<sup>94</sup> However, there are not yet any in vivo human studies or even case reports, so it cannot be recommended for clinical use.

Some have suggested a possible benefit of corticosteroids for retinal injury following methanol poisoning. In an uncontrolled case series, 13 of 15 patients showed improvement in their vision after treatment with 1 g of methylprednisolone daily for 3 days, with one having worsening vision and one unchanged.<sup>238</sup> A patient in another case report had permanent vision loss despite corticosteroid therapy using the same regimen.<sup>76</sup> Another uncontrolled case series used a slightly different dosing regimen, with 250 mg of intravenous methylprednisolone administered every 6 hours followed by oral prednisolone 1 mg/kg daily for 10 days. After treatment, the mean best corrected visual acuity improved, but methanol concentrations were not reported so exposure was not confirmed, and acuity data were not reported for individual patients, so it is unclear whether any worsened.<sup>1,223</sup> Another series of 4 patients with mild methanol poisoning given the same treatment regimen showed some improvement in vision.<sup>243</sup> An uncontrolled case series with delayed presentations, incomplete follow-up, and an inconsistent corticosteroid regimen showed improvement in some patients.<sup>221,235</sup> In a series of 63 patients with methanol poisoning from a 2009 epidemic in India, all patients with evidence of optic neuritis (at least 60% of 46 survivors), were treated with retrobulbar injections of triamcinolone (dose not reported); 75% had some improvement.<sup>233</sup> Currently, although limited data support the routine use of corticosteroids in methanol poisoning,<sup>241</sup> it is reasonable to give 1 gm of methylprednisone for 3 days given the low risk and possible benefit for a devastating clinical outcome.

Stem cell transplantation is an emerging therapy that shows promise for treating vision loss from methanol poisoning. One case series of 5 patients with complete blindness from methanol poisoning between were treated with stem cells ranging from 1 week to 12 weeks after exposure. All showed significant recovery of their vision.<sup>17</sup>

## SPECIAL CONSIDERATIONS

### Poisoning Epidemics

As discussed earlier, toxic alcohol poisoning epidemics can at times overwhelm local capacity to provide antidotal therapy and hemodialysis, necessitating triage decisions in allocating resources. Equally important is early recognition of an epidemic and effective communication with the

population to try to identify affected people. Reaching patients before they become severely ill can potentially prevent bad outcomes. During an outbreak in Iran in 2013, multiple strategies were used, including text messaging, radio broadcasting, encouraging patients to find their drinking partners, and loudspeaker announcements near health care facilities, to encourage people to spread the word about contaminated alcoholic beverages, while emergency operation centers coordinated the medical response and distribution of patients to local dialysis centers. Mortality during the epidemic was much lower than other recent outbreaks, although the lack of methanol concentrations in affected patients makes the actual denominator unclear.<sup>102</sup> Where available, syndromic surveillance is another strategy for early identification of an epidemic. In places where it is politically possible, shutting down local bars and liquor shops is effective at limiting the extent of an outbreak of methanol poisoning,<sup>216</sup> though data on admissions for ethanol withdrawal after instituting this approach were not reported. Another strategy to mitigate harm from methanol epidemics is empiric pre-hospital oral ethanol administration in patients with suspected methanol poisoning.<sup>282,289</sup>

### Pregnant Women and Perinatal Exposure

There are very few reported cases of pregnant women with toxic alcohol poisoning, but some conclusions can be drawn from the available data. Toxic alcohols readily cross the placenta, and perinatal maternal methanol ingestion has resulted in death of a newborn.<sup>22</sup> One woman was initially misdiagnosed with eclampsia after ingesting ethylene glycol and presenting with seizures and metabolic acidosis in her 26th week of pregnancy. An emergency cesarean section was performed, and she was later treated with hemodialysis and ethanol once the correct diagnosis was recognized. The child was severely ill, with an initial pH of 6.63 and an initial serum ethylene glycol concentration of 220 mg/dL. The baby was treated with exchange transfusion and ultimately survived without sequelae after a long hospital course.<sup>146</sup> In rat but not rabbit models of chronic high-dose ethylene glycol exposure, fetal axial skeletal malformations occur and are thought to be caused by glycolate.<sup>51</sup> No human case of chronic exposure has yet been reported.

## OTHER ALCOHOLS

### Propylene Glycol

Propylene glycol is commonly used as an alternative to ethylene glycol in “environmentally safe” antifreeze. It is also used as a diluent for many pharmaceuticals (such as phenytoin and lorazepam). This alcohol is successively metabolized by ADH and ALDH to lactate, so a metabolic acidosis results. This can result in extremely high lactate concentrations typically that would be incompatible with life if generated by any disease process. In other diseases associated with lactate accumulation and metabolic acidosis, the lactate is a reflection of underlying anaerobic metabolism, a marker of severe illness rather than part of the underlying pathophysiology. Lactic acidosis from propylene glycol is surprisingly well tolerated because it represents nothing more sinister than its own metabolism, and it is rapidly cleared by oxidation to pyruvate, which then undergoes normal carbohydrate metabolism (Chap. 46).

### Benzyl Alcohol

Benzyl alcohol is used as a preservative for intravenous solutions. Although it is no longer used in neonatal medicine, it was responsible for “neonatal gasping syndrome,” involving multiorgan system dysfunction, metabolic acidosis, and death because of its metabolism to benzoic acid and hippuric acid (Chap. 46).<sup>82,167</sup>

## SUMMARY

- Early manifestations of toxic alcohol poisoning includes inebriation, and subsequent toxicity results from metabolism to organic acid anions that cause metabolic acidosis and end-organ effects. Only very high concentrations of methanol cause inebriation.

- The time required for metabolism results in a delay before toxicity is clinically manifest.
- Until serum concentrations are available, the serum anion gap and osmol gap help with decision making, but do not exclude toxicity if the history is concerning.
- Therapy consists of ADH antagonism with fomepizole or ethanol, as well as adjunctive therapy with bicarbonate, folate or folic acid, pyridoxine, and thiamine.
- Hemodialysis is the definitive therapy for clinically ill patients as it removes the alcohol as well as toxic metabolites while correcting the metabolic acidosis and electrolyte abnormalities.

## FOMEPIZOLE

Mary Ann Howland

## INTRODUCTION

Fomepizole, a competitive inhibitor of alcohol dehydrogenase (ADH), prevents the formation of toxic metabolites from ethylene glycol and methanol. It also has a role in halting the disulfiram-ethanol reaction and in limiting the toxicity from a variety of xenobiotics that rely on ADH for metabolism to toxic metabolites. In addition, as both an inducer and an inhibitor of certain cytochrome P450 CYP enzymes, the presence of fomepizole leads to drug interactions.

## HISTORY

In 1963, Theorell described the inhibiting effect of pyrazole on the horse ADH nicotinamide adenine dinucleotide (NAD<sup>+</sup>) enzyme-coenzyme system.<sup>83,106</sup> Pyrazole blocked ADH by complexation, and the administration of pyrazole to animals poisoned with methanol and ethylene glycol improved survival.<sup>107</sup> However, pyrazole also inhibited other liver enzymes, including catalase and the microsomal ethanol-oxidizing system.<sup>75</sup> Additional adverse effects of pyrazole administration resulted in bone marrow, liver, and kidney toxicity, and these effects increased in the presence of ethanol and methanol.<sup>87</sup> These factors led to the search for less toxic compounds with comparable mechanisms of action.

In 1969, Li and Theorell found that both pyrazole and 4-methylpyrazole (fomepizole) inhibited ADH in human liver preparations,<sup>74</sup> and studies in rodents found that fomepizole, unlike pyrazole, was relatively nontoxic regardless of the presence or absence of ethanol.<sup>14</sup> Subsequent studies of fomepizole in monkeys and humans poisoned with methanol and ethylene glycol confirmed both the inhibitory effect and relative safety of fomepizole.<sup>21,22,87</sup>

## PHARMACOLOGY

## Chemistry

Fomepizole has a molecular weight of 82 Da, and a  $pK_a$  of 2.91 at low concentrations and a  $pK_a$  of 3.0 at high concentrations. The free base is used in the United States, whereas the salts are used in Europe. The free base is chemically equivalent to the chloride and sulfate salts at physiologic pH.<sup>28</sup>

## Mechanism of Action

Fomepizole is a potent competitive inhibitor of ADH with a very high affinity for ADH, thereby blocking the metabolism of methanol and ethylene glycol to their respective toxic metabolites.<sup>88</sup>

Values for  $K_m$  are estimated for the toxic alcohols and the  $K_i$  with fomepizole. The smaller the  $K_m$ , the higher the affinity of the substrate (alcohol) for the enzyme, and the lower the concentration of the substrate to achieve  $V_{max}$  (maximum velocity of the reaction of 50%) of the enzyme. The  $K_i$  is the inhibition constant for the inhibitor. Studies in monkey and human liver tissue demonstrate that fomepizole is a competitive inhibitor of alcohol dehydrogenase.<sup>78,96</sup> In monkey liver, fomepizole demonstrated very similar  $K_i$ 's for both

ethanol and methanol at 7.5 and 9.1  $\mu\text{mol/L}$ , respectively.<sup>78</sup> The affinity was 10 times higher when human liver was used.<sup>95</sup> Studies in monkeys demonstrate that a fomepizole concentration of 9 to 10  $\mu\text{mol/L}$  (0.74–0.8 mcg/mL) is needed to inhibit the metabolism of methanol to formate.<sup>14,87</sup> In human liver, the concentration needed to achieve inhibition is about 0.9 to 1  $\mu\text{mol/L}$ .<sup>74,95</sup> The most recent trial using intravenous (IV) fomepizole attempted to maintain a serum fomepizole concentration above 10  $\mu\text{mol/L}$ . Current dosing calls for a serum fomepizole concentration of 100 to 300  $\mu\text{mol/L}$  to ensure a margin of safety.<sup>1</sup>

Cytochrome P450 (CYP) 2E1 oxidizes ethanol and a number of other xenobiotics, including acetaminophen, carbon tetrachloride, nitrosamines, and benzene to toxic metabolites. Fomepizole, like ethanol and isoniazid, induces CYP2E1 in rat liver and kidney, but not in the lung, through a posttranscriptional mechanism via stabilization and not involving increase in messenger RNA.<sup>90</sup> However, when fomepizole is present, CYP2E1 is inhibited. It is not until after fomepizole is eliminated that the consequences of induction are manifest.<sup>18,112,113</sup> In hepatocyte culture, fomepizole stabilizes and maintains the induced metabolic activity of the isoenzyme for about one week.<sup>114</sup>

## Pharmacokinetics

The volume of distribution of fomepizole is about 0.6 to 1 L/kg; it is metabolized to 4-carboxypyrazole, an inactive metabolite that accounts for 80% to 85% of the administered dose.<sup>84,90</sup> In healthy human volunteers, oral doses of fomepizole are rapidly absorbed and demonstrate saturation and nonlinear kinetics.<sup>55,80,90</sup> The  $K_m$  was estimated to be 75  $\mu\text{mol/L}$  in 2 studies, and 0.94  $\mu\text{mol/L}$  at a dose of 15 mg/kg to 2.49  $\mu\text{mol/L}$  at a dose of 7 mg/kg in 2 analyses, although the reason for the discrepancy is not known.<sup>55,80,81,90</sup> First-order kinetics were exhibited at concentrations below the  $K_m$ , whereas zero-order elimination occurred at concentrations 100% to 200% of the  $K_m$ .<sup>55</sup> Thus, elimination of fomepizole at doses of 10, 20, 50, and 100 mg/kg was 3.66, 5.05, 10.3, and 14.9  $\mu\text{mol/L/h}$ , respectively.<sup>55</sup> Classical Michaelis-Menten kinetics would predict that the elimination rate should be comparable at the 2 higher doses. The authors speculate that the differences are attributable to the existence of other metabolic pathways with different affinities that predominate at different fomepizole concentrations. Following multiple doses, the elimination of fomepizole increases at 36 to 48 hours, most likely because of autoinduction.<sup>90</sup> After 96 hours fomepizole elimination apparently changed to first order elimination with a half-life of 1.5 to 2 hours, from zero order elimination. At a single dose of 20 mg/kg, the apparent half-life of fomepizole calculated from the linear portion of the curve was 5.2 hours and occurred when serum concentrations were less than 100  $\mu\text{mol/L}$ . Peak concentrations after oral administration were achieved within 2 hours and were 132, 326, 759, and 1,425  $\mu\text{mol/L}$  following 10, 20, 50, and 100 mg/kg doses, respectively. Every increase of 10 mg/kg in the oral dose of fomepizole raised the serum concentration 130 to 160  $\mu\text{mol/L}$ .<sup>55</sup> The renal clearance was low (0.016 mL/min/kg), and only 3% of the administered dose was excreted unchanged in the urine.<sup>55</sup>

In the 2 pharmacokinetic studies in healthy volunteers, oral administration produced similar serum concentrations to IV fomepizole.<sup>80,90</sup> The pharmacokinetics of IV fomepizole were studied in 14 patients being treated for ethylene glycol toxicity.<sup>84</sup> A mean peak concentration of 342  $\mu\text{mol/L}$  (200–400  $\mu\text{mol/L}$ ) was achieved following a loading dose of 15 mg/kg (183  $\mu\text{mol/kg}$ ).<sup>84,102</sup> A significant weakness of this toxicokinetic study is that the effect of simultaneous

serum ethanol concentrations was not analyzed. The lowest serum fomepizole concentration of 105  $\mu\text{mol/L}$  was present at 8 hours after the loading dose. The rate of elimination was determined to be zero order at 16  $\mu\text{mol/L/h}$  compared with a first-order elimination half-life of 3 hours during hemodialysis (HD). Other authors have reported similar fomepizole clearances (13  $\mu\text{mol/L/h}$ ).<sup>25</sup> A pharmacokinetic analysis in patients poisoned with methanol or ethylene glycol demonstrated a mean peak fomepizole concentration of 226  $\mu\text{mol/L}$  (19 mcg/mL), an apparent half-life of 14.5 hours (in the presence of methanol or ethylene glycol), and an apparent half-life of 40 hours in the presence of ethanol, in addition to methanol or ethylene glycol.<sup>110</sup> In the sole death, hepatic tissue contained 12 mcg/g of fomepizole, even when the serum concentration was less than 1 mcg/mL (12  $\mu\text{mol/L}$ ).<sup>110</sup>

The hemodialysis clearance of fomepizole ranges from 50 to 137 mL/min.<sup>37,62</sup> An analysis of the concentration of fomepizole in dialysis fluid revealed an extraction ratio of approximately 75% and a dialysance of 117 mL/min, which was very similar to a simultaneous ethylene glycol determination.<sup>37</sup> The dialysance was similar to urea in a pig model and suggests no significant protein binding of fomepizole.<sup>56</sup>

The pharmacokinetic interactions between fomepizole and ethanol were studied in a double-blind crossover design in healthy human volunteers.<sup>60</sup> Fomepizole was given orally in doses of 10, 15, and 20 mg/kg 1 hour prior to oral ethanol at 0.5 to 0.7 g/kg as a 20% solution in orange juice. Fomepizole decreased the elimination rate of ethanol by approximately 40%, from 12 to 16 mg/dL/h to about 7 to 9.5 mg/dL/h. When fomepizole was administered IV at 5 mg/kg over 30 minutes and ethanol was administered orally at doses to achieve a concentration of 50 to 150 mg/dL for 6 hours beginning at the end of the fomepizole infusion, the elimination of fomepizole was decreased by approximately 50%.<sup>60</sup> This decrease occurred without a change in the amount or fraction of unchanged fomepizole appearing in the urine. The authors suggested that the ethanol probably inhibited the metabolism of fomepizole to 4-carboxypyrazole. A single low dose of fomepizole given to humans had a maximal effect on ethanol metabolism at 1.5 to 2 hours.<sup>13</sup> Thus, ethanol and fomepizole mutually inhibit the elimination of the other, thereby maintaining higher serum concentrations than otherwise expected.<sup>79,85</sup> Methanol also decreases the elimination of fomepizole by approximately 25% in the monkey.<sup>87</sup>

## ROLE IN METHANOL TOXICITY

### In Vitro and Animal Studies

Studies using human livers demonstrate the inhibitory effect of fomepizole on alcohol dehydrogenase.<sup>95</sup> Studies in monkeys, the animal species that most closely resembles humans in metabolizing methanol, also demonstrate the inhibitory effect of fomepizole in preventing the accumulation of formate.<sup>12,30,87,89</sup>

### Human Experience

The 2 largest fomepizole case series to date involved 11 and 8 patients, respectively, who were given IV fomepizole in the approved US dosing regimen.<sup>20,22</sup> Following administration, formate concentrations in all patients fell, and the arterial pH increased.<sup>22</sup> Case reports demonstrate similar findings.<sup>25,42,45</sup>

### Effect on Methanol and Formate Concentrations

Methanol exhibits dose-dependent kinetics.<sup>59</sup> At low doses (0.08 g/kg), which achieve serum concentrations of about 10 mg/dL, methanol elimination is first order, with a half-life of about 2.5 to 3 hours.<sup>63,68</sup> In concentrations of approximately 100 to 200 mg/dL, methanol exhibits zero-order kinetics and is eliminated at about 8.5 to 9 mg/dL/h in untreated humans<sup>61</sup> and 4.4 to 7 mg/dL/h in untreated monkeys.<sup>35,92</sup> When monkeys were given 3 g/kg of methanol with resultant serum concentrations of about 500 mg/dL, the elimination of methanol exhibited apparent first-order kinetics. This alteration is likely caused by the greater contribution of other first-order pathways, such as pulmonary and urinary elimination, which account for a greater fraction of the total body clearance under these circumstances.<sup>59</sup> Once fomepizole was administered, the elimination of methanol became first order in

humans, and the half-life of methanol was about 54 hours but the range was from 22 to 87 hours.<sup>22,49</sup> When the metabolism of methanol to formate is blocked, formate is eliminated with a half-life dependent on formate concentration, folate stores, kidney function, urinary pH, and exogenous folate and bicarbonate therapies. When formate was administered to monkeys in the absence of methanol, formate half-life was 30 to 50 minutes.<sup>30</sup> In monkeys given methanol followed by fomepizole, the formate concentrations decreased by more than 80% in 2 hours.<sup>12</sup> An analysis of formate concentrations in 6 patients with methanol poisoning treated with fomepizole, folate, and sodium bicarbonate revealed a formate half-life of 235  $\pm$  83 minutes.<sup>64</sup> A more recent analysis involving 8 patients with methanol poisoning treated with fomepizole and sodium bicarbonate revealed a formate half-life of 156 minutes.<sup>49</sup>

## ROLE IN ETHYLENE GLYCOL TOXICITY

### In Vitro and Animal Studies

Monkeys given 3 g/kg of ethylene glycol intraperitoneally recovered without treatment, whereas those given 4 g/kg died without therapy. All those given 4 g/kg of ethylene glycol with fomepizole 50 mg/kg intraperitoneally survived.<sup>29</sup>

### Human Experience

The first 3 patients treated with oral fomepizole improved clinically and tolerated the therapy.<sup>4</sup> Subsequent case reports and case series using fomepizole orally or IV, with or without hemodialysis, also demonstrated the effectiveness of fomepizole in preventing glycolate accumulation.<sup>5,16,21,24,43,46,48,62,91,94,102</sup>

### Effect on Ethylene Glycol and Glycolate Concentrations in Humans

Kidney function is essential for the elimination of ethylene glycol. With normal kidney function, the half-life of ethylene glycol is about 8.6 hours.<sup>102</sup> Based on pooled human data, the half-life of ethylene glycol after alcohol dehydrogenase is blocked by fomepizole is about 14 to 17 hours in patients with normal kidney function, and about 49 hours in patients with impaired kidney function defined as a serum creatinine greater than 1.2 mg/dL.<sup>4,46,73,102</sup> Based on a limited number of determinations, the renal clearance of ethylene glycol averaged 31.5 mL/min during the first 2 days; the corresponding creatinine clearance was 112 mL/min, and estimated total body clearance during fomepizole therapy was 57 mL/min.<sup>5</sup> These calculations suggest that the renal clearance of ethylene glycol accounted for only 55% of estimated total body clearance. In a study where neither kidney function was defined nor the amount of glycolate excreted unchanged by the kidneys described, glycolate had a mean half-life of 10  $\pm$  8 hours in patients treated with fomepizole before hemodialysis, and a mean half-life of less than 3 hours during hemodialysis.<sup>57,65,91</sup>

## ROLE IN TOXICITY FROM DIETHYLENE GLYCOL, DISULFIRAM, AND OTHER XENOBIOTICS

Fomepizole successfully terminated the adverse reactions resulting from the use of disulfiram administered to volunteers pretreated with a small dose of ethanol, in a chronic alcoholic surreptitiously given disulfiram by his wife, and in 2 patients who intentionally ingested ethanol in addition to an overdose of disulfiram.<sup>76,99</sup> Pretreatment with oral fomepizole was also successful in preventing the facial flushing and tachycardia typically associated with ethanol administration in ethanol-sensitive Japanese volunteers.<sup>53,54</sup>

Several animal studies and a few case reports suggest that fomepizole is effective in limiting the toxicity secondary to diethylene glycol (DEG), triethylene glycol, and 1,3-difluoro-2-propanol.<sup>10,16,38,100,101,108</sup> In particular an analysis of DEG concentrations and its metabolites in stored serum, urine and CSF from the Panama epidemic in 2006 revealed the presence of elevated 2-hydroxyethoxyacetic acid (HEAA) in serum and CSF and of diglycolic acid in serum, urine, and CSF in patients compared to controls.<sup>101</sup> It is hypothesized that these metabolites are most likely responsible for the nephrotoxicity and neurotoxicity associated with DEG.<sup>31,66,67,97,101</sup> Fomepizole blocks the metabolism of DEG to these toxic metabolites and is recommended as early

as possible after ingestion before metabolism of DEG occurs<sup>10,88</sup> along with urgent HD.

The role of fomepizole in overdoses secondary to 2-butoxyethanol (ethylene glycol monobutyl ether, butyl Cellosolve) is unclear,<sup>52</sup> but fomepizole is reasonable for administration within several hours of ingestion and before rapid metabolism of butoxyethanol to butoxyacetic acid occurs.<sup>82,93</sup> Isopropanol is metabolized in part by alcohol dehydrogenase, but fomepizole therapy is not indicated, as this intervention would prolong the metabolism of isopropanol to acetone without any clinical benefit.<sup>1,69</sup>

## COMPARISON TO ETHANOL

Ethanol effectively inhibits the metabolism of methanol and ethylene glycol to their respective toxic metabolites and has been used for many years.<sup>44,109,116</sup> Although very inexpensive, ethanol has many disadvantages, compared to fomepizole.<sup>7,71,105,111</sup> The affinity of ethanol for ADH is much lower than fomepizole, and rather than compete with the active site on ADH, it acts as a competitive substrate.<sup>88</sup> Ethanol causes central nervous system depression that is at least additive to that of the methanol or ethylene glycol, and dosing difficulties occur as a result of the rapid and often unpredictable rate of ethanol metabolism (Antidotes in Depth: A34).<sup>7,9,111,115</sup> Fomepizole has the advantage of being a very potent competitive inhibitor of alcohol dehydrogenase without producing CNS depression. Fomepizole dosing is much easier and does not require therapeutic monitoring of its serum concentration; administration and monitoring errors occur more frequently with ethanol.<sup>72,105</sup> Limited adverse effects of fomepizole include local reactions at the site of infusion when concentrations exceeding 25 mg/mL are used, nausea, dizziness, anxiety, headache, rash, transiently elevated aminotransferases, and eosinophilia. Fomepizole is preferred to ethanol for all of the above reasons. Ethanol is recommended for use when fomepizole is not readily available with the exception that ethanol is most likely preferred in a mass casualty situation until sufficient supplies of fomepizole could be procured.<sup>72,103</sup>

## ADVERSE EFFECTS AND SAFETY ISSUES

Retinol dehydrogenase, an isoenzyme of ADH is responsible for converting retinol to retinal in the retina. For this reason, it was essential to study whether fomepizole would inhibit this enzyme and produce retinal damage.<sup>87,89</sup> Studies in several animal species demonstrated that fomepizole has limited toxicity, with no ophthalmic toxicity.<sup>12</sup> Two of the largest case series and 2 case reports confirm the lack of retinal toxicity with fomepizole and demonstrate the reversibility of methanol-induced visual toxicity when patients are treated with fomepizole and hemodialysis before permanent ophthalmic damage developed.<sup>21,22,36,104</sup>

The LD<sub>50</sub> (median lethal dose for 50% of test subjects) of fomepizole in mice and rats is 3.8 mmol/kg after IV administration and 7.9 mmol/kg following oral administration.<sup>77</sup> An oral placebo-controlled, double-blind, single-dose, randomized, sequential, ascending-dose study was performed in healthy volunteers to determine fomepizole tolerance at 10 to 100 mg/kg.<sup>59</sup> There were no adverse effects in the 10- and 20-mg/kg groups, whereas at 50 mg/kg, 3 of 4 subjects experienced slight to moderate nausea and dizziness within 2.5 hours of fomepizole administration. All subjects reported these same symptoms at 100 mg/kg, which lasted for 30 hours in one individual without vital sign or laboratory abnormalities. The most common adverse effects of the use of fomepizole reported by the manufacturer (in a total of 78 patients and 63 volunteers) were headache (14%), nausea (11%), and dizziness, increased drowsiness, and dysgeusia or metallic taste (6%).<sup>1,39</sup> Other less commonly observed adverse effects include phlebitis, rash, fever, and eosinophilia. A case report of a patient severely poisoned with ethylene glycol suggested a temporal association between IV fomepizole administration during hemodialysis and the development of bradycardia and hypotension. However, this patient was severely acidemic, and when the patient received the fomepizole postdialysis no such adverse effects were noted.<sup>70</sup> Divided daily doses of fomepizole up to 20 mg/kg for 5 days were administered without any demonstrable toxicity.<sup>86</sup> The most common laboratory

abnormality after fomepizole administration is a transient elevation of aminotransferase concentrations, which was reported in 6 of 15 healthy volunteers.<sup>58</sup> In the 2 largest case series of patients treated with fomepizole for toxic alcohol poisoning, there were no adverse events classified as “definitely” or “probably” related to fomepizole.<sup>21,22</sup> One patient received fomepizole 99 times for repetitive ethylene glycol self-poisoning without adverse effects.<sup>51</sup> Fomepizole safety and effectiveness in pediatric patients is not established, but children who have ingested ethylene glycol and methanol were treated successfully.<sup>6,17,19,26,32,33,40,47,110</sup>

## PREGNANCY AND LACTATION

Fomepizole is pregnancy category C. Animal studies have not been conducted. One case report of a pregnant woman treated twice with fomepizole for inhalation of a carburetor cleaner containing methanol is reported in the literature but follow-up information on the fetus was never obtained. The risks of methanol and ethylene glycol poisoning are so consequential (including neonatal death) that it is recommended that fomepizole be administered when toxicity is present or anticipated with these toxic alcohols.<sup>8,15,23,34,88</sup> If fomepizole is not available, then ethanol is recommended. There are no studies that have examined the amount of fomepizole in breast milk although the low molecular weight suggests that it will be excreted into breast milk. It is likely that the toxic alcohol for which the fomepizole is being used would also be excreted into breast milk.<sup>23</sup> Therefore it is recommended that breast feeding be temporarily discontinued until fomepizole is predicted to be eliminated from the body (about 24 hours after the last dose) and the toxic alcohol has been eliminated.

## DOSING AND ADMINISTRATION

The loading dose of fomepizole is 15 mg/kg IV, followed in 12 hours by 10 mg/kg every 12 hours for 4 doses. If therapy is necessary beyond 48 hours, the dose is then increased to 15 mg/kg every 12 hours, for as long as necessary. This increase is recommended because fomepizole stimulates its own metabolism.<sup>76</sup> Patients undergoing hemodialysis require additional doses of fomepizole to replace the amount removed during hemodialysis.

The manufacturer recommends dosing fomepizole every 4 hours during hemodialysis.<sup>1,39</sup> We recommend the administration of fomepizole at the beginning of hemodialysis if the last dose was given more than 6 hours earlier. At the completion of hemodialysis, we recommend the administration of the next scheduled dose if more than 3 hours have transpired, or one-half of the dose if 1 to 3 hours have passed. Following hemodialysis dosing of fomepizole every 12 hours is reinstated.

It is expected that patients undergoing continuous renal replacement therapy (CRRT) such as continuous venovenous hemodialysis (CVVHD) or continuous venovenous hemodiafiltration (CVVHDF) would also require an increase in the dose of fomepizole. Theoretically since the amount of removal with these CRRT modalities is not as extensive as with HD, a reasonable recommendation would be to administer the fomepizole every 8 hours during the CVVHD or CVVHDF.

Fomepizole must be diluted in 100 mL of 0.9% sodium chloride solution or 5% dextrose in water (D<sub>5</sub>W) before IV administration, and then infused over 30 minutes to avoid venous irritation and thrombophlebitis. Once diluted, fomepizole remains stable for 24 hours when stored in a refrigerator or at room temperature.<sup>1</sup>

Fomepizole therapy should be continued until the methanol or ethylene glycol is no longer present in sufficient concentrations to produce toxicity. We recommend continuing therapy until the serum toxic alcohol concentration is predicted or measured to be below 25 mg/dL in the absence of any acid–base disturbances.<sup>1–3</sup>

The threshold concentrations for hemodialysis for methanol or ethylene glycol can be based on measurements when analyses can be done in a timely fashion. The duration of fomepizole therapy in the absence of hemodialysis can be estimated based on the assumption of half-life of the toxic alcohol when blocked with fomepizole. The half-life of methanol is approximately 54 hours in the presence of fomepizole with a range of 22 to 87 hours.<sup>20,49</sup>

The half-life of ethylene glycol in the presence of fomepizole is approximately 14 to 17 hours in patients with normal kidney function, and 49 hours in patients with impaired kidney function.<sup>4,48,102</sup>

The need for hemodialysis is based on the presence of toxic metabolites inferred by the presence of metabolic acidosis and end-organ damage; the ability of the kidney to eliminate ethylene glycol, glycolic acid and formate, the risk benefit of hemodialysis, and the length of time to remain hospitalized for elimination of the remaining methanol and ethylene glycol.<sup>50,98</sup>

## FORMULATION AND ACQUISITION

Fomepizole is marketed in branded and generic formulations in 1.5-mL vials of 1 g/mL. Temperatures of less than 77°F (25°C) cause the contents of the fomepizole vials to solidify. Warming reliquesfies the product without adversely affecting its potency.

## SUMMARY

- Fomepizole is a potent competitive inhibitor of ADH that inhibits the metabolism of methanol, ethylene glycol, diethylene glycol and other xenobiotics that use ADH in the formation of toxic metabolites.
- Once ADH is blocked and sustained, the decision to use hemodialysis depends on how much damage has occurred to the organs of elimination, the acid-base status of the patient, and how well the body can eliminate both the parent compound and the toxic metabolites formed prior to fomepizole administration.
- Fomepizole is safe and, although it has been used successfully orally, only an IV dosing regimen is approved and available.
- Fomepizole is more costly than ethanol, but its many advantages over ethanol, including the ability to deliver care outside an intensive care unit, which makes fomepizole the preferred antidote in most circumstances.
- Ethanol is likely to be preferred in a mass casualty situation until sufficient supplies of fomepizole are procured.

## ETHANOL

Mary Ann Howland

## INTRODUCTION

Ethanol is used therapeutically as a competitive substrate for xenobiotics metabolized by alcohol dehydrogenase, thus limiting the bioactivation of those xenobiotics to toxic metabolites. Methanol and ethylene glycol are potentially lethal xenobiotics metabolized by this pathway.<sup>16,17</sup> Ethanol also inhibits the metabolism of short-chain polyethylene glycols, such as di- and triethylene glycol,<sup>70</sup> and competes with monofluoroacetate and fluoroacetamide for binding to the citric acid cycle. Ethanol also affects the cytochrome (CYP) enzyme system, especially CYP2E1, for which it has biphasic properties as an inducer and an inhibitor similar to fomepizole and isoniazid. The competitive relationship of ethanol with toxic xenobiotics is used to therapeutic advantage, but the effect of ethanol on the CYP system often leads to unwanted drug interactions and pharmacokinetic tolerance after several days of administration.

## HISTORY

Ethanol has been used as an antidote for methanol poisoning since the 1940s and for ethylene glycol since the 1960s.<sup>2</sup>

## PHARMACOLOGY

## Mechanism of Action

Ethanol works as a competitive substrate for alcohol dehydrogenase, inhibiting the metabolism of xenobiotics such as methanol and ethylene glycol that employ this enzyme.

## Affinity for Alcohol Dehydrogenase

The dose of ethanol necessary to achieve competitive inhibition depends on the relative concentrations of the toxic alcohols and their affinity for the enzyme. An affinity constant,  $K_m$ , is used to express the degree of affinity: the lower the  $K_m$  value, the stronger the affinity. The following equates millimoles or milligrams for alcohols: 1 mmol ethanol equals 46 mg, 1 mmol methanol equals 32 mg, and 1 mmol ethylene glycol equals 64 mg. A millimolar concentration means millimoles per liter (mM). A summary of in vitro experiments using human liver cells demonstrated a  $K_m$  for alcohol dehydrogenase of 30 mM for ethylene glycol, 7 mM for methanol, and 0.45 mM for ethanol.<sup>40,55,56</sup> This means that the molar affinity of ethanol for alcohol dehydrogenase is 67 times that of ethylene glycol and 15.5 times that of methanol. Using human alcohol dehydrogenase and a simulation model the oxidation of 50 mM of methanol and ethylene glycol were inhibited by 20 mM (92 mg/dL) of ethanol and 50 mM (4 mg/dL) of fomepizole.<sup>38</sup> Studies in methanol-poisoned monkeys revealed that when ethanol was administered at a molar ethanol-to-methanol ratio (E/M) of 1:4, the metabolism of methanol was reduced by 70%; at a 1:1 E/M ratio, metabolism was reduced by greater than 90%.<sup>43</sup> In these experiments, the dose of methanol was kept constant at about 1 g/kg (32 mmol/kg), whereas the dose of ethanol was varied. Although the serum methanol concentration was not measured, a calculation using this

dose and a volume of distribution ( $V_d$ ) of 0.6 L/kg would predict a serum concentration of about 166 mg/dL. Even in molar ratios as high as 1:8, methanol did not inhibit ethanol metabolism. When ethylene glycol and methanol are administered together in a 0.5:1 molar ratio, ethylene glycol did not inhibit methanol metabolism.<sup>43</sup> When compared with methanol, smaller amounts of ethanol are required to block the metabolism of ethylene glycol, as the affinity of ethylene glycol for alcohol dehydrogenase is less than that of methanol.<sup>30,40,55,56,59,68</sup> We agree with most authors<sup>1,30,68</sup> who recommend either a serum ethanol concentration of 100 mg/dL, or at least a 1:4 molar ratio of ethanol to methanol or ethylene glycol, whichever is greater. Using this ratio, 100 mg/dL (approximately 22 mmol/L) of ethanol protects against 88 mmol/L (286 mg/dL) of methanol or 88 mmol/L (546 mg/dL) of ethylene glycol. Inhibiting the metabolism of methanol and ethylene glycol impedes the formation of toxic metabolites and prevents the development of metabolic acidosis.<sup>18,21,29,68</sup> After this toxic metabolic pathway is blocked with ethanol, renal, pulmonary, and extracorporeal routes of toxic alcohol removal become the sole mechanisms for elimination.

## PHARMACOKINETICS

Ethanol administered orally is rapidly absorbed and achieves peak concentrations in about 1 to 1.5 hours.<sup>13,20,41,69</sup> The amount of ethanol absorbed after oral administration is highly variable and dependent on a number of factors, such as ethanol dose, fasting, nutritional status, accelerated gastric emptying, gender, genetics, chronic alcohol use, lean body mass, and increasing age, as well as the presence of certain  $H_2$ -receptor antagonists.<sup>10,14,20,33,37,66,72,75</sup> Sufficient concentrations are generally achieved when 0.8 g/kg of ethanol is given orally over 20 minutes.<sup>10,13,14,20,37,69</sup>

Given that the  $V_d$  for ethanol is approximately 0.6 L/kg,<sup>15,77</sup> the loading dose of ethanol is obtained by the following formula:

$$\begin{aligned}
 \text{Loading dose} &= C_p \times V_d \\
 &= 1 \text{ g/L (100 mg/dL)} \times 0.6 \text{ L/kg} \\
 &= 0.6 \text{ g/kg}
 \end{aligned}$$

$C_p$  = plasma concentration, which is comparable to the serum concentration

For a 70-kg person, the loading dose would be 42 g (70 kg  $\times$  0.6 g/kg) of ethanol, or 420 mL of 10% V/V (volume-to-volume) ethanol. This calculation assumes that the specific gravity of ethanol is 1 g/mL. However, a 0.8 g/kg or 8 mL/kg loading dose of a 10% ethanol solution is recommended in order to provide a margin of safety because of the variabilities in  $V_d$  and the ongoing metabolism that occurs during administration.<sup>34,57</sup> The intravenous (IV) loading dose should be administered over 20 to 60 minutes, as tolerated by the patient. The 10% ethanol concentration is preferable to the 5% concentration to limit the volume of fluid administered. It is also recommended not to use more concentrated solutions to limit local venous irritation and avoid postinfusion phlebitis. Because of the free water content and significant hypertonicity of the 10% solution, the patient should be closely observed for the development of hyponatremia.

To maintain an ethanol concentration of 100 mg/dL, ethanol replacement must equal ongoing elimination (66–130 mg/kg/h). The average hourly dose for a 70 kg person is 4.6 g, but higher doses are required in ethanol-tolerant patients (100–150 mg/kg/h) or others who may have induced

enzymes, and in those undergoing hemodialysis (250–350 mg/kg/h) (Chap. 6).<sup>17,30,44,53,54</sup>

## ROLE IN METHANOL AND ETHYLENE GLYCOL TOXICITY

When administered in a timely fashion after methanol and ethylene glycol ingestion and before the accumulation of the toxic metabolites, case reports and utilization in mass poisonings confirm the efficacy of ethanol in preventing sequelae.<sup>12,14,32,36,50,67,73,81,82</sup> A half-life of 46.5 hours for methanol was reported in a patient who had received a sufficient blocking quantity of ethanol,<sup>53</sup> which is quite similar to the 54 hours reported in a case series of methanol poisoned patients treated only with fomepizole.<sup>8,32</sup> In another case series of 3 methanol poisoned patients treated with ethanol, the median methanol half-life was 43.1 hours (range 30.3–52.0 hours).<sup>51</sup> In the presence of sufficient inhibitory concentrations of ethanol, the half-life of ethylene glycol in 2 patients with normal kidney function was 17.5 hours, which was comparable with 17 hours in a case series of ethylene glycol poisoned patients receiving only fomepizole with normal kidney function.<sup>12,66</sup> An ethylene glycol half-life of 15.4 hours was reported in one woman with repetitive poisoning who was treated 60 separate times with ethanol.<sup>27,80</sup>

## ADVERSE EFFECTS AND SAFETY ISSUES

Problems encountered with the administration of ethanol include further risk of central nervous system (CNS) depression, behavioral disturbances, or ethanol-related toxicity, such as nausea, emesis, hepatitis, pancreatitis, hypoglycemia, dehydration, various administration and monitoring errors resulting in fluctuating serum concentrations (subtherapeutic and supratherapeutic ethanol concentrations and premature discontinuation), and potential drug interactions resulting in disulfiramlike reactions.<sup>3,19,24,39,45,47,50,52,74,78</sup>

## PREGNANCY AND LACTATION

Ethanol (injection) is US Food and Drug Administration pregnancy category C. Ethanol crosses the placenta and reaches the fetus. Ethanol is teratogenic, and the American Academy of Pediatrics (AAP) recommends that pregnant women abstain from all alcohol consumption. It is likely that

the short duration of ethanol therapy, when used to compete with alcohol dehydrogenase, during the second or third trimester, has a minimal risk of inducing fetal alcohol syndrome. Ethanol should only be used following a risk-benefit analysis, particularly in the first trimester.<sup>9</sup> Ethanol has been used to manage methanol poisoning in pregnancy when fomepizole was unavailable.<sup>6,22</sup> Because of the potentially devastating maternal and fetal effects of methanol or ethylene glycol,<sup>4,6,35</sup> if an antidote is required in a pregnant woman to treat an overdose and fomepizole is not available, then ethanol is recommended,<sup>47</sup> until fomepizole and/or hemodialysis can be effected.<sup>71</sup> Ethanol crosses into breast milk and, depending on the dose of ethanol and the time since ingestion, causes CNS depression and ethanol toxicity in the breast-fed infant. We recommend that breast-feeding should be temporarily discontinued until the ethanol is eliminated as well as the toxic alcohol for which it is being used.

## DOSING AND ADMINISTRATION

Ethanol is given either orally or IV (Tables A34–1 and A34–2). Concentrations of 20% to 30% orally and 5% to 10% IV are well tolerated. Intravenous administration has the advantages of complete absorption<sup>34</sup> and avoidance of most gastrointestinal symptoms, and is recommended in an unconscious or uncooperative patient. The disadvantages of IV ethanol include difficulty in obtaining and preparing an IV ethanol solution, which results in significant delays in administration, the hyperosmolarity of a 10% ethanol solution approximately 1,900 mOsm/L, and the possibilities of osmotic dehydration, hyponatremia, and venous irritation.

Regardless of route, the objective is to rapidly achieve and maintain a serum ethanol concentration of at least 100 mg/dL, which is adequate for enzyme inhibition in most cases. Inhibition is best achieved by administering a loading dose of ethanol, followed by a maintenance dose.

Because ethanol elimination varies in each individual, frequent serum ethanol determinations should be obtained to ensure adequate dosing while also monitoring blood glucose and fluid and electrolyte status. In addition, any increase in the anion gap or decrease in bicarbonate concentration implies that the ethanol concentration is inadequate to achieve blockade of alcohol dehydrogenase and the ethanol dosing should be increased.

**TABLE A34–1** Intravenous Administration of 10% Ethanol

Loading Dose <sup>a</sup>	Volume (mL) <sup>b</sup> (given over 1 hour as tolerated)					
	10 kg	15 kg	30 kg	50 kg	70 kg	100 kg
0.8 g/kg of 10% ethanol	80	120	240	400	560	800
Maintenance Dose <sup>c</sup>	mL/h for various weights <sup>d</sup>					
	10 kg	15 kg	30 kg	50 kg	70 kg	100 kg
<b>Ethanol naïve</b>						
80 mg/kg/h	8	12	24	40	56	80
110 mg/kg/h	11	16	33	55	77	110
130 mg/kg/h	13	19	39	65	91	130
<b>Ethanol tolerant</b>						
150 mg/kg/h	—	—	—	75	105	150
<b>During hemodialysis</b>						
250 mg/kg/h	25	38	75	125	175	250
300 mg/kg/h	30	45	90	150	210	300
350 mg/kg/h	35	53	105	175	245	350

<sup>a</sup>A 10% V/V concentration yields approximately 100 mg/mL. <sup>b</sup>For a 5% concentration, multiply the amount by 2. <sup>c</sup>Infusion to be started immediately following the loading dose. Concentrations above 10% are recommended not to be used for intravenous administration. The dose schedule is based on the premise that the patient initially has a zero ethanol concentration. The aim of therapy is to maintain a serum ethanol concentration of 100–150 mg/dL, but constant monitoring of the ethanol concentration is required because of wide variations in endogenous metabolic capacity. Ethanol will be removed by hemodialysis, and the infusion rate of ethanol must be increased during hemodialysis. Prolonged ethanol administration may lead to hypoglycemia. <sup>d</sup>Rounded to the nearest milliliter.

TABLE A34-2 Oral Administration of 20% Ethanol

Loading Dose <sup>a</sup>	Volume (mL)					
	10 kg	15 kg	30 kg	50 kg	70 kg	100 kg
0.8 g/kg of 20% ethanol, diluted in juice (administered orally or via nasogastric tube)	40	60	120	200	280	400
Maintenance Dose <sup>b</sup>	mL/h for various weights <sup>c,d</sup>					
	10 kg	15 kg	30 kg	50 kg	70 kg	100 kg
<b>Ethanol naïve</b>						
80 mg/kg/h	4	6	12	20	28	40
110 mg/kg/h	6	8	17	27	39	55
130 mg/kg/h	7	10	20	33	46	66
<b>Ethanol tolerant</b>						
150 mg/kg/h	—	—	—	38	53	75
<b>During hemodialysis</b>						
250 mg/kg/h	13	19	38	63	88	125
300 mg/kg/h	15	23	46	75	105	150
350 mg/kg/h	18	26	53	88	123	175

<sup>a</sup>A 20% V/V concentration yields approximately 200 mg/mL. <sup>b</sup>Concentrations above 30% (60 proof) are not recommended for oral administration. The dose schedule is based on the premise that the patient initially has a zero ethanol concentration. The aim of therapy is to maintain a serum ethanol concentration of 100–150 mg/dL, but constant monitoring of the ethanol concentration is required because of wide variations in endogenous metabolic capacity. Ethanol will be removed by hemodialysis, and the dose of ethanol must be increased during hemodialysis. Prolonged ethanol administration may lead to hypoglycemia. <sup>c</sup>Rounded to the nearest milliliter. <sup>d</sup>For a 30% concentration, multiply the amount by 0.66.

## FORMULATION AND ACQUISITION

A practical problem often involves preparing the ethanol to be given since commercial preparations of 5% ethanol in 5% dextrose are no longer available in the US for IV administration.<sup>5</sup> Not having a commercially available preparation increases the delay to administration of IV ethanol and the potential for a medication error in preparation. Sterile ethanol USP (absolute ethanol, dehydrated, preservative free) 98% can be added to 5% dextrose to make a solution of approximately 10% ethanol concentration; 55 mL of absolute ethanol is added to 500 mL of 5% dextrose to produce a total volume of 555 mL (10% = 10 mL in 100 mL; in this case, 55 mL in 555 mL or 55/555). In almost all circumstances (eg, except in which the gastrointestinal tract cannot be used or mental status changes preclude oral administration), oral ethanol is recommended over the extemporaneous preparation of IV ethanol. Ethanol in a 20% concentration is administered either orally or via a nasogastric tube. If oral administration is chosen, then it is important to remember that in the United States the “proof” number on the label is double the concentration; that is, “100-proof” ethanol is 50% ethanol by volume (50 mL/100 mL). Vodka is usually 40% (80 proof) and can be diluted one to one to make a 20% concentration. If fomepizole is unavailable recommend that the pharmacy have vodka on the premises to use as an alternative. Stocking vodka should not excuse the failure to obtain fomepizole once the shortage of fomepizole is over.

## COMPARISON TO FOMEPIZOLE

Although ethanol was the standard antidote for toxic alcohols for many years in both adults and children,<sup>61,79</sup> and has the advantages of easy accessibility to oral ethanol and low acquisition cost, fomepizole is a very potent inhibitor of alcohol dehydrogenase with many important advantages.<sup>23,25,31,42,46–48,58,62</sup> Although the acquisition cost of fomepizole is greater than for ethanol, the many advantages of fomepizole over ethanol make fomepizole the preferable antidote in most circumstances, and overall hospital costs including critical care resources, hemodialysis, and laboratory analyses are equivalent or less, depending on the health care and reimbursement system<sup>7,11,64,66,76</sup> (Antidotes in Depth: A33 and Chap. 106).<sup>39,65,74</sup> Ethanol is easier to deploy, particularly in the prehospital setting, in mass poisonings,<sup>36,50,60,63,81,82</sup> or resource-poor settings.

## SUMMARY

- The disadvantages of ethanol compared with fomepizole (when available) make ethanol an outmoded antidote under most circumstances.
- When administered appropriately, ethanol prevents further metabolism of methanol and ethylene glycol to their respective toxic metabolites.
- Neither fomepizole nor ethanol affects the toxic metabolites already present in the body.
- Once alcohol dehydrogenase is blocked, the decision whether to use hemodialysis depends on the degree of end-organ damage that has occurred, how well the body can eliminate the parent compound without the benefit of hemodialysis, and the extent to which toxic metabolites are already present.
- With the use of either ethanol or fomepizole without subsequent hemodialysis, the increase in hospital length of stay in an intensive care unit or on a medical floor is substantial for methanol poisoned patients or those poisoned with ethylene glycol who have poor kidney function.<sup>26,28,62</sup>
- Ethanol is recommended in a mass casualty situation until sufficient supplies of fomepizole are procured.<sup>36,50,81,82</sup>

## DIETHYLENE GLYCOL

Capt. Joshua G. Schier

**HISTORY AND EPIDEMIOLOGY**

Diethylene glycol (DEG) is a solvent with physical and chemical properties similar to propylene glycol, a xenobiotic that is used throughout the chemical industry. Pharmaceutical-grade propylene glycol is a safe and commonly used solvent for water-insoluble pharmaceuticals (Chap. 46). However, unlike propylene glycol, DEG is a potent nephrotoxic and neurotoxic chemical. Substitution of DEG for propylene glycol and other diluents such as glycerin in oral pharmaceutical elixirs has repeatedly caused epidemics of mass poisoning (Chap. 2). This substitution usually occurred early in the pharmaceutical manufacturing process because of a variety of reasons, including the intentional mislabeling of DEG as an inexpensive replacement diluent for pharmaceutical-grade glycerin, for financial gain and various other reasons.<sup>37,45</sup> As medication-associated DEG mass poisonings recurred over time, numerous quality assurance and control guidelines were developed to identify DEG-contaminated materials. Failure to adhere to these guidelines throughout the pharmaceutical manufacturing and distribution process contributes to this persistent public health problem.<sup>45</sup> In DEG poisoning, patients develop acute kidney injury (AKI) that often rapidly progresses to kidney failure. Patients who developed AKI and do not die quickly after exposure, often become dialysis dependent. A subset who survive the initial poisoning also develop neurological signs and symptoms. These patients either deteriorate further after the onset of neurologic signs and symptoms and die, or they recover from their initial poisoning event, but suffer neurologic sequelae that tends to improve with time.<sup>42,47</sup>

The metabolism of DEG and the pathophysiology of DEG-associated disease are incompletely understood and most of what is known comes from animal studies. Indeed, very little data regarding DEG and its metabolites are available from biological samples of humans poisoned by DEG. It was once thought that DEG was metabolized to 2 ethylene glycol molecules, which, when metabolized to glycolic acid and oxalic acid, caused AKI; this theory has been disproven.<sup>20</sup> Current evidence supports that the terminal DEG metabolite diglycolic acid (DGA) is the nephrotoxin.<sup>10,28,38</sup> Diglycolic acid is neurotoxic as well based on a single published case report of DGA ingestion.<sup>40</sup> This Special Consideration will provide a brief history and epidemiology of DEG poisoning, describe existing pharmacokinetic and toxicokinetic data collected primarily from animal studies, and then discuss available information on the toxic dose, pathophysiology, clinical manifestations, testing and treatment for DEG poisoning. When specific doses of DEG in the literature were reported in milliliters per kilogram, they were converted to grams per kilogram by taking into account the density of DEG (1.118 g/mL) and the concentration. If information on concentration was not provided, then a 100% concentration was assumed. For the reader's convenience, the original dose (if it was in milliliters per kilogram) and commensurate DEG concentration are provided following the converted dose in grams per kilogram or milligrams per kilogram.

Diethylene glycol is produced by the condensation of 2 ethylene glycol molecules forming an ether bond,<sup>1</sup> which yields a compound with a molecular weight of 106 g/mol.<sup>1,42</sup> It was first identified in 1869 and is used in industry and manufacturing.<sup>1</sup> Currently, DEG is used as an antifreeze, as a finishing agent for wool, cotton, silk, and other fabrics, as well as in dye

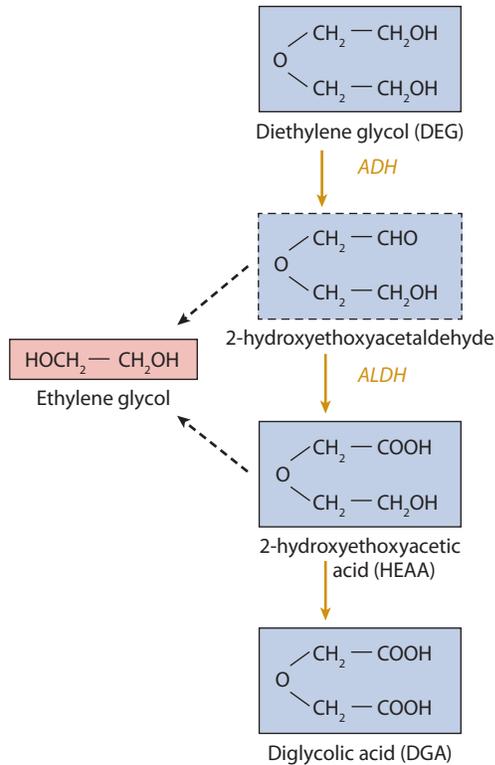

manufacturing. It is also often used as an intermediate in the production of polymers, higher glycols, morpholine, and dioxane.<sup>31</sup> Diethylene glycol is chemically inert and has a higher boiling point than ethylene glycol. Its other physical properties are quite similar to ethylene glycol, including a sweet taste.<sup>19,50</sup> Its physical properties enable it to serve as an excellent solvent for delivery of water-insoluble substances. Unfortunately, its use as a diluent for various pharmaceuticals intended for human consumption resulted in the vast majority of reported cases of poisoning.<sup>5,7,8,12,15-17,25,33-35,37,46,47</sup> In these recurring events, DEG was substituted for a safe and appropriate diluent such as glycerin or propylene glycol. Diethylene glycol poisoning is also reported from the intentional addition of DEG to wine as a sweetener,<sup>48,49</sup> consumption as a substitute for ethanol,<sup>52</sup> and following topical application of DEG-containing medicinal products.<sup>8,11</sup> Finally, there are numerous isolated case reports of DEG poisoning resulting from the consumption of DEG-containing products such as radiator fluid or antifreeze,<sup>52</sup> brake fluid,<sup>6</sup> Sterno,<sup>39</sup> "fog solution,"<sup>718</sup> cleaning solutions,<sup>1</sup> and wallpaper stripper.<sup>30</sup>

**PHARMACOKINETICS/TOXICOKINETICS****Absorption and Distribution**

In rodents, DEG is highly greater than or equal to 75% and almost immediately absorbed after ingestion. It is distributed primarily based on blood flow, with the kidneys receiving the most DEG, followed by the brain, the spleen, liver, and muscles. The degree of protein binding and the volume of distribution ( $V_d$ ) in humans is unknown but the  $V_d$  in the rat is approximately 1 L/kg.<sup>19</sup> Maximal DEG plasma concentrations occur within 4 hours of ingestion: the ratio of DEG in plasma to red blood cells is 3:2 (approximately 60% of a dose is found in the plasma).<sup>3,19,50</sup> In animal studies, diethylene glycol readily crosses the blood-brain barrier, and concentrations peak in brain tissue (CSF concentration not reported) within 3 to 4 hours of exposure.<sup>19</sup>

**Metabolism**

Existing animal data demonstrate that as much as 40% of an ingested dose undergoes hepatic metabolism, with most of that eliminated in the urine.<sup>19,29,32</sup> Diethylene glycol is metabolized by alcohol dehydrogenase (ADH) to 2-hydroxyethoxyacetaldehyde, which is then further metabolized by aldehyde dehydrogenase (ALDH) to 2-hydroxyethoxyacetic acid (HEAA).<sup>3,20</sup> This is either renally excreted, oxidized to DGA (also known as 2,2-oxybisacetic acid) or converted to 1,4-dioxan-2-one under extremely acidic conditions.<sup>20</sup> The predominant pathway depends on numerous factors such as dose, degree of kidney function, and acid-base status of the patient.<sup>2,20,28,29</sup> The DEG ether bond linking the 2 ethylene glycol molecules is stable and is not hydrolyzed. Ingestion of DEG and subsequent metabolism does not therefore result in ethylene glycol release.<sup>2,20,31</sup> However, a small amount of ethylene glycol is formed as an intermediate after formation of 2-hydroxyethoxyacetaldehyde. This likely originates from either the aldehyde or HEAA metabolites (Fig. SC9-1).<sup>2</sup> Serum HEAA concentrations peak approximately 4 hours following small DEG ingestions (2 g/kg), but a delayed peak at 8 to 24 hours occurs with larger exposures (10 g/kg) in rodents. Rats that ingest relatively small doses of DEG (2 g/kg) and rats given larger amounts of DEG with coadministration of an ADH blocker (10 g/kg + fomepizole) do not accumulate DGA in their serum over time. Blood DGA concentrations in rats dosed with 10 g/kg of DEG and fomepizole are not significantly different from control rat blood DGA concentrations. Furthermore, DEG elimination half-lives in

**FIGURE SC9–1.** Metabolic pathway for DEG based on animal studies and on the results presented in this report. Metabolites in solid boxes are observed following administration of DEG to animals; those in dashed boxes are theoretical intermediates. Because fomepizole reduced the amount of EG in the urine, its origin is shown as coming from the aldehyde or acid intermediate, rather than from DEG itself. ALDH = aldehyde dehydrogenase. Diglycolic acid is also known as oxybisacetic acid. (Reproduced with permission from Besenhofer LM, Adegboyega PA, Bartels M, et al. Inhibition of metabolism of diethylene glycol prevents target organ toxicity in rats. *Toxicol Sci.* 2010 Sep;117(1):25-35.)

the 2 groups dosed with 10 g/kg (one with fomepizole and without) were not significantly different, and almost the entire DEG dose given to the DEG plus fomepizole group was recovered in the urine. This suggests that elimination from the body is mainly controlled by urinary elimination of DEG, rather than by metabolism. Larger doses (10 g/kg) in rat studies, without simultaneous coadministration of an ADH inhibitor, are associated with clinically significant serum DGA concentrations that peak at 24 hours postingestion. If kidney function is impaired, concentrations of both HEAA and DGA continue to climb in a dose-dependent manner.<sup>3</sup>

### Elimination

Animal studies utilizing DEG with radiolabeled carbon report that (>60%) of a dose is eliminated within 24 hours of ingestion and all (>90%) within 72 hours.<sup>29,31</sup> The majority of a DEG dose is eliminated unchanged in the urine (>60%).<sup>19,29</sup> The proportion of DEG excreted in the urine increases when compared to metabolites as the dose increases, probably because of saturation of hepatic metabolism.<sup>29,31</sup> This effect persists for approximately 24 hours following exposure. This effect was not demonstrable beyond 24 hours either because the dose was small enough such that it was rapidly eliminated or because the dose was large enough to induce AKI.<sup>29</sup> As the dose increases, the probability of developing AKI increases, which results in decreased elimination of both DEG and its metabolites. Up to 30% of a DEG dose is eliminated via the kidneys as HEAA.<sup>2,13,20,29</sup> Many initial investigations did not either look for or detect DGA, probably because of small exposures in the range of 1.1 g/kg, which did not result in substantial DGA generation.<sup>20</sup> For those reasons, DGA metabolic data was not available until more recently.<sup>2,3</sup> Both HEAA and DGA are transported into the liver and

the kidneys in a dose-dependent manner. Kidney tissue concentrations of HEAA are correlated directly with peak blood concentrations, but DGA concentrations are not. In fact, kidney tissue DGA concentrations are approximately 100 times greater than peak blood DGA concentrations, suggesting much greater accumulation in the kidney.<sup>3</sup> This accumulation explains the low concentrations of urinary DGA noted experimentally.<sup>3</sup> In rodent studies of DGA ingestion limited to 48 hours, DGA is detected in the urine, but at concentrations 50 times lower than HEAA.<sup>2</sup> However, biologic samples in DEG-poisoned humans many days after exposure and in the presence of AKI demonstrated a predominance of urinary DGA concentrations and a relative absence of urinary HEAA.<sup>44</sup> These findings are likely due to a number of different reasons such as the delayed blood peak of DGA when compared with HEAA, the greater time interval from exposure to sampling, which affords a greater likelihood of HEAA metabolism to DGA (compared with experimental animal data), and saturation of kidney tubule cell uptake of DGA. Finally, small amounts of a given DEG dose are eliminated in a dose-dependent fashion via fecal excretion (<3%) and exhalation (<7%).<sup>19,29,31,42</sup> Animal studies also demonstrate that small amounts of DEG with radiolabeled carbon are not eliminated, but rather are distributed to and collected in certain tissues such as muscle, fat, and skin (<4% each) and the intestines, liver, and kidneys (<2% each).<sup>29,31</sup>

Two studies reported data on apparent half-lives calculated from serial DEG concentrations. The first reported that oral doses of 6.7 and 13.4 g/kg (6 and 12 mL/kg of assumed 100% DEG) result ED in half-lives of 8 and 12 hours, respectively.<sup>50</sup> The second report suggests ED that when animals were given DEG doses of 1.1, 5.5, and 10.9 g/kg (1, 5, and 10 mL/kg of 97.5% DEG), most (64%, 87%, and 91%, respectively) of the dose is eliminated in the first 16 hours after exposure with calculated apparent half-lives of 3 to 4 hours. The remainder is then eliminated much more slowly with apparent half-lives ranging from 39 to 49 hours.<sup>19</sup>

Several rodent studies reported data on apparent elimination half-lives collected from serial urinary DEG measurements in pharmacokinetic investigations. These same studies demonstrated that a DEG dose-dependent osmotic diuresis occurs. As the ingested dose increases from 1.1 to 19.6 g/kg (1–17.5 mL/kg of >99% DEG), it induces a fourfold increase in urine production. This effect plateaus at approximately 19.6 g/kg (17.5 mL/kg of >99% DEG).<sup>19</sup> Diethylene glycol elimination undergoes zero order kinetics for the first 9 to 18 hours following ingestion. This correlates temporally with the osmotic diuresis that contributes to this phenomenon.<sup>19,29</sup> During this time, apparent elimination half-lives range from 6 hours at doses of 1.1 to 5.5 g/kg (1–5 mL/kg of 97.5% DEG) to 10 hours for doses of 10.9 g/kg (10 mL/kg of 97.5% DEG).<sup>19</sup> First-order kinetics ensue thereafter with apparent elimination half-lives that are dose-dependent and range from 3 to 13 hours.<sup>2,3,19,29</sup> Based on limited animal data, 12 hours seems to be sufficient to eliminate 94% of a dose assuming an elimination half-life of 3 hours at doses of 1.1 to 5.5 g/kg (1–5 mL/kg of 97.5% DEG).<sup>29,32</sup> However, several other studies with similar exposures (2 g/kg) suggest apparent urinary elimination half-lives as high as 5 to 6 hours. This suggests that more than 12 hours is needed to eliminate the majority of a similar dose.<sup>2,19</sup> Apparent half-lives are prolonged to at least 13 hours in more substantial poisonings (10 g/kg)<sup>3</sup> and as kidney function becomes impaired, DEG and its metabolites are unable to be excreted effectively, thereby prolonging apparent elimination half-lives further. This information is of importance in determining the appropriate observation period for a patient with a suspected or known DEG exposure.

### TOXIC DOSE

Rodent studies report that doses of up to 2 g/kg are minimally toxic and that doses of approximately 10 g/kg result in significant toxicity.<sup>2</sup> However, rodents are relatively resistant to the clinical effects of DEG poisoning compared to humans. Human data are limited, established primarily from the history of affected patients from mass poisonings, and usually represent an estimated cumulative exposure that occurred over a certain time period, rather than a single point of time. The median estimated toxic dose from the 1995 Haitian mass poisoning was approximately 1.5 g/kg

(range, 0.25–4.94 g/kg) (1.34 mL/kg; range, 0.22–4.42 mL/kg of 100% DEG).<sup>33</sup> This estimation is similar to the doses reported for the elixir of sulfanilamide mass poisoning in the United States in the 1930s.<sup>7</sup> The estimated toxic dose (0.36 g/kg) based on patient recall in the 2006 DEG mass poisoning in was lower than previous mass poisonings for which data was available.<sup>47</sup> The reason for this lower toxic dose in this mass poisoning is unclear. One proposed explanation is that it involved an older population with more chronic diseases when compared with other mass poisonings that affected younger, presumably healthier persons. Postmortem DEG concentrations from an Argentinean mass poisoning reported a lethal dose ranging from 0.014 to 0.170 mg/kg,<sup>12,14</sup> although these data are most likely inaccurate, possibly by a factor of at least 1,000.<sup>41</sup> In addition, the analytical testing techniques used in this report may have been subject to error due to cross-reactivity with other metabolites formed as the result of normal postmortem processes.<sup>41</sup> These data also are inconsistent with the fact that polyethylene glycol solutions with trace DEG concentrations yielding average total DEG exposures of 11 mg (range, 2–22 mg) administered for whole-bowel irrigation in adults do not cause adverse effects. Thus, total cumulative DEG exposures of up to 22 mg in adults appear to be safe.<sup>51</sup> The trace DEG concentrations found in these polyethylene glycol solutions likely reflect a minor contamination or byproduct produced during the manufacturing process, however this issue is unstudied. Quantities far in excess of the Argentinean analysis are estimated to occur in adults from nonprescription health products containing trace amounts of DEG (maximum value, 6.3 mg) currently sold in the United States.<sup>43</sup> There were no reports of DEG poisoning associated with the products tested in this report.

In summary, the minimum toxic DEG dose in an acute, single-dose exposure is unclear but limited data suggest that single, small total exposures of less than or equal to 22 mg in an adult are not associated with adverse health effects. Analysis of past DEG mass poisoning incidents suggests that cumulative exposures of as little as 0.25 g/kg are associated with illness,<sup>33</sup> but this number cannot be used as a reliable cutoff to exclude poisoning.

The minimum toxic dose of DGA is unknown, but ingestion of 100 g in an adult was fatal. The actual absorbed dose is probably much less since the patient in this case report vomited immediately after ingestion but still died.<sup>40</sup>

## **PATHOPHYSIOLOGY**

Accumulation of HEAA and DGA in the blood causes a metabolic acidosis that was prevented by early administration of an ADH inhibitor such as fomepizole.<sup>2,3</sup> Although there are no published reports examining the efficacy of ethanol to block DEG metabolism, it would also be expected to be efficacious. Inhibition of DEG metabolism with an ADH inhibitor prevents kidney and liver toxicity<sup>2</sup> and decreases lethality in rodents.<sup>20</sup> The parent compound (DEG) does not appear to be toxic based on these same studies.<sup>2,20,27,28</sup> Diglycolic acid is likely to be the major if not sole cause of nephrotoxicity in DEG poisoning. Animal studies consistently demonstrate an association between the presence of DGA with toxicity, and the absence of toxicity when DGA is not present.<sup>26,38</sup> Studies with human proximal tubule cells demonstrate that DGA-induced cell death is due to necrosis via uptake by a sodium-dicarboxylate-1 transporter, which probably occurs because of its structural similarities to citric acid cycle intermediates.<sup>28</sup> Additional studies demonstrate that DGA preferentially inhibits succinate dehydrogenase, but has no effect on the other citric acid cycle enzyme activities.<sup>27</sup> In vitro data suggest that the mechanism is likely related to the ability of DGA to chelate calcium and subsequently preventing substrate and reducing equivalent availability for oxidative phosphorylation.<sup>10</sup> These activities ultimately result in interruption of mitochondrial respiration, leading to decreased energy production (and subsequent availability) and proximal tubule cell necrosis.<sup>10</sup> These studies also suggest that neither DEG nor HEAA causes cellular toxicity in kidney tissue (in vitro proximal tubule cell testing) and that acidemia enhances DGA toxicity.<sup>26,28</sup> Elevations in blood urea nitrogen and plasma creatinine concentrations correlate moderately well with elevations in tissue DGA concentrations.<sup>2</sup> Diethylene

glycol exhibits a steep threshold dose response. Doses of 2 and 5 g/kg were neither associated with overt clinical illness, nor were they associated with detectable kidney diglycolic acid tissue concentrations. This is in contrast to rodents dosed with 10 g/kg of DEG, which developed nephrotoxicity, metabolic acidosis, and markedly elevated kidney DGA tissue concentrations.<sup>26</sup> Furthermore, direct dosing of rodents with DGA exhibited a similar pattern. Severe toxicity (kidney and liver) was noted in animals receiving 300 mg/kg DGA, whereas no toxicity was noted in those animals that received 100 mg/kg DGA.<sup>38</sup> Thus, DEG doses capable of producing substantial target organ accumulation of DGA are needed for nephrotoxicity and there is likely some saturable point at which DGA accumulation in target organs begins to occur.<sup>26,38</sup>

The histopathology of DEG-associated nephrotoxicity primarily involves the proximal convoluted tubules as expected and affects the renal cortex, in which necrosis, hemorrhage, and vacuolization develop.<sup>42</sup> Elevations in hepatic aminotransferases also occur probably because of DEG, HEAA, and DGA accumulation in the liver.<sup>3,30,31</sup>

The neurotoxicity of DEG poisoning includes a severe peripheral neuropathy, encephalopathy, and other signs and symptoms.<sup>42,47</sup> The pathophysiology of this neurotoxicity spectrum is unclear; however, limited testing results of cerebrospinal fluid samples taken from DEG-poisoned patients cases from the 2006 Panama mass poisoning suggest an association with DGA.<sup>44</sup> The single reported human case of a pure DGA ingestion demonstrated clinical and pathologic findings, including severe neurotoxicity, very similar to DEG poisoning. This further supports the hypothesis that the aforementioned signs and symptoms of DEG-associated neurotoxicity are likely due to DGA.<sup>40</sup>

## **CLINICAL MANIFESTATIONS**

The signs, symptoms, and severity of DEG poisoning are dependent on various factors such as duration of exposure, dose, and other intrinsic host factors such as the presence of comorbidities. Following ingestion, symptoms typical of ethanol intoxication such as lethargy, confusion, “drunkenness,” and altered mental status begin rapidly and last for several hours.<sup>4,42</sup> Clinical signs and symptoms of a metabolic acidosis including tachypnea and hypernea are reported.<sup>3,42</sup> Although nausea, vomiting, abdominal pain, diarrhea, headache, and confusion are reported with DEG poisoning,<sup>6,42</sup> nephrotoxicity (acute kidney injury) remains the single consistent feature of all cases. This finding manifests over 1 to 3 days following ingestion as a progressive course of oliguria, anuria, or both.<sup>37,42,47</sup>

In some of the reported DEG mass poisonings, patients presented in AKI with profound metabolic acidosis and acidemia.<sup>34</sup> Many of these mass poisonings were in children who received relatively high DEG doses in the form of a pediatric pharmaceutical such as liquid acetaminophen.<sup>33</sup> In the 2006 Panama mass poisoning, the overwhelming majority of patients were adults who probably ingested smaller doses per unit body weight when compared to pediatric victims of past mass poisonings (although they were probably consumed for a longer period of time). Most of these patients presented to health care facilities with vague gastrointestinal or respiratory symptoms and were found to have AKI.<sup>37,47</sup> Many subsequently developed bilateral cranial nerve VII (facial nerve) paralysis and peripheral extremity weakness, often within several days. Finally, many also rapidly developed encephalopathy, coma, and death in the subsequent 24 to 48 hours.<sup>47</sup> This pattern of AKI, followed days later by the appearance of neurologic signs and symptoms such as unilateral or bilateral cranial nerve VII paresis or paralysis, peripheral neuropathy, encephalopathy, autonomic nervous system instability, and coma is frequently reported.<sup>1,17,18,24,39,42,47</sup>

Two case reports document primarily demyelinating peripheral neuropathies,<sup>30,39</sup> but data from the large numbers of patients who received nerve conduction testing from the Panama mass poisonings, as well as other case reports<sup>18,24,47</sup> demonstrate that axonal sensorimotor neuropathy with secondary demyelination is the typical clinical course. Only those DEG-poisoned patients who develop some degree of AKI are at risk for developing neurotoxicity.<sup>24,36,42,47</sup>

Long-term outcomes among DEG poisoning survivors are not well characterized. In one study, patients who remained hemodialysis-dependent after acute illness resolution generally remained hemodialysis dependent. Those who rapidly recovered from their initial AKI event appear to retain normal or at least adequate long-term kidney function for at least the 2 years following exposure. Patients with DEG-associated neurologic findings tended to improve over time. Delayed-onset (beyond the typical initial course of acute DEG poisoning) renal and neurological toxicity is unlikely to occur based on the single longitudinal study of DEG-poisoned survivors.<sup>9</sup>

## DIAGNOSTIC TESTING

The clinician will have to rely on a high index of suspicion, a good exposure history and more commonly encountered “routine” testing methodologies including serum electrolytes, blood gas measurements, and kidney function studies upon initial presentation. Use of the osmol gap calculation for evaluating the potential of a toxic alcohol (including DEG) has limitations.<sup>21,22</sup> Generally, the osmol gap should never be used to exclude the possibility of a toxic alcohol ingestion. However, in the authors’ experience, very large gaps (>30 mOsm/L), especially in the setting of a suspected or possible poisoning, are likely to be due to some exogenous, osmotically active, xenobiotic that was ingested or otherwise absorbed. The reader is referred to Chaps. 12 and 106 for a complete discussion on this topic. Nerve conduction studies are helpful in establishing the pattern of neuropathy if present. Otherwise, routine laboratory and diagnostic tests are used as needed to help evaluate end organ damage.

Although laboratory assays for DEG in whole blood, serum, plasma, and urine are commercially available at specialized toxicology testing laboratories, they are not available in most hospital laboratories. A study conducted during the 2006 Panama DEG mass poisoning demonstrated statistically significant differences in urinary DEG concentrations among cases (range, 50–4,000 ng/mL) and controls (undetectable). Biologic samples collected from the 2006 Panama investigation demonstrated that serum and urine DGA concentrations were significantly associated with patient status (OR > 999;  $P < 0.0001$ ). Diglycolic acid holds promise as a potential biomarker for DEG poisoning, but further work validating the methodology is needed.<sup>44</sup> One study found that among 14 DEG-poisoned patients who presented without neurologic signs and symptoms, but who had initially elevated CSF protein concentrations (without pleocytosis), almost all ( $n=13$ ; 93%) developed progressive neurologic sequelae within a few days following CSF collection.<sup>47</sup>

## TREATMENT

Treatment options include observation, gastrointestinal decontamination, supportive care, administration of an ADH inhibitor therapy, and hemodialysis. There is no evidence of clinical benefit or even reduced bioavailability of DEG following orogastric or nasogastric lavage or the administration of oral activated charcoal.<sup>23</sup> Nevertheless, given the limited data regarding the role of gastrointestinal decontamination techniques in DEG poisoning, the profound dose-related clinical effects, and the liquid state of the xenobiotic, it is reasonable to perform nasogastric lavage for an individual who presents recently (within 1–2 hours) after ingestion for a large amount of a liquid product containing DEG in order to try to remove unabsorbed DEG in the stomach. It is also reasonable to administer a dose of activated charcoal if presentation is within 1 to 2 hours of ingestion.

Animal evidence suggests that the osmotic diuretic effect of DEG causes large urinary volume losses in the immediate postexposure period. Adequate volume repletion and resuscitation should be performed as soon as possible. The patient should be closely monitored for decreases in urine output and fluid input and output recorded. Fluids need to be adjusted if AKI develops. There is no evidence for using forced diuresis; however, we recommend that all patients are well hydrated (after appropriate resuscitation if needed) to ensure maintenance of euvoolemia and a steady urine output. This is appropriate for several reasons, including (1) DEG is primarily eliminated unchanged in the urine via the kidneys; (2) inadequate resuscitation and/or suboptimal hydration beyond the initial fluid resuscitation period contributes

to prerenal azotemia, thereby decreasing elimination of unchanged DEG; (3) any impairment in kidney function will result in decreased elimination of unchanged DEG with a resultant increase in available DEG for metabolism to toxic metabolites such as DGA; and (4) animal studies suggest that when doses associated with adverse health effects (10 g/kg) are given in addition to fomepizole, almost the entire dose is eliminated unchanged in the urine.<sup>2</sup> Careful attention to acid–base status is essential because limited *in vitro* work with DGA and human proximal tubule cells suggest that acidemia enhances the toxicity of DGA.<sup>27,28</sup> The use of intravenous sodium bicarbonate therapy for controlling metabolic acidosis is unstudied and therefore not routinely recommended at this time.

An ADH inhibitor such as fomepizole is recommended in suspected or known DEG poisoning to prevent nephrotoxicity, although most of the supporting evidence is from animal studies (Antidotes in Depth: A33). This same evidence suggests that the parent compound is not nephrotoxic.<sup>2,20,28</sup> Neurotoxicity seems to only appear following DEG metabolite-associated AKI.<sup>42</sup> Therefore, based on current evidence, administration of a metabolism blocker such as fomepizole seems unlikely to contribute to neurotoxicity (a possible health risk if the parent compound were toxic). In the absence of human dosing data for fomepizole in DEG poisoning, the dosing regimen used for other toxic alcohols is reasonable. Hemodialysis is recommended if clinical evidence of acidemia or end organ toxicity is present. Although the minimal toxic dose of DEG is unknown, cumulative exposures at or above 250 mg/kg (the lower limit of the range reported in the Haiti mass poisoning) are potentially life threatening. A single report documented higher prehemodialysis and lower posthemodialysis concentrations of DEG suggesting that it is cleared by hemodialysis, although the gradient was relatively small (0 and 1.6 mg/dL).<sup>6</sup> Nevertheless, the volume of distribution and molecular weight of DEG suggest that hemodialysis would be effective.<sup>19,42</sup> The endpoint of fomepizole therapy or need for additional rounds of dialysis is unclear, but the relatively new commercial availability of techniques for the determination of whole blood, plasma, serum and urine DEG concentrations with careful attention to acid–base status will be helpful in guiding therapy. At this time, there is insufficient human data to conclude that fomepizole monotherapy (without hemodialysis) in human DEG poisoning is completely protective as the currently available, albeit limited, evidence shows it prevents nephrotoxicity and that the DGA metabolite is the most likely cause of the neurotoxicity that follows onset of AKI. Therefore it is a reasonable management approach to take for suspected or known DEG poisoning as discussed above. However, early nephrology consultation for hemodialysis in cases of suspected severe DEG poisoning is also recommended. Consultation with a medical toxicologist or poison control center will be helpful.

Exposures to amounts of DEG less than those known to be definitely associated with poisoning present management dilemmas. The following sections consist of reasonable treatment protocols, which will need to be modified depending on the individual situation. In all exposures, a medical toxicologist should be consulted as the circumstances surrounding the exposure are invariably different and may affect management.

Mass poisonings–derived toxic doses of DEG are not reliable measures for excluding poisoning. Patients with a reliable history of a minimal ingestion, such as an unintentional sip of a low-concentration DEG-containing product, are unlikely to be at risk for toxicity. For those individuals careful observation coupled with serial chemistries, blood gas measurements, and an osmol gap to rapidly identify onset of renal function and acid–base abnormalities is reasonable. Decisions are more complicated for those adult patients with slightly larger DEG ingestions of relatively low concentrations (5%) such as exposures consisting of more than a sip but less than a “mouthful.” Although the true minimum toxic dose of DEG is unknown, an example of the aforementioned situation might involve an unintentional ingestion of 30 mL (approximately a mouthful) of a 5% DEG product by volume in an adult. This is approximately 1.5 mL of pure DEG, which is equivalent to about 1.7 g, which in an 80-kg adult is about 21 mg/kg. The lower end of the estimated toxic dose range in Haiti was 250 mg/kg, which is more than 10 times higher. Therefore careful observation is reasonable if the dose

and product concentrations are reliable and there were no other potential risk factors for DEG-associated illness, such as preexisting kidney disease. Such an exposure in a 3-year-old child weighing 16 kg would yield a dose of 110 mg/kg, an exposure of greater concern that would warrant more aggressive treatment. Unfortunately, ascertainment of the true volume ingested and product concentration is usually difficult, which contributes to the problem of estimating risk based on patient history. If in doubt as to the extent or severity of dose and/or potential for toxicity, proceed with at least fomepizole therapy and follow-up DEG-specific testing.

Patients with signs or symptoms of alcohol intoxication, but who did not consume ethanol should be suspected of having a potentially life-threatening DEG ingestion and treated as discussed in the previous section. Asymptomatic patients with ingestions beyond the “unintentional sip or taste” should be observed for at least 24 hours regardless of therapy protocol choice. Serial laboratory determinations to monitor acid–base status should be obtained and evaluated for at least 24 hours based on DEG toxicokinetics.

Unless laboratory testing documents a minimal or absent exposure, the patient’s clinical, acid–base, and kidney function status should be followed for at least 24 hours for evidence of DEG poisoning. For patients receiving fomepizole, this 24-hour period should begin 12 hours following the last dose of fomepizole. If clinical evidence of nephrotoxicity or acidemia appears, then fomepizole is recommended in addition to hemodialysis.

For those patients presenting to health care facilities with an acidemia, oliguria or anuria within 24 to 36 hours of a DEG ingestion, fomepizole is recommended in addition to emergent hemodialysis. Regardless of the patient’s acid–base and electrolyte status. This recommendation is based in part on animal studies showing that serum DGA concentrations peak at 24 hours following ingestion, DGA is nephrotoxic, sequesters in kidney tissue,<sup>3,27,28</sup> and its half-life increases with larger doses.<sup>3</sup> Early presentation to health care facilities (<10 hours from ingestion) and aggressive treatment (gastrointestinal decontamination, fomepizole, and hemodialysis) appeared to be associated with better outcomes in patients treated with fomepizole or ethanol for DEG exposure.<sup>1,4,6,18,39</sup> In one of these cases, a 15-year-old girl who was witnessed to ingest approximately 22.4 g of DEG (patient weight unknown) was managed with orogastric lavage and early (<3 hours) fomepizole therapy alone; the patient had a good outcome with no renal or neurologic dysfunction (other than inebriation).<sup>4</sup> For those patients presenting later than 36 to 48 hours after a DEG ingestion with the aforementioned signs and symptoms, fomepizole and hemodialysis are recommended. Although the ability of these therapies to limit the damage of DEG and its toxic metabolites will be less (vs earlier implementation), it will be of value with regard to correcting electrolyte imbalances and managing AKI.

Although there are no published reports examining the efficacy of ethanol in blocking DEG metabolism, it is expected to act similarly to fomepizole. Hence, it is a reasonable alternative therapy if fomepizole and hemodialysis are unavailable and a rapid transfer to another hospital is not possible.

## SUMMARY

- Patients with suspected or known exposures to DEG present a diagnostic and therapeutic challenge.
- Emerging work demonstrates that the DEG metabolite DGA, and not the parent compound, is nephrotoxic and most likely neurotoxic.
- Alcohol dehydrogenase inhibitor therapies such as fomepizole have a role in treating DEG poisoning, and urgent hemodialysis is recommended for substantial ingestions and/or when evidence of acidemia and/or end-organ toxicity is present.
- Diethylene glycol poisoned patients who develop AKI are at risk for severe neurotoxicity.
- Diethylene glycol ingestion should be suspected in patients presenting with AKI and neurologic signs and symptoms such as cranial nerve VII paresis or paralysis, or extremity weakness consistent with a peripheral neuropathy.

## CASE STUDY 11

**History** A 2-year-old (12 kg) girl was transported to the hospital by ambulance after having a witnessed seizure at home. The child was healthy, born at term, and without any significant past medical history. Although her family had recently immigrated to the United States, she was followed in a primary care clinic and was fully vaccinated. She had one screening test for lead, which was “normal.” Her mother relates that their house had problems with roaches, mice, and rats and she thinks her husband applied a chemical to deal with the problem.

About 20 minutes before the girl became ill, her mother saw the child pick up something from the corner of the room and immediately thereafter removed some material that looked like food from the child’s mouth. The girl subsequently lost consciousness and began to shake. The mother called 9-1-1 and when EMS arrived the child was intermittently seizing. Lorazepam (1 mg IM) was administered and EMS gave the child supplemental oxygen for transport. The paramedics reported that the child stopped seizing during transport but started again upon arrival to the emergency department.

**Physical Examination** On arrival, the child was seizing with the following vital signs: blood pressure, 90/40 mm Hg; pulse, 160 beats/min, respiratory rate, 36 breaths/min; temperature, 100°F (37.7°C); oxygen saturation, 100% on a 100% nonrebreather mask and rapid reagent glucose of 160 mg/dL. There were no signs of trauma. The skin was moist, pupils were 4 to 5 mm and fixed, the chest was clear, heart sounds were regular, and her abdomen was soft. Neurologic examination revealed repetitive symmetrical movements of the limbs, slight eye deviation to the left, and a lack of responsiveness to stimulation.

**Initial Management** Another 1 mg dose of lorazepam was given IM, while an IV line was being inserted. Additional blood samples were obtained for complete blood

count, electrolytes, liver function tests, and creatine phosphokinase. The child continued to seize and a 2-mg IV dose of lorazepam was administered that terminated the seizure. Repeat vital signs were notable for a pulse of 165 beats/min and a rectal temperature of 100.6°F (38.1°C). Blood cultures were sent and the child was given an empiric dose of ceftriaxone. An ECG was obtained and showed sinus tachycardia with normal axis and intervals.

**What Is the Differential Diagnosis?** In addition to infectious, structural, and traumatic causes for repeated seizures, the history is suggestive of pesticide poisoning. Pesticides are defined by the US Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) as “any substance or mixture of substances intended for preventing, destroying, repelling, or mitigating any pest, and any substance or mixture of substances intended for use as a plant regulator, defoliant, or desiccant.” Since 1947, the production, use, and distribution of pesticides in the United States have been regulated under FIFRA and its subsequent amendments in 1972, 1975, and 1978. In 1970, the US Environmental Protection Agency (EPA) was given the authority to administer and enforce FIFRA regulations. Under FIFRA, all pesticides and their manufacturers must be registered with the EPA, and the pesticide must be classified for either general use or restricted use by licensed or certified applicators. Additionally, according to FIFRA, rodenticides are classified by their toxicities and must be labeled by signal words as designated in [Table CS11–1](#). The WHO applies a similar classification scheme for all pesticides based on either oral or dermal LD<sub>50</sub>.

Unfortunately, as is so commonly the case, not only was the mother unaware of the name or type of pesticide used, but also both the original container and label were missing. Furthermore, there was a possibility that the product used was brought from the parent’s home country and was either

illegal or unlicensed in the United States. As a result, clinicians are often forced to provide empirical treatment based largely on clinical diagnosis. An understanding of the likely possibilities in [Tables CS11–2](#) improves both diagnostic utility and treatment decisions.

**What Clinical and Laboratory Analyses Help in the Evaluation of This Patient’s Presentation?** The possible pesticides when ingested that are most likely to result in seizurelike activity or status epilepticus include organic phosphorus compounds and carbamates (Chap. 110), organic chlorines (Chap. 111), monofluoroacetate and fluoroacetamide (Chap. 113), strychnine (Chap. 114), thallium (Chap. 99), zinc and aluminum phosphide, and tetramine (Chap. 112). The absence of associated clinical manifestations helps eliminate some of the choices: organic phosphorus compounds and carbamates (eg, salivation, lacrimation, urination, defecation, bradycardia, bronchorrhea, miosis), thallium (the onset was rapid and there was an absence of painful peripheral neuropathy), strychnine (not true seizures, consciousness should be preserved until hyperthermia, hypoxia, or hypercarbia becomes severe), and aluminum phosphide (absence of vomiting with characteristic odor of rotten fish). Although routine laboratory testing has little utility here, the absence of a profound metabolic acidosis might suggest that monofluoroacetate and fluoroacetamide are not responsible for this clinical presentation. Certain dangerous rodenticides imported for illicit use include tetramine (status epilepticus) and aldicarb (a carbamate found in *tres pasitos*). Unfortunately, because there are no rapidly available tests to help establish this diagnosis, treatment will have to be based entirely on the clinical assessment.

### Further Diagnosis and Treatment

Shortly after the third dose of lorazepam, the child began to seize again and endotracheal intubation was performed. Following intubation, the child was placed

**TABLE CS11–1** US Environmental Protection Agency Toxicity Classification of Pesticides

Category and Signal Word	Oral LD <sub>50</sub> (mg/kg)	Dermal LD <sub>50</sub> (mg/kg)	Inhalation LC <sub>50</sub> (mg/L)	Eye Irritation	Skin Irritation
I Danger	0–50	0–200	0–0.05	Corrosive: corneal opacity not reversible within 21 days	Corrosive
II Warning	50–500	200–2,000	0.05–0.5	Corneal opacity reversible within 8–21 days; irritation persisting for 7 days	Severe irritation at 72 hours
III Caution	500–5,000	2,000–20,000	0.5–5.0	Corneal opacity; irritation reversible within 7 days	Moderate irritation at 72 hours
IV None	>5,000	>20,000	>5.0	Irritation cleared within 24 hours	Mild or slight irritation at 72 hours

## CASE STUDY 11 (CONTINUED)

on a continuous infusion of propofol. A nasogastric tube was inserted and 10 g of activated charcoal was instilled into the stomach. The child was transferred to the PICU and attached to a video EEG monitor, where intermittent seizure activity was noted over the next 12 to 16 hours. A non-contrast CT scan of the head was normal and a lumbar puncture was performed to exclude meningitis. The following day, the

father brought in the original package and the product was identified as tetramine.

Over the subsequent 24 hours, the propofol infusion was titrated to a lower dose and then discontinued. The child was able to be extubated and appeared clinically normal. Because the package was brought from their home country and not imported, authorities were not notified. The parents were educated about safe use of pesticides, and

a social worker was able to help coordinate legal exterminating efforts by the landlord.

**Acknowledgments** Authors from previous editions, including Neal E. Flomenbaum, Mary Ann Howland, Richard Weisman, Rebecca Tominack, and Susan Pond, contributed to the development of [Tables CS11–2](#) as well as the discussion of FIFRA.

TABLE CS11-2 Management of Specific Rodenticide Ingestions

Rodenticide Name	Physical Characteristics	Toxic Mechanism	Estimated Fatal Dose	Signs and Symptoms	Onset	Antidotes and Other Treatments <sup>a</sup>
<b>Highly Toxic Signal Word: DANGER<sup>b</sup> (LD<sub>50</sub> &lt; 50 mg/kg)</b>						
Thallium	White, crystalline, odorless, tasteless.	Combines with mitochondrial sulfhydryl groups, interferes with oxidative phosphorylation.	14 mg/kg	Anorexia, abdominal pain, diarrhea, painful neuropathy, delirium, coma, seizures, alopecia (late), Mees lines.	GI symptoms acutely, other symptoms 12–14 hours delay.	Activated charcoal, Prussian blue (Chap. 99).
Sodium monofluoroacetate (SMFA, compound 1080)	White, crystalline, odorless, tasteless, water soluble.	Fluoroacetate to fluorocitrate; interferes with tricarboxylic acid cycle.	3–7 mg/kg	Seizures, coma, tachycardia, PVCs, VT, VF, ST-T wave changes, rhabdomyolysis (hypocalcemia).	30 minutes–20 hours	Experimental regimens (Chap. 113).
Sodium fluoroacetamide (compound 1081)	Same as SMFA.	Same as SMFA; fluoride toxicity.	13–14 mg/kg	Same as SMFA.	Same as SMFA.	Same as SMFA.
Strychnine	Bitter taste.	Glycine receptor antagonist on spinal cord motor neurons.	Children: 15 mg Adults: 1–2 mg/kg	Restlessness, anxiety, twitching, hyperextension alternating with relaxation, intense pain, trismus or facial grimacing (“risus sardonius”), inability to swallow, opisthotonos.	10–20 minutes	Quiet room, IV midazolam, diazepam, neuromuscular blockade (Chap. 114).
Zinc phosphide	Heavy, gray, crystalline powder, water insoluble, “rotten fish” or “phosphorus” odor; normally used as 1% concentration.	Inhibition of oxidative phosphorylation.	40 mg/kg in rats	Releases phosphine on contact with water or acid or in GI tract. “Rotten fish” breath odor, black vomitus, GI and cardiovascular toxicity, acute respiratory distress syndrome, agitation, coma, seizures, hepatic and renal toxicity.	Within hours; inhalation may have delayed onset.	Dilution with sodium bicarbonate water or milk (Chap. 108).
Elemental phosphorus (yellow or white phosphorus)	Yellow, waxy paste, fat soluble, water insoluble.	Local irritation and burns on contact followed by GI, liver, and kidney damage, and interferes with clotting.	1 mg/kg (more toxic if dissolved in alcohol, fats, oils).	Skin and GI burns, “smoking” luminescent vomitus and stools with garlic odor, jaundice, dysrhythmias, coma, delirium, seizures, cardiac arrest.	1–2 hours	Supportive care (Chap. 112).
Arsenic trioxide	White, crystalline powder.	Combines with sulfhydryl groups and interferes with a variety of enzymatic reactions.	1–4 mg/kg	Dysphagia, nausea and vomiting, bloody diarrhea, cardiovascular collapse (VT, torsade de pointes), garlic odor, altered mental status, late sensory/motor neuropathy.	Symptoms: 1 hour Death: 1–24 hours.	Succimer, dimercaprol until urine arsenic concentration <50 mcg/L Hemodialysis to remove chelation compound if acute kidney injury develops (Chap. 86).
Barium (soluble forms: carbonate, chloride, hydroxide)	Yellow, white, slightly lustrous.	Inhibits calcium activated potassium rectifier channels.	20–30 mg/kg	Headache, paresthesias, muscle weakness, paralysis, nausea, vomiting, diarrhea, abdominal pain, prolonged QT interval, dysrhythmias, cardiac and pulmonary failure. Hypokalemia, neuromuscular blockade.	1–8 hours	Orogastric lavage followed by oral magnesium sulfate at 250 mg/kg for children and 30 gm for adults, potassium replacement (Chap. 107).
PNU ( <i>N</i> 3-pyridylmethyl- <i>N'</i> - <i>p</i> -nitrophenyl urea, Vacor)	Yellow, resembling cornmeal or yellow green powder in bait; odor: peanuts.	Interferes with nicotinamide metabolism in pancreas (destroying pancreatic β cells), central and peripheral nervous system, and heart.	5 mg/kg	Nausea and vomiting, abdominal pain, severe orthostatic hypotension, hyperglycemia with or without ketoacidosis, gastrointestinal perforation, pneumonia, neuropathy.	4–48 hours	Nicotinamide (niacinamide) 500 mg IV or IM (historically used, but likely unavailable), manage diabetic ketoacidosis.
Tetramine (tetramethylene disulfotetramine, TETS, TEM)	White powder.	Noncompetitive, GABA antagonism by direct blockade of chloride ionophore.	5–10 mg/kg	Refractory status epilepticus, fainting, coma, coronary ischemia.	0.5–13 hours	Benzodiazepines, barbiturates, propofol, neuromuscular blockers.

<b>Moderately Toxic Signal Word: WARNING<sup>a</sup> (LD<sub>50</sub><sup>b</sup> 50–500 mg/kg)</b>						
$\alpha$ -Naphthylthiourea (ANTU)	Odorless, slightly bitter, fine, blue-gray powder, water-insoluble.	Unknown	>4 g/kg	Hypothermia, dyspnea, crackles, clear pulmonary froth, cyanosis. Acute respiratory distress syndrome.	?	Supportive care.
Cholecalciferol (vitamin D <sub>3</sub> )	0.075% pellets, 364 pellets/oz (1 pellet = 2308 U vitamin D).	Hypercalcemia.	?	Headache, lethargy, weakness, fatigue, polyuria, acute kidney injury and failure, hypertension, hypercalcemia.	Hours to days	Fluids; if severe: furosemide, prednisone, calcitonin, bisphosphonates hemodialysis (Chap. 44).
<b>Low Toxicity Signal Word: CAUTION<sup>a</sup> (LD<sub>50</sub><sup>b</sup> 500–5,000 mg/kg)</b>						
Red squill	Bitter taste.	Cardioactive steroid poisoning. Inhibition of Na <sup>+</sup> ,K <sup>+</sup> -ATPase	?	Myocardial irritability, blurred vision, hyperkalemia.	30 minutes–6 hours	Digoxin-specific Fab, atropine (Chap. 62).
Norbormide (dicarboximide)	Yellow cornmeal bait, peanut butter, 1% concentration.	Vasoconstriction and ischemia in rats only via specific norbormide receptor in rat smooth muscle.	Unknown, toxicity at < 300 mg.	Transient hypothermia and hypotension.	?	Supportive care.
Bromethalin	7.5% concentrate, green pellets, with Bitrex (denatonium benzoate).	Uncouples oxidative phosphorylation; interrupts nerve impulse conduction.	?	Muscle tremors, myoclonic jerks, flexion of major muscles, coma?, ataxia, focal motor seizures.	Immediate	Supportive care.
<b>Anticoagulants: Short-Acting</b>						
Warfarin	Yellow cornmeal, rolled oats (0.025%).	Anticoagulation via interference with clotting factors II, VII, IX, X.	>5–20 mg/day for > 5 days	Elevated INR; bleeding death from hemorrhage.		Vitamin K, fresh-frozen plasma as indicated, prothrombin complex concentrate (Chap. 58 and Antidotes in Depth: A18).
<b>Anticoagulants: Long-Acting</b>						
<i>Hydroxycoumarins</i>						
4-Hydroxycoumarin (brodifacoum, difenacoum)	0.005% grain-based bait.	} Anticoagulation via interference with clotting factors II, VII, IX, X. }		} Elevated INR; bleeding, death from uncertain hemorrhage. }	} Delayed several days. }	} Vitamin K, fresh-frozen plasma as indicated. Prothrombin complex concentrate. }
Coumatufuryl (warfacide)	0.5% for dilution to 0.025% white powder, tasteless, odorless.					
<i>Indandiones</i>						
Pindone	Moldy, acrid odor, fluffy yellow powder, concentrations 0.005–2.5%.	} Anticoagulation via interference with clotting factors II, VII, IX, X. }		} Chronic ingestion possibly produces cardiac and neurologic signs and symptoms, elevated INR; bleeding, death from uncertain hemorrhage. }	} Delayed several days. }	} Vitamin K, fresh-frozen plasma as indicated Prothrombin complex concentrate. }
Diphacinone	0.005%–2.0%					
Chlorophacinone	0.005%–2.5%					
Valone	0.005%–2.5%					
<sup>a</sup> Gastrointestinal decontamination should be provided as appropriate (Chap. 5); only unique or controversial aspects are discussed in this table. <sup>b</sup> The LD <sub>50</sub> values used in this table are derived from data on acute oral ingestions of the commercial product based on rats. In some cases, the commercial product contains a very small percentage of the active ingredient. The signal words that appear on labels of registered products may differ from the signal word assigned to the acute oral LD <sub>50</sub> test because the label may also reflect another study (acute dermal or inhalational LD <sub>50</sub> ) requiring a more severe signal word. See Table 110–1 for the Consumer Product Safety Commission definitions and use of signal words as indicators of potential hazard of toxicity. Barium (Ba)	
Atomic number	= 56
Atomic weight	= 137.3 Da
Normal concentration	
Serum	< 0.2 mg/L (1.46 μmol/L)

### HISTORY AND EPIDEMIOLOGY

Although barium is utilized in various forms in developed nations, exposure to barium salts is uncommon and clinically significant poisoning is rare. Acute, clinically relevant exposures occur most commonly following the intentional ingestion of the soluble salts found in rodenticides, insecticides, or depilatories.<sup>10,11</sup> Barium carbonate has an appearance similar to flour, which is reported to be responsible for most unintentional barium poisonings.<sup>9,13</sup>

Barium salts and barium hydroxide are extensively employed in industry particularly in thermoplastics and the manufacture of synthetic fibers, soap manufacture, and in lubricants (Table 107-1). Toxicity occurs following occupational exposure to barium salts through ingestion, inhalation,<sup>34</sup> or explosion of the propellant barium stypnate.<sup>15</sup> Despite the fact that barium sulfate is insoluble, rare cases of unintentional toxicity are reported during radiographic procedures and include complications associated with oral<sup>24</sup> and rectal administration.<sup>14,19,22,27</sup> Toxicity and death occurred when solutions were unintentionally contaminated with soluble contrast barium salts.<sup>29</sup>

### CHEMISTRY

Barium is a soft metallic element that was first isolated by Sir Humphry Davy in 1808. With an atomic weight of 137.3 Da, barium is located at number 56 in the periodic table (between cesium and lanthanum). The metal oxidizes easily when exposed to water or alcohol, has a melting point of 1,341°F (727°C) and a boiling point of 3,398°F (1,870°C). Elemental barium is not found in nature; it normally occurs as an oxide, dioxide, sulfate (barite), or carbonate (witherite). Chemically, barium resembles calcium more than it resembles any other element. Although some barium salts are naturally occurring, most used commercially are produced from the more commonly found carbonates or oxides. Barium salts are typically classified as either water soluble or insoluble, but the solubility of all barium salts increases as pH falls. The soluble salts acetate, chloride, hydroxide, oxide, nitrate, and (poly) sulfide are the most commonly associated with toxicity (Table 107-1). Barium (poly) sulfide also produces toxicity through the formation of hydrogen sulfide when ingested and exposed to gastric hydrochloric acid. Poorly soluble barium carbonate is converted by gastric acid to highly soluble barium chloride. The other insoluble barium salts such as arsenate, chromate, fluoride, oxalate, and sulfate are rarely associated with toxicity.

### TOXICOKINETICS

Toxicity can result from ingestion of as little as 200 mg of a barium salt. Oral lethal doses are reported to range from 1 to 30 g of a barium salt. Occupational exposure to barium fumes of greater than 0.02 mg/m<sup>3</sup> are associated with health effects.<sup>38</sup> Exposure to inhaled particulate insoluble barium causes pulmonary baritosis, which consists of very fine punctate and annular lesions and some slightly larger nodular lesions.<sup>38</sup>

Following ingestion, 5% to 10% of soluble barium salts are absorbed,<sup>16</sup> with the rate of absorption dependent on the degree of water solubility of the salt. The time to peak serum concentration is 2 hours.<sup>16</sup>

The toxicokinetics are characterized by a rapid redistribution phase, followed by a slow decrease of serum barium concentrations, with a reported half-life ranging between 18 and 85 hours.<sup>16,28</sup> Renal elimination of the absorbed dose accounts for 10% to 28% of total barium excretion, with the predominant route of fecal elimination through the gastrointestinal tract.

In published case reports of symptomatic patients, serum barium concentrations range from 3.7 to 41.1 mg/L.<sup>2,9,23,25,28,31,33</sup> Death is uncommon following ingestion, but occurs most commonly in clinical settings with limited health care resources.<sup>13</sup> Death from an ingestion of barium chloride was associated with the following barium concentrations at autopsy: blood, 9.9 mg/L; bile, 8.8 mg/L; urine, 6.3 mg/L; and gastric contents, 10 g/L.<sup>17</sup>

Intravasation is a rare but serious complication of radiologic studies in which barium sulfate is administered under pressure, such as a barium enema. Following a small perforation, barium sulfate leaks into the peritoneal cavity or portal venous system.<sup>22</sup> Although sudden cardiovascular collapse occurs, it is unclear whether this is the result of venous occlusion

**TABLE 107-1** Barium Salts: Solubility and Common Usages

Barium Salt	Solubility (mg/L at 20°C)	Common Uses
Acetate	58.8	Textile dyes
Carbonate	0.02 increases in an acid pH; also, can be converted to barium chloride by gastric acid (HCl)	Rodenticide, welding fluxes, pigments, glass, ceramics, pyrotechnics, electronic devices, welding rods, ferrite magnet materials, optical glass, manufacture of caustic soda and other barium salts
Chloride	375	Textile dyes, pigments, boiler detergents, in purifying sugar, as mordant in dyeing and printing textiles, as water softener, in manufacture of caustic soda and chlorine, polymers, stabilizers
Fluoride	1.2	Welding fluxes
Nitrate	87	Optical glass, ceramic glazes, fireworks (green), explosives, antiseptic preparation
Oxide	34.8	In glass, ceramics, refining oils and sugar, as an additive in petroleum products and also as materials of plastics, pharmaceuticals, polymers, glass, and enamel industries
Stypnate	—	Propellant used in manufacture of explosive detonators

Sulfide	Slightly soluble in H <sub>2</sub> O	Depilatories, manufacture of fluorescent tubes

(pulmonary embolism), overwhelming sepsis, or barium toxicity.<sup>7,32,37</sup> In at least one case report of intravasation, signs and symptoms were consistent with barium toxicity and elevated barium concentrations were confirmed.<sup>24</sup> Under these circumstances if hypokalemia is present, then barium toxicity can be assumed.

Additionally, intravenous administration of barium sulfate has occurred as the result of unintentional administration. Recognition followed by aspiration through a central venous catheter was associated with a good outcome.<sup>30</sup>

## PATHOPHYSIOLOGY

Hypokalemia is due to redistribution of potassium from the extracellular to intracellular compartment. This is thought to be due to 2 synergistic mechanisms. Barium inhibits calcium-activated potassium rectifier channels, reducing outward flow of potassium; this occurs in the context of persistent  $\text{Na}^+$ ,  $\text{K}^+$ -ATPase pump electrogenesis leading to a shift of extracellular potassium into the cell.<sup>3</sup>

Intracellular trapping of potassium leads to depolarization and paralysis.<sup>18</sup> Additionally, the inhibition of potassium channels increases vascular resistance and reduces blood flow<sup>4,6</sup> and is the likely mechanism for hypertension and metabolic acidosis with an elevated lactate concentration.

Although severe hypokalemia contributes significantly to paralysis, some authors report that muscle weakness correlates better with barium concentrations than with potassium concentrations.<sup>25,33</sup> This suggests a possible direct effect of barium on either skeletal muscle or neuromuscular transmission.

## CLINICAL MANIFESTATIONS

Abdominal pain, nausea, vomiting, and diarrhea commonly occur within 2 hours of ingestion.<sup>13</sup> Esophageal injury and hemorrhagic gastritis are also reported.<sup>1,18</sup>

Severe hypokalemia is the cardinal feature of barium toxicity and typically occurs within 2 hours following oral or parenteral exposure. Hypokalemia is exacerbated by blood transfusions, suggesting that fresh red blood cells provide a new reservoir for  $\text{K}^+$  sequestration.<sup>15</sup> Progressive hypokalemia is associated with ventricular dysrhythmias, hypotension, profound flaccid muscle weakness, and respiratory failure (Chaps. 12, 15, and 22).<sup>3</sup>

Other effects less commonly reported include hypertension, metabolic acidosis with an elevated lactate concentration, hypophosphatemia, and rhabdomyolysis.<sup>16</sup> Altered level of consciousness, seizures,<sup>8</sup> and parkinsonism with findings on magnetic resonance imaging of bilateral hyperintensity of the basal ganglia are reported.<sup>12</sup> It is unclear whether these latter findings are due to direct toxicity, deposition of barium, or secondary to tissue ischemia.

## DIAGNOSTIC TESTING

Barium can be measured by a variety of techniques. Mass spectrometry and graphite furnace atomic absorption spectrometry can quantitatively measure barium in blood and urine.<sup>18,20</sup> Serum barium concentrations are not readily available, but values greater than 0.2 mg/L are considered abnormal.<sup>5</sup>

Following acute exposures, patients should have serum electrolytes (particularly potassium and phosphate) measured hourly while performing continuous electrocardiographic monitoring. Creatine phosphokinase (CK), acid-base status, and kidney function should also be measured. In one case, abdominal radiography showed barium, but the sensitivity and specificity of radiography for barium poisoning is unknown.<sup>18</sup>

## MANAGEMENT

Toxicologic etiologies for flaccid paralysis such as hypermagnesemia, botulism, and the administration of neuromuscular blockers should be evaluated while the serum potassium concentration is being determined. Once the hypokalemia is diagnosed, other causes of acute hypokalemia (Chap. 12) associated with paralysis such as periodic hypokalemic paralysis, toluene toxicity, and diuretic use are included in the differential diagnosis if there is no history or laboratory confirmation of barium exposure.

Patients who are asymptomatic at 6 hours following ingestion with normal potassium concentrations can be discharged. Patients with signs

or symptoms of toxicity should be admitted to an intensive care unit with expectant management of respiratory compromise and cardiovascular instability.

## DECONTAMINATION

Activated charcoal is unlikely to be effective. Orogastric lavage is reasonable in patients who present early after ingestion, but lavage is unlikely to provide substantial benefit in patients who are already symptomatic or who have had spontaneous emesis. Oral sodium sulfate administration theoretically prevents absorption by precipitating unabsorbed barium ions as insoluble, nontoxic barium sulfate. Oral magnesium sulfate has had similar efficacy.<sup>21</sup> Early administration of oral magnesium sulfate is a reasonable intervention; the dose is 250 mg/kg for children and 30 g for adults.<sup>23</sup> Intravenous magnesium sulfate or sodium sulfate is not recommended because of its potential to produce acute kidney injury due to precipitation of barium in the renal tubules.<sup>25,36</sup>

Patients in respiratory failure should receive assisted ventilation. Expedient correction of hypokalemia is important to minimize the risk or to treat cardiac dysrhythmias. It should be anticipated that large doses of potassium replacement (400 mEq in 24 hours) will be required to correct serum potassium although as noted above repletion of potassium alone may be inadequate to improve the resting membrane potential or muscle strength<sup>18</sup> (Chap. 12). As hypokalemia is due to intracellular sequestration of potassium, potassium supplementation increases the total body potassium load. In this situation, rebound hyperkalemia should be expected when barium is eliminated, especially in patients with acute or chronic kidney disease. Observation and serial evaluation for this clinical complication is essential.

## Elimination Enhancement

If hypokalemia is unable to be corrected or if the correction of hypokalemia does not restore normal motor function and muscle strength, hemodialysis is recommended. Case reports suggest that hemodialysis for the management of severe barium toxicity is associated with rapid clinical improvement.<sup>2,28,31,35</sup> Additionally, in a case report, continuous veno-venous hemodiafiltration provided a clinically significant increase in measured barium elimination, stabilized serum potassium concentrations, and was associated with rapidly improved motor strength.<sup>18</sup>

## Management of Intravasation

Following intravasation of oral barium sulfate patients should be admitted to an intensive care unit. Expectant management should include evaluation of intraabdominal sepsis, hemorrhage and trauma, pulmonary embolus, and barium toxicity.<sup>22</sup> Prophylactic antibiotics use appears reasonable and serial determinations of serum potassium concentrations are warranted. Computed tomography scanning of the chest and abdomen can demonstrate both the location and extent of the barium sulfate administered.<sup>32</sup>

## SUMMARY

- Although poisoning by barium salts is rare, these salts are widely used in industry and therefore represent a substantial risk for human exposure.
- The hallmark of barium salt toxicity is rapidly developing and severe hypokalemia with attendant weakness progressing to paralysis.
- In addition to supportive care, the mainstay of treatment is rapid correction of hypokalemia.
- Hypokalemia results from an intracellular shift of potassium. As toxicity resolves and potassium redistributes into the extracellular space, cautious evaluation for the development of hyperkalemia is essential.
- Extracorporeal therapies are reasonable in cases of refractory hypokalemia.

### HISTORY AND EPIDEMIOLOGY

The proper use of pesticides has a beneficial role in human health by increasing the quality and quantity of crops. Alternatively, acute and chronic pesticide poisoning are significant causes of morbidity and mortality worldwide, especially in developing countries, making pesticide poisoning a global public health problem.<sup>78,191</sup>

Fumigants are nonspecific pesticides applied to kill and control rodents, nematodes, insects, weed seeds, and fungi anywhere in soil, in structures, crops, grains, and commodities.<sup>37</sup> They represent a diverse group of pesticides that are dissimilar in their chemical structures, physical properties, and mechanisms of toxicity (Tables 108–1 and 108–2). Many fumigants, particularly the halogenated solvents, have been largely abandoned because of their toxicity. In the 1987 Montreal Protocol, an international agreement was adopted to phase out ozone-depleting chemicals, such as methyl bromide, which was scheduled to be discontinued in 2005. Unfortunately, many agricultural companies received exemptions, as satisfactory substitutes for some of methyl bromide uses have not emerged.

Because fumigants exist as solids that release toxic gases on reacting with water (zinc phosphide, aluminum phosphide) or with acids (sodium or calcium cyanide), as liquids (ethylene dibromide, dibromochloropropane, formaldehyde) that can vaporize at ambient temperature, or as gases (methyl bromide, hydrogen cyanide, ethylene oxide), inhalation is the most common route of exposure (Table 108–1). In their gaseous forms, fumigants are generally heavier than air and will be found concentrated just above the ground surface and lower floors of buildings.

Their exposure risk is enhanced by their general lack of warning properties, non-species-selective effects, and high potency. Although xenobiotics from many different chemical classes were used in the past as fumigants, only a few remain in use today in the United States. This chapter summarizes the remaining US fumigants and also highlights important fumigants that are in use in developing countries.

### METAL PHOSPHIDES AND PHOSPHINE

#### Introduction

In addition to the organic phosphorus and organic chlorine compounds, metal phosphides (aluminum, zinc, magnesium, and calcium) have been used as rodenticides and fumigants around the world for many years. The metal phosphides are advantageous because of their low cost, high effectiveness in destroying harmful insects and rodents, freedom from toxic residue, and lack of adverse effects on seed viability. Metal phosphides are used to protect grain held in silos, in the holds of ships, and during transportation by rail. They are generally admixed with the grain at a predetermined

rate at the initiation of storage.<sup>163</sup> Following exposure to ambient moisture, the metal phosphides release phosphine gas (PH<sub>3</sub>). Exposure to water results in rapid release, highlighting the concern for their use as chemical weapons.<sup>25</sup> Phosphine gas itself is also used in the synthesis of flame retardants, organic phosphorus compounds, pharmaceuticals, and in the production of semiconductors.<sup>170</sup>

#### History and Epidemiology

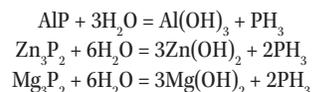

Over the last decades, cases of PH<sub>3</sub> and metal phosphide poisonings have escalated, carrying a high mortality rate, likely related to the use of these chemicals for suicides.<sup>42,64,93,98,131,179,190,197</sup> Unintentional poisoning as a result of negligence or ignorance are also reported.<sup>54,120,160,172</sup> Aluminum phosphide (ALP) poisoning is one of the commonest causes of poisoning both in adults and children in agricultural societies and developing countries, such as India, Sri Lanka, and Iran.<sup>68,72,110,148,173,177</sup> The incidence of ALP poisoning is low in developed countries;<sup>155,160</sup> however, PH<sub>3</sub> poisoning has increased in frequency as it is a by-product of the use of red phosphorus in the synthesis of methamphetamines.<sup>33,215</sup>

#### Physicochemical Properties

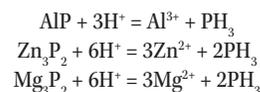

Commercially, ALP (molecular weight of 57.95 Da) is most widely available as a greenish-gray tablet or pellet bag and granular form that has a garlic odor. The 3-g tablet usually contains ALP (56%), ammonium carbamate, and urea, which liberates PH<sub>3</sub> (up to 1 g), ammonia, and carbon dioxide. Each pellet (0.6 g) releases 0.2 g PH<sub>3</sub>.

Zinc phosphide (Zn<sub>3</sub>P<sub>2</sub>; molecular weight of 258.1 Da) is available as a dark-gray powder or as quadrilateral crystals that have an odor of acetylene or rotten fish. Calcium phosphide (Ca<sub>3</sub>P<sub>2</sub>; molecular weight of 182.2 Da) is available as a reddish-brown crystal powder. Magnesium phosphide (Mg<sub>3</sub>P<sub>2</sub>; molecular weight of 134.8 Da) is a white crystalline solid.<sup>15,143</sup>

In the presence of moisture or acid, metal phosphides are converted to PH<sub>3</sub> (hydrogen phosphide, phosphorus trihydride, molecular weight of 34 Da):

or

The release of PH<sub>3</sub> is even more vigorous after contact with an aqueous acid, such as hydrochloric acid. The residue, Al(OH)<sub>3</sub>, is nontoxic.<sup>15,170</sup> Phosphine gas is flammable, and other by-products of commercial tablets (diphosphine gas) are spontaneously flammable in air concentrations above the lower explosive limit (LEL) of 1.8% v/v.<sup>100,130,175,201,214,216</sup> In aqueous solutions, PH<sub>3</sub> produces phosphinic, phosphonic and phosphoric acids, which are all corrosive and produce exothermic reactions.<sup>130,170</sup>

Although PH<sub>3</sub> is colorless and odorless in pure form up to toxic concentrations (200 parts per million {ppm}), the presence of substituted phosphines and diphosphines imparts a decaying fish or garlic odor that is detectable at concentrations of as little as 2 ppm.<sup>159,163,170</sup>

#### Toxicokinetics

Following ingestion—the most common route of exposure—metal phosphides react with acidic fluid in the gastrointestinal (GI) tract to release PH<sub>3</sub>,

**TABLE 108–1** Physical Properties and Industrial Uses of Fumigants

Fumigant	Color	State	Flammability	Odor	Use
Phosphine	Colorless	Gas	High	Rotten fish Garlic	Rodenticide
Methyl bromide	Colorless	Gas	No	None at low concentrations. Sweet chloroformlike at high concentrations	Soil Structural Crop
Dichloropropene	Yellow	Liquid	No	Garlic	Soil
Sulfuryl fluoride	Colorless	Gas	No	None	Structural

TABLE 108-2 Comparison of Clinical Effects of Fumigants

Fumigant	Mucous Membrane Irritation	Dermatitis	Burns (Frostbite)	Gastrointestinal: Nausea, Vomiting, Abdominal Pain	Hepatic Dysfunction	Chest Pain	Adult Respiratory Distress Syndrome	Nephrotoxicity	Hypotension	Dysrhythmias	Mental Status Changes
Phosphine	++	–	–	+	+	+	+	+	++	+	+
Methyl bromide	± High concentration	+	+	+	+	+	+	+	+	+	+
Dichloropropene	+	+	–	+	+	+	+	+	+	+	+
Sulfuryl fluoride	± High concentration	+	+	+	–	–	+	+	++	–	+

– = Absent; + = Present; ++ = Very substantial; ± = Variable.

which is rapidly absorbed. Metal phosphides may be absorbed as microscopic particles of unhydrolyzed salt and subsequently converted to  $\text{PH}_3$ . Phosphine gas is also absorbed from respiratory tract mucosa if inhaled. Dermal absorption is insignificant.<sup>15</sup>

There are no data about distribution of  $\text{PH}_3$  in humans, but it would be expected that as a small soluble molecule  $\text{PH}_3$  is widely distributed.<sup>15,163</sup> Its half-life ranges from 5 to 24 hours based on various factors.<sup>209</sup> Phosphine gas is detectable in the blood of severely poisoned patients and is also found in the kidney, brain, and liver of decedents following ingestion.<sup>11,49</sup> In vitro studies demonstrated that  $\text{PH}_3$  interacts irreversibly with free hemoglobin and hemoglobin in intact erythrocytes (rat and human) that results in the production of Heinz bodies and hemichromes, which are methemoglobin derivatives.<sup>40,161</sup> Rare clinical presentations such as intravascular hemolysis and methemoglobinemia support the involvement of erythrocytes in the biotransformation of  $\text{PH}_3$  in humans.<sup>163</sup>

Phosphate, hypophosphite, and phosphite are identified in the urine, whereas  $\text{PH}_3$  itself is exhaled.<sup>81,163</sup>

### Toxicodynamics

The toxicity of metal phosphides is due to  $\text{PH}_3$  release. Phosphine gas is a protoplasmic toxin. The mechanisms of toxicity include blocking the electron transport chain and oxidative phosphorylation through noncompetitive inhibition of cytochrome-c oxidase.<sup>9,182</sup> Phosphine gas decreases the activities of mitochondrial complexes I, II, IV, V. This inhibits cellular respiration and ATP production and leads to the formation of highly reactive hydroxyl radicals that cause additional damage.<sup>10,26,59,60,102,170,182,185</sup> Phosphine gas also inhibits catalase, induces superoxide dismutase, and reduces the glutathione (GSH) concentration. All of these effects combine to result in lipid peroxidation, protein denaturation of cell membranes, and DNA damage, leading to widespread cellular damage and ion channel dysfunction.<sup>10,47,48,50,60,82,94,102,109,170,185,200,203</sup>

Because  $\text{PH}_3$  is corrosive, it directly injures the alveolar capillary membrane in addition to producing oxidative injury, leading to an acute respiratory distress syndrome (ARDS).<sup>81,179</sup> Although both AIP and  $\text{PH}_3$  inhibit cholinesterase activity, this effect is unlikely to have substantial clinical relevance.<sup>6,127,128,142,162</sup>

### Toxic Dose

Ingestion of 1 g of zinc phosphide can cause toxicity in humans, and death is reported after ingestion of 4 g. Ingestion of 500 mg of AIP can be fatal.<sup>16</sup> The recommended exposure limit (REL) of  $\text{PH}_3$  in the workplace is less than 0.3 ppm as a time-weighted average (TWA) for up to 10 hours per day during a 40-hour work week, and 1 ppm as a 15-minute short-term exposure limit (STEL) that should not be exceeded at any time during a workday. The National Institute of Occupational Safety and Health established 50 ppm as the concentration that is immediately dangerous to life or health (IDLH) for  $\text{PH}_3$ .<sup>153,196</sup> Workplace standards are not available for AIP specifically.<sup>196</sup>

### Clinical Manifestations

The smell of garlic or decaying fish on the breath is a common finding and results from oral or inhalational poisoning with metal phosphides and  $\text{PH}_3$ .<sup>160</sup> The clinical manifestations are dependent on the dose, route of entry, and time since exposure.<sup>81</sup> After ingestion, the onset of toxicity usually is slightly more rapid for AIP (10–15 minutes) than for zinc phosphide (20–40 minutes).<sup>80,108</sup> In patients with mild poisoning, nausea, repeated vomiting, thirst, diarrhea, abdominal discomfort or pain, especially epigastric pain, and tachycardia are common clinical manifestations. In those with moderate to severe effects, palpitations, tachypnea, GI manifestations, dysrhythmias, ARDS, hypotension, shock, and cardiovascular collapse, occur rapidly.<sup>72,93,98,106,109,110,131,146,163,177,197</sup>

Restlessness, anxiety, dizziness, ataxia, numbness, paresthesias, and tremor are universally observed, but central nervous system (CNS) manifestations are not prominent until a secondary event, such as hypoxia occurs.<sup>93,110,197</sup> Late and severe neurologic findings include delirium, convulsions, ischemic/hemorrhagic stroke and coma.<sup>1,27,55</sup>

Following limited  $\text{PH}_3$  inhalational exposure, patients commonly have airway irritation and breathlessness.<sup>170</sup> Other features include chest tightness, tachycardia, headache, nausea, vomiting, diarrhea, numbness, muscle weakness, and diplopia.<sup>72,80,196</sup>

Uncommon complications of metal phosphides and  $\text{PH}_3$  poisoning include gastroenteritis, hepatitis,<sup>51</sup> ascites,<sup>22</sup> pancreatitis,<sup>211</sup> myocardial infarction,<sup>104,111</sup> acute pericarditis,<sup>44</sup> pleural effusion,<sup>67,198</sup> rhabdomyolysis,<sup>163</sup> acute tubular necrosis, adrenocortical congestion, hemorrhage and/or necrosis,<sup>12</sup> and delayed esophageal stricture or tracheoesophageal fistulas.<sup>23,105,113,123,152,210</sup>

Liver and kidney failure, as well as disseminated intravascular coagulation (DIC), are also rarely reported following acute poisoning.<sup>22,54,72,163,196</sup>

### Diagnostic Testing

Initial investigations should include electrocardiography (ECG) and continuous cardiac monitoring, chest radiograph, blood glucose, blood gases, serum electrolytes, complete blood count (CBC), liver, and kidney function studies.

Hypokalemia is common after oral poisoning.<sup>98,131,163</sup> Magnesium concentrations are reported as normal, increased, or decreased.<sup>10,41,43,45,46,180,181,183,197</sup> Hypoglycemia as a result of impaired gluconeogenesis, glycogenolysis, and possibly due to adrenal insufficiency is common and at times severe and persistent.<sup>52,66,107,137</sup> Hyperglycemia and metabolic acidosis are also reported.<sup>93,134,135,177,197</sup> Hemolysis, methemoglobinemia, leukopenia, and hyperbilirubinemia are unusual complications of metal phosphides poisonings.<sup>112,116,146,156,170,176,188,193</sup>

Electrocardiographic abnormalities are very common, but highly variable, and include rhythm disturbances, ST segment and T wave changes, QRS complex widening, and conduction defects that revert to a normal pattern within several days.<sup>43,103,170,179,189</sup> During the first 3 to 6 hours after poisoning,

sinus tachycardia is predominant, followed over the next 6 to 12 hours by ST segment and T wave changes, conduction disturbances, and dysrhythmias.<sup>187</sup> Ventricular tachycardia, ventricular fibrillation, supraventricular tachycardia, and atrial flutter/fibrillation are the most common consequential dysrhythmias.<sup>184</sup> Echocardiography typically reveals cardiac dysfunction, dilation, and hypokinesia or akinesia of the left ventricle that typically resolves over several days.<sup>5,24,25,79</sup>

Chest radiography shows diffuse infiltration, pulmonary edema, ARDS, and atelectasis.<sup>143,170</sup> As aluminum and  $\text{PH}_3$  both inhibit cholinesterase,<sup>6,127,128,162</sup> measurement of cholinesterase activity in the presence of cholinergic findings is recommended.<sup>110</sup>

### Toxicological Analyses

Chemical analysis for  $\text{PH}_3$  in blood or urine is not recommended and is not typically helpful as  $\text{PH}_3$  is rapidly oxidized to phosphite and hypophosphite.<sup>15,81,163</sup> The presence of  $\text{PH}_3$  is suggested by a positive silver nitrate test on gastric contents or exhaled breath. In this test, which is a simple and sensitive method to detect  $\text{PH}_3$ , paper impregnated with silver nitrate will turn black (silver phosphide) in the presence of  $\text{PH}_3$ .<sup>141</sup> The detection limit of the test is 0.05 ppm for  $\text{PH}_3$ .

The ammonium molybdate test is another chemical method that is used for the qualitative or quantitative analysis of phosphorus,  $\text{PH}_3$ , and phosphides in the stomach contents and postmortem samples. Formation of canary yellow precipitates confirms the presence of  $\text{PH}_3$  or phosphides.<sup>65,114</sup>

Headspace gas chromatographic with a nitrogen-phosphorous detector (HS-GC/NPD) is a specific and sensitive test for  $\text{PH}_3$  or phosphides.<sup>149</sup> Headspace gas chromatography coupled with mass spectrometry (HS-GC-MS) was described for the analysis of the  $\text{PH}_3$  metabolites in biological samples. The detection limit of this method for  $\text{PH}_3$  is 0.2 mcg/mL.<sup>217</sup> Unfortunately, none of these tests are available in a time frame to permit their clinical utility.

### Prognosis

The mortality rate following ingestion of metal phosphides is reportedly 31% to 77%.<sup>41-43,63,98,109,121,131,174,177,197</sup> Most of the deaths occur within 12 to 24 hours and are due to cardiovascular collapse.<sup>8,189</sup> After 24 hours, most of the deaths are due to refractory shock, severe acidemia, and ARDS.<sup>213</sup> Fulminant hepatic failure develops within 72 hours after poisoning and is another cause of delayed death.<sup>12</sup>

In some studies of acute AIP poisoning, vomiting after ingestion was significantly more common in survivors. Nonsurvivors ingested significantly higher doses of AIP and had greater delays from exposure to treatment initiation. In nonsurvivors blood pressure and level of consciousness were significantly altered on admission.<sup>93,173,177,197</sup> The Acute Physiology and Chronic Health Evaluation (APACHE) Score and Simplified Acute Physiology Score (SAPS) are significantly higher in nonsurvivors than survivors.<sup>98,131,174</sup>

Metabolic acidosis with an elevated lactate concentration is an index of severity of AIP poisoning. It was demonstrated that there is significant correlation between blood lactate concentration and time of death in the nonsurvivors. Also, derived from this study, the line of best fit connecting the blood lactate concentration of 5.4 mmol/L at 4 hours and 2.8 mmol/L at 24 hours post ingestion was used to predict the likelihood of death.<sup>63</sup>

### Treatment

The victim should immediately be removed from the area of exposure to fresh air, and supplemental oxygen should be provided as needed.<sup>81,163</sup> Clinical staff and other health care professionals should use universal precautions, including gloves, goggles, N95 respirators and other PPE as indicated (Special Considerations: SC2),<sup>141</sup> with the understanding that a particulate mask will not protect against  $\text{PH}_3$ . Staff should also be aware of the risk for spontaneous ignition.<sup>175,214</sup> As  $\text{PH}_3$  is absorbed cutaneously, the patient's clothes should be removed and the skin and eyes decontaminated with water as early as possible.<sup>72</sup>

In oral exposure, gastric emptying is reasonable if it is done within a few hours of ingestion and significant emesis has not already occurred (Chap. 5). The acidic content of stomach facilitates the conversion of metal phosphides

to  $\text{PH}_3$ . As a result, some authors suggest the oral administration of sodium bicarbonate (88 mEq), but this is not supported by clinical trials, and therefore not recommended at this time.<sup>4,81,82,84,93,110,124,200</sup> Potassium permanganate ( $\text{KMnO}_4$ ) (1:10,000) was used as an adjunct to gastric lavage to oxidize  $\text{PH}_3$  to nontoxic phosphate.<sup>4,82,84,93,124,158,197,200</sup> Neither this approach nor the use of boric acid<sup>186</sup> is recommended because of multiple associated risks and no proven benefit.<sup>140</sup>

There is limited evidence that activated charcoal (AC) (Chap. 5 and Antidotes in Depth: A1) fails to reduce GI absorption even if administered rapidly following ingestion.<sup>84,93,110</sup> Its use is therefore not routinely recommended.<sup>124</sup>

In vitro studies suggest that lipid, mainly vegetable oils and liquid paraffin, inhibit  $\text{PH}_3$  release from the ingested AIP.<sup>4,76,93,165,171,187</sup> Unfortunately, aspiration is a significant risk with oil ingestion and these data are too premature to recommend the routine use of oils at this time.

Management should be rapidly initiated based on a history and clinical examination that support metal phosphides or  $\text{PH}_3$  poisoning, and should not be delayed for a confirmatory diagnosis.<sup>81</sup> Standard supportive care to address ventilatory and vital sign abnormalities should be administered. If necessary, norepinephrine or phenylephrine are recommended.<sup>81,84</sup>

As there is no known specific antidote, management remains primarily intensive monitoring and supportive treatment, to allow sufficient time for the poison to be eliminated. Hypoglycemia, hypokalemia, and ARDS, should be managed conventionally.<sup>81,84,163</sup> Aggressive correction of severe acidemia in acute AIP poisoning with IV sodium bicarbonate theoretically improves the outcome,<sup>84,106,125</sup> and is reasonable as long as the sodium load can be tolerated.

In view of the role of oxidative stress in toxicity from metal phosphides or  $\text{PH}_3$ , antioxidants such as *N*-acetylcysteine (NAC), vitamin C, vitamin E, magnesium, melatonin, and methylene blue were investigated both in experimental and clinical studies.<sup>38,50</sup>

The beneficial effects of NAC in animal studies are variable.<sup>13,71</sup> In a human study, NAC administration at a dose of 140 mg/kg IV infusion as a loading dose and 70 mg/kg IV infusion every 4 hours up to 17 doses significantly decreased the plasma malondialdehyde (MDA) concentration as a biomarker of lipid peroxidation, the duration of hospitalization, and rate of intubation. In that study, the mortality rate in NAC treatment and control groups were 36% and 60%, respectively.<sup>200</sup> In another clinical study, NAC administration significantly decreased the mortality rate and increased the duration of survival in fatal cases in the treatment group.<sup>3</sup> For these reasons, we recommend the utilization of NAC at these doses (Antidotes in Depth: A3).

Administration of vitamin E (alpha tocopherol) at a dose of 400 mg IM, every 12 hours for 72 hours in a human study, significantly decreased the plasma MDA concentration and the necessity for, and duration of, intubation and mechanical ventilation. This treatment also significantly decreased the mortality rate from 50% in control group to 15% in treatment group.<sup>82</sup> Given these encouraging results and limited safety concerns, it is reasonable to administer vitamin E in cases of life-threatening toxicity, if it is available.

In a limited study, the use of oral liothyronine with a dose of 50 mcg in the first 6 hours of poisoning as an adjuvant therapy in acute AIP poisoning was suggested to decrease lipid peroxidation and improve systolic blood pressure and arterial blood pH.<sup>73</sup> There is inadequate evidence to recommend routine utilization at this time.

The use of magnesium sulfate ( $\text{MgSO}_4$ ) in metal phosphides or  $\text{PH}_3$  poisoning remains controversial and unsubstantiated.<sup>81,163,183</sup> Because of the low risk of the use of  $\text{MgSO}_4$  in metal phosphides or  $\text{PH}_3$  poisoning and the recent study showing its usefulness,<sup>177</sup> it is reasonable to utilize  $\text{MgSO}_4$  utilization at standard intravenous doses.<sup>84</sup> Dysrhythmias should be treated with standard antidysrhythmics.<sup>84,102,136,166</sup>

The benefit of highdose insulin (HDI) treatment (Antidotes in Depth: A21) is suggested by preliminary investigations in that insulin promotes energy production from carbohydrates, restores calcium flux, and improves myocardial contractility.<sup>85</sup> There is inadequate evidence to routinely recommend this intervention; however, in cases of refractory shock, a trial of HDI is reasonable.

The use of an intraaortic balloon pump in circulatory failure due to acute AIP poisoning is reported.<sup>21,61,138,178</sup> It is only recommended following failure of all other procedures.

Clinical studies showed the beneficial effects of venoarterial extracorporeal membrane oxygenation (VA-ECMO) with regard to improvement of short-term survival patients with acute AIP poisoning. If available, VA-ECMO is recommended in the management of a subset of acute AIP-poisoned patients with severe left ventricular dysfunction (LV ejection fraction  $\leq 35\%$ ), refractory cardiogenic shock, and severe acidemia (pH  $\leq 7$ ) who do not respond to conventional treatment.<sup>61,86,139,144,145</sup>

One study reported the beneficial effect of IV administration of lipid emulsion (20%) at a dose of 10 mL/hour in 2 cases with AIP poisoning.<sup>19</sup> Given the lack of beneficial evidence for intravenous lipid emulsion (ILE) in oral overdoses, its complication rate, and its ability to interfere with ECMO, we recommend not to use ILE in this setting unless there are no other options in cardiac resuscitation available (Antidotes in Depth: A23). High-dose L-carnitine (1 g 3 times a day for 10 days) was given as an essential cofactor in fatty acid metabolism.<sup>61</sup>

Because the experimental and clinical evidence shows that both PH<sub>3</sub> and aluminum inhibit acetylcholinesterase,<sup>6,127,128,162</sup> atropine and pralidoxime have theoretical roles in management.<sup>110</sup> Further studies are recommended to confirm usefulness of oximes.<sup>142</sup> Neither atropine nor oximes are routinely recommended at this time.

In another experimental study, the protective role of iron sucrose as an electron receiver was shown potentially be a competitor with mitochondrial respiratory chain complexes.<sup>185</sup> Once again these data are too preliminary to recommend the use of this approach.

Experimental data suggest that hyperbaric oxygenation (HBO) improves the survival time of poisoned rats, with no change in the mortality rate.<sup>164</sup> There is inadequate evidence to recommend the use of HBO for this toxin.

Hemodialysis is not very effective in removing PH<sub>3</sub><sup>83,151</sup> but is recommended in patients with acute kidney failure, severe metabolic acidemia, or fluid overload.<sup>61,81</sup>

The sole recognized approach remains intensive care monitoring and supportive treatment.

## METHYL BROMIDE

### History and Epidemiology

Methyl bromide was used as an anesthetic in the early 1900s, but fatalities halted this practice. Today, methyl bromide is used widely as a fumigant for all types of dry food stuffs, in grain elevators, mills, ships, warehouses, greenhouses, and food-processing facilities for the control of nematodes, fungi, and weeds. It is also used as an insecticide, fire extinguisher, and refrigerant, although its domestic use was banned in 1987. Methyl bromide is also used as a methylating chemical in manufacturing and as a low-boiling solvent for extracting oils from nuts, seeds, and flowers. It is termed a structural or commodity fumigant, which is a class term from the Environmental Protection Agency.

Historically, poisonings involving the general public were mainly associated with the methyl bromide used in fire extinguishers. Other poisoning involved unauthorized entry into buildings being fumigated with methyl bromide.<sup>20,87,117</sup>

Occupational and environmental exposures to methyl bromide as a fumigant are most common. Hazardous materials incidents are reported for methyl bromide, during manufacture or as a result of use and transport,<sup>28,32,69</sup> but they are relatively uncommon in plant employees or residents living adjacent to agricultural fields where methyl bromide is applied.<sup>32,36</sup> Before 1955, the majority of methyl bromide poisonings resulted from chemical manufacture and filling operations. Since then, fumigation has become the major source of fatalities and fumigators, and greenhouse workers are the highest-risk group. In many countries, the use of methyl bromide is restricted to trained and licensed personnel.<sup>62</sup>

Methyl bromide has a threshold limit value–time weighted average (TLV-TWA) of 5 ppm and the IDLH concentration is 2,000 ppm. The Occupational Safety and Health Administration (OSHA) permissible exposure limit is 20 ppm.

Methyl bromide (CH<sub>3</sub>Br) is a halogenated aliphatic hydrocarbon. It is a colorless gas at room temperature and standard pressure.<sup>34</sup> It is 3 times heavier than air. It is odorless except at high concentrations, when it has a burning taste and sweet, chloroformlike smell. Commercially, it is available as a liquefied gas. Some formulations also contain chloropicrin or amyl acetate as a warning agent.

### Toxicokinetics

Inhalation is the primary route of exposure, although methyl bromide is rapidly absorbed through the dermal and oral routes. After absorption, methyl bromide or metabolites are rapidly distributed to many tissues, including the lungs, adrenals, kidneys, liver, brain, testis, and fat. The major organs of distribution observed immediately after exposure includes fat, lungs, liver, adrenals, and kidneys.

The metabolism of methyl bromide is not completely elucidated. Methyl bromide is partially converted to inorganic bromide in man and bromide concentrations in blood and target organs increase after exposure to methyl bromide.<sup>20,36</sup> It is metabolized to methyl glutathione by the enzyme glutathione *S*-transferase (GST) and is then converted into the neurotoxic metabolites of methanethiol and formaldehyde.<sup>119</sup>

Depending on the route of exposure, 16% to 40% is eliminated as metabolized methyl bromide in the urine and only 4% to 20% is eliminated in the expired air as parent compound. Biliary excretion accounts for about 46% of the elimination, generally within 24 hours following oral exposure.<sup>7,132,133</sup> Methyl bromide is hydrolyzed and produces methanol and hydrobromic acid in animal models.

### Toxicodynamics

The mode of action of methyl bromide is still not understood. Several mechanisms of toxicity are postulated, including the direct cytotoxic effect of the intact methyl bromide molecule or toxicity due to one of its metabolites.

Methyl bromide is a potent alkylating agent with high affinity for sulfhydryl and amino groups. It reacts in vitro with a number of sulfhydryl-containing enzymes and causes irreversible inhibition of microsomal metabolism.<sup>20,75,192</sup> It binds to amine groups in amino acids, interfering with protein synthesis and function. Also it may methylate many other cellular components such as GSH, proteins, DNA, and RNA.<sup>31,194</sup> The methanethiol and formaldehyde metabolites may have a role in neurologic and visual changes. The bromide ion concentrations are insufficient to explain methyl bromide toxicity.

### Clinical Manifestations

Inhalation of more than 10,000 ppm for more than a few minutes is sufficient to cause death.<sup>87</sup> Severe poisoning produces tremor, convulsion, rapid loss of consciousness, dysrhythmias, and death. Convulsions generally occur in fatal cases, but ARDS leading to respiratory failure or cardiovascular collapse is the leading cause of death. Pulmonary symptoms begin with cough or shortness of breath that rapidly progresses to bronchitis, pneumonitis, and ARDS.<sup>91</sup> In contrast, following low concentration exposure, a characteristic delay of up to 48 hours in the onset of manifestations is expected. Headache, dizziness, abdominal pain, nausea, vomiting, chest pain, and difficulty breathing are the manifestations of mild to moderate exposure. Some individuals initially manifest irritant symptoms of the eye, nasopharynx, and oropharynx, which are misdiagnosed as influenza or another viral illness. Visual disturbances such as blurred or double vision are also reported.<sup>39,74</sup>

The neurologic effects of methyl bromide poisoning are the most consequential and often occur without antecedent irritant effects. Initial CNS signs and symptoms that manifest in the first few hours after exposure include headache, dizziness, numbness, drowsiness, euphoria, confusion, diplopia, dysmetria, dysarthria, agitation and mood disorders, or inappropriate affect. Those findings progress rapidly in the first day or manifest over the next few days include ataxia, intention tremor, fasciculation, myoclonus, delirium, seizures, and coma.<sup>14,34,56-58</sup>

Methyl bromide also causes severe irritation, erythema, corrosive skin injury, blisters, and vesicles predominantly in moist areas or pressure points such as groin, axilla and wrist.<sup>92,218</sup> Liver and kidney damage are also described.<sup>20,87</sup>

Most patients who develop seizures or coma will not survive, and in those who survive, recovery typically takes months. Permanent sequelae such as neuropsychiatric impairment, ataxia, muscular weakness, irritability, blurred vision, myoclonus, and electroencephalographic (EEG) disturbances are frequent.<sup>30,204</sup>

### Diagnostic Testing

The standard laboratory evaluations such as CBC, serum electrolytes, blood urea nitrogen (BUN), creatinine, ammonia concentration, blood gases, urinalysis, hepatic enzymes, chest radiography, and ECG, should be obtained after an acute exposure.

Although a serum bromide concentration will help to confirm the diagnosis, it is not readily available in most laboratories. Furthermore, it does not always correlate with the severity of the exposure and does not facilitate clinical management. Serum bromide concentrations are reported to remain elevated for a week or more following an acute exposure.<sup>95</sup> Hemoglobin adducts are used as a biologic index for exposure to methyl bromide.<sup>101</sup> Hemoglobin adducts have a life span of about 2 months, so workers who even have only intermittent exposure to methyl bromide benefit from testing.

The findings on magnetic resonance imaging following methyl bromide toxicity are symmetric T2 signal abnormalities in posterior putamen, subthalamic nuclei, restiform bodies, vestibular nuclei, inferior colliculi, and periaqueductal gray matter and also symmetric involvement of inferior colliculi and periaqueductal gray, as well as dentate nuclei, dorsal pons, and inferior olives.<sup>70</sup>

### Treatment

The poisoned or exposed individual should be immediately removed from the area of exposure to fresh air. Rescue and decontamination should be performed only by personnel wearing personal protective equipment. In patients with respiratory and cardiac arrest, cardiopulmonary resuscitation should be initiated immediately when it is safe to perform. The clothing should be removed carefully, as methyl bromide adheres to clothing, including rubber and leather, and placed in plastic bags and disposed appropriately. The affected skin should be washed with soap and water. Decontamination includes irrigation of the eyes with copious amounts of 0.9% sodium chloride solution or water. It is also reasonable to administer at least one dose of oral AC following ingestion, although there is no supporting documentation for any benefit. Medical management should proceed as it would for any hazardous materials event (Chap. 132).

Management is primarily general and supportive care, and often requires intensive care unit management of coma, seizures, ARDS, and hepatic and kidney failure. Administer supplemental oxygen and treat bronchospasm, ARDS, and seizures. Seizures are common and difficult to control with traditional anticonvulsants such as benzodiazepines. Pentobarbital, high-dose thiopental, and propofol are required in many cases.<sup>95</sup> All exposed patients should be monitored for a minimum of 24 to 48 hours to detect delayed effects, especially ARDS.

Although dimercaprol was used for the treatment of methyl bromide poisoning, its effectiveness is only reported in less severely affected patients<sup>87</sup> and there is inadequate evidence to support the use of dimercaprol. The use of NAC is not studied in controlled prospective trials, but its effectiveness is reported in mild to moderate poisonings.<sup>95</sup> For this reason and the benignity of NAC, we recommend the utilization of NAC at standard doses.

There are no data indicating the benefit of alkalization or hemoperfusion. Hemodialysis can rapidly clear serum bromide, but tissue injury following exposure occurs as the bromide is released into the serum, suggesting that the methylation of neuronal proteins and neurologic injury has already occurred. Post hemodialysis, neurologic improvement is reported, but severe disabilities typically remain. Thus, there is inadequate evidence to support the use of hemodialysis.

## DICHLOROPROPENE

### History and Epidemiology

1,3-Dichloropropene is a volatile chlorinated aliphatic hydrocarbon that was introduced in 1945 and is primarily used as a soil fumigant for nematodes. Its use escalated after the restriction of ethylene dibromide, methyl bromide, and dibromochloropropane in 1956. The current formulation contains dichloropropene solubilized in soybean oil.<sup>205</sup>

Exposures are reported during production, application, and ingestion, most commonly in occupational settings where formulations are manufactured or applied. Unintentional releases during transport resulted in several poisonings.<sup>126</sup> The OSHA standard TLV-TWA for dermal exposure is 1 ppm.<sup>118</sup>

### Toxicokinetics

Dichloropropene is rapidly absorbed by the oral, inhalational, and dermal routes. Oral exposure is theoretically possible through contaminated groundwater, but this is not reported in humans. Inhalation is the primary route of human exposure and dichloropropene is rapidly absorbed from the lungs.<sup>29,207</sup>

No human data describe systemic distribution, but animal studies show that tissue concentrations after dichloropropene ingestion were highest in the stomach, followed by the blood, bone, brain, heart, kidneys, liver, bladder, skin, skeletal muscle, spleen, ovaries, testes, and fat.<sup>18</sup>

The metabolism of dichloropropene is similar to that of other chlorinated hydrocarbon solvents such as carbon tetrachloride and chloroform (Chap. 105). In humans, dichloropropene is metabolized in liver via oxidation in a phase I biotransformation,<sup>17,129,195</sup> which is catalyzed by CYP2E1<sup>77</sup> and then glutathione-dependent biotransformation.<sup>29,207,212</sup> Toxicity is proposed to result from metabolism via an electrophilic epoxide intermediate.<sup>208</sup> Most of the glutathione-conjugated form of dichloropropene is eliminated by the kidneys, and smaller amounts are eliminated in the feces.<sup>53,96,205</sup>

### Toxicodynamics

Human and animal health effects include damage to the liver, kidney, lung, CNS, myocardium, GI tract, skin, and mucous membranes. The exact mechanisms of toxicity are not clear, but data suggest that there is more than one mechanistic pathway in humans.

Glutathione depletion is documented in the rat model. The dose and route of dichloropropene correlated with toxicity and outcome in rodent models. At 100 mg/kg in mice, hepatotoxicity occurred by the intraperitoneal route, but not after oral gavage. At 700 mg/kg administered by the intraperitoneal route, hepatic failure and death resulted.<sup>17</sup> The higher dose correlated with a 130-fold increase in dichloropropene epoxide formation. Interestingly, in a rat hepatocyte model, pretreatment with the antioxidant,  $\alpha$ -tocopherol, prevented cell death.<sup>199</sup>

### Clinical Manifestations

Signs and symptoms of acute oral or inhalational exposure include nausea, vomiting, bloody diarrhea, pancreatitis, hepatotoxicity, tachycardia and hypotension,<sup>90</sup> dyspnea,<sup>97</sup> ARDS,<sup>90</sup> CNS depression,<sup>126</sup> acute kidney injury (acute tubular necrosis),<sup>90</sup> and muscle pain and weakness.<sup>126</sup> Coagulopathy and thrombocytopenia, hyperglycemia, severe metabolic acidosis,<sup>90</sup> and intravascular fluid depletion secondary to hemorrhage are reported. Dermal manifestations include contact hypersensitivity,<sup>87,205,206</sup> erythema,<sup>126</sup> and profuse sweating.<sup>90</sup> Mucous membrane irritation including erythema, edema, and irritation of the eyes, ears, nose, and throat occurs.<sup>126,205</sup> Concentrations above 1,000 ppm cause lacrimation.<sup>2</sup> Hematologic malignancies including lymphoma and histiocytic lymphoma were reported after prolonged (6 years) dichloropropene exposure.<sup>126</sup>

Radiographic abnormalities typically lag behind clinical signs. It may take up to 8 hours before abnormalities appear on chest radiography, even in symptomatic patients.<sup>90</sup>

Weight loss, hyperemia and superficial ulcerations of the nasal mucosa, inflammation of the pharynx, bleeding from swollen gums,<sup>126</sup> hepatic aminotransferase elevations, and kidney function abnormalities<sup>29</sup> are reported after chronic exposure to dichloropropene.

## Diagnostic Testing

Liver and kidney function should be monitored following acute poisoning.<sup>90</sup> No additional or specific tests are recommended beyond those needed for supportive care. Biomonitoring for exposure to dichloropropene is under development.<sup>29</sup> Hepatic gamma-glutamyl transpeptidase (GGT) concentrations are increased in fumigators, but the increase is not statistically significant. However, this finding suggests hepatic enzyme induction. In fumigators, erythrocyte GST and GSH concentrations decreased with increased serum creatinine concentrations and increased urine concentrations of albumin and retinol-binding protein when compared with controls.<sup>29</sup>

## Treatment

Because of the volatility of dichloropropene, caution should be used to avoid continued inhalational and dermal exposure for both the patient and the health care professionals. Symptomatic and supportive care should be provided as for methyl bromide. Following ingestion, oral AC is reasonable, but there is no proven value. Orogastric lavage is also reasonable in a patient presenting shortly following ingestion. Exposed eyes should be irrigated with copious amounts of water or 0.9% sodium chloride solution for at least 15 minutes, and exposed skin should be similarly washed with soap.<sup>115</sup>

There are no data to support specific therapies beyond supportive care, although the use of antioxidant therapy and NAC warrants further study. The patients should be monitored for at least 24 hours after exposure.

## SULFURYL FLUORIDE

### History and Epidemiology

Sulfuryl fluoride has been used since 1957 as a structural fumigant insecticide to control wood-boring insects such as termites in homes. Structure or tent fumigation is performed by completely enclosing a house or other structure in plastic or a tarpaulin, and then sulfuryl fluoride is pumped in as a compressed gas. Chloropicrin is typically added as a warning agent. Although sulfuryl fluoride is commonly used in Florida, California,<sup>147,157</sup> and Washington, a 5-year review of fumigant illness did not contain any reports of sulfuryl fluoride toxicity.<sup>32</sup>

### Toxicokinetics and Toxicodynamics

Sulfuryl fluoride gas is colorless, odorless, and heavier than air. The TLV-TWA for sulfuryl fluoride is 5 ppm; TLV-STEL is 10 ppm; IDLH is 200 ppm.<sup>154</sup>

Little is known about the toxicokinetics of sulfuryl fluoride in humans, and the exact mechanism of toxicity is not understood. The respiratory, central nervous, and cardiovascular systems are the primary target organ systems.<sup>168</sup> The measurable fluoride concentrations in patients with sulfuryl fluoride poisoning and the development of fluorosis in models of chronic, low-concentration exposures suggest that the release of fluoride is of major pathophysiologic consequence.<sup>157</sup> Fluoride complexes with calcium and magnesium, resulting in hypocalcemia and hypomagnesemia (Chap. 104).<sup>88</sup>

### Clinical Manifestations

Case reports of sulfuryl fluoride exposure describe acute and subacute clinical courses that share many similarities to methyl bromide poisoning. Initial manifestations, especially in limited exposures, include nausea, vomiting, diarrhea, abdominal pain, cough, and dyspnea. Irritation of mucosal surfaces produces salivation and nasopharyngitis, lacrimation, and conjunctival injection. Central nervous system manifestations include paresthesias, irritability, agitation, tetany, refractory seizures, and coma. Finally, fluoride toxicity results in profound shock, cardiac dysrhythmias, wide QRS complexes, prolongation of the QT interval, torsade de pointes, hyperkalemia, and ARDS (Chap. 104).<sup>157,167</sup>

Memory and dexterity testing were abnormal in structural fumigation workers exposed to both methyl bromide and sulfuryl fluoride.<sup>35</sup>

### Diagnostic Testing

Patients with sulfuryl fluoride exposure require monitoring of serum calcium, magnesium, and potassium concentrations. Patients should have an ECG performed and be attached to continuous cardiac monitoring to

observe for QRS complex widening, QT interval prolongation, and dysrhythmias. Serum fluoride concentrations, although not helpful for acute management, may help as a confirmatory diagnostic test.

## Treatment

In patients with inhalational exposure, after removal from the scene to fresh air, the patients should be partially disrobed to avoid further exposure to any liberated sulfuryl fluoride gas.

In treating sulfuryl fluoride poisoning, aggressive treatment of hypocalcemia with calcium gluconate or calcium chloride should be expected (Antidotes in Depth: A32). Similar to the management of methyl bromide, intensive care is often required for seizures, dysrhythmias, bronchospasm, and ARDS. As the fluoride ion is excreted in the urine, fluid resuscitation is recommended to maintain a steady urine output.<sup>202</sup>

## METHYL IODIDE

Iodomethane or methyl iodide is a monohalomethane and mainly used as a chemical reagent in the manufacturing of different pharmaceuticals and pesticides.<sup>89,169</sup> It is proposed as a fumigant to replace methyl bromide.

Human poisoning with methyl iodide is rare. Recently there are reports of dermal exposure with severe burns, respiratory insufficiency, and delayed neuropsychiatric sequel. Cerebellar and Parkinson findings followed by the development of cognitive impairment and the late appearance of psychiatric disturbances (personality change) are reported.<sup>89,99,122,150,169</sup>

There is no antidote for the treatment of methyl iodide poisoning. Successful treatment requires early diagnosis and cessation of exposure. It is difficult to distinguish the neurotoxic syndromes due to methyl iodide poisoning from other neurodegenerative conditions, infectious processes, and psychiatric disorders, especially when there is a lag time between exposure and onset of clinical manifestations.<sup>122</sup>

## SUMMARY

- Exposure to fumigants follow inhalation, dermal exposure, or ingestion depending on the specific fumigant and the physical state.
- The fumigants are associated with multiorgan failure and, following acute exposure, adversely affect the cardiovascular, respiratory, and central nervous systems.
- Treatment involves removal from exposure and removal of outer clothing. Dermal decontamination is not generally needed given the volatile nature of most fumigants.
- First-responder protection from inhalation is important to prevent poisoning for these health care workers.

### HISTORY, CLASSIFICATION, AND EPIDEMIOLOGY

Herbicides, defined as any chemical that regulates the growth of a plant, encompass a large number of xenobiotics of varying characteristics. Herbicides are used around the world for the destruction of plants in the home environment and also in agriculture in which weeds are particularly targeted. Poisoning follows acute (intentional or unintentional poisoning) or chronic (such as occupational) exposures. Depending on the herbicide and the characteristics of the exposure, this may lead to clinically significant poisoning, including death. This chapter focuses on the most widely used herbicides and also those associated with significant clinical toxicity. In particular, risk assessment and the management of patients with a history of acute herbicide poisoning are emphasized.

Prior to the 1940s, the main method of weed control and field clearance was manual labor, which was time consuming and expensive. A range of xenobiotics were tested, including metals and inorganic compounds; however, their efficacy was limited. The first herbicide marketed was 2,4-dichlorophenoxyacetic acid (2,4-D) during the 1940s, followed by other phenoxy acid compounds. Paraquat was marketed in the early 1960s, followed by dicamba later that decade. The development of new herbicides is an active area of research and new herbicides and formulations are frequently released into the market. This includes a number of novel structural compounds for which clinical toxicology data are unavailable. Hundreds of xenobiotics are classified as herbicides and a much larger number of commercial preparations are marketed. Some commercial preparations contain more than one herbicide to potentiate plant destruction. From another perspective, crops are being developed that are resistant to particular herbicides to maximize the selective destruction of weeds without reducing crop production.

Herbicides are the most widely sold pesticides in the world; in 2007 they accounted for approximately 40% of the total world pesticide market and 48% of the pesticide market in the United States. Home and garden domestic use accounts for 7% of the overall herbicide use in the United States, whereas the remainder is used in agriculture, government (eg, vegetation control on highways and railways), and industry. In each of the US market sectors, herbicides were 4 of the top 5 used pesticides in 2012, including glyphosate, atrazine, metolachlor-S, and 2,4-D.<sup>33</sup>

Not all herbicide exposures are clinically significant. In developed countries, most acute herbicide exposures are unintentional and the majority of patients do not require admission to a hospital. The National Poisoning Database System (NPDS) of the American Association of Poison Control Centers (AAPCC) describes approximately 10,000 herbicide exposures each year. Over the last 12 years, there were approximately 5 deaths per year and 20 patients per year with clinical outcomes categorized as “major” that were attributed to herbicide poisoning (Chap. 130). Most deaths were due to paraquat and diquat, although recently glyphosate and phenoxy acid compounds are more commonly implicated. Cases of severe poisoning that required hospitalization usually followed intentional self-poisoning. Significant toxicity including death also occurs with unintentional (eg, storage of an herbicide in food or drink containers) or criminal exposures.

### Classification

Hundreds of xenobiotics have herbicidal activity and they are subclassified by a number of methods. Most commonly they are categorized in terms of their spectrum of activity (selective or nonselective), chemical structure, mechanism of action (contact herbicides or hormone dysregulators), use (preemergence or postemergence), or their toxicity to rats such as the amount of that xenobiotic killing 50% of exposed animals ( $LD_{50}$ ). Certain

xenobiotics are classified as plant growth regulators rather than herbicides, but in this chapter all are considered to be herbicides.

Table 109–1 lists the extensive range of herbicides in current use.<sup>49</sup> By convention, they are subclassified according to their chemical class and their World Health Organization (WHO) hazard classification. Unfortunately, the utility of these (or any other) methods of classification to predict the hazard to humans with self-poisoning is not proven.

The WHO categorizes pesticides by their  $LD_{50}$ . This system does not consider morbidity or the effect of treatments. Further, the calculated  $LD_{50}$  varies among studies in the same type of animal, and between different species. For example, in the case of paraquat, the  $LD_{50}$  in rats, monkeys, and guinea pigs is reported as 125, 50, and 25 mg/kg, respectively.<sup>83</sup> It should be emphasized that the intended application of the WHO hazard classification was for the risk assessment following occupational exposures to operators using the product as intended. Furthermore, the  $LD_{50}$  is determined by using the pure herbicide compound, whereas human poisoning follows exposure to proprietary formulations that also contain coformulants, and these often contribute to the overall toxicity. Preparations that decrease human toxicity without compromising herbicidal activity are also being developed, for example, paraquat containing lysine salicylate.

Herbicides within a single chemical class can manifest different clinical toxicity; for example, glyphosate is an organic phosphorus compound that does not inhibit acetylcholinesterase, which contrasts with insecticides of a similar structure. The mechanism of action of herbicides in plants usually differs from the mechanism of toxicity in humans; indeed, for some herbicides the mechanism of human toxicity is poorly described.

### Contribution of Coformulations

Commercial herbicide formulations are identified by their active ingredients but they almost always contain coformulants that often contribute to clinical toxicity. Hydrocarbon-based solvents and surfactants improve the contact of the herbicide with the plant and enhance penetration. Coformulants are generally considered “inactive” or “inert” because they lack herbicidal activity; however, increasingly their contribution to the human toxicity of a formulation is being appreciated.

The most widely discussed example of a coformulant dominating the toxicity of an herbicide product is that of glyphosate-containing products, which is discussed below. Another example is imazapyr, which has an  $LD_{50}$  in rats of 1,500 mg/kg intraperitoneally (IP) compared with 262 mg/kg IP when administered as the product Arsenal. This difference is attributed to the surfactant nonylphenol ethoxylate used in this product, which has an  $LD_{50}$  of 75 mg/kg IP. In vitro studies with a number of formulations demonstrate increased cardiovascular toxicity compared with the technical herbicides.<sup>13</sup> Similarly, coformulants increase the in vitro toxicity from phenoxyacetic acid derivatives and glufosinate.

Impurities generated during manufacture or storage of the herbicide formulation also contribute to toxicity. For example, phenolic by-products from the manufacture of phenoxyacetic acid herbicides are reported in commercial formulations. Some proprietary products contain a combination of herbicidal compounds that probably have additive effects, further complicating the risk assessment of an acute exposure.

### Epidemiology

The incidence of poisoning with individual herbicides depends on their availability. Availability is associated with local marketing practices and is reflected in sales in the domestic sector. For example, paraquat poisonings

**TABLE 109–1** Characteristics of the Major Herbicides Categorized by Chemical Class and WHO Hazard Classification

Chemical Class <sup>a</sup>	Applications, Usage Data, and Mechanism of Action in Plants, If Known <sup>b</sup>	WHO Hazard Class <sup>c</sup>	Compounds Included	Clinical Effects, Treatments, and Supportive Care
Alcohol and aldehyde	Broad-spectrum contact herbicide	Ib	Allyl alcohol (prop-2-en-1-ol) and acrolein (the metabolite of allyl alcohol)	Local irritation, cardiotoxicity, pulmonary edema, and death. Administer <i>N</i> -acetylcysteine or mesna.
Amide, Fig. 109–1	<p>Selective for grasses pre- or postemergence</p> <p>In 2012, acetochlor, propanil, metolachlor, and metolachlor-S were among the top herbicides used in the United States.</p> <p>Multiple mechanisms of action, including inhibition of photosynthesis at photosystem II and/or inhibition of dihydropteroate synthase and/or inhibition of cell division through inhibition of the synthesis of very-long-chain fatty acids and/or inhibition of acetolactate synthase (interferes with branched amino acid synthesis) and/or inhibition of microtubule assembly.</p> <p>Some compounds are also included in other chemical classes, including asulam (carbamate); oryzalin (dinitroaniline); clomeprop (phenoxy); diclosulam, flumetsulam, and metosulam (triazolopyrimidines).</p>	III	<p><i>Anilide derivatives:</i> Acetochlor, alachlor, dimethachlor, flufenacet, mefluidide, metolachlor, propachlor, propanil (DCPA)</p> <p><i>Nonanilide derivatives:</i> Chlorthiamid, diphenamid</p>	<p>See text for anilide derivatives. There are limited human data about the non-anilide derivatives. Lethargy or sedation preceded death in animals exposed to chlorthiamid. Behavioral changes, ataxia, and prostration were noted in animals exposed to diphenamid. Drowsiness and tachypnea were noted in goats following acute poisoning with napropamide. Oryzalin inhibits human carbonic anhydrase. Methemoglobinemia results, the treatment of which is methylene blue (Antidotes in Depth: A43).</p>
		U	<p><i>Anilide derivatives:</i> Butachlor, domeprop, diclosulam, flamprop, flumetsulam, metosulam, mefenacet, metazachlor, pentanochlor, pretilachlor</p> <p><i>Nonanilide derivatives:</i> Asulam, bromobutide, dimethenamid, isoxaben, napropamide, oryzalin, propyzamide, tebutam</p>	
Aromatic acid	<p>In 2012, dicamba was the eighth most used herbicide in the domestic sector in the United States.</p> <p>Dicamba is commonly coformulated with phenoxyacetic acid compounds</p> <p>Inhibits acetolactate synthase and/or inhibition of microtubule assembly and/or indole acetic acid–like (synthetic auxins).</p>	III	Dicamba, 2,3,6-trichlorobenzoic acid (2,3,6-TBA)	<p>Bispyribac causes gastrointestinal irritation, sedation and death (case fatality 1.8%; asystolic arrest reported).<sup>30</sup> Minimal toxicity from dicamba, but some products are corrosive to the gut, and rhabdomyolysis and acute pancreatitis are reported.<sup>87</sup> Human data are limited for the other compounds, particularly single-agent exposures. In animals, myotonia, dyspnea, and death are reported with dicamba and 2,3,6-TBA poisoning.</p>
		U	Bispyribac, chloramben (amiben), chlorthal, clopyralid, pyriminobac, pyriithiobac, quinclorac, quinmerac	
Arsenical	Unknown	III	Dimethylarsinic acid (cacodylic acid), methylarsonic acid (MAA or MSMA)	Chap. 86
Benzothiazole	Indole acetic acid–like (synthetic auxins) and/or inhibits photosynthesis at photosystem II.	U	Benazolin, methabenzthiazuron	Limited human data.
Bipyridyl	<p>Nonspecific, postemergence, contact herbicide</p> <p>Photosystem I electron diversion</p> <p>These compounds are part of a larger group of quaternary ammonium herbicides, including difenzoquat, which is also a pyrazole compounds (see below).</p>	II	Paraquat, diquat	See text for paraquat and diquat.
Carbanilate	Inhibits photosynthesis at photosystem II and/or inhibits mitosis or microtubule organization	U	Carbetamide, desmedipham, phenmedipham, propham	Limited human data.
Cyclohexane oxime	<p>Postemergence, selective for grasses</p> <p>Inhibits acetyl-CoA carboxylase (lipid biosynthesis inhibitors)</p>	III	Butoxydim, sethoxydim, tralkoxydim	Limited human data.
		U	Alloxydim, cycloxydim, cyhalofop	

(Continued)

**TABLE 109–1** Characteristics of the Major Herbicides Categorized by Chemical Class and WHO Hazard Classification (*Continued*)

<i>Chemical Class<sup>a</sup></i>	<i>Applications, Usage Data, and Mechanism of Action in Plants, If Known<sup>b</sup></i>	<i>WHO Hazard Class<sup>c</sup></i>	<i>Compounds Included</i>	<i>Clinical Effects, Treatments, and Supportive Care</i>
Dinitroaniline	Preemergence, selective for grasses In 2012, trifluralin and pendimethalin were among the top 20 herbicides used in the United States overall, while trifluralin and pendimethalin were among the top 10 used in the domestic sector Inhibits microtubule assembly.	III U	Fluchloralin, pendimethalin Benfluralin (benefin), butralin, dinitramine, ethalfluralin, oryzalin, prodiamine, trifluralin	Pendimethalin induces mild clinical toxicity in most cases, but gastroduodenal injury, sedation, seizures, hypotension and death due to respiratory failure are reported, usually within 24 hours. Limited human data for the others Aniline metabolites are reported from trifluralin and oryzalin, which induce methemoglobinemia and hemolysis with prolonged exposures. For which methylene blue, blood transfusions and supportive care are recommended (Antidotes in Depth: A43). In rats, fluchloralin induces hyperexcitability, tremors, and convulsions prior to death. Agitation, trembling, and fatigue occur in rats following lethal doses of trifluralin. Many of these compounds are poorly absorbed and some are subject to enterohepatic recycling.
Dinitrophenol	Uncoupling (membrane disruption)	Ib	Dinoterb, DNOC (4,6-dinitro- <i>o</i> -cresol)	Limited human data; methemoglobinemia is reported in animals. Dinitrophenol uncouples oxidative phosphorylation.
Diphenylether	Postemergence (particularly broad leaves) Contact herbicide, inhibits protoporphyrinogen oxidase, and/or inhibits carotenoid biosynthesis Aclonifen is also an amine compound.	III U	Acifluorfen, fluoroglycofen Aclonifen, bifenox, chlomethoxyfen, oxyfluorfen	Limited human data.
Halogenated aliphatic	Inhibit lipid synthesis	U	Dalapon, fluopropanate	Limited human data.
Imidazolinone	Inhibit acetolactate synthase, interfering with branched amino acid synthesis	U	Imazamethabenz, imazapyr, imazaquin, imazethapyr	Limited human data. In a small case series, imazapyr induced sedation, respiratory distress, metabolic acidosis, hypotension, and hepatorenal dysfunction.
Inorganic	Nonselective	III U	Sodium chlorate Ammonium sulfamate	Nausea, vomiting, diarrhea, metabolic acidosis, kidney failure, hemolysis, methemoglobinemia, rhabdomyolysis, and disseminated intravascular coagulation. Treatment includes hemodialysis and erythrocyte and plasma transfusion. Methemoglobinemia is usually unresponsive to methylene blue (a single report suggested benefit when used within 6 hours of exposure <sup>63</sup> ) Limited human data.
Nitrile	Preemergence, selective for grasses Inhibits photosynthesis at photosystem II and/or inhibition of cell wall (cellulose) synthesis Commonly coformulated with phenoxyacetic acid compounds	II U	Bromoxynil, ioxynil Dichlobenil	Limited human data of single-substance exposures. In animals, it uncouples oxidative phosphorylation and induces CNS toxicity. Similar clinical effects noted in humans.
Organic phosphorus	Bensulide: preemergence selective for grasses. Glyphosate and glufosinate are nonselective postemergence herbicides. In 2012, glyphosate was the most used pesticide in the United States and the second most used in the domestic sector. Bialaphos and glufosinate inhibit glutamine synthetase, bensulide inhibits lipid synthesis, and glyphosate inhibits EPSP synthase, which interferes with aromatic amino acid synthesis.	II III U	Butamifos, bialaphos (bilanafos), anilofos, bensulide, piperophos Glufosinate Fosamine, glyphosate	Limited human data. Bialaphos is metabolized to glufosinate in plants, but in humans only the metabolite L-amino-4-hydroxymethyl-phosphonyl-butyrac acid has been found. Clinical effects of poisoning include apnea, amnesia, and metabolic acidosis. Anilofos and bensulide are shown to inhibit acetyl cholinesterase. See text for glufosinate and <a href="#">Fig. 109–5</a> See text for glyphosate and <a href="#">Fig. 109–7</a> ; Limited human data for fosamine.

Phenoxy (Fig. 109–8)	Postemergence, selective for grasses	II	<i>Phenoxyacetic derivatives</i> : 2,4-D	See text for phenoxyacetic derivatives; similar clinical features of toxicity are noted for the chlorinated nonphenoxyacetic acid compounds. Mild clinical toxicity from fenoxaprop-ethyl in acute overdose. <sup>132</sup> Limited human data on poisoning for others. Fluazifop 0.07 mg/kg was safely administered to humans in a volunteer study.
	In 2012, 2,4-D was the fifth most used herbicide in the United States but the most used in the domestic sector (mecoprop was third and MCPA ninth).	III	<i>Nonphenoxyacetic derivatives</i> : haloxyfop, quizalofop-P	
	Inhibits acetyl-CoA carboxylase (lipid biosynthesis inhibitors; fops) or indole acetic acid-like (auxin growth regulators; chlorinated compounds)	U	<i>Phenoxyacetic derivatives</i> : MCPA, 2,4,5-T <i>Nonphenoxyacetic derivatives</i> : Bromofenoxim, 2,4-DB, dichlorprop, diclofop, fluazifop, MCPB, mecoprop (MCP), quizalofop, propaquizafop <i>Nonphenoxyacetic derivatives</i> : Clomeprop, fenoxaprop-ethyl	
	Clomeprop is also an amide compound.	U		
Pyrazole	Inhibition of 4-hydroxyphenyl-pyruvate dioxygenase or photosystem I electron diversion (difenzoquat is also a quaternary ammonium compound)	II	Difenzoquat	Limited human data.
		III	Pyrazoxyfen, pyrazolynate	
		U	Azimsulfuron	
Pyridazine	Preemergence application. Inhibits photosynthesis at photosystem II	III	Pyridate	Limited human data.
Pyridazinone	Inhibits photosynthesis at photosystem II or inhibits carotenoid biosynthesis at the phytoene desaturase step.	U	Chloridazon, norflurazon	Limited human data. In animals, chloridazon interferes with mitochondrial function. Respiratory distress, seizures, and paralysis precede death.
Pyridine	Inhibits carotenoid biosynthesis at the phytoene desaturase step and/or inhibits microtubule assembly and/or indole acetic acid-like (synthetic auxins).	III	Triclopyr	Limited human data on poisoning, but triclopyr appears to be low toxicity, <sup>87</sup> except for one case of acute poisoning with metabolic acidosis, coma and cardiotoxicity; yet, recovery was complete. Triclopyr 0.5 mg/kg was safely administered to humans in a volunteer study. Picloram 5 mg/kg was safely administered to humans in a volunteer study.
		U	Diflufenican, dithiopyr, fluroxypyr, fluthiacet, picloram	
Thiocarbamate	Preemergence, selective for grasses Inhibits lipid synthesis	II	EPTC, molinate, pebulate, prosulfocarb, thiobencarb, vernolate	Molinate 5 mg was orally administered to volunteers. Limited human data, including effects on cholinesterase. Some compounds display variable inhibition of nicotinic receptors, esterases, and aldehyde dehydrogenase in animals. Cycloate induces neurotoxicity in rats.
		III	Cycloate, esprocarb, triallate	
		U	Tiocarbazil	
Triazine (Fig. 109–9)	Mostly preemergence and nonselective In 2007 atrazine was the second most used herbicide in the United States. Inhibits photosynthesis at photosystem II	II	Cyanazine, terbumeton	See text.
		III	Ametryn, desmetryn, dimethametryn, simetryn	
		U	Atrazine, prometon, prometryn, propazine, simazine, terbuthylazine, terbutryn, trietazine	
Triazinone	Inhibits photosynthesis at photosystem II	II	Metribuzin, hexazinone	Limited human data. With hexazinone, rats and guinea pigs experience lethargy and ataxia, progressing to clonic seizures prior to death, while dogs were not particularly sensitive. Goats experience sedation, lethargy, and impaired respiration with metamitron poisoning.
		III	Metamitron	
Triazole	Postemergent, nonselective Commonly coformulated with ammonium thiocyanate. Inhibits lycopene cyclase; chlorophyll or carotenoid pigment inhibitor	U	Amitrole (aminotriazole)	Limited human data on single-agent exposures. Ingestion of 20 mg/kg in a human and > 4,000 mg/kg in rats did not induce symptoms.
Triazolone	Inhibits acetolactate synthase	U	Flucarbazone	Limited human data.
Triazolopyrimidine	Inhibits acetolactate synthase. These herbicides are also amide compounds.	U	Diclosulam, flumetsulam, metosulam	Limited human data. Asthma is reported from occupational exposures to flumetsulam.

(Continued)

**TABLE 109-1** Characteristics of the Major Herbicides Categorized by Chemical Class and WHO Hazard Classification (*Continued*)

<i>Chemical Class<sup>a</sup></i>	<i>Applications, Usage Data, and Mechanism of Action in Plants, If Known<sup>b</sup></i>	<i>WHO Hazard Class<sup>c</sup></i>	<i>Compounds Included</i>	<i>Clinical Effects, Treatments, and Supportive Care</i>
Uracil	Mostly preemergence. Inhibit photosynthesis at photosystem II	U	Bromacil, lenacil, terbacil	Limited human data.
Urea	Both pre- and postemergence Inhibits acetolactate synthase (interferes with branched amino acid synthesis) and/or inhibits photosynthesis at photosystem II and/or inhibition of carotenoid biosynthesis	III U	Isoproturon, isouron, tebuthiuron Bensulfuron, chlorbromuron, chlorimuron, chlorotoluron, cinosulfuron, cyclosulfamuron, daimuron, dimefuron, diuron, fenuron, fluometuron, linuron, methylidymron, metobromuron, metoxuron, metsulfuron, monolinuron, neburon, nicosulfuron, primisulfuron, pyrazosulfuron, rimsulfuron, siduron, sulfometuron, thifensulfuron, triasulfuron, tribenuron, triflusaluron	Limited human data. Some urea herbicides are metabolized to aniline compounds, which induce methemoglobinemia and hemolysis (similar to propanil, see text). Given the limited experience in treating poisonings with urea herbicides, it is reasonable to apply treatments described for amide herbicide poisoning (see text); success with methylene blue is reported. Wheezing is reported from occupational exposures to chlorimuron. Animal studies suggest that isoproturon causes CNS depression and tebuthiuron causes lethargy, ataxia, and anorexia.
Miscellaneous	Clomazone: may be coformulated with propanil Clomazone and fluridone: chlorophyll or carotenoid pigment inhibitor Bentazone: pre- and postemergence for control of broadleaf plants. Inhibits photosynthesis Fluridone: chlorophyll or carotenoid pigment inhibitor	II III U	Clomazone, endothal Bentazone, quinochlorimuron Benfuresate, cinmethylin, ethofumesate, fluridone, flurochloridone, oxadiazon	Limited human data; in one case vomiting and gastric and pulmonary hemorrhage preceded death. Animal studies suggest that clomazone inhibits acetylcholinesterase and endothal induces lethargy, respiratory, and hepatic dysfunction. In vitro, clomazone induces oxidative stress and inhibits acetylcholinesterase. Bentazone: gastrointestinal irritation, hepatic failure, acute kidney injury, dyspnea, muscle rigidity, confusion, death Limited human data.

<sup>a</sup>Many of these classes can be further subclassified on the basis of chemical structure; however, the relationship between structure and clinical effects is not adequately described. The classification listed here is adapted from [http://www.alanwood.net/pesticides/class\\_herbicides.html](http://www.alanwood.net/pesticides/class_herbicides.html). Accessed December 9, 2012. <sup>b</sup>The mechanism by which a number of herbicides regulate plant growth is not fully described. The mechanisms listed here are adapted from <http://www.plantprotection.org/HRAC/MOA.html> (Accessed December 9, 2012) and <http://www.ces.purdue.edu/extmedia/WS/WS-23-W.html> (Accessed December 9, 2012). <sup>c</sup>WHO Hazard Classification scale for oral liquid exposures of the technical grade ingredient based on rat LD<sub>50</sub> (mg/kg body weight): Ia = "extremely hazardous," <20 mg/kg; Ib = "highly hazardous," 20–200 mg/kg; II = "moderately hazardous," 200–2,000 mg/kg; III = "slightly hazardous," > 2,000 mg/kg; and U = "technical grade active ingredients of pesticides unlikely to present acute hazard in normal use."

CNS = central nervous system; WHO = World Health Organization.

are now comparatively rare in the United States (it remains the 23rd most commonly used pesticide in the United States<sup>33</sup>), whereas the incidence of glyphosate poisoning has increased. Similarly, after paraquat was banned in Japan (late 1980s) and Korea (2012), there was an increase in the number of glufosinate poisonings.

Herbicide poisoning is a major issue in developing countries of the Asia-Pacific region where subsistence farming is common and herbicide use is relatively high. By contrast, the incidence of severe herbicide poisoning is less in developed countries because the population is concentrated in urban areas where access is limited to lower-toxicity herbicides that are sold in smaller volumes as diluted formulations intended for household use (Chaps. 110 and 136).

### Regulatory Considerations

When properly used, most herbicide formulations have a low toxic potential for applicators because they are poorly absorbed across the skin and respiratory membranes. When inappropriately used, in particular when there is enteral (or rarely parenteral) exposure, toxicity is more pronounced.

The toxicity on herbicides varies among individual xenobiotics and many are intrinsically more toxic than medications when ingested with suicidal intent. Restrictions of the availability and formulation of toxic herbicides by regulatory authorities improve outcomes from herbicide poisoning. For example, in the context of self-poisoning, in Sri Lanka the replacement of highly toxic pesticides with less toxic compounds decreased the overall mortality<sup>97</sup> without altering agricultural outputs.<sup>72</sup> Prospective cohort studies are useful for estimating the case fatality of individual herbicides in the context of intentional self-poisoning, particularly when encountered in the same clinical environment. For example, in Sri Lanka the following herbicide case fatalities are reported: fenoxaprop-*P*-ethyl, 0%;<sup>132</sup> bispyribac, 1.8%;<sup>30</sup> glyphosate, 3.2%;<sup>100</sup> 4-chloro-2-methylphenoxyacetic acid (MCPA), 4.4%;<sup>98</sup> propanil, 3.1% to 10.7%;<sup>99</sup> and paraquat, 50% to 70%.<sup>128</sup> This information is of interest to regulatory authorities in their control of the marketing, sales, and formulation of herbicides.

Regulatory bodies must also evaluate other factors, including the cost and efficacy of herbicides and their fate in the environment. An ideal herbicide is one that is selective for the target plant and does not migrate far from the site of application. Selective targeting occurs when the herbicide is rapidly inactivated or binds strongly to soil components. For example, paraquat and glyphosate are inactivated when they contact soil, which is favorable because they remain in the region of application. By contrast, atrazine is more mobile, allowing it to leach into groundwater and migrate great distances. While the concentration of atrazine at distant sites is low, there is concern that it has the potential to alter the growth and development of nontarget plants and animals.<sup>104</sup>

## GENERAL COMMENTS FOR THE MANAGEMENT OF ACUTE HERBICIDE POISONING

### Diagnosis

Herbicide poisoning is diagnosed following a specific history or other evidence of exposure (such as an empty or partially used bottle) and associated clinical symptoms. A detailed history, including the type of herbicide, amount, time since poisoning, and symptoms, is essential. It is necessary to determine the actual brand in many cases because of variability in salts, concentrations, and coformulants. Furthermore, in some cases it is also necessary to determine the specific type of a brand; for example, the product called Roundup contains glyphosate but it is sold in different formulations worldwide within market sectors.

Depending on local laboratory resources, the diagnosis is confirmed using a specific assay, such as paraquat and glufosinate, but these are not usually available in a clinically meaningful time frame.

The low incidence of herbicide poisoning in some regions often means that it is not considered in the differential diagnosis when a history is not available. Therefore, a high index of suspicion is necessary and clinicians should be familiar with the features of herbicide poisoning.

The pathophysiology of acute herbicide poisoning, and therefore the clinical manifestations, vary between individual compounds. Some herbicides induce multisystem toxicity due to interactions with a number of physiologic systems. The mechanism of toxicity and pathophysiological changes in humans are discussed below for each herbicide individually.

### Initial Management

An accurate risk assessment is necessary for the proper triage and subsequent management of patients with acute herbicide poisoning. Risk assessment involves an understanding of the dose ingested, time since ingestion, clinical features, patient factors, and availability of medical facilities. All intentional exposures should be assumed significant. If a patient presents to a facility that is unable to provide sufficient medical and nursing care or does not have ready access to necessary antidotes, then arrangements should be made to rapidly and safely transport the patient to an appropriate health care facility.

For many herbicides, the initial management of an acute poisoning follows standard guidelines. All patients should receive prompt resuscitation emphasizing the airway, breathing, and circulation. Gastrointestinal toxicity, such as nausea, vomiting, and diarrhea, is common, leading to salt and water depletion that requires the administration of antiemetics and intravenous fluids.

Gastrointestinal decontamination decreases absorption of the herbicide from the gut, reducing systemic exposure. We generally recommend not to perform gastric lavage in acute poisoning because patients usually present too late or have self-decontaminated from vomiting and diarrhea. However, gastric lavage is reasonable for patients presenting shortly after an ingestion of a liquid formulation for which treatment options are limited. Ingestion of a corrosive product is a relative contraindication. Depending on the procedure used, this treatment is potentially harmful and should only be conducted by an experienced clinician when the airway is protected. Oral activated charcoal is recommended if the patient presents within 1 to 2 hours of ingestion of an herbicide known to cause significant poisoning. In the case of herbicides with prolonged absorption (eg, propanil, MCPA), later administration of activated charcoal is reasonable. Specific antidotes are available for only a few herbicides, which reflect their ill-defined mechanisms of toxicity. Extracorporeal techniques, including hemoperfusion and hemodialysis, decrease the systemic exposure by increasing the rate of elimination. The role of these treatments is discussed below for each pesticide.

Dermal decontamination is recommended if the patient has incurred cutaneous exposure. The patient should be washed with soap and water, and contaminated clothes, shoes, and leather materials should be removed and safely discarded.

Laboratory investigations are useful for determining the evolution of organ toxicity, including serial measurement of liver and kidney function, electrolytes, and acid-base status. Abnormalities should be corrected when possible. Respiratory distress and hypoxia with focal respiratory crackles soon after presentation are likely to result from aspiration pneumonitis, which should be confirmed on chest radiography.

We recommend a minimum of 6 hours of observation for patients with a history of acute ingestion, unless otherwise stated below. For patients with a history of intentional ingestion and gastrointestinal symptoms, we recommend at least 24 hours of observation depending on the herbicide, given that clinical toxicity will progress or be delayed in some cases.

### Occupational and Secondary Exposures (Including Nosocomial Poisoning)

Concern has been expressed regarding the risk of nosocomial poisoning to staff and family members who are exposed to patients with acute herbicide poisoning. However, the risk to health care staff providing clinical care is low compared with other occupations, such as agricultural workers in whom acute toxicity is rarely observed. Universal precautions using nitrile gloves are recommended to provide sufficient protection for staff members.

Few cases of secondary poisoning, if any, are confirmed, and effects in these potentially exposed individuals were generally mild, such as nausea,

dizziness, weakness, and headaches, probably relating to inhalation of the hydrocarbon solvent. These symptoms usually resolve after exposure to fresh air. Biomarkers for monitoring occupational exposures, as in the case of pesticide applicators, are outside the scope of this chapter.

### Amide Compounds, Particularly Anilide Derivatives

Anilide compounds are the most widely used amide herbicides, of which propanil (3,4'-dichloropropionanilide {DCPA}), alachlor (2-chloro-2',6'-diethyl-*N*-methoxymethylacetanilide), and butachlor (*N*-butoxymethyl-2-chloro-2',6'-diethylacetanilide) are particularly common. Other amide herbicides and available toxicity data are listed in Table 109-1. In 2012, acetochlor, propanil, metolachlor, and metolachlor-S were among the most commonly used herbicides in the United States.<sup>33</sup> Anilide compounds are selective herbicides used mostly in rice cultivation in many parts of the world. Acute self-poisoning is reported particularly in Asia where subsistence farming is common. Toxicity data are limited for most compounds, except for propanil, butachlor, metachlor, and alachlor. The case fatality of propanil exceeds 10%, compared with a combined mortality of less than 3% for butachlor, metachlor, and alachlor in case series from Asia.

### Pharmacology

Most of the clinical manifestations of propanil poisoning are mediated by its metabolites. 3,4-Dichlorophenylhydroxylamine is the most toxic metabolite and it directly induces methemoglobinemia and hemolysis in a dose-related manner. 3,4-Dichlorophenylhydroxylamine is cooxidized with oxyhemoglobin ( $\text{Fe}^{2+}$ ) in erythrocytes to produce methemoglobin ( $\text{Fe}^{3+}$ ).

However, toxicity is not solely due to methemoglobinemia. Isolated methemoglobin levels exceeding 50% are usually required for fatal outcomes, but fatal propanil poisoning is reported with methemoglobin levels as low as 40%.<sup>17,86,129,130</sup> Therefore, other toxic mechanisms must contribute to clinical outcomes. Rats show signs of toxicity despite inhibition of the hydrolytic enzymes that metabolize propanil (Fig. 109-1) and in the absence of methemoglobinemia, supporting direct toxicity from propanil itself.<sup>115</sup> Dose-dependent kidney and liver cytotoxicity are noted in mice with chronic dosing. Coformulants may also contribute.

The hydroxylamine metabolite depletes glutathione, although this is not consistently reported. Other possible toxicities from the metabolism of propanil include nephrotoxicity, lipid peroxidation, myelotoxicity, and immune dysfunction; the significance of these toxicities is poorly defined.

Para-hydroxylated aniline and other compounds are products of alachlor, butachlor, and acetochlor (2-chloro-*N*-ethoxymethyl-6'-ethylacet-*o*-toluidide)

metabolism and reduces glutathione and induce hepatotoxicity or cancer, particularly in rats.

### Pharmacokinetics and Toxicokinetics

Absorption is rapid in animals, with a peak serum concentration expected one hour postingestion. The volume of distribution ( $V_d$ ) of propanil is not defined, but is expected to be large given that both propanil and 3,4-dichloroaniline are highly lipid soluble. This  $V_d$  is consistent with data in the channel catfish in which uptake and distribution of propanil were noted to be extensive.

Anilide compounds undergo sequential metabolic reactions that produce toxic xenobiotics (Fig. 109-1). The first reaction is hydrolysis of the anilide to an aniline compound. This reaction is catalyzed by an esterase known as arylamidase, which has a high capacity in humans compared to rats ( $K_m = 473 \mu\text{M}$  and  $271 \mu\text{M}$ , respectively) and sometimes by the cytochrome P450 system. Examples include the bioconversion of propanil to 3,4-dichloroaniline and also conversion of alachlor and butachlor to 2,6-diethylaniline. These aniline intermediates are then oxidized by cytochrome P450, although the responsible enzyme is not defined. *N*-Hydroxylation of 3,4-dichloroaniline produces the hydroxylamine compound that induces hemolysis and methemoglobinemia, which are the most obvious manifestations of propanil poisoning.<sup>76,77,115</sup>

These bioactivation reactions appear to be fairly rapid, whereas 3,4-dichloroaniline and methemoglobin are formed within 2 to 3 hours of parenteral administration of propanil to animals. The hydroxylation of 3,4-dichloroaniline is saturable ( $K_m = 120 \mu\text{M}$  in rats) and slower than arylamidase, leading to a prolonged elimination of 3,4-dichloroaniline following large exposures. In the case of alachlor, butachlor, and acetochlor, parahydroxylated aniline compounds are produced, which appear to be carcinogens in rats.

These metabolic reactions are similar to those of dapsone, which are well characterized: the severity of methemoglobinemia relates to the amount of the dapsone hydroxylamine, metabolite, which varies with dose, and cytochrome P450 activity (Chap. 124).

Propanil displays nonlinear toxicokinetics in humans with prolonged absorption continuing for approximately 10 hours following ingestion. Bioconversion to 3,4-dichloroaniline occurs largely within 6 hours, although it is particularly variable, which reflects interindividual differences in esterase activity, dose, or coexposure to cholinesterase inhibitors.<sup>99</sup> The median apparent elimination half-life of propanil is 3.2 hours compared with 3,4-dichloroaniline, which has a highly variable elimination profile. In general, the concentration of 3,4-dichloroaniline exceeds that of propanil and remains elevated for a longer period.<sup>99</sup> In a case of coingestion of carbaryl, the peak 3,4-dichloroaniline concentration was observed at 24 hours,<sup>42</sup> whereas in a fatal case the concentration of 3,4-dichloroaniline continued to increase until at least 30 hours postingestion.<sup>99</sup> By 36 hours postingestion, the concentration of 3,4-dichloroaniline is low in survivors, so clinical toxicity is unlikely to increase beyond this time.<sup>99</sup>

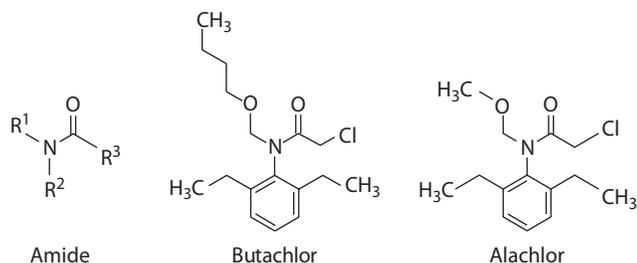

### Pathophysiology

The predominant clinical manifestation in acute poisoning is methemoglobinemia. Methemoglobin is unable to bind and transport oxygen, inducing a relative hypoxia at the cellular level despite adequate dissolved arterial oxygen content. This leads to end-organ dysfunction, including central nervous system depression, hypotension, and acidemia. Because the plasma concentration of 3,4-dichloroaniline remains elevated, the potential production of methemoglobin persists for a protracted period of time.<sup>42,86,129</sup> Sedation due to the direct effect of propanil or a hydrocarbon coformulant solvent causes hypoventilation, which contributes to cellular hypoxia. Failure to correct these abnormalities may lead to irreversible injury and death.

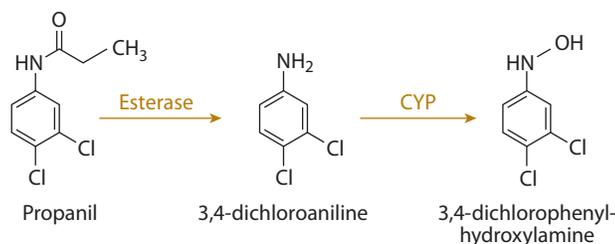

### Clinical Manifestations

Methemoglobinemia, hemolysis and anemia, coma, and death are reported following acute propanil poisoning. These occur in the clinical context of cyanosis, acidemia, and progressive end-organ dysfunction. A case fatality as high as 10.7% is reported and the median time to death was 36 hours. Patients who die tend to be older with a depressed Glasgow Coma Scale score and elevated concentration of propanil. Nausea, vomiting, diarrhea, tachycardia,

#### A. Common Anilide Xenobiotics

#### B. Bioconversion of Propanil

**FIGURE 109-1.** Structures of common anilide compounds and the bioconversion of propanil.

dizziness, and confusion are also reported in patients who do not develop severe poisoning.<sup>99</sup> However, with earlier recognition and improved use of methylene blue and a color chart for categorizing severity of methemoglobinemia, mortality decreased to 3.1%.

Alachlor, metachlor, and butachlor are less toxic than propanil, with a case fatality less than 3% with self-poisoning.<sup>71,112</sup> The manifestations of acute poisoning are usually mild, including gastrointestinal symptoms, agitation, dyspnea, and abnormal liver enzymes.<sup>71,112</sup> Major symptoms include seizures, rhabdomyolysis, acidemia, kidney failure, and cardiac dysrhythmias; hypotension and coma preceded death.<sup>71,112</sup> Methemoglobinemia was not reported in these studies. Hepatic dysfunction was reported following dermal occupational exposure to butachlor.

Cyanosis was reported following acute ingestion of mefenacet (2-benzothiazol-2-yloxy-*N*-methylacetanilide) and imazosulfuron (1-{2-chloroimidazo(1,2-*a*) pyridin-3-ylsulfonyl}-3-{4,6-dimethoxypyrimidin-2-yl}urea) in the context of normal coximetry. This was attributed to formation of a green pigment (green-colored urine was also reported), and no other symptoms of toxicity were observed.<sup>114</sup>

Acute metolachlor (2-chloro-*N*-{6-ethyl-*o*-tolyl}-*N*-{(1*RS*)-2-methoxy-1-methylethyl}acetamide) poisoning in goats induced predominantly neuromuscular symptoms, including tremors, ataxia, and myoclonus, which progressed rapidly to death. Kidney and hepatocellular toxicity were also noted. Acute acetochlor exposures in rats induced methemoglobinemia and hepatocellular toxicity.

### Diagnostic Testing

Patients with a history of propanil poisoning should be investigated for the presence of methemoglobinemia (Chap. 124). In the absence of co-oximetry, simple color charts can be used to support the diagnosis and severity of methemoglobinemia and to direct the use of antidotes at the bedside.

While the concentrations of propanil and 3,4-dichloroaniline reflect clinical outcomes, this relationship is less marked for 3,4-dichloroaniline during the first 6 hours, which probably relates to the time for bioconversion from propanil.<sup>99</sup> However, propanil and 3,4-dichloroaniline assays are not commercially available and this observation was not validated. Further, the relationship between concentration and outcomes may depend on patient comorbidities.

### Management

The minimum toxic dose has not been determined and the potential for severe poisoning and death is high, so all patients with amide herbicide ingestions should be treated as significant and monitored for a minimum of 12 hours. Patients with symptomatic ingestions should be treated cautiously, including continuous monitoring for 24 to 48 hours, preferably in an intensive care unit.

Routine clinical observations are sufficient to detect signs of poisoning, in particular sedation and cyanosis, which are noted early postingestion. The time to death is usually greater than 24 hours so there is an opportunity to initiate treatment. There are no controlled clinical or laboratory data available on the effect of any specific treatment in acute symptomatic propanil poisoning, so management is largely focused on reversal of methemoglobinemia and supportive care.

### Resuscitation and Supportive Care

Prompt resuscitation and close observation are required in all patients. Patients should be monitored clinically including pulse oximetry, and receive supportive care including supplemental oxygen, intravenous fluids, and ventilatory and hemodynamic support as required. In the absence of coximetry analysis, significant methemoglobinemia should be suspected when cyanosis does not correct with high-flow oxygen and ventilatory support. Bedside visual assessment, using blood added to absorbent paper, is an accurate method to quantify the degree of methemoglobinemia.<sup>113</sup> Euglycemia should be ensured since adequate glucose concentrations are required for reversal of methemoglobin. Hemoglobin concentrations should be monitored to detect hemolysis, and folate supplementation is recommended during the recovery phase if anemia is significant.

### Gastrointestinal Decontamination

Toxicokinetic studies of propanil demonstrate a prolonged absorption phase, so it is reasonable to administer activated charcoal to the patient a number of hours postingestion.

### Extracorporeal Removal

Data are extremely limited and based on a single report it does not have a role in routine care. A report of combined hemodialysis and hemoperfusion noted a propanil elimination half-life of one hour,<sup>86</sup> but similar half-lives are reported in patients who have not received this treatment.<sup>99</sup> Exchange transfusion has the potential to decrease the concentration of propanil and free hemoglobin, while replacing reduced hemoglobin and hemolyzed erythrocytes. Exchange transfusion may be particularly useful in the treatment of patients who also have glucose-6-phosphate dehydrogenase (G6PD) deficiency. However, the function of transfused erythrocytes is temporarily impaired posttransfusion because of depletion of 2,3-bisphosphoglycerate and G6PD during storage. Further, transfusion reactions such as acute respiratory distress syndrome (ARDS) are a concern, particularly when oxygenation is already impaired. In the absence of controlled studies, the role of such treatments in the routine management of acute propanil poisoning is poorly defined and cannot be recommended at this time (Chap. 6).

### Antidotes

Methylene blue (Antidotes in Depth: A43) is the first-line treatment for methemoglobinemia. Methylene blue has a half-life of 5 hours, which is commonly shorter than that of 3,4-dichloroaniline, so rebound poisoning (ie, an increase in methemoglobin following an initial recovery postadministration of methylene blue) is anticipated and has been observed with a bolus regimen. This is prevented by administration of methylene blue as a constant infusion.

Other potential treatments for methemoglobinemia from propanil include toluidine blue, *N*-acetylcysteine, ascorbic acid, and cimetidine, but no clinical studies have assessed the role of these potential antidotes in the management of propanil poisoning.

## BIPYRIDYL COMPOUNDS, PARAQUAT AND DIQUAT

Bipyridyl compounds are nonselective contact herbicides. The most widely used is paraquat (1,1'-dimethyl-4,4'-bipyridinium), but diquat (1,1'-ethylene-2,2'-bipyridylium) is also commonly used (Fig. 109-2). Paraquat is one of the most toxic pesticides available. Ingestion of as little as 10 to 20 mL of the 20% wt/vol solution is sufficient to cause death. Overall, the mortality rate varies between 50% and 90%; however, in cases of intentional self-poisoning with concentrated formulations, mortality approaches 100%. An increasing number of countries are banning the sale of paraquat in view of its high toxicity. Diquat is less toxic than paraquat, so it is frequently coformulated with paraquat (allowing a lower concentration of paraquat) or used as an alternative in countries where paraquat is severely restricted. Nevertheless, deaths are still reported from intentional and unintentional diquat poisoning in the United States. Because more data are available on paraquat than diquat, much of the following discussion and information relates particularly to paraquat.

### Pharmacology

Paraquat and diquat formulations are highly irritating and often corrosive, causing direct injury. They induce intracellular toxicity by the generation of

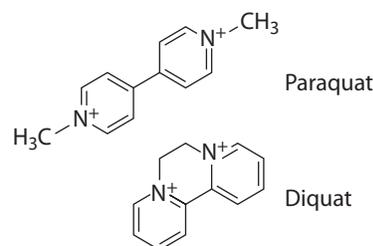

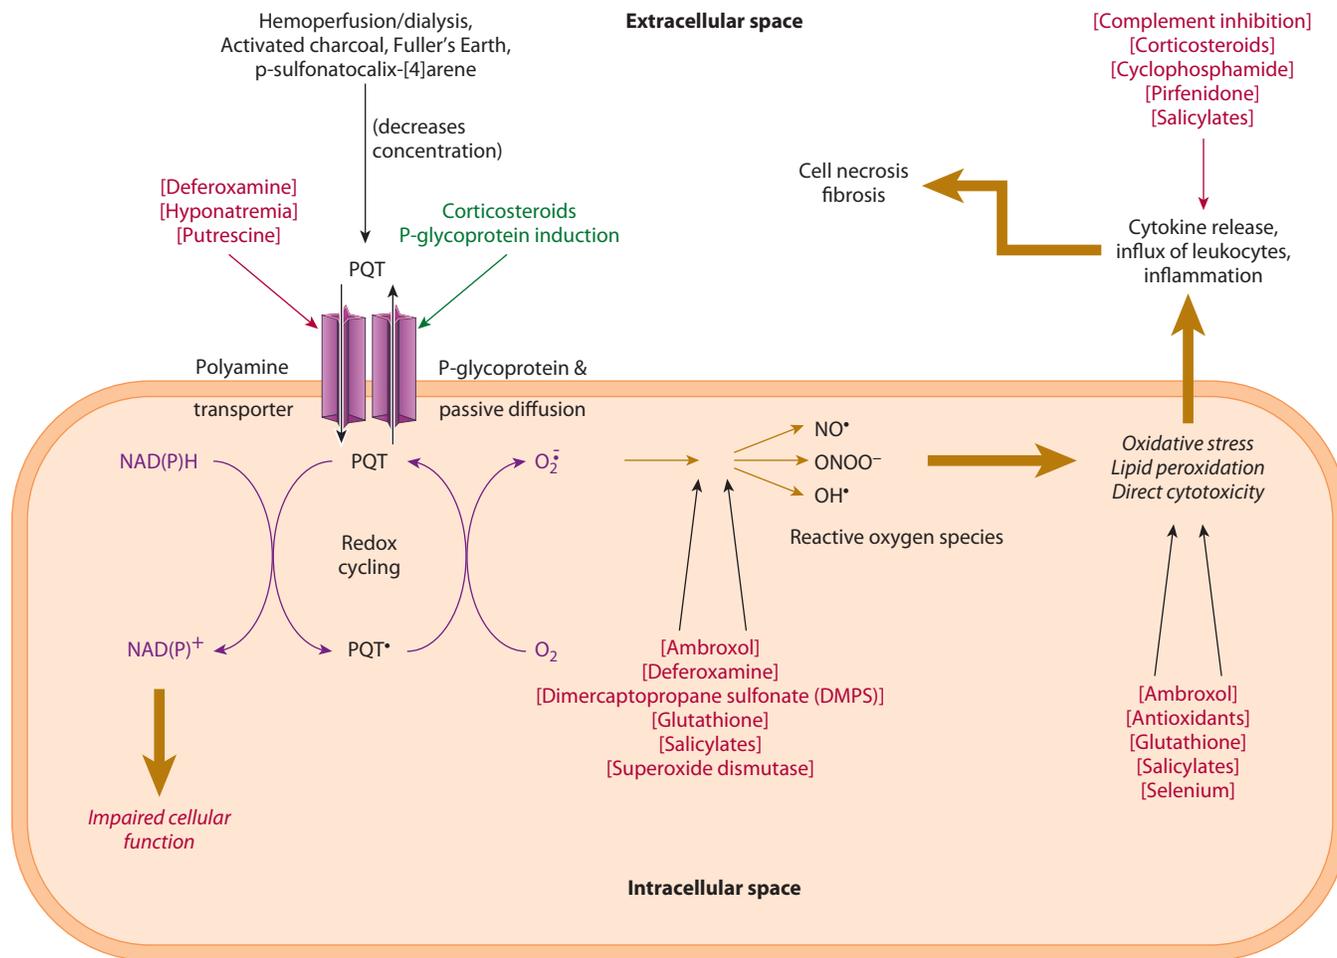

FIGURE 109-2. Structures of paraquat and diquat.

**FIGURE 109-3.** Toxicology of paraquat (PQT) and proposed mechanisms of action of potential treatments. Antioxidants include vitamins C and E and glutathione donors (particularly *N*-acetylcysteine, *S*-carboxymethylcysteine). PQT<sup>•</sup> = paraquat radical; NO<sup>•</sup> = nitric oxide; ONOO<sup>-</sup> = peroxynitrite; OH<sup>•</sup> = hydroxyl radical.

reactive oxygen species that nonspecifically damage the lipid membrane of cells, inducing cellular injury and death. Once paraquat enters the intracellular space it is oxidized to the paraquat radical. This radical is subsequently reduced by diaphorase in the presence of nicotinamide adenine dinucleotide phosphate (NADPH) to re-form the parent paraquat compound and superoxide radical, a reactive oxygen species. This process is known as redox cycling (Fig. 109-3). The superoxide radical is susceptible to further reactions by other intracellular processes, leading to formation of other reactive oxygen species, including hydroxyl radicals and peroxynitrite. Reactive oxygen species are potent cytotoxics. Paraquat redox cycling continues if NADPH and oxygen are available. Depletion of NADPH prevents recycling of glutathione and interferes with other intracellular processes, including energy production and active transporters, exacerbating toxicity. Intracellular protective mechanisms, such as glutathione, superoxide dismutase, and catalase, are overwhelmed or depleted following large exposures. Taken together, these cytotoxic reactions induce cellular necrosis, which is followed by an influx of neutrophils and macrophages. The reactions contribute to the inflammatory response and promote fibrosis and destruction of normal tissue architecture over a number of days.<sup>2,18</sup>

Supplemental oxygen probably increases the generation of reactive oxygen species.

### Pharmacokinetics and Toxicokinetics

Absorption is limited following dermal exposures, although prolonged exposures (at least several hours) to concentrated formulations degrades the epithelial barrier, allowing some systemic absorption. Absorption across the respiratory epithelium is limited.

The oral bioavailability of paraquat in humans is estimated to be less than 5%,<sup>16</sup> yet an oral exposure of as little as 10 mL of the 20% wt/vol formulation is sufficient for significant poisoning to occur. Absorption is rapid and the peak concentration occurs within one hour. The peak paraquat plasma concentration correlates with the amount ingested. Paraquat was reformulated with an emetic along with an alginate (Gramoxone Inteon) that formed a gelatinous mixture on contact with gastric acid, limiting release of the paraquat into the stomach. This formulation reduced paraquat absorption in animals<sup>37</sup> and initially appeared to improve outcomes from self-poisoning in humans (mortality of 64% compared with 74% with the standard preparation),<sup>126</sup> but this observation was not sustained.<sup>128</sup>

Paraquat binds minimally to plasma proteins. Paraquat and diquat rapidly distribute to all tissues and then redistribute back to the central circulation.<sup>84</sup> In humans, the distribution half-life is approximately 5 hours. Paraquat is taken up by alveolar cells through an active energy-dependent polyamine transporter. Paraquat accumulates in alveolar cells, peaking at around 6 hours postingestion in patients with normal kidney function, but later in the context of kidney impairment.<sup>5</sup> Paraquat slowly redistributes from the lungs into the systemic circulation as the plasma concentration falls. By contrast, diquat uptake occurs to a limited extent.

Paraquat and diquat are not metabolized. Elimination is primarily renal with more than 90% of a dose being excreted within the first 24 hours of poisoning if kidney function is maintained.<sup>45</sup> Systemic clearance initially exceeds that of GFR because of active secretion.<sup>12</sup> Impaired kidney function commonly occurs with paraquat and diquat poisoning, particularly beyond 24 to 48 hours postingestion, which decreases excretion and potentiates poisoning. Elimination is prolonged in this setting with a terminal half-life of

around 80 hours in humans.<sup>45</sup> Paraquat is detected in the urine of surviving patients beyond 30 days despite plasma concentrations being quite low 48 hours postingestion.<sup>3</sup>

### Pathophysiology

Paraquat and diquat induce nonspecific cellular necrosis. Lung and kidney injuries are prominent in acute paraquat poisoning because of the high concentrations found in these cells.

Acute pneumonitis and hemorrhage, followed by ongoing inflammation and progressive pulmonary fibrosis, reduces oxygen diffusion and induces dyspnea and hypoxia, which interferes with normal cellular function.<sup>22</sup>

Paraquat induces acute tubular necrosis due to direct toxicity to the proximal tubule in particular, and to a lesser degree distal structures. Other factors contributing to the development of acute kidney injury include hypoperfusion from hypovolemia and/or hypotension and direct glomerular injury. Varying degrees of oliguria, proteinuria, hematuria, and glycosuria are reported.<sup>12</sup> Acute kidney injury interferes with normal fluid and electrolyte homeostasis, as well as interfering with paraquat elimination, which promotes systemic toxicity.

Necrosis of the gastrointestinal tract limits absorption and causes fluid shifts that contribute to hypotension induced by direct vascular toxicity. Hypotension impairs tissue perfusion and if uncorrected progresses to irreversible shock. Failure to correct these abnormalities leads to irreversible organ injury and death.

### Clinical Manifestations

Topical exposures induce painful irritation to the eyes (including formation of a conjunctival pseudomembrane) and skin, progressing to ulceration or desquamation depending on the concentration of the solution, duration of exposure, and adequacy of decontamination. Intravenous administration induces severe poisoning from small exposures.

Most ingestions of bipyridyl compounds induce poisoning, in which ingestion of as little as 5 mL of paraquat 20% wt/vol causes death in more than 50% of cases. Outcomes are more favorable in pediatric patients because of the higher proportion with unintentional poisoning. Gastrointestinal toxicity occurs early, including nausea, vomiting, and abdominal and oral pain. Diarrhea, ileus, and pancreatitis are also reported. Necrosis of mucous membranes, occasionally referred to as pseudodiphtheria,<sup>117</sup> and ulceration are prominent findings that occur within 12 hours. Oromucosal injury without systemic features is observed following brief oral exposures without swallowing. Dysphagia and odynophagia follow larger exposures and progress to esophageal rupture, pneumomediastinum and mediastinitis, subcutaneous emphysema, and pneumothorax, which are usually preterminal events. Death is more likely in those patients who experience a peripheral burning sensation.<sup>29</sup>

Respiratory symptoms are prominent in patients with paraquat poisoning, including acute respiratory distress syndrome manifesting as dyspnea, hypoxia, and increased work of breathing. Ingestions of greater than 50 mL of 20% wt/vol formulation causes multiorgan dysfunction with rapid onset of death within days of ingestion in most patients. Features include hypotension, acute kidney and liver injury, severe diarrhea, and hemolytic anemia.

By contrast, ARDS is less marked with diquat ingestion or following smaller exposures of paraquat (<15–20 mL of 20% wt/vol formulations). In the case of paraquat, the acute respiratory impairment is often followed by progressive pulmonary fibrosis and death weeks or months postingestion. Varying degrees of acute kidney injury and hepatic dysfunction occur.<sup>6,48</sup> Acute kidney injury peaks around 5 days postingestion and resolves within 3 weeks in survivors.<sup>54</sup> Paraquat-induced pulmonary injury is reported to resolve to near-normal function over months to years in survivors.<sup>66</sup>

Diquat does not concentrate in the pneumocytes as readily as paraquat. Therefore, if the patient survives the multiorgan dysfunction, pulmonary fibrosis is less likely to occur.<sup>131</sup> Seizures are reported with diquat poisoning and uncommonly with paraquat.

Ingestion of the adjuvant for Gramoxone Inteon (20% methanol, 20% sodium lignosulfonate, 10% alkylaryl polyoxyethylene ether) induces minor

gastrointestinal adverse effects, an elevated serum osmolar gap, and metabolic acidosis with hyperlactatemia, but outcomes are favorable.<sup>80</sup>

### Diagnostic Testing

Paraquat poisoning is diagnosed when there is a history of exposure and the recognized clinical features, so a high index of clinical suspicion is required. Differential diagnoses include other caustic exposures, sepsis, or other cellular poisons such as phosphine, colchicine, or iron.

The presence of a bipyridyl compound in blood confirms exposure but availability of these assays is increasingly limited. The urinary dithionite test is a simple and quick method for confirming (or excluding) paraquat and diquat poisoning. Various methods are reported, including the addition of 1 g of sodium bicarbonate and 1 g of sodium dithionite, or 1 to 2 mL of 1% sodium dithionite in 1 to 2 M sodium hydroxide, to 10 mL of urine. A color change (blue for paraquat and green for diquat) confirms ingestion—the darker the color, the higher the concentration.<sup>3,58,103</sup> If the test is negative on urine beyond 6 hours after ingestion, a large exposure is unlikely, but repeat testing should be conducted over 24 hours. When the dithionite test is conducted on plasma (eg, add 200  $\mu$ L of 1% sodium dithionite in 2 M sodium hydroxide to 2 mL plasma from the patient), a positive result is specific for death, but a negative test does not exclude severe poisoning or death.<sup>58</sup>

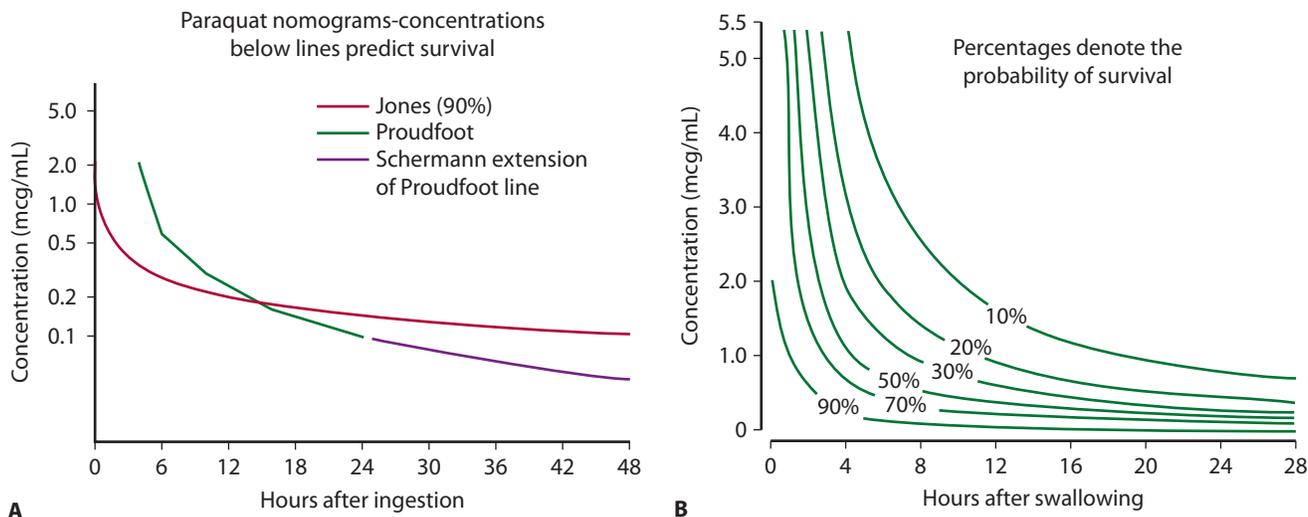

Given that outcomes from paraquat poisoning are generally poor, diagnostic tests help differentiate patients who are likely to survive compared to those in whom death is almost certain. The dose of paraquat is a well-established predictor of death, although this information often is not accurately known at the time of admission. Investigations in patients with acute paraquat poisoning have attempted to determine the severity of poisoning and better define prognosis. Unfortunately, few are validated so their predictive ability is unconfirmed. A range of prognostic tests has been reviewed<sup>24</sup> and a selection of these are discussed below.

Quantitative analysis of the concentration of paraquat in plasma is useful for prognostication, and a number of similar nomograms have been developed to assist with this process (eg, Fig. 109–4). The paraquat concentration must be interpreted relative to the time since ingestion, and each method performs similarly.<sup>110</sup> The Severity Index of Paraquat Poisoning (SIPP) is also calculated with this information, by multiplying the plasma concentration (mg/L) by the time since ingestion (hours). Here, SIPP less than 10 predicts survival, SIPP 10 to 50 predicts death from lung fibrosis, and SIPP more than 50 predicts death from circulatory failure.<sup>107</sup> Determination of the concentration of paraquat in the urine of exposed patients also predicts outcomes. Barriers to the use of these methods include the limited availability of quantitative paraquat assays (leading to a long turnaround time) and the accuracy of the time of ingestion.

Other methods for predicting outcomes from paraquat poisoning have used combinations of simple laboratory tests, including blood gas analysis, complete blood count, electrolytes, uric acid, pancreatitis, kidney function, and liver function tests.<sup>24</sup> Various specific changes are proposed to predict death (eg, metabolic acidosis with an elevated lactate concentration) and increasingly complicated algorithms are being developed, but few are validated. In general, any abnormal result raises the suspicion of a significant poisoning and serial testing is warranted.

An elevated admission creatinine concentration or albuminuria predicts death but is neither sensitive nor specific, although the higher the creatinine concentration, the higher the risk of death.<sup>31,54,58,102</sup>

The rate of increase in creatinine concentration is a simple and practical test to predict prognosis. An increase less than 0.03 mg/dL/h (3  $\mu$ mol/L/h) over 5 hours predicts survival,<sup>95</sup> or greater than 0.05 mg/dL/h (4.3  $\mu$ mol/L/h) over 12 hours (sensitivity 100%, specificity 85%, likelihood ratio 7) predicts death.<sup>102</sup> A similar relationship was noted for cystatin C, in which a rate of increase in cystatin C greater than 0.009 mg/L/h over 6 hours (sensitivity 100%, specificity 91%, likelihood ratio 11) predicted death.<sup>102</sup> This method of prognostication is advantageous because it is determined irrespective of the time of poisoning. Paraquat and diquat interfere with creatinine assays using the Jaffe method, but this is mostly an issue with concentrations exceeding

**FIGURE 109-4.** Nomograms for plasma paraquat concentrations. (A) Compilation of 3 nomograms proposed by Proudfoot et al,<sup>94</sup> Scherrmann et al,<sup>108</sup> and Jones et al.<sup>52</sup> (B) Hart paraquat nomogram.<sup>36</sup> In A, concentrations below lines predict survival. In B, lines link concentrations of equal probability of survival. (Reproduced with permission from Eddleston M, Wilks MF, Buckley NA. Prospects for treatment of paraquat-induced lung fibrosis with immunosuppressive drugs and the need for better prediction of outcome: a systematic review. *QJM*. 2003 Nov;96(11):809-824.)

100 mg/L, which are rarely observed and would be associated with severe clinical toxicity.<sup>92</sup> Other biomarkers of kidney function have been explored but their role in clinical management is not confirmed, nor did they improve on existing methods.

Computed tomography provides prognostic information based on the proportion of lung with ground-glass opacification. For example, ground-glass opacities in 11% to 12% of lung within 4 to 6 days postingestion predicted death in two studies, but in another less than 20% predicted survival and greater than 40% predicted death. Progression of consolidation, fibrosis, and pleural effusion over 2 to 3 days are also strong indicators of poor prognosis.

### Management

Because death follows ingestion of as little as 5 mL of the 20% wt/vol paraquat, all exposures should be treated as potentially life threatening. Patients suspected of ingesting paraquat should be observed in hospital for at least 6 hours postingestion or until a urinary dithionite test is conducted.

Many medical interventions are proposed for the treatment of patients with acute paraquat poisoning but data supporting their efficacy are lacking. Dose-response studies for most of these interventions are also unavailable, and although cell-based and animal studies provide insights into the dose-response, this does not readily translate to human therapeutics.

Given the high likelihood of death from acute paraquat poisoning, many publications report concurrent administration of a number of therapies in the hope of a benefit, including activated charcoal, acetylcysteine, vitamins C and E, immunosuppressants, and hemodialysis and/or hemoperfusion. Xue-bijing (a preparation made from 5 traditional Chinese medicines reported to have antiinflammatory properties) and ulinastatin are used in some hospitals in China and supported by animal studies. The literature is complicated by case reports describing survival in patients who were administered one or a combination of these and other therapies, despite apparently poor prognosis. Various other treatments have been studied in animals including pirfenidone, complement inhibition, sivelestat, bosentan, *p*-sulfonatocalix-[4]arene, dimercaptopropane sulfonate, ambroxol, sucralfate, bone marrow mesenchymal stem cell transplantation and selenium, but human data are lacking. We have no evidence to recommend treatment with any of these regimens.

The choice of which interventions should be administered to a patient is made on a case-by-case basis by the treating physician in consultation with relevant resources. In the context of the anticipated prognosis (see above), detailed discussion with the patient and relatives early in the presentation is recommended to determine their preference for treatment. In general, a comprehensive treatment regimen is reasonable in patients who present

very early (within 2 hours of poisoning) or those with a faintly positive dithionite urinary test. Here, treatments that reduce the exposure to paraquat by either reducing absorption or increasing clearance must be initiated promptly. In contrast, active treatment is not recommended in patients in whom this test is strongly positive, or those with hemodynamic compromise or evolving lung injury. Instead, palliation should be the priority, including supplemental oxygen for hypoxia and morphine for dyspnea and oropharyngeal and abdominal pain.

Serial pulse oximetry measurements and chest radiographs will demonstrate onset and progression of lung injury. Lung transplantation has been tried in patients with delayed respiratory failure, but it was largely unsuccessful because of the prolonged elimination half-life of paraquat.<sup>6</sup> However, successful lung transplantation was reported when performed 56 days postpoisoning after 12 days of extracorporeal membrane oxygenation therapy. Patients developing acute kidney injury should receive hemodialysis or hemofiltration per usual guidelines if active treatment is to be pursued, and these treatments also enhance elimination of herbicide if commenced promptly (see below).

### Resuscitation and Supportive Care

All patients should receive prompt routine resuscitation and close observation. Supplemental oxygen should only be administered to patients for palliation when there is confirmed hypoxia and/or prognosis is extremely poor. Although controlled hypoxia does not prevent the development of pulmonary injury, unnecessary supplemental oxygen theoretically hastens the progression of injury. In patients with established lung injury, ventilatory support is reasonable to improve oxygenation and reduce dyspnea.

Intravenous fluids should be administered to patients who are volume depleted from reduced intake, diarrhea, or third-space shifts, as this reduces the severity of acute kidney injury and promotes renal clearance of paraquat. Care is required with volume resuscitation in the context of acute kidney injury to prevent fluid overload. Electrolyte abnormalities should be corrected as required.

Ongoing management includes regular clinical observations including urine output quantification, daily routine laboratory tests (or more frequently if clinically indicated) in patients receiving active treatment and supportive care. Analgesia for oral and abdominal pain should be administered as required, including intravenous opioids, such as morphine, and possibly topical anesthetics, such as lidocaine. Plain radiographs or a CT of the chest provide information on lung and esophageal injury, which may be prognostic as noted above.

### Gastrointestinal Decontamination

Activated charcoal is recommended for all patients presumed to have ingested paraquat as soon as possible, within 2 hours of exposure. Paraquat is coformulated with an emetic so a degree of self-decontamination frequently occurs by the time of presentation to hospital. Fuller's Earth and activated charcoal decrease absorption of paraquat to a similar extent but Fuller's Earth is in limited supply.<sup>4</sup> Because paraquat is rapidly absorbed, decontamination must be commenced within a few hours of ingestion to be useful. Gastric lavage is not shown to improve outcomes overall.<sup>127</sup>

### Extracorporeal Removal

Extracorporeal techniques, in particular hemoperfusion and hemodialysis, increase the elimination of paraquat, which decreases the systemic exposure, and potentially toxicity. Although published data regarding the efficacy of these treatments are contradictory or limited, extracorporeal treatments are recommended in cases of large exposures if the treatment can be initiated within a few hours of ingestion.

Paraquat clearance by hemoperfusion is similar to endogenous clearance but exceeds it when there is impaired kidney function.<sup>53,67</sup> Hemoperfusion is more efficient than hemodialysis, and elimination is maximized when treatment is initiated within the first couple of hours because the plasma concentration is high.<sup>39</sup> Further, given that paraquat rapidly distributes from the circulation, prompt treatment is necessary to limit the uptake into pulmonary and other tissues.<sup>89</sup>

Experimentally, hemoperfusion reduces mortality in dogs only when it is commenced within a few hours of poisoning, and repeated treatments did not significantly increase clearance.<sup>89</sup> Other animal studies have suggested benefits from hemoperfusion when performed within one hour, including a decrease in paraquat exposure, less end-organ damage and a reduction in inflammatory cytokines, but no mortality benefit.

Past experience suggested that extracorporeal treatments do not sufficiently improve mortality in humans, particularly when the concentration is greater than 3 mg/L.<sup>35</sup> Hemoperfusion followed by continuous venovenous hemofiltration prolonged the time to death compared with hemoperfusion alone without changing the overall mortality in nonrandomized studies and a meta-analysis that included three randomized controlled trials (n = 290 patients). However, increasing publications from eastern Asia suggest a clinical benefit from these therapies if commenced early, within 4 to 6 hours of ingestion and possibly with repeat treatment or with concurrent hemodialysis.

The risk of harm from extracorporeal techniques reflects the requirement for central venous access, metabolic disequilibrium, or increased clearance of antidotes, although such risks are low.

### Antidotes

A large number of potential antidotes are under study in the treatment of acute paraquat poisoning. The combination of antidotes (if any) that will improve outcomes is not known, so it is not possible to recommend specific antidotes or dosages in routine clinical care.

Antidotes attempt to counteract the effects of paraquat by targeting various steps in the pathogenesis of organ dysfunction or to alter cellular uptake (Fig. 109–3). Unfortunately, despite their potential promise in animal studies, none of these antidotes are proven to reduce mortality in humans. Some of the interventions that decrease paraquat exposure by decreasing absorption<sup>126</sup> or increasing elimination<sup>57</sup> were shown to prolong the time to death. Therefore, clinicians commonly combine these treatments as part of a multimodal approach in the hope that it will reduce mortality. There are insufficient published data to support this approach, but in view of the high mortality from paraquat this approach is not generally considered to add to patient's risk. Therefore, such a multimodal approach to treatment may be reasonable in certain cases, such as early presentations of less than 50 mL of 20% wt/vol formulations when extracorporeal treatments are also available. Examples of specific potential antidotes are detailed here.

Immunosuppression with corticosteroids (dexamethasone or methylprednisolone) and cyclophosphamide are the most extensively studied

antidotes in humans. Early randomized controlled trial data (3 trials, n = 164 patients) suggested a benefit from these treatments but because of limitations in study design these results were not considered conclusive.<sup>68</sup> This was followed by a larger randomized controlled trial (n = 298) that reported no mortality benefit from high-dose immunosuppression (cyclophosphamide, methylprednisolone, dexamethasone) in patients with acute paraquat poisoning.<sup>28</sup> Therefore, although nonrandomized studies support a potential benefit, this immunosuppressive regimen is not recommended.

Generation of reactive oxygen species is an important step in the pathogenesis of paraquat poisoning (Fig. 109–3). This leads to cytotoxicity, the extent of which depends on the concentration of paraquat and the efficiency of endogenous protective mechanisms such as vitamin C (ascorbic acid), vitamin E ( $\alpha$ -tocopherol), and glutathione. Administration of these vitamins and/or a glutathione donor (eg, *N*-acetylcysteine, *S*-carboxymethylcysteine, captopril) or other scavenging agents such as superoxide dismutase and amifostine and deferoxamine is not routinely recommended because they are not proven to be beneficial, and potentially vitamin C might increase oxidative toxicity.<sup>22</sup>

Some treatments influence the toxicokinetics of paraquat at the cellular level. Xenobiotics that decrease the uptake of paraquat into pneumocytes were studied such as putrescine, spermidine, and deferoxamine, but their effect is limited and they do not alter efflux. Corticosteroids, particularly dexamethasone and methylprednisolone, were shown in animal models to induce P-glycoprotein, which increases the cellular efflux and excretion of paraquat although data regarding the extent to which paraquat is a substrate for P-glycoprotein are conflicting. Therefore, these treatments are not routinely recommended.

Salicylates are proposed to inhibit multiple steps in the pathogenesis of paraquat poisoning, including decreasing production of reactive oxygen species, inhibition of NF- $\kappa$ B, antithrombotic effects, and chelation of paraquat.<sup>20,21</sup> Sodium salicylate 200 mg/kg decreased reactive oxygen species production and inflammation and improved survival in rats.<sup>20</sup> Similarly, lysine acetylsalicylate 200 mg/kg improved survival in rats in a dose-finding study.<sup>23,46</sup> A small pilot study noted a delayed time to death in patients receiving intravenous acetylsalicylic acid. Other antidotes and treatments have also been proposed, but less information regarding their effects is available. Therefore, these treatments are not routinely recommended.

### Treatment Recommendations

Most clinical studies have not demonstrated favorable outcomes, in contrast to animal studies. This reflects larger poisonings, increased sensitivity or delayed institution of therapy in human reports. Because some studies report a delayed time to death in patients who receive an intervention, this has suggested a possible effect and prompted further research into dose–response and the effect of combination therapy. In patients with a poor prognosis, active treatment, particularly with invasive modalities such as hemoperfusion/dialysis, will interfere with end-of-life care. Based on these principles, our recommendations favor intervention when there is a hope of recovery, while avoiding unfounded experimental technologies.

The prognosis in patients presenting more than 12 hours after ingesting 50 mL or more of paraquat 20% wt/vol, those with a positive plasma dithionite test, or those with a SIPP greater than 50 is so poor that treatment should focus on symptom control and end-of-life support and palliation.

The prognosis in patients presenting within 6 hours of ingesting less than 50 mL of paraquat, those with a faint-positive dithionite test, or those with a SIPP less than 50 is also poor, but prompt multimodal treatment with volume resuscitation, oral activated charcoal (or Fuller's Earth), hemoperfusion or hemodialysis, intravenous corticosteroids, acetylsalicylate, *N*-acetylcysteine, deferoxamine, and vitamin E can be considered on a case-by-case basis. It cannot be overemphasized that potential benefits of these treatments (if any) is time-critical so they must be commenced immediately. If any of these treatments are not available at the initial treatment center it is reasonable to transfer the patient to a center that can provide them within the stated time frame. Excluding dermal exposures, other exposures not yet mentioned are

associated with poor prognosis and unlikely to respond to treatment. However, if resources are available and psychosocial or cultural factors support aggressive treatment then the previous-mentioned treatment regimen can be attempted (but a benefit is not anticipated). In particular, it is not recommended that such patients be transferred to another center to receive active treatment.

It is unfortunate that paraquat is so inexpensive and effective as an herbicide when outcomes from unintentional and intentional poisoning are so devastating despite maximal medical treatment. Ultimately, the key focus to reducing deaths from paraquat poisoning is to ban its sale (or at least highly restrict its availability to commercial operators), which is supported by outcome data from a number of countries.

## GLUFOSINATE

Glufosinate (Fig. 109–5) is a nonselective herbicide used predominantly in Japan and Korea, but it is the 25th most commonly used pesticide in the United States.<sup>33</sup> Commercial preparations contain 14% to 30% glufosinate as the ammonium or sodium salt, with anionic surfactants. Case fatalities between 6.1% and 17.7% are reported from glufosinate poisoning, and increasing age is a risk factor.<sup>74</sup>

### Pharmacology

Glufosinate is neurotoxic, although the specific mechanism is incompletely described. Because it is structurally similar to glutamate, studies have explored whether it interferes with glutamate networks in the central nervous system. Studies in rats demonstrate both agonism and antagonism to glutamate receptors and no effect on other receptors in the brain.<sup>34</sup> Glufosinate also interferes with glutamine synthetase activity, which induces hyperammonemia. Ammonia concentrations were not markedly altered in rats,<sup>34</sup> but hyperammonemia is observed following self-poisoning.<sup>34,60,73,124</sup>

Cellular toxicity appears to be persistent; for example, mouse studies note that effects persist beyond 2 weeks after an acute exposure.

Glufosinate was not found to inhibit cholinesterase enzymes in rat studies,<sup>34</sup> although this is reported in humans on occasion, including one case in which it decreased to 40% of the lower limit of normal with subsequent recovery.<sup>124</sup>

The extent to which the surfactant contributes to clinical toxicity is not confirmed. Rat studies suggest that hemodynamic changes due to glufosinate ammonium formulations are entirely caused by the surfactant component rather than glufosinate itself.<sup>59</sup> Surfactants may also cause uncoupling of oxidative phosphorylation, although this was not demonstrated in the study of a single case of glufosinate ammonium poisoning.<sup>70</sup>

### Pharmacokinetics and Toxicokinetics

Kinetic analysis of glufosinate is limited to animal studies and a few human case reports. Minor differences in kinetics of the D- and L-glufosinate enantiomers are observed between patients, the clinical implications of which are not known.

The peak concentration is observed 1 hour postingestion in mice administered the formulated product, and less than 15% of a dose is absorbed by rats.

Glufosinate does not appear to bind to plasma proteins to a significant extent. The  $V_d$  was calculated to be 1.44 L/kg in a case of acute poisoning by assuming that the renal excretion of glufosinate is similar to animals.<sup>38</sup> Glufosinate distributes into the central nervous system, but the rate of distribution to the cerebrospinal fluid has not been characterized. It is theorized

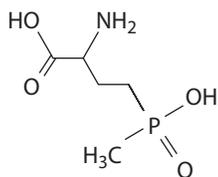

FIGURE 109–5. Structure of glufosinate.

that glufosinate distributes into the central nervous system, slowly, perhaps due to active transporters, where it accumulates, which is why the onset of respiratory depression is delayed.<sup>44</sup> Indeed, seizures have occurred in some patients after glufosinate was no longer detectable in the blood.<sup>124</sup> However, this theory was not supported in a case in which glufosinate was not detected in the cerebrospinal fluid 6 hours after a seizure that occurred 30 hours postingestion.<sup>121</sup> Yet in another case of acute poisoning, the cerebrospinal fluid concentration was one-third the serum concentration 27 hours postingestion. Seizures occur 3 hours after the administration of intracerebral glufosinate in rats, which further challenges the theory that distribution kinetics influence the delayed onset of seizures in humans.<sup>34</sup>

Glufosinate is subject to minimal metabolism and the majority of the bioavailable dose of glufosinate is excreted unchanged in urine.

The elimination half-life is 4 hours in rats, whereas in rabbits elimination is biphasic with a terminal elimination half-life of 1.9 hours, which is not dose dependent. Kinetic data in humans are limited to a small number of cases of acute intentional poisoning in which the elimination profile appeared biphasic with a distribution half-life of 2 to 4 hours and a terminal elimination of 10 to 18 hours.<sup>38,41,118</sup>

### Pathophysiology

It is not known whether the manifestations of glufosinate poisoning represent a primary (toxic) or secondary (downstream) effect. The most important manifestations are neurologic, with respiratory impairment that reduces oxygen delivery and subsequently compromises cellular function. Hypotension also impairs tissue perfusion and if uncorrected progresses to shock. Failure to correct these abnormalities leads to irreversible cellular injury and death.

### Clinical Manifestations

Nausea and vomiting are early features of acute poisoning. An altered level of consciousness precedes severe neurotoxicity, which occurs between 4 and 50 hours postingestion, but usually within 24 hours, and includes seizures and central respiratory failure requiring ventilatory support.<sup>60,73,74</sup> These toxicities often persist for a number of days. In rats, following the intraperitoneal administration of glufosinate, the onset of seizures is also delayed by a number of hours and the time to onset decreases in a dose-dependent manner.<sup>75</sup>

Other manifestations of acute poisoning include cardiac dysrhythmias, fever, amnesia (both antegrade and retrograde), diabetes insipidus, and rhabdomyolysis. Refractory hypotension is often preterminal.<sup>60,73,74</sup>

### Diagnostic Testing

Glufosinate poisoning is diagnosed clinically in the context of a history of exposure. Glufosinate assays are available for clinical use in Japan and a nomogram was developed for predicting clinical outcomes (Fig. 109–6).<sup>40</sup> Clinical chemistry assays including kidney function, blood gases, electrolytes, creatine kinase, and ammonia concentrations support clinical management.

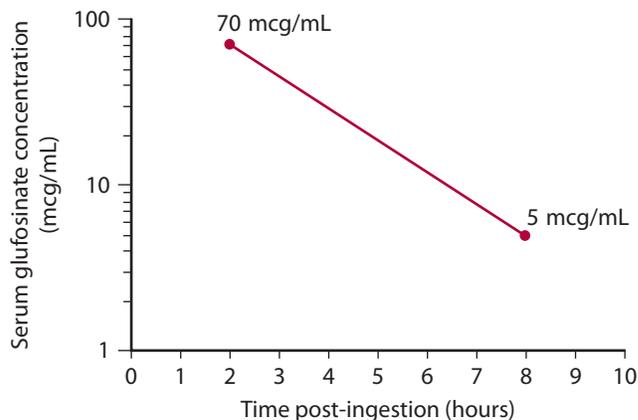

FIGURE 109–6. Glufosinate nomogram as described by Hori et al.<sup>40</sup> Concentrations above the line are associated with more severe poisoning.

Metabolic acidosis is more common with severe poisoning.<sup>74</sup> The ammonia concentration peaks 24 to 48 hours postingestion and increasing concentrations suggest an increased risk of neurotoxicity.<sup>34,60,73</sup> An increase in serum S100B protein precedes the onset of neurotoxicity.

### Management

Toxicity is not consistently dose-dependent and severe symptoms are reported following unintentional ingestion, so all patients with oral exposures should be carefully monitored. Patients with confirmed exposures should be monitored for a minimum of 48 hours because the onset of clinical toxicity is often delayed. Prior to discharge, each patient should be carefully screened to identify those with cognitive impairment.

### Resuscitation and Supportive Care

Routine resuscitation, close observation, and supportive care are required. Careful monitoring for the onset of respiratory failure is necessary and early intubation and ventilation is recommended in symptomatic patients. Given that glufosinate and metabolites are primarily renally cleared, intravenous fluids to maintain a consistent urine output is reasonable. Seizures should be treated in a standard manner initially with benzodiazepines as first-line therapy, which was effective in animal studies. Biochemical and acid–base abnormalities should be corrected as per usual care.

### Gastrointestinal Decontamination

In most reports of glufosinate poisoning, gastric lavage and activated charcoal were administered, but it is not possible to determine whether these interventions improved clinical outcomes. The high incidence of both seizures and respiratory failure from glufosinate poisoning are relative contraindications to the administration of activated charcoal to patients with an unprotected airway.

### Extracorporeal Removal

Hemodialysis and hemoperfusion were both used and hemodialysis was superior in terms of extraction of glufosinate from whole blood *in vitro*, with an extraction ratio of 80%. The clearance by hemodialysis is less than 60% of renal clearance in patients with normal kidney function. Although prompt hemodialysis in patients promotes a decrease in the concentration of glufosinate and probably ammonia, it is not known if this prevents the occurrence of neurotoxicity such as seizures, so its role in routine management is poorly defined. It is reasonable to administer these treatments in patients with severe poisoning and also in those with impaired kidney function.

### Antidotes

Specific antidotes are not available. Benzodiazepines should be first-line therapy for seizures.

## GLYPHOSATE

Glyphosate (Fig. 109–7) is a nonselective postemergence herbicide. It is used extensively worldwide, most commonly as the isopropylamine salt but also a potassium salt. Glyphosate-containing herbicides are available in various formulations: 1% to 5% glyphosate (ready to use) or 30% to 50% (concentrate requiring dilution before use). In 2012, glyphosate was the most frequently used herbicide in the United States and the second most commonly used herbicide in the domestic sector.<sup>33</sup> Products containing glyphosate trimesium are less widely used and differ with respect to their toxicity profile. Glyphosate is banned in some countries because of data suggesting that it is a

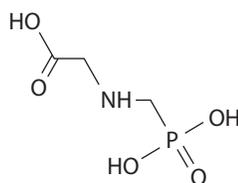

FIGURE 109–7. Structure of glyphosate.

carcinogen. However, this topic is extensively debated, and in March 2017 the EPA concluded that glyphosate is not likely to be carcinogenic to humans.

### Pharmacology

Glyphosate inhibits 5-enolpyruvylshikimate-3-phosphate synthase in plants, which interferes with their aromatic amino acid synthesis; this enzyme is not present in humans.

The mechanism of toxicity of glyphosate-containing herbicides to humans is not adequately described. The formulation is irritating and high concentrations are corrosive, causing direct injury to the gastrointestinal tract. Despite being an organic phosphorus compound, glyphosate does not inhibit acetylcholinesterase. Patients with severe poisoning manifest multi-system effects, suggesting that the formulation is either nonspecific in its action or that it interferes with a physiologic process common to a number of systems. Proposed mechanisms include disruption of cellular membranes and uncoupling of oxidative phosphorylation, which are interrelated. Indeed, the mechanism of toxicity varies between different glyphosate salts. In 2 cases of glyphosate trimesium poisoning, cardiopulmonary arrest occurred within minutes of ingestion.<sup>81,116</sup> Because this is not reported from glyphosate isopropylamine, it is possible that these products differ in the mechanism of toxicity.

Experimentally, there is minimal (if any) mammalian toxicity from glyphosate itself. Glyphosate is categorized as WHO class “U” (unlikely to present acute hazard in normal use; the dose of a xenobiotic predicted to kill 50% of exposed animals  $LD_{50} > 4,000$  mg/kg).<sup>49</sup> Surfactant coformulants are likely the more toxic component in glyphosate-containing herbicides. Polyoxyethyleneamine (tallow amine;  $LD_{50}$  equal to 1,200 mg/kg) is the most common surfactant formulated in these products, but others are also used. Systemic exposure to surfactants induces hypotension, which is primarily due to direct effects on the heart and blood vessels.<sup>13</sup> Surfactants directly disrupt cellular and subcellular membranes, including those of mitochondria, which has the potential to lead to systemic symptoms.<sup>32</sup> Coformulated potassium and isopropylamine contribute to toxicity. Isopropylamine has a rat  $LD_{50}$  of 111 to 820 mg/kg, decreases vascular resistance, and either increases or decreases cardiac contractility and rate.<sup>50,93</sup>

### Pharmacokinetics and Toxicokinetics

The kinetics of the surfactant are not described. The relevance of the kinetics of glyphosate is questioned because its contribution to clinical toxicology is minimal; however, it is summarized here for completeness. Glyphosate does not penetrate the skin to a significant extent. Up to 40% of an oral dose is absorbed in rats, although this could increase when ingested as a concentrated solution with injury to the gastrointestinal epithelium. The peak glyphosate plasma concentration occurs within 2 hours of ingestion and distribution appears to be limited. Glyphosate does not readily cross the placenta according to an *ex vivo* model.<sup>82</sup> Glyphosate has an elimination half-life of less than 4 hours and is excreted unchanged in the urine.<sup>7,9,43,100,125</sup>

### Pathophysiology

It is not known whether the manifestations of glyphosate poisoning represent a primary (toxic) or secondary (downstream) effect. Disruptions of oxidative phosphorylation globally impair normal cellular function as a result of limited energy supply (discussed further with the pathophysiology of phenoxy herbicides). Similarly, direct toxicity to cell membranes (including those of the mitochondria) interferes with normal cellular processes such as ion channels. Both disruptions induce multiorgan toxicity. Hypotension and dysrhythmias impair tissue perfusion, and liver and kidney injuries induce metabolic disequilibria and acidemia, which impair normal physiologic processes. Pulmonary toxicity induces hypoxia, which further compromises normal cellular functioning. Failure to correct these abnormalities leads to irreversible cellular toxicity and death.

### Clinical Manifestations

Abdominal pain with nausea, vomiting, and/or diarrhea are the most common manifestations of acute poisoning. These are mild and self-resolving

except in patients with severe poisoning due to inflammation, ulceration, or infarction of the gut wall. Severe diarrhea and recurrent vomiting result in dehydration. Gastrointestinal burns and necrosis occur with high doses of concentrated formulations and are associated with hemorrhage. Extensive erosion of the upper gastrointestinal tract is associated with more severe systemic poisoning and prolonged hospitalizations.<sup>14,15,47,79,100</sup>

Severe poisoning manifests as multiorgan failure, including hypotension, cardiac dysrhythmias, kidney and liver dysfunction, hyperkalemia, pancreatitis, pulmonary edema or pneumonitis, altered level of consciousness including encephalopathy, seizures, and metabolic acidosis. These effects range from transient to severe, progressing over 12 to 72 hours to resistant shock, respiratory failure, and death. Hypotension relates to both hypovolemia (fluids shifts and increased losses) and/or direct cardiovascular toxicity.<sup>7,15,65,69,79,100,111,120</sup>

Intravenous self-administration of glyphosate-containing herbicide caused hemolysis in one patient, and intramuscular self-administration caused rhabdomyolysis in another.

A large prospective study reported a case fatality of 3.2% in patients presenting to rural hospitals in Asia in which resources are limited,<sup>100</sup> but mortality reported in other studies varied from 2% to 30%.<sup>15</sup> These differences in outcomes likely reflect differences in timely access to health care services, available medical facilities, variability in glyphosate formulations, or selection bias related to case-referral. Proposed risk factors for death include a large exposure, delayed presentation to hospital, elevated glyphosate concentration, and increasing age.<sup>15,79,100,111</sup>

Respiratory, ocular, and dermal effects occur following occupational use of these preparations but are usually of minor severity.

## Diagnostic Testing

Acute poisoning with a glyphosate-containing herbicide is diagnosed on the basis of a history of exposure and clinical findings. The differential diagnoses are wide, including any xenobiotic or medical condition associated with gastrointestinal effects and progressive multisystem toxicity.

A number of clinical criteria for the classification of severity are suggested, but none are validated.<sup>7,100,120,122</sup> There are no readily available specific clinical investigations to guide management or estimate prognosis in acute poisoning. Higher plasma glyphosate concentrations are associated with more severe poisoning, for example concentrations greater than 734 mg/L predicted death in one study.<sup>100</sup> A review noted that severe poisoning is associated with concentrations greater than 1,000 mg/L.<sup>7</sup> These concentrations probably reflect the amount of exposure, because glyphosate is minimally toxic. Quantitative glyphosate assays are not routinely available for clinical use.

Targeted laboratory and radiologic investigations should be conducted in patients demonstrating anything more than mild gastrointestinal symptoms. Pulse oximetry and blood gas measurements detect metabolic disequilibrium and respiratory impairment. Electrolytes should be measured early because some formulations contain glyphosate as a potassium salt and severe hyperkalemia and electrocardiographic changes are reported.

Patients who develop marked nonspecific organ toxicity (eg, acute kidney injury, pulmonary edema, metabolic acidosis (including an elevated lactate concentration, sedation, dysrhythmias, hypotension) are more likely to die.<sup>15,62,64,79,100</sup>

Endoscopy identifies erosions or ulceration following exposures to the concentrated formulation, although this will not prompt a change in management. Further, endoscopy of an inflamed viscus presents a risk of perforation.

## Management

Retrospective studies suggest a correlation between ingestion, severity of poisoning, and death.<sup>64,100,106,122</sup> All patients except for those with trivial exposures should be observed for a minimum of 6 hours. In particular, patients presenting with intentional self-poisoning or ingestion of a concentrated formulation must be carefully monitored. If gastrointestinal symptoms are noted then the patient should be observed for a minimum of 24 hours given

that clinical toxicity may progress. Because the toxicity of individual surfactants was not determined, treatment does not vary depending on specific coformulants.

## Resuscitation and Supportive Care

All patients should receive prompt resuscitation, close observation, and routine supportive care; other treatments are largely empiric. The airway is usually maintained but respiratory distress and failure occur, which require supplemental oxygen and possibly mechanical ventilation. The optimal management of hypotension is complicated because its etiology is potentially related to hypovolemia, negative inotropy, and/or reduced vascular resistance. A detailed clinical review is required, followed by cautious administration of intravenous fluids to the patient. If the response to prompt administration of 20 to 30 mL/kg intravenous fluid to the patient is insufficient or there is increasing pulmonary congestion, then vasopressors are recommended. Other investigations such as echocardiography and central venous pressure will guide management, if available.

Biochemical and acid–base abnormalities, such as hyperkalemia, should be corrected where possible. The contribution of uncoupling of oxidative phosphorylation to clinical toxicity and death is proposed, but no specific treatment is available. In the context of acute poisoning with glyphosate-containing herbicides, signs suggestive of uncoupling of oxidative phosphorylation, such as hyperthermia, metabolic acidosis with elevated lactate concentration, and hypoglycemia, often represent a preterminal event. Hemodialysis or hemofiltration should be administered to patients developing acute kidney injury per usual guidelines if active treatment is to be pursued. Survival is reported with severe glyphosate poisoning (respiratory failure, persistent ventricular tachycardia and shock refractory to inotropes, and acidemia) using extracorporeal membrane oxygenation therapy.

## Gastrointestinal Decontamination

No data exist to support the role of gastrointestinal decontamination in acute poisoning with glyphosate-containing herbicides beyond the usual recommendations discussed above.

## Extracorporeal Removal

The role of extracorporeal removal in routine care is not known, but we recommend using it in patients with severe poisoning. Patients who received hemodialysis have survived severe poisoning; however, other patients have died despite this treatment. There are limited quantitative data reporting direct clearances, and uncertainty regarding which compound to measure.

## Antidotes

No specific antidotes are proposed or tested for the treatment of acute poisoning with glyphosate-containing herbicides, which relates in part to the unknown mechanism of toxicity.

## PHENOXY HERBICIDES (PHENOXYACETIC DERIVATIVES), INCLUDING 2,4-D AND MCPA

Phenoxy compounds are selective herbicides that are widely used in both developing and developed countries. A large number of compounds are included in this category; however, the most widely used are the phenoxyacetic derivatives. This includes 2,4-dichlorophenoxyacetic acid (2,4-D), 4-chloro-2-methylphenoxyacetic acid (MCPA), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T; no longer available), and mecoprop (MCP; 2-(4-chloro-2-methylphenoxy)propionic acid; Fig. 109–8). Other phenoxy herbicides and available toxicity data are listed in Table 109–1. In 2012, 2,4-D was the fifth most commonly used herbicide in the United States but the most commonly used herbicide in the domestic sector (MCP was third and MCPA the ninth most commonly used in the domestic sector).<sup>33</sup>

Agent Orange, a defoliant popularly used during the Vietnam War, was composed of an equal mixture of 2,4-D and 2,4,5-T. This product also contained contaminant dioxins, in particular 2,3,7,8-tetrachlorodibenzodioxin which was a by-product of the manufacture of phenoxy herbicides. This dioxin is a persistent organic pollutant that is alleged to induce chronic

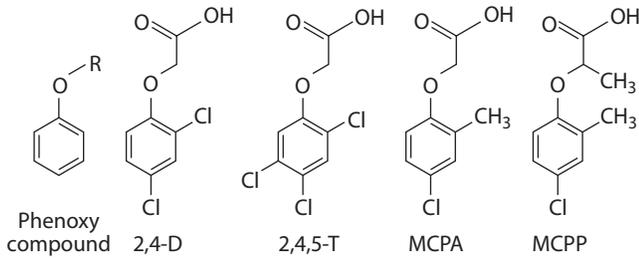

FIGURE 109–8. Structures of common phenoxy herbicides.

health conditions and cancer, although this is debated. This chapter discusses only the outcomes of acute exposures to phenoxy herbicides.

### Pharmacology

The mechanism of toxicity of phenoxy compounds is not well described. The formulation is irritating or caustic, causing direct injury to the gastrointestinal tract. Patients with severe poisoning manifest multisystem effects, suggesting that the formulation is either nonspecific in its action or that it interferes with a physiological process common to a number of systems. As with other herbicide preparations, this reflects the uncertain contributions of coformulants such as bromoxynil, ioxynil or surfactants.

In rats, high plasma concentrations of MCPA damage cell membranes and induce toxicity, but the correlation between plasma concentrations, membrane damage, and toxicity is poor. Dose-dependent acute kidney injury from 2,4-D is observed in rats.

Uncoupling of oxidative phosphorylation also contributes to the development of severe clinical toxicity. Phenoxyacetic derivatives demonstrate concentration-dependent uncoupling of rat mitochondria in vitro, although the specific process that is disrupted is not sufficiently described.<sup>10,133</sup> Features of uncoupling of oxidative phosphorylation were observed antemortem in clinical studies of patients with large phenoxy herbicide exposures.<sup>98</sup>

Phenoxy acid compounds inhibit the voltage-gated chloride channel (CLC-1) in skeletal muscles, which is thought to contribute to the neuromuscular toxicity of these compounds. Dysfunction of CLC-1 induces myotonia due to hyperpolarization of the cell membrane. Other CLC channels are important for normal renal physiology. There are differences in the degree of inhibition between individual phenoxy acid compounds, which likely contributes to the variability in animal LD<sub>50</sub> and possibly clinical features.

Other possible mechanisms of toxicity relate to their similarity to acetic acid, interfering with the utilization of acetylcoenzyme A (acetyl-CoA), or action as a false messenger at cholinergic receptors.<sup>8</sup>

### Pharmacokinetics and Toxicokinetics

Animal studies and human case reports demonstrate nonlinear kinetics for the phenoxy herbicide compounds. Dose-dependent changes in absorption, protein binding, and clearance all occur, and each will influence the concentration-time profile.

Absorption is usually first order;<sup>1</sup> however, the time to peak concentration is delayed with increasing doses, which suggests saturable absorption and is supported by cell culture studies that demonstrate active absorption of these herbicides by a hydrogen ion-linked monocarboxylic acid transporter.<sup>55,61,101,123</sup>

As the dose of MCPA increases, there is a change in the semilogarithmic plasma concentration–time profile from linear to a biphasic convex profile. The inflection of this elimination curve in rats is approximately 200 mg/L,<sup>25,26,101,123</sup> which appears to reflect saturation of albumin binding. As the plasma concentration exceeds this point, the proportion of herbicide that is free (unbound) increases.<sup>101</sup> This increases the  $V_d$  and prolongs the apparent plasma elimination half-life.

Another contributing mechanism to the observed biphasic convex concentration-time profile is saturation of renal clearance for which there is some interspecies variability. Dose-dependent renal clearance is attributed

to saturation of an active transport process or direct nephrotoxicity. Renal clearance also varies with urine production because of reabsorption from the distal tubule.

Similar to data from animal studies, the semilogarithmic plasma concentration–time curve of phenoxy herbicides in humans with acute poisoning is generally convex, with an apparent inflection from a longer (but highly variable) to shorter elimination half-life between 200 and 300 mg/L. The elimination half-lives are prolonged, contributing to the persistence of clinical toxicity and occurrence of death a number of days postingestion of a phenoxyacetic herbicide.<sup>98,101</sup>

Alterations in blood pH theoretically change tissue distribution because phenoxyacetic herbicides are weak acids ( $pK_a$  approximately 3). Here, acidemia increases the proportion that is nonionized, and therefore lipophilic, which increases tissue binding and distribution. This is observed in vitro and is similar to that observed for salicylates (Chap. 37). Similarly, an alkaline plasma pH is expected to decrease tissue (and probably receptor) binding and increase plasma concentrations.

Experience with acute human poisonings noted a poor correlation between plasma concentrations and peak toxicity.<sup>98</sup> This probably reflects a discordance between plasma (measured) and intracellular (eg, mitochondrial) concentrations.

### Pathophysiology

Direct injury to the gastrointestinal tract causes vomiting and diarrhea, which induces hypovolemia and electrolyte abnormalities.<sup>8</sup> Nonspecific cellular toxicity and uncoupling of oxidative phosphorylation interfere with normal function of ion channels and other cellular functions, preventing normal physiological processes.

Uncoupling of oxidative phosphorylation disrupts mitochondrial function, and causes inefficiency in energy production. Here, there is an increase in heat production out of proportion to the generation of ATP. Varying degrees of uncoupling of oxidative phosphorylation occur. The initial physiological response to uncoupling is to increase mitochondrial respiration to maintain the supply of ATP, which increases heat production and respiratory rate. As ATP falls there is an increase in glycolysis, causing hypoglycemia and metabolic acidosis with an elevated lactate concentration. If the mitochondrial defect persists then there will be hyperthermia and insufficient ATP for essential cellular functions, including active transport pumps such as  $Na^+,K^+$ -ATPase. This is followed by a loss of cellular ionic and volume regulation, which if persistent, is irreversible and cell death occurs. Because mitochondria are the primary supplier of ATP for most physiologic systems, uncoupling of oxidative phosphorylation is expected to induce multisystem toxicity.

### Clinical Manifestations

Severe toxicity is more commonly reported in patients ingesting herbicide preparations containing both a phenoxy acid derivative with bromoxynil or ioxynil.

Vomiting, myotonia, confirmed on electromyography, and miosis are prominent features of 2,4-D poisoning in dogs. Severity varies in a dose-dependent manner, peaking 12 to 24 hours postingestion and persisting for a number of days.

Gastrointestinal toxicity including nausea, vomiting, abdominal or throat pain, and diarrhea are common. Other clinical features include neuromuscular findings (myalgia, rhabdomyolysis, weakness, myopathy, myotonia, and fasciculations), central nervous system effects (agitation, sedation, confusion, miosis), tachycardia, hypotension, acute kidney injury, and hypocalcemia. In some patients, these effects persist for a number of days.<sup>98</sup>

Tachypnea with respiratory alkalosis occurs in patients with phenoxy herbicide poisoning, some of whom died, which is consistent with increased mitochondrial respiration from mild uncoupling. More severe poisoning is characterized by metabolic acidosis, hyperventilation, hyperthermia, elevated creatine kinase, generalized muscle rigidity, progressive hypotension, pulseless electrical activity, or asystole.<sup>8,19,85,98</sup>

The mortality from acute phenoxy herbicide poisoning is high. A systematic review of all acute phenoxy herbicide poisoning described severe clinical toxicity in most patients, including death in one-third of the cases.<sup>8</sup> Subsequently, a prospective study of MCPA exposures demonstrated minor toxicity in greater than 80% of patients and a mortality of 4.4% (8 of 181 patients).<sup>98</sup> When death occurs, it is usually delayed by 24 to 48 hours postingestion and results from cardiorespiratory arrest. The exact mechanism of death is inadequately described, but appears to relate to uncoupling of oxidative phosphorylation or other metabolic dysfunction including acute kidney injury, as discussed above.

### Diagnostic Testing

Commercial assays for the specific measurement of phenoxy herbicides are not available to assist in the diagnosis of acute poisoning. Further, their role in the management of acute poisoning is not confirmed because the relationship between plasma phenoxy herbicide concentration and clinical toxicity appears to be poor.<sup>98</sup> Sedation is reported with a plasma phenoxy concentration above 80 mg/L,<sup>96</sup> whereas concentrations more than 500 mg/L are associated with severe toxicity.<sup>27</sup> A patient survived severe MCPA poisoning (hypotension and limb myotonia) with a plasma concentration of 546 mg/L. The myotonia persisted for days and resolved when the MCPA plasma concentration was less than 100 mg/L.<sup>109</sup> By contrast, death following MCPA poisoning is reported at plasma concentrations as low as 107 mg/L to 230 mg/L.<sup>51,90,98</sup>

Monitoring of electrolytes, kidney function, pulse oximetry, and blood gases is recommended to detect progression of organ toxicity. Hypoalbuminemia predisposes to severe poisoning.<sup>101</sup> Creatine kinase should be determined because rhabdomyolysis is reported following acute poisoning. Urinalysis will identify myoglobinuria. There are insufficient data describing the role of these measurements for prognostication.

### Management

All patients with significant poisonings, particularly those with symptomatic oral ingestions, should be treated cautiously, including continuous monitoring for 24 to 48 hours preferably in an intensive care unit. Initial mild toxicity such as gastrointestinal symptoms with normal vital signs and level of consciousness does not preclude subsequent severe toxicity and death.<sup>98</sup>

Animal studies suggest that phenoxy herbicide toxicity increases when elimination is impaired. Empirically, this supports the use of treatments that reduce exposure by either decreasing absorption or increasing elimination. Unfortunately, there is insufficient evidence to recommend specific interventions in patients with acute phenoxy herbicide poisoning. However, an adequate urine output (>1 mL/kg/h) optimizes the renal excretion of phenoxy herbicides as well as decreasing renal toxicity from rhabdomyolysis. Because signs consistent with uncoupling of oxidative phosphorylation are associated with a poor outcome, when present more advanced treatments such as hemodialysis should be used.<sup>8,98</sup>

### Resuscitation and Supportive Care

All patients should receive routine resuscitation, close observation, and supportive care. It is reasonable to correct electrolyte abnormalities, and acidemia as acidemia promotes the distribution of weak acids and increases the intracellular concentration.

### Gastrointestinal Decontamination

Gastrointestinal decontamination is recommended to patients per the guidelines listed in Chap. 5. However, administration of activated charcoal beyond the usual time frame is reasonable given that absorption appears to be saturable.

### Extracorporeal Removal

Urgent hemodialysis is recommended in patients with severe poisoning. Because phenoxy compounds are small and water soluble, and subject to saturable protein binding with large exposures (increasing the free concentration), they are likely to be cleared by extracorporeal techniques.

Extracorporeal elimination using resin hemoperfusion, hemodialysis, or plasmapheresis was studied in a few cases, with clearances approaching 75 mL/min.

### Antidotes

There are no specific antidotes for phenoxy herbicides, but sodium bicarbonate or other alkalinizing agents favorably alter the kinetics of phenoxy herbicides.

Data from animal studies and case reports suggest that urinary alkalization increases the elimination of phenoxy herbicides due to “ion trapping.” For example, renal 2,4-D clearance was increased from 5.1 to 63 mL/min when urine pH increased from 5.0 to 8.0.<sup>91</sup> Compared with a total clearance of approximately 30 mL/minute or less in volunteer studies,<sup>56,105</sup> this increase in renal clearance is potentially significant. Prospective, randomized studies are required to confirm the efficacy of urinary alkalization in humans. Plasma alkalization theoretically limits the distribution of phenoxy compounds from the central circulation by “ion trapping.”

It is reasonable to alkalinize the urine to a pH greater than 7.5 in patients who are symptomatic, particularly if there are features of uncoupling of oxidative phosphorylation or metabolic acidosis. Alkalinization is rarely associated with adverse effects when administered to patients with care and close observation (Antidotes in Depth: A5).

## TRIAZINE COMPOUNDS, INCLUDING ATRAZINE

The 1,3,5-triazine or s-triazine compound (Fig. 109–9) is central to a large number of compounds, including herbicides, other pesticides (eg, cyromazine), resins (eg, melamine), explosives (RDX or C-4), and anti-infectives. Triazine herbicides are widely used, and in 2012 atrazine was the second most used pesticide in the United States.<sup>33</sup> However, cases of acute poisoning are infrequent. Other herbicides included in this group are listed in Table 109–1. These selective herbicides are used pre- or post-emergence for weed control.

The safety of atrazine from an environmental health perspective is debated because of its persistence and propensity to spread across water systems and potential toxicity from chronic exposure. This led to restrictions on the use of triazine compounds in the European Union.

### Pharmacology

The mechanism of toxicity is not fully determined, although it might relate to uncoupling of oxidative phosphorylation. Atrazine is a direct arteriolar vasodilator. Some metabolites of atrazine, particularly those remaining chlorinated, are thought to retain biologic activity.<sup>2</sup> Similarly, clinical features of prometryn poisoning resolved posthemodialysis despite persistence of the parent herbicide, suggesting that toxic metabolites or coformulants were eliminated.<sup>11</sup>

### Pharmacokinetics and Toxicokinetics

Approximately 60% of an oral atrazine dose is absorbed in rats and the concentration peaks beyond 3 hours.<sup>78</sup> The absorption phase of triazine compounds appears to be prolonged in humans in which the serum or plasma concentration continues to increase during treatment with hemodialysis.<sup>11,88</sup> Atrazine is rapidly dealkylated to a metabolite that binds strongly to hemoglobin and plasma proteins, allowing it to be detected in the blood for months. Metabolites are excreted in the urine, and around 25% of them are conjugated to glutathione.<sup>78</sup>

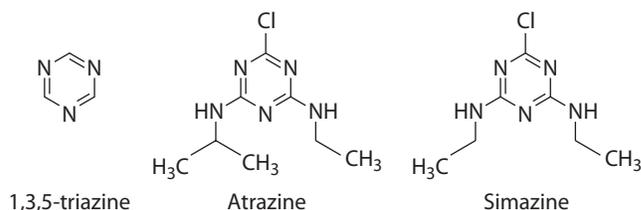

FIGURE 109–9. Structures of common triazine herbicides.

The metabolism of atrazine has been studied in humans following occupational exposures, and animals, and a range of metabolites are described, in particular glutathione conjugates. Other metabolic products from dealkylation and oxidation are also present.

Dermal absorption of atrazine is incomplete but increases with exposure to the proprietary formulation. Atrazine metabolites are readily measured in the urine of atrazine applicators.

### Clinical Manifestations

There are limited cases of triazine herbicide poisoning. Vomiting, depressed levels of consciousness, tachycardia, hypertension, acute kidney injury, and metabolic acidosis with an elevated lactate concentration were described in a patient with acute prometryn and ethanol poisoning.<sup>11</sup> Similar clinical signs, in addition to hypotension with a low peripheral vascular resistance, were noted in a case of poisoning with atrazine, amitrole (Table 109–1), ethylene glycol, and formaldehyde. This was followed by progressive multiorgan dysfunction and death due to refractory shock 3 days later.<sup>88</sup> Death following acute ametryn poisoning (coformulated with xylene and cyclohexanone) is reported, but the mechanism of death was not apparent.<sup>119</sup>

### Diagnostic Testing

In a single case report, clinical toxicity did not directly relate to the concentration of prometryn, but the relationship to the concentration of metabolites was not determined.<sup>11</sup> Routine biochemistry and blood gases are useful for monitoring for the development of systemic toxicity.

### Management

The limited number of publications of triazine herbicide poisoning are inadequate to guide specific management of patients with acute triazine poisoning.

### Resuscitation and Supportive Care

Routine resuscitation, close observation, and supportive care should be provided to all patients. Ventilatory support and correction of hypotension and metabolic disequilibria are appropriate.

### Gastrointestinal Decontamination.

It is reasonable to administer activated charcoal to patients beyond one hour because of the slow absorption of these compounds.

### Extracorporeal Removal

Hemodialysis corrected metabolic acidosis in a case of prometryn poisoning without decreasing the serum concentration of prometryn. In the absence of direct measurements of clearance, the efficacy of hemodialysis in removing prometryn cannot be determined, but is probably limited.<sup>11</sup> Hemodialysis clearance of atrazine was 250 mL/minute (extraction ratio 76%), but only 0.1% of the dose was removed after 4 hours of treatment. Further, similar to the previous case, atrazine concentrations continued to increase during the treatment.<sup>88</sup>

### Antidotes

No antidotes are available for the treatment of triazine herbicide poisoning.

## SUMMARY

- A large number of heterogeneous xenobiotics are classified as herbicides; the toxicity in humans is not completely described for many of these xenobiotics.
- Coformulants, such as surfactants and solvents, probably contribute to clinical toxicity in commercial preparations.
- Many herbicides induce multisystem toxicity for which treatments are often unsatisfactory, although some compounds induce organ-specific toxicity.
- All patients with acute intentional poisoning should be carefully observed for the development of poisoning.
- The priorities of treatment include prompt resuscitation, consideration of antidotes, a detailed history, ongoing monitoring, and supportive care.

- More research is required to better define the clinical syndromes associated with herbicide poisoning, the toxicokinetics of relevant compounds, and the efficacy of treatments including antidotes.
- Prospective case series are useful for describing the toxicity of herbicides in humans. These guide clinicians in the management of poisoning, and also inform regulatory agencies regarding the relative toxicity of different herbicides, which prompt actions that reduce risk to human health.
- Regulatory agencies should monitor data research describing outcomes from unintentional and intentional self-poisoning, and actively ban or severely restrict the availability of highly toxic herbicides, in particular those for which an antidote is not available.

# INSECTICIDES: ORGANIC PHOSPHORUS COMPOUNDS AND CARBAMATES

Michael Eddleston

## INTRODUCTION

Globally and historically, pesticide poisoning has killed approximately 150,000 people each year, with anticholinesterase compounds responsible for about two-thirds of these deaths. Most deaths occur in rural Asia where intentional self-harm is common and where highly toxic organic phosphorus (OP) insecticides are still widely used in agriculture and available in households at times of stress.<sup>67,104</sup> Severe occupational or unintentional poisoning also happens where these highly toxic insecticides are used,<sup>241</sup> but deaths are generally less common.

Anticholinesterase poisoning is uncommon in industrialized countries where access to toxic pesticides is more controlled and a far smaller proportion of the population works in agriculture. However, when anticholinesterase poisoning does occur, patients often require intensive care with long hospital stays.<sup>85,117,199</sup> A further threat is the terrorist use of OP insecticides such as parathion to poison a water supply or flour used in bread baking. Food-borne poisoning occurs regularly in rural Asia,<sup>57,180</sup> such poisoning occurring in industrialized countries would result in hundreds of casualties being treated by clinicians with little experience of this frequently lethal toxic syndrome.

## HISTORY AND EPIDEMIOLOGY

The first potent synthetic organic phosphorus (OP) anticholinesterase, tetraethylpyrophosphate (TEPP), was synthesized by Clermont in 1854. In 1932, Lange and Krueger wrote of choking and blurred vision following inhalation of dimethyl and diethyl phosphorofluoridates. Their account inspired Schrader in Germany to begin investigating these compounds, initially as pesticides, and later as warfare agents (Chap. 126). During this research, Schrader's group synthesized hundreds of compounds, including the pesticide parathion and the chemical weapons sarin, soman, and tabun.<sup>115</sup> Since that time, it is estimated that more than 50,000 OP compounds have been synthesized and screened for pesticidal activity, with dozens being produced commercially.<sup>39</sup>

Carbamates were first identified by Western scientists in the 19th century when the use of the Calabar bean (*Physostigma venenosum*) was recognized in tribal cultural practice in West Africa.<sup>114</sup> In 1864, Jobst and Hesse isolated an active alkaloid component they named physostigmine, which was used medicinally to treat glaucoma in 1877.<sup>114</sup> The synthesis of aliphatic esters of carbamic acid in the 1930s led to the development of carbamate pesticides, marketed initially as fungicides. In 1953 the Union Carbide Corporation first marketed carbaryl, the insecticide being prepared at the plant in Bhopal during the catastrophic release of methyl isocyanate in 1984 (Chap. 2).<sup>7</sup>

Although the term *organophosphate* is often used in both clinical practice and literature to refer to all phosphorus-containing pesticides that inhibit cholinesterase, phosphates are compounds in which the phosphorus atom is surrounded by 4 oxygen atoms, which is not the case for most OP compounds. Some chemicals, such as parathion, contain thioesters, whereas others are vinyl esters. Those cholinesterase-inhibiting (anticholinesterase) insecticides that contain phosphorus are collectively termed *organic phosphorus* compounds in this chapter. Those that contain the OC=ON linkage are termed carbamates.

Anticholinesterase pesticides are broadly grouped according to their toxicity by the World Health Organization's Classification of Pesticides into 5 groups,<sup>248</sup> from Class Ia "Extremely hazardous" through to "Active ingredients unlikely to present acute hazard in normal use" (Table 110-1). This classification is based upon comparative rat oral lethal dose for 50% of those exposed (LD<sub>50</sub>) data of the active ingredient and is useful in its ability to

distinguish very toxic OPs (such as parathion, rat oral LD<sub>50</sub> 13 mg/kg) that have killed many thousands of people from relatively safe OPs (such as temephos, rat oral LD<sub>50</sub> 8,600 mg/kg) that have not been reported to cause harm in humans. However, the rat LD<sub>50</sub> is less useful in distinguishing between pesticides within the same class. Here, differential toxicity is likely to be due to differences in response to treatment, speed of onset, or co-formulants.<sup>52,74</sup>

The case fatality for OP and carbamate poisoning varies according to the insecticides used in local agriculture (and therefore taken for self-harm) and the health care services available. Where fast-acting, highly toxic pesticides are used for self-harm, deaths will occur before patients present to hospital. Hospital-based data therefore will have a falsely low case fatality, although often still high at 10% to 30%.<sup>67</sup> However, during the 1980 to 1990s, the case fatality for parathion poisoning in Munich's toxicology intensive care units (ICUs) was approximately 40%.<sup>85,253</sup> This was likely because ambulances were able to reach the patients early, before death, but after the patients had become symptomatic with this fast-acting OP. Some had already aspirated or suffered hypoxic brain injury prior to arrival of medical care. Despite resuscitation at the scene, many patients died from these complications of the pre-hospital events (in particular, loss of consciousness leading to aspiration and hypoxic brain injury) rather than from direct cholinergic effects of the OP insecticide. Few of these patients would have survived to hospital admission in lower-income countries. More recently, because parathion has become less common in Germany after its ban, the case fatality of OP-poisoned patients admitted to the Munich intensive unit has fallen to 5/33 (15%).<sup>117</sup> However, the case fatality for parathion poisoning remained high (3/7, 43%).

Although a major clinical problem in the developing world, the current annual estimate of at least 100,000 deaths is substantially less than previous estimate from the 1990 to 2000s of 200,000 per year due to a major migration from rural to urban areas in China and Taiwan,<sup>40,178</sup> reducing access to highly hazardous pesticides, and the implementation of highly effective pesticide regulation in countries such as Sri Lanka, Bangladesh, and South Korea.<sup>37,41a,105,137</sup>

As the most toxic WHO Toxicity Class 1a and 1b insecticides (such as parathion, methyl-parathion, monocrotophos) are gradually being withdrawn from agriculture across the world, the case fatality for OP and carbamate pesticide poisoning is declining. The 100,000 deaths annually probably represent around 1 to 2 million admissions for anticholinesterase poisoning. It is not yet clear that the reduction in mortality is reflected in reduced health care costs—an increasing number of survivors who required intensive care will increase costs as this is the most important health care cost for managing poisoned patients.<sup>242</sup> Much of this intensive care is required for respiratory failure and pulmonary injury.<sup>119</sup> Modeling in 2007 suggested that the

TABLE 110-1 WHO Classification of Pesticide Toxicity<sup>248</sup>

Class		LD <sub>50</sub> for the rat (mg/kg body weight)			
		Oral		Dermal	
		Solids	Liquids	Solids	Liquids
Ia	Extremely hazardous	≤5	≤20	≤10	≤40
Ib	Highly hazardous	5–50	20–200	10–100	40–400
II	Moderately hazardous	50–500	200–2,000	100–1,000	400–4,000
III	Slightly hazardous	>500	>2,000	>1,000	>4,000

20% to 30% of patients who develop respiratory failure cumulatively received 1.1 to 2.3 million days of ventilation every year, requiring the constant use of 3,000 to 6,000 ventilators worldwide.<sup>104</sup> These figures for acute poisoning undoubtedly omit numerous unreported and possibly unrecognized illnesses resulting from lower level occupational and environmental exposure to these chemicals.

Typically, patients present following unintentional or suicidal ingestion of anticholinesterase insecticides or after working in areas recently treated with these compounds. Children and adults develop toxicity while playing in or inhabiting a residence recently sprayed or fogged with OP compounds by a pesticide applicator. Direct dermal contact with highly hazardous insecticides is dangerous.<sup>10,108</sup> Outbreaks of mass poisoning regularly occur in the developing world,<sup>57,180</sup> and less commonly in the United States,<sup>28</sup> from contamination of crops or food. Epidemics of toxicity are also reported among groups illegally importing and using the potent carbamate aldicarb.<sup>27</sup> Unfortunately, OPs and carbamates are also used for homicide.

## PHARMACOLOGY

### Organic Phosphorus Compounds

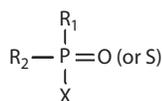

Organic phosphorus compound poisoning results in a rise in the concentration of acetylcholine (ACh) at muscarinic and nicotinic cholinergic synapses, which, in turn, leads to the syndrome of cholinergic excess. Figure 110-1 shows the basic formula for cholinesterase-inhibiting OP compounds. The “X” or “leaving group” determines many of the characteristics of the compound and provides a means of classifying OP insecticides into 4 main groups (Table 110-2). Group 1 compounds contain a quaternary nitrogen at the X position, and are collectively termed phosphorylcholines. These chemicals were originally developed as warfare agents, are powerful cholinesterase inhibitors, and can directly stimulate cholinergic receptors, presumably because of their structural resemblance to ACh. Group 2 compounds are called fluorophosphates because they possess a fluorine molecule as the leaving group. Like group 1 compounds, these compounds are volatile and highly toxic, making them well suited as warfare agents. The leaving group of group 3 compounds is a cyanide molecule or a halogen other than fluorine. The best-known compounds in this group are cyanophosphates such as the warfare agent tabun.

The fourth group is the broadest and comprises various subgroups based on the configuration of the R<sub>1</sub> and R<sub>2</sub> groups (Fig. 110-1), with the majority falling into the category of either a dimethoxy or diethoxy compound. Most of the insecticides in use today are in Group 4.

Direct-acting OP compounds (oxons) inhibit acetylcholinesterase (AChE) without needing to be metabolized in the body. However, many pesticides, such as parathion and malathion, are indirect inhibitors (prodrugs or thions) requiring partial metabolism (to paraoxon and malaaxon, respectively) within the body to become active. Desulfuration to the oxon occurs in the intestinal mucosa and liver following absorption.<sup>216</sup>

The OPs bind to a hydroxyl group at the active site deep inside a cleft in the AChE enzyme. As the leaving group of the OP insecticide is split off by AChE, a stable but reversible bond results between the remaining substituted phosphorus of the OP and AChE, effectively inactivating the enzyme (Figs. 110-2 and 110-3).

Although splitting of the choline-enzyme bond in normal ACh metabolism is completed within microseconds, the severing of the OP compound-enzyme bond is prolonged. The half-life of this reaction depends on the chemistry of the substituted phosphate. The in vitro half-life for spontaneous reactivation of human AChE inhibited by dimethoxy OPs is 0.7 to 0.86 hours,

**FIGURE 110-1.** General structure of organic phosphorus compounds. X represents the leaving group. R<sub>1</sub> and R<sub>2</sub> may be aromatic or aliphatic groups that can be identical.

that of diethoxy inhibition 31 to 57 hours.<sup>87</sup> Spontaneous reactivation is therefore far quicker with dimethoxy OPs; however, this is only clinically relevant in patients with more moderate OP toxicity because, in patients with high OP concentrations, the reactivated AChE is simply reinhibited again.

Oximes, such as pralidoxime or obidoxime, markedly speed up the rate of reactivation.<sup>87</sup> However, if the phosphorus is allowed to remain bound to the AChE, because of late or inadequate administration of oximes, an alkyl group is nonenzymatically lost (Fig. 110-3), a process called “aging.” Once aging occurs, the AChE can no longer be reactivated by oximes. Again, the half-life of this reaction is determined by the substituted phosphorus. The in vitro half-life of human AChE after poisoning with dimethoxy OPs is 3.7 hours, compared to 31 hours after diethoxy poisoning.<sup>87</sup> Clinically, this means that patients who present to a hospital 4 hours after poisoning with a dimethoxy OP will already have 50% of their AChE irreversibly inhibited; after 14 hours, the patients will be refractive to oxime therapy.<sup>80,87</sup> In contrast, patients poisoned by diethoxy OPs presenting within 14 hours will have little aged AChE and should be responsive to oximes.<sup>80,87</sup> De novo synthesis of AChE is required to replenish its supply once aging has occurred (see Diagnostic Testing section below).<sup>221</sup>

Organic phosphorus compounds also vary by lipid solubility,<sup>19</sup> rate of activation (conversion from thion to oxon) and rate of AChE inhibition,<sup>87</sup> and relative potency of inhibition of AChE and of the plasma enzyme butyrylcholinesterase (BuChE).

A few OP compounds do not fulfill the usual dimethoxy or diethoxy classification and have one of the alkyl groups linked to the phosphate by a sulfur molecule, rather than oxygen (eg, profenofos, prothiofos, methamidophos). Aging seems to be particularly rapid for these OPs, so that oximes have poor efficacy.<sup>81</sup>

### Carbamates

Carbamate insecticides are *N*-methyl carbamates derived from carbamic acid (Fig. 110-4). Medicinal carbamate compounds that inhibit cholinesterases include physostigmine, pyridostigmine, and neostigmine. By contrast, thiocarbamate fungicides and herbicides (eg, maneb, mancozeb) do not inhibit AChE and so do not produce the cholinergic toxic syndrome.

When exposed to carbamates, AChE undergoes carbamylation in a manner similar to phosphorylation by OP compounds,<sup>244</sup> allowing ACh to accumulate in synapses. However, aging does not occur and the carbamate-AChE bond hydrolyzes spontaneously, reactivating the enzyme. As such, the duration of cholinergic symptoms in carbamate poisoning is generally less than 24 hours. However, complications that result from the cholinergic syndrome, in particular, pulmonary complications of the acute poisoning, can last much longer.

## PHARMACOKINETICS AND TOXICOKINETICS

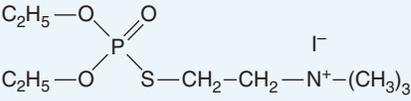

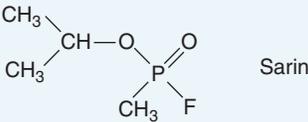

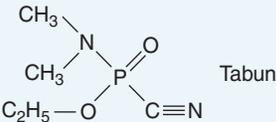

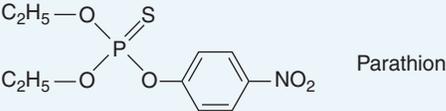

### Organic Phosphorus Compounds

Organic phosphorus compounds are well absorbed from the lungs, gastrointestinal tract, mucous membranes, and conjunctiva following inhalation, ingestion, or topical contact.<sup>93</sup> Although absorption through intact skin appears to be relatively low,<sup>99</sup> percutaneous exposure to highly toxic compounds can cause severe toxicity.<sup>42,240</sup> The presence of broken skin, dermatitis, and higher environmental temperatures further enhances cutaneous absorption.<sup>93</sup>

Acute and chronic poisonings occur. The difficulty in removing these compounds from the skin and clothing explains some chronic poisonings; inadequate skin and respiratory protection during pesticide application is responsible for many cases of occupational poisonings.

The time to peak plasma concentration after self-poisoning is unknown. Human volunteer studies, using very low doses of chlorpyrifos, found C<sub>max</sub> to be around 6 hours after oral ingestion.<sup>176</sup> However, patients ingesting large amounts of oxon or fast-acting thion OPs often become symptomatic within minutes,<sup>85,151</sup> suggesting that absorption is rapid. In addition, the chlorpyrifos study<sup>176</sup> was performed with pure chlorpyrifos, not the formulated agricultural pesticide with solvents and surfactants that would be ingested

TABLE 110-2 The Classification of Organic Phosphorus Compounds by Groups, Showing Leaving Groups and Examples of Each Group

Group 1—phosphorylcholines Leaving group: substituted quaternary nitrogen Echothiophate iodide		Echothiophate iodide
Group 2—fluorophosphates Leaving group: fluoride Dimefox, sarin, mipafox		Sarin
Group 3—cyanophosphates, other halophosphates Leaving group: CN-, SCN-, OCN-, halogen other than fluoride Tabun		Tabun
Group 4—multiple constituents Leaving group: Dimethoxy Azinphos-menthyl, bromophos, chlorothion, crotoxyphos, dicapthion, dichlorvos, dicrotophos, dimethoate, fenthion, malathion, mevinphos, parathion-methyl, phosphamidon, temephos, trichlorfon Diethoxy Carbophenothion, chlorfenvinphos, chlorpyrifos, coumaphos, demeton, diazinon, dioxathion, disulfoton, ethion, methosfolan, parathion, phorate, phosfolan, TEPP Other dialkoxy Isopropyl paraoxon, isopropyl parathion Diamino Schradan Chlorinated and other substituted dialkoxy Haloxon Trithioalkyl Merphos Triphenyl and substituted triphenyl Triorthocresyl phosphate (TOCP) Mixed substituent Crufomate, cyanofenphos		Parathion
		Triorthocresyl phosphate

for self-harm. These solvents potentially change the toxicokinetics of the OP compound.

Most OP compounds are lipophilic,<sup>19</sup> with a large volume of distribution, and therefore rapidly distribute into tissue and fat, where they are protected

from metabolism. Radiolabeled parathion injected into mice distributes most rapidly into the cervical brown fat and salivary glands, with high concentrations also measured in the liver, kidneys, and ordinary adipose tissue.<sup>91</sup> Adipose tissue gradually accumulates the highest concentrations. Redistribution from these stores allows measurement of circulating OP compound concentrations for up to 48 days post ingestion.<sup>50,94</sup>

The quantity of patient fat, as well as the lipophilicity of the OP compound, affects the outcome of poisoning. A Korean study of overweight patients (BMI >25) showed a longer duration of ventilation, intensive care, and hospital admission after poisoning with highly lipophilic OP insecticides compared to nonlipophilic OP insecticides.<sup>145</sup> This difference between highly lipophilic and nonlipophilic OP compounds did not occur in patients with a BMI of 25 or less.

The cholinergic crisis sometimes recurs in patients if unmetabolized OPs are mobilized from fat stores.<sup>93</sup> Highly lipophilic compounds such as fenthion and dichlofenthion (both with a Log Kow octanol/water coefficient >4) are particularly likely to cause this phenomenon.<sup>50,74,161</sup> Dimethoate, methamidophos and oxydemeton methyl are 3 common OPs that are not lipophilic (Log Kow <1), with small volumes of distribution and high plasma OP concentrations that do not appear to cause recurrent cholinergic crises.

The distribution of OPs into fat will likely include both activated and inactivated compound. When released from the fat hours to days later, the inactivated thion will require activation to cause clinical features.

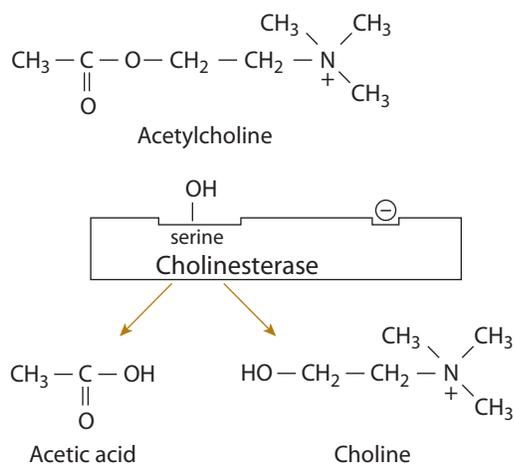

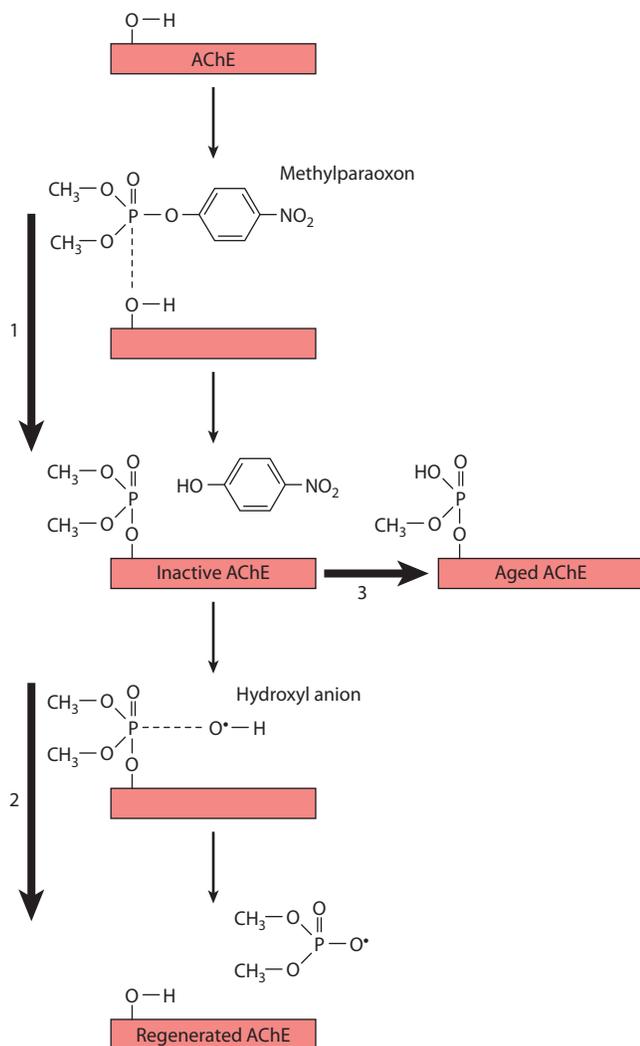

FIGURE 110-2. Normal metabolism of acetylcholine by acetylcholinesterase to choline and acetic acid.

**FIGURE 110-3.** Mechanism of inhibition of acetylcholinesterase by an organic phosphorus compound. A dimethylated organic phosphorus pesticide (eg, methylparaoxon) inhibits AChE function by phosphorylating the serine hydroxyl group at the enzyme's active site (reaction 1). This reaction occurs very quickly. Active AChE is subsequently regenerated by a hydroxyl ion attacking the acetylated serine residue, removing the phosphate moiety, and releasing active enzyme (reaction 2). This regenerative process, however, is much slower than inhibition, requiring hours to days to occur (spontaneous reactivation  $t_{1/2}$  ~ 0.7 hours for dimethyl and 30 hours for diethyl compounds). While in the inactive state, the enzyme is prone to "aging" (reaction 3) in which one alkyl side-chain of the phosphoryl moiety is removed nonenzymatically, leaving a hydroxyl group in its place. Aged AChE can no longer react with water and regeneration no longer occurs. This reaction occurs considerably faster with enzymes that are inhibited by dimethylated pesticides ( $t_{1/2}$  ~ 3.3 hours) than those inhibited by diethylated pesticides ( $t_{1/2}$  ~ 30 hours). The slower the regenerative process, the greater the quantity of inactive AChE available for aging. Pralidoxime catalyzes the regeneration of active acetylcholinesterase by exerting a nucleophilic attack on the phosphoryl group, transferring it from the enzyme to itself. By speeding up reaction 2, it reduces the quantity of inactive AChE available for ageing. However, because ageing occurs more rapidly with dimethylated OP compounds, pralidoxime is only useful before about 12 hours with dimethylated enzyme. (Data from Eddleston M, Szinicz L, Eyer P, et al. Oximes in acute organophosphorus pesticide poisoning: a systematic review of clinical trials. *QJM*. 2002 May;95(5):275-283.)<sup>88</sup>

**FIGURE 110-4.** General structure of carbamate insecticides.

Thion OPs are activated by cytochrome P450 enzymes in the liver and intestinal mucosa. The precise CYP450s responsible vary according to the concentration of OP. For example, at low concentrations, chlorpyrifos, diazinon, parathion, and malathion are all metabolized and activated in vitro by CYP1A2 and 2B6.<sup>30,31</sup> However, at the higher concentrations more likely to occur after self-poisoning, CYP3A4 becomes dominant. The CYP450 enzymes involved in metabolism of active oxons to inactive metabolites are less clear.

Studies indicate that the activity of the human plasma enzyme paraoxonase (PON) is related to susceptibility to some acute and chronic effects of OP poisoning.<sup>43,210,212</sup> Paraoxonase is an A-esterase that can hydrolyze the active (oxon) metabolites of some but not all OP insecticides. Activity differs significantly among animal species. Animal models of OP poisoning demonstrate protection from toxicity when exogenous PON is administered, and greater susceptibility to poisoning when enzyme-deficient animals (such as genetically engineered knockout mice) are exposed.<sup>210</sup> Some authors propose that genetic polymorphisms in human PON activity lead to variations in interindividual susceptibility to some OP compounds.<sup>43</sup> However, the clinical relevance of these polymorphisms after poisoning are unclear.

### Carbamates

Carbamate insecticides are absorbed across skin and mucous membranes, and by inhalation and ingestion. Peak cholinesterase inhibition occurred within 30 minutes of oral administration in rats.<sup>177</sup> Most carbamates undergo hydrolysis, hydroxylation, and conjugation in the liver and intestinal wall, with 90% excreted in the urine within 3 to 4 days.<sup>16</sup>

There is a view that carbamates, unlike OPs, do not easily enter the brain.<sup>12</sup> However, carbamates cause CNS depression in humans,<sup>193</sup> have lipophilic Log Kow values,<sup>19</sup> and rat studies show inhibition of brain cholinesterases with multiple carbamates.<sup>177</sup> Furthermore, post mortem studies demonstrate high concentrations of carbamates in cerebrospinal fluid and brain.<sup>112,167</sup> The evidence at present therefore suggests that they do not differ markedly from OPs in this aspect.

One important distinction between carbamates and OPs is that the carbamate-cholinesterase bond does not "age." Acetylcholinesterase inhibition is reversible, with spontaneous hydrolysis occurring usually within several hours. In addition, there appears to be less variation between carbamates than occurs between OP compounds. In a prospective case series of 1,288 patients who ingested carbosulfan, fenobucarb, or carbofuran, toxicity did not appear to vary markedly according to the carbamate ingested; the case fatality did however vary according to the concentration and formulation of the insecticide.<sup>143</sup>

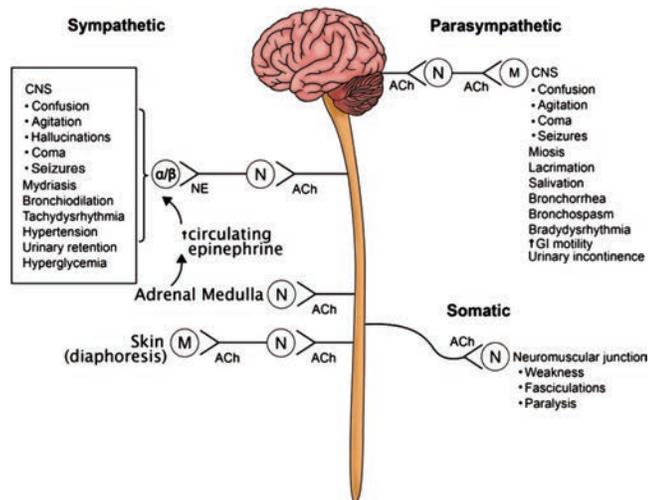

### PATHOPHYSIOLOGY

#### Cholinesterase Inhibition

Acetylcholine is a neurotransmitter found at both parasympathetic and sympathetic ganglia, skeletal neuromuscular junctions, terminal junctions of all postganglionic parasympathetic nerves, postganglionic sympathetic fibers to most sweat glands, and at some nerve endings within the central nervous system (Fig. 110-5). As the axon terminal is depolarized, vesicles containing ACh fuse with the nerve terminal, releasing ACh into the synapse or neuromuscular junction (NMJ). Acetylcholine then binds postsynaptic receptors, leading to activation (G proteins for muscarinic receptors and ligand-linked ion channels for the nicotinic receptors). Activation alters the flow of  $\text{K}^+$ ,  $\text{Na}^+$ , and  $\text{Ca}^{2+}$  ionic currents on nerve cells, and alters the membrane potential of the postsynaptic membrane, resulting in propagation of the action potential.

Organic phosphorus and carbamate compounds are inhibitors of carboxylic ester hydrolases within the body, including acetylcholinesterase (AChE, EC 3.1.1.7), butyrylcholinesterase (plasma or pseudocholinesterase, BuChE, EC 3.1.1.8), plasma and hepatic carboxylesterases (alioesterases), paraoxonases (A-esterases), chymotrypsin, and other nonspecific proteases.<sup>33</sup>

Acetylcholinesterase hydrolyzes ACh into 2 inert fragments: acetic acid and choline (Fig. 110-2). Under normal circumstances, virtually all ACh released by the axon is hydrolyzed rapidly, with choline undergoing reuptake into the presynaptic terminal where it is reused to synthesize ACh.

**FIGURE 110–5.** Pathophysiology of cholinergic syndrome as it affects the autonomic and somatic nervous systems.

Acetylcholinesterase is found in human nervous tissue and skeletal muscle, and on erythrocyte (ie, red blood cell {RBC}) cell membranes.<sup>157</sup>

Butyrylcholinesterase is a liver-derived protein found in human plasma, liver, heart, pancreas, and brain. Although the function of this enzyme is not well understood, its activity can be easily measured and has important clinical implications in anesthesia (Chap. 66).

Inhibition of AChE at synapses is generally thought to account for all, or the majority, of clinical features of both OP and carbamate compound poisoning. However, these compounds also inhibit many other enzymes;<sup>33</sup> the clinical effects of these interactions are not yet understood.

Markers of oxidative stress are raised after OP poisoning<sup>47,194,232</sup> leading some to suggest a pathogenic role for mitochondrial dysfunction and oxidative stress in OP poisoning<sup>134</sup> and trials of antioxidants such as acetylcysteine.<sup>83,208</sup> However, whether oxidative stress is simply an association or pathogenic in OP-poisoned patients is not yet clear.

### Effect of Coformulants and Alcohol

Patients who drink agricultural pesticides in self-harm actually ingest formulated pesticides rather than the pure anticholinesterase compound or “active ingredient” (AI). Organic phosphorus compounds sold for agricultural use are typically emulsifiable concentrates (EC) in which the AI (eg, dimethoate) is mixed with an organic solvent such as xylene or cyclohexanone and a surfactant/emulsifier. Unfortunately, the compounds used for coformulation are highly variable, being optimized by each pesticide manufacturer for each OP. As a result, coformulants often differ between the same OP produced by 2 companies, and for different OPs produced by one company. Coformulants are much less likely to be a problem when people are exposed to agricultural insecticides that have been diluted for use, as occurs in sprayers exposed to their spray.

The clinical effect of self-poisoning with these coformulants, in addition to the carbamate or OP AI, is not yet clear. Complications of surfactant poisoning are well described in glyphosate poisoning<sup>25</sup> (Chap. 109) but not with OP or carbamate insecticides. The acute toxicity of the solvents appears to be low—for example, the rat oral LD<sub>50</sub>s for xylene and cyclohexanone are 4,000 to 5,000 and 1,620 mg/kg, respectively. However, in a minipig model of acute oral dimethoate 40% emulsifiable concentrate (EC40) poisoning, early respiratory arrest occurred at a point when red blood cell AChE was little inhibited, suggesting a non-AChE mechanism.<sup>79</sup> Early work showed that dimethoate toxicity could be increased markedly by changing solvent;<sup>34</sup> more recent work with chlorpyrifos demonstrates a modest change in toxicity after changing the solvent.<sup>227</sup> The minipig model indicates that the toxicity of dimethoate EC40 requires both the dimethoate AI and the cyclohexanone solvent, with changes in the solvent reducing toxicity.<sup>79</sup> Although potentially

important, the major differences in the clinical syndrome noted in patients between dimethoate EC40, chlorpyrifos EC40, and fenthion EC50 cannot be attributed to the solvent because most pesticides in that study were generic, using 40% xylene as the solvent.<sup>74</sup> Further clinical studies with accurate measurement of all elements of the formulation in the plasma are required to address the importance of coformulants in human self-poisoning.

A further effect of the solvent/surfactant occurs after aspiration. Ingestion of large quantities of OPs or carbamates causes rapid loss of consciousness and respiratory arrest, increasing the risk of aspiration with pesticide AI, solvent, surfactant, and gastric contents. The relative role of gastric contents and pesticide is not yet clear. Aspiration pneumonitis is a major clinical problem in OP poisoning and cannot simply be treated with oximes and atropine.<sup>66</sup>

Pesticides are frequently coingested with ethanol, particularly by men,<sup>229</sup> raising questions about the effect of the alcohol on outcome after OP poisoning.<sup>70</sup> Two cohorts, of people ingesting either dimethoate EC40 or profenofos EC50, demonstrated an association between ingestion of ethanol and poor outcome.<sup>59,76</sup> However, analysis of blood ethanol and pesticide concentrations in the dimethoate cohort showed that the ethanol did not directly affect the clinical outcome;<sup>76</sup> instead, high ethanol blood concentrations were associated with high dimethoate concentrations, suggesting that inebriation caused people to drink larger amounts of pesticide, worsening outcome due to the direct toxic effects of the pesticide.

### CLINICAL MANIFESTATIONS

Clinical manifestations vary according to the particular OP insecticide involved, the dose and route of exposure, and the time since exposure. Features are classified as acute (usually less than 24 hours), delayed (from 24 hours to 2 weeks), and late (after 2 weeks).<sup>191</sup>

#### Acute Toxicity—Organic Phosphorus Compounds

Clinical findings of acute toxicity from OPs derive from excessive stimulation of muscarinic and nicotinic cholinergic receptors by ACh in the central and autonomic nervous systems, and at skeletal neuromuscular junctions (Fig. 110–5). The typical patient with severe OP poisoning is one who is unresponsive, with pinpoint pupils, muscle fasciculations, diaphoresis, emesis, diarrhea, salivation, lacrimation, urinary incontinence, and (after self-poisoning) an odor of garlic or solvents.

#### Timing of Clinical Features

The timing of onset of symptoms varies according to the route, the degree of exposure, and the particular OP involved. This is important because more rapid onset of poisoning will reduce the likelihood of the patient reaching health care safely, before onset of respiratory failure or of complications such as aspiration. Out-of-hospital cardiorespiratory arrest in most parts of the world will result in the patient’s death; in a Korean study, with an effective emergency ambulance system, only 22% and 10% of insecticide-poisoned patients with an out-of-hospital cardiac arrest survived to admission and discharge, respectively.<sup>182</sup> In other parts of the rural developing world, with longer distances and weaker emergency care systems, survival will be even lower.

Some patients ingesting large quantities of concentrated agricultural formulations become symptomatic as soon as 5 minutes following ingestion. Most patients with acute poisoning become symptomatic within a few hours of exposure, and practically all who will become ill show some features within 24 hours.

Oxon OP compounds (such as mevinphos and monocrotophos) are already active on exposure and patients become symptomatic quickly. Since some thion OPs are very rapidly converted to oxons, these OPs also rapidly produce symptoms—patients ingesting parathion can be unconscious within minutes.<sup>85</sup> In contrast, patients ingesting thions that are slowly converted to active oxons (such as fenthion) often do not show symptoms for hours.<sup>74</sup>

The speed of onset will be affected by the quantity ingested and the toxicity<sup>87</sup> of the OP: patients ingesting very large doses or highly toxic pesticides will more rapidly inhibit a clinically significant proportion of their AChE and exhibit features earlier.

Lipid solubility also likely affects time to onset. Fat-soluble OPs (with log Kow of >3-4) will rapidly distribute to fat stores, in the process reducing their concentration in extracellular fluid, where they impart their clinical effect (eg, fenthion<sup>74</sup>). Significant poisoning with such OPs is commonly delayed—respiratory failure with fenthion for example typically occurs after 24 hours in contrast to less fat soluble OPs.<sup>78</sup>

Symptoms following OP exposure last for variable lengths of time, again based on the compound and the circumstances of the poisoning. For example, highly lipophilic compounds, such as dichlofenthion or fenthion, cause recurrent cholinergic effects for many days in some patients following oral ingestion as they are released from fat stores.<sup>50,161,190</sup>

### Clinical Features

Patients usually present awake and alert, complaining of anxiety, restlessness, insomnia, headache, dizziness, blurred vision, depression, tremors, and/or other nonspecific symptoms.<sup>15,174</sup> In moderate-severe poisoning, the level of consciousness then deteriorates rapidly to confusion, lethargy, and coma. Where careful observational studies have been done, convulsions appear to be uncommon in adult OP pesticide poisoning compared to OP nerve agent poisoning.<sup>74,235</sup> The convulsions that do occur are likely due to hypoxia as a complication of acute cholinergic poisoning.

The effects of excessive ACh on the autonomic nervous system is variable because cholinergic receptors are found in both the sympathetic and parasympathetic nervous systems (Fig. 110-5). Excessive muscarinic activity is characterized by several mnemonics, including “SLUD” (salivation, lacrimation, urination, defecation) and “DUMBELS” (defecation, urination, miosis, bronchospasm or bronchorrhea, emesis, lacrimation, salivation). Of these, miosis is the most consistently encountered sign. Profuse bronchorrhea mimics pulmonary edema.<sup>174</sup> Excessive fluid loss results in salt and water depletion. Body temperature is often low acutely, rising to normal or higher with treatment and time.<sup>163</sup>

Although muscarinic findings are emphasized in these mnemonics, muscarinic signs are not always clinically dramatic or initially predominant. Parasympathetic effects can be offset by excessive autonomic activity from stimulation of nicotinic adrenal receptors (resulting in catecholamine release) and postganglionic sympathetic fibers.<sup>221</sup> Mydriasis, bronchodilation, and urinary retention can occur as a result of sympathetic activity. Increased sympathetic activity usually precipitates white blood cell demargination, resulting in leukocytosis.<sup>172,174</sup>

Excessive adrenergic influences on metabolism cause glycogenolysis<sup>222</sup> with hyperglycemia and ketosis that have been mistaken for diabetic ketoacidosis.<sup>159,251</sup> Transient glycosuria was reported in 16 of 23 (69%) of OP or carbamate poisoned patients in one series.<sup>211</sup> Hyperglycemia at presentation is associated with worse outcome;<sup>165</sup> however, in a small study, a medical history of diabetes mellitus was not associated with worse outcome.<sup>150</sup>

Hyperamylasemia appears to be relatively common in OP poisoning, occurring in 4/47 (9%) adults in one series<sup>204</sup> and 5/17 (29%) children in a second.<sup>239</sup> However, both included various anticholinesterase pesticides; a series of only malathion-poisoned patients reported hyperamylasemia in 47/75 (63%).<sup>46</sup> The amylase is likely pancreatic because animal studies show OP-induced damage<sup>120</sup> and human poisoning cases show associated pancreatic edema and/or rarely necrotizing pancreatitis.<sup>181</sup> The incidence of subclinical and clinical pancreatitis varies according to the OP ingested and perhaps the coformulants. Acute poisoning is associated with multiple temporary effects on thyroid and pituitary hormones.<sup>65,106</sup>

Cardiovascular manifestations reflect mixed effects on the autonomic nervous system (including increased sympathetic tone), together with the consequences of OP-induced hypoxia and hypovolemia. Troponin rises are reported, as well as ST segment elevation.<sup>38,129</sup> Admission heart rate is usually normal, with relatively few patients showing a tachycardia greater than 100 beats/min or bradycardia less than 60 beats/min. Patients who receive atropine before admission are infrequently tachycardic.

The literature is filled with reports of QT interval prolongation and ventricular dysrhythmias.<sup>13,100,136,202,203</sup> However, these reports are complicated

by the fact that many patients had their ECG done before they received any atropine or were so ill that atropine was ineffective. The first is illustrated by a description of 46 patients with OP or carbamate poisoning in which “ECG recordings [were] taken on arrival ... before the start of atropine treatment.”<sup>203</sup> The reported cardiac rhythms are confounded by the hypoxia and hypovolemia that characterize the cholinergic syndrome. In another study, 29 of the 35 patients with such dysrhythmias died.<sup>154</sup>

In contrast, when 1950 Sri Lanka patients poisoned with WHO Class II OP or carbamate compounds were evaluated, serious dysrhythmias were very rare in patients adequately resuscitated with atropine, intravenous fluids and when available oxygen.<sup>139</sup> In a case series of oxygenated and atropinized OP-poisoned patients in intensive care (27/33 due to aspiration pneumonia) it is mixed group of OP compounds QT interval prolongation was noted in 9/33 (27.3%) of patients, but in only 5 was the corrected QT (QTc) interval greater than 500 ms.<sup>117</sup> The median QTc interval in fatal cases was only 497 ms versus 428 ms in survivors. However, bradycardia and torsade de pointes occurred after stopping atropine in 5 patients, suggesting that atropine had been treating a potential complication of OP compound poisoning.

Hypotension occurs because of stimulation of vascular receptors by excessive circulating ACh, severe volume loss, or myocardial dysfunction.<sup>8,131</sup> Severe hypotension is a particularly significant problem in poisoning with the unusually fat-insoluble OP dimethoate.<sup>51,74</sup> In these cases, fatal poisoning is characterized by early respiratory failure followed by hypotension that only transiently responds to vasopressors. Such a syndrome is not reported after poisoning with fat-soluble OPs such as chlorpyrifos and fenthion.<sup>74</sup> The exact role of direct cardiotoxicity and peripheral vasodilation is unclear, and whether this syndrome occurs with other fat-insoluble OPs, such as methamidophos and oxydemeton methyl.<sup>51</sup> There is evidence to suggest that the solvent in dimethoate EC40, cyclohexanone, is partially responsible for this severe hypotension.<sup>79</sup>

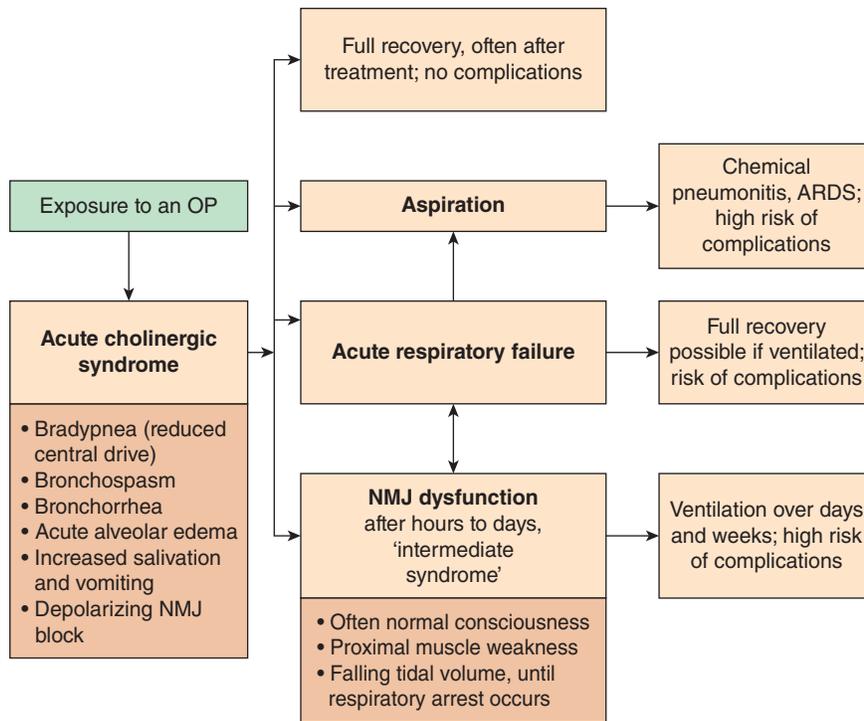

Acute respiratory complications of OP poisoning (Figs. 110-6 and 110-7) include the direct pulmonary effects of bronchorrhea and bronchoconstriction, NMJ failure in the diaphragm and intercostal muscles, and loss of central respiratory drive.<sup>54,119</sup> If severe and occurring before patients reach medical care, these effects will lead to hypoxemia and respiratory arrest, the most common cause of death after OP poisoning. Both bronchorrhea and bronchoconstriction respond to adequate atropine therapy. Unfortunately, neither NMJ failure nor loss of central respiratory drive responds to atropine, and patients must be ventilated until respiratory function recovers.

An additional early respiratory complication is hydrocarbon aspiration that may occur after ingestion of commercially formulated pesticides (Fig. 110-6). The incidence of aspiration and the consequences of aspiration—whether chemical pneumonitis, pneumonia, or acute respiratory distress syndrome—are not yet known and likely differ according to the OP, dose, and coformulants. In one German case series of patients requiring intensive care, 27/33 (81.8%) had aspiration pneumonia.<sup>117</sup>

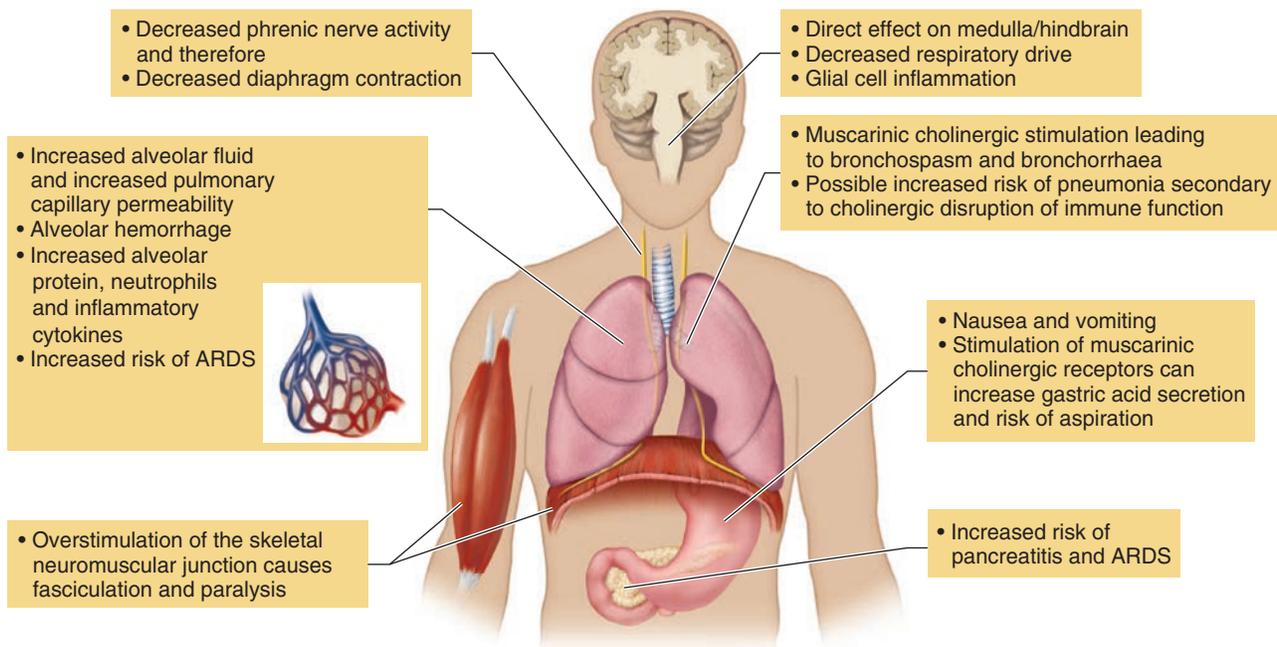

Acetylcholine stimulation of nicotinic receptors also governs skeletal muscle activity. The effects of excessive cholinergic stimulation at the NMJ are similar to that of a depolarizing neuromuscular blocker (succinylcholine) and initially result in fasciculations or weakness. Severe poisoning results in paralysis.<sup>236</sup> Rarely, patients present with paralysis from nicotinic effects without any other initial signs and symptoms suggestive of OP toxicity.<sup>90,97</sup>

Extrapyramidal parkinsonian effects such as rigidity and choreoathetosis are reported after severe anticholinesterase poisoning,<sup>22</sup> persisting for several days after cholinergic features have resolved. They occur in severely ill patients requiring intensive care for more than a week.<sup>195</sup> However, the appearance of frank parkinsonism during acute poisoning is uncommon.<sup>130</sup>

Liver and kidney injury are not considered common features of OP or carbamate poisoning.<sup>174</sup> Liver injury occurred in poisoned patients receiving obidoxime.<sup>11</sup> Although severe acute kidney injury (AKI) requiring hemodialysis occurs,<sup>36</sup> a prospective Indian case series of 400 patients found no cases of acute kidney injury.<sup>219</sup> Substantial muscle injury also seems rare, although modest rises in creatine kinase are recognized in OP-poisoned patients in ICUs, possibly due to muscle injury from sustained paralysis and

**FIGURE 110-6.** Respiratory system toxicity secondary to organic phosphorus compound poisoning. ARDS = acute respiratory distress syndrome; NMJ = neuromuscular junction of OP = organic phosphorus compound. (Reproduced with permission from Hulse EJ, Davies JO, Simpson AJ, et al. Respiratory complications of organophosphorus nerve agent and insecticide poisoning. Implications for respiratory and critical care. Am J Respir Crit Care Med. 2014 Dec 15;190(12):1342-1354.)

**FIGURE 110-7.** Pulmonary complications of organic phosphorus (OP) poisoning. Exposure to OP compounds causes the acute cholinergic syndrome characterized by reduction in central respiratory drive, bronchospasm, and hypoxia due to bronchorrhea and alveolar edema, and depolarizing neuromuscular junction (NMJ) block. This either resolves or progresses to acute respiratory failure that would be fatal without medical input. Reduced consciousness and loss of airway control in the cholinergic syndrome increases the risk of aspiration, resulting in chemical pneumonitis that will worsen oxygenation and progress to ARDS. Overstimulation of the NMJ causes chronic peripheral dysfunction that occurs simultaneously with the acute cholinergic syndrome or after it has resolved with normal cerebral function (then termed the “intermediate syndrome”). This NMJ dysfunction often requires days and weeks of mechanical ventilation with associated risk of ventilator-associated pneumonia and barotrauma. (Reproduced with permission from Hulse EJ, Davies JO, Simpson AJ, et al. Respiratory complications of organophosphorus nerve agent and insecticide poisoning. Implications for respiratory and critical care. Am J Respir Crit Care Med. 2014 Dec 15;190(12):1342-1354.)

little movement.<sup>123</sup> Two cases of rhabdomyolysis and AKI followed severe monocrotophos poisoning.<sup>96</sup> It is also possible that renal or muscle injury is due to solvents in the insecticides, such as cyclohexanone.<sup>184</sup>

### Acute Toxicity—Carbamates

The acute effects of poisoning from carbamate insecticides are similar to those of OP insecticides, with coma and acute respiratory failure occurring after substantial exposure. Cholinergic features tend to last for shorter durations after poisoning, often for a matter of hours, rather than days. Persistent cholinergic features over many days are not reported for carbamate poisoning; however, complications of toxicity such as aspiration pneumonia can last for many days.<sup>143</sup>

### Delayed Syndromes

#### Neuromuscular Junction Dysfunction (Intermediate Syndrome)

A syndrome of delayed muscle weakness without cholinergic features or fasciculations resulting in respiratory failure was first reported by Wadia in 1974 as type II paralysis<sup>236</sup> and further refined by Senanayake and Karaliedde in 1987 as the intermediate syndrome.<sup>206</sup> The syndrome is defined as occurring 24 to 96 hours after acute OP poisoning, and after resolution of the cholinergic crisis.<sup>1,132,206,236</sup> Patients develop proximal muscle weakness, especially of the neck flexors, and cranial nerve palsies, and progress to respiratory failure that lasts for up to several weeks.<sup>132</sup> Consciousness is preserved unless complicated by hypoxia or pneumonitis. The syndrome is important since apparently well patients suddenly develop respiratory failure; patients must be carefully observed for proximal muscle weakness if deaths are to be prevented.<sup>18,183</sup> The first sign is often weakness of neck flexion such that patients cannot lift their head off the bed. It is also recognized as occurring rarely with carbamate poisoning.<sup>121</sup>

Although the exact pathophysiology of the syndrome is unknown, it is clearly due to NMJ dysfunction, with respiratory failure resulting from weakness affecting the diaphragm and intercostal muscles. Preservation of consciousness suggests that the central respiratory drive is not involved. One theory is that overwhelming NMJ stimulation causes downregulation of the NMJ synaptic machinery.<sup>53,206</sup> This would require time to be repaired, even after the pesticide is removed from the body, explaining the long duration of ventilation needed by many patients.<sup>78</sup>

Cases and small case series of NMJ dysfunction suggest that it is more common with certain OPs, such as parathion, methyl parathion, malathion, and fenthion. Unfortunately, large cohorts of poisoning with specific OPs receiving standardized treatments are rarely reported, making comparisons of incidence between OPs difficult. However, 2 cohorts indicate that the intermediate syndrome causing respiratory failure is more common in fenthion poisoning than chlorpyrifos, malathion, or fenitrothion poisoning.<sup>78,235</sup>

Clinical examination for proximal muscle weakness remains the most reliable means of identifying the occurrence of intermediate syndrome.<sup>132</sup> Electromyograms often show tetanic fade, and suggest both pre- and post-synaptic involvement.<sup>132</sup> Characteristic electrophysiological features appear before onset of neurologic features and respiratory paralysis.<sup>122</sup> The majority of patients developing weakness do not progress to respiratory failure, indicating that intermediate syndrome is a spectrum disorder.

Another study of severely poisoned patients suggested that the occurrence of intermediate syndrome strongly correlated with the initial degree of cholinergic crisis, and seemed to be a continuum with the neuromuscular paralysis resulting from the early stages of poisoning.<sup>123</sup> This view is supported by early work<sup>53</sup> and a more recent study of dimethoate poisoning, which showed that peripheral NMJ dysfunction can occur simultaneously with the cholinergic syndrome.<sup>78</sup> Patients with moderate to severe dimethoate poisoning typically require intubation for respiratory failure soon after ingestion, during the acute cholinergic syndrome. However, this is relatively short-lived and patients recover consciousness after a few days. As the cholinergic syndrome settles and the patients regain consciousness, with presumed recovery of the central respiratory drive, they are still unable to ventilate. Similar to patients with classical intermediate syndrome, they require ventilatory support for

several weeks until their NMJ recovers function. In contrast, this case series showed that the classic intermediate syndrome—respiratory failure after resolution of the cholinergic syndrome—sometimes occurs before 24 hours and after 96 hours.<sup>78</sup>

These studies suggest that the original intermediate syndrome is just one important aspect of OP-induced peripheral NMJ dysfunction. It seems likely that the relative incidence and timing of the intermediate syndrome or delayed NMJ dysfunction for different OPs is determined by the rapidity and quantity of AChE inhibition. Where inhibition is intense, with fat-insoluble OPs like dimethoate that have very high plasma concentrations, NMJ dysfunction comes on early, before recovery from the cholinergic crisis. Fat-soluble OPs, such as fenthion, cause a more protracted AChE inhibition, likely explaining why fenthion induced NMJ dysfunction and respiratory failure occur later.<sup>78</sup>

Some authors suggest that insufficient oxime therapy explains the intermediate syndrome.<sup>20</sup> The occurrence of NMJ dysfunction in chlorpyrifos poisoning may well be due to inadequate oxime therapy. However, adequate oxime therapy after, for example, malathion poisoning<sup>215</sup> is probably irrelevant because AChE inhibited by this dimethyl OP shows poor biochemical reactivation after oxime therapy. Regardless, delayed NMJ dysfunction is possibly due to ineffective AChE reactivation, whether due to inadequate oxime doses or to poisoning with OP insecticides that do not respond to oxime therapy.

Animal studies of dimethoate poisoning have shed some light on this condition. These studies produced NMJ dysfunction and showed that it did not occur after poisoning with dimethoate active ingredient alone. Instead, it occurred after poisoning with the agricultural EC40 formulation that included both the dimethoate active ingredient and the solvent, cyclohexanone.<sup>79</sup> This raises the possibility that NMJ dysfunction is due to an interaction of solvent and active ingredient. All reported cases have occurred after self-poisoning by drinking agricultural formulations of OP insecticides; further human studies are required to clarify the role of solvents and the possible mechanisms of effect.

#### Organic Phosphorus Compound-Induced Delayed Neuropathy

Peripheral neuropathies occur with chronic OP compound exposures days to weeks following acute exposures, due to phosphorylation and inhibition of the enzyme neuropathy target esterase (NTE, now identified as a lysophospholipase) within nervous tissue.<sup>95,124</sup> This enzyme catalyzes breakdown of endoplasmic reticulum-membrane phosphatidylcholine, the major phospholipid of eukaryotic cell membranes. Neuropathic OPs (such as chlorpyrifos, dichlorvos, isofenphos, methamidophos<sup>153</sup>) cause a transient loss of NTE activity, putatively disrupting membrane phospholipid homeostasis, axonal transport, and glial-axonal interactions.<sup>95</sup>

Such neuropathies sometimes result from exposure to OPs that do not inhibit RBC cholinesterase or produce clinical cholinergic toxicity.<sup>35</sup> The more commonly implicated chemicals include triaryl phosphates, such as triorthocresyl phosphate (TOCP), and dialkyl phosphates, such as mephosfolan, mipafox, and chlorpyrifos.<sup>125</sup> Pathologic findings demonstrate effects primarily on large distal neurons, with axonal degeneration preceding demyelination.

Contaminated foods and beverages were responsible for epidemics of OP compound-induced delayed polyneuropathies and encephalopathy. In the 1930s, thousands of individuals in the United States became weak or paralyzed after drinking a supplement containing TOCP—an outbreak nicknamed “Ginger Jake paralysis” (Chap. 22).<sup>166</sup> Contaminated cooking and mineral oils were responsible for outbreaks of delayed polyneuropathies in Vietnam and Sri Lanka.<sup>56,205</sup> Vague distal muscle weakness and pain are often the presenting symptoms and progress to paralysis.<sup>102</sup> The administration of atropine or pralidoxime does not alter the onset and clinical course of these symptoms.<sup>231</sup> Pyramidal tract signs appear weeks to months after acute exposures. Electromyograms and nerve conduction studies are helpful in diagnosis by identifying the type of neuropathy (such as axonopathy, myelinopathy, or transmission neuropathy) and differentiating it from similar presentations

such as Guillain-Barré syndrome.<sup>3</sup> Recovery of these patients is variable and occurs over months to years, with residual deficits common.<sup>166,205</sup>

Delayed neuropathies are not usually associated with carbamate insecticides. One reason for this difference is presumed to be that aging of the neuropathy target esterase pesticide complex is a requirement for neuronal degeneration. Paradoxically, one study suggested that subgroups of carbamates actually bind neuropathy target esterase and exert a protective effect against more toxic OP compounds.<sup>4</sup> However, delayed neuropathy does occur rarely after poisoning with carbamates.<sup>61,228,249</sup> These cases involved ingestions of carbaryl, *m*-tolyl methyl carbamate, and carbofuran, included both sensory and motor tracts, and tended to resolve over 3 to 9 months. Electromyogram findings were variable.

### Behavioral Toxicity

Behavioral changes also occur after acute or chronic exposure to OP compounds.<sup>86,213</sup> Signs and symptoms include confusion, psychosis, anxiety, drowsiness, depression, fatigue, and irritability. Electroencephalographic changes last for weeks in some cases.<sup>101</sup> Single-photon emission computed tomography (SPECT) scanning revealed morphologic changes in the basal ganglia of one child following poisoning.<sup>24</sup> A deficit in cognitive processing was noted after acute OP self-poisoning that lasts for at least 6 months and is not found in matched patients who poisoned themselves with paracetamol.<sup>48,49</sup> Although multiple small studies have shown some effect,<sup>86,169,201</sup> thus far there is no clear evidence for neuropsychiatric deficits resulting from subclinical exposure to OPs.

### Chronic Toxicity

Illness results from chronic exposure to excessive amounts of OP compounds. Chronic exposure most commonly occurs in workers who have regular contact with OPs, but also occurs in individuals who have repeated contact with insecticides in their living environment. Cholinergic ophthalmic preparations have led to toxicity.<sup>155</sup> Although tolerance to acute cholinergic systemic effects of OP insecticides (including death in rats) is observed with long-term exposures,<sup>93</sup> persons who have repeated contact have developed symptoms after many months. These effects range from vague neurologic complaints, such as weakness and blurred vision, to miosis, nausea, vomiting, diarrhea, diaphoresis, and other cholinergic effects (eg, DUMBELS, SLUD).<sup>5,6,155,214</sup> Butyrylcholinesterase activity is usually the most sensitive measure of exposure, and workers in contact with these chemicals should have baseline BuChE testing for comparison and monitoring.<sup>113</sup>

Studies have linked the onset of Parkinson's disease with chronic exposure to pesticides including OP compounds.<sup>60</sup> Although statistics derived from some epidemiologic studies suggest a connection with pesticide exposure,<sup>84</sup> others studies have failed to find an association between OP compounds and Parkinson's disease (for example ref<sup>220</sup>). Overall, the studies have been retrospective in nature and confounded by recall bias. However, a recent case-control study using a geographic information system-based exposure assessment tool to estimate ambient exposure to OPs in central California found an adjusted odds ratio of 2.24 (95% confidence intervals 1.58–3.19).<sup>237</sup>

## DIAGNOSTIC TESTING

### Organic Phosphorus Compounds

When faced with a patient in cholinergic crisis who presents with a history of acute exposure to an OP cholinesterase inhibitor insecticide, the diagnosis is straightforward. Although textbooks list a variety of clinical signs for the cholinergic crisis (eg, DUMBELS, SLUD), most patients with significant poisoning are simply identified by the presence of pinpoint pupils, excessive sweat, and breathing difficulty.<sup>72</sup> However, when the history is unreliable or does not suggest poisoning, the physician must turn to other means to confirm the diagnosis of OP or carbamate poisoning. However, treatment of an ill patient with a cholinergic syndrome should not await confirmation of the diagnosis.

The most appropriate laboratory tests for confirming cholinesterase inhibition by insecticides are tests that measure (1) specific insecticides

and active metabolites in biologic tissues and (2) cholinesterase activity in plasma or blood. Unfortunately, although urine and serum assays for OP compounds and their metabolites are available,<sup>109,141</sup> such testing is rarely obtainable within hours. Moreover, toxic concentrations are not established for most compounds. Currently, therefore, verifying cholinesterase inhibitor poisoning relies on measurement of cholinesterase activity.<sup>69,93</sup>

### Cholinesterase Activity

The 2 cholinesterases commonly measured are butyrylcholinesterase (BuChE, plasma cholinesterase, EC 3.1.1.8) and red blood cell (RBC) acetylcholinesterase (AChE, EC 3.1.1.7). The former is produced by the liver and then secreted into the blood, where it metabolizes xenobiotics, including succinylcholine, pyrethroid insecticides, and cocaine. Red blood cell AChE is expressed from the same gene as the enzyme found in neuronal synapses. The main difference is in their mechanism of membrane attachment, which is due to posttranslational modification (RBC AChE is glycoposphatidylinositol linked to the RBC whereas neuronal AChE forms dimers and tetramers that are attached to the postsynaptic membrane by other proteins).<sup>157</sup> Inhibition of either RBC AChE or BuChE only serves as a marker for cholinesterase inhibitor poisoning, because inhibition of these enzymes specifically does not contribute to signs and symptoms of poisoning.

There is tremendous variability between OP compounds in the degree and duration with which they affect particular cholinesterases.<sup>75,140,164</sup> After a significant exposure, BuChE activity usually falls first, followed by a decrease in RBC AChE activity. The sequence is highly variable, but by the time patients present with acute symptoms, activities of both cholinesterase have usually fallen well below baseline values.<sup>174</sup> Of note, the presence of BuChE, AChE, and other esterases varies markedly between species,<sup>146</sup> complicating the interpretation of animal studies. Furthermore, AChE occurs at very low concentrations in human plasma;<sup>146</sup> therefore, papers citing human serum AChE activity are likely measuring serum BuChE.

### Butyrylcholinesterase

Butyrylcholinesterase activity usually recovers before RBC AChE activity, returning to normal within a few days after a mild exposure in the absence of a repeat exposure.<sup>44</sup> However, BuChE activity is less specific for exposure than is RBC AChE activity. Low BuChE activity is also found in patients with a number of disorders, including hereditary deficiency of the enzyme, malnutrition, hepatic parenchymal disease, chronic debilitating illnesses, and iron deficiency anemia.<sup>133</sup>

The wide normal range of BuChE activity allows for patients with high normal values to suffer significant falls in activity, yet still register near normal BuChE activity on assay.<sup>44</sup> Additionally, day-to-day variation in the activity of this enzyme in healthy individuals may be as high as 20%.<sup>110</sup>

Furthermore, because BuChE inhibition varies between OPs and does not cause clinical effects, an admission value by itself is of little value in predicting outcome. An admission value will only predict outcome if the ingested OP is known and its clinical usefulness has been studied specifically for this OP.<sup>75</sup> For example, most patients who die with chlorpyrifos poisoning have a BuChE activity of around zero on admission; however, because chlorpyrifos is a very potent BuChE inhibitor, many other chlorpyrifos-poisoned patients who do not die also present with zero BuChE activities. In contrast, because dimethoate is a poor inhibitor of BuChE, the majority of patients who die from dimethoate poisoning have a BuChE activity on admission that is higher than many chlorpyrifos-poisoned patients who remain clinically well.<sup>75</sup>

### Red Blood Cell Acetylcholinesterase

Red blood cell AChE activity is thought to more accurately reflect nervous tissue AChE activity than plasma BuChE, with Namba proposing that inhibition of greater than 50% is required for clinical features.<sup>174</sup> Acutely, for some OPs, RBC AChE activity correlates closely with nervous system AChE activity, with NMJ dysfunction associated with greater than 70% inhibition.<sup>226</sup> However, this is not always the case. Patients with acute profenofos poisoning have complete inhibition of their RBC AChE activity without any apparent

cholinergic or neuromuscular signs.<sup>81</sup> Similarly, in an animal model, RBC AChE activity did not reflect clinical severity, perhaps due to the role of co-formulated solvents.<sup>79</sup> It is therefore unclear at present how useful RBC AChE activity is in grading poisoning severity and measurement of AChE activity should not be used to predict outcome or guide management.<sup>89</sup>

One advantage of RBC AChE over BuChE is that its activity should be related to blood hemoglobin (Hb) concentration, reducing variation due to varying hematocrits.<sup>245</sup> Most Caucasians have a normal value of 600–700 mUnit/micromol Hb; a small study of Caucasians reported a mean of 651 with a SD of +/-18 mUnit/micromol Hb.<sup>245</sup>

After poisoning, and in the absence of oximes, RBC AChE takes many weeks to recover because erythrocytes in circulation at the time of OP exposure must be replaced. An average of 66 days is necessary for RBC AChE activity to recover following severe inhibition (assuming no treatment with oxime), and activity may take up to 100 days to return to normal. Rat studies suggest that neuronal AChE activity returns to normal more rapidly than RBC AChE.<sup>103</sup>

Depressed RBC AChE activity also results from exposures or conditions other than OP or carbamate poisoning, for example, pernicious anemia and during therapy with antimalarial or antidepressant medicines (Table 110–3).<sup>135,168</sup>

Blood samples for cholinesterase activity must be obtained in the appropriate blood tubes. Tubes containing fluoride will permanently inactivate the enzymes, yielding falsely low activities, and should never be used. Specimens for RBC AChE are usually drawn into tubes containing a chelating anticoagulant such as EDTA to prevent clot formation. Butyrylcholinesterase does not require an anticoagulant and can be drawn into a tube without chelators or anticoagulants.

Organic phosphorus compounds and oximes in collected blood samples will continue to interact with RBC AChE; small differences in time between sampling and assay results in marked artificial variation in results. The most accurate way to take blood for AChE activity measurement is to immediately dilute it 1:20 or 1:100 at the bedside into saline or water cooled to 4°C, before rapidly freezing the sample. This process slows down both inhibitory and reactivating reactions in the tube, allowing more uniform results.<sup>69,245</sup> Such rapid reactions do not occur with BuChE and bedside dilution and cooling are not therefore required.

### Protein Adducts

Current research is attempting to find ways of detecting OP exposure many weeks after the event. New techniques using mass spectrometry aim to

identify phosphorylated proteins, such as albumin or BuChE, in blood samples.<sup>146a,186,217</sup>

### Carbamates

Carbamates inhibit neuronal AChE, RBC AChE, and BuChE. The relative ease with which spontaneous decarbamylation of AChE takes place results in the measurement of relatively normal RBC AChE activity despite severe cholinergic symptoms if the assay is not performed within several hours of sampling.<sup>175</sup> This emphasizes the importance of cooling and then freezing the blood sample within minutes of collection (see above). As with OP pesticide poisoning, the wide “normal” range of BuChE activity makes interpretation of BuChE activity difficult at times when the patient’s baseline values are unknown. Red blood cell AChE inhibition is short-lived after carbamate poisoning, returning to normal within hours compared to days after OP insecticide poisoning.<sup>230</sup>

### Atropine Challenge

An atropine challenge (administration of a 0.6–1 mg of atropine to test for cholinergic features responsive to atropine) has long been recommended. However, there are no studies of the sensitivity and specificity of the test, or of its predictive values. Patients with substantial poisoning will show no response to the small dose of atropine; in contrast, patients with either mild poisoning or no poisoning will develop antimuscarinic features. In the light of this lack of clarity on usefulness, we recommend against this approach to diagnosis.

### Electromyogram Studies

Although measuring cholinesterase activity is the test most often used to estimate tissue and neuronal AChE activity, small studies support the use of repetitive nerve stimulation testing as an accurate method of quantifying AChE inhibition at the neuromuscular junction.<sup>9,21,122</sup> Further studies are required to determine the role of EMG studies in the diagnosis of anticholinesterase poisoning.

### Differential Diagnosis

The differential diagnosis for cholinergic poisoning includes 3 main categories (Table 110–4). The first comprises insecticides and other noninsecticidal cholinesterase inhibitors including the medicinal anticholinesterases such as neostigmine and pyridostigmine. This entire group of xenobiotics often produce low BuChE and low RBC AChE activity. Newer pharmaceuticals used to treat Alzheimer disease, such as donepezil and rivastigmine, inhibit AChE but symptomatic overdose of these xenobiotics appears rare.<sup>144,209</sup>

**TABLE 110–3** Interpreting Cholinesterase Activity Values

	<i>Red Blood Cell Acetylcholinesterase</i>	<i>Butyrylcholinesterase</i>
Advantage	Better reflection of synaptic inhibition	Easier to assay, declines faster
Site	RBC	CNS white matter, plasma, liver, pancreas, heart
Regeneration (untreated)	1% per day	25%–30% in the first 7–10 days
Normalization (untreated with oxime)	35–100 days	28–42 days
Use	Unsuspected prior exposure with normal butyrylcholinesterase	Acute exposure
False depression	Pernicious anemia, hemoglobinopathies, antimalarial treatment, oxalate blood tubes	Liver dysfunction, malnutrition, hypersensitivity reactions, drugs (succinylcholine, codeine, morphine), pregnancy or deficiency

**TABLE 110–4** Categories of Cholinergic Poisoning

Cholinesterase inhibitors
Organic phosphorus insecticides
Organic phosphorus ophthalmic medications
Carbamate insecticides
Carbamate medications
Cholinomimetics
Pilocarpine
Carbachol
Aceclidine
Methacholine
Bethanechol
Muscarine-containing mushrooms
Nicotine alkaloids
Coniine
Lobeline
Nicotine

The second category includes xenobiotics with cholinomimetic activity. These cholinomimetics directly stimulate muscarinic or nicotinic cholinergic receptors, but do not inhibit AChE. In exposed individuals, BuChE and RBC AChE activity should be normal. Cholinomimetics include preparations of carbachol, methacholine, pilocarpine, and bethanechol. Nonpharmaceuticals such as muscarine-containing mushrooms are also cholinomimetic (Chap. 117).

Finally, a third category of xenobiotics, the nicotine alkaloids (eg, nicotine, lobeline, and coniine), acts on nicotinic ACh receptors and causes CNS, autonomic, and skeletal muscle symptoms similar to those occurring in OP and carbamate toxicity, but without causing cholinesterase inhibition (Chap. 82). Poisoning with noncholinergic pesticides such as neonicotinoids sometimes causes increased secretions that may be mistaken for anticholinesterase poisoning.<sup>58</sup>

## MANAGEMENT

### Organic Phosphorus Compounds

The primary cause of death after anticholinesterase poisoning is respiratory failure and hypoxemia. This results from muscarinic effects on the cardiovascular and pulmonary systems (bronchospasm, bronchorrhea, aspiration, bradycardias, or hypotension), nicotinic effects on skeletal muscles (weakness and paralysis), loss of central respiratory drive, and rarely seizures (Figs. 110-6 and 110-7). Therefore, initial treatment for a patient exposed to OP compounds should be directed at ensuring an adequate airway and ventilation, and at stabilizing cardiorespiratory function by reversing excessive muscarinic effects.<sup>69,72</sup> Seizures not secondary to hypoxemia should be treated with standard benzodiazepine anticonvulsant.

Maintenance of the patient's airway should be ensured by early endotracheal intubation and positive-pressure ventilation in patients who are comatose, have significant weakness, or who are unable to handle copious secretions. Only a neuromuscular blocker that is not primarily metabolized by cholinesterases should be used to induce pharmacologic paralysis if needed. The duration of action of the depolarizing agent succinylcholine and the nondepolarizing agent mivacurium, for example, will be extended in the presence of low BuChE activity, causing paralysis lasting for several hours.<sup>207</sup>

### Antimuscarinic Therapy

Excessive muscarinic activity should be controlled at the same time as resuscitation to aid respiration and oxygenation. The muscarinic antagonist atropine competitively blocks ACh at muscarinic receptors to reverse excessive secretions, miosis, bronchospasm, vomiting, diarrhea, diaphoresis, and urinary incontinence.<sup>92,111</sup>

For adolescents and adults, an intravenous loading bolus of between 1 and 3 mg (depending on the severity of symptoms) is recommended; doses for children should start at 0.05 mg/kg up to adult doses. Doses should be titrated against effect, individualizing therapy for the patient. Although previously guidelines had recommended repeating doses of 1 to 5 mg every 2 to 20 minutes until "atropinization" had occurred,<sup>68</sup> the most rapid method of controlling excessive cholinergic activity is to give doubling doses every 5 minutes if the response to the previous dose is inadequate.<sup>68,72</sup>

This approach, of doubling or incremental doses, was tested against a standard bolus dose approach in a randomized controlled trial.<sup>2</sup> Patients were randomized to receive either 2 to 5 mg of atropine (depending on severity), repeated every 10 to 15 minutes as required, or 1.8 to 3 mg of atropine (depending on severity) followed by doubling doses every 5 minutes as required. Atropine doses were continued until all clinical signs of "atropinization" (see below) were clearly evident; atropine was then given as further bolus doses at increasing intervals or as a constant infusion, respectively. All patients received pralidoxime (1–2 g every 8–12 hours). The incremental approach was associated with reaching atropinization at a median of 24 minutes versus 152 minutes with standard bolus dosing, despite administration of similar total doses of atropine (136 vs 109 mg, respectively). This faster administration of atropine was associated with more rapid

resuscitation and stabilization as shown by the improved outcome: mortality with bolus atropine was 22.5% (18/80) and with incremental atropine was 8% (6/75) ( $P < .05$ ). Incremental dosing was also associated with less atropine toxicity, less NMJ failure, and less requirement for ventilation.<sup>2</sup>

"Atropinization" is classically said to occur when patients exhibit dry skin and mucous membranes, decreased or absent bowel sounds, tachycardia, reduced secretions, no bronchospasm (in absence of other causes such as aspiration), and usually, mydriasis.<sup>68</sup> However, patients die from cardiorespiratory compromise, not wet skin or miosis. As a result, cardiorespiratory parameters, not pupil size or the presence of sweating, should guide administration of atropine. Atropine dosing should aim to reverse bronchorrhea and bronchospasm, and to provide adequate blood pressure and heart rate for tissue oxygenation (eg, systolic blood pressure >90 mm Hg and heart rate >80 beats/min). All variables are easily and rapidly assessed.

Once atropinization occurs, an infusion of atropine, is recommended initially giving 10% to 20% of the total loading dose per hour (usually maximum 2 mg/h). Regular checks for signs of under- or overatropinization should guide the use of further boluses followed by changes in the infusion rate, or discontinuation of the infusion.<sup>72</sup> Infusions have been used for as long as 32 days in patients poisoned by fat-soluble OPs that continue to redistribute from the fat and freshly inhibit AChE.<sup>94</sup>

Some texts recommend not giving atropine until oxygen is administered because of the risk of inducing ventricular tachyarrhythmias. If true, this would have serious implications for patients in low-income countries or remote regions where oxygen is frequently unavailable and where the advice would delay administration of potentially life-saving atropine. Administration of atropine during resuscitation without oxygen to a cohort of 1900 OP or carbamate insecticide self-poisoned patients in Sri Lanka was not associated with tachyarrhythmias.<sup>139</sup> A review of the evidence base for this statement revealed that it originated from just 2 human case reports and from dog studies of limited relevance.<sup>139</sup> We therefore disagree with this recommendation. All patients showing signs of cholinergic toxicity should receive titrated atropine dosing whether oxygen is available or not.

The presence of marked tachycardia (>120–140 beats/min in a well-hydrated patient not withdrawing from alcohol), mydriasis, absent bowel sounds, and urinary retention after atropine administration indicates over-atropinization or atropine toxicity. This is unnecessary and possibly dangerous because of associated hyperthermia, confusion, and agitation.<sup>72</sup> Tachycardia is not however an absolute contraindication to atropine therapy because it can result from hypoxia, hypovolemia, aspiration pneumonitis, or agitation.

Large doses of atropine may be needed to reverse the bronchospasm, bronchorrhea, and bradycardia associated with severe OP compound toxicity.<sup>174</sup> Some patients with mild symptoms need only 1 or 2 mg of atropine to reverse cholinergic toxicity, but moderately poisoned adults often require total doses as large as 40 mg.<sup>63,68</sup> Some adults received more than 1,000 mg of atropine in 24 hours (with adequate pralidoxime dosing) without demonstrating antimuscarinic effects, and total doses as high as 11,000 mg during the course of treatment are reported.<sup>116</sup> However, the additional benefit of such extreme doses over more modest doses is unclear. A study from German ICUs, in which supportive care was likely optimized, reported that much smaller doses of around 1 mg/h were associated with adequate control of muscarinic features after initial atropinization.<sup>224</sup>

Atropine does not reverse nicotinic effects. Therefore, patients who improve after receiving atropine should be closely monitored in a critical care setting for impending respiratory failure from delayed NMJ dysfunction. Patients should be clinically examined regularly for proximal muscle weakness (particularly neck flexor weakness); once recognized, tidal volume or negative inspiratory force measurements should be made at least every 4 to 6 hours to detect impending respiratory failure and allow early initiation of ventilatory support.

When antimuscarinic CNS toxicity becomes evident yet peripheral cholinergic findings necessitate the administration of more atropine (eg, bradycardia, bronchorrhea), some authors recommend substituting glycopyrrolate for

atropine because its quaternary ammonium structure limits CNS penetration.<sup>196</sup> One randomized clinical trial (RCT) compared atropine with glycopyrrolate in ICU management of OP poisoning, but was too small to detect any difference between regimens.<sup>14</sup> The initial intravenous dose of glycopyrrolate for adults and adolescents is 1–2 mg, repeated as needed, or in children 0.025 mg/kg up to adult doses. As with atropine, some patients with severe poisoning require higher doses of glycopyrrolate. Although scopolamine (hyoscine) has been used in place of atropine,<sup>142,196</sup> it may cause more pronounced CNS effects. The use of penehyclidine, a relatively M<sub>1</sub>-, M<sub>3</sub>-, and M<sub>4</sub>-specific muscarinic antagonist with reduced cardiac effects, is recommended instead of atropine in China;<sup>45,250</sup> if it becomes widely available, larger studies are required to compare its effectiveness to atropine.

However, it is not clear that such approaches are required. In a large case series of patients treated by necessity outside of a critical care unit, atropinization without CNS toxicity could be safely accomplished by titrating the dose to clinical features and slowing atropine infusions whenever absent bowel sounds, confusion, or hyperthermia were detected.<sup>72</sup> We do not recommend the routine use of glycopyrrolate, scopolamine, or penehyclidine for anticholinesterase-poisoned patients.

The anticholinergic and  $\alpha_1$  adrenergic receptor antagonist anisodamine (7 $\beta$ -hydroxyhyoscyamine) is used in China for OP poisoning.<sup>82</sup> Its use has been recommended when high-dose atropine is considered insufficient;<sup>238</sup> however, in this study atropinization took a mean of 29.2 and 24.3 hours in the patients receiving atropine, or atropine plus anisodamine, respectively, suggesting an inadequate atropine dosing regimen. It is again not clear whether additional drugs are required if atropine administration is done appropriately.

## Oximes

Phosphorylated AChE undergoes hydrolytic regeneration at a very slow rate. However, this process can be enhanced by using an oxime such as pralidoxime chloride (2-PAM) or obidoxime (Fig. 110-3).<sup>87</sup> Regeneration of AChE lowers ACh concentrations, improving both muscarinic and nicotinic effects. An immediate rise in RBC AChE activity, hopefully paralleling a rise in neuronal AChE activity, occurs after effective administration of oximes.<sup>74,225</sup>

As discussed above, phosphorylated AChE becomes aged, and therefore unresponsive to oximes, at different rates according to the chemistry of the OP.<sup>87</sup> Oximes therefore are recommended early, within 3 to 4 hours of exposure, after dimethoxy OP poisoning. In contrast, they can still be highly efficacious 48 hours after diethoxy OP poisoning, with some effect even when given several days after exposure. In cases of poisoning with highly fat-soluble OP insecticides, in which OP leaking out of fat stores can freshly inhibit AChE, oximes might be efficacious for weeks.<sup>243</sup> Case reports support this reasoning by noting dramatic effects in reversing paralysis, weakness, and cholinergic symptoms after late administration of pralidoxime.<sup>161,173</sup>

However, the clinical effectiveness of oximes in large-dose OP insecticide self-poisoning is still unclear.<sup>80,247</sup> The first clinical experience with pralidoxime was reported in the late 1950s by Namba, who treated 5 patients with occupational parathion poisoning.<sup>173</sup> All patients responded well to pralidoxime 1 g IV. As expected from occupational inhalational exposure, none of the patients were severely ill. Namba subsequently reported the use of much higher doses of pralidoxime, of 1- to 2-g bolus loading doses followed by 0.5 g/h, in patients with severe parathion poisoning.<sup>171</sup> He also noted that some OPs, including malathion, did not respond well to pralidoxime.<sup>172</sup> These caveats were subsequently lost, with the use of pralidoxime 1 g, followed by a second 1-g bolus after a few hours as necessary, being recommended for all cases.

Extensive clinical experience of bolus pralidoxime regimens in Asia led to widespread doubt about their efficacy for self-poisoning.<sup>80</sup> Asian clinicians have traditionally used 1 g of pralidoxime every 4 to 6 hours for 1 to 3 days, producing high peaks and deep troughs in blood pralidoxime concentration. In a 1992 ecological study, Sri Lankan doctors reported finding no difference in OP insecticide case fatality during a 6-month period when pralidoxime was not available in their hospital, compared to periods when it was available.<sup>35</sup> They argued that pralidoxime was of little clinical benefit

and, because it was expensive, should not be routinely used for treating OP-poisoned patients. European clinician researchers responded that the doses being used were too low and that higher doses, more akin to Namba's second regimen, were required.<sup>127</sup> Two further trials from south India reported no effect<sup>128</sup> or even harm<sup>41</sup> from pralidoxime therapy.

All these clinical trials aimed for a plasma oxime concentration of around 4 mcg/mL, a target based on a single study with a single nerve agent in cats<sup>218</sup> that should not have been extrapolated to human OP pesticide poisoning in general.<sup>87</sup> In vitro studies with human RBCs suggest that a higher concentration of around 100 micromolar (approximately 20 mcg/mL) is required for sustained reactivation,<sup>87,225</sup> resulting in the recommendation from a WHO group that all patients receive a loading dose of at least 30 mg/kg pralidoxime chloride, followed by at least 8 mg/kg/h.<sup>126</sup> A subsequent RCT from India showed that very high doses of pralidoxime iodide, a 2-g loading dose followed by 1 g/h, reduced death and length of ventilation in moderately poisoned patients who presented early and were treated in an ICU.<sup>185</sup> However, similar doses of pralidoxime chloride do not reactivate AChE in severe poisoning with dimethoate and other dimethoxy pesticides.<sup>74</sup>

A second RCT from Sri Lanka was unable to demonstrate a benefit from similarly high doses of pralidoxime in symptomatic patients of all severity treated in a resource-poor hospital.<sup>73</sup> This trial compared no pralidoxime chloride with a 2-g bolus over 20 minutes followed by 0.5 g/h for up to 7 days or when atropine was no longer required, in addition to standard therapy. Although the study was stopped earlier than planned, pralidoxime was associated with an adjusted hazard ratio {HR} of 1.69 (95% confidence interval 0.88–3.26, P = .12) for death.

Although a subsequent Cochrane review concluded that current evidence was insufficient to indicate whether oximes are harmful or beneficial,<sup>29</sup> it is possible that some of the difference between the outcomes in the 2 major trials is due to the very high level of supportive care available in India. Despite being less severely poisoned, 66% of Indian patients were intubated at baseline compared to 17% of Sri Lankan patients. This high level of supportive care is not available in rural resource-poor district hospitals that see most OP-poisoned patients globally.

Another reason for the apparent lack of efficacy of oximes may be the very large doses of OP insecticide ingested during self-harm. For example, a typical ingested dose of 100 mL of a 40% parathion formulation contains 40 g of active ingredient. This equals 666 mg/kg parathion for a 60-kg adult, a dose 51-fold greater than the rat oral LD<sub>50</sub> for parathion of 13 mg/kg.<sup>248</sup> It is perhaps not surprising that standard doses of oximes are unable to counter such huge doses, with any reactivated oxime simply being reactivated by the high concentration of OP in the blood.<sup>80</sup>

All the clinical trials included in the Cochrane review assessed pralidoxime salts. Obidoxime<sup>87</sup> is used in some countries, including Germany<sup>85,225</sup> and Iran,<sup>11</sup> with reportedly beneficial effects. Although use of high-dose obidoxime is associated with liver injury,<sup>11</sup> this does not seem to be the case when doses of 250 mg as a loading dose followed by 750 mg per 24 hours are used.<sup>87</sup> The use of newer oximes such as HI-6 and HLo-7 has not yet been reported in pesticide-poisoned patients. However, in vitro studies suggest that they will not be highly effective for human AChE inhibited by a range of OP pesticides.<sup>246</sup>

The exact role of oximes is currently unclear. However, we recommend that oximes be given as soon as possible after exposure to increase the chance of benefit. The difference between Indian and Sri Lankan studies suggests that they should be administered in a critical care environment to reduce the risk of serious complications. The duration of use is unclear. It is reasonable to stop oxime administration when atropine is no longer clinically required. Electrophysiological and clinical observation may allow the benefit of oxime administration to be assessed before atropine is stopped. Transiently stopping the infusion after 2 to 3 days and carefully observing for clinical or electrophysiological deterioration is a reasonable approach to deciding whether to continue oxime therapy.

Titration-dose pralidoxime regimens have been recommended, due to reduced case fatality in a study with historical controls<sup>64</sup> and in a small

RCT.<sup>147</sup> However, titration was performed against BuChE activity after pralidoxime doses, which is problematic because BuChE is rarely reactivated by oximes and its inhibition is not pathologic.<sup>140</sup> It is possible that titrated regimens may offer benefit, but more data are required and this approach is not currently recommended.

Some aspects of oximes are not well understood. Their quaternary ammonium compound structure is thought to reduce their passage across the blood–brain barrier and prevent CNS effects.<sup>221</sup> However, obidoxime has been detected in cerebrospinal fluid,<sup>87</sup> and at least one case report describes pralidoxime-induced improvements in mental status and electroencephalograms not attributable to improved ventilation or perfusion.<sup>152</sup>

### Benzodiazepines

Animal studies demonstrate that administering benzodiazepines along with oximes in the treatment of poisoning with OP nerve agents or the insecticide dichlorvos increases survival and decreases the incidence of seizures and neuropathy.<sup>62</sup> Diazepam also decreases cerebral morphologic damage resulting from OP compound–related seizures.<sup>158</sup> One study suggests that diazepam attenuates OP-induced respiratory depression,<sup>62</sup> postulating that the benzodiazepines attenuate the overstimulation of central respiratory centers caused by OP compounds. However, seizures are uncommon in large case series of patients poisoned by OP insecticides,<sup>74,235</sup> and no clinical studies have been performed yet to determine whether benzodiazepines offer benefit to humans.<sup>156</sup> In the absence of this evidence, benzodiazepines should be used to treat OP-related seizures and agitation and to aid intubation, but should not be given routinely to all cases.<sup>156</sup>

The treatment of intermediate syndrome is supportive with airway protection and mechanical ventilation. There are no data demonstrating that pralidoxime or atropine is effective in treating this disorder, although patients require these medications to control concurrent cholinergic symptoms. The weakness and paralysis commonly resolve in 5 to 18 days.<sup>78,122,123</sup>

### Other Drug Treatments

The therapies discussed above affect only limited mechanisms involved in OP poisoning. Multiple additional therapies have been tested in animals but none have been shown to be beneficial in large clinical trials and none are used widely in clinical practice.<sup>71,189</sup> Future clinical trials may identify patients for whom they would be beneficial. Treatments that have been proposed include magnesium<sup>17,179,233</sup> or clonidine<sup>188</sup> to reduce presynaptic acetylcholine release, fresh-frozen plasma as a source of BuChE for scavenging OP pesticides,<sup>107,192</sup> and sodium bicarbonate.<sup>197</sup> A systematic review found eight clinical studies or trials of magnesium sulfate that suggested benefit but all were too small to provide definitive evidence.<sup>26a</sup> Lipid emulsions has also been suggested because of the high lipid solubility of most OP insecticides and their solvents;<sup>162,252</sup> however, an *in vitro* study suggested that the lipid actually stabilizes the OP from degradation.<sup>234</sup> More definitive studies are required; none of these therapies are currently recommended for anticholinesterase poisoning.

### Decontamination

Cutaneous absorption of OP pesticides and carbamates requires removal of all clothing as soon as possible after resuscitation and administration of atropine and oxygen. Medical personnel should avoid self-contamination by wearing neoprene or nitrile gloves. Skin should be triple-washed with water, soap, and water, and rinsed again with water. Although alcohol-based soaps are sometimes recommended to dissolve hydrocarbons, these products can be difficult to find, and rapid skin cleansing is the primary goal. Cutaneous absorption also results from contact with OP and carbamate compounds in vomitus and diarrhea if the initial exposure was by ingestion. Oily insecticides may be difficult to remove from thick or long hair, even with repeated shampooing, and shaving scalp hair may be necessary. Exposed leather clothing or products should be discarded because decontamination is very difficult once impregnation has occurred.

Military institutions are now experimenting with cholinesterase sponges for cutaneous OP decontamination.<sup>98</sup> The sponge consists of a cholinesterase

enzyme covalently linked and immobilized in a polyurethane matrix. The sponge is reportedly effective in removing OP compounds from skin and surfaces.<sup>98</sup>

In potentially life-threatening acute ingestions, if emesis has not occurred, the patient presents within 2 hours, and the airway can be protected, the stomach contents should be evacuated by lavage using a nasogastric tube. Although there are data suggesting that activated charcoal adsorbs some OP insecticides, a study of 1,310 Sri Lankan patients with OP or carbamate poisoning found no clear benefit from the use of multiple-dose activated charcoal.<sup>77</sup> For patients with anticholinesterase poisoning in whom the airway can be protected we recommend a single dose of 1 g/kg activated charcoal.

Health care providers must always maintain caution when coming into contact with stomach contents or other body fluids when managing these cases.<sup>148</sup> Bystanders were poisoned by providing mouth-to-mouth resuscitation to a victim of an intentional ingestion of diazinon.<sup>138</sup> There are also reports of nosocomial poisoning in ED staff. However, in only one paper were BuChE activities tested<sup>32</sup> to support the hypothesis of nosocomial poisoning, and none showed any evidence of inhibition. Clinical experience from South Asia suggests that nosocomial poisoning with OP pesticides is unlikely as long as standard universal precautions are followed.<sup>198</sup> It is possible that any nonspecific illnesses and anxiety are due to the solvents coformulated with the pesticides.<sup>148</sup>

Overall, the current view is best summarized by an Australian consensus statement on nosocomial poisoning that found little evidence that health care workers were at risk of such poisoning. In particular, it noted that timely resuscitation and medical assessment should take precedence over decontamination.<sup>148</sup>

### Extracorporeal Elimination

Hemodialysis and/or hemoperfusion are sometimes recommended for OP and carbamate insecticide–poisoned patients, particularly in East Asia.<sup>23,118,149</sup> The EXTRIP group has not yet published an opinion on this subject. Such approaches might offer some benefit if provided early for poisoning with OP insecticides such as dimethoate<sup>170</sup> and dichlorvos<sup>187</sup> that have small volumes of distribution<sup>200</sup> or where solvents are a substantial component of the overall toxicity. However, at present, there is insufficient data to recommend extracorporeal purification for anticholinesterase insecticide poisoning.

### Disposition

After atropinization, patients with cholinesterase inhibitor poisoning should be carefully and frequently observed for evidence of (1) deteriorating neurologic function and potential paralysis and (2) need for an increase or reduction in atropine dosing.

Cholinesterase activities can be measured to monitor their recovery.<sup>85,223</sup> However, clinical assessment is a more reliable marker of recovery because cholinesterase activities are often substantially reduced for many days after poisoning. We do not recommend using cholinesterase activities to make decisions on discharge. It is reasonable to discharge a patient who becomes asymptomatic and has not required atropine for 1 to 2 days. Although recurrent cholinergic crises and/or respiratory failure can occur after several days, such patients have usually previously shown clinical signs of toxicity. Patients should not be allowed to go home wearing clothing that was worn when the poisoning occurred.

### Carbamates

The treatment of patients with carbamate insecticide poisoning is similar to treatment of patients with OP poisoning. Urgent resuscitation and titrated dosing of atropine should be performed for all patients.

The efficacy of oximes for carbamate poisoning is unclear. Murine studies with pralidoxime and carbaryl indicate that the oxime dose used is important for outcome.<sup>160</sup> However, guinea pig studies of atropine and pralidoxime for aldicarb and methomyl poisoning showed no *in vitro* reactivation of AChE and no additional effect of oxime above that of atropine.<sup>26</sup> Human experience is limited; a case series of aldicarb–poisoned patients reported the use of low-dose pralidoxime (mean dose of 400 mg over the first 10 hours) but provided no evidence for efficacy.<sup>193</sup> Fortunately, because of the rapid hydrolysis

of the carbamate-AChE complex (see above), symptoms, including weakness and paralysis, usually resolve within 24 to 48 hours without oxime therapy. We do not recommend the routine administration of oximes to patients poisoned by carbamate insecticides.

However, administering pralidoxime to a poisoned patient in a cholinergic crisis is appropriate when it is not known whether the patient is suffering from OP or carbamate pesticide poisoning.

Significant inhibition of RBC AChE and BuChE by carbamates generally does not last for more than 1 to 2 days, assuming absorption is complete. Patients exposed to carbamates usually have normal cholinesterase activities by the time of discharge. There are no reported cases of recurrent or delayed poisonings following carbamate insecticide poisoning. However, of note, complications of poisoning with carbamates, such as aspiration and hypoxic brain injury, can last many days.<sup>143</sup>

## SUMMARY

- Organic phosphorus and carbamate compounds kill approximately 100,000 people each year.
- Poisoning with these pesticides is not uniform: they differ markedly in their human toxicity, pharmacokinetics, associated clinical syndromes, and response to therapy.
- Symptoms result from inhibition of AChE and overstimulation of muscarinic and nicotinic receptors in synapses of the autonomic and central nervous systems and at the NMJ.
- Patients with substantial poisoning present with the cholinergic crisis and have pinpoint pupils, excessive sweating and salivation, and respiratory failure due to bronchospasm, bronchorrhea, loss of central respiratory drive, and dysfunction of neuromuscular junction.
- Atropine is recommended in doubling doses to attain atropinization before being continued as an infusion at a dose individualized for the patient.
- Patients may develop NMJ dysfunction that progresses to respiratory failure; such patients often require ventilatory support for weeks.
- The effectiveness of oximes is unclear for pesticide self poisoning; it is dependent on the dose and type of OP ingested and the time to oxime administration. Where available, oximes are recommended as soon as possible after ingestion and in concert with atropine.
- Cholinergic features can recur many days after ingestion of highly fat-soluble compounds such as fenthion due to redistribution from fat stores.
- Patients should be carefully observed to ensure that the dose of atropine is not inadequate or excessive, any recurrence of cholinergic toxicity is identified and treated quickly, and NMJ dysfunction is recognized early, before the onset of respiratory failure.

## ATROPINE

Mary Ann Howland

## INTRODUCTION

Atropine is the prototypical antimuscarinic xenobiotic. It is a competitive antagonist at both central and peripheral muscarinic receptors that is used to treat patients with symptoms following exposures to muscarinic agonists such as pilocarpine, *Clitocybe* and *Inocybe* mushroom species, and acetylcholinesterase inhibitors. The latter group includes pesticides, such as carbamate and organic phosphorus compounds, chemical weapons nerve agents, and some xenobiotics used to treat patients with Alzheimer disease, such as donepezil and rivastigmine.

## HISTORY

Many plants contain the tropane alkaloids atropine and/or scopolamine. One notable example is *Atropa belladonna*, named by Linnaeus after Atropos, the goddess of fate in Greek mythology who could cut short a person's life. Belladonna means beautiful woman in Italian and comes from the practice by Italian women of placing belladonna extract in their eyes to produce aesthetically pleasing mydriasis.<sup>14</sup> In the early 1800s, atropine was isolated and purified from plants. In the 1860s, Fraser experimented with the dose-response relationship between atropine and physostigmine in various organs such as the heart and the eye.<sup>28</sup> Experiments in the 1940s with cholinesterase inhibitors demonstrated that atropine reversed many of the effects of these xenobiotics and protected animals against doses 2 to 3 times the dose necessary to kill 50% of the animals (LD<sub>50</sub>).<sup>62</sup>

## PHARMACOLOGY

## Chemistry

Tropane alkaloids are bicyclic nitrogen-containing compounds that are naturally found in the plants of the families Solanaceae (eg, *Datura stramonium*) and Erythroxylaceae (eg, *Erythroxycoc coca*) and have a long history of use as poisons and medicinals. Atropine (D,L-hyoscyamine), like scopolamine (L-hyoscyine), is a tropane alkaloid with a tertiary amine structure that allows central nervous system (CNS) penetration. Only L-hyoscyamine is active and found in nature. Quaternary amine antimuscarinics such as glycopyrrolate, ipratropium, tiotropium, methylhomatropine, and methylatropine bromide are charged and do not cross the blood-brain barrier into the CNS (Fig. A35-1). The process of isolation results in racemization and forms D,L-hyoscyamine.

## Mechanism of Action

Centrally acting muscarinic antagonists include atropine, scopolamine, and homatropine. Glycopyrrolate, ipratropium, and tiotropium act peripherally.

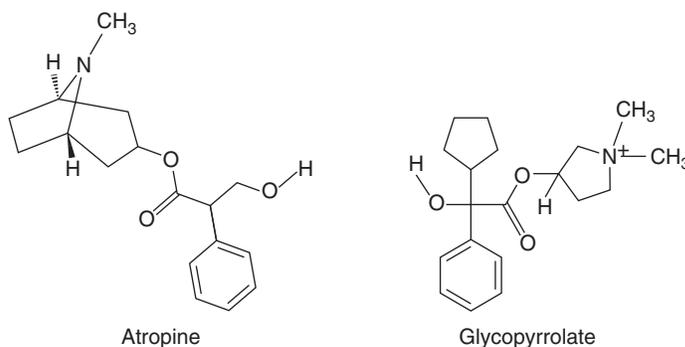

Scopolamine is approximately 10 times more potent than atropine.<sup>40</sup> Homatropine is approximately one-tenth as potent as atropine, depending on the measured outcome and route of administration.<sup>38</sup> Cholinergic receptors consist of muscarinic and nicotinic subtypes. Muscarinic receptors are coupled to G proteins and either inhibit adenylate cyclase (M<sub>2</sub>, M<sub>1</sub>) or increase phospholipase C (M<sub>1</sub>, M<sub>3</sub>, M<sub>5</sub>). Muscarinic receptors are widely distributed throughout the peripheral and central nervous systems.<sup>31</sup>

The competitive blockade of muscarinic receptors in normal individuals results in dose-dependent clinical effects that vary by organ system based on the degree of endogenous parasympathetic tone.<sup>14,31</sup> In adults, low doses (0.5 mg) of atropine sometimes cause a paradoxical bradycardia of about 4 to 8 beats/min, not evident with rapid intravenous (IV) administration. The paradoxical bradycardia produced at low doses of atropine is attributed to the inhibition of peripheral M<sub>1</sub> presynaptic postganglionic parasympathetic neurons. Stimulation of these receptors by acetylcholine inhibits the further release of acetylcholine, and atropine interferes with this negative feedback.<sup>14,60</sup> Not all studies demonstrate this paradoxical decrease in heart rate.<sup>9</sup>

Higher doses of atropine in adults (2 mg) produce noticeable dryness of the mouth and sweat glands, feelings of warmth, flushing, tachycardia, reactive dilated pupils, blurred near vision, drowsiness, postural hypotension, and urinary hesitation. At even higher doses of atropine (3–5 mg) in adults all symptoms are exaggerated, with escalating degrees of hyperthermia, tachycardia, drowsiness, difficulty voiding, prolonged gastrointestinal transit time, and decreased peristalsis. Doses of greater than or equal to 10 mg of atropine produce incapacitation with hot, dry, flushed skin, dilated pupils, blurred vision, very dry mouth, tachycardia, urinary retention, constipation, increased drowsiness or disorientation, hallucinations, stereotypical movements, bursts of laughter, delirium, and finally, coma, and rarely death.<sup>14,30</sup>

Cholinesterase inhibitors prevent the breakdown of acetylcholine by acetylcholinesterase, thereby increasing the amount of acetylcholine available to stimulate cholinergic receptors at both muscarinic and nicotinic subtypes, although the degree of effect varies widely among the class. Atropine is a competitive antagonist of acetylcholine only at muscarinic receptors and not nicotinic receptors.<sup>17</sup>

Miosis from the topical ophthalmic administration of a cholinesterase inhibitor is not typically reversed by the systemic administration of atropine.<sup>22,30</sup> The systemic administration of 354 mg of atropine made one patient floridly

**FIGURE A35-1.** The comparison of atropine, a tertiary amine structure which permits central nervous penetration, and glycopyrrolate, which is a quaternary amine structure and thus does not cross the blood-brain barrier.

anticholinergic, but did not counteract the ophthalmic effects following topical ophthalmic administration of a cholinesterase inhibitor.<sup>30</sup>

### Pharmacokinetics and Pharmacodynamics

Atropine is absorbed rapidly from most routes of administration including inhalation, oral, and intramuscular (IM).<sup>4</sup> Ingestion of 1 mg of atropine produces maximal effects on heart rate and on salivary secretions in one and 3 hours, respectively. The duration of action lasts from 12 to 24 hours, depending on the dose.

The distribution half-life of atropine following IV administration is approximately one minute. The apparent volume of distribution ( $V_d$ ) is about 2 to 2.6 L/kg.<sup>38</sup> As a result of the rapid distribution, within 10 minutes after IV administration less than 5% of the dose remains in the serum. The serum concentrations of atropine are similar at one hour following either 1 mg IV or IM in adults.<sup>4,11</sup> The elimination half-life is 6.5 hours.<sup>50</sup>

Following IM administration of 0.02 mg/kg in adults, the absorption rate and elimination rates are comparable for the racemic D,L-hyoscyamine and the active L-hyoscyamine at 8 minutes and 2.5 hours, respectively. The mean peak serum concentration and the area under the curve (AUC) are higher for the racemic mixture, indicating a stereochemical difference in pharmacokinetics.<sup>38</sup> Renal elimination accounts for 34% to 57% of the excretion of the dose, and the majority of renal elimination occurs within 6 hours.<sup>4</sup> Serum concentrations of L-hyoscyamine correlate with effects on heart rate and the antisialagogue effects. Serum concentrations of L-hyoscyamine below 0.5 mcg/L in an adult volunteer study were correlated with bradycardia, whereas higher concentrations caused tachycardia.<sup>38</sup>

A radioreceptor assay was developed to analyze the pharmacokinetics of the active enantiomer of atropine, referred to as (*S*)-L-hyoscyamine.<sup>58</sup> The sample for retrospective analysis of plasma concentrations was 6 organic phosphorus compound-poisoned patients from a previous clinical trial that included frequent blood samples and a detailed patient chart, and the atropine dose was linearly correlated with steady-state plasma concentrations. Elimination kinetics after an atropine bolus found a half-life of 1.5 hours, a  $V_d$  of 1.2 L/kg, a clearance of 13 mL/min/kg with a  $k_e$  of 0.536/h.

Intraosseous (IO) administration in minipigs demonstrated a pharmacokinetic profile similar to IV atropine.<sup>45</sup> The time to maximum concentration following a dose of 0.25 mg/kg was 2 minutes with both IV and IO injection, compared to 3.5 minutes for IM injection. Intraosseous administration in normal and hypovolemic swine demonstrated similar findings with very rapid absorption and distribution, although the hypovolemic swine had a comparatively longer half-life.<sup>18</sup> Atropine autoinjectors are now given to first responders for use during chemical weapons nerve agent attacks. The administration of 2 mg of atropine by autoinjector was compared with 2 mg administered by conventional needle and syringe into the deltoid of 6 adult subjects.<sup>55</sup> The onset of tachycardia and the time to maximal increase in heart rate occurred sooner with the autoinjector (16 minutes vs 23 minutes, and 34 minutes vs 41 minutes, respectively). An analysis of radiographs of contrast material injected by autoinjector or conventional IM administration into the leg of a dog demonstrated that the autoinjector appeared to “spray” the material into a larger tissue area, resulting in a faster rate of absorption.<sup>55</sup>

Ophthalmic administration of atropine causes cycloplegia and mydriasis by blocking the  $M_3$  muscarinic receptor on the iris sphincter muscle.<sup>44</sup> The peak mydriatic effect occurs within 30 to 40 minutes and persists for 7 to 10 days. By contrast, the effects of topical homatropine on the eye occur sooner than topical atropine (10–30 minutes for mydriasis and 30–90 minutes for cycloplegia) and are shorter in duration (6–48 hours).

The effects on pupillary dilation after systemic atropine administration depend on the dose and route of administration. An IM dose of 0.01 mg/kg into the thigh of healthy adults produced no change in pupil size,<sup>19</sup> whereas subcutaneous administration into the upper arm of doses of 0.5, 1, and 2 mg per a 70-kg person produced a dose-dependent increase in pupil size. An oral dose of 0.02 mg/kg also produced pupillary dilation.<sup>16,35</sup>

An investigation of the bioavailability of atropine ophthalmic drops in healthy adults revealed approximately a 65% systemic absorption, but with a

wide individual variability.<sup>37</sup> The time to maximum serum concentration was 30 minutes, and the apparent elimination half-life was 2.5 hours.

The pharmacokinetics of 3 inhaled doses of atropine from a metered dose nebulizer was compared with 2 mg of IM atropine in healthy adults.<sup>32</sup> Peak concentrations were comparable for the 2-mg inhaled and 2-mg IM atropine doses. The time to peak concentration following inhalation averaged 1.3 hours. Other dosage forms are being investigated as alternate ways to administer atropine in patients with organic phosphorus compound poisoning. Both a novel nanoatropine dry powder inhaler and a submicronic atropine in ethanol saline solution for nebulization are being evaluated to rapidly achieve blood concentrations of atropine in the hopes of circumventing IM administration.<sup>43</sup> Submicronic atropine sulfate nebulized solution, achieved therapeutic atropine concentrations in 5 minutes in healthy volunteers.<sup>43</sup> Another example is the development of a fast-disintegrating sublingual atropine sulfate tablet.<sup>7</sup>

### ROLE IN ORGANIC PHOSPHORUS AND CARBAMATE TOXICITY

Atropine is recommended as the first line in therapy for the muscarinic effects of organic phosphorus and carbamate toxicity, which prevents patients from drowning in their own secretions.

One of the earliest descriptions of the effectiveness of atropine in parathion and tetraethylpyrophosphate insecticide poisoning was published in 1955.<sup>29</sup> Atropine improved survival when administered early and continued with adequate maintenance doses, intubation, and ventilation. Parathion and tetraethylpyrophosphate insecticide exposure led to heart block and bronchoconstriction in dogs, whereas humans were more likely to develop a relative bradycardia. Humans were more likely to die from respiratory causes resulting from central apnea, diaphragmatic weakness, and bronchorrhea.

In 1971, a landmark case series and review of organic phosphorus compound (OP) insecticide poisonings was published. Included was a table classifying the severity of poisoning along with treatment protocols for each level of severity.<sup>46</sup> This regimen served as the foundation of treatment regimens (atropine and pralidoxime) for many years.

In the 1930s and 1940s, the Germans synthesized OP insecticides (acetylcholinesterase inhibitors) that were further developed as chemical weapons nerve agents (Chap. 126).<sup>54</sup> Although these xenobiotics inhibit acetylcholinesterase in a manner similar to traditional OP insecticides, these so-called nerve agents also affect other cholinesterases, and at high doses directly affect nicotinic and muscarinic receptors. Atropine was chosen in the late 1940s as the standard antidote for these nerve agents. The dose of atropine needed to antagonize these nerve agents is much less than that needed to effectively antagonize traditional OP insecticides, largely because of differences in pharmacokinetics. The benefits of adding pralidoxime to atropine were noted in the 1950s, and in the 1960s, pralidoxime was established as a standard antidote in addition to atropine for these xenobiotics (Antidotes in Depth: A36).

### ADVERSE EFFECTS AND SAFETY ISSUES

When atropine is used in the absence of a cholinergic agonist, adverse effects begin at 0.5 mg IV in the adult and include dry mouth and decreased sweat. However, in the presence of muscarinics or anticholinesterases, these effects do not typically occur until many milligrams of atropine are administered.

An unintentional atropine dose of 1,000 mg orally in one patient resulted in typical manifestations of anticholinergic poisoning that began within a short time and lasted 4 days.<sup>2</sup> In 2 hours, the patient went from feeling hot and flushed with blurred vision to stupor. Over the ensuing 24 hours he became tachycardic, hyperthermic, and comatose with mydriatic nonreactive pupils and shallow respirations. By 40 hours, he started to respond to his name and his temperature had normalized, but he had dry mucous membranes with mydriatic nonreactive pupils. He went from coma to restlessness, hallucinations, and paranoia. At 4 days, he regained a normal mental status with amnesia for the previous 4 days.

A survey of pediatric emergency departments in Israel reported on 240 children who unintentionally received atropine by autoinjections or autoinjector

system administration, self-administration, needle injury, or delivery to an unintended site during the Persian Gulf crisis.<sup>6</sup> Half of the children developed systemic effects that correlated with the doses of atropine administered. Eight percent of effects were serious, but there were no seizures or deaths.

Systemic atropine toxicity also occurs when too large a dose of atropine, scopolamine, or homatropine is instilled in the eye, especially in children.<sup>48</sup> A medication error by a home hospice team led to the administration of atropine ophthalmic drops in the eye rather than a desired sublingual administration resulting in significant ophthalmic toxicity. A literature review dating from 1890 to 2004 identified 16 cases of seizures attributed to cycloplegic ophthalmic instillation with 9 of the cases secondary to atropine.<sup>57</sup> Excessive absorption from other routes of administration such as rectal or inhalation would also be expected to result in toxicity.<sup>53</sup> In the event of an atropine overdose, physostigmine, a reversible, CNS active, cholinesterase inhibitor, is the antidote of choice (Antidotes in Depth: A11).<sup>47</sup> Schizophrenic patients in the 1950s were often given atropine as a treatment. Within 15 to 20 minutes of getting 32 to 212 mg of IM atropine, patients became restless and often confused. This progressed to muscular incoordination, ataxia, weakness, and garbled speech.<sup>27</sup> These patients then progressed to disorientation with illusions, visual hallucinations, delirium, and coma. The coma often lasted for 4 to 6 hours, and then patients recovered in a manner that in some respects is similar to the reverse of the poisoning. Regardless of the dose of atropine required to induce the coma, physostigmine 4 mg IM completely reversed the toxicity within 20 minutes, although the reversal only lasted for 30 to 45 minutes.<sup>27,47</sup> One additional case describes a patient who ingested 10 mL of 1.5% atropine ophthalmic drops (for a total of 150 mg). He was treated in an ED with 1 mg physostigmine administered IV over 3 to 5 minutes to a total dose of 11 mg over 75 minutes. He then required 3 additional 1 mg doses of physostigmine in the ICU until complete recovery.<sup>56</sup>

In adults, low doses (0.5 mg) of atropine sometimes causes a paradoxical bradycardia of about 4 to 8 beats/min, not evident with rapid IV administration.<sup>14,35</sup> Other precautions or contraindications to consider when administering atropine include those associated with all antimuscarinics and include narrow angle closure glaucoma, obstructive uropathy, gastroparesis, pylorospasm, relaxation of the lower esophageal sphincter, and myasthenia gravis. Of course these complications must be weighed against the possible life-threatening nature of OP, carbamate, and chemical weapons nerve agent poisoning.

## PREGNANCY AND LACTATION

Atropine is classified by the Food and Drug Administration (FDA) as pregnancy category C. Based on human data, atropine crosses the placenta and is recommended for use when indicated.<sup>13,59</sup> The American Academy of Pediatrics classifies atropine as compatible with breast-feeding.<sup>13</sup>

## DOSING AND ADMINISTRATION

Although the dosage regimen of atropine for organic phosphorus compound poisoning in adults was evaluated in a randomized, controlled trial, and there is considerable variation in recommendations in the literature.<sup>23,24</sup> A prospective, observational study suggested that a dose doubling, titrated protocol provided equal efficacy and less atropine toxicity compared with an ad hoc dosing protocol.<sup>49</sup> Experience suggests that atropine should be initiated in adults in doses of 1 to 2 mg IV for mild to moderate poisoning and 3 to 5 mg IV for severe poisoning with unconsciousness.<sup>46</sup> We recommend that this dose be doubled every 3 to 5 minutes until improvement is observed, at which time dose doubling can stop and similar or smaller doses should be used as needed.<sup>24,51</sup> A recent open-label randomized trial conducted in Bangladesh compared conventional bolus-dose atropine (2–5 mg IV every 10–15 minutes) to a doubling-dose IV atropine protocol (1.8–3 mg IV initially and then doubled every 5 minutes until atropinization occurred, followed by an infusion of 10% to 20% of the total atropinization dose IV every hour). For inclusion in the study, patients had to have more than mild organic phosphorus compound toxicity. The time to atropinization decreased by more

than 90% from 152 to 24 minutes, atropine toxicity decreased from 28% to 12%, incidence of intermediate syndrome decreased, and survival increased. We believe that the most important end point for adequate atropinization is the resolution of bronchorrhea and secondarily the reversal of muscarinic toxicity. However, it is important not to confuse abnormal focal auscultatory sounds associated with pulmonary aspiration with those of extensive bronchorrhea.<sup>24,51</sup> We recommend achieving clear lungs, heart rate greater than or equal to 80 beats/min, and systolic blood pressure exceeding 90 mm Hg as the important goals of therapy. Dry axillae and the absence of pinpoint pupils are additional goals.<sup>25</sup> Once these end points are achieved, it is reasonable to establish a maintenance dose of atropine. Several groups suggest and we agree with administering 10% to 20% of the loading dose as an IV infusion every hour as a starting point with meticulous, frequent reevaluation and titration.<sup>1,23,24</sup> Atropine can be diluted in 0.9% sodium chloride, with rates of 0.5 to 1.5 mg/h of atropine commonly used.<sup>49</sup> For example, if a patient received atropine 2 mg IV, then 4 mg in 5 minutes, and 8 mg in 5 minutes, when improvement in bronchorrhea is noticeable, the total loading dose to initial control would be 14 mg in 10 minutes. The initial IV infusion dose of atropine would be 1.4 mg/h. This could be achieved by mixing 10 mg of atropine in 100 mL of 0.9% sodium chloride to make a concentration of 0.1 mg/mL and infusing it at 14 mL (1.4 mg)/h. If too much atropine is administered, the patient will demonstrate signs of peripheral and central anticholinergic toxicity as described above.

The IV/IO starting dose of atropine in children is 0.02 mg/kg up to the adult dose.<sup>5,51,61</sup> A continuous infusion of 0.025 mg/kg/h was successfully used in a 2-year-old child following a fenthion poisoning.<sup>12</sup> Although a minimum dose of 0.1 mg has been advocated, this dose would be toxic to infants less than 5 kg and is not recommended.<sup>10</sup>

## Dosing for Chemical Weapons Nerve Agents

In the event that a person is exposed to a chemical weapons nerve agent, atropine is recommended in a dosage suitable for both the severity of the poisoning and the age of the patient. In a conscious adult with cholinergic effects, 2 mg of atropine IV or IM should be administered every 5 to 10 minutes until shortness of breath improves and drying of secretions occurs.<sup>54</sup> One adult autoinjector of atropine for IM administration, Mark 1 Nerve Agent Antidote Kit (NAAK), contains 2 mg of atropine, and therefore multiple injectors are often required. Similarly the autoinjector of atropine, AtroPen, comes in a variety of doses that are color coded with the green pen containing 2 mg and labeled for adults and children weighing more than 90 lb (usually corresponding to 10 years and older).<sup>8</sup>

Based on a limited amount of information, total doses of 2 to 4 mg of atropine are usually sufficient, which is much lower than the dose for most organic phosphorus compound exposures.<sup>24,26,36,54</sup> Patients who are unconscious or apneic require higher total doses, with 5 to 15 mg usually sufficing.<sup>54</sup> The appropriate total Mark 1 autoinjector doses of atropine for children depend on age and weight.<sup>33,41</sup> For ages 3 to 7 (13–25 kg), one autoinjector (2 mg) of atropine and one autoinjector of pralidoxime (600 mg) are recommended, resulting in a projected atropine dose of 0.08 to 0.15 mg/kg. For ages 8 to 14 years, 2 autoinjectors of atropine and 2 autoinjectors of pralidoxime are recommended, resulting in a projected atropine dose of 0.08 to 0.15 mg/kg. For patients older than 14 years, 3 autoinjectors of atropine and pralidoxime are recommended, resulting in a projected dose of atropine of less than 0.11 mg/kg. In an emergency for children younger than 3 years of age, a risk-to-benefit analysis would suggest injecting one autoinjector of atropine and one of pralidoxime. If time permits and only one autoinjector is available for use, it is recommended to transfer its contents to a small sterile vial for traditional IM administration with a needle and syringe.<sup>34</sup> We recommend that children younger than one year be administered one pediatric atropine autoinjector (0.5 mg), such as AtroPen (Meridian Medical Technologies, Inc), if available, and children older than one year be administered the Mark 1 autoinjector as described above.

When IV administration of atropine is not feasible, it is reasonable to administer IO at the standard IV dose. However, the dose for endotracheal

administration in adults should be 2 to 2½ times the IV dose, diluted in 5 to 10 mL of 0.9% sodium chloride solution or sterile water. For children, we recommend following the 2015 American Heart Association guidelines for pediatric advanced life support, which recommend 0.04 to 0.06 mg/kg in a child endotracheally, followed by a flush of 5 mL of 0.9% sodium chloride solution and then 5 manual ventilations to enhance absorption.<sup>5</sup>

## FORMULATION AND ACQUISITION

Atropine injection is available in many different strengths, with the following amounts in each 1 mL vial or ampule: 50 mcg, 300 mcg, 400 mcg, 500 mcg, 800 mcg, and 1 mg. Atropine is also available in prefilled 5- or 10-mL syringes with a concentration of 0.1 mg/mL for adults and in 5-mL syringes with a concentration of 0.05 mg/mL for children.<sup>9</sup>

The AtroPen Auto-Injector is a prefilled syringe designed for IM injection by an autoinjector into the outer thigh.<sup>8</sup> It is available in 4 strengths: 0.25 mg (yellow label), 0.5 mg (blue label), 1 mg (dark red label), and 2 mg (green label).

Atropine is also packaged in a kit designed for IM injection with a second autoinjector containing 600 mg of pralidoxime in 2 mL of sterile water for injection with 40 mg benzyl alcohol and 22.5 mg glycine. The pralidoxime injector is accompanied by an atropine autoinjector containing 2.1 mg of atropine in 0.7 mL of a sterile solution containing 12.47 mg glycerin and not more than 2.8 mg phenol. This particular combination kit is called a “Mark I Nerve Agent Antidote Kit” and is designed for IM use in case of a nerve agent attack. The needles are 0.8 inches in length.<sup>42</sup> The Mark I NAAK was replaced in great part by the DuoDote Autoinjector System and the analogous, military-designated Antidote Treatment Nerve Agent Autoinjector (ATNAA), which uses technology that sequentially administers 2.1 mg in 0.7 mL atropine followed by 600 mg in 2 mL pralidoxime chloride IM through the same syringe. The 23-gauge needle is 0.8 inches in length.<sup>21</sup>

Atropine is available orally in 300-, 400-, and 600-mcg tablets.

The expiration date for certain MARK I autoinjectors was extended because of drug shortages. In case of a shortage during an emergency, large numbers of atropine syringes can be compounded by a pharmacist from atropine powder using a standard syringe batching system.<sup>39</sup> In vitro evidence suggests that outdated atropine retains its potency and that an atropine solution prepared from powder is stable for at least 3 days.<sup>20,52</sup> Other sources of atropine to consider in an emergency during a shortage would be atropine eye drops, which come as a 1% concentration (10 mg/mL). Homatropine, available as eye drops in a 2% or 5% concentration, compared favorably with atropine in preventing lethality when administered IM in a pretreatment rodent model using dichlorvos. In this experimental model, homatropine appeared to be half as potent as atropine.<sup>15</sup> Glycopyrrolate and scopolamine are other atropine alternatives. Atropine is maintained as part of the Strategic National Stockpile (SNS) for formulary in repositories in numerous locations throughout the United States.

## SUMMARY

- Atropine has many clinical uses as a competitive antagonist at both central and peripheral muscarinic receptor sites.
- The use of atropine is extensive for patients with bradycardias, in advanced cardiac life support, and in those exposed to acetylcholinesterase inhibitors in the workplace, in the home, and potentially on the battlefield.
- Atropine should be dosed to the resolution of bronchorrhea caused by the muscarinic toxidrome using a dose-titrated doubling protocol.

## PRALIDOXIME

Mary Ann Howland

## Related Xenobiotics

Organic phosphorus pesticides and nerve agents both penetrate the central nervous system (CNS). A disadvantage of pralidoxime is that in vivo rat studies demonstrate only a 10% CNS penetration.<sup>39,73</sup> Strategies to enhance the penetration of oximes across the blood-brain barrier (BBB) include enhancing lipophilicity by adding a fluorine atom into the ring structure, designing a glucose-oxime drug that could use facilitated glucose transporters to cross the BBB, designing a prodrug of pralidoxime that could be oxidized to the active drug once it had crossed the BBB, conjugating the oxime with amidine, and by using a targeted nanoparticle drug delivery system.<sup>56</sup>

Obidoxime (Toxogonin, LuH-6) is an oxime used outside the United States that contains 2 active sites per molecule and is considered by some to be more effective than pralidoxime.<sup>24,25,99</sup> An in vitro study using human erythrocyte AChE supported the superiority of obidoxime to pralidoxime in reactivating AChE inhibited by the dimethyl phosphoryl (malaoxon, mevinphos) and diethyl phosphoryl OP compounds (paraoxon). On a molar basis, obidoxime is approximately 10 to 20 times more effective in reactivating AChE than pralidoxime.<sup>99</sup> A potential disadvantage is the concern that the phosphorylobidoxime generated from the reactivation of AChE by obidoxime could reinhibit AChE if not metabolized by a plasma enzyme similar or identical to human paraoxonase 1 (PON1). Paraoxonase exhibits polymorphism,<sup>22</sup> and one in 20 patients may not be able to metabolize this phosphorylobidoxime compound. Phosphorylpralidoxime is unstable and does not accumulate. A molecular docking simulation study demonstrated that pralidoxime had better positioning at the oxyanion hole compared to obidoxime, allowing better reactivation of methamidophos-inhibited AChE.<sup>49</sup> The H series of oximes (named after Hagedorn; HI-6, HIo-7) were developed to act against the chemical warfare nerve agents (Chap. 126).<sup>6</sup> These oximes have superior effectiveness against sarin, VX, and certain types of newer pesticides (eg, methyl-fluorophosphonylcholines).<sup>3,11,41,46,50,72,99,100</sup> Unfortunately, they are less efficacious for traditional OP insecticide poisoning, and their toxicity profile is inadequately defined.<sup>11,41,46,50,72,99,100</sup> In addition to reactivating AChEs, the Hagedorn oximes demonstrate direct central and peripheral anticholinergic effects at supratherapeutic concentrations.<sup>72</sup>

## Mechanism of Action

Organic phosphorus compounds are powerful inhibitors of carboxylic esterase enzymes, including acetylcholinesterase (AChE; true cholinesterase, found in red blood cells, nervous tissue, and skeletal muscle) and plasma cholinesterase or butyrylcholinesterase (BuChE) (found in plasma, liver, heart, pancreas, and brain).<sup>61</sup> The OP binds firmly to the serine-containing esteratic site on the enzyme, inactivating it by phosphorylation (Fig. 110-3).<sup>40,62,84</sup> This reaction results in the accumulation of acetylcholine at muscarinic and nicotinic synapses in the peripheral and central nervous systems, leading to the clinical manifestations of OP poisoning. Following phosphorylation, the enzyme is inactivated and can undergo one of 3 processes; endogenous hydrolysis of the phosphorylated enzyme, reactivation by a strong nucleophile, such as pralidoxime, and aging, which involves biochemical changes that stabilize the inactivated phosphorylated molecule and render it incapable of reactivation by oximes.

Endogenous hydrolysis of the bond between the enzyme and the OP is generally extremely slow and is considered insignificant. This is in contrast to the rapid hydrolysis of the related bond between the enzyme and many

## INTRODUCTION

Pralidoxime chloride (2-PAM) is the only cholinesterase-activating xenobiotic currently available in the United States. It is used concomitantly with atropine in the management of patients poisoned by organic phosphorus (OP) compounds. Administration should be initiated as soon as possible after exposure, but can be effective even days later and therefore is recommended for all symptomatic patients independent of delay. Continuous infusion is preferable to intermittent administration for patients with serious toxicity, and a prolonged therapeutic course is required.

## HISTORY

It was recognized that certain phosphate esters were potent and irreversible inhibitors of acetylcholinesterase (AChE).<sup>94,95</sup> Identification of an anionic site on AChE led to the theory that a compound could be developed that would bind to this site and remove the phosphate ester, thereby reactivating AChE. In 1951, Wilson demonstrated the key concept that cholinesterases inhibited by organic phosphorus compounds could be reactivated using hydroxylamine. Several hydroxylamine derivatives were studied and led to the design of pralidoxime (2-PAM), which American and British scientists independently synthesized as 2-PAM in 1955.<sup>65,95</sup>

## PHARMACOLOGY

## Chemistry

Pralidoxime chloride is a quaternary pyridinium oxime with a molecular weight of 173 Da. The chloride salt exhibits excellent water solubility and physiologic compatibility. Pralidoxime iodide has a molecular weight of 264 Da, is less water soluble, and can potentially induce iodism.<sup>3</sup>

carbamates. The positively charged quaternary nitrogen of pralidoxime is attracted to the negatively charged anionic site on the phosphorylated enzyme, bringing it close to the phosphorus moiety (Fig. 110–3). Pralidoxime then exerts a nucleophilic attack on the phosphate moiety, successfully releasing it from the AChE enzyme.<sup>93</sup> This action liberates the enzyme to a variable extent depending on the OP in question and restores enzymatic function.<sup>51</sup> The diethoxy organic phosphorus compounds (eg, chlorpyrifos, diazinon, ethyl parathion) take days to age ( $t_{1/2}$ , 33 hours to age) in comparison to hours ( $t_{1/2}$ , 3 hours to age) for the dimethoxy organic phosphorus compounds (eg, dimethoate, dichlorvos, fenthion, fenitrothion, malathion, monocrotophos) (Table 110–2).<sup>18,26</sup>

Pralidoxime is important at nicotinic sites where atropine is ineffective, most often typically improving muscle strength within 10 to 40 minutes after administration.<sup>62,84</sup> This effect is vital to maintaining the muscles of respiration. Pralidoxime is also synergistic with atropine; it liberates cholinesterase enzyme so that additional acetylcholine can be metabolized while atropine inhibits the effects of acetylcholine at cholinergic receptors. This suggests that pralidoxime has a synergistic effect with atropine in compromised patients.<sup>25,62</sup> Some OP compounds respond much better to pralidoxime than others, depending on the affinity of pralidoxime for the particular type of phosphorylated enzyme, its reactivating ability, concentrations of both the oxime and the OP, aging, and OP redistribution from a depot site such as fat.<sup>24,99</sup>

The CNS benefits of pralidoxime are controversial, as the molecule is a quaternary nitrogen compound and not expected to cross the BBB.<sup>39,53,62</sup> A rat experiment using a microdialysis technique demonstrated only 10% CNS penetration of pralidoxime.<sup>73</sup> Following exposure to IV fenitrothion, IV administration of pralidoxime in rats failed to improve survival or to reactivate brain cholinesterase, whereas with direct brain instillation pralidoxime partially restored brain cholinesterase and eliminated fatalities.<sup>87</sup> Intranasal oxime (obidoxime) delivery can circumvent the BBB and decreased mortality from 41% to zero in a murine paraoxon model.<sup>45</sup> Clinical observations have certainly suggested a CNS action of pralidoxime with a prompt return of consciousness reported in some cases.<sup>61,62,70,93</sup> A 3-year-old child who was comatose from parathion was given 500 mg of 2-PAM IV over 15 minutes with continuous electroencephalographic (EEG) monitoring. Within 2 minutes, there was a dramatic response on the EEG, followed rapidly by normalization of consciousness.<sup>38</sup>

Early work with feline models led to a proposal that a serum concentration of greater than or equal to 4 mcg/mL was a desired therapeutic concentration for pralidoxime.<sup>82</sup> However, more recent *in vitro* work with human erythrocytes and a mouse hemidiaphragm model suggests that higher serum concentrations are actually needed.<sup>96,99</sup> Twenty percent reactivation was achieved in 5 minutes with serum concentrations of 10 mcg/mL.<sup>99</sup> A simulation and analysis suggests that serum concentrations between 10 and 15 mcg/mL (50–100  $\mu\text{mol/L}$ ) are necessary for optimal treatment of severely poisoned patients.<sup>22,101</sup> These recommendations await validation in poisoned patients. Serum concentrations are not available in a timely manner, but may help in the design of future pralidoxime dosing protocols.

Organic phosphorus compounds inhibit BuChE (plasma cholinesterase) and AChE to different extents and are affected by oximes differently.<sup>19</sup> Butyrylcholinesterase is made in the liver and transported to the blood, where it metabolizes certain xenobiotics like cocaine and succinylcholine. Additionally, BuChE can be affected by disease states, and normal values show wide variation, making interpretation in any individual difficult without a preexposure concentration. Butyrylcholinesterase has no relationship to the manifestations of toxicity following an OP exposure. If performed correctly, and the OP does indeed inhibit BuChE, then the normalization can be utilized as a surrogate marker for OP or carbamate elimination from the body.<sup>42</sup> The benefit of this surrogate marker in contrast to monitoring manifestations of toxicity is a potential research tool. Likewise, the reactivation of BuChE by pralidoxime is dependent on the concentration of pralidoxime, often has a flat dose response, is quite variable, and is susceptible to aging.<sup>44</sup> For example, in an *in vitro* model of human blood taken from healthy volunteers and treated with paraoxon, pralidoxime was able to reactivate 1.3% and

18.1% of erythrocyte AChE at pralidoxime concentrations of 10 and 100  $\mu\text{mol}$ , respectively, compared with only 1% and 5.5% of BuChE with 10 and 100  $\mu\text{mol}$  concentrations of pralidoxime.<sup>38</sup>

By contrast to the usefulness of pralidoxime in the management of the cholinergic syndrome, current understanding of the pathophysiology of the intermediate syndrome is inadequate to determine whether pralidoxime can prevent its development (Chap. 110).<sup>81</sup> If cholinergic receptor desensitization due to ineffective AChE reactivation is responsible for the cause of the muscle weakness, then pralidoxime would only be likely to prevent the syndrome if the OP compound in question was responsive to pralidoxime (eg, chlorpyrifos) in the dose ingested, pralidoxime was administered before aging occurred and the solvent formulation of the compound was not contributory.<sup>12,19</sup>

In addition to the intermediate syndrome, certain OP compounds may lead to the development of delayed-onset neurotoxicity, which involves inhibition of neuropathy target esterases (now known as lysophospholipases). This delayed neurotoxicity cannot be prevented or treated by pralidoxime.<sup>20,54</sup>

### Pharmacokinetics and Pharmacodynamics

Pralidoxime chloride pharmacokinetics are characterized by a 2-compartment model. Pharmacokinetics values vary depending on whether calculations are determined in healthy volunteers or poisoned patients. The volume of distribution ( $V_d$ ) is larger in poisoned patients and most likely accounts for the prolonged elimination phase.<sup>22</sup>

In volunteers, the  $V_d$  is about 0.8 L/kg and the  $t_{1/2}$  is 75 minutes.<sup>35,68,79</sup> Pralidoxime is renally excreted, and within 12 hours, 80% of the dose is recovered unchanged in the urine.<sup>37,78</sup>

A dose of 10 mg/kg of pralidoxime administered intramuscularly (IM) to volunteers results in peak serum concentrations of 6 mcg/mL (reached 5–15 minutes after IM injection) and a half-life of approximately 75 minutes.<sup>78</sup> Following a standard 30-minute IV infusion dose of 1 g of pralidoxime in a 70 kg man, the serum concentration fell to less than 4 mcg/mL (no longer thought to be considered a serum concentration goal) at 1.5 hours. In a simulated model, a continuous infusion of 500 mg/h of pralidoxime led to a concentration greater than 4 mcg/mL after 15 minutes, which could be maintained throughout the infusion.<sup>85</sup> In a human volunteer study, an IV loading dose of 4 mg/kg over 15 minutes followed by 3.2 mg/kg/h for a total of 4 hours maintained serum pralidoxime concentrations greater than 4 mcg/mL for 4 hours. The approximately same total dose, 16 mg/kg, administered over 30 minutes only maintained those concentrations for 2 hours.<sup>55</sup> In poisoned patients receiving continuous infusions of pralidoxime as opposed to intermittent infusions, both the  $V_d$  and the  $t_{1/2}$  are increased.<sup>78</sup> A  $V_d$  of 2.77 L/kg, an elimination  $t_{1/2}$  of 3.44 hours, and a clearance of 0.57 L/kg/h were reported in poisoned adults given a mean loading dose of 4.4 mg/kg followed by an infusion of 2.14 mg/kg/h.<sup>93</sup> In poisoned children and adolescents, the  $V_d$  varied with severity of poisoning from 8.8 L/kg in the severely poisoned patients to 2.8 L/kg in moderately poisoned patients.<sup>75</sup> After a mean loading dose of 29 mg/kg followed by a continuous infusion of about 14 mg/kg/h, a steady-state serum concentration of 22 mcg/mL, a  $t_{1/2}$  of 3.6 hours, and a clearance of 0.88 L/kg/h were calculated.<sup>75</sup>

Oral administration of salts of pralidoxime (not used clinically because of OP poisoning–induced vomiting) demonstrated a peak concentration at 2 to 3 hours, a  $t_{1/2}$  of 1.7 hours, and an average urine recovery of 27% of unchanged pralidoxime in humans.<sup>43</sup> Oral administration demonstrated clinical efficacy in a mice murine model.<sup>8</sup>

Autoinjector administration of 600 mg of pralidoxime chloride in an adult man (9 mg/kg) produced a concentration above 4 mcg/mL at 7 to 16 minutes, a maximum serum concentration of 6.5 mcg/mL at about 28 minutes, and a  $t_{1/2}$  of 2 hours.<sup>68,77</sup> In 24 healthy volunteers, following 600 mg pralidoxime via the DuoDote autoinjector delivery system, a  $C_{\text{max}}$  of  $7 \pm 3$  mcg/mL, a  $t_{1/2}$  of  $2 \pm 1$  hours and  $t_{\text{max}}$  of  $28 \pm 15$  minutes were achieved. When stratified by gender, the  $C_{\text{max}}$  was 36% higher in women, the  $t_{1/2}$  was longer (153 minutes vs 107 minutes) and the  $t_{\text{max}}$  was achieved sooner (23 minutes vs 32 minutes).<sup>16</sup>

Using traditional needle and syringe IM administration requires a longer time to achieve comparable serum concentrations. The autoinjectors more widely disperse the medication in the tissues, resulting in faster absorption.<sup>71,79</sup>

## ROLE IN ORGANIC PHOSPHORUS COMPOUND TOXICITY: EFFICACY RELATED TO TIME OF ADMINISTRATION AFTER POISONING

The sooner after exposure to an OP, the more likely pralidoxime is to be effective. Timely administration reduces the likelihood that aging of the OP–AChE complex has occurred and is completed. However, there is no absolute time limitation on reactivation function, as long as the patient remains symptomatic.

Early in vitro evidence suggested that the successful use of cholinesterase reactivators depended on administration within 24 to 48 hours of exposure to the OPs; afterward, the acetylcholinesterases would be irreversibly inactivated.<sup>4,14,32,33,74</sup> The 48-hour limit was derived from in vitro experiments using a small number of tightly bound compounds and reactivators and data from plasma cholinesterase enzyme activity, which is now recognized to be relatively resistant to oxime-nucleophilic attack. These early data were accepted without consideration of their relevance to human systems, the use of newer and less tightly bound OP compounds, temperature and pH variation, blood flow, fat solubility, active metabolites, and species specificity. Fat-soluble OP compounds redistribute from fat stores over time and can continue to newly inhibit AChE for days.

An in vitro experiment assessed the effect of aging on the ability of pralidoxime to regenerate rat erythrocyte and brain cholinesterases using 3 different OP compounds.<sup>88</sup> The rate of reactivation of erythrocyte and brain cholinesterases was significantly decreased over time for fenitrothion and methyl parathion, with no reactivation occurring at 48 hours. This is partly because dimethylated (dimethoxy) OP pesticides age more quickly than diethoxy phosphorylated compounds.<sup>20</sup> By contrast, a very high reactivation rate for ethyl parathion was still apparent at 48 hours. Thus, the structure of the OP compound is important in the rates of aging and reactivation with pralidoxime. Fenitrothion and methyl parathion are both *o,o'*-dimethoxy OP compounds as are dichlorvos, dimethoate, fenthion, and malathion whereas ethyl parathion is an *o,o'*-diethoxy OP compound, as are chlorpyrifos and diazinon.<sup>88</sup> Other studies also suggest that pralidoxime remains effective for more than 48 hours following exposure to diethyl OPs and to some fat-soluble OPs.<sup>2,5,8,13,17,20,22,59,69,92</sup>

## ROLE IN ORGANIC PHOSPHORUS COMPOUND TOXICITY: HUMAN TRIALS

There are 4 randomized clinical trials examining the efficacy of pralidoxime for the management of OP poisoning. Two of these trials were done in the 1990s in India using doses of pralidoxime now considered to be inadequate.<sup>20</sup> Neither study demonstrated a benefit for pralidoxime and, in fact, suggested an increase in mortality in patients receiving the higher but still inadequate dose of pralidoxime. Criticisms include a delay in administration and an inadequate duration of treatment. The third clinical trial included 200 patients in India who were moderately to severely poisoned with an OP compound.<sup>64</sup> All patients received a 2-g loading dose of pralidoxime iodide over 30 minutes before being randomized to receive 1 g over 1 hour every 4 hours for 48 hours or a continuous infusion of 1 g/h for 48 hours. Beyond 48 hours, all patients received 1 g every 4 hours until no longer ventilator dependent. In the continuous pralidoxime infusion arm, there was a significant reduction in atropine requirements, a smaller number of patients require intubation, fewer days of intubation, and a reduction in mortality from 8% to 1%. It should be noted that the iodide salt of pralidoxime was used and would equate to about 650 mg/h of the chloride salt.<sup>23</sup> Even though the majority of the patients by history ingested dimethoate, a dimethoxy compound with high lethality and rapid aging, the time to admission and administration of pralidoxime was very short, with a median time of 2 hours. Criticisms of the study include a lack of blinding, no measurement of AChE or pesticide concentrations, and no objective monitoring of neuromuscular function.<sup>23</sup> By contrast, the most recent trial performed in Sri Lanka was unable to demonstrate a beneficial effect of pralidoxime in 121 patients compared to 114 patients treated with placebo.<sup>21</sup> There was no difference in mortality between groups, although

pralidoxime effectively reactivated red cell AChE inhibited by diethoxy OP insecticides. It also reactivated red cell AChE inhibited by dimethoxy OP insecticides, but less so, as expected. In comparison to the third study,<sup>64</sup> these patients arrived later (4.4 vs 2 hours), and the extent of supportive care was inferior. The exact reasons for these disparate results are unclear.

## ROLE IN CARBAMATE TOXICITY

Acetylcholinesterases inactivated by most carbamates spontaneously reactivate with half-lives of 1 to 2 hours, and typical clinical recovery occurs in several hours. However, in severe cases, cholinergic findings may persist for 24 hours.<sup>10,29</sup> Pralidoxime is rarely indicated for carbamate poisoning, but it is not contraindicated as previously suggested. This erroneous conclusion was based solely on data regarding a single carbamate, carbaryl, and inappropriately applied to all carbamates. Pralidoxime decreased the rate of carbamylation of 16 insecticidal carbamates, though it modestly increased the rates for 3, one of which was carbaryl.<sup>15</sup> In another experiment, pralidoxime had no effect on the reactivation of human erythrocyte AChE carbamylated by aldicarb, methomyl, and carbaryl.<sup>47</sup> Furthermore, animal studies demonstrated the beneficial effects of pralidoxime in decreasing the lethality of several carbamate insecticides,<sup>63,80</sup> though it worsened the toxicity of carbaryl. An in vitro kinetic study demonstrated a 60% increased rate of inhibition with carbaryl and pralidoxime.<sup>91</sup> It was suggested that this is possibly because the carbamate–oxime complex may actually be a more potent cholinesterase inhibitor than carbaryl alone.<sup>29,63,80</sup> However, even in the presence of carbaryl, the combination of atropine plus an oxime, a more clinically relevant situation, resulted in survival data comparable to that of atropine alone.<sup>29</sup> Previous animal data may also be confounded by the use of excessive doses of pralidoxime.<sup>57</sup> The evidence in total suggests that pralidoxime is rarely a necessary adjunct to atropine for a patient with a pure carbamate overdose. However, there are case reports, particularly with aldicarb, where pralidoxime appears to improve outcome.<sup>10</sup> Thus, pralidoxime should never be withheld in a seriously poisoned patient out of concern that a cholinergic xenobiotic is a carbamate.<sup>47</sup> Pralidoxime should be used in conjunction with atropine and rarely as the sole therapy in OP or carbamate poisoning.<sup>34</sup>

## ADVERSE EFFECTS AND SAFETY ISSUES

At therapeutic doses of pralidoxime in humans, adverse effects are minimal.<sup>27,28,60–62,70,85</sup> Transient dizziness, blurred vision, and elevations in diastolic blood pressure appear to be related to the rate of administration.<sup>35,55</sup> Doses of 45 mg/kg produce blood pressure elevations that persist for several hours, but are reversed with IV phentolamine.<sup>77</sup> The most recent randomized clinical trial revealed a higher percentage of patients with tachycardia and hypertension associated with pralidoxime compared to placebo after both the loading dose and the continuous infusion (75% vs 49% and 30% vs 14%). Rapid IV administration has produced sudden cardiac and respiratory arrest as a result of laryngospasm and muscle rigidity,<sup>36,66,76,97</sup> whereas IM administration in volunteers produced diplopia, dizziness, headache, drowsiness, nausea, tachycardia, increased systolic blood pressure, hyperventilation, decreased kidney function, muscular weakness, and pain at the injection site.<sup>68</sup> Elevations in hepatic aminotransferase concentrations were observed in volunteers administered autoinjector doses of 1,200 to 1,800 mg; these enzyme concentrations returned to normal in 2 weeks.<sup>68</sup> An important safety issue is inadvertent provider or patient contact with the “active” needle end of autoinjectors or autoinjector systems, triggering unintended administration, self-administration, needle injury, or delivery to an unintended site.

## PREGNANCY AND LACTATION

Pralidoxime is FDA pregnancy risk category C. Reproduction studies have not been done, and human case reports are limited. However, considering the maternal benefit of pralidoxime, it should be used as clinically indicated to protect the maternal fetal dyad. The use of pralidoxime should not be withheld because of pregnancy.<sup>9</sup> It is unknown whether pralidoxime is excreted into breast milk.

## DOSING AND ADMINISTRATION

The optimal dosage regimen for pralidoxime is unknown. A loading dose of 2 g over 30 minutes followed by a maintenance dose in adults of 1 g/h of pralidoxime iodide was used in the study from India.<sup>64</sup> One gram of pralidoxime iodide is approximately equal to 650 mg of pralidoxime chloride.<sup>64</sup> The package insert, last updated in 2012, recommends a pediatric loading dose of 20 to 50 mg/kg (not to exceed 2,000 mg/dose) over 15 to 30 minutes followed by a continuous infusion of 10 to 20 mg/kg/h.<sup>69</sup> The package insert also recommends an adult dose of 1 to 2 g in 100 mL of 0.9% sodium chloride given intravenously over 15 to 30 minutes, with an additional dose in one hour if muscle weakness persists and then given every 10 to 12 hours if muscle weakness persists.<sup>69</sup> This dose is most likely insufficient in severely poisoned adult patients. The package insert then goes on to state that pharmacokinetic evidence suggests that a loading dose followed by a continuous infusion is more likely to maintain therapeutic serum concentrations as compared to intermittent dosing.<sup>69</sup> Difficulties arise because a target serum concentration in humans has not been established, although in vitro studies suggest a target concentration closer to 17 mcg/mL compared with the 4 mcg/mL previously suggested.<sup>22,24,38</sup> This is complicated by the possibility that there is a ceiling dose and that some OP compounds are more easily reactivated than others. In addition, pharmacokinetic studies in volunteers suggest that a continuous infusion maintains a target concentration with less variation compared with intermittent boluses.<sup>55</sup>

Based on all of the above, we recommend a loading dose of pralidoxime chloride of 30 mg/kg (up to 2 g) over 15 to 30 minutes followed by a maintenance infusion of 8 to 10 mg/kg/h for adults (up to 650 mg/h) and 10 to 20 mg/kg/h for children (up to 650 mg/h).<sup>83</sup>

The addition of 20 mL of sterile water for injection to the 1-g vial of pralidoxime chloride results in a 5% solution (50 mg/mL). Following reconstitution, the pralidoxime should be used within several hours. This solution can be further diluted to a volume of 100 mL of 0.9% sodium chloride solution for IV infusion, or a concentration of 10 to 20 mg/mL. The loading dose can be infused over 15 to 30 minutes. If pulmonary edema is present, the 1 g of pralidoxime in 20 mL can be infused slowly over not less than 5 minutes.<sup>69</sup>

Although IV administration is preferred, IM administration is acceptable using a 1-g vial of pralidoxime reconstituted with 3 mL of sterile water or 0.9% sodium chloride for injection to provide a solution containing 300 mg/mL (concentrations above 35% weight/volume produce muscle necrosis in animals).<sup>78</sup> This could be used until an IV site is established. Intraosseous administration is likely to be as effective or superior to IM delivery and was demonstrated to achieve excellent serum concentrations in a swine model.<sup>89</sup> Patients with reduced kidney function may require dosage adjustment, but there are no specific recommendations on how to accomplish this. In patients with ARDS, the dose can be given as a 5% solution by a slow IV injection over at least 15 to 30 minutes.<sup>78</sup>

Depending on the severity of a nerve agent exposure, one to 3 injections with a pair of autoinjectors containing atropine and pralidoxime or one to 3 injections of a DuoDote autoinjector that contains both atropine and pralidoxime in one device and injects both automatically should be administered into the outer thigh and held in place for 10 seconds (administration is similar to that of an EpiPen autoinjector). The number of autoinjector doses administered to a child depends on the age and weight of the child.<sup>30,52</sup> For children aged 3 to 7 years (13–25 kg), one autoinjector of atropine and one autoinjector of pralidoxime is recommended for administration, which should result in a projected pralidoxime dose of 24 to 46 mg/kg. For children aged 8 to 14 years, 2 autoinjectors of atropine and 2 autoinjectors of pralidoxime is recommended for administration. These injections should result in a projected pralidoxime dose of 24 to 46 mg/kg. For anyone older than 14 years of age, 3 autoinjectors of atropine and pralidoxime is recommended for administration. This results in a projected dose of pralidoxime of less than 35 mg/kg. For children younger than 3 years, during an emergency, one autoinjector of atropine and one of pralidoxime may be administered in accordance with a risk-to-benefit analysis. If time permits and only autoinjector doses are available, its contents may be transferred to a small sterile vial for traditional IM administration with a needle and syringe.<sup>31</sup>

## Duration of Treatment

The signs and symptoms of OP poisoning usually manifest within minutes but infrequently are delayed up to 24 hours.<sup>62</sup> Delayed manifestations occur with the fat-soluble compounds, such as fenthion or chlorfenthion. The route of exposure also influences the onset of systemic symptoms. For example, there are delays following dermal contact, which does not occur following ingestion or inhalation. When symptoms are either delayed or prolonged, or when treatment is delayed, extended therapy with pralidoxime will usually be indicated.<sup>1,7,59</sup> In one case of poisoning with the fat soluble compound fenthion, 5 days elapsed before cholinergic symptoms appeared, and some symptoms then persisted for 30 days.<sup>59</sup> Pralidoxime and atropine were administered continuously in varying doses for the time that the patient was symptomatic. Therefore, the most practical recommendation is to continue the pralidoxime until symptoms have resolved and atropine has not been needed for 12 to 24 hours.<sup>19</sup> Other recommendations for estimating the duration of pralidoxime therapy include (1) measuring the serum or urinary concentration of the OP compound, (2) measuring serial determinations of plasma cholinesterase (increasing concentrations suggests the elimination of the OP compound), (3) incubating the patient's serum with an exogenous source of AChE or butyrylcholinesterase to assess inhibition, and (4) incubating the patient's inhibited red blood cell cholinesterase with a high concentration of oxime in vitro, to assess reactivation.<sup>21</sup> However, none of these measures are practical. Measurements of urinary concentrations of OP or AChE or BuChE are not likely to happen in real time. Furthermore, BuChE is not a good surrogate for OP inhibition.

In summary, duration of pralidoxime therapy is variable, dependent on the particular OP and dose ingested, and different for each patient. A reasonable approach would be to discontinue the pralidoxime when the patient has improved and no longer requires atropine. The patient must be observed carefully for recrudescence of toxicity potentially from a fat-soluble long-acting OP. If symptoms return, therapy with pralidoxime and atropine should be continued for at least an additional 24 hours.

## FORMULATION AND ACQUISITION

Pralidoxime chloride (Protopam) is supplied in 20-mL vials containing 1 g of powder, ready for reconstitution with sterile water or 0.9% sodium chloride for injection.<sup>67,69</sup>

As noted above, pralidoxime chloride is also available for IM administration by an autoinjector containing 600 mg of pralidoxime in 2 mL of sterile water for injection with 20 mg of benzyl alcohol and 11.26 mg of glycine. The 2-PAM autoinjector is also packaged in a kit containing 600 mg of pralidoxime in 2 mL of sterile water for injection with 40 mg of benzyl alcohol and 22.5 mg of glycine, accompanied by an autoinjector containing 2.1 mg of atropine in 0.7 mL of a sterile solution containing 12.47 mg of glycerin and not more than 2.8 mg of phenol. This kit is called a "Mark I Nerve Agent Antidote Kit (NAAK)" and is designed to be used IM by first responders in case of a nerve agent attack. The needles extend 0.8 inches in length. The Mark I NAAK was replaced by the DuoDote Autoinjector System and the analogous, military-designated Antidote Treatment Nerve Agent Autoinjector (ATNAA), which use technology that sequentially administers 2.1 mg of atropine in 0.7 mL followed by 600 mg of pralidoxime chloride in 2 mL IM through the same syringe.<sup>16</sup> The 23-gauge needle is 0.8 inches in length. Pralidoxime is maintained as part of the Strategic National Stockpile (SNS) formulary in repositories in numerous locations throughout the United States.

## SUMMARY

- Pralidoxime is an effective reactivator of AChE in many OP compound poisonings primarily reversing neuromuscular manifestations.
- The sooner pralidoxime is administered after the onset of OP toxicity, the more effective it is likely to be, although there is no absolute time limitation on reactivation function.
- Pralidoxime and atropine are synergistic and should be used together in the management of patients with OP poisonings.

- If a patient requires multiple doses of atropine for muscarinic symptoms or has neuromuscular weakness, then the use of 2-PAM is recommended.
- Because newer, highly fat-soluble OP compounds are currently available, it is necessary to administer atropine and 2-PAM for more prolonged periods of time than previously suggested.
- It is reasonable to stop 2-PAM when the patient is clinically well, atropine is no longer needed and neuromuscular weakness, if initially present, has recovered.

# INSECTICIDES: ORGANIC CHLORINES, PYRETHRINS/PYRETHROIDS, AND INSECT REPELLENTS

Michael G. Holland

## ORGANIC CHLORINE PESTICIDES

### History and Epidemiology

Until the 1940s, commonly available pesticides included highly toxic arsenicals, mercurials, lead, sulfur, and nicotine. When Nobel Prize-winning chemist Paul Müller demonstrated the insecticidal properties of dichlorodiphenyltrichloroethane (DDT) in the early 1940s, a whole new class of pesticides was introduced. The organic chlorine insecticides (DDT, lindane, cyclodienes, and others) were inexpensive to produce, nonvolatile, environmentally stable, and had relatively low acute toxicity when compared to previous insecticides. Most organic chlorines have a negative temperature coefficient, making them more insecticidal at lower temperatures, and less toxic to warm-blooded organisms (Table 111-1).<sup>168</sup> Widespread use of these insecticides occurred from the 1940s until the mid-1970s. They were highly effective and revolutionized modern agriculture, allowing unprecedented crop output from each acre of arable land. Because of their stability, organic chlorines were used extensively in structural protection (termites, carpenter ants) and soil treatments. Medical and public health applications of DDT and its analogues were also found in the control of typhus body louse, and eradication of malaria in many countries by eliminating the mosquito vector.<sup>36</sup> By 1953, DDT alone was credited for saving an estimated 50 million lives, and with averting one billion cases of human disease, and is credited with eliminating malaria from the United States and Europe. It is suggested that because of this consequential impact on human health, DDT is the single most important factor in the world population explosion that occurred between 1950 and 1970.<sup>48</sup>

However, the properties that made these chemicals such effective insecticides were suspected as posing environmental hazards: they are slowly metabolized, lipid soluble, chemically stable, and environmentally persistent. In her 1962 book, *Silent Spring*,<sup>17</sup> Rachel Carson, a biologist with the US Fish and Wildlife Service, claimed that since organic chlorines are bioconcentrated and biomagnified up the food chain, this persistence could eventually lead to increases in cancer in the future, as well as having adverse effects on wildlife. The controversy arose when scientific opinions suggested that organic chlorine residues caused eggshell thinning and decreased reproductive success in predatory birds.<sup>47</sup> Although testing on domesticated birds,<sup>18,26,126,166</sup> when fed large amounts of DDT, showed little or no eggshell thinning, testing in mallard ducks did.<sup>42,43</sup> Hearings before the Environmental Protection Agency (EPA) regarding DDT registration focused also on the unproven fear of placing future generations at risk of cancer. This, and the demonstration of persistent DDT residues in all humans, even those living in areas where DDT was never utilized (eg, Native Alaskans) led to the severe restriction or total ban of DDT and most other organic chlorines in North America and Europe.<sup>36</sup> There is considerable evidence that since DDT was banned, less-effective replacements have placed many more millions at risk for malaria, and is at least in part responsible for millions of preventable deaths from this disease.<sup>100,123,124</sup> Dichlorodiphenyltrichloroethane is still considered a highly effective mosquito control agent with a low order of acute toxicity and is very inexpensive compared to newer replacement insecticides. For these reasons, the World Health Organization (WHO) exempted DDT from its list of banned pesticides, and it is still widely used for malaria control programs in many countries, because alternatives are more expensive and must be applied more frequently. Current use of DDT for indoor residual spraying is ongoing in endemic areas in Africa, and is considered safe and effective as a public health initiative to control malaria, even in areas with drug resistant strains.<sup>131</sup>

Organic chlorine pesticides are complex, cyclic polychlorinated hydrocarbons having molecular weights generally in the range of 300–550 Da. They are nonvolatile solids at room temperature. Most act as central nervous system stimulants.

The organic chlorine pesticides are grouped into 4 categories based on their chemical structures and similar toxicities: (a) DDT and related analogues; (b) cyclodienes (the related isomers aldrin, dieldrin, and endrin; and heptachlor, endosulfan) and related compounds (toxaphene, dieldrin) (c) hexachlorocyclohexane (still in clinical use as the pediculicide lindane) or “gamma-benzene hexachloride” (Table 111-1 and Fig. 111-1); and (d) mirex and chlordecone. These organic chlorine insecticide compounds differ substantially, both between and within groups, with respect to toxic doses, mechanism of action, skin absorption, fat storage, metabolism, and elimination.<sup>36</sup> The signs and symptoms of toxicity in humans, however, are remarkably similar within each group.

### Toxicokinetics

#### Absorption

All of the organic chlorine pesticides are well absorbed orally and by inhalation; transdermal absorption is variable. Absorption by any route is affected by the vehicle and the physical state (solid or liquid) of the pesticide. None of the organic chlorines are water-soluble, and are usually either dissolved in organic solvents or manufactured as powders for dusting.

DDT and its analogues methoxychlor, dicofol, and chlorobenzilate are very poorly absorbed transdermally, unless the pesticide is dissolved in a suitable hydrocarbon solvent.<sup>121</sup> Dichlorodiphenyltrichloroethane has limited volatility, so that air concentrations are usually low, and toxicity by the respiratory route is unlikely.

All of the cyclodienes have significant transdermal absorption rates and extent. Cutaneous absorption of dieldrin is approximately 50% that of the oral route. Oral absorption of the cyclodienes is also high, and significant poisonings have occurred when foodstuffs were contaminated with these pesticides.<sup>15,21</sup> Toxaphene is poorly absorbed through the skin in both acute and chronic exposures.<sup>136</sup>

Lindane is well absorbed after skin application, and in adults has a documented forearm skin absorption rate of 9.3% of a topically applied dose over 24 hours.<sup>57</sup> Anatomic sites vary in their absorptive capacities: axillary rates are 3.6 times faster, and scrotal skin absorption is 42 times faster than that of forearm skin.<sup>13,61,78,146</sup> Animal studies and case reports suggest that the young, the malnourished, and those who receive repeated topical doses are at risk for increased accumulation and toxicity.<sup>113</sup> Hot baths, occlusive clothing or bandages, the vehicle for the lindane, and a disturbed cutaneous integrity, such as eczema, fissures, and other violations of the skin, all enhance dermal penetration.<sup>145,146</sup> The state of hydration of the skin also affects the amounts absorbed, so that bathing just prior to application enhances absorption and increases the likelihood of toxicity.<sup>98,146</sup> Lindane is a stable compound, and volatilizes easily when heated. It was previously used extensively in home vaporizers, and toxicity was common via inhalation, and when vaporizer tablets were unintentionally ingested by children. Review of data when lindane was ingested therapeutically as an anthelmintic demonstrates that 40 mg/day for 3–14 days generally produced no adverse effects.<sup>36</sup>

Mirex and chlordecone are efficiently absorbed via skin, by inhalation, and orally.<sup>56</sup>

TABLE 111-1 Classification of Organic Chlorine Pesticides

Classes of Organic Chlorines	Specific Organic Chlorine	Current EPA Registration (US)	Acute Oral* Toxicity (Man)	Dermal Absorption	Lipid Solubility	Specific Characteristics
Hexachlorocyclohexanes	Lindane ( $\gamma$ isomer)	Topical scabicide; agricultural use canceled 2006	Moderate	High	Low	Seizures, CNS excitation; musty odor
DDT and analogues	DDT—Dichlorodiphenyltrichloroethane	Banned 1972	Slightly to moderately	Low	Highest	Tremors, CNS excitation; odorless
	Methoxychlor	Banned 2003	Slightly	Low	Moderate	Less toxic DDT substitute
	Dicofol	Residential use banned 1998; cotton, citrus, apple	Slightly	Low	Low	
	Chlorobenzilate	Banned 1983	Slightly	Low	Low	Much less environmental persistence than DDT
Cyclodienes and related compounds	Aldrin	Banned 1974	Highly	High	High	Rapidly metabolized to dieldrin; mild “chemical” odor
	Dieldrin	Banned 1974	Highly	High	High	Stereoisomer of endrin; early and late seizures; odorless
	Endrin	Banned 1974	Very Highly	High	None	Most toxic organic chlorine; rapid onset seizures, status epilepticus
	Chlordane	Banned 1988	Moderately	High	High	Early and late seizures occur
	Endosulfan	RED <sup>a</sup> 2002	Highly	High	Low	Strong sulfur odor
	Heptachlor	Restricted: fire ant control, soil treatment	Moderately	High	High	Toxic metabolite heptachlor epoxide; odor of camphor
	Isobenzan	Never Registered	Highly	Moderate	High	Also inhibits Mg <sup>2+</sup> -ATPase; mild “chemical” odor
	Dienochlor	Banned	NA	Low	Low	Toxic metabolite binds to glutathione
Toxaphene (polychlorinated camphene)	Banned 1982	Moderately to highly	Low	Low	Seizures; turpentine-like odor, often mixed with parathion	
Chlordecone and Mirex	Chlordecone	Banned 1977	Moderately	High	High	“Kepone shakes”; seizures not seen, structurally similar to mirex
	Mirex	Banned 1976	Slightly	High	High	(?) Converted to chlordecone, toxicity identical

<sup>a</sup>RED = Re-registration eligibility decision.

\*ACUTE ORAL TOXICITY: (from EPA- <https://www.epa.gov/pesticide-registration/label-review-manual> July 2014, accessed January 26, 2017) (see SC-9-1)

Category I LD<sub>50</sub> < 50 mg/kg Label Language: DANGER Skull and Crossbones Fatal if swallowed = very highly or highly toxic

Category II LD<sub>50</sub> > 50 mg/kg < 500 mg/kg WARNING No symbol May be fatal if swallowed = moderately toxic

Category III LD<sub>50</sub> > 500 mg/kg < 5,000 mg/kg CAUTION No symbol Harmful if swallowed = slightly toxic

Category IV LD<sub>50</sub> > 5,000 mg/kg CAUTION or no signal word No symbol No hazard statement required; registrant may choose to use Category III statement

{947 US Environmental Protection Agency Office of Pesticide Programs 2016}

## Distribution

All organic chlorines are lipophilic, a property that allows penetration to their sites of action in insects and mammals.<sup>31</sup> The fat-to-serum ratios at equilibrium are high, in the range of 660:1 for chlordane;<sup>65</sup> 220:1 for lindane;<sup>137</sup> and 150:1 for dieldrin.<sup>37</sup> Central nervous system redistribution of the organic chlorines to the blood and then to fat most likely accounts for the apparent rapid CNS recovery despite the persistent substantial total body burden. Not surprisingly, there is a direct correlation between the concentration of DDT or dieldrin in the brain of rats and the clinical signs produced after a single dose of the insecticide.<sup>36,39</sup>

## Metabolism

The high lipid solubility and very slow metabolic disposition of DDT, DDE (dichlorodiphenyl dichloroethylene, the primary metabolite of DDT), dieldrin, heptachlor, chlordane, mirex, and chlordecone causes significant adipose tissue storage and increasing body burdens in chronically exposed populations.<sup>56</sup> Organic chlorines that are rapidly metabolized and eliminated, such as endrin (an isomer of dieldrin), endosulfan, lindane, methoxychlor, dienochlor, chlorobenzilate, dicofol, and toxaphene tend to have less persistence in body tissues, despite being highly lipid soluble.<sup>121</sup>

Most organic chlorines are metabolized by the hepatic microsomal enzyme systems by dechlorination and oxidation, with subsequent conjugation. However, for some insecticides metabolism results in the production of a metabolite with more toxicity than the parent compound, such as heptachlor to heptachlor epoxide, chlordane to oxychlordane, and aldrin to dieldrin.

In animals, most organic chlorine pesticides are capable of inducing the hepatic microsomal enzyme systems.<sup>34,171</sup> Enzyme induction changes the biodegradation of the pesticide in rodents.<sup>151</sup> In certain animal models the acute toxicity of organic phosphorus compounds and carbamates is to be reduced by the administration of organic chlorines, presumably by induction of the hepatic microsomal metabolism of the organic phosphorus compound. This effect is ameliorated by administering the liver microsomal enzyme system inhibitor piperonyl butoxide.<sup>36,171</sup> However, induction of hepatic enzymes is not described in man, except in rare cases of massive exposure with concomitant neurologic findings.<sup>56,65</sup>

## Elimination

The half-lives of fat-stored compounds and poorly metabolized organic chlorines such as DDT and chlordecone are measured in months or years, compared to the elimination half-life of lindane, which is 21 hours in

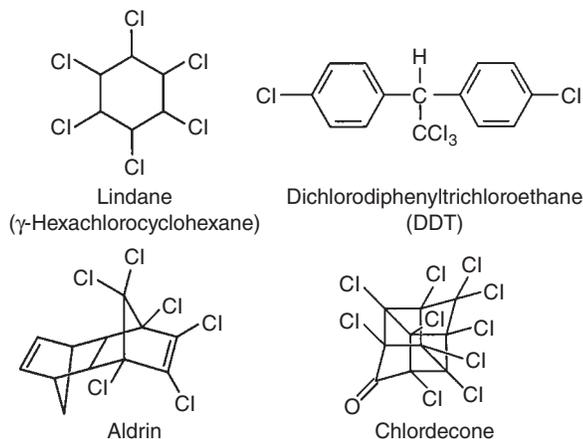

FIGURE 111-1. Structures of various organic chlorine pesticides.

adults.<sup>99</sup> The primary route of excretion of the organic chlorines is in the bile, but most also produce detectable urinary metabolites. However, as with other compounds excreted in bile, most of the organic chlorines, such as mirex and chlordecone, have significant enterohepatic or enteroenteric recirculation.<sup>11,33,56</sup> All of the lipophilic compounds are excreted in maternal milk.<sup>128</sup>

### Mechanisms of Toxicity

The same neurotoxic properties that make the organic chlorines lethal to the target insects make them potentially toxic to higher forms of life. The organic chlorines exert their most important effects in both the central and peripheral nervous systems. Electrophysiologic studies demonstrate that the organic chlorine insecticides affect the membranes of excitable cells by either interfering with repolarization, by prolonging depolarization (both are Na<sup>+</sup> channel effects), or by impairing the maintenance of the polarized state of the neuron (gamma-aminobutyric acid (GABA<sub>A</sub>) chloride ionophore effects). The end result is hyperexcitability of the nervous system and repetitive neuronal discharges with subsequent inhibition of further depolarization.<sup>48</sup>

The voltage-gated Na<sup>+</sup> channel is a common site of action for neurotoxins, both natural and synthetic. There are at least 10 separate binding sites on the Na<sup>+</sup> channel, including those for local anesthetics and anticonvulsants. Dichlorodiphenyltrichloroethane, as well as the pyrethroids (see below), bind at the same site on these channels (Fig. 111-2).

There are 2 primary gates in the Na<sup>+</sup> channel: the M gate and H gate. The extracellular entrance (the M gate) is voltage dependent, whereas the intracellular entrance (H gate) operates due to conformational changes in protein structure. Depolarization opens the voltage-dependent M gate, rapid influx of Na<sup>+</sup> then causes conformational change and closes the H gate, inactivating Na<sup>+</sup> influx. When repolarization restores polarity, the M gate closes and the H gate then re-opens, and the Na<sup>+</sup> channel returns to its resting state, ready to be activated again.

Dichlorodiphenyltrichloroethane and its analogues preferentially bind to the Na<sup>+</sup> channel when the M gate is open, allowing prolonged inward sodium conductance, repetitive action potentials, and extended tail currents. This occurs primarily in the peripheral nervous system with DDT and analogues, and prolonged axonal firing and repetitive stimulus eventually leads to nerve paralysis and death in target insects, whose Na<sup>+</sup> channels have much greater affinity for these insecticides than those in mammals.<sup>35,41,104,105,107,147</sup> In test animals, these Na<sup>+</sup> channel effects are manifested as exaggerated responses such as abnormal startle reflexes and tremors after low-level stimuli.<sup>73,158</sup> Further evidence of binding to the Na<sup>+</sup> channel and prolonging its open state as being the primary mechanism of action is the amelioration of DDT-induced tremor by pretreatment with phenytoin, a sodium channel blocker that acts by reducing the ability of voltage-dependent Na<sup>+</sup> channels to recover from inactivation.<sup>73,159</sup> Dichlorodiphenyltrichloroethane also inhibits Ca<sup>2+</sup>-ATPase,

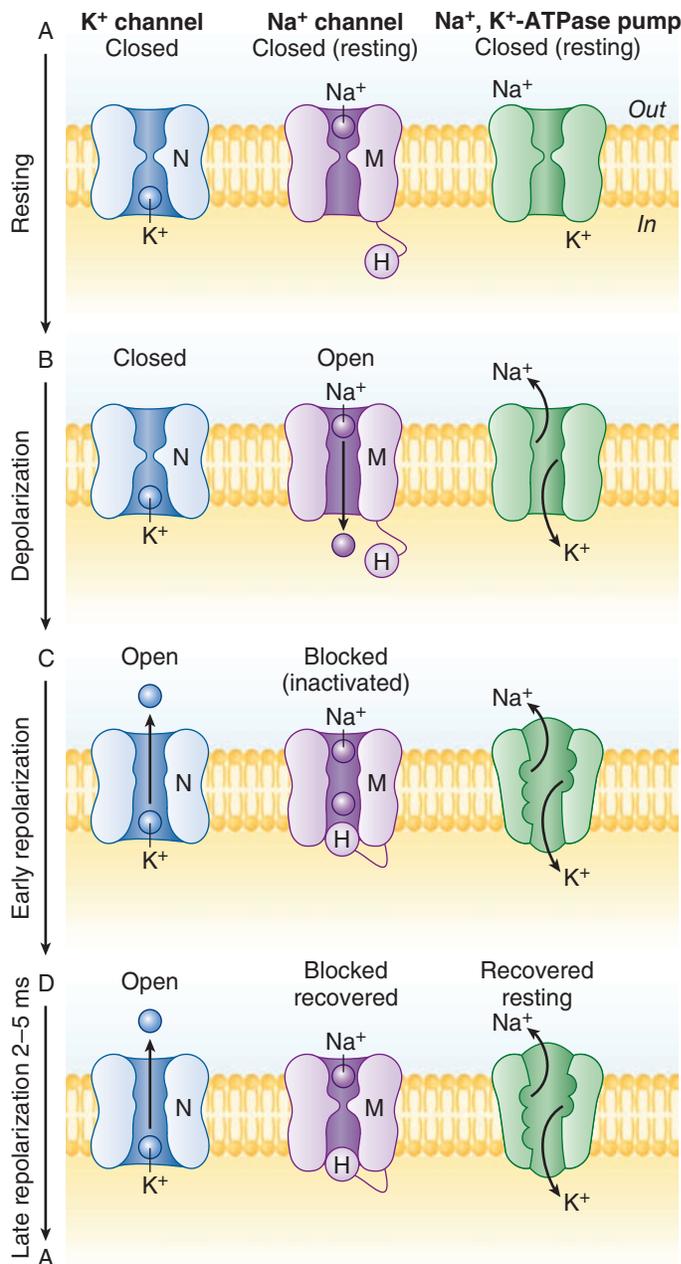

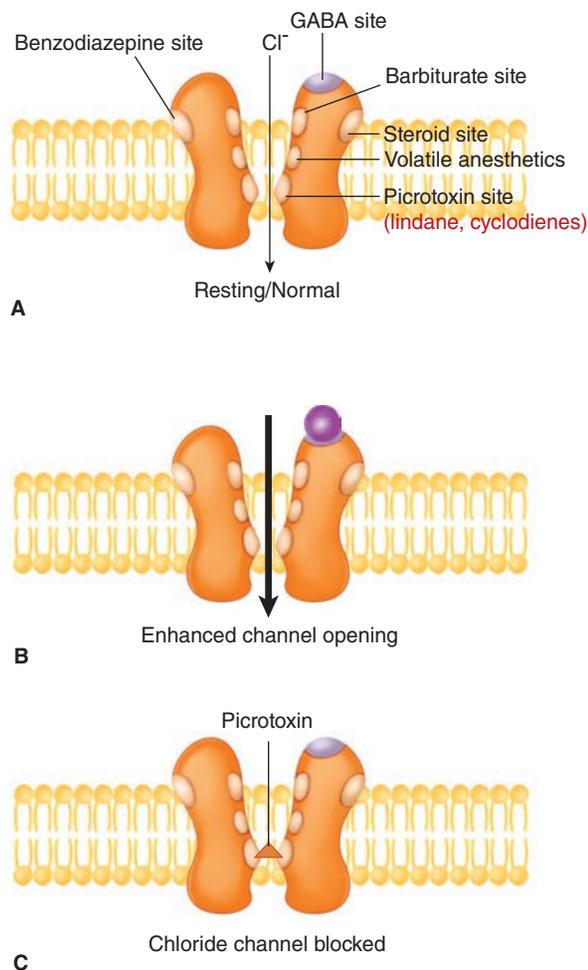

FIGURE 111-2. Sodium channel. Schematic drawing of voltage-gated neuronal Na<sup>+</sup> channel: demonstrating 4 phases of activation: (1) Closed, resting state: M gate closed, H gate open, cell is at normal polarized state, ready for activation. (2) Stimulus resulting in depolarization causes voltage-dependent M gate to open, allowing rapid Na<sup>+</sup> flow intracellularly, depolarizing the cell (H gate is open). (3) Inactivated (blocked) state: M gate still open, but depolarization causes a conformational change in the channel, and causes H gate to rapidly close (voltage independent), inactivating intracellular Na<sup>+</sup> flow. K<sup>+</sup> channels open to assist in repolarization (4) As repolarization is accomplished by Na<sup>+</sup>, K<sup>+</sup>-ATPase and K<sup>+</sup> channels, the voltage-dependent M gate closes again, conformational change reverts back to a recovered/resting position, and the H gate reopens. When the K<sup>+</sup> channel and Na<sup>+</sup>, K<sup>+</sup>-ATPase have completed repolarization the resting state (1) will be restored.

located on the external cell membrane. Inhibition of this pump likely contributes to membrane instability and repetitive discharges due to a reduction in external calcium concentrations.<sup>35</sup>

The cyclodienes and lindane act as GABA antagonists. They inhibit GABA binding at the GABA<sub>A</sub>-receptor-chloride ionophore complex in the CNS, by interacting at the picrotoxin binding site.<sup>102</sup> In fact, the degree of binding at this site correlates well with the amount of Cl<sup>-</sup> influx inhibited and the

**FIGURE 111-3.** Chloride channel. (A) Under resting conditions, a tonic influx of chloride maintains the nerve cell in a polarized state. (B) Binding of GABA or an indirect-acting GABA agonist (benzodiazepine, barbiturate, volatile anesthetic) opens the chloride channel. The subsequent chloride influx hyperpolarizes the cell membrane, making the neuron less likely to propagate an action potential in response to a stimulus. (C) GABA antagonists, such as picrotoxin, block the chloride channel, reducing chloride influx. The resulting decreased membrane polarity causes the neuron to become hyperexcitable to even those stimuli that are normally subthreshold in nature (Chap. 13).

relative neurotoxicity of each insecticide (Figs. 13-9, 13-10, and 111-3).<sup>8,64</sup> Indeed, development of cyclodiene resistance seems to be related to alterations of the GABA<sub>A</sub>-receptor-chloride ionophore complex in these affected insects.<sup>9,105</sup> This also explains the efficacy of GABA agonists, such as benzodiazepines and phenobarbital, in treating the seizures and neurotoxicity of the cyclodienes<sup>70</sup> and lindane.<sup>175</sup> Toxaphene also inhibits GABA binding at the GABA<sub>A</sub> receptor-chloride ionophore complex.<sup>136</sup>

The mechanisms of action of mirex and chlordane are not as well understood. They inhibit Na<sup>+</sup>,K<sup>+</sup>-ATPase, and Ca<sup>2+</sup>-ATPase. However, lindane, DDT, and the cyclodienes also inhibit these enzymes yet produce very different symptoms of toxic effects, suggesting that these mechanisms aren't responsible for the clinical manifestations that occur in mirex and chlordane poisoning. Phenytoin and serotonin agonists exacerbate the prominent tremor that occurs with chlordane intoxication, but conversely attenuate the tremors in DDT poisoning, which further supports a different mechanism than the Na<sup>+</sup> channel effects of DDT.<sup>48</sup> Mirex and chlordane are poor inhibitors of GABA binding at the GABA<sub>A</sub>-receptor-chloride ionophore complex; therefore, their mechanism of action is likely not at this site,<sup>56</sup> and seizures are not described with mirex or chlordane. Organic chlorines predispose test animals to cardiac dysrhythmias,<sup>121</sup> presumably via myocardial sensitization, similar to the chlorinated hydrocarbon solvents (Chaps. 15 and 105).

## Drug Interactions

There are theoretical consequences of hepatic enzyme induction, such as enhanced metabolism of therapeutic drugs and/or reduced efficacy. Dysfunctional uterine bleeding was attributed to enhanced oral contraceptive metabolism induced by chlordane, but this report involved a single patient with weeks of excessive exposure to chlordane.<sup>65</sup> A large group of workers poisoned by chlordane over many months had some increased hepatic microsomal activity, but no evidence of drug interactions or adverse clinical effects.<sup>56</sup> Thus, induction of the hepatic microsomal enzyme system by organic chlorines probably occurs only with extended, substantial exposure.<sup>121</sup> There are no definitive reports of enhanced metabolism of therapeutic drugs or adverse reactions because of microsomal enzyme induction in man.

## Clinical Manifestations

### Acute Exposure

In sufficient doses, organic chlorines lower the seizure threshold (DDT and related Na<sup>+</sup>-channel agents) or remove inhibitory influences (antagonism to GABA effects) and produce peripheral and central nervous system stimulation, with resultant tremors, seizures, respiratory failure, and death.<sup>35,70</sup> After DDT exposure, tremor is often the only initial manifestation, except following extensive exposure. Nausea, vomiting, hyperesthesia of the mouth and face, paresthesias of face, tongue, and extremities, headache, dizziness, myoclonus, leg weakness, agitation, and confusion can follow after large exposures. Seizures only occur after very high exposures, usually following large intentional ingestions.<sup>48,70</sup> Dichlorodiphenyltrichloroethane has a relatively low order of acute toxicity, and high doses of DDT (>10 mg/kg) are usually necessary to produce effects.<sup>70</sup> However, with lindane, the cyclodienes, and toxaphene, there typically are no prodromal signs or symptoms, and more often than not, the first manifestation of toxicity is a generalized seizure.<sup>35,70</sup> If seizures develop, they often occur within 1 to 2 hours of ingestion when the stomach is empty, but delays of up to 5 to 6 hours are reported when the ingestion follows a substantial meal.<sup>70</sup>

Seizures related to dermal application of 1% lindane for treatment of ectoparasitic diseases are reported following a single inappropriate application<sup>92,113,155</sup> or, more commonly, after repetitive prolonged exposures.<sup>89,118</sup> The time from application to seizure onset varies from hours to days. The seizures are often self-limited, but recurrent seizures and even status epilepticus are reported. Analysis of an epidemic of lindane poisoning related to the unintentional substitution of lindane powder for sugar used in coffee demonstrated a delay of 20 minutes to 3 hours before the onset of nausea, vomiting, dizziness, facial pallor, severe cyanosis of the face and extremities, collapse, convulsions, and hyperthermia. Affected patients ingested an average of 86 mg/kg of lindane in a single dose.<sup>36</sup>

The cyclodienes are also notable for their propensity to cause seizures that often recur for several days following an acute exposure. If the seizures are brief and hypoxia has not occurred, recovery is usually complete. Electroencephalographic (EEG) abnormalities were recorded before, during, and following seizures showing that the cyclodienes affected seizure threshold/activity.<sup>87</sup> Hyperthermia secondary to central mechanisms, increased muscle activity, and/or aspiration pneumonia is common.<sup>48</sup>

Status epilepticus is a common occurrence in patients with intentional endosulfan ingestions. In 25 cases of endosulfan self-poisonings in Nepal, more than half of the patients developed refractory status epilepticus, and 8 died.<sup>94</sup>

The ingestion of combinations of xenobiotics has resulted in significantly increased toxicity, as demonstrated with DDT and lindane, and is probably the result of synergy.<sup>70</sup>

### Lindane: Specific Risks

Patients are at risk for developing central nervous system toxicity from improper topical therapeutic use, such as excessive amounts used or applications, or after baths or under occlusive dressings; young children (<2 years) and the elderly appear to be at greatest risk. Toxicity also occurs after unintentional oral ingestion of topical preparations.<sup>106</sup>

Despite the availability of safer and equally or more effective treatments such as permethrin, lindane is still used because of its lower cost than permethrin and generally good safety profile, when used according to directions. However, less is being used<sup>58</sup> now that permethrin products are available in less-expensive generic forms and the cost advantage of lindane is gone.

An evaluation of published English-language case reports and those submitted to the US Food and Drug Administration (FDA) divided toxicity into those associated with concentrations of lindane greater than or less than 1%.<sup>89</sup> Only 6 of 26 cases could be considered probably related to 1% lindane;<sup>3</sup> 6 of these cases were the result of ingestion or inappropriate skin application.<sup>3</sup> However, a comprehensive review of all published adverse events associated with topical lindane (67 cases) showed that although most of the serious adverse reactions (16 deaths, 11 seizures) occurred following ingestions or excessive use, labeled use accounted for 11 seizures and 4 deaths.<sup>106</sup> In 1995, the FDA added a black-box warning to lindane emphasizing its potential for neurotoxicity, and it was relegated to second-line therapy for ectoparasitic skin infections.<sup>162</sup> In 2013, the FDA published a Postmarket Drug Safety Information for Patients and Providers, which restricted the sale of lindane and required extensive warning labels about adverse events even with labeled use.<sup>58</sup> The sale of lindane-containing products for use in humans was banned in California in 2004 because of its toxicity and environmental concerns,<sup>15</sup> and other states are considering it. In 2009, the American Academy of Pediatrics (AAP) recommended stopping the use of lindane for the treatment of lice or scabies, even as second-line therapy.

### Chronic Exposure

Chlordecone (Kepone), unlike the other organic chlorines, produces an insidious picture of chronic toxicity related to its extremely long persistence in the body. Because of poor industrial hygiene practices in a make-shift chlordecone factory in Hopewell, Virginia, 133 workers were heavily exposed for 17 months in 1974–1975. They developed a clinical syndrome that became known as the “Hopewell epidemic,” which consisted of a prominent tremor of the hands, a fine tremor of the head, and trembling of the entire body, known as the “Kepone Shakes.” Other findings included weakness, opsoclonus (rapid, irregular, dysrhythmic ocular movements), ataxia, altered mental status, rash, weight loss, and elevated liver enzymes. Idiopathic intracranial hypertension, oligospermia, and decreased sperm motility were also found in some of these workers. Severely affected workers even exhibited an exaggerated startle response, remarkably similar to that seen in animal studies. The exposures were so intense that some workers went home covered with chlordecone, and several workers’ wives developed neurologic symptoms, presumably from exposures while laundering their husbands’ work clothes.<sup>33,56</sup>

There is much concern in environmental health centers on persistent organic chemicals, the organic chlorine residues and PCBs being prime examples. However, because many of these persistent pollutants have been outlawed in many processes and countries, human burden appears to be decreasing.<sup>96</sup>

### DDT and Breast Cancer

Dichlorodiphenyltrichloroethane and other organic chlorine insecticides have estrogenic effects.<sup>38,148</sup> Because breast cancer incidence rates in the United States have steadily climbed 1% per year since the 1940s, coinciding with the worldwide use of DDT, it is postulated that women who have higher concentrations of estrogenic organic chlorine compounds (eg, DDT, polychlorinated biphenyls [PCBs]) are at risk for developing breast cancer.<sup>132–134,174</sup>

Several small case–control studies of women with breast cancer showed that women with the disease had higher average body burdens of DDT, DDE, and PCBs than their age-matched controls. These studies implicated the organic chlorines as a possible cause of human breast cancer. However, subsequent larger studies have shown no increased risk of breast cancer because of exposure to organic chlorines,<sup>16</sup> and that currently accepted hereditary and lifestyle risk factors were present in the patients with cancer.<sup>76,90,132–134</sup> In fact, other natural dietary estrogens such

as flavonoids, lignans, sterols, and fungal metabolites are present in the human diet, and these xenobiotics have much higher estrogenic potency; the organic chlorine contribution is probably minimal by comparison.<sup>63</sup> One interesting reported suggests age at first exposure, that is, age less than 14 years (prior to menarche), as having an association with later breast cancer.<sup>32</sup> However, most case–control studies do not supported an association between DDT and breast cancer.<sup>14,66,77,80,142,143</sup> A meta-analysis of 22 studies found strong evidence to discard the putative relationship between *p,p'*-DDE concentrations and breast cancer risk;<sup>95</sup> 2 more recent meta-analyses also confirmed the lack of any increased risk for breast cancer associated with DDT or DDE.<sup>79,111</sup>

### Diagnostic Information

The history of exposure to an organic chlorine pesticide is the most critical piece of information, because exposure is otherwise rare. By law, the package label of these products must list the ingredients, the concentrations, and the vehicle. The EPA-registered use of the insecticide will be helpful in determining which organic chlorine is involved. The presence of an unusual odor in the mouth, in the vomitus, or on the skin is helpful. Toxaphene, a chlorinated pinene, has a mild turpentine-like odor, and endosulfan has a unique “rotten egg” sulfur odor (Table 111–1). Following ingestion, an abdominal radiograph often reveals the presence of a radiopaque chlorinated pesticide, because chlorine increases the radiopacity of the xenobiotics (Chap. 8). A large number of other xenobiotics lead to seizures as the first manifestation of toxicity, and must be in the differential of an unknown exposure (Chaps. 13 and 22).

### Laboratory Testing

Gas chromatography can detect organic chlorine pesticides in serum, adipose tissue, and urine.<sup>37,76</sup> If confirmation is necessary for purposes of documentation of source, the concentrations of organic chlorines can be measured. If the patient’s history and toxidrome are obvious, then laboratory evaluation is unnecessary, as this determination will not alter the course of management, and these blood tests are not available on an emergent basis. At present, there are no data correlating health effects and serum or tissue concentrations. Routine surveillance of serum concentrations in the occupationally exposed is not currently performed.<sup>37</sup>

Most humans studied have measurable concentrations of DDT in adipose tissue. In a study of a community with a very large exposure to DDT, serum DDT concentrations increased proportionally with age. These increasing concentrations were not associated with any apparent adverse health effects, but there was an association with increasing concentrations of the liver enzyme gamma-glutamyltransferase (GGT), although significant hepatotoxicity did not occur. The CDC’s *Fourth National Report on Human Exposure to Environmental Chemicals* demonstrated the presence of numerous organic chlorine pesticide residues in the lipid fraction of serum of US residents. These concentrations tend to increase with patient age, consistent with the bio-accumulation and fat-storing properties of the chemicals.<sup>19,24</sup> More recently, studies of occupationally exposed pesticide applicators and persons living in targeted regions confirmed higher serum concentrations over those not exposed, but no ill health effects are documented.<sup>131</sup>

Serum lindane concentrations can be used to document exposure, and clinical signs and symptoms of toxicity correlated with average blood concentrations.<sup>33</sup> Lindane-exposed workers with chronic neurologic symptoms showed an average blood lindane concentration of 0.02 mg/L.<sup>3,70</sup> A limited series of patients with acute lindane ingestion suggests that a serum concentration of 0.12 mg/L correlates with sedation, and that 0.20 mg/L is associated with seizures and coma.<sup>3</sup> After cutaneous application, lindane concentrations in the CNS are 3 to 12 times higher than serum concentrations.<sup>40,146</sup> None of these tests are available in the acute care setting, and cannot aid in diagnosis or management.

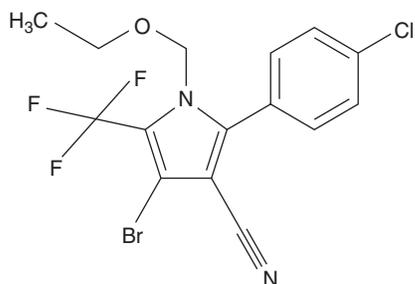

### Management

As with any patient who presents with an altered mental status, dextrose and thiamine in an adult should be administered as clinically indicated. Skin

decontamination is essential, and clothing should be removed and placed in a plastic bag and disposed of appropriately as a biohazardous waste, and the skin washed with soap and water. Health care providers should be protected with rubber gloves and aprons. Because these pesticides are almost invariably liquids, a nasogastric tube is reasonable for suction and lavage gastric contents, if the ingestion was recent (Chap. 5). Because many mixtures contain petroleum distillates as their solvent vehicles, the benefit of AC is limited. Standard seizure management and control with benzodiazepines and barbiturates is recommended as needed, and additional medications such as propofol may also be necessary, due to the risk of recurrent seizures and status epilepticus. The use of cholestyramine, a nonabsorbable bile acid-binding anion exchange resin that was successfully used in chlordecone poisonings in humans (see below), showed a statistically significant benefit on decreasing seizure incidence and mortality in a murine experimental model.<sup>85</sup> Oil-based cathartics should never be used, as they may facilitate absorption. There is some evidence that sucrose polyester (ie, olestra, a nonabsorbed synthetic dietary oil substitute) increases excretion of a wide variety of fat-soluble organic chlorine chemicals, especially those undergoing enterohepatic recirculation, by fecal elimination.<sup>81,101</sup> This effect was demonstrated in dioxin-poisoned patients who were administered olestra in fat-free potato chips,<sup>67</sup> and was employed in treating Ukrainian president Viktor Yushchenko, among other therapeutic regimens.<sup>149</sup> Sucrose polyester is a reasonable inexpensive and more palatable alternative to cholestyramine to increase excretion in patients with chronic organic chlorine toxicity.

Cholestyramine or sucrose polyester resin is recommended for all patients symptomatic from chlordecone, and possibly other organic chlorines. Chlordecone undergoes both enterohepatic and enteroenteric recirculation, which can be interrupted by cholestyramine at a dosage of 16 g/day. Cholestyramine increased the fecal elimination of chlordecone 3- to 18-fold in industrial workers exposed during the Hopewell epidemic, resulting in clinical improvement.<sup>33</sup> Sucrose polyester is a reasonable adjunct for enhancing excretion.

### Chlorfenapyr

Chlorfenapyr is a member of a newer class of pesticides known as pyrroles.<sup>75</sup> It is not typically grouped with the organochlorines, even though it is an organic compound containing chlorine, but is structurally unrelated to the other OCs. The mechanism of action of chlorfenapyr is different from the typical Na<sup>+</sup>-channel or GABA<sub>A</sub> antagonism mechanisms of the OC pesticides covered in this chapter. Chlorfenapyr itself is a pro-insecticide, and requires CYP enzyme metabolic activation by removal of the *N*-ethoxymethyl group, producing the free pyrrole (designated CL 303268) which is a lipophilic weak acid with very strong insecticidal activity. This pyrrole interferes with ATP production by uncoupling mitochondrial oxidative phosphorylation.<sup>75</sup> Acute ingestions have a high case-fatality ratio (8 of 24 in a 2004 case series in Japan).<sup>49</sup> A unique, consistent, yet disturbing feature of these poisonings is a long latency between ingestion and onset of toxic effects. Several case reports describe long relatively asymptomatic intervals after intentional suicidal ingestions lasting several days to a week or two before the onset of nausea, fever, and diaphoresis, which is usually followed by CNS manifestations (often with leukoencephalopathy on magnetic resonance imaging) and complete cardiovascular collapse and

death.<sup>6,82,157</sup> Some cases had relatively mild clinical effects of intermittent fever, thirst, and diaphoresis for a few days as the only abnormality prior to rapid collapse and death.<sup>30</sup> An agricultural worker died 7 days after spraying chlorfenapyr without wearing a respirator or personal protective garments; his presentation with fever, diaphoresis, and thirst for a week after exposure prior to collapse was remarkably similar to the suicidal ingestion cases.<sup>74</sup>

In insects, the microsomal enzyme inhibitor piperonyl butoxide antagonizes the insecticidal activity of chlorfenapyr by inhibiting the conversion into its active pyrrole metabolite. It is unknown whether CYP inhibitors would be useful in preventing conversion in human exposures, but to date GI decontamination and hemodialysis were not effective.

### PYRETHRINS AND PYRETHROIDS

The natural pyrethrins are the active extracts from the flower *Chrysanthemum cinerariaefolium*. These insecticides are important historically, having been used in China since the first century A.D.,<sup>36</sup> and developed for commercial application by the 1800s. They are produced by organic solvent extraction from ground *Chrysanthemum* flowers. The resulting concentrates have greater than 90% purity. Pyrethrum, the first pyrethrin identified, consists of 6 esters derived from chrysanthemic acid and pyrethric acid. These insecticides are highly effective contact poisons, and their lipophilic nature allows them to readily penetrate insect chitin (exoskeleton) and paralyze the nervous system through interactions at the voltage-dependent Na<sup>+</sup> channel.<sup>31,41,103,121,147</sup> When applied properly, they have essentially no systemic mammalian toxicity because of their rapid hydrolysis. Pyrethrins break down rapidly in light and in water, and therefore have no environmental persistence or bioaccumulation. This fact makes the pyrethrins extremely safe after human exposures, but unsuitable for commercial agriculture, because the constant reapplication would be cost prohibitive.

The pyrethroids are the synthetic derivatives of the natural pyrethrins<sup>144</sup> (Table 111-2 and Fig. 111-4). They were developed in an effort to produce more environmentally stable products for use in agriculture. Originally, the pyrethroids were divided into 2 groups based on the toxic syndromes they elicited in test animals. The T syndrome (for tremor seen in rats) was produced by intravenous administration of pyrethrin and most (15 of 18) of the pyrethroids that did not contain a cyano group at the central ester linkage (see below). The CS syndrome (for choreoathetosis and salivation) was produced by 12 of the 17 pyrethroids that had an  $\alpha$ -cyano group at the ester linkage. The original studies delineating the T or CS method of classification did not test several new currently registered pyrethroid pesticides, and the testing methods involved intravenous or intracerebral administration, which are not relevant to human exposures.<sup>144</sup>

The predominant classification scheme used today is based on the structure of the pyrethroid, their clinical manifestations in mammalian poisoning, its actions on insect nerve preparations, and its insecticidal activity. Type I pyrethroids have a simple ester bond at the central linkage without a cyano group. Commonly used type I pyrethroids include permethrin, allethrin, tetramethrin, and phenothrin. The type II pyrethroids have a cyano group at the carbon of this ester linkage. Type II pyrethroids in common use include cypermethrin, deltamethrin, fenpropathrin, fluralinate, and fenvalerate. The cyano group greatly enhances neurotoxicity of the type II pyrethroids in both mammals and insects, and type II pyrethroids tend to produce the CS syndrome in test animals and are generally considered more potent and toxic than the type I pyrethroids (Fig. 111-4).<sup>47,97,120,121,144</sup>

The development of the pyrethroids can also be divided into “generations,” based on efficacy and dates of introduction.<sup>168</sup> The first generation began in 1949, with the development of allethrin. The second generation began in 1965, with the introduction of tetramethrin. The major advance of the second generation was a dramatic increase in potency compared with the pyrethrins. The third generation, introduced in the 1970s, including fenvalerate and permethrin, were the first pyrethroids with practical agricultural use. They were more potent, and more environmentally stable, with efficacious crop residues lasting 4 to 7 days. The current fourth generation

TABLE 111–2 Synthetic Pyrethroids in Common Use

Pyrethroid Class	Generic Name	Generation of Pyrethroid, Dates Introduced (If Available)
Type I	Allethrin	1st generation; first synthetic pyrethroid, 1949
	Bioallethrin	2nd generation, 1969; trans isomer of allethrin
	Dimethrin	Not available
	Phenothrin	2nd generation, 1973
	Resmethrin	2nd generation, 1967; 20× strength of pyrethrum
	Bioresmethrin	2nd generation, 1967; 50× strength of pyrethrum, isomer of resmethrin
	Tetramethrin	2nd generation, 1965
	Permethrin	3rd generation, 1972; effective topical scabicide and miticide, low toxicity
	Bifenthrin	4th generation

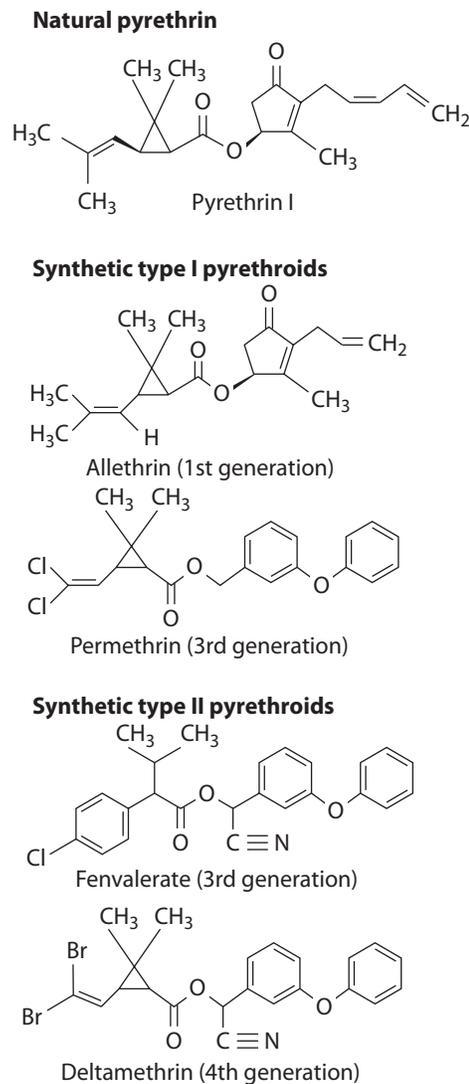

FIGURE 111–4. Representative structures of pyrethrin and pyrethroids.

includes mostly type II pyrethroids, which have greater insecticidal activity, are photostable, do not undergo photolysis “splitting” in sunlight, possess minimal volatility, and provide extended residual effectiveness for up to 10 days under optimum conditions.<sup>97,168</sup>

More than 1,000 pyrethroids have been synthesized, of which 16 to 20 are in widespread use today.<sup>12,36</sup> Pyrethrins and pyrethroids are found in more than 2,000 commercially available products. These insecticides have a rapid paralytic effect (“knock down”) on insects.

Most mammalian species are relatively resistant, because the pyrethrins can be rapidly detoxified by ester cleavage and oxidation.<sup>112</sup> Toxicity of the pyrethrins and pyrethroids is enhanced in insects by combination with microsomal enzyme inhibitors such as piperonyl butoxide (a synthetic analogue of sesamin, the methylenedioxyphenyl component of sesame oil) or *N*-octyl bicycloheptene dicarboximide.<sup>7,115</sup>

Permethrin, a type I pyrethroid, is used medicinally for topical treatment of ectoparasitic conditions in humans, and impregnated in clothing and mosquito netting for its insect repellent properties. It has an excellent safety profile, with approximately 2% or less absorbed systemically through the skin.<sup>98</sup> Comprehensive reviews have confirmed that 5% permethrin is the drug of choice for scabies treatment, with the best efficacy versus safety profile of topical treatments for scabies and lice.<sup>129,167</sup>

West Nile virus was first identified in the United States in 1999 and rapidly spread to most US states by 2006. Outbreaks of encephalitis caused by West Nile virus (WNV) have occurred in the late summer and early autumn

months in the United States since 1999. Although birds are the reservoirs for WNV, transmission to humans occurs via mosquito bites, and hence many states and municipalities have increased their aerial spraying in an effort to control mosquito vectors of this disease. Most spraying programs use pyrethroid insecticides because of their favorable safety profile, and their efficacy against the adult mosquito. More recently, the CDC and Prevention has recommended several pyrethroids specifically for aerial spraying and indoor residual spraying for mosquito control in endemic Zika areas of the United States.<sup>160</sup> These widespread spraying programs have increased the potential for human exposures to these xenobiotics. A Centers for Disease Control and Prevention study of pyrethroid spraying for WNV did not reveal an increase in detectable pyrethroid metabolites in the general public living in the sprayed areas.<sup>5</sup> Another study of asthma surveillance showed no increases in emergency department visits because of asthma-related conditions for the periods after pyrethroid spraying.<sup>83</sup>

## Toxicokinetics

### Absorption

Pyrethrins are well absorbed orally and via inhalation, but skin absorption is poor. Piperonyl butoxide is also well absorbed orally, but likewise has poor dermal penetration.<sup>115</sup> The oral toxicity of pyrethrins in mammals is extremely low, because they are so readily hydrolyzed into inactive compounds. Their dermal toxicity is even lower, owing to their slow penetration and rapid metabolism.<sup>48,112</sup>

The pyrethroids are more stable than the natural pyrethrins, and significant systemic toxicity occurs following large ingestions.<sup>71</sup> An average of 35% (range 27%–57%) of orally administered cypermethrin is absorbed in human volunteers.<sup>174</sup> Most exposures are from dermal absorption, the rate of which varies depending on the solvent vehicle. In the same volunteer study noted above, a mean of 1.2% (range 0.85%–1.8%) of dermally applied cypermethrin in soybean oil vehicle was absorbed systemically.<sup>174</sup> Intradermal metabolism of pyrethroids is documented in test animals, and likely further limits systemic absorption.<sup>12</sup> Direct absorption of pyrethroids through the skin to the peripheral sensory nerves probably accounts for the facial paresthesias that occur in these cases, as symptoms are prominent in pesticide sprayers in areas of direct contact.<sup>28,91</sup> Absorption probably also occurs through the oral mucosa, as noted by a large study of Chinese insecticide sprayers who frequently used their mouths to clear clogged spray nozzles. The pyrethroids are also absorbed via inhalation; however, in these same sprayers, inhalation was not found to be a clinically significant route of exposure as analyzed by breathing zone assays.<sup>28</sup> The pyrethroids are not volatile compounds, so inhalation is always due to powders or sprayed mists, and mucosal and pulmonary toxicity can also be due to hydrocarbon solvent vehicles. Systemic absorption and resultant effects can follow massive exposures, such as occurs in enclosed spraying or other extreme conditions.

### Distribution

The pyrethroids and pyrethrins are lipophilic and as such are rapidly distributed to the central nervous system. Because they are rapidly metabolized, there is no storage or bioaccumulation, which limits chronic toxicity.<sup>47,48</sup>

### Metabolism

Natural pyrethrins are readily metabolized by mammalian microsomal enzymes, and hence are essentially nontoxic to humans. They can induce CYP3A and CYP2B enzymes *in vitro* in human cultured hepatocytes, but clinical significance is doubtful.<sup>114</sup>

The synthetic pyrethroids are readily metabolized in animals and man by hydrolases and the CYP microsomal system. The metabolites are of lower toxicity than the parent compounds.<sup>144</sup> Piperonyl butoxide, a CYP enzyme inhibitor in insects, enhances the potency of pyrethrins and pyrethroids 10- to 300-fold to target insects. It is often added to insecticide preparations to ensure lethality, as the initial “knock down” effect of a pyrethroid alone is not always lethal to the insect.<sup>47</sup> Testing of piperonyl butoxide on antipyrine metabolism (measure of CYP enzyme function) in humans at a dose exceeding 50 times that received in all-day confined space pesticide spraying revealed no effect on this enzyme system.<sup>115</sup>

### Elimination

There is no evidence that the pyrethroids undergo enterohepatic recirculation. Deltamethrin disappeared from the urine of exposed workers within 12 hours, and fenvalerate disappeared within 24 hours.<sup>28</sup> Parent compounds, and metabolites of the pyrethroids, are found in the urine.<sup>121</sup> The pyrethroids have several common metabolites, some of which are also environmental breakdown products, that can be assayed.<sup>93,152</sup> Detection of these metabolites in the urine may be from a subject's exposure to the parent compound or from its metabolite in the environment.

### Pathophysiology

Like DDT, pyrethrins and pyrethroids prolong the activation of the voltage-dependent Na<sup>+</sup> channel by binding to it in the open state, causing a prolonged depolarization, as evidenced by an extended tail current seen with squid axon voltage clamp experiments.<sup>104,105</sup> Although DDT affects primarily the insect peripheral nervous system (PNS), the pyrethroids affect the insect CNS as well as the PNS.<sup>41</sup> Because DDT and pyrethrin/pyrethroids bind to the same site on insect Na<sup>+</sup> channels, resistance to one class can often cause cross-resistance to the other class.<sup>107</sup> The voltage-sensitive Na<sup>+</sup>-channel binding is responsible for the insecticidal activity and the toxicity of the pyrethroids to nontarget species. Natural pyrethrins and type I synthetic pyrethroids induce repetitive or “burst discharges” following a single stimulus, because they hold

the Na<sup>+</sup> channel in its open state. The actual amplitude of the tail current is determined by the concentration of the pyrethroids, regardless of type. Type II pyrethroids cause the Na<sup>+</sup> channel to remain open longer and allow a more prolonged period of depolarization of the resting membrane potential, causing a longer duration of the tail current, and eventual paralysis due to neurotransmitter depletion.<sup>147,165</sup> Type II pyrethroids are thus more potent, and lead to significant after-potentials and eventual nerve conduction block. The mammalian voltage-dependent Na<sup>+</sup> channel, unlike the insect, has many isoforms, which helps explain the relative resistance in mammalian species (>1,000-fold less susceptible). Different pyrethroids have varied effects on these mammalian Na<sup>+</sup> channels, and the effects are not additive, and in fact may be antagonistic.

Pyrethroids also have activity at certain isoforms of the voltage-sensitive Ca<sup>2+</sup> channel, which would explain the neurotransmitter release that occurs in pyrethroid intoxication. Additionally, pyrethroids block voltage-sensitive Cl<sup>-</sup> channels in test animals, producing the salivation as part of the CS syndrome. These effects contribute to enhanced CNS toxicity,<sup>144</sup> and is likely responsible for the choreoathetosis that occurs in animal models of severe type II poisonings.<sup>119</sup> Some studies show some interference of the type II pyrethroids with the GABA<sub>A</sub>-mediated inhibitory Cl<sup>-</sup> channels in high concentrations.<sup>31,103</sup> Antagonism of the GABA<sub>A</sub> Cl<sup>-</sup> channels likely has a significant role in human pyrethroid exposures, and probably contributes to the seizures following severe poisoning by type II pyrethroids.<sup>103,119</sup> The pyrethroids also have activity at the peripheral benzodiazepine receptor, as evidenced by decreased salivation in test animals when this receptor was blocked.<sup>117</sup> The clinical significance of this in humans is currently unknown.

Natural pyrethrins and type I pyrethroids have a negative temperature coefficient, similar to DDT, and are more selectively toxic to non-warm-blooded target species, but also less effective at warmer environmental temperatures. Type II pyrethroids have a positive temperature coefficient, which makes them more insecticidal at higher ambient temperatures and thus more useful in agricultural applications.<sup>103,168</sup> However, this at least partly explains the greater toxicity of type II pyrethroids to warm-blooded species as compared to type I.<sup>103</sup>

### Clinical Manifestations

Pyrethrum probably has an LD<sub>50</sub> of well over 1 g/kg in man, as extrapolated from animal data. Most cases of toxicity associated with the pyrethrins are the result of allergic reactions.<sup>112,169</sup> Theoretically, those at highest risk for allergic reactions would be patients who are sensitive to ragweed pollen, 50% of whom may cross-react with chrysanthemums (ragweed and chrysanthemum are in the same botanical family). These allergic reactions are postulated to be due to residual natural components present in the extracts.<sup>121</sup> However, recent reviews have cast some doubt on this explanation. First, there have been only 4 cases of life-threatening respiratory reactions reported in the literature, 3 of which were in known asthmatics.<sup>115</sup> Second, the presence of residual natural proteins is unlikely, as the purification procedures would allow little, if any, residuals.<sup>62</sup> Third, most reported cases of contact urticaria have been erroneously classified as type I hypersensitivity reactions.<sup>62</sup> The synthetic pyrethroids can cause histamine release *in vitro*,<sup>44</sup> but generally do not induce IgE-mediated allergic reactions.<sup>15</sup>

In animals, type I pyrethroid poisoning most closely resembles that of DDT, with extensive tremors, twitching, increased metabolic rate, and hyperthermia. Excluding the rare possibility of skin irritation or allergy, the type I pyrethroids are unlikely to cause systemic toxicity in humans. It has been shown experimentally that pyrethroids have greater than 1,000-fold more affinity for insect Na<sup>+</sup> channels than for those of mammals, explaining their low toxicity in higher life forms. This selectivity, along with the negative temperature coefficient and slower insect metabolism, combines to make the type I pyrethroids approximately 15,000 times more toxic in insects than humans.<sup>105</sup> The type II pyrethroids are generally more potent, and cause profuse salivation, ataxia, coarse tremor, choreoathetosis, and seizures in animals. In humans, poisoning with type II pyrethroids causes paresthesias (secondary to Na<sup>+</sup> channel's effects in cutaneous sensory nerves

after topical exposure),<sup>91</sup> salivation, nausea, vomiting, dizziness, fasciculations, altered mental status, coma, seizures, and acute respiratory distress syndrome.<sup>71</sup> A review of more than 500 cases of acute pyrethroid poisoning from China highlights some similar manifestations between a massive acute type II pyrethroid overdose and an organic phosphorus compound overdose (salivation, vomiting, seizures). However, serious atropine toxicity and death has resulted when poisoning from a type II pyrethroid was mistaken for an organic phosphorus compound, and treatment was directed at these seemingly muscarinic signs.<sup>71</sup> Features such as acute respiratory distress syndrome can be caused by solvents and surfactants present in the agricultural products.<sup>7</sup> Although the type II pyrethroids contain a cyanide moiety, cyanide poisoning does not occur, and cyanide antidotal therapy is not indicated.

Most significant unintentional exposures are dermal, especially in occupational settings, and local symptoms predominate in the majority of these cases. Systemic effects from insecticidal sprayings are reported from wind drift or inappropriate handling, and the more potent type II pyrethroids predominate in case reports. An exposure of workers possibly affected by wind drift from a mixture of 32 ounces of the type II pyrethroid cyfluthrin mixed with 18.5 gallons of petroleum oil and 1,800 gallons of water was reported in California in 2006. Spraying occurred in a citrus grove, and 23 female workers in an adjacent vineyard were possibly exposed. These workers complained of a “chemical” odor, and felt ill with headaches, nausea, eye irritation, weakness, anxiety, and shortness of breath. They were all evaluated in hospitals and discharged home. Despite the fact that no cyfluthrin was detected on these workers’ clothing or on foliage in the field where they were alleged to have been exposed, the report concluded that cyfluthrin was the cause; no estimate of the contribution of the petroleum vehicle to the symptoms was posited.<sup>25</sup> The predominant feature after significant cutaneous exposures is local paresthesias in the areas of skin contact, due to Na<sup>+</sup>-channel effects on cutaneous sensory nerves. Local skin irritation occurred in up to 10% of workers spraying pyrethroid insecticides, but rarely occurs after medicinal use of the pyrethroid creams and shampoos. Some pyrethroid compounds can be very corrosive to the eyes.<sup>121</sup>

Intentional ingestions represent the most serious exposures, because of the higher doses involved, and the greater exposures to vehicles and solvents. However, a study of 48 cases of permethrin/xylene/surfactant mixtures (38 were suicidal ingestions) revealed that mild GI signs and symptoms predominated (73%: sore throat, mouth ulcerations, dysphagia, epigastric pain, vomiting). Pulmonary signs and symptoms were documented in 29%, and 8 patients (including 1 death) had aspiration pneumonitis. Thirty-three percent had CNS symptoms: confusion (13%), coma (21%), and seizures (8%). The involvement of the central nervous system and lungs was less common, but clinically more significant.<sup>177</sup> The relative contributions of the 70% xylene and 10% surfactant was likely responsible for much of the GI and pulmonary effects, though it was not discussed in the report.

### Chronic Exposures

Because the pyrethroids are rapidly metabolized and are not biopersistent compounds, they are shown not to cause cumulative toxicity. A single case of motor neuron disease resulted from heavy daily inhalation exposure to pyrethroid mixtures in a combined space for 3 years, which resolved after exposure ceased.<sup>45</sup> Some investigators express concerns regarding possible neurotoxicity of the pyrethroids. However, a review noted that regulatory studies in multiple species showed no evidence supporting gross neurodevelopmental toxicity or adult neuronal loss in man.<sup>119</sup> In Germany, a unique situation exists where numerous civil lawsuits allege that multiple chemical sensitivity (MCS) is caused by pyrethroid exposures. Study of this phenomenon yields no scientific data to support this contention,<sup>10</sup> and the controversy is fueled by civil litigation, popular media sensationalizing, and subsequent public fear.<sup>4</sup>

### Treatment

Initial treatment should be directed toward skin decontamination, as most poisonings occur from exposures by this route. For patients with intentional

oral ingestions of a type II pyrethroid we recommend a single standard dose of AC, provided the diluent of the pyrethroid does not contain a petroleum solvent. Contact dermatitis and acute systemic allergic reactions should be treated in the usual manner, utilizing histamine blockers, corticosteroids, and inhalational beta-adrenergic agonists as clinically indicated.

Treatment of systemic toxicity is entirely supportive and symptomatic, because no specific antidote exists. Benzodiazepines should be used for tremor and seizures. Topical vitamin E oil (D,L- $\alpha$ -tocopherol) is especially effective in preventing and treating the cutaneous paresthesias due to topical pyrethroid exposures.<sup>12,121</sup>

### ARTHROPOD REPELLENTS

Mosquitoes transmit more diseases to humans than any other biting insect. Worldwide, more than 700 million people are infected yearly by mosquito bites that transmit such diseases as malaria, viral encephalitis, yellow fever, dengue fever, bancroftian filariasis, and epidemic polyarthritis. Most recently, *Aedes aegypti* mosquitoes were found to transmit Zika virus and chikungunya. Novel approaches to mosquito control also includes impregnation of indoor house paints with various insecticides (organic phosphorus compounds) and insect growth regulators. WHO estimated 214 million cases of malaria worldwide in 2015, and an estimated 438,000 deaths, of which 306,000 deaths were of children younger than 5 years.<sup>170</sup>

Although malaria is not a significant risk in the United States, numerous mosquito-borne diseases are present, and the exposures are growing. Nearly 44,000 cases of West Nile virus (WNV) disease is reported in the United States since 1999 in 48 states, and more than 1,900 people have died. In 2015 alone, 2175 cases of WNV were reported to the CDC. Many more cases of illness go unreported.<sup>23</sup> More recently, the CDC has confirmed Zika virus infections in the continental United States from January 2015 through January 2017 as 246 local cases (not travel associated), but 34,249 locally acquired cases were registered in Puerto Rico.<sup>22</sup> Because of the severe birth defects associated with Zika and the severe illnesses associated with other arthropod-borne illnesses (chikungunya, dengue, etc.), mosquito repellents have become important public health tools. The *A. aegypti* mosquito, vector of Zika, chikungunya, dengue fever, and yellow fever, is more difficult to avoid because they feed both day and night, and humans are their primary blood meal source, so they primarily breed in cities and crowded population areas. *N,N*-Diethyl-3-methylbenzamide (DEET) is the time-tested primary weapon for the past 5 decades. However, much controversy continues to surround DEET despite a remarkable safety profile with over a half-century of global use by billions of people. A growing trend in the United States and many Western cultures is a chemophobia against synthetic products like DEET. Many people favor plant-based “natural” or “organic” repellents, paralleling the increasing consumer preference for natural or organic foods. Several xenobiotics are proposed, but thus far few are shown by objective blinded studies to even approach the efficacy of DEET, much less surpass it. Numerous comprehensive reviews of the subject demonstrated the superiority of DEET in most cases, and it remains the insect repellent standard by which all others are measured (Table 111–3).

### DEET

The topical insect repellent *N,N*-diethyl-3-methylbenzamide (DEET, former nomenclature *N,N*-diethyl-*meta*-toluamide) was patented by the US Army in 1946, and commercially marketed in the United States since 1956. Currently, it is used worldwide by more than 200 million persons annually. The EPA estimates that 38% of the US population uses DEET each year. Despite the current search for alternatives, DEET is still the most effective repellent available, and that with the most clinical toxicity information.<sup>59,60</sup>

Formulations of DEET can be purchased without prescription in concentrations ranging from 5% to 100%, and in multiple formulations of solutions, creams, lotions, gels, and aerosol sprays. Mosquitoes are attracted to their hosts by temperature and chemical attractants, principally CO<sub>2</sub> and lactate. The mechanism by which DEET repels insects was thought to be due to some interference with the chemoreceptors that detect lactic acid and CO<sub>2</sub>.<sup>59,116</sup>

TABLE 111-3 Comparative Efficacy and Toxicity of Commonly Available Insect Repellents

Insect Repellent	EPA Approval	EPA Toxicity Rating <sup>a</sup>	Efficacy in Lab and Field Studies <sup>b</sup>	Notes
DEET	1957 (1980)	III	Most efficacious in lab and field studies; proven protection against ticks and mosquitoes	>50 years of experience, billions of users 10%–30% solution: safe, effective when used as directed
Picaridin (Bayrepel)	2001	IV	20% solution: Lab: Equivalent to DEET Field: Essentially equivalent to DEET	All studies done on 20% picaridin; no studies done with 7% US formula Recommended by CDC as a DEET alternative
IR3535 (substituted β amino acid)	1999	IV	Lab: Inferior to DEET Field: None available	Recommended by CDC as a DEET alternative
Oil of lemon eucalyptus (p-menthane diol)	2000	IV (I, ocular)	Equivalent to DEET for mosquitoes; not tested for tick bite prevention	Recommended by CDC as a DEET alternative
BioUD (2-undecanone)	2007	IV	Lab: Equivalent to 7% DEET Field: Equal to 25% and 30% DEET	Studies performed by patent holders and developers of IR, no impartial evidence
Citronella oil	1948	IV	Lab study: Ineffective	Candles only provide some repellency when within 1 meter

<sup>a</sup>EPA Acute Toxicity Ratings: Category I = very highly or highly toxic; Category II = moderately toxic; Category III = slightly toxic; Category IV = practically nontoxic. <sup>b</sup>Lab tests: arm-in-cage studies for mosquito repellency; Field studies: actual biting or tick attachment assays in natural conditions.

ACUTE ORAL TOXICITY: (from EPA- <https://www.epa.gov/pesticide-registration/label-review-manual> July 2014, accessed January 26, 2017)

Category I LD<sub>50</sub> < 50 mg/kg Label Language: DANGER Skull and Crossbones Fatal if swallowed—very highly or highly toxic

Category II LD<sub>50</sub> > 50 mg/kg < 500 mg/kg WARNING No symbol May be fatal if swallowed—moderately toxic

Category III LD<sub>50</sub> > 500 mg/kg < 5,000 mg/kg CAUTION No symbol Harmful if swallowed—slightly toxic

Category IV LD<sub>50</sub> > 5,000 mg/kg CAUTION or no signal word No symbol No hazard statement required; practically nontoxic -registrant may choose to use Category III statement

{947 US Environmental Protection Agency Office of Pesticide Programs 2016}

However, novel work demonstrated that DEET itself is actually detected by the mosquito's olfactory receptors and repels them independently of whether the normal physical or chemical attractants are present.<sup>154</sup> Formulations of DEET can feel greasy or sticky, and can dissolve or damage some plastics (eyeglass frames, watches) and synthetic fabrics.

### Toxicokinetics

*N,N*-Diethyl-3-methylbenzamide is extensively absorbed via the GI tract.<sup>163</sup> Skin absorption is significant, depending on the vehicle and the concentration. Transdermal absorption of 30% to 45% DEET in ethanol is significantly higher than 100% DEET solution in an in vitro human skin model.<sup>150</sup> This has led to development of microencapsulated liposphere formulas and polyethylene glycol-based solutions that reduce absorption and increase repellent time and efficacy in animal models.<sup>46</sup>

*N,N*-diethyl-3-methylbenzamide does not bind to stratum corneum, and only 0.08% or less of a dose remains in the skin 8 hours after application.<sup>116</sup> DEET is lipophilic, and skin absorption usually occurs within 2 hours, although it is eliminated from plasma within 4 hours. The volume of distribution is large, in the range of 2.7 to 6.2 L/kg in animal studies. DEET is extensively metabolized by oxidation and hydroxylation by the hepatic microsomal enzymes, primarily by the isozymes CYP2B6, 3A4, 2C19, and 2A6.<sup>163</sup> DEET is excreted in the urine within 12 hours, mainly as metabolites, with 15% or less appearing as the parent compound.<sup>60,116</sup>

*N,N*-diethyl-3-methylbenzamide toxicity reports and studies are extensively reviewed in terms of acute and chronic toxicity. It is safe for use in pregnant and lactating women;<sup>88</sup> it has no specific target organ toxicity or oncogenicity in any observed rat, mouse, or dog studies;<sup>140</sup> and chronic DEET exposure together with other insecticides showed no increased cancer risks.<sup>110</sup>

### Pathophysiology

The exact mechanism of DEET toxicity is unknown. Reviews of adverse reactions to DEET reported 26 cases with major morbidity, including

encephalopathy, ataxia, convulsions, respiratory failure, hypotension, anaphylaxis, or death, particularly after ingestion or dermal exposure to large amounts.<sup>20,60,108,109,156,164</sup> These primarily neurologic adverse reactions occurred mainly in children, and most involved prolonged use and excessive dosing beyond what is currently recommended. One fatal case involved a child who was known to be heterozygous for ornithine carbamoyl transferase (OCT) deficiency, and death was because of a Reylelike syndrome with hyperammonemia. This child experienced prior episodes of hyperammonemia unrelated to DEET use, and DEET does not appear to affect, or be affected by, OCT activity in humans.<sup>108</sup> There is currently no evidence that enzyme polymorphism affects DEET metabolism or influences individual susceptibility to toxicity.

Although single, large, acute oral doses (1–3 g/kg) in rats produced seizures and CNS damage,<sup>138,139</sup> smaller acute doses (500 mg/kg and less) and chronic multigenerational dosing in another rat study produced no obvious toxicity.<sup>139</sup> Teratogenicity studies in rats and rabbits failed to demonstrate toxicity except at the highest doses,<sup>140,176</sup> and DEET was not found to be carcinogenic.<sup>116,140</sup> In view of the billions of applications, the number of reports of toxicity appears exceedingly small, and suggests a remarkably wide margin of safety.<sup>60,68,108,109,125,153,164</sup>

### Clinical Manifestations

Most calls to poison control centers regarding DEET exposures involve minor or no symptoms, and symptomatic exposures occur primarily when DEET is sprayed in the eyes or inhaled.<sup>164</sup> Except for suicidal ingestions, most serious reactions consist of seizures in children overexposed via the dermal route; in fact, some of these cannot be definitely attributed to DEET.<sup>68,108</sup> Most symptoms resolve without treatment and the majority of patients with serious toxicity recover fully with supportive care. A single case report of severe poisoning developed in a man with extreme exposure. He used 30% DEET on his entire body several times daily for a prolonged time period, with an entire bottle used the day prior to admission. He developed weakness, and nausea that progressed to confusion and shortness of breath. Metabolic acidosis,

elevated lactate concentration, acute kidney injury requiring hemodialysis, and worsening weakness requiring mechanical ventilation developed. His blood DEET concentration was 130 ppb (mcg/L). No seizures developed, and he experienced a full neurologic recovery after a prolonged hospitalization.<sup>122</sup> When toxicity data and the few cases of encephalopathy and death allegedly related to DEET use are closely analyzed, the actual role of DEET remains purely speculative.<sup>29</sup>

### Treatment

Patients with DEET exposures are treated with supportive care aimed at the primarily neurologic symptoms. In cases of dermal exposures, skin decontamination should be a priority to prevent further absorption. For patients with intentional oral ingestions it is reasonable to give a single dose of AC if it has been less than 2 hours after ingestion and there are no contraindications such as seizures, decreased mental status, or vomiting.

An extensive review of the safety risk of DEET repellent use confirms its safe use for all populations when used according to labeling guidelines.<sup>153</sup> Despite its good safety profile, avoiding the overuse of DEET seems prudent. The American Academy of Pediatrics (AAP) revised its recommendations for insect repellent use due to the emergence of WNV infections and Zika and chikungunya (prior recommendations were for use of products with DEET <10%).<sup>141</sup> They found that DEET-containing products are the most effective mosquito repellents available, and are also effective against a variety of other insects, including ticks. Insect repellents with a DEET concentration from 10% to 30% (the maximum recommended for children) appear to be equally safe when used according to the directions on the product labels. The safety of DEET does not appear to relate to differences in these concentrations, and higher concentrations have longer durations of effects.<sup>1</sup> As indicated in the AAP handbook, repellents are not recommended for children younger than 2 months of age.<sup>2</sup>

The higher concentrations prolong the repellency period, but there is a plateau at about 50% DEET concentration, and about 6 hours is likely the maximum protection time from any single application of conventional formulations. Newer longer-acting DEET formulations in lipids or polymers cause the DEET to evaporate more slowly, which affords protection for greater than 6 hours and also less systemic absorption.<sup>86,135</sup> Because the lower concentrations recommended for children last approximately 2 hours, frequent reapplication is usually unnecessary. Most mosquitoes are most active for a few hours preceding and following dusk, and prior recommendations were to apply only during high-risk times. However, because *A. aegypti* mosquito feeds both day and night, bite avoidance is important in areas where this vector and its diseases are a risk, so insect repellents are needed around the clock. DEET should be promptly washed off the child's skin when protection is no longer needed. Soaking the skin is not more effective and can contribute to toxicity. DEET should be applied only to exposed skin. Application on abraded skin or skin with rashes should be avoided. Care should be taken to avoid exposure to eyes and sensitive skin areas. Avoid use on children's hands, so that the child does not wipe on eyes, mouth, genitalia, and so on. Adults should apply DEET to their own hands and then wipe onto the child's face, rather than spraying onto a child's face.

Previous recommendations for conventional mosquito control were that DEET combination products that include sunscreen should not be used, because these combination products were found to mutually enhance the percutaneous absorption of each component in both a porcine in vivo study<sup>84</sup> and in an in vitro mouse skin model.<sup>130</sup> Because *A. aegypti* is most active during the day, combination products may be useful in this setting, but should be used judiciously. Other options for protection include mechanical means, such as mosquito netting, as well as permethrin-impregnated clothing for tick prevention.

## NEWER INSECT REPELLENTS

The efficacy of any drug, treatment, or repellent is directly related to compliance with the treatment. Despite its demonstrated efficacy and safety, many people view chemical insect repellents such as DEET as potentially

harmful, and avoid their use. Several survey results in the United States and Canada revealed that 56% of people believe repellents are likely to be harmful to children, and 45% believed insect repellents are likely to sicken adults.<sup>172</sup> This has led to an intense search for effective alternatives to DEET-based repellents. Although their efficacy is not superior to DEET, their safety is likely at least equivalent to that of DEET. A review of the National Poison Data System from 2000 to 2015 of more than 68,000 exposures reveals that DEET, picaridin, and other non-DEET-containing insect repellents appear to have a low order of toxicity; the vast majority resulted in minimal effects after unintentional ingestions.<sup>27</sup>

### Picaridin (Bayrepel, KBR3023)

Picaridin is also known as Bayrepel and KBR 3023 in Europe. It is a piperidine derivative, and has low acute oral, dermal, and inhalation toxicity. The EPA classifies it as toxicity category IV for acute inhalation toxicity and primary dermal irritation, the lowest rating available (class III for oral ingestion). It is not a dermal sensitizer, and no developmental toxicity was observed in chronic animal feeding studies. It was also not shown to be mutagenic in a battery of tests, and is not considered carcinogenic.<sup>50</sup> Picaridin is nearly as efficacious as DEET in comparison studies of the 20% solution used in Australia and Europe, and the 20% solution is now also available in the United States. Picaridin has significantly less percutaneous systemic absorption than DEET, even when mixed with sunscreens.<sup>127</sup>

### Oil of Lemon Eucalyptus (PMD; *p*-Menthane-3,8-Diol)

Oil of lemon eucalyptus occurs naturally in the lemon eucalyptus plant (*Eucalyptus citriodora* also known as *Corymbia citriodora*). It is marketed in the United States under the brand name "OFF! Botanicals Insect Repellent." The natural oil can be extracted from the eucalyptus leaves and twigs; commercially the active ingredient, *p*-menthane-3,8-diol (PMD), is chemically synthesized, and is structurally similar to menthol. In its pure form, it is a solid at room temperature, and has a faint mintlike odor. *p*-Menthane-3,8-diol is placed into toxicity category IV for acute oral toxicity, dermal toxicity, and skin irritation, and toxicity category I for eye irritation (toxicity category II for the end-use product). It is not a skin sensitizer. The EPA has determined that there is reasonable certainty of no harm to the US population or subpopulations, including infants and children, as the result of the uses of *p*-menthane-3,8-diol to formulate insect repellents.<sup>51</sup> This compound, oil of lemon eucalyptus, is not to be confused with eucalyptus oil, a toxic essential oil containing 1,8-cineole, which has no insect repellent properties.

### IR3535

IR3535 is a substituted beta-amino acid structurally similar to naturally occurring beta-alanine. The US EPA has classified IR3535 as a biochemical, based on the fact that it is functionally identical to naturally occurring beta alanine: both repel insects, the basic molecular structure is identical, the end groups are not likely to contribute to toxicity, and it acts to control the target pest via a nontoxic mode of action. It is a liquid that contains 98% active ingredient and 2% inert ingredients. It has been used as an insect repellent in Europe for more than 20 years with no substantial adverse effects. It is not as effective as DEET for mosquito control and is therefore not recommended for malaria-endemic areas,<sup>69</sup> and presumably also inadequate for protection against *A. aegypti*. Toxicity tests show that IR3535 is not harmful when ingested, inhaled, or used on skin.<sup>52,53</sup> It is currently marketed in the United States by Avon Corporation as Skin-So-Soft Bug Guard Plus IR3535, at concentrations of 7.5% to 15%.

### 2-Undecanone (BioUD; Methyl Nonyl Ketone)

A newly formulated natural repellent, 2-undecanone, was approved for use as an insect repellent by the EPA in 2007, and is known by the brand name of BioUD. Its active ingredient is derived from the wild tomato plant, *Lycopersicon hirsutum* Dunal f. *glabratum* C. H. Mull.<sup>172</sup> 2-Undecanone (also known as methyl nonyl ketone) was originally registered in 1966 as a dog and cat repellent/training aid and an iris borer deterrent. It received EPA approval as a topical insect repellent in 2007. The EPA RED documents that in studies

using laboratory animals, methyl nonyl ketone exhibited no toxicity via the oral and inhalation routes and was placed in toxicity category IV. Methyl nonyl ketone was slightly toxic (toxicity category III) for dermal toxicity, eye irritation, and dermal irritation and was a weak dermal sensitizer. Because it has a long history of safe use, is from a natural source, and is an approved food additive, it is considered essentially nontoxic. Methyl nonyl ketone is currently found in only one insect repellent in the form of both a lotion and a spray known as HOMS BiteBlocker Insect Repellent.<sup>54</sup> The manufacturer lists a nonpublished study on its Web site of a field test showing protection from mosquito bites surpassed that of a DEET 30% at 6 hours, and equivalent at 4 hours.<sup>72</sup> A 2008 study done by the inventors and patent holders showed it was only as efficacious as lower-DEET-concentration products in laboratory arm-in-cage trials, but field trials revealed efficacy equivalent to 25% to 30% DEET formulations.<sup>172</sup>

### Oil of Citronella

Plant-derived essential oil products are considered minimum-risk pesticides and are exempt from EPA registration under section 25 (b) of the Federal Insecticide Fungicide and Rodenticide Act. Oil of Citronella has been used for more than 50 years as an insect repellent and as an animal repellent in candles and topical skin products. These products, which have little efficacy, are not expected to cause harm to humans, pets, or the environment when used according to the label.<sup>55</sup>

### LEGAL STANDARDS FOR AN INSECTICIDE LABEL

The Federal Insecticide, Fungicide and Rodenticide Act of 1962 established criteria for a “signal word” on an insecticide label, which implies the degree of toxicity based on an oral LD<sub>50</sub>. Also, the label on the original container of these products is usually instructive and should always be brought to the medical facility (Table CS11–1).

### SUMMARY

- Organic chlorine insecticide agricultural use has largely been eliminated in the United States and Europe, but remains a problem in the developing world. DDT, with a low order of acute toxicity, remains an important tool for control of malaria vector mosquitoes and is approved for indoor spraying in Africa. Organic chlorines classically cause neurologic toxicity (tremors, seizures) when ingested.
- While pharmaceutical use of lindane for topical ectoparasitic infestations is still available in most US states, use has decreased greatly in favor of less-toxic permethrin preparations, and now accounts for only 2% of the prescriptions written for these conditions.
- Synthetic pyrethroid insecticides are the most commonly used insecticides for home use, and have a lower order of toxicity than organic chlorine or organic phosphorus insecticides. Their primary mechanism of action is similar to the DDT-type organic chlorines, acting on the insect voltage-gated sodium channel. The type II pyrethroids are more potent, and can cause systemic toxicity (CNS, pulmonary) when ingested, and GABA<sub>A</sub> antagonism may play a role in their toxicity, as well as the solvents and surfactants in the formulations.
- Arthropod repellents containing DEET are still the most efficacious formulas and have many years of safe use in billions of people worldwide, when used as directed. Neurologic toxicity is described only after extreme exposure situations.
- Some newer insect repellents have efficacy approaching that of DEET, and few reported toxicities. As these newer repellents become more commonly used, significant toxicities are not expected.

## PHOSPHORUS

Michael C. Beuhler

Phosphorus (P)	
Atomic number	= 15
Atomic weight	= 30.97 Da
Normal concentration	
Serum	= 3–4.5 mg/dL (1–1.4 mmol/L) as phosphate

### HISTORY AND EPIDEMIOLOGY

Phosphorus is a nonmetallic essential element discovered hundreds of years ago that exists in 3 forms, with white phosphorus being the most important from a toxicological standpoint. The word “phosphorus” means light-bearer, which originates from its property of glowing when exposed to air. Its luminescent and pyrotechnic qualities resulted in widespread use in matches and fireworks, and its toxic properties was historically used as a rodenticide. It is still encountered occasionally and remains in use for munitions and in chemical syntheses. Biologically, it is present in living organisms as the phosphate ion that is an entirely different entity than the elemental phosphorus and not considered in this chapter.

Phosphorus is a nonmetallic element not naturally found in its elemental form; the white allotropic form was isolated from urine by Hennig Brandt in 1669. White phosphorus has been used in munitions since World War I for its antipersonnel effect as well as its warning, incendiary, and smoke producing properties. It is also used in fireworks in countries other than the United States (where consumer-grade fireworks containing white phosphorus are illegal) and for some chemical synthetic processes. White phosphorus was used extensively in the past as a rodenticide but is no longer permitted for this purpose in the United States. Because of the potential use of phosphorus for illicit drug manufacturing of methamphetamines, its sale is monitored by the US Drug Enforcement Administration. Before modern regulation, it was used in scientifically unsubstantiated remedies primarily because its phosphorescent and reactive qualities suggested potency. Its occasional use for homicides was limited by its characteristic luminescent, smoking qualities; however, it remains a method of suicide in some countries.

At the beginning of the 20th century, phosphorus was used in millions of “strike anywhere” matches (lucifers). However, safety concerns with the matches and illnesses in the workers producing the matches prompted a shift from using the more dangerous white phosphorus in the match heads to substituting the safer red phosphorus in the strikers. Workers chronically exposed to white phosphorus developed “phossy jaw,” an illness characterized by disfiguring osteonecrosis of the mandible along with multiple draining abscesses and bony loss. Although the disease was actually of low prevalence among phosphorus workers, the painful, visible deformities in otherwise healthy young people drew widespread attention.

### CHEMISTRY AND PHARMACOLOGY

Phosphorus, atomic number 15, is in group 15 (CAS group VA) which is made up of nonmetals, metalloids, and metal elements; shares chemical properties with nitrogen (above) and arsenic (below) in the periodic table. Elemental phosphorus exists in several different allotropes (polymorphs); the 2 common forms considered in this chapter are red phosphorus and the highly reactive white phosphorus. The black allotrope is reasonably stable at standard conditions and has potential novel application in electronics because of its semiconductive planar crystalline structure and multiple anisotropic physical properties. However, the black allotrope is rarely encountered, relatively nontoxic, and will not be considered further.

White phosphorus is a waxy whitish to yellow solid with a melting point of 111.4°F (44.1°C); after ignition, it will have a gummy to liquid form. Often there is a small amount of red phosphorus in samples of white phosphorus, resulting in discoloration and explaining the term “yellow” phosphorus. The glow when exposed to air is due to the formation of reactive luminescent phosphorus oxides on its surface. White phosphorus is insoluble in water and often stored under it. It is soluble in carbon disulfide, which is the most common solvent used for dissolution as it is much less soluble in other organic solvents. White phosphorus is very reactive, igniting spontaneously in air at approximately 93°F (34°C), oxidizing to form phosphorus pentoxide (P<sub>4</sub>O<sub>10</sub>), phosphorus trioxide (P<sub>4</sub>O<sub>6</sub>), and potentially trace amounts of unreacted white phosphorus that usually appears as a white fume (smoke) having a garliclike smell. These anhydrous oxides of phosphorus are hygroscopic, reacting with water to form phosphorus-containing acids as well as with organic molecules in dehydrating reactions.

Red phosphorus is a red powdery compound of limited toxicologic significance. It is not luminescent, it does not combust in air, and its toxicity is orders of magnitude less than that of white phosphorus.

### PHARMACOKINETICS AND TOXICOKINETICS

White phosphorus is well absorbed from the intestinal tract, and coingestion with fats, alcohol, and liquids increases toxicity, probably from increased absorption.<sup>7,8</sup> However, GI absorption is not always complete, which is quite evident when patients pass luminescent, smoking stools. White phosphorus is also well absorbed through the skin, with burns contributing to the absorption; however, fragments can remain unabsorbed in the skin for days.<sup>22</sup> Significant morbidity and mortality occur from large surface area burns. White phosphorus is also absorbed by inhalation, although this exposure route is rare with current industrial hygiene practices.

After ingestion, phosphorus is found in high concentrations within 3 hours in the liver (greatest concentration), blood, and kidneys.<sup>4,13</sup> The final amount of internalized phosphorus likely depends on the dose and its exact form, such as the particle size and the presence of a nonpolar solvent. The conversion of absorbed phosphorus to its oxidized forms is believed to be rapid, on the order of hours.<sup>15</sup> Absorbed phosphorus is eliminated after undergoing (likely nonenzymatic) oxidation to phosphate and probably other minor phosphorus acids; phosphorus may also form biological adducts, but this has not been determined.<sup>15,21</sup>

Internally absorbed white phosphorus has significant toxicity. A dose of only about 1 mg/kg in adults is likely to cause significant morbidity, but a lethal dose of 3 mg is reported in a child; part of the outcome variability may be due to differences between the exposure and the absorbed amount.<sup>3</sup> The mortality from white phosphorus ingestion is difficult to estimate, because the majority of reported cases occurred prior to the development of critical care. Historically, significant ingestions carried a 25% mortality rate.<sup>11</sup>

### PATHOPHYSIOLOGY

The mechanism of dermal injury from white phosphorus differs significantly from that of ingested white phosphorus. Externally, white phosphorus reacts with oxygen (ie, burns) to form phosphorus pentoxide and other phosphorus oxides. Phosphorus pentoxide readily reacts with water in an exothermic reaction, producing corrosive phosphoric acid.<sup>14</sup> Additionally, phosphorus pentoxide reacts with (dehydrates) some organic molecules. These 3 mechanisms of exothermic, acid-producing, and dehydrating reactions all contribute to the tissue injury observed, although the most damaging

mechanism is the thermal injury from the heat of the reaction, as evidenced by the relatively short distance of tissue penetration by the acid and the relatively large amount of available water.<sup>6,26</sup> The evidence for describing white phosphorus as a cytoplasmic poison is mostly derived from electron microscopy, which demonstrates an initial cytoplasmic injury of the rough endoplasmic reticulum rather than initial nuclear or mitochondrial changes, but white phosphorus has an effect on mitochondrial energetics and oxidant effects.<sup>12,20</sup>

A resurgence of toxicity and human injury indirectly related to red phosphorus resulted from the increase in North American domestic methamphetamine production. Red phosphorus is used in conjunction with elemental iodine to produce hydroiodic acid, the ultimate reducing agent required to convert ephedrine to methamphetamine. In this situation, red phosphorus contributes to human injury by causing fire because of its unintentional conversion to highly flammable white phosphorus. Toxicity occurs because during heating, the reaction products of iodine and red phosphorus often generate phosphine (PH<sub>3</sub>), a pulmonary irritant and metabolic inhibitor gas (Chap. 108). Phosphine is only produced in significant amounts during an active methamphetamine “cook” using the red phosphorus method. This gas most likely contributes to some of the pulmonary effects occurring with chronic exposures in methamphetamine laboratories, as well as several of the deaths resulting from performing the synthesis in an area with limited ventilation in order to hide the characteristic odors.<sup>27</sup>

Red phosphorus has limited direct toxicologic significance. It can cause gastrointestinal (GI) irritation when ingested in significant amounts, but it is orders of magnitude less toxic than white phosphorus. All further references to phosphorus in this chapter refer to white phosphorus.

## CLINICAL MANIFESTATIONS

### General

The clinical manifestations of oral phosphorus poisoning are classically described in 3 stages. The initial effects are delayed for a few hours, and the degree of delay partially depends on the dose. During the first phase, patients experience vomiting, hematemesis, and abdominal pain, with hypotension and death occurring within 24 hours after large ingestions.<sup>8</sup> During the second stage, there is transient resolution of the toxic effects. During the third stage, the patient develops hepatic injury with coagulopathy, jaundice, and acute kidney injury with oliguria and uremia. Altered mental status and seizures, independent of electrolyte abnormalities, are also reported. However, clinical experience demonstrates that 3 distinct phases are the exception rather than the rule, with significant overlap or absence of the “quiescent” second stage and death potentially occurring within hours of ingestion.<sup>7,17</sup> In the first 6 hours postexposure, poor prognostic signs include altered sensorium, cyanosis, hypotension, metabolic acidosis, elevated prothrombin time, and hypoglycemia.<sup>7</sup> Survival to 3 days serves as a good prognostic sign. However, deaths also occur weeks later in the clinical course.<sup>8</sup> Recovery usually occurs over 1 to 2 weeks.

### Gastrointestinal

Initial symptoms after ingestion of phosphorus include nausea, vomiting, and abdominal pain. Both diarrhea and constipation are reported but are much less common. The breath and vomitus are sometimes described as having a garlic or musty sweet odor. The vomitus and diarrhea are sometimes luminescent and smoking, but this specific finding occurs infrequently. The smoking effect is caused by the combustion of phosphorus upon its exposure to air after being eliminated unabsorbed from the GI tract. Phosphorus causes an inflammatory injury to the GI tract characterized by local hemorrhage and hematemesis, but generally perforation does not occur. Massive GI bleeding occurs later in the clinical course, particularly when hepatic failure and coagulopathy are present.<sup>11</sup>

### Renal/Electrolytes

In a rat model of dermal burns from phosphorus, an initial diuresis occurs followed by acute kidney injury manifested by hyperkalemia, hyponatremia,

and hyperphosphatemia.<sup>1</sup> Renal cell swelling and necrosis with vacuolar degeneration of proximal convoluted tubules was also observed.<sup>1</sup> Poisoned patients demonstrated an increase in urinary white and red blood cells with casts and proteinuria.<sup>3</sup> In humans, acute kidney injury from phosphorus is most likely acute tubular necrosis resulting from hypotension, salt and water depletion, and a direct toxic effect.<sup>8</sup>

Significant electrolyte disturbances result from both ingestion and dermal absorption of phosphorus. Hypocalcemia is common, but hypercalcemia is also occasionally reported.<sup>14</sup> Hyperphosphatemia reportedly accompanies the hypocalcemia but is not universal and can occur at any time in the clinical course.<sup>3</sup> The hyperphosphatemia is partially due to the conversion of absorbed phosphorus to phosphate. In an animal model, those that died had increased concentrations of phosphate, decreased concentrations of calcium, and hyperkalemia as early as one hour postexposure.<sup>2</sup> Hyperkalemia is occasionally reported in humans and may be secondary to tissue injury and acute kidney injury.<sup>1</sup> The electrolyte disturbances are likely a leading cause of early mortality from phosphorus.

### Cardiovascular

When death occurs within 24 hours of the ingestion, it is likely the result of cardiovascular collapse. One series of 41 patients who attempted suicide demonstrated a variety of initial electrocardiographic (ECG) abnormalities. Abnormal T waves predominated in 24 patients, and there were also 2 cases of ventricular fibrillation. An increasing number of ECG abnormalities occurred in patients with larger ingestions, although electrolyte abnormalities were not described in many patients.<sup>5</sup> An animal model of phosphorus exposure demonstrated prolonged QT interval and ST segment changes along with electrolyte abnormalities, suggesting that many of the ECG changes might be due to electrolyte abnormalities.<sup>2</sup> A small study of phosphorus exposure in rats observed a decrease in amino acid uptake in myocytes suggesting a direct toxic effect. Human autopsies of several poisoned patients demonstrated fatty degeneration of the myocardium and vacuolated cytoplasm many hours postingestion.<sup>25</sup>

### Hepatic

Phosphorus is a potent hepatotoxin. Increased prothrombin time, hyperbilirubinemia, and hypoglycemia usually occur within 3 days, with earlier signs of hepatic failure such as jaundice and coagulopathy indicative of a poor prognosis.<sup>8,16</sup> The increase in hepatic aminotransferases occurs over several days, usually peaking at or below 1,000 IU/L and almost invariably less than 3,000 IU/L.<sup>11</sup> Other biochemical effects demonstrated by experimental phosphorus toxicity include an increase in glucose-6-phosphate activity and impairment of triglyceride metabolism and protein synthesis. When death occurs after several days (as opposed to within 24 hours), hepatic injury is usually implicated. If survival occurs, the hepatic damage usually resolves over several months, although persistent periportal fibrosis is reported.<sup>16</sup>

With absorption of sufficient quantities, phosphorus causes a dose-related zone 1 or periportal hepatic injury, in contrast to the centrilobular pattern (zone 3) that occurs with many other hepatotoxins, such as acetaminophen and carbon tetrachloride (Chap. 21). Fatty degenerative changes and fatty infiltrates are also observed within 6 hours of ingestion.<sup>7</sup> Other histological changes include acute necrosis with large vacuoles and inflammatory changes. Some authors report microvesicular fatty degeneration of hepatocytes in patients who died early.<sup>29</sup> Electron microscopy in a rat model demonstrated an increase in the rough endoplasmic reticulum and an increase in the cytoplasmic fat without initial mitochondrial or nuclear injury.<sup>12</sup> Although the early pathologic effects appear to be predominantly cytoplasmic, the formation of nuclear vacuoles also occur.<sup>16</sup>

### Nervous System

Central nervous system effects include headache, altered mental status, coma, and rarely seizures. The altered mental status is probably due partially to the presence of other organ dysfunction and shock; one example of the former is the encephalopathy secondary to hepatic injury. Patients with initial

alterations in mental status or coma have an increased mortality rate independent of the presence of any electrolyte abnormalities.<sup>17</sup>

### Dermal/Mucous Membranes

Dermal phosphorus exposure causes extensive burns, and this occurs most frequently in the military setting. The burns are described as emitting a garlic odor and displaying a yellow color that fluoresces under ultraviolet light.<sup>5</sup> Necrosis of the wounds is common when wound decontamination is incomplete. Depending on the release conditions, white phosphorus can be a solid or liquid but will be mostly liquid upon ignition. Liquid white phosphorus splatters and can penetrate clothing; burning clothing commonly exacerbates the burn area.<sup>14,18</sup> Dermal penetration is likely as a result of its lipophilicity and a compromised dermal barrier caused by the burn injury. The smoke produced by burning white phosphorus contains phosphorus pentoxide and is irritating to the conjunctiva and mucosa of the oropharynx and lungs.

Following a large burn, systemic illness manifested by electrolyte, cardiovascular, and hepatic abnormalities results from absorbed phosphorus.<sup>12</sup> A 12% to 15% body surface area burn in a rat was lethal 50% of the time; human morbidity from large skin burns is similarly high. Rats with dermal burns from phosphorus subsequently developed kidney and liver injury. Healing time from phosphorus burns is prolonged when compared with thermal burns.<sup>8</sup>

### DIAGNOSTIC TESTING

Serum elemental phosphorus concentrations are not clinically available, and a serum phosphate concentration while potentially elevated does not reflect the serum elemental phosphorus concentration nor any body burden of elemental phosphorus. The diagnosis of phosphorus poisoning must rely on the history and physical examination. However, for optimal supportive care of the patient, many laboratory factors must be monitored, such as ECG, electrolytes, serum pH, hepatic function, glucose, kidney function, and coagulation parameters.

### MANAGEMENT

#### Protection of Health Care Workers

At the absolute minimum, gloves and ocular protection (ie, face shield) should be used when managing a white phosphorus-poisoned patient until all elemental contamination is removed. Caution should be exercised with decontamination and subsequent storage of contaminated clothing. Following ingestion, vomitus and diarrhea must be considered potentially hazardous due to fire risk and should be carefully handled. Any phosphorus fragments removed from the patient as well as all potentially contaminated clothing items should be kept under water. Fires and explosions are reported during GI decontamination efforts, and the smoke from burning white phosphorus is irritating to the eyes and lungs and should be avoided.<sup>19</sup>

#### General

General supportive care is the mainstay of treatment. Cardiac monitoring; serial monitoring of calcium, phosphate, and potassium concentrations; and ECGs are essential for patients with a history of significant ingestion or overt toxicity as dysrhythmias can occur rapidly.<sup>8</sup> Electrolyte disturbances such as hyperkalemia, hypocalcemia, and hypercalcemia should be corrected. With a systemically absorbed toxic dose of phosphorus, hepatic injury will occur, and thus directed supportive care should be provided such as fresh-frozen plasma and vitamin K, when indicated. Adequate serum glucose concentrations are required to provide reducing equivalents through glycolysis and the glucose-6-phosphate dehydrogenase (G6PD) pathways, especially when there is evolving hepatic injury. Corticosteroids have not been shown to improve outcome following ingestions of white phosphorus and are not routinely recommended.<sup>16</sup> Direct contact of phosphorus with the eye can result in serious ophthalmic injury. Immediate copious ophthalmic decontamination with water rather than with copper sulfate is recommended (see Dermal Exposure).<sup>24</sup> A careful examination should be conducted by an ophthalmologist whenever possible.

#### Dermal Exposure

Initial treatment is to halt continuing injury by extinguishing combustion of the phosphorus. This should be performed by covering and lightly pressing

down on any areas with a clean cloth (gauze) soaked in cool water or a 0.9% sodium chloride solution to limit the white phosphorus contact with atmospheric oxygen. Significant amounts of the white phosphorus will stick to the gauze or the cloth when removed 3 to 5 minutes later.<sup>28</sup> Clothing should be removed and fresh-soaked gauze immediately applied to skin areas beneath to prevent the remaining phosphorus that passed through the fabric from igniting. Subsequently, large amounts of cool water can be used to remove any phosphorus fragments. However, pouring water on burning phosphorus is very dangerous as burning phosphorus splashes unpredictably. Even with small amounts of dermal contamination caution should be exerted as spilling pieces of burning phosphorus originating from patient's wounds have injured health care workers; personal protective equipment including eye protection should be used. In the past, sodium bicarbonate decontamination solution was recommended, but because the tissue injury is not due to the production of acid and because no clinical benefit was demonstrated, specific neutralization fluids should not be used.<sup>6,26</sup> Water dilutes any phosphoric acid present and reacts with the phosphorus pentoxide to limit the damaging dehydrating reactions. All removed bandages and clothing should be kept wet or under water to prevent reignition.

Careful debridement is the next critical step as wounds that have not undergone adequate decontamination heal poorly, requiring additional debridement. Smoking pieces of phosphorus (ie, those emanating a white vapor) are not "burning" and not hot enough to cause thermal burns, but the oxidation process should be arrested. Fragments of phosphorus from the wound should be placed under water to prevent a fire hazard. Particles of phosphorus can be visualized by using a Woods lamp as the chemical burns have a yellowish fluorescence. One author recommends turning off the lights to look for the glow of the phosphorescent particles; presumably this will work only if copper or silver metal wash solution are not used, but due to lack of experience with this method along with problems of working in a completely dark area, this method is not routinely recommended.<sup>9</sup> Because of the increased solubility of phosphorus in hydrophobic solvents, it is important not to use ointments until the wound is completely decontaminated.

A copper(II) sulfate solution was previously recommended for "decontamination" (a misnomer in this case). Copper sulfate reacts with phosphorus to produce copper phosphide, a dark compound that is more easily visualized in the tissues. This dark material coats the particle, but the entire particle is not converted to copper phosphide. Additionally, this coating decreases the reaction of phosphorus with oxygen for a limited time and the particles should cease to smoke and will not phosphoresce. The application of high concentrations of copper sulfate solutions on damaged human tissue should not be done because of potential systemic toxicity such as hemolysis caused by the copper (Chap. 92).<sup>24</sup> This is especially concerning in patients at increased risk for oxidant injury, such as those with G6PD deficiency. The injurious solutions of copper sulfate historically used ranged from 2% to 5% and were applied for several hours to the wounds, resulting in substantial amounts of copper absorption and morbidity.

However, it is reasonable to utilize dilute copper sulfate solutions for the complete approach to the treatment of phosphorus wounds, acknowledging that this therapy is controversial, potentially harmful, especially in patients at risk for oxidant injury (G6PD deficiency) and not routinely available. It is possible that a dilute copper sulfate solution (0.5%–1.0%) applied once to the wound and then rinsed off with water will not result in the morbidity that occurred with the more concentrated rinses and will provide temporary neutralization of the outer surface of the phosphorus. This approach would be reasonable to assist in identification of the small pieces of phosphorus (after gross decontamination) that are difficult or impossible to visualize by darkening the fragments, especially in those with less experience débriding these wounds. Animal models suggest improved healing from the initial treatment with a copper solution, but a human case series did not find a difference in hospitalization days for those who were treated with copper sulfate compared with those who were not.<sup>6</sup> The copper phosphide-coated particles must be removed as they still react slowly, will release copper ions and will cause toxicity. It is important to restate that a single dilute copper sulfate

solution wash is not a decontamination therapy but a temporizing treatment that allows for better visualization for physical debridement, and this solution must be rinsed away immediately after application.<sup>9</sup> Pads soaked in copper sulfate should not be used; this is because of the high concentration of copper, and the prolonged contact time that would promote a dangerous amount of systemic copper absorption.

Silver nitrate is suggested as a potential solution to replace the use of copper sulfate. It forms an insoluble, minimally reactive silver phosphide. Its use and preparation is similar to that described above and as such silver nitrate (1%–2% solution) is a temporary neutralization tool and not a decontamination therapy. It does not have the detrimental physiologic effects that inter-nalized copper ions cause. However, there is very limited experience with this approach and no detailed human data, and although there may be some qualities that could make it more attractive than dilute copper solutions, it is not recommended at this time for lack of data. Silver forms an insoluble precipitate with chloride and cannot be combined with 0.9% sodium chloride solutions; therefore, the amount of soluble silver ion that reaches the imbedded phosphorus may be more limited than with copper because of the presence of relatively large amounts of chloride ion in living tissues.<sup>23</sup>

A reasonable approach is to begin by decontaminating the wound using a Woods lamp and/or a darkened room looking for phosphorescence. It would be reasonable to then apply a single transient dilute copper sulfate solution as described above with subsequent rinse to improve visualization and temporarily neutralize very small phosphorus particles. After decontamination, good wound care and burn management is required, because these burns (like other chemical burns) can be deep and require an extended period of time to heal. As discussed, incomplete decontamination is a common cause for delayed wound healing and there are cases of reactive fragments removed from the wound days after injury.<sup>22</sup> Patients with significant burns should be admitted to a burn intensive care unit for close monitoring of cardiovascular, kidney, and electrolyte status for several days at the minimum. Because of the potential instability of these patients, it is important to weigh the risk-to-benefit ratio of transfer to a specialized center. The experience of the receiving center with phosphorus burns in addition to the acuity and severity of the injury are important factors in making this decision.

### Gastrointestinal Exposure

There is no good evidence that GI decontamination or antidotal therapy is efficacious following phosphorus ingestion. In the past, several different lavage fluids were recommended, ranging from the mostly benign (sodium bicarbonate) to the potentially dangerous (potassium permanganate). Milk might also be potentially harmful because of its lipophilic components due to the potential for increased phosphorus absorption. Some authors postulate better outcome with earlier GI decontamination by lavage, but no reliable studies are available.<sup>16</sup> There is the possibility that activated charcoal will bind to white phosphorus, although there are no human data to support its use and so it cannot be routinely recommend. However, despite the lack of data of efficacy, given the poor outcome of patients with large ingestions of phosphorus, gastric decontamination is recommended, even if there has already been vomiting. The tissue injury caused by phosphorus is not expected to cause early esophageal perforation, and so lavage is not contraindicated. Either an orogastric (OG) or nasogastric (NG) tube should be used, with the OG tube being preferred because of the variability in particle size in many products, although recognizing that an OG tube has greater risk associated with use than an NG tube (Chap. 5). Caution (gloves, eye protection at the minimum) should be exercised with any lavaged material to protect caregivers as spontaneous ignition can occur. Because of the risk of fire and explosion, it would be reasonable to keep the free end of the OG tube under water while inserting and instilling small amounts of water (not air) to check for proper placement, although this is only supported by one case report.<sup>19</sup>

It appears that the hepatic injury is much more likely with ingested phosphorus exposure than following dermal exposure. *N*-Acetylcysteine (NAC) would be reasonable as a potential adjunct in the treatment of phosphorus toxicity because of its antioxidant effects. Although NAC was used in a limited

human series, the numbers were small ( $n = 9$  of 15) and there was no difference seen.<sup>11</sup> The use of superoxide dismutase in an animal model suggested benefit but did not limit morbidity, and a separate animal model suggested benefit from glutathione; therefore, limiting oxidant injury may play a role in treatment.<sup>10</sup> There is no theoretical harm in using NAC for phosphorus toxicity, and so it would be reasonable as part of the treatment regimen. Methionine was used many years ago in the treatment of a few patients, but the number of treated patients was too few to draw any conclusions and is not recommended.<sup>7</sup> When liver transplantation was performed for phosphorus-induced hepatic failure, outcomes have been suboptimal, probably because of concomitant toxicity occurring in the central nervous and cardiovascular systems.

### SUMMARY

- White phosphorus was and is commonly used in warfare, causing morbidity through dermal burns.
- These burns require immediate quenching with wet cloths and adequate debridement while protecting health care workers.
- Following ingestion, typically in suicide attempts, morbidity remains quite high, and treatment options are limited to unproven decontamination therapies.
- Signs and symptoms of white phosphorus toxicity include vomiting, abdominal pain, confusion, dysrhythmias, hepatic injury, and acute kidney injury.
- As early mortality is believed to be due to electrolyte abnormalities and cardiac dysrhythmias, vigilant critical care is the mainstay of therapy.
- It would be reasonable to administer NAC, but it has not been shown to alter human outcomes.

# SODIUM MONOFLUOROACETATE AND FLUOROACETAMIDE

Fermin Barrueto Jr.

## HISTORY AND EPIDEMIOLOGY

Sodium monofluoroacetate (SMFA) occurs naturally in plants native to Brazil, Australia, and South and West Africa (eg, gifblaar {*Dichapetalum cymosum*}).<sup>11</sup> The highest concentration (8.0 mg/g) is found in the seeds of a South African plant, *Dichapetalum braunii*.<sup>11</sup> In the 1940s, SMFA was marketed as a rodenticide (CAS No. 62-74-8) and assigned the compound number 1080, which was registered as its trade name. Fluoroacetamide, a similar pesticide, is known as Compound 1081 (CAS No. 640-19-7). These compounds are widely effective as poisons against most mammals and some amphibians.<sup>26</sup> Both products were banned in the United States in 1972, except to protect sheep and cattle from coyotes. Collars embedded with SMFA are placed around the neck of livestock, the typical point of attack for coyotes.

Sodium monofluoroacetate is used extensively in New Zealand and Australia to control the possum population and other animal species considered pests that have no natural predators. In 1986, Compound 1080 was used to control the feral and free-ranging dogs in the Galapagos Islands due to their lack of a predator and their disruption of the sea turtle nests.<sup>33</sup> Its continued use is extremely controversial, but following a recent review of the ramifications of the use of 1080, the government of New Zealand retained both the aerosolized and collar applications. Reported cases of human poisoning with SMFA are uncommon, and the epidemiology is poorly understood. There have been only 68 reported cases from 1999 to 2017 with no deaths in the National Poisoning Database System of the American Association of Poison Control Centers (Chap. 130).

## TOXICOKINETICS AND TOXICODYNAMICS

Sodium monofluoroacetate is an odorless and tasteless white powder with the consistency of flour. When dissolved in water, it is said to have a vinegarlike taste. Sodium monofluoroacetate and fluoroacetamide are well absorbed by the oral and inhalational routes.<sup>10,11,12,27</sup> Detailed toxicokinetic data are lacking in humans, but in sheep, up to 33% of an ingested dose is excreted unchanged in the urine over 48 hours. Glucuronide and glutathione conjugates were isolated.<sup>11</sup> Substantial defluorination is not thought to occur in vivo. The serum half-life is estimated to be 6.6 to 13.3 hours in sheep.<sup>10</sup> Sodium monofluoroacetate has a lethal dose of 50% of those exposed ( $LD_{50}$ ) of 0.07 mg/kg in dogs.<sup>19</sup> The oral dose thought to be lethal to humans is 2 to 10 mg/kg.<sup>3</sup>

## PATHOPHYSIOLOGY

Sodium monofluoroacetate, a structural analog of acetic acid (Fig. 113-1), is an irreversible inhibitor of the citric acid cycle (Fig. 11-3). Monofluoroacetic acid enters the mitochondria, where it is converted to

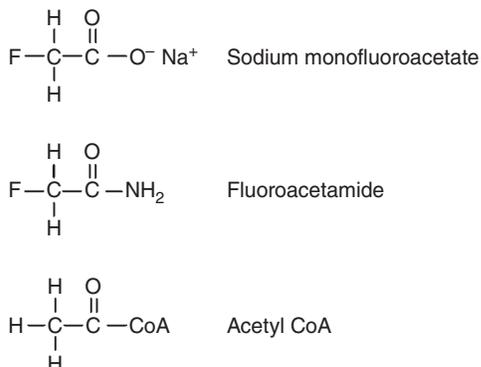

FIGURE 113-1. Structural similarities among acetyl-CoA, sodium monofluoroacetate, and fluoroacetamide.

monofluoroacetyl-coenzyme A (CoA) by acetate thiokinase. Mitochondrial citrate synthase is then joined with the monofluoroacetyl-CoA complex with oxaloacetate to form fluorocitrate. Fluorocitrate then covalently binds aconitase, preventing the enzyme from any further metabolic activity in the citric acid cycle.<sup>17</sup> Thus, fluorocitrate acts as a “suicide inhibitor” of aconitase, producing a biochemical dead end. The net toxicity caused by fluorocitrate results from the increase in citric acid cycle substrates proximal to inhibition of aconitase and the depletion of substrates distal to the step catalyzed by aconitase. This inhibition of aconitase impairs energy production, leading to anaerobic metabolism and metabolic acidosis with an elevated lactate concentration. Additionally, other citric acid cycle intermediates increase in concentration, contributing to the toxicity.  $\alpha$ -Ketoglutarate depletion, caused by the lack of isocitrate, leads to glutamate depletion since  $\alpha$ -ketoglutarate is a precursor of glutamate synthesis. Glutamate depletion leads to urea cycle disruption and ammonia accumulation. Impaired fatty acid oxidation leads to ketosis. Excess citrate binds to divalent cations such as calcium causing hypocalcemia.

Disruption of the citric acid and urea cycles affects every system in the human body, but the most consequential effects occur in the central nervous system and the cardiovascular system. Fluoride toxicity from enzymatic defluorination of sodium monofluoroacetate and fluoroacetamide does not occur substantially in vivo and is of minor significance.

## CLINICAL MANIFESTATIONS

The majority of the clinical experience with SMFA is associated with intentional self-poisoning; fluoroacetamide poisoning is presumed to have a similar presentation.<sup>9,16,18,29</sup> Most patients develop symptoms within 6 hours after exposure. In the largest case series of 38 Taiwanese patients who ingested SMFA, 7 died.<sup>6</sup> The most common clinical findings recorded at the time of emergency department (ED) presentation were nausea and vomiting (74%), diarrhea (29%), agitation (29%), and abdominal pain (26%).<sup>6</sup> The mean time to presentation to the hospital was  $10.9 \pm 5.7$  hours for those who died and  $3.4 \pm 0.6$  hours for the survivors. All deaths occurred within 72 hours of admission to the hospital. The presence of respiratory distress or seizures was a prognostic indicator of death. All 7 patients who died had systolic blood pressures less than 90 mm Hg on presentation to the ED, a finding noted in only 16% of the survivors.<sup>6</sup>

In a case series involving 2 patients, invasive hemodynamic monitoring revealed persistent low systemic vascular resistance and increased cardiac output despite adequate fluid resuscitation.<sup>7</sup> The authors theorized that the cardiovascular response was triggered by ATP depletion and inhibition of gluconeogenesis.<sup>7</sup> Anaerobic metabolism, mitochondrial inhibition, and sensitivity of the vasculature to SMFA are also confounding factors.

The initial neurologic manifestations consist of agitation and confusion with progression to seizures. Neurologic sequelae such as cerebellar dysfunction are likely permanent though there is a case report of reversible leukoencephalopathy.<sup>15,30,31,34,35</sup> Another report describes a 15-year-old girl who survived an initial exposure to SMFA but later developed cerebellar dysfunction and cerebral atrophy, demonstrated by brain computed tomography (CT).<sup>30</sup> Prolongation of the QT interval, premature ventricular contractions, ventricular fibrillation, ventricular tachycardia, and other dysrhythmias are documented.<sup>6</sup> Sodium monofluoroacetate has negative inotropic effects, except in one case report that described episodic hypertension.<sup>25</sup> Signs and symptoms associated with severe poisoning include seizures, respiratory distress, and hypertension.

## DIAGNOSTIC TESTING

The presence of SMFA and fluoroacetamide is confirmed in the blood and urine with gas chromatography–mass spectrometry and thin-layer chromatography.<sup>1,5,20</sup> Simultaneous analysis for other rodenticides that can induce seizures, for example, “tetramine,” is reportedly performed by gas chromatography in China, where exposure to these xenobiotics is more probable.<sup>2,4,32</sup> Like tetramine, SMFA is classified as a potential chemical weapon.<sup>13</sup> An elevated serum citrate concentration was proposed as a useful marker for exposure to SMFA.<sup>4</sup> However, none of these analyses can be performed in a clinically relevant period. A combination of history, clinical signs and symptoms, and common laboratory tests can assist with the diagnosis.

Hypokalemia, anion gap metabolic acidosis, and an elevated creatinine concentration<sup>8</sup> are associated with severe poisoning but are very nonspecific.<sup>6</sup> The predominant electrolyte abnormality is hypocalcemia. Creatinine, aminotransferase and bilirubin concentrations are also elevated in some cases and likely result from multisystem organ toxicity. Ketones are present in urine and serum. A complete blood cell count will reveal leukocytosis. An electrocardiogram is valuable in the diagnosis of SMFA exposure; a prolonged QT interval, atrial fibrillation with a rapid ventricular response, ventricular tachycardia, and other dysrhythmias are reported.<sup>6,28</sup> An initial CT scan of the brain can be normal, but subsequent scans will reveal cerebral atrophy.<sup>30</sup> When compared to presentation a weighted magnetic resonance imaging (MRI) on day 7 post ingestion showed reversible symmetric high signal intensity in the cerebellar peduncles, corpus callosum, internal capsules, and corona radiata in an SMFA-poisoned patient with a sublethal ingestion.<sup>15</sup> Brain single photon emission computed tomogram (SPECT) was also normal 14 days later.

## TREATMENT

Initial decontamination should include removal of clothes and cleansing of skin with soap and water. Because there is no proven antidote for SMFA or fluoroacetamide poisoning, orogastric lavage is reasonable for exposed patients who present to the ED prior to significant emesis. For patients who present within one to 2 hours of ingestion should receive we recommend 1 g/kg of activated charcoal (AC) orally. A rat study showed that colestipol is more effective than AC in binding SMFA.<sup>21</sup> Activated charcoal is more accessible, and the speed of administration would outweigh a theoretical benefit of increased binding of colestipol.

In a cat model, glycerol monoacetate (monacetin) at a dose of 0.5 mL/kg every 30 minutes prolonged survival. In this context, monacetin functions as an acetate donor for ultimate incorporation into citrate in place of fluoroacetate.<sup>29</sup> Both ethanol and glycerol monoacetate are converted to acetyl-CoA and compete with monofluoroacetyl-CoA for binding of citrate synthase. This prevents the “suicide-inhibition” of aconitase, subsequent increase in citrate, and the formation of the toxic metabolite fluorocitrate.<sup>29</sup> Availability of monacetin for human use is limited, and appropriate human dosing is unknown.

Ethanol was used in some human cases, although the appropriate dose is unknown.<sup>6,7,24</sup> A reasonable therapeutic dose is the amount of ethanol required to obtain and sustain an ethanol serum concentration of 100 mg/dL (Antidotes in Depth: A34). One intriguing case report involved a patient who ingested 240 mg of SMFA (typically a lethal dose) mixed with a Taiwanese wine (30% ethanol) and survived.<sup>6</sup> It is possible that the ethanol decreased or delayed the toxicity of SMFA.

In a mouse model, use of a combination of calcium salts, sodium succinate, and  $\alpha$ -ketoglutarate improved survival.<sup>22</sup> The rationale of using these antidotes is to provide citric acid cycle intermediates distal to the inhibited aconitase in an attempt to improve energy production. These antidotes were not effective unless calcium was coadministered, emphasizing the importance of replenishing electrolytes, particularly the divalent cations chelated by citrate.<sup>14,23,28</sup> Access to  $\alpha$ -ketoglutarate or sodium succinate for a human case would be limited and its use is reasonable; however, aggressive electrolyte replacement, especially the divalent

cations, is recommended and the importance is highlighted by this animal model.

If a patient develops hypotension and shock, rapid administration of intravenous 0.9% NaCl followed by a vasopressor, such as norepinephrine is recommended. Supportive care, correction of electrolyte abnormalities (especially calcium and potassium), ethanol infusion, and monitoring for dysrhythmias (prolonged QT interval) and seizures are the mainstays of treatment.

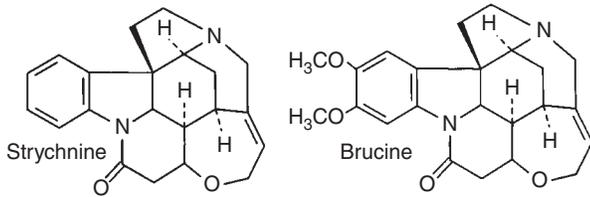

## SUMMARY

- Sodium monofluoroacetate and fluoroacetamide are potent pesticides that inhibit the citric acid cycle, disrupting cellular energy production.
- Patients exposed to SMFA typically present with nausea, vomiting, agitation, and abdominal pain, which is followed by hypotension, respiratory distress, shock, seizures, and death.
- Hypokalemia, hypocalcemia, metabolic acidosis with an elevated lactate, and elevation of serum creatinine also occur.
- Treatment of SMFA and fluoroacetamide poisoning largely involves replenishing electrolytes, correcting hypotension with intravenous fluids and vasopressors if necessary, monitoring for dysrhythmias, and treating seizures.
- Ethanol is a therapy with a biological mechanism and theoretical benefit. It is relatively familiar, readily available, and can be administered safely.

## HISTORY AND EPIDEMIOLOGY

Strychnine alkaloid occurs naturally in *Strychnos nux-vomica*, a tree native to tropical Asia and North Australia, and in *Strychnos ignatii* and *Strychnos tiente*, trees native to South Asia. The alkaloid was first isolated in 1818 by Pelletier and Caventou.<sup>5,15</sup> It is an odorless and colorless crystalline powder that has a bitter taste when dissolved in water. In addition to strychnine, the dried seeds of *S. nux-vomica* contain brucine, a structurally similar, although less potent, alkaloid.<sup>87</sup> Strychnine is available from commercial sources in its salt form, usually as nitrate, sulfate, or phosphate.

Strychnine was first introduced as a rodenticide in 1540, and in subsequent centuries was used medically as a cardiac, respiratory, and digestive stimulant,<sup>44</sup> as an analeptic,<sup>90</sup> and as an antidote to barbiturate<sup>89</sup> and opioid overdoses.<sup>59</sup> Nonketotic hyperglycemia,<sup>9,80</sup> sleep apnea,<sup>76</sup> and snake bites<sup>15</sup> were also once considered indications for strychnine use. In 1982, at least 172 commercial products were found to contain strychnine, including 77 rodenticides, 25 veterinary products, and 41 products made for human use.<sup>83</sup> In subsequent years, the use of strychnine significantly decreased; some countries such as the European Union banned its use as a rodenticide in 2006, and most of its prior medicinal indications are no longer utilized. Currently, strychnine is only widely used for moles, gophers, and pigeons and as a research tool for the study of glycine receptors. Most commercially available strychnine-containing products contain about 0.25% to 0.5% strychnine by weight.<sup>83</sup>

Between 1926 and 1928, strychnine killed more than 3 Americans every week.<sup>5,27</sup> In 1932, it was the most common cause of lethal poisoning in children,<sup>5,83</sup> and one-third of the unintentional poison-related deaths in children younger than 5 years were attributed to strychnine.<sup>60</sup> Currently, strychnine poisoning is rare and continues to decrease in the United States, although deaths are still reported. The Toxic Exposure Surveillance System (TESS) and National Poison Data System (NPDS) data of the American Association of Poison Control Centers (AAPCC) reported 1163 strychnine exposures including 5 deaths during the 10 years from 2006 to 2015 (Chap. 130).

In the modern era, strychnine poisoning typically results from deliberate exposure with suicidal and homicidal intent,<sup>27,48</sup> as well as from unintentional poisoning by a Chinese herbal medicine (Maqianzi)<sup>16</sup> and a Cambodian traditional remedy (slang nut).<sup>46,48,51</sup> Maqianzi is used to treat limb paralysis, severe rheumatism, inflammatory disease, and skeletal fluorosis<sup>50</sup> whereas slang nut is used to treat gastrointestinal diseases. The bitter taste of strychnine has led to its use as an adulterant in heroin<sup>42</sup> and cocaine.<sup>13,22,64</sup> There are also reports of strychnine poisoning from adulterated amphetamines,<sup>22</sup> 3,4-methylenedioxymethamphetamine (MDMA),<sup>25</sup> Spanish fly,<sup>12</sup> and from the ingestion of gopher bait.<sup>52</sup>

## TOXICOKINETICS

Standard references list the lethal dose of strychnine as approximately 50 to 100 mg.<sup>18,33,34,70,92</sup> However, mortality resulting from doses as low as 5 to 10 mg and, conversely, survival following exposures of 1 to 15 g of strychnine are

reported.<sup>6,18,82,95</sup> Some of this variation likely results from differing routes of administration, with parenteral administration being more toxic than oral, the limitations of self-reported exposure quantities, and advances in supportive care.

Strychnine is rapidly absorbed from the gastrointestinal tract and mucous membranes. Poisoning is reported from dermal absorption of strychnine stored in an alkaline solution, in which strychnine exists in the nonionized, alkaloid form.<sup>35</sup> Protein binding is minimal, and strychnine is rapidly distributed to peripheral tissues<sup>91</sup> with a large volume of distribution (13 L/kg).<sup>39</sup> Based on postmortem findings, the highest concentrations of strychnine are found in the liver,<sup>57,70,78</sup> bile,<sup>70</sup> blood,<sup>70</sup> and gastric contents.<sup>70,78</sup> Relatively less strychnine is identified in kidney, urine, and brain.<sup>78</sup>

Strychnine is metabolized by hepatic cytochrome P450 enzymes, mainly CYP3A4<sup>1,53,61</sup> producing strychnine-*N*-oxide as the major metabolite,<sup>1</sup> the toxicity of which is about 1/10th of the original alkaloid.<sup>55</sup> This metabolism is increased by P450 induction.<sup>43,47</sup> Several urinary metabolites are identified,<sup>45</sup> and 1% to 30% of strychnine is excreted unchanged in urine,<sup>10,38,69</sup> in decreasing proportions when larger amounts are ingested.<sup>81,91</sup> Strychnine elimination follows first-order kinetics with an elimination half-life of 10 to 16 hours.<sup>26,69,94</sup>

## PATHOPHYSIOLOGY

Glycine, one of the major inhibitory neurotransmitters in the spinal cord, opens a ligand-gated chloride (Cl<sup>-</sup>) channel, thus allowing the inward flow of Cl<sup>-</sup> (Fig. 13-12).<sup>20</sup> As Cl<sup>-</sup> moves inward, the cell becomes hyperpolarized, reducing neuronal excitability. Strychnine competitively inhibits the binding of glycine to the  $\alpha$ -subunit of the glycinergic chloride channel.<sup>13,19,94</sup> Although strychnine affects all parts of the central nervous system in which glycine receptors are found, the most significant effect is in the spinal cord. With loss of the glycine inhibition at the motor neurons in the ventral horn, there is a loss of inhibitory influence on the normally suppressed reflex arc. The result is increased impulse transmission to the muscles, producing generalized muscular contraction. Rabbits pretreated with glycine had a 40% increase in the strychnine "seizure" threshold, illustrating the competitive nature of strychnine and glycine activity on the glycinergic chloride channel.<sup>17,77</sup> Tetanus toxin (tetanospasmin) causes an identical clinical syndrome of muscular contractions, but does so by preventing the release of presynaptic glycine and does not function as a competitive antagonist. In dogs, strychnine has positive chronotropic and inotropic effects on the heart,<sup>84</sup> but this effect is unlikely to exert a major effect in human poisoning.

## CLINICAL MANIFESTATIONS

Oral strychnine poisoning is characterized by a rapid onset of signs and symptoms of toxicity beginning within 15 to 60 minutes of ingestion<sup>32</sup> and, although less well documented, effects occur sooner following parenteral or nasal administration. Delayed onset of clinical effects are rarely reported.<sup>23,34</sup> The typical findings of poisoning are involuntary, generalized muscular contractions resulting in neck, back, and limb pain. The contractions are easily triggered by trivial stimuli such as turning on a light, and each episode usually lasts for 30 to 120 seconds.<sup>83</sup> These episodes recur for as long as 12 to 24 hours. Differences in the strength of various opposing muscle groups result in the classic signs of opisthotonus, facial trismus, and risus sardonicus, with flexion of the upper limbs and extension of lower limbs predominating. Hyperreflexia, clonus, and nystagmus<sup>11,62</sup> are also evident on examination. Because strychnine affects glycine inhibition mainly in the spinal cord, the

patient typically remains fully alert until metabolic complications occur. The combination of convulsive motor activity involving both sides of the body in the conscious patient often results in imprecise descriptions such as “conscious seizure” or “spinal seizure.” Hemodynamically, both hypotension<sup>24,26,64</sup> and hypertension<sup>13,29,63</sup> in the presence of bradycardia<sup>14,24,26,64</sup> or tachycardia<sup>13,14</sup> are reported. Hyperthermia, presumably from increased muscular activity, is typical, and temperatures as high as 109.4°F (43°C) are reported.<sup>13</sup> Other nonspecific signs and symptoms include dizziness, vomiting, and chest and abdominal pain.<sup>62</sup>

Early in the course of strychnine poisoning, mortality is mainly due to hypoventilation and hypoxia secondary to muscular contractions.<sup>29</sup> Life-threatening complications include rhabdomyolysis, with subsequent myoglobinuria and acute kidney injury,<sup>14</sup> hypoxia or hyperthermia-induced multiorgan failure, aspiration pneumonitis,<sup>85</sup> anoxic brain injury, and pancreatitis.<sup>41</sup> Rarely, local neuromuscular sequelae such as weakness, myalgia, and anterior tibial compartment syndrome are reported.<sup>13</sup> As expected, the prognosis is directly correlated with the delay to care and the subsequent duration and magnitude of the episodes of muscle contractions.<sup>31</sup>

## DIFFERENTIAL DIAGNOSIS

The diagnosis of strychnine poisoning is mainly established on clinical grounds, based on exposure history and compatible clinical manifestations, but can be confirmed by detection of strychnine in biological specimens. Several diagnoses are included, the most important of which is tetanus because it produces similar muscular hyperactivity. In a patient with tetanus, however, the onset of symptoms is more gradual and the duration of the complications much more protracted than in the case of strychnine poisoning. Frequently, the diagnosis of tetanus is suggested by a history of recent injury, injection drug use, or the presence of a wound. Additionally, patients with tetanus will often be unimmunized or have undocumented or incomplete tetanus immunization.

The motor activity associated with strychnine poisoning is best differentiated from generalized seizures by the presence of a normal sensorium during the period of diffuse convulsions. That is, most patients with bilateral convulsions are having generalized seizures, which by definition involves the reticular activating system, producing unconsciousness. It is conceivable, although extraordinarily rare, to have bilateral focal seizures producing apparent “generalized” convulsions. In the case of strychnine, because the reticular activating system is not involved, the mental status of the patient is classically preserved. The presence of consciousness in a patient with a generalized convulsion is highly suggestive of a diagnosis of either strychnine poisoning or tetanus, at least in the early phase of the clinical course. As time progresses and management is delayed this finding will be obscured by metabolically induced alterations in sensorium.<sup>17</sup> When there is an alteration in the level of consciousness, an electroencephalogram (EEG) is recommended, to document the presence or absence of a seizure focus. A computed tomography (CT) scan of the head will help to exclude structural brain lesions, and a lumbar puncture is helpful to exclude meningitis or encephalitis. Hypocalcemia, hyperventilation, and myoclonus secondary to kidney or liver failure are evaluated by appropriate routine laboratory testing. Although a drug induced dystonic reaction is reasonable to include in the differential diagnosis when there is a relevant history, dystonic reactions are usually static, whereas strychnine poisoning results in dynamic muscular activity. Serotonin toxicity, malignant hyperthermia, neuroleptic malignant syndrome, and stimulant-associated toxicity all resemble late phases of strychnine poisoning, but other features of the history or physical examination usually help distinguish them from either strychnine or tetanus.

## DIAGNOSTIC TESTING

Respiratory and metabolic acidosis both occur commonly in patients with strychnine poisoning. Metabolic acidosis is associated with elevated serum lactate concentrations,<sup>13</sup> whereas respiratory acidosis secondary to hypoventilation results from diaphragmatic and respiratory muscle failure. Survival of patients with serum pHs in the range of 6.5 to 6.6 is well

documented.<sup>13,29,30,32,54,94</sup> The lowest pH and highest lactate concentration reported in a patient with subsequent full recovery was 6.5 and 32 mmol/L,<sup>13,94</sup> respectively. Thus, profound acidemia in strychnine poisoning is not necessarily associated with a poor prognosis.<sup>7,8,13,73</sup> By contrast to the metabolic acidosis with elevated lactate concentration that occurs in shock, the elevated lactate concentration of strychnine poisoning results from overactivity of the muscle instead of undersupply or underutilization of oxygen and nutrients.

Besides acidemia, other laboratory abnormalities expected from prolonged muscular activity include hyperkalemia and those associated with rhabdomyolysis and acute kidney injury.<sup>13</sup> Other reported findings included stress-induced leukocytosis,<sup>13,41</sup> elevated aminotransferase concentrations,<sup>41,62,88</sup> hypocalcemia,<sup>13,39</sup> hypernatremia,<sup>32</sup> and hypokalemia.<sup>28,62,84</sup> The electrocardiogram is expected to remain normal or reflect changes consistent with the above electrolyte disturbances.<sup>39</sup> Chest radiography is appropriate to evaluate for aspiration pneumonitis or acute respiratory distress syndrome.

Strychnine can be detected by a variety of methods such as thin-layer chromatography,<sup>66</sup> high-performance liquid chromatography,<sup>2</sup> ultraviolet spectrometry,<sup>66</sup> a simple colorimetric reaction,<sup>66</sup> gas chromatography–mass spectrometry,<sup>14,57,69,78</sup> gas chromatography flame ionization detector,<sup>92</sup> and capillary electrophoresis.<sup>96</sup> With the exception of the bedside colorimetric reaction, none of these tests are routinely available in a time frame useful to assist in clinical decisions. Strychnine is also detectable in concentrations as low as 0.01 mg/L in tissue, and strychnine resists postmortem putrefaction.<sup>2,21,58,72</sup> Even when available, quantitative concentrations do not correlate with clinical toxicity. Reported blood strychnine concentrations in fatal poisoning ranged from 0.5 to 61 mg/L.<sup>92</sup> Conversely, the highest initial blood concentration associated with survival was 4.73 mg/L from blood drawn 1.5 hours postingestion;<sup>93</sup> a concentration as low as 0.06 mg/L was found in a patient who solely had muscular irritability.<sup>26</sup>

## MANAGEMENT

In patients with strychnine poisoning, inducing vomiting is absolutely contraindicated because of the risk of aspiration and loss of airway control following rapid onset of muscle contractions. Orogastric lavage is reasonable in patients with early presentations and or life-threatening ingestion histories (Chap. 5).<sup>3</sup> When orogastric lavage is reasonable, the airway should be protected and secured with an endotracheal tube before attempting lavage. Activated charcoal (AC) binds strychnine effectively at a ratio of approximately 1:1; 1 g of AC will bind 950 mg of strychnine.<sup>4,87</sup> In animal models, pretreatment<sup>67</sup> and posttreatment<sup>71</sup> with AC increase the median lethal dose in 50% of test subjects (LD<sub>50</sub>) for strychnine. Clinical evidence of the effectiveness of AC for strychnine ingestion was first demonstrated in 1831, when Professor Touery survived the ingestion of a lethal dose of strychnine by using AC in a demonstration before the French Academy of Medicine, thus a single dose of 1 g/kg of oral AC is recommended.

Currently, there is no evidence to recommend the use of multiple-dose AC or whole-bowel irrigation for strychnine poisoning. Forced diuresis was previously suggested as an effective means of enhancing the elimination of strychnine,<sup>87</sup> subsequent data failed to demonstrate an increase in clearance,<sup>81</sup> and it is not recommended. Peritoneal dialysis, hemodialysis, and hemoperfusion are been extensively studied. However, because strychnine is rapidly distributed to the tissues<sup>91</sup> with a large volume of distribution (13 L/kg), extracorporeal drug elimination procedures are unlikely to be useful and therefore not justified.

Supportive treatment remains the most important aspect of management in the majority of cases. The focus of care is to stop the muscular hyperactivity as soon as possible to prevent the metabolic and respiratory complications. At all times, unnecessary stimuli and manipulation of the patient should be avoided, as these activities trigger muscle contractions. Benzodiazepines remain the first-line treatment for strychnine-induced muscular hyperactivity.<sup>83,93</sup> Although much of the evidence concerning the efficacy of benzodiazepines is based on clinical experience with diazepam,<sup>37,45,64</sup> any of the other commonly used benzodiazepines (midazolam or lorazepam) would likely have similar effects. The initial dose

of the benzodiazepine chosen should be the standard dose used for other indications, although the use of doses greater than 1 mg/kg diazepam or its equivalent are reported to achieve control of convulsions.<sup>40,56</sup> Prior to establishing intravenous access, lorazepam or midazolam can be given intramuscularly or intraosseously. Dosing should be repeated at pharmacologically appropriate intervals until the patient demonstrates muscle relaxation and the contractions cease. In addition to benzodiazepines, propofol and barbiturates are also effective, although we recommend them as secondary therapies, in treating the strychnine-induced hyperactivity.<sup>36,51,74,86</sup> Benzodiazepines and barbiturates both work through agonism of  $\gamma$ -aminobutyric acid (GABA) receptor chloride complexes to increase the inhibitory neurotransmission to the spinal cord from the brain, and thus raise the reflex arc threshold.<sup>79</sup> If these measures fail to control the muscular hyperactivity, a nondepolarizing neuromuscular blocker (NMB) is recommended. Only nondepolarizing NMBs should be used, because succinylcholine itself, a depolarizing NMB, induces muscle contractions.<sup>13,26,51,64,81</sup> It is important to remember that strychnine has no direct effects on consciousness, so that sedation must always accompany neuromuscular blockade. Generally, therapy is continued for approximately 24 hours, at which time the benzodiazepines and/or NMBs can be tapered as tolerated.

The most important therapy for the metabolic complications of strychnine poisoning is to expeditiously stop the production of metabolic by-products by terminating the muscular hyperactivity. Hyperthermia should be treated rapidly by active cooling with ice water immersion, cooling blanket, or mist and fan, depending on the magnitude of temperature elevation (Chap. 29). Means to prevent rhabdomyolysis induced acute kidney injury include adequate fluid administration to ensure good urine output (>1 mL/kg/h), the use of urinary alkalization with sodium bicarbonate (Antidotes in Depth: A5),<sup>75</sup> and temporary renal replacement therapy, if acute kidney failure occurs. Metabolic acidemia rapidly resolves when muscular activity is controlled.<sup>13,68</sup>

Effective management in the first few hours of strychnine poisoning is crucial for survival. If the patient is supported adequately for the first 6 hours, this is generally a good prognostic sign.<sup>13,34</sup> All significantly poisoned patients should be managed in an intensive care unit with the help of a regional poison control center or a medical toxicologist. For asymptomatic patients unintentionally exposed to strychnine, an observation period of 12 hours is sufficient to exclude significant risk.

## SUMMARY

- Strychnine is a lethal poison that is no longer frequently encountered, except in areas where it is used as a rodenticide.
- A “conscious seizure” is the characteristic presentation of strychnine toxicity, and is rapidly followed by life threatening metabolic and respiratory consequences.
- The mainstay of treatment is supportive care with the goal of rapidly aborting muscular contractions, providing adequate airway management, and rapidly treating hyperthermia and/or metabolic abnormalities.
- Although benzodiazepines are generally sufficient, neuromuscular paralysis with a nondepolarizing NMB are required in refractory cases.
- Generally, the prognosis of strychnine poisoning is good, if the patient is adequately supported and survives the first 6 hours of toxicity.

## ARTHROPODS

Daniel J. Repplinger and In-Hei Hahn

### TAXONOMY

*Arthropoda* means “joint-footed” in Latin and describes the jointed bodies and legs connected to a chitinous exoskeleton of arthropods.<sup>5</sup> The majority of arthropods are benign to humans and environmentally beneficial. Some clinicians regard bites and stings as inconsequential and more of a nuisance than a threat to life. However, some spiders have toxic venoms that produce dangerous, painful lesions or significant systemic effects. Important clinical syndromes are produced by bites or stings from animals in the phylum Arthropoda, specifically the classes Arachnida (spiders, scorpions, and ticks) and Insecta (bees, wasps, hornets, and ants) (Table 115–1). Infectious diseases transmitted by arthropods, such as the various encephalitides, Rocky Mountain spotted fever, human anaplasmosis, babesiosis, ehrlichiosis, and Lyme disease, are not discussed in this chapter.

Arthropoda comprises the largest phylum in the animal kingdom. It includes more species than all other phyla combined (Fig. 115–1).<sup>5</sup> At least 1.5 million species are identified, and half a million or more are yet to be classified. Araneism (pertaining to spiders) or arachnidism (spiders including other arachnids) results from the envenomation caused by a spider bite. “Bites” are different from “stings.” Bites are defined as creating a wound using the oral pole with the intention for either catching or envenomating prey or blood feeding,<sup>93,194</sup> or for the purpose of feeding such as in arthropods that have mouthparts for chewing or sucking. “Stings” occur from a modified ovipositor at the aboral pole that is also able to function in egg laying as in bees and wasps. In scorpions the sting is not a modified ovipositor and the “tail” is not a tail but the metasoma section of the abdomen. Stinging behavior typically is used for defense. Most spiders are venomous, and the venom weakens the prey, enabling the spider to secure and digest their prey. However, there is one family of spiders, Uloboridae, which does not have a venom gland, a venom duct, or duct opening in the fangs. Spiders in general

are not aggressive toward humans unless they are provoked. The chelicerae (mouthparts composed of basal section and hinged fang) of many species have fangs that are too short to penetrate human skin.

Spiders are divided into categories based on whether they pursue their prey as hunters or trappers. Trappers snare their prey by spinning webs, then feed on their prey and enshrine excess victims in a cocoon silk to be eaten later. The order of spiders (Araneae) differs from other members of the class (Arachnida) because of various anatomic differences best assessed by an entomologist/arachnologist. Simplistically, the arachnids have 4 pairs of joined legs whereas insects have 3 pairs. The arachnid’s body is divided into 2 parts (cephalothorax and unsegmented abdomen, except for some spiders in Mesothelae and also some Mygalomorph {tarantula-type} relatives that have abdominal plates) connected by a small pedicel and 2, 3, or 4 pairs (Mesothelae contain up to 6 pairs) of spinnerets from which silk is spun. Two pedipalps are attached anteriorly on the cephalothorax on either side of their chelicerae and are used for sensation, manipulation of food and objects, and in males are modified for sperm transfer. Spiders have 8 eyes and are quite myopic, although there are instances when they have 2, 4, 6, or even no eyes. Prey is localized by touch as they land in the spider’s web, though not all spiders produce webs or use silk to capture prey. Most spiders use venom to kill or immobilize their prey. The spiders of medical importance in the United States include the widow spiders (*Latrodectus* spp), the violin spiders (*Loxosceles* spp), and the hobo spider (*Eratigena agrestis*). Although there is some disagreement as to the extent of the danger of hobo spiders in the United States, they are not considered dangerous in Europe. In Australia, the funnel web spider (*Atrax robustus*) and *Hadronyche* species cause serious illness and even death. In South America, the Brazilian Huntsmen (*Phoneutria fera*) and Brazilian armed spider, Aranha Armadeira (*Phoneutria nigriventer*) are threats to humans.

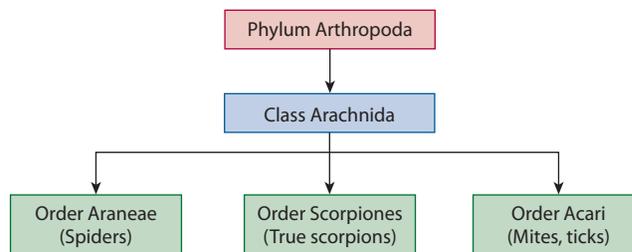

**TABLE 115–1** North American Insects and Other Arthropods That Bite, Sting, or Nettle Humans

Arthropod	Description
Honeybee ( <i>Apis mellifera</i> )	Hairy, yellowish brown with black markings
Bumblebee and carpenter bee ( <i>Bombus</i> spp and <i>Xylocopa</i> spp)	Hairy, larger than honeybees and colored black and yellow
Vespid (yellow jackets, hornets, paper wasps)	Short-waisted, robust, black and yellow or white combination
Schecoids (thread-waisted wasps)	Threadlike waist
Nettling caterpillars (browntail, lo, hag, and buck moths, saddleback and puss caterpillars)	Caterpillar shaped
Southern fire ant ( <i>Solenopsis</i> spp)	Ant shaped
Spiders ( <i>Arachnida</i> ) black widow, brown recluse	Body with 2 regions: cephalothorax and abdomen; 8 legs
Scorpions ( <i>Centruroides</i> )	Eight-legged, crablike, stinger at the tip of the abdomen; pedipalps (pincers) highly developed (not a true insect)
Centipedes ( <i>Chilopoda</i> )	Elongated, wormlike, with many jointed segments and legs; one pair of poison fangs behind head

### HISTORY AND EPIDEMIOLOGY

Since the time of Aristotle, spiders and their webs were used for medicinal purposes. Special preparations were concocted to cure a fantastic array of ailments, including earache, running of the eyes, “wounds in the joints,” warts, gout, asthma, “spasmodic complaints of females,” chronic hysteria, cough, rheumatic afflictions for the head, and stopping blood flow.<sup>228</sup>

One *Latrodectus* species has an infamous history of medical concern, hence the name *mactans*, which means “murderer” in Latin.<sup>182</sup> Hysteria regarding spider bites peaked during the 17th century in the Taranto region of Italy. The syndrome tarantism, which is characterized by lethargy, stupor, and a restless compulsion to walk or dance, was blamed on *Lycosa tarantula*, a spider that pounces on its prey like a wolf. Deaths were associated with these outbreaks. Dancing the rapid tarantella to music was the presumed remedy. The real culprit in this epidemic was *Latrodectus tredecimguttatus*.<sup>182</sup>

**FIGURE 115–1.** Taxonomy of the phylum Arthropoda.

**TABLE 115–2** North American Spiders of Medical Importance

Genus	Common Name
<i>Araneus</i> spp	Orb weaver
<i>Argiope</i> spp	Orange argiope
<i>Bothriocyrtum</i> spp	Trap door spider
<i>Chiracanthium</i> spp	Running spider
<i>Drassodes</i> spp	Gnaphosid spider
<i>Heteropoda</i> spp	Huntsman spider
<i>Latrodectus</i> spp	Widow spider
<i>Liocranoides</i> spp	Running spider
<i>Loxosceles</i> spp	Brown, violin, or recluse spider
<i>Lycosa</i> spp	Wolf spider
<i>Misumenoides</i> spp	Crab spider
<i>Neoscona</i> spp	Orb weaver
<i>Peucetia</i> spp	Green lynx spider
<i>Phidippus</i> spp	Jumping spider
<i>Rheostica (Aphonopelma)</i> spp	Tarantula
<i>Steatoda grossa</i>	False black widow spider
<i>Eratigena</i> spp	Hobo spider
<i>Ummidia</i> spp	Trap door spider

Other epidemics of arachnidism occurred in Spain in 1833 and 1841.<sup>153</sup> In North America, there was an increase in spider bites during the late 1920s; Rome reported large numbers in 1953; Yugoslavia reported a large number of cases between 1948 and 1953.<sup>33,153</sup> These epidemics may be related to actual reporting biases as well as climatic variations.<sup>182</sup> Spider bites are more numerous in warmer months, presumably because both spiders and humans are more active during that season.

Approximately 200 species of spiders are associated with envenomations.<sup>191,195</sup> Eighteen genera of North American spiders produce poisonings that require clinical intervention (Table 115–2). In one series of 600 suspected spider bites, 80% were determined to result from arthropods other than spiders, such as ticks, bugs, mites, fleas, moths, butterflies, caterpillars, flies, beetles, water bugs, and some members (ants, bees, wasps) of order Hymenoptera. Ten percent of the presumed bites actually were manifestations of other nonarthropod disorders.<sup>193,195</sup>

From 2011 through 2015, an annual average of approximately 8500 spider exposures and 34,000 insect exposures were reported to US poison control centers (Chap. 130). Over this time, only 5 fatalities were reported, 3 of which were from the Hymenoptera category. Overall, this represents a marked decline in reported cases over the last decade. From 2006 to 2007, an annual average of 14,000 spider exposures and 44,000 insect exposures were reported to US poison control centers. No more than 2 fatalities were reported per year. One was from the Hymenoptera category, and the other was an unknown spider exposure. Although the total number of reported cases has declined dramatically, the average number of fatal exposures remains stable (Chap. 130).

Most information on the clinical presentation of spider bites continues to be unreliable because it is based on case reports and case series. Frequently, the cases do not have any expert confirmation of the actual spider involved, which propagates misinformation about different spiders, particularly with necrotic arachnidism. For example, cutaneous anthrax was mistaken for a cutaneous necrotic spider bite.<sup>190</sup> Additionally, the white tail spider (*Lampona* spp) was suspected for more than 20 years to cause necrotic lesions. Ultimately a prospective study of confirmed spider bites refuted this myth by reporting more than 700 confirmed spider bites in Australia.<sup>124–126</sup> Because most arthropod-focused research involves characterizing the structure of spider toxins rather than verifying clinical presentations, it is important to produce clinical studies that have bites confirmed by the presence of the spider that is identified by an expert. Definite spider bites or stings are established by (1) evidence of a bite or sting soon after the incident or the creature is seen to bite or sting and (2) collection of the particular creature, either alive or dead, with positive identification of the creature by an expert biologist/taxonomist in the field relating to the creature.<sup>125,127</sup>

### BLACK WIDOW SPIDER (*LATRODECTUS MACTANS*; HOURGLASS SPIDER)

Five species of widow spiders are found in the United States: *Latrodectus mactans* (black widow; Fig. 115–2A), *Latrodectus hesperus* (Western black widow), *Latrodectus variolus* (found in New England, Canada, south to Florida, and west to eastern Texas, Oklahoma, and Kansas), *Latrodectus bishopi* (red widow of the South), and *Latrodectus geometricus* (brown widow or brown button spider; Fig. 115–2B). They are present in every state except for Alaska. Dangerous widow spiders in other parts of the world include *L. geometricus* and *Latrodectus tredecimguttatus* (European widow spider found in southern Europe), *Latrodectus hasselti* (red back widow spider found in Australia, Japan, and India; Fig. 115–2C), and *Latrodectus cinctus* (found in South Africa). These spiders live in temperate and tropical latitudes in places such as stone walls, crevices, wood piles, outhouses, barns, stables, and rubbish piles. They molt multiple times and as a result can change colors. The ventral markings on the abdomen are species specific, and the classic red hourglass-shaped marking is noted in only *L. mactans*. Other species have variations on their ventral surface, such as triangles and spots.

A

B

C

**FIGURE 115–2.** Widow spiders. (A) The North American black widow spider, *Latrodectus mactans*. Note the hourglass on the abdomen. (B) The brown widow spider, *Latrodectus geometricus*. (C) The Australian red back spider, *Latrodectus hasselti*. (Used with permission from the American Museum of Natural History.)

Typically, the female *L. mactans* is shiny, jet-black, and large (8–10 mm), with a rounded abdomen and a red hourglass mark on its ventral surface. Her larger size and ability of her fangs to penetrate human skin make her more venomous and toxic than the male spider, which resembles the immature spider in earlier stages of development and is smaller, lighter in color, and has a more elongated abdomen and fangs that usually are too short to envenomate humans (Table 115–3). Black widow females are trappers and inhabit large, untidy, irregularly shaped webs. Webs are placed in or close to the ground and in secluded, dimly lit areas that can trap flying insects, such as outdoor privies, barns, sheds, and garages.<sup>5</sup>

### Pathophysiology

The venom is more potent on a volume-per-volume basis than the venom of a pit viper and contains 7 active components with molecular weights of 5,000 to 130,000 Da.<sup>5</sup> The 7 components are 5 latroinsectotoxins ( $\alpha$ -,  $\beta$ -,  $\gamma$ -,  $\delta$ -,  $\epsilon$ -LITs) (insect-specific neurotoxins),  $\alpha$ -latrocrustatoxin ( $\alpha$ -LCT)

(crustacean-specific neurotoxin), and  $\alpha$ -latrotoxin (vertebrate-specific neurotoxin).<sup>102</sup>  $\alpha$ -Latrotoxin binds, with nanomolar affinity, to the specific presynaptic receptors neurexin I- $\alpha$  and Ca<sup>2+</sup>-independent receptor for  $\alpha$ -latrotoxin (CIRL), otherwise known as *latrophilin*.<sup>30,111,123</sup> The binding triggers a cascade of events: conformational change allowing pore formation by tethering the toxin to the plasma membrane; Ca<sup>2+</sup> ionophore formation; translocation of the N-terminal domain of  $\alpha$ -LTX into the presynaptic intracellular space, and intracellular activation of exocytosis of norepinephrine, dopamine, neuropeptides, acetylcholine, glutamate, and  $\gamma$ -aminobutyric acid (GABA), respectively. This massive release of neurotransmitters is what causes the clinical envenomation syndrome known as latrodectism.<sup>5,169,193</sup>

### Clinical Manifestations

Widow spiders are shy and nocturnal. They usually bite when their web is disturbed or upon inadvertent exposure in shoes and clothing. A sharp pain typically described as a pinprick occurs as the victim is bitten. A pair of red

**TABLE 115–3** Brown Recluse and Black Widow Spiders: Comparative Characteristics

	<i>Brown Recluse (Loxosceles spp)</i>	<i>Black Widow (Latrodectus spp)</i>
Description of the spider	Female brown, 6–20 mm, violin-shaped mark on dorsum of cephalothorax; female greater toxicity than male	Female: jet black, 8–10 mm, red hourglass mark on ventral surface, female greater toxicity than male. Male: smaller and lighter in color, often with red or white markings on dorsal surface
Major venom component	Sphingomyelinase D	$\alpha$ -Latrotoxin
Pathophysiology of envenomation	Vascular injury, dermatonecrosis, hemolysis	Massive presynaptic discharge of neurotransmitters; lymphatic and hematogenous spread, neurotoxicity
Epidemiology	Bites more common in warmer months  North America (southern and Midwestern states): <i>L. reclusa</i> South America: <i>L. laeta</i> , <i>L. gaucho</i> Europe: <i>L. rufescens</i> Africa (southern): <i>L. parrami</i> , <i>L. spiniceps</i> , <i>L. pilosa</i> , <i>L. bergeri</i> Asia/Australia: Rare	Bites more common in warmer months in subtropical and temperate areas; perennial in tropics North America: <i>L. mactans</i> , <i>L. hesperus</i> , <i>L. geometricus</i> Europe: <i>L. tredecimguttatus</i> Africa (southern): <i>L. indistinctus</i> Australia: <i>L. hasselti</i> Asia/South America: Rare
Clinical effects	Cutaneous Initial (0–2 hours after bite): Painless, erythema, edema 2–8 hours: Hemorrhagic, ulcerates, painful 1 week: Eschar  Months: Healing  Hematologic Methemoglobinemia, hemolysis, thrombocytopenia, disseminated intravascular coagulopathy  Renal: Kidney failure, acute tubular necrosis	Cutaneous Initial (5 minutes–1 hour after bite): Local pain 1–2 hours: Puncture marks Hours: Regional lymph nodes swollen, central blanching at bite site with surrounding erythema  CVS: Initial tachycardia followed by bradycardia, dysrhythmias, initial hypotension followed by hypertension GI: Nausea, vomiting, mimic acute abdomen Hematologic: Leukocytosis  Resolution over several days Metabolic Hyperglycemia (transient) Musculoskeletal: Hypertonia, abdominal rigidity, “facies latrodectismica” Neurologic CNS: Psychosis, hallucinations, visual disturbance, seizures Peripheral nervous system: Pain at the site Autonomic nervous system: Increased secretions; sweating, salivation, lacrimation, diarrhea, bronchorrhea, mydriasis, miosis, priapism, ejaculation Renal: Glomerulonephritis, oliguria, anuria Respiratory: Bronchoconstriction, acute respiratory distress syndrome
Treatment	Analgesia Wound care	Analgesia Muscle relaxants Antivenom

spots often evolve at the site, although the bite is commonly unnoticed.<sup>49,152</sup> The bite mark itself tends to be limited to a small puncture wound or wheal and flare reaction that often is associated with a halo (Table 115–3). However, the bite from *L. mactans* produces *latroductism*, a constellation of signs and symptoms resulting from systemic toxicity. Some cases do not progress; others show severe neuromuscular effects within 30 to 60 minutes. The effects from the bite spread contiguously. For example, if a person is bitten on the hand, the pain progresses up the arm to the elbow, shoulder, and then toward the trunk during systemic poisoning. Typically, a brief time to symptom onset denotes severe envenomation. One patient developed latroductism following the intentional intravenous injection of a crushed whole black widow spider.<sup>41</sup>

One grading system divides the severity of the envenomation into 3 categories.<sup>56</sup> Grade 1 envenomations range from no symptoms to local pain at the envenomation site with normal vital signs. Grade 2 envenomations involve muscular pain at the site with migration of the pain to the trunk, diaphoresis at the bite site, and normal vital signs. Grade 3 envenomations include the grade 2 findings with abnormal vital signs; diaphoresis distant from the bite site; generalized myalgias to back, chest, and abdomen; and nausea, vomiting, and headache.

The myopathic syndrome of latroductism involves muscle cramps that usually begin 15 to 60 minutes after the bite. The muscle cramps initially occur at the site of the bite, but later involves rigidity of other skeletal muscles, particularly muscles of the chest, abdomen, and face. The pain increases over time and occurs in waves that cause the patient to writhe. Large muscle groups are affected first. Classically, severe abdominal wall spasm occurs and is confused with a surgical abdomen, especially in children who cannot relate the history to the initial bite.<sup>38</sup> Muscle pain often subsides within a few hours but can recur for several days. Transient muscle weakness and spasms is reported to persist for weeks to months.

Additional clinical findings include “facies latroductismica,” which consists of sweating, contorted, grimaced face associated with blepharitis, conjunctivitis, rhinitis, cheilitis, and trismus of the masseters.<sup>152</sup> A fear of death, *pavor mortis*, is described.<sup>152</sup> Nausea, vomiting, sweating, tachycardia, hypertension, muscle cramping, restlessness, compartment syndrome at the site of the bite, and, rarely, priapism are also reported.<sup>5,57,116,215</sup> The mechanism of compartment syndrome developing after a black widow spider envenomation is unclear, but 2 postulated theories include rhabdomyolysis and the venom affecting the blood vessels leading to engorgement and obstruction of the venous outflow. In one case, the compartment syndrome was treated with antivenom, and the patient recovered without the need for a fasciotomy.<sup>57</sup> Recovery usually ensues within 24 to 48 hours, but clinical findings are reported to last several days with more severe envenomations. Life-threatening complications include severe hypertension, respiratory distress, myocardial infarction, cardiovascular failure, and gangrene.<sup>41,56-78,163,178,182</sup> In the past 20 years, more than 40,000 presumed black widow spider bites were reported to the American Association of Poison Control Centers (Chap. 130). Death is rarely reported. There were 2 reported fatalities in Madagascar from envenomation by *L. geometricus*, one from cardiovascular failure and the other from gangrene of the foot.<sup>182</sup> The most recent fatality reported from Greece resulted from myocarditis secondary to envenomation by *L. tredecimguttatus*,<sup>181</sup> confirmed by a local veterinarian. The patient developed severe dyspnea, hypoxemia, cyanosis, cardiomyopathy, and global hypokinesia of the left ventricle confirmed by echocardiography, followed by death 36 hours later; antivenom was not available. On autopsy, diffuse interstitial and alveolar edema, with mononuclear infiltrate of the myocardium and degenerative changes, were noted, and toxicologic analysis for xenobiotics, as well as all blood, urine, bronchial, serologic, and viral cultures, were negative. The paucity of death is presumed to result from the improvement in medical care, the availability of antivenom, or the limited toxicity of the spider.

### Diagnostic Testing

Laboratory data generally are not helpful in management or predicting outcome. According to one study, the most common findings include

leukocytosis and increased creatine phosphokinase and lactate dehydrogenase concentrations.<sup>56</sup> Currently, no specific laboratory assay is capable of confirming latroductism. However, the clinical situation, such as suspected compartment syndrome, would warrant the need to check laboratory tests and other studies to evaluate the sequelae of the black widow spider envenomation.

### Management

Treatment involves establishing an airway and supporting respiration and circulation, if indicated. Wound evaluation and local wound care, including tetanus prophylaxis, are essential.<sup>237</sup> The routine use of antibiotics is not recommended.

Pain management is a substantial component of patient care and depends on the clinical findings. Using the grading system, grade 1 envenomations require only cold packs and orally administered nonsteroidal antiinflammatory drugs. For grade 2 and 3 envenomations, intravenous (IV) opioids and benzodiazepines are often reasonable for pain control and muscle spasm.

In the past, 10 mL 10% calcium gluconate solution was given IV to decrease cramping. However, a retrospective chart review of 163 patients envenomated by the black widow concluded that calcium gluconate was ineffective for pain relief compared with a combination of IV opioids and benzodiazepines.<sup>56,138</sup> Another study found greater neurotransmitter release when extracellular calcium concentrations were increased, suggesting that administration of calcium is irrational in patients suffering from latroductism.<sup>191</sup> The mechanism of action of calcium remains unknown, and its efficacy is anecdotal; therefore, we do not recommend calcium administration for pain management.

Although often recommended, methocarbamol (a centrally acting muscle relaxant) and dantrolene also are ineffective for treatment of latroductism.<sup>138,196</sup> A benzodiazepine, such as diazepam, is more effective for controlling muscle spasms and achieves sedation, anxiolysis, and amnesia. Management should primarily emphasize supportive care, with opioids and benzodiazepines for controlling pain and muscle spasms, because the use of antivenom risks anaphylaxis and serum sickness.

*Latroductus* antivenom (Merck) is rapidly effective and curative. In the United States the antivenom formulation is effective for all species, but is available as a crude hyperimmune horse serum that is reported to cause anaphylaxis and serum sickness. The morbidity of latroductism is high, with pain, cramping, and autonomic disturbances, but mortality is low. Hence controversy exists over when to administer the black widow antivenom (BW-AV). We recommend BW-AV for severe reactions (eg, hypertensive crisis or intractable pain), to high-risk patients (eg, pregnant women suffering from a threatened abortion), or for treatment of priapism.<sup>138,182</sup> The usual dose is one to two vials diluted in 50 to 100 mL 5% dextrose or 0.9% sodium chloride solution, with the combination infused over 1 hour (Antidotes in Depth: A37). Skin testing may elicit a hypersensitivity reaction to horse serum but the absence of a reaction does not exclude the occurrence of hypersensitivity reactions; therefore, we recommend against skin testing. An observational case series of 96 patients who received BW-AV found no cases of shortness of breath, angioedema, bronchospasm, hypotension, or death. In this series, adverse events occurred in 4% and were deemed mild to moderate and treated supportively.<sup>172</sup> However, an anaphylactic reaction to the BW-AV was reported after a negative skin test in both a boy and a man<sup>121,166</sup> who subsequently died from the anaphylactic reaction. Both were being treated for intractable pain after failing intravenous opioid management. Pretreatment with histamine H<sub>1</sub>- or H<sub>2</sub>-antagonists, or both, and epinephrine is beneficial in preventing histamine release and anaphylaxis. Patients with allergies to horse serum products and those who have received antivenom or horse serum products are at risk for immunoglobulin E (IgE)-mediated hypersensitivity reactions and, though efficacy is largely unproven, it is reasonable to pretreat with antihistamines and corticosteroids and have epinephrine available.

A purified F(ab')<sub>2</sub> fragment *Latroductus mactans* antivenom, Analatro, recently underwent a phase 2 clinical trial and is currently being investigated

in a phase 3 trial (Antidotes in Depth: A37). Antivenin *Latrodectus* Equine Immune F(ab')<sub>2</sub> is currently available in Mexico but not yet FDA approved in the United States. This randomized trial included 24 patients and found no statistically significant difference in overall pain reduction compared to placebo, but the patients receiving antivenom had more rapid reduction of pain. No significant adverse events occurred in either group, specifically no incidence of anaphylaxis or anaphylactoid reactions.<sup>67</sup> However, as a phase 2 trial, this study was intended to examine efficacy and cannot be interpreted to establish safety.

In Australia, a purified equine-derived IgG-F(ab')<sub>2</sub> antivenom for the red back spider *L. hasselti* (RBS-AV) is available. The RBS-AV (CSL, Melbourne, Australia) is administered intramuscularly and given as first-line therapy to patients presenting with systemic signs or symptoms in Australia. Since its introduction in 1956, no deaths were reported, and the incidence of mild allergic reactions to RBS-AV was only 0.54% in 2,144 uses.<sup>224</sup>

However, an underpowered prospective cohort study of confirmed red back spider bites failed to show that intramuscular antivenom was better than no treatment when all patients were followed over a one-week period.<sup>126</sup> This study did note that only 17% of patients were pain-free at 24 hours with antivenom treatment. Therefore, intramuscular antivenom appears to be less effective than previously thought, and the route of administration requires review. A monoclonal Fab specific for the  $\alpha$ -latrotoxin was demonstrated to be highly effective in neutralizing the toxin *in vivo* in mice and shows promise for study in humans for severe black widow spider envenomation.<sup>12,39</sup> Inadvertent use of RBS-AV successfully treated envenomations from the comb-footed spider (*Steatoda* spp),<sup>127</sup> and the *Steatoda* venom and clinical effects are similar to the *Latrodectus* venom but milder in clinical presentation.<sup>100</sup>

### BROWN RECLUSE SPIDER (*LOXOSCELES RECLUSA*; VIOLIN OR FIDDLEBACK SPIDER)

*Loxosceles reclusa* was confirmed to cause necrotic arachnidism in 1957, although reports of systemic effects following brown spider bites have appeared since 1872.<sup>10</sup> This spider has a brown violin-shaped mark on the dorsum of the cephalothorax, 3 dyads of eyes arranged in a semicircle on top of the head, and legs that are 5 times as long as the body. It is small (6–20 mm long) and gray to orange or reddish brown (Fig. 115–3A). *Loxosceles* spiders weave irregular white, flocculent adhesive webs that line their retreats.<sup>89</sup> Spiders in the genus *Loxosceles* have a worldwide distribution. In the United States, other species of this genus, which include *L. rufescens*, *L. deserta*, *L. devia*, and *L. arizonica*, are prominent in the Southeast and Southwest.<sup>9</sup> *L. rufescens* was inadvertently introduced in several buildings in New York City. Though it is unclear how they initially arrived there, they were most likely transported on personal belongings and cartons of materials.<sup>212</sup> They are hunter spiders that live in dark areas (wood piles, rocks, basements), and their foraging is nocturnal. They are not aggressive but will bite if antagonized (Table 115–3). These spiders live up to 2 or more years. They are resilient and can survive up to 6 months without water or food and can tolerate temperatures from 46.4°F to 109.4°F (8°–43°C).<sup>98</sup> Like the black widow spider, the female is more dangerous than the male. *Loxosceles* venom has variable toxicity, depending on the species, with *Loxosceles intermedia* venom causing more severe clinical effects in humans.<sup>15,16</sup> The peak time for envenomation is from spring to autumn, and most victims are bitten in the morning. One study examined 182 patients enrolled over 23 months who presented to the emergency department (ED) for a chief complaint of spider bite. The study found that only 3% (7/182) were ultimately confirmed by their treating physician to have the diagnosis of a spider bite, whereas 84% (152/182) had a skin and soft tissue infection (SSTI), 9 patients were bitten by other animals; 6 patients were given other non-bite diagnoses, such as erythema multiforme, subcutaneous nodules, and folliculitis; and 8 patients had no diagnostic category recorded. Of the 7 patients who had a confirmed spider bite, only one brought the spider in for identification, whereas the others saw a spider or witnessed a bite, and one patient did not witness or feel a bite.<sup>218</sup> Community-acquired methicillin-resistant *Staphylococcus aureus*

(B) A typical envenomation from the brown recluse spider. (Used with permission from the Fellowship in Medical Toxicology, New York University School of Medicine, New York City Poison Center.)

(MRSA) was the most common cause of skin and soft tissue injuries (SSTIs), accounting for 70% of positive wound cultures performed. Hence the spider bite diagnosis is frequently misused, and a diagnosis of dermatonecrotic wound of uncertain etiology would be more accurate.<sup>218</sup>

### Pathophysiology

The venom is cytotoxic. The 2 main constituent enzymes of the venom are sphingomyelinase D and hyaluronidase, though other subcomponents include deoxyribonuclease, ribonuclease, collagenase, esterase, proteases, alkaline phosphatase, and lipase.<sup>66,143,233</sup> Hyaluronidase is a spreading factor that facilitates the penetration of the venom into tissue but does not induce lesion development.<sup>143</sup> Sphingomyelinase D is the primary constituent of the venom that causes necrosis and red blood cell hemolysis and also causes platelets to release serotonin.<sup>143</sup> Sphingomyelinase also reacts with sphingomyelin in the red blood cell membrane to release choline and *N*-acylsphingosine phosphate, which triggers a chain reaction, releasing inflammatory mediators, such as thromboxanes, leukotrienes, prostaglandins, and neutrophils, leading to vessel thrombosis, tissue ischemia, and skin loss.<sup>143</sup> Early perivascular collections of polymorphonuclear leukocytes with hemorrhage and edema progress to intravascular clotting. Coagulation and vascular occlusion of the microcirculation occurs, ultimately leading to necrosis.<sup>208</sup>

## Clinical Manifestations

The clinical spectrum of loxoscelism is divided into 3 major categories. The first category includes bites in which very little, if any, venom is injected. A small erythematous papule appears, which then becomes firm before healing and is associated with a localized urticarial response. In the second category, the bite undergoes a cytotoxic reaction. The bite initially is reported to be painless or have a stinging sensation, followed by blistering, bleeding, and ulceration 2 to 8 hours later (Table 115–3). The lesion then increases in diameter, with demarcation of central hemorrhagic vesiculation, then ulceration, the development of violaceous necrosis surrounded by ischemic blanching of skin and outer erythema and, finally induration over 1 to 3 days. This is also known as the “red, white, and blue” reaction (Fig. 115–3B).<sup>139,243</sup> Necrosis of the central blister occurs in 3 to 4 days, with eschar formation between 5 and 7 days. After 7 to 14 days, the wound becomes indurated and the eschar falls off, leaving an ulceration that heals by secondary intention. Local necrosis is more extensive over fatty areas (thighs, buttocks, and abdomen).<sup>143</sup> The size of the ulcer determines the time for healing. Large lesions up to 30 cm require months or more to heal.

Upper airway obstruction was reported in a child who was bitten on his neck and subsequently developed progressive cervical soft tissue edema with airway obstruction and dermatonecrosis 40 hours later.<sup>97</sup> Another case reported stridor and respiratory distress following a brown recluse envenomation of the ear. Although the presentation is rare, respiratory status should be evaluated when an envenomation occurs on the head and neck.<sup>92</sup>

The third category consists of systemic loxoscelism, which is not predicted by the extent of cutaneous reaction, and occurs 24 to 72 hours after the bite. The young are particularly susceptible.<sup>96,197</sup> The clinical manifestations of systemic loxoscelism include fever, chills, weakness, edema, nausea, vomiting, arthralgias, petechial eruptions, rhabdomyolysis, disseminated intravascular coagulation, hemolysis that is reported to progress to hemoglobinuria, acute kidney injury, and death.<sup>27,44,85,96,150,203,240</sup> However, in North America, the incidence of systemic illness and mortality is rare.<sup>7</sup>

## Diagnostic Testing

Bites from other spiders, such as *Cheiracanthium* (sac spider), *Phidippus* (jumping spider), and *Argiope* (orb weaver), also produce necrotic wounds. These spiders are often the actual culprits when the brown recluse is mistakenly blamed. Definitive diagnosis is achieved only when the biting spider is positively identified. No routine laboratory test for loxoscelism is available for clinical application, but several techniques are presently used for research purposes. The lymphocyte transformation test measures lymphocytes that have undergone blast transformation up to one month after exposure to *Loxosceles* venom. The lymphocytes incorporate thymidine into the nucleoprotein, providing a quantitative assay.<sup>8</sup> A passive hemagglutination inhibition test (PHAI) was developed in guinea pigs. The PHAI assay is based on the property of certain brown recluse spider venom components to spontaneously adsorb to formalin-treated erythrocyte membranes and the ability of the brown recluse spider venom to inhibit antiserum-induced agglutination of venom-coated red blood cells.<sup>18</sup> The test is 90% sensitive and 100% specific for 3 days postenvenomation and is useful for early diagnosis of brown recluse spider envenomation.<sup>18</sup> An enzyme-linked immunoassay (ELISA) test specific for *Loxosceles* venom in biopsied tissue can confirm the presence of venom for 4 days postenvenomation,<sup>18</sup> and in an experimental model using rabbits, the antigen was recoverable using the ELISA assay from 14 to 21 days.<sup>155</sup> The drawbacks of using a skin biopsy are the invasive nature of the procedure, which can result in further scarring with an increased potential for infection, and the lack of proof that skin biopsy is able to diagnose early envenomations prior to the development of dermatonecrosis. Another ELISA test utilizing serum for detection of venom antigens was developed that correctly discriminates the mice inoculated with antigens from *L. intermedia* venom. The ELISA immunoassay test and antivenom would become useful diagnostic tools if envenomation is proved or disproved early.<sup>53</sup> A venom-specific enzyme immunoassay that uses hair, skin biopsies, or aspirated

tissue near a suspected lesion to detect the presence of venom up to 7 days after injury is under investigation.<sup>142,159</sup> In Brazil, ELISA testing is used to detect the venom of *Loxosceles gaucho* in wounds and patient sera, but the technique is not in widespread clinical use.<sup>49</sup>

Clinical laboratory data include the findings of hemolysis, hemoglobinuria, and hematuria. Coagulopathy is often present, with laboratory data significant for elevated fibrin split products, decreased fibrinogen concentrations, and a positive D-dimer assay. Other tests include increased prothrombin time (PT) and partial thromboplastin time (PTT), leukocytosis (up to 20,000–30,000 cells/mm<sup>3</sup>), spherocytosis, Coombs-positive hemolytic anemia, thrombocytopenia, or abnormal kidney and liver function tests.<sup>5,12,89,193,195,197,238</sup>

## Treatment

Optimal local treatment of the lesion is controversial. The most prudent management of the dermatonecrotic lesion is wound care, immobilization, tetanus prophylaxis, analgesics, and antipruritics as warranted (Table 115–4).<sup>5,89,235,238</sup> Early excision or intralesional injection of corticosteroids appears unwarranted.<sup>188</sup> Corrective surgery can be performed several weeks after adequate tissue demarcation has occurred. In one case series, the use of curettage of the lesion to remove necrotic and indurated tissue from the lesion, thus eliminating any continuing action of the lytic enzymes on the surrounding tissue.<sup>114</sup> These patients had wound healing without further necrosis and minimal scarring. Vacuum-assisted closure, otherwise known as negative-pressure wound therapy, is also described in a series of clinical cases in the surgical literature as a means to treat necrotic wounds caused by presumed brown recluse spider bites more quickly than the traditional methods, due to increased bacterial clearance and dermal perfusion, modulating the inflammatory response, extracting toxic substances, and accelerated rate of granulation tissue formation.<sup>241</sup> Electric shock delivered via stun guns was not found to be useful in a guinea pig envenomation model.<sup>18</sup> Cyproheptadine, a serotonin antagonist, was not beneficial in a rabbit model.<sup>175</sup> A randomized, controlled study evaluating the efficacy of topical nitroglycerin for envenomated rabbits showed no difference in preventing dermatonecrosis and suggested the possibility of increased systemic toxicity.<sup>147</sup> Additionally, intradermal injection of trypsin failed to show any benefit in a guinea pig model.<sup>42</sup> Antibiotics are recommended to treat cutaneous or systemic infections when present, but they are not recommended prophylactically.

Early use of dapsone (in patients who develop a central purplish bleb or vesicle within the first 6–8 hours) is reported to inhibit local infiltration of the wound by polymorphonuclear leukocytes.<sup>139</sup> The dosage previously recommended was 100 mg twice daily for 2 weeks.<sup>186</sup> However, prospective trials with large numbers of patients are lacking. One study compared the efficacy of erythromycin and dapsone therapy, erythromycin and antivenom therapy, and erythromycin, dapsone, and antivenom therapy (developed in rabbits based on a previous study).<sup>185</sup> Although the treatment groups were very small, all groups showed wound healing at approximately 20 days despite the different therapies used. The major limitation of the study includes the definition of a spider bite diagnosis (the study used the following criteria: a patient feeling the spider bite, seeing the spider, or having a clinically plausible necrotic

**TABLE 115–4 Management of Brown Recluse Spider Bite**

General Wound Care	Local Wound Care	Systemic
Clean	Serial observations	Antipruritic/antianxiety and/or analgesics
Tetanus prophylaxis as indicated	Natural healing by granulation	Antibiotics for secondary bacterial infection
Immobilize and elevate bitten extremity	Delayed primary closure	Antivenom (experimental)
Apply cool compresses; avoid local heat	Delayed secondary closure with skin graft	
	Gauze packing, if applicable	

lesion). The study suggests that the use of dapsone may eliminate the need for surgery following bites and that antivenom therapy was most effective clinically if the patient never developed the necrotic lesion. However, there is not enough information to recommend the use of dapsone in the management of *Loxosceles* envenomation at this time. Hepatitis, methemoglobinemia (Chap. 124), and hemolysis are associated with dapsone use.<sup>189</sup>

An underpowered animal study evaluated the effects on the size of skin lesions induced by *Loxosceles* envenomation by treatment with hyperbaric oxygen therapy, dapsone, and combined hyperbaric oxygen therapy and dapsone.<sup>112</sup> The study concluded that there was no clinically significant change in necrosis or induration by these treatment modalities. Further evaluation of these interventions remains appropriate. Another study using hyperbaric oxygen for treatment of *Loxosceles*-induced necrotic lesions in rabbits revealed no clinical improvement in the size of the lesion; however, the histology of the lesions improved. Whether this finding is of consequence is unknown.<sup>112,217</sup> There is currently not enough evidence to recommend hyperbaric oxygen therapy for *Loxosceles* envenomation. Although the use of colchicine, a leukocyte inhibitor, was previously recommended, we do not advocate this treatment because of potential colchicine toxicity.<sup>193</sup> Rabbit-derived intradermal  $\alpha$ -anti-*Loxosceles* Fab ( $\alpha$ -Loxd) fragments attenuated the dermatonecrotic inflammation of rabbits injected with *L. deserta* venom in a time-dependent fashion.<sup>94</sup> At time 0 after envenomation, no lesion developed was blocked. At time 1 and 4 hours after envenomation, the  $\alpha$ -anti-Loxd Fab antivenom continued to suppress lesion development, although the longer the delay in treatment, the smaller the difference in treatment and control lesion areas. At time 8 and 12 hours post-envenomation, there was no difference in lesion size. The typical 24-hour delay in lesion development makes the diagnosis difficult, and the antivenom would likely be useless if administered late in the clinical course. The antivenom is not available for commercial use.

One preclinical study investigating treatment of *Loxosceles* envenomations used an antiloxoscelic serum that was produced from recombinant sphingomyelinase D that was derived from the sphingomyelinase of the *L. intermedia* and *L. laeta* spiders. The isolated sphingomyelinase from the respective *Loxosceles* species carried the full biological effects of the entire venom. This antiloxoscelic serum, when administered IV into rabbits that were given intradermal injections of the loxoscelic venom from *L. laeta* and *L. intermedia*, had greater neutralizing activity than when compared to the existing antiarachnid serum, which is made by hyperimmunizing horses against the venom of *L. gaucho*, *P. nigriventer*, and the scorpion *Tityus serrulatus*. In Brazil and South America, most of the envenomations occur with the *L. laeta* and *L. intermedia*, not *L. gaucho*. Knowing which species envenomated the patient could help determine which antiserum is indicated.<sup>70</sup>

Patients manifesting systemic loxoscelism or those with expanding necrotic lesions should be admitted to the hospital. All patients should be monitored for evidence of hemolysis, acute kidney injury, or coagulopathy. If hemoglobinuria ensues, increased IV fluids and urinary alkalinization can be used in an attempt to prevent acute kidney injury. Hemolysis, if significant, can be treated with transfusions. Patients with coagulopathy should be monitored with serial complete blood cell count, platelet count, PT, PTT, fibrin split products, and fibrinogen. Disseminated intravascular coagulopathy requires treatment, based on severity.

### **HOBO SPIDER (*ERATIGENA AGRESTIS*, NORTHWESTERN BROWN SPIDER, WALCKENAER SPIDER)**

Formerly known as *Tegenaria agrestis*, the hobo spider is native to Europe and was introduced to the northwestern United States (Washington, Oregon, Idaho) in the 1920s or 1930s.<sup>234</sup> These spiders build funnel-shaped webs within wood piles, crawl spaces, basements, and moist areas close to the ground. They are brown with gray markings and 7 to 14 mm long. They are most abundant in the midsummer through the fall. They bite if provoked or threatened but otherwise retreat quickly when disturbed.<sup>23</sup> The literature is sparse in reported hobo spider bites that are verified by a specialist. There is only one confirmed hobo spider bite resulting in a necrotic lesion.<sup>59</sup>

A 42-year-old woman with a history of phlebitis who felt a burning sensation on her ankle rolled her pants and found a crushed brown spider, which was later confirmed to be *E. agrestis*.<sup>52</sup> She complained of persistent pain, nausea, and dizziness, and a vesicular lesion developed within several hours. The vesicle ruptured and ulcerated the next day. The lesion initially was 2 mm, but over the next 10 weeks enlarged to 30 mm in diameter and was circumscribed with a black lesion, at which time she sought medical advice. She was given a course of antibiotics, which did not limit the progression of this ulcer. Subsequently, the patient was unable to walk, and she was found to have a deep venous thrombosis. The other cases implicating Hobo spiders as a cause for dermatonecrotic injuries are based on proximity of the Hobo spider or other large brown spiders that are unidentified. *Eratigena agrestis* venom implanted into rabbit skin produces hemorrhagic dermatonecrotic lesions dermally and systemically.<sup>234,235</sup>

The venom from European Hobo spiders and US Hobo spiders was analyzed using liquid chromatography to address the question of variability between the 2 spiders. *Eratigena agrestis* originating from Europe is considered medically harmless. Liquid chromatography (European Hobo *E. agrestis* from the United Kingdom and American Hobo *E. agrestis* from Washington State, United States) found little variability between the 2 venoms to account for their differential necrotic effects.<sup>28</sup> The authors suggest 4 possibilities for the discrepancy between the European Hobo and American Hobo spiders: (1) an evolutionary change accounted for the novel necrotic effects; (2) venom chemistry is similar but the habitat might account for the difference in behavior; (3) venom chemistry and habitat are similar but an extrinsic factor such as a bacterium found in the US Hobo spider might be the cause for the necrotic effects; (4) *E. agrestis* do not directly or indirectly cause necrotic arachnidism and are incorrectly analyzed.<sup>28</sup> The authors suggest that either a bacterium such as *Mycobacterium ulcerans*, known to cause slow-developing ulcers on human skin, might coexist on the chelicerae of the *E. agrestis*, which is highly unlikely because of the presence of antibacterial peptides in the venom,<sup>110,242</sup> or the more likely circumstance that *E. agrestis* is incorrectly suggested as being a cause for necrotic arachnidism. Further evidence to suggest that the *E. agrestis* is not likely to be a culprit for necrotic arachnidism is based on a study that evaluates the possibility of the ability of the spider to carry and transfer pathogenic bacteria including the MRSA and analyzes the hemolytic properties of the venom.<sup>88</sup> More than 100 *E. agrestis* adult spiders were collected, and a bacterial diversity assay was conducted to find a total of 6 gram-positive and 4 gram-negative bacteria genera identified, which was consistent with the bacteria found in the fauna of the natural environment of the Pacific Northwest and several occurring on human and animal skin. Spiders were then exposed to MRSA on polyethylene disks because the tissue lesions caused by this bacterium is often confounded with a necrotic arachnidism. No MRSA was found on either the spiders or the surfaces to which the MRSA-exposed spiders were subjected, although the MRSA was found to persist on the polyethylene disks. Finally, the hobo spider venom was analyzed to determine its hemolytic activity in vertebrate blood. Compared to the known *Loxosceles reclusa* hemolytic activity of 37%, the potential of *E. agrestis* venom hemolytic activity was negligible at 0.62% and 0.93% for male (n = 5) and female (n = 7) spiders, respectively. Misdiagnosis of spider bites is common. Wounds can be misleading and can occur from the reaction of other organisms such as ticks and other arthropods, superinfection with anthrax or another organism or underlying medical conditions like diabetes and leukemia or bacterial infections. The need to revisit the hobo spider toxicity syndrome with further studies that show direct evidence of *E. agrestis* causing necrotic arachnidism in humans is warranted before it is concluded that any necrotic arachnidism in the Pacific Northwest is caused by *E. agrestis*.

### **Pathophysiology**

The toxin was fractionated, with 3 peptides identified as having potent insecticidal activity and no discernible effects in mammalian *in vivo* assays.<sup>131</sup> The peptide toxins TaITX-1, TaITX-2, and TaITX-3 exhibit potent insecticidal properties by acting directly in the insect central nervous system and not at

the neuromuscular junction.<sup>131</sup> Insects envenomated with *E. agrestis* venom and the insecticidal toxins purified from the venom developed a slowly evolving spastic paralysis. Currently, little is known about the toxin and its mechanism of action in humans.

### Clinical Manifestations

The toxicity of hobo spider venom is questionable; however, it occasionally causes dermatonecrosis secondary to infection. Other causes of dermatonecrotic lesions should be excluded. The most common symptom associated with the spider bite is a headache that persists for up to one week.<sup>59</sup> Other manifestations including nausea, vomiting, fatigue, memory loss, visual impairment, weakness, and lethargy, are reported.<sup>59,235</sup>

### Diagnostic Testing

No specific laboratory assay confirms envenomation with *E. agrestis* spider.

### Treatment

Treatment emphasizes local wound care and tetanus prophylaxis, although systemic corticosteroids are reasonable for hematologic complications. Surgical graft repair for severe ulcerative lesions is warranted when there is no additional progression of necrosis.<sup>59</sup>

## TARANTULAS

Tarantulas are primitive mygalomorph spiders that belong to the family Theraphosidae, a subgroup of Mygalomorphae (Greek word *mygale* for field mouse).<sup>54,201</sup> There are more than 1,500 species, with 54 species found in the deserts of the western United States.<sup>177</sup> Because of their great size and reputation, tarantulas are often feared. They are the largest and hairiest spiders, popular as pets, and are found throughout the United States as well as in tropical and subtropical areas (Fig. 115–4). The life span of the female can exceed 15 to 20 years. They have poor eyesight and usually detect their victims by touch and vibrations. Their defense lies in either their painful bite with erect fangs or by barraging their victim with urticating hairs that are released on provocation.<sup>54</sup> Only the New World tarantulas (tarantulas indigenous to the Americas) have and use the urticating hairs to defend themselves.<sup>54</sup>

Tarantulas bite when provoked or roughly handled. Based on the few case reports, their venom has relatively minor effects in humans but can be deadly for canines and other small animals, such as rats, mice, cats, and birds.<sup>38,128</sup> Small prey might actually be killed by the physical nature of having fangs impaled many times through their bodies. A study from Australia covering

a 25-year span reported only 9 confirmed bites by Theraphosid spiders in humans and 7 confirmed bites in canines—in 2 cases, the owner was bitten after the dog.<sup>19,128</sup> At least 4 genera of tarantulas (*Lasiadora*, *Grammostola*, *Acanthoscurria*, and *Brachypelma*) possess urticating hairs that are released in self-defense when the tarantulas rub their hind legs against their abdomen rapidly to create a small cloud.<sup>93</sup> There are 6 different types of urticating hairs. Type 1 hairs are found on tarantulas in the United States and are the only hairs that do not penetrate human skin. Type 2 hairs are incorporated into the silk web retreat but are not thrown off by the spider. Type 3 hairs can penetrate up to 2 mm into human skin. Type 4 hairs belong to the South American *Grammostola* spider and can cause severe respiratory inflammation. Urticarial hairs or setae are composed of chitin, lipoproteins, and mucopolysaccharides, which are recognized as foreign bodies triggering a humoral response in the mammalian immune system. Chitin is proinflammatory and activates T helper cells to stimulate activated macrophages to produce chitinases, which will break down the chitin but also trigger inflammation. Besides cell-mediated inflammation, spider setae also trigger IgE-mediated hypersensitivity.<sup>19,51</sup>

### Pathophysiology

Tarantula venom, specifically the venoms of *Aphonopelma hentzi* (synonym of *Dugesia hentzi* {Arkansas tarantula}) and other members of the genus *Aphonopelma* (Arizona or Texas brown tarantula), contains hyaluronidase, nucleotides (adenosine triphosphate {ATP}, adenosine diphosphate {ADP}, and adenosine monophosphate {AMP}), and polyamines (spermine, spermidine, putrescine, and cadaverine) that are essential to prey.<sup>43,136,201</sup> The role of spermine is unclear, but hyaluronidase is a spreading factor that allows more rapid entrance of venom toxin by destruction of connective tissue and intercellular matrix. Adenosine triphosphate potentiates death in mice exposed to the *A. hentzi* venom and lowers the LD<sub>50</sub> in comparison to venom without ATP.<sup>52,152</sup> Both venoms cause skeletal muscle necrosis when injected intraperitoneally in mice.<sup>87</sup> The primary injury results in rupture of the plasma membrane, followed by the inability of mitochondria and sarcoplasmic reticulum to maintain normal concentrations of calcium in the cytoplasm leading to cell death. *Aphonopelma* venom is similar to scorpion venom in composition and clinical effects. Novel xenobiotics were discovered in the venom that can act on potassium channels, calcium channels, and the acid-sensing ion channels that elucidate the molecular mechanism of voltage-dependent channel gating and their respective physiologic roles.<sup>79,80</sup>

### Clinical Manifestations

Although relatively infrequent in occurrence, bites present with puncture or fang marks. They range from being painless to a deep throbbing pain that are reported to last several hours without any inflammatory component.<sup>128</sup> Fever occurs in the absence of infection, suggesting a direct pyrexia action of the venom. Rarely, bites create a local histamine response with resultant itching, and hypersensitive individuals can have more severe reactions and, less commonly, mild systemic effects such as nausea and vomiting.<sup>93,128</sup> Contact reactions from the urticating hairs are more likely to be the health hazard than the spider bite. The urticating hairs provoke local histamine reactions in humans and are especially irritating to the eyes, skin, and respiratory tract. Tarantula urticating hairs cause intense inflammation that often remain pruritic for weeks. An allergic rhinitis is known to develop if the hairs are inhaled.<sup>136</sup> Tarantula hairs resemble sensory setae of caterpillars: both are type 3 hairs that can migrate relentlessly and cause multiple foci of ophthalmic inflammation.<sup>118</sup> *Ophthalmia nodosa*, a granulomatous nodular reaction to vegetable or insect hairs, is reported with casual handling of tarantulas.<sup>22,26</sup> Other ophthalmic findings include setae in the corneal stroma, anterior chamber inflammation, migration into the retina, and secondary glaucoma and cataracts.<sup>31</sup>

### Treatment

Treatment is largely supportive. Cool compresses and analgesics should be given as needed. All bites should receive local wound care, including tetanus prophylaxis if necessary. If the hairs are barbed, as in some species, they can be removed by using adhesive such as duct tape or cellophane tape followed

**FIGURE 115–4.** The Mexican redknee tarantula, *Brachypelma smithi*. (Used with permission from the American Museum of Natural History.)

by compresses or irrigation with 0.9% sodium chloride solution. If the hairs are located in the eye, then surgical removal will be required, followed by medical management of inflammation. If the hairs are difficult to remove and the patient has persistent ophthalmic pain and discomfort, then a therapeutic pars plana vitrectomy is necessary to reduce the antigenic load and to improve clinical symptomatology.<sup>115</sup> Urticarial reactions should be treated with oral antihistamines and topical or systemic corticosteroids.

## FUNNEL WEB SPIDERS

Australian funnel web spiders are a group of large Hexathelidae mygalomorphs that cause a severe neurotoxic envenomation syndrome in humans. The fang positions of funnel web spiders (as well as the tarantulas) are vertical relative to their body, which requires the spider to rear back and lift the body to attack. The length of fangs reach up to 5 mm. This spider bites tenaciously and occasionally requires extraction from the victim.<sup>161</sup> *Atrax* and *Hadronyche* species are found along the eastern seaboard of Australia. *Atrax robustus*, also called the Sydney funnel web spider, is the best known and is located around the center of Sydney, Australia.<sup>161</sup> Funnel web spiders tend to prefer moist, temperate environments.<sup>161</sup> They are primarily ground dwellers and live in burrows, crevices in rocks, and around foundations of houses. They build tubular or funnel-shaped webs.<sup>93</sup> At night, the spiders ascend the tubular web and wait for their prey. The Sydney funnel web spider is considered one of the most poisonous spiders. It was responsible for 14 deaths between 1927 and 1980, at which time an antivenom was introduced.<sup>221,222</sup>

### Pathophysiology

Originally called robustotoxin from *A. robustus* spider and versutoxin from the *Hadronyche versuta* spider, the toxin which is now referred to as atracotoxin or atraxin ( $\delta$ -ACTX-Arl and  $\delta$ -ACTX-Hvla, respectively) is the lethal protein component of *A. robustus* venom and is unique in its toxicity affecting primates and newborn mice, although other mammals are susceptible in higher doses.<sup>161,220,222,239</sup> Atracotoxin is a 42-amino acid peptide that targets mammals by increasing the ion conductance at voltage-gated sodium channels via trapping the voltage sensor domain IV S4 segment of the channel in an inward conformational change, preventing the closure of the ion channel, thereby evoking a fulminant neurotransmitter release at the autonomic and/or somatic synapses.<sup>148,170</sup> Hence  $\delta$ -ACTX produces an autonomic storm, releasing acetylcholine, noradrenaline, and adrenaline. In monkeys, a 5 mcg/kg intravenous infusion dose of robustotoxin from male *A. robustus* spiders causes dyspnea, blood pressure fluctuations leading to severe hypotension, lacrimation, salivation, skeletal muscle fasciculation, and death within 3 to 4 hours.<sup>167</sup> Versutoxin, a toxin from the Blue Mountain funnel web spider, is closely related to robustotoxin and has demonstrated voltage-dependent slowing of sodium channel inactivation.<sup>171</sup>

### Clinical Manifestations

A biphasic envenomation syndrome is described in humans and monkeys.<sup>221,222</sup> Phase 1 consists of localized pain at the bite site, perioral tingling, piloerection, and regional fasciculations (most prominent in the face, tongue, and intercostal muscles). Fasciculations progress to more overt muscle spasm; masseter and laryngeal involvement may threaten the airway.<sup>220</sup> Other features include tachycardia, hypertension, cardiac dysrhythmias, nausea, vomiting, abdominal pain, diaphoresis, lacrimation, salivation, and acute respiratory distress syndrome (ARDS), which often is the cause of death in phase 1.<sup>239</sup> Phase 2 consists of resolution of the overt cholinergic and adrenergic crisis; secretions dry up, and fasciculations, spasms, and hypertension resolve. This apparent improvement is occasionally followed by the gradual onset of refractory hypotension, apnea, and cardiac arrest.<sup>222</sup>

### Treatment

Pressure immobilization using crepe bandage to limit lymphatic flow and immobilization of the bitten extremity is reported to inactivate the venom and is recommended to be applied if symptoms of envenomation are present. Funnel web venom is one of the few animal toxins known to undergo local inactivation. Monkey studies and a human case report support the utility of

pressure immobilization.<sup>98,223</sup> After injecting *A. robustus* venom subcutaneously in monkeys, pressure-immobilization technique increased survival by retarding the venom movement and also by allowing the local peripheral enzymes inactivating the venom.<sup>221,223</sup>

The patient should be transferred to the nearest hospital with the bandage in place and then stabilized and placed in a resuscitation facility with adequate ampules of antivenom readily available before the bandage is removed; otherwise, a precipitous envenomation will potentially occur during the removal of the pressure bandage. A purified IgG antivenom protective against *Atrax* envenomations was developed in rabbits.<sup>221</sup> One ampule of the antivenom contains 100 mg purified rabbit IgG or 125 units of neutralizing capacity per ampule.<sup>239</sup> It is shown to be effective for more than 40 humans bitten by the *Atrax* species.<sup>223</sup> The starting dose is 2 ampules if systemic signs of envenomations are present, and 4 ampules if the patient develops ARDS or decreased mental status. Doses are repeated every 15 minutes until clinical improvement occurs.<sup>239</sup> Up to 8 ampules is common in a severe envenomation. However, a recent study of 9 funnel web spider envenomations utilized a venom-specific enzyme immunoassay to measure venom concentrations in the serum before and after administration of antivenom. The results indicated that the starting dose of 2 ampules is sufficient to bind all free venom, but the envenomation may have irreversible effects such as myocarditis and ARDS.<sup>158</sup> Since anaphylaxis is not reported,<sup>223</sup> the manufacturer no longer recommends premedication. Serum sickness is rare after funnel web antivenom administration, with only one reported case in a patient who received 5 ampules of antivenom.<sup>160</sup>

## SCORPIONS

Scorpions are invertebrate arthropods that have existed for more than 400 million years.<sup>58</sup> Of the 650 known living species, most of the lethal species are in the family Buthidae (Table 115-5). The genera of the family Buthidae include *Centruroides*, *Tityus*, *Leiurus*, *Androctonus*, *Buthus*, and *Parabuthus*.<sup>58</sup> Scorpions envenomate humans by stinging rather than biting. Their 5-segmented metasoma ("tail") contains a terminal bulbous segment called the *telson* that contains the venom apparatus (Fig. 115-5). More than 100,000 medically significant stings likely occur annually worldwide, predominantly in the tropics and North Africa.<sup>1,25,70,103,129,141</sup> According to American Association of Poison Control Centers data from 1995 to 2015, approximately 11,000 to 19,000 scorpion annual exposures occurred in the United States, mostly in the southwestern region. Only one death was reported during this period, involving a 3-year-old boy who expired despite receiving antivenom (Chap. 130). These members of the class Arachnida rarely cause mortality in victims older than 6 years.<sup>188</sup> The venomous scorpions in the United States are *Centruroides exilicauda* and *Centruroides vittatus*. The most important is *C. exilicauda*, previously called *Centruroides sculpturatus* Ewing and *Centruroides gertschii* (bark scorpion; Table 115-6).<sup>83</sup>

### Pathophysiology

Components of scorpion venom are complex and species specific.<sup>106,180,188,189</sup> Buthidae venom is thermostable and consists of phospholipase, acetylcholinesterase, hyaluronidase, serotonin, and neurotoxins. Four neurotoxins,

designated toxins I to IV, were isolated from *C. exilicauda*. Some of the toxins target excitable membranes,<sup>67,82,104,156,198</sup> especially at the neuromuscular junction, by opening sodium channels. The results are repetitive depolarization of nerves in both sympathetic and parasympathetic nervous systems causing catecholamine and acetylcholine release, respectively, and associated cardiac ischemia, and action at the juxtaglomerular apparatus, causing increased renin secretion.<sup>64,188</sup> The clinical effects of *Tityus* scorpion sting are related to elevated concentrations of interleukin (IL)-1 $\beta$ , IL-6, IL-8, IL-10, kinins,<sup>86</sup> and tumor necrosis factor (TNF)- $\alpha$ , which correlate with the severity of envenomation and hyperamylasemia.<sup>63,87</sup>

### Clinical Manifestations

Scorpion stings produce a local reaction consisting of intense pain, erythema, tingling or burning, and occasionally discoloration and necrosis without tissue sloughing (Table 115–6). Envenomation from some scorpion species produces systemic effects that include autonomic storm consisting of cholinergic and adrenergic effects. Cardiotoxic effects include myocarditis, dysrhythmias, and myocardial infarction.<sup>67,82,104,156,198</sup> Electrocardiographic

**TABLE 115–6** Envenomation Gradation for *Centruroides exilicauda* (Bark Scorpion)<sup>63</sup>

Grade	Signs and Symptoms
I	Site of envenomation Pain and/or paresthesias Positive tap test (severe pain increases with touch or percussion)
II	Grade I in addition to Pain and paresthesias remote from sting site (eg, paresthesias moving up an extremity, perioral “numbness”)
III	One of the following: Somatic skeletal neuromuscular dysfunction: jerking of extremity(ies), restlessness, severe involuntary shaking and jerking, which may be mistaken for seizures Cranial nerve dysfunction: blurred vision, roving eye movements (opsoclonus) hypersalivation, dysphagia, tongue fasciculation, upper airway dysfunction, slurred speech
IV	Both cranial nerve dysfunction and somatic skeletal neuromuscular dysfunction

(ECG) abnormalities are reported to persist for several days and include sinus tachycardia, sinus bradycardia, bizarre broad-notched biphasic T-wave changes with additional ST segment elevation or depression in the limb and precordial leads, appearance of tiny Q waves in the limb leads consistent with an acute myocardial infarction pattern, occasional electrical alternans, and prolonged QT interval.<sup>104,106</sup> Other reported effects include pancreatitis, coagulation disorders, ARDS, massive hemoptysis, cerebral infarctions in children, seizures, and a shock syndrome that occasionally precedes but usually follows the hypertensive phase.<sup>24,73,82,104,105,198,210</sup>

A 3-category classification system for scorpion envenomations worldwide was proposed. Category 1 is “mild” and involves local manifestations such as erythema, edema, sweating, numbness, and fasciculations. Category 2 is “moderate” and involves abdominal pain, vomiting, generalized diaphoresis, tachypnea, tachycardia or bradycardia, hypertension, agitation, hypersalivation, dysphagia, fever, and/or hyperglycemia. Category 3 is “severe” and indicates patients who present with cardiovascular complications such as congestive heart failure, dilated cardiomyopathy, cardiogenic shock, dysrhythmias, or severe hypertension. Severe envenomation also includes pulmonary manifestations such as pulmonary edema and ARDS; gastrointestinal findings such as acute pancreatitis or peptic ulceration; as well as neurologic manifestations such as hypertensive encephalopathy, coma, or seizures. The presence of diarrhea is associated with increased incidence of respiratory failure, neurologic failure, liver failure, and death.<sup>200</sup>

In the United States, *C. exilicauda* stings produce local paresthesias and pain that is accentuated by tapping over the envenomated area (tap test) without local skin evidence of envenomation.<sup>58,188</sup> Symptoms begin immediately after envenomation, progress to maximum severity in 5 hours, and may persist for up to 30 hours.<sup>58,188</sup> Autonomic findings include hypertension, tachycardia, diaphoresis, emesis, and bronchoconstriction. The somatic motor effects reported include ataxia, muscular fasciculations, restlessness, thrashing, and opsoclonus.<sup>64,180</sup>

### Treatment

Because most envenomations do not produce severe effects, local wound care, including tetanus prophylaxis and pain management, usually is all that is warranted. In young children or patients who manifest severe toxicity, hospitalization is recommended. Treatment emphasizes support of the airway, breathing, and circulation. However, children rarely require respiratory support.<sup>180</sup> Corticosteroids, antihistamines, and calcium have been administered without any known benefit.<sup>63</sup> Continuous intravenous midazolam infusion is often used for *C. exilicauda* scorpion envenomation until resolution of the abnormal motor activity and agitation occurs.<sup>91</sup>

The clinical severity dictates the need to use antivenom for grade III and grade IV envenomations (Table 115–6).<sup>63</sup> When an equine-derived F(ab')<sub>2</sub> product called Alacramyn, developed in Mexico against the *Centruroides limpidus* venom, was administered to critically ill US children with neurotoxicity from scorpion stings, there was a rapid resolution of toxicity, decreased need for sedation, and reduced concentrations of circulating unbound venom.<sup>34</sup> This antivenom was subsequently approved in the United States in 2011 and called Anascorp (Bioclon, Mexico)<sup>70</sup> (Antidotes in Depth: A38). Because the neurotoxic syndrome occurs almost exclusively in children younger than 10 years, antivenom use is most likely to be considered in children. However, intractable pain in adults not responding to reasonable doses of opioids or other systemic effects that pose a danger to the patient or a fetus are reasonable indications for antivenom therapy.

Atropine has been used to reverse the excessive oral secretions in *C. exilicauda* scorpion envenomation, with some success in healthy children.<sup>219</sup> Routine use is not recommended and should be limited to species such as *Parabuthus transvaalicus* in southern Africa,<sup>219</sup> whose envenomations cause a prominent cholinergic crisis. Potentiation of the adrenergic effects causing cardiopulmonary toxicity is reported.<sup>21</sup> Atropine use to reverse the effects of stings from scorpions from India, South America, the Middle East, and Asia is contraindicated because these scorpions cause an “autonomic storm” with transient cholinergic stimulation followed by sustained adrenergic hyperactivity.<sup>20,219</sup>

## TICKS

In 1912, Todd described a progressive ascending flaccid paralysis after bites from ticks.<sup>230</sup> Three families of ticks are recognized: (1) Ixodidae (hard ticks), (2) Argasidae (soft ticks), and (3) Nuttalliellidae (a group that has characteristics of both hard and soft ticks and not thought to be parasitic compared to ixodids and argasids). The terms *hard* and *soft* refer to a dorsal scutum or “plate” that is present in the Ixodidae but absent in the Argasidae. Both types are characteristically soft and leathery, and both have clinical importance. Ixodidae females are capable of enormous expansion up to 50 times their weight in fluid and blood.<sup>90</sup> The paralytic syndrome is induced following envenomation during the larva, nymph, and adult stages and is related to the tick obtaining a blood meal. The following discussion focuses only on tick paralysis (TP) or tick toxicosis and not on any of the infectious diseases associated with tick bites. Most of the major tick-borne diseases in North America are transmitted by Ixodid ticks except for relapsing fever, which is spread by the soft tick of the genus *Ornithodoros* or *Pediculus humanus* (human louse).

In North America, *Dermacentor andersoni* (Rocky Mountain wood tick), *Dermacentor variabilis* (American dog tick), and *Amblyomma americanum* (Lone Star tick) are the most commonly implicated causes of TP.<sup>96,230</sup> Typically, tick toxicosis occurs in the Southeast, Rocky Mountain, and Pacific Northwest regions of the United States, but cases are also reported in the Northeast.<sup>69</sup> In Australia, the *Ixodes holocyclus* or Australian marsupial tick is the most common offender.<sup>96,230</sup> *Ixodes holocyclus* is the most potent of the paralyzing ticks in the world and is known to paralyze dogs, cats, sheep, mice, foals, pigs, chickens, and humans.<sup>151</sup>

### Pathophysiology

Venom secreted from the salivary glands during the blood meal is absorbed by the host and systemically distributed. To allow successful feeding over several days, ticks need to overcome the host's hemostatic, inflammatory, and immune mechanisms by producing anticoagulants, fibrinolytic enzymes, antiplatelet, and vasodilator substances.<sup>137,187</sup> The saliva also contains some cement to anchor the tick to the host; however, the hypostome of the *I. holocyclus* reaches up to 980 microns into the host's skin and does not need cement support.<sup>6</sup> Paralysis results from the neurotoxin “ixobotoxin,”<sup>165</sup> which inhibits the release of acetylcholine at the neuromuscular junction and autonomic ganglia, very similar to botulinum toxin.<sup>99,165</sup> Both botulinum toxin and ixobotoxin demonstrate temperature dependence in rat models and show increased muscular twitching activity as the temperature is reduced.<sup>60,151</sup> The salivary toxin of *I. holocyclus* directly affects vascular and cardiac potassium channels by blockade, and this action differed from the respiratory distress caused by progressive muscle paralysis.<sup>11</sup> Cardiovascular function is decreased in dogs with TP. The dogs developed acute left-sided congestive heart failure and prolonged QT intervals.<sup>47</sup>

### Clinical Manifestations

Usually the tick must remain on the person for 5 to 6 days in order to result in systemic effects. Several days must pass before tick salivary glands begin to secrete significant quantities of toxin. Once secreted, the toxin does not act immediately and undergoes binding and internalization, in a similar sequence to botulinum toxin.<sup>18,60,133</sup> Ticks typically attach to the scalp but are found on any part of the body, including the ear canals and anus. Children, particularly girls, and adult men in tick-infested areas are predominantly affected. One large series of 305 cases in Canada reported that 21% were adults older than 16 years.<sup>205</sup> Among the children, 67% were girls; in adults, 83% were male. The distribution was attributed to the difficulty of detecting ticks in long hair and the possible greater exposure of adult men to tick-infested environments. Children are reported to appear listless, weak, ataxic, and irritable for several days before they develop an ascending paralysis that begins in the lower limbs. Fever usually is absent. Other manifestations include sensory symptoms such as paresthesias, numbness, and mild diarrhea. These symptoms are followed by absent or decreased

deep-tendon reflexes and an ascending generalized weakness that can progress to bulbar structures involving speech, swallowing, and facial expression within 24 to 48 hours, as well as fixed, dilated pupils and disturbances of extraocular movements.<sup>99,205</sup> Other atypical presentations are reported and include the following: a child presenting with double vision and being unable to see before the neuromuscular changes occurred, and a healthy elderly man presenting with unilateral weakness and numbness in the left arm for 2 days. Both patients fully recovered after the removal of the tick.<sup>69</sup> If the tick is not removed, respiratory weakness is reported to lead to hypoventilation, lethargy, coma, and death. Unlike the *Dermacentor* spp of North America, removal of the *I. holocyclus* tick does not result in dramatic improvement for several days to weeks. The maximal weakness is often not reached until 48 hours after the tick has been removed or drops off.<sup>99</sup> It is imperative to closely observe patients for possible deterioration. A recent 60-year meta-analysis of TP in the United States reviewed 50 well-documented cases from 1946 to 2006 supporting the above findings.<sup>75</sup> The demographics were analyzed and the following remained the same: (1) TP is a highly predictable regional disease found in the US Pacific Northwest (WA), the West (CA, CO), and the Southeast (GA, MS, NC, SC, VA), and very few cases occurred outside those areas; (2) TP remains a highly predictable seasonal disease occurring during the spring to summer seasons; (3) TP remains more common in females of all ages (80% female/male 4.9:1); (4) Tick attachment sites on the head and scalp continued to predominate over all other attachment sites, representing 48% of the reported attachment sites, 20% occur behind the ear; (5) The Rocky Mountain wood tick (*D. andersoni*) was the only TP vector in the western United States (CA, WA, CO) when reported, and *D. variabilis*, the American dog tick, was the only TP vector from the southeastern United States (GA, NC) when reported.

The differential diagnosis is extensive and includes Guillain-Barré syndrome (GBS), the Miller-Fisher variant of Guillain-Barré, poliomyelitis, botulism, transverse myelitis, myasthenia gravis, periodic paralysis, elapid snakebites, marine neurotoxin poisoning, acute cerebellar ataxia, and spinal cord lesions (Chap. 38). The cerebrospinal fluid remains normal, and the rate of progression is rapid, unlike GBS and poliomyelitis.<sup>75,81,202</sup> The edrophonium test to assess for myasthenia gravis is negative. Nerve conduction studies in patients with TP frequently resemble those of patients with early stages of GBS: findings in both conditions include prolonged latency of the distal motor nerves, diminished nerve conduction velocity, and reduction in the amplitudes of muscle and sensory-nerve action potentials.<sup>81</sup> With GBS, there is a prolongation of the F wave, however, that does not occur with TP, reflecting the more proximal demyelination of the nerve root.<sup>101</sup> The other causes for acute ascending flaccid paralysis should be eliminated by a complete history, including environmental exposure, hobbies, workplace, travel, ingestions, obtaining appropriate laboratory testing, psychiatric evaluations if needed, and of course a thorough physical examination.

### Treatment

Other than removal of the entire tick, which is curative, treatment is entirely supportive. Proper removal of the tick is very important, otherwise infection or incomplete tick removal are able to occur. The tick should be grasped as close to the skin surface as possible with blunt curved forceps, tweezers, or gloved hands. Steady pressure without crushing the body should be used; otherwise, expressed fluid is reported to infect the patient and lead to inoculating the patient with a higher dose of toxin or infectious agent. After tick removal, the site should be disinfected. Traditional methods of tick removal using petroleum jelly, topical lidocaine, fingernail polish, isopropyl alcohol, or a hot match head are ineffective and often induces the tick to salivate or regurgitate into the wound.<sup>168</sup> It should be remembered that the very same vectors responsible for tick toxicosis also cause infectious illnesses such as babesiosis, Rocky Mountain spotted fever, anaplasmosis, ehrlichiosis, tularemia, Colorado tick fever, tick-borne relapsing fever, and Lyme disease. Since *I. holocyclus* of Australia is considerably more toxic and patients are more likely to deteriorate before they improve, close observation is required for several days until improvement is certain.<sup>81</sup>

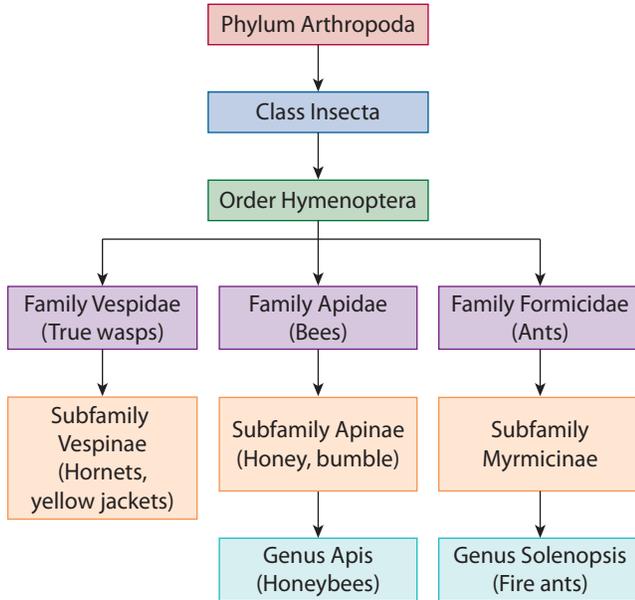

FIGURE 115-6. Taxonomy of the order Hymenoptera.

## HYMENOPTERA: BEES, WASPS, HORNETS, YELLOW JACKETS, AND ANTS

Within the order Hymenoptera are 3 families of clinical significance: Apidae (honeybees and bumblebees), Vespidae (yellow jackets, hornets, and wasps), and Formicidae (ants, specifically fire ants). These insects (Fig. 115-6) are of great medical importance because their stings are the most commonly reported and can cause acute toxic and fatal allergic reactions. In the 1960s and 1970s, an estimated 40 deaths per year were attributed to anaphylaxis secondary to Hymenoptera stings in the United States.<sup>17,209</sup> However, from 2008 to 2015 there have been only 6 deaths related to envenomations from bees, wasps, and hornets reported to the National Poison Data System, probably due to increased public awareness of allergic reactions and easier access to medical care (Chap. 130).

*Apis* and *Bombus* species (honeybees and bumblebees) generally build nests away from humans and are passive unless disturbed, but nests of both the honeybees and bumblebees are also found in walls and rodent burrows near homes. Honeybee workers only sting once because their stinger is a modified ovipositor that resides in the abdomen and its shaft is barbed and has a venom sac attached. Once the stinger embeds into the skin, the stinger disembowels the bee. Bumblebees, however, can sting multiple times. Vespids, on the other hand, are more aggressive and build nests in human living areas, such as in trees and under awnings; yellow jackets inhabit shrubs, trees, and the ground. They, too, are able to sting multiple times.<sup>93</sup> The introduction of the Africanized honeybee in Brazil (because originally they were thought to be a more efficient honey producer) has caused significant economic and health issues. The bees have migrated toward the southern border of the United States and pose a greater threat to humans. Africanized honeybees are characterized by large populations, can make nonstop flights of at least 20 km, and have a tendency toward mass attack with little provocation.<sup>162</sup>

### Pathophysiology

Several allergens (Table 115-7) and pharmacologically active compounds are found in honeybee venom. The 3 major venom proteins are found in the honeybee: melittin, phospholipase A<sub>2</sub>, and hyaluronidase.<sup>146</sup> Other proteins include apamin, acid phosphatase, and other unidentified proteins. Phospholipase A<sub>2</sub> is the major antigen/allergen in bee venom.<sup>32</sup>

Melittin is the principal component of honeybee venom. It acts as a detergent to disrupt the cell membrane and liberate potassium and biogenic amines.<sup>14</sup> Histamine release by bee venom is largely mediated by mast cell

TABLE 115-7 Composition of Hymenoptera Venom

Vespid (Wasps, Hornets, Yellow Jackets)	Apids (Honeybees)	Formicids (Fire Ants)
Biogenic amines (diverse)	Biogenic amines (diverse)	Biogenic amines (diverse)
Phospholipase A phospholipase B	Phospholipase A phospholipase B (?)	Phospholipase A <sub>2</sub>
Hyaluronidase	Hyaluronidase	Hyaluronidase
Acid phosphatase	Acid phosphatase	Piperidines
Mast cell–degranulating peptide	Minimine	
Kinin	Mellitin	
	Apamin	
	Mast cell–degranulating peptide	

degranulation peptide. Apamin is a neurotoxin that acts on the spinal cord. Apamin binds to the Ca<sup>2+</sup>-triggered K<sup>+</sup> channel and depresses delayed hyperpolarization to cause its toxicity, which is seen in the mouse model as uncoordinated movements leading to spasms, jerks, and convulsions of a spinal origin.<sup>109</sup> Adolapin inhibits prostaglandin synthase and has antiinflammatory properties that account for its use in arthritic therapy.<sup>207</sup> Phospholipase A<sub>2</sub> and hyaluronidase are the chief enzymes in bee venom.

The 3 major proteins in vespid venoms serve as allergens and are accompanied by a wide array of vasoactive peptides and amines.<sup>146</sup> The intense pain following vespid stings is largely caused by serotonin, acetylcholine, and wasp kinins. Antigen 5 is the major allergen in vespid venom.<sup>163</sup> Its biologic function is unknown. Mastoparans have action similar to mast cell degranulation peptide, but weaker.<sup>14</sup> Phospholipase A<sub>2</sub> is thought to be responsible for inducing coagulation abnormalities.<sup>174</sup>

### Clinical Manifestations

Normally, the honeybee sting results in immediate pain, a wheal-and-flare reaction, and localized edema without a systemic reaction. Vomiting, diarrhea, and syncope occur with a higher dose of venom resulting from multiple stings.<sup>35</sup> Rarely, a sting in the oropharynx produces airway compromise.<sup>209</sup>

Toxic reactions occur with multiple stings (more than 500 stings are described as possibly fatal and occur with Africanized honeybees)<sup>93</sup> and include gastrointestinal (GI) effects, headache, fever, syncope and, rarely, rhabdomyolysis, acute kidney injury, and seizures.<sup>35</sup> Other rare complications include idiopathic intracranial hypertension,<sup>227</sup> cerebral infarction, and ischemic optic neuropathy<sup>204</sup> and parkinsonism<sup>145</sup> and are thought to occur because of the proximity of the sting near the head and neck. Bronchospasm and urticaria are typically absent.

This type of toxic reaction differs from the hypersensitivity reactions or anaphylactic reactions because it is not an IgE-mediated response, but rather a direct effect from the venom itself. Hypersensitivity reactions, including anaphylaxis, occur from Hymenoptera stings. These reactions are IgE mediated. The IgE antibodies attach to tissue mast cells and basophils in individuals who were previously sensitized to the venom. These cells are activated, allowing for progression of the cascade reaction of increased vasoactive substances, such as leukotrienes, eosinophil chemotactic factor-A, and histamine. An anaphylactic reaction is not dependent on the number of stings. Patients who are allergic to Hymenoptera venom develop a wheal-and-flare reaction at the site of the inoculum. The shorter the interval between the sting and symptom onset, the more likely the reaction will be severe. Fatalities can occur within several minutes; even initially mild symptoms are reported to be followed by a fulminant course. Generalized urticaria, throat and chest tightness, stridor, fever, chills, and cardiovascular collapse ensue.

## Treatment

Application of ice at the site usually is sufficient to halt discomfort. Stingers from honeybees should be removed by scraping with a credit card or scalpel, as opposed to pulling, which potentially releases additional retained venom. Since the stinger in other bee species typically stays within the insect, this removal technique will not be necessary if other bee species are involved. Therapy is aimed at supportive care that includes standard therapy for anaphylaxis with epinephrine, diphenhydramine, and corticosteroids.

## FIRE ANTS

There are native fire ants in the United States, but the imported fire ants *Solenopsis invicta* and *Solenopsis richteri* are significant pests that have no natural enemies. They are native to Brazil, Paraguay, Uruguay, and Argentina but were introduced into Alabama in the 1930s. They have spread rapidly throughout the southern United States, damaging crops, reducing biologic diversity, and inflicting severe stings to humans.<sup>225</sup> *Solenopsis invicta*, the most aggressive species, now infests 13 southern states and was introduced into Australia.<sup>211,214</sup> Allergic reactions to ant stings were limited to the jumper ant (*Myrmecia pilosula*, other *Myrmecia* spp) and the greenhead ant (*Rhytidoponera metallica*, *Odontomachus*, *Cerapachys*, and *Brachyponera* spp) in Australia until February 2001, when the imported red fire ant was identified at 2 sites in Brisbane.<sup>211</sup> The mode of introduction is unknown but are postulated to have originated from the transport of infested cargo. Fire ants range from 2 to 6 mm in size. They live in grassy areas, garden sites, and near sources of water. The nests are largely subterranean and have large, conspicuous, dome-shaped above-ground mounds (up to 45 cm above the ground), with many openings for traffic. The mounds can contain 80,000 to 250,000 workers and one or more queens that live for 2 to 6 years and produce 1,500 eggs daily.<sup>236</sup> Fire ants are named for the burning pain inflicted after exposure, and necrosis can result at the site. The imported fire ant attacks with little warning. By firmly grasping the skin with their mandibles, both the fire ant and the jumper ant can repeatedly inject venom from a retractile stinger at the end of the abdomen. Pivoting at the head, the fire ant injects an average of 7 or 8 stings in a circular pattern.<sup>214</sup>

## Pathophysiology

The venom inhibits Na<sup>+</sup>, K<sup>+</sup>-ATPases, reduces mitochondrial respiration, uncouples oxidative phosphorylation, adversely affects neutrophil and platelet function, inhibits nitric oxide synthetase, and perhaps activates coagulation.<sup>130,132</sup> Unlike the venoms of wasps, bees, and hornets that contain mostly aqueous-containing proteins, the imported fire ant venom is 95% alkaloid, with a small aqueous fraction that contains soluble proteins.<sup>149</sup> Of the alkaloids, 99% is a 2,6-disubstituted piperidine that has hemolytic, antibacterial, insecticidal, and cytotoxic properties.<sup>71</sup> There is also some *in vivo* evidence that the Solenopsin alkaloids inhibit nitric oxide synthetase activity and have direct cardiotoxic, convulsant, and respiratory depressant activities.<sup>120,244</sup> These alkaloids do not cause allergic reactions, but they produce a pustule and pain. The aqueous portion of the venom contains the allergenic activity of fire ant venom, *Sol i I* to *IV*.<sup>113,214</sup> The proteins identified in the venom include a phospholipase, a hyaluronidase, and the enzyme *N*-acetyl- $\beta$ -glucosaminidase.<sup>72,214</sup>

## Clinical Manifestations

In the United States, residents of health care facilities who are immobile or cognitively impaired are at risk for fire ant attacks, especially when the facility lacks pest control techniques for fire ants.<sup>72</sup> Three categories are suggested based on the reactions to the imported fire ant: local, large local, and systemic.<sup>214</sup> *Local reactions* occur in nonallergic individuals. *Large local reactions* are defined as painful, pruritic swelling at least 5 cm in diameter and contiguous with the sting site. *Systemic reactions* involve signs and symptoms remote from the sting site. The sting initially forms a wheal that is described as a burning itch at the site, followed by the development of sterile pustules. In 24 hours, the pustules umbilicate on an erythematous base. Pustules are reported to last 1 to 2 weeks.<sup>93</sup> Late cutaneous allergic reactions occur in

some persons who experience indurated pruritic lumps at the site of subsequent stings.<sup>71</sup> Large reactions lead to tissue edema sufficient to compromise blood flow to an extremity. Anaphylaxis occurs in 0.6% to 6% of persons who have been stung.<sup>214</sup> Often, healing occurs with scarring in 10 to 14 days.

The majority of individuals who die after fire ant attacks succumb to heart failure.<sup>72</sup> These individuals primarily came from nursing homes; however, the solenopsins were found to strongly inhibit myocardial contractility, which might explain the heart failure that occurred after massive envenomations.<sup>72,120</sup>

## Diagnosis

Clinical clues such as pustule development at the sting site after 24 hours, species identification, and history help to identify fire ant exposure. No laboratory assays to determine exposure are available. Fire ant allergy can be determined by correlating the clinical manifestation of fire ant sting reactions with imported fire ant-specific IgE determined by skin testing or radioallergosorbent test.

## Treatment

Local reactions require cold compresses and cleansing with soap and water. We recommend topical or injected lidocaine with or without 1:100,000 epinephrine, and topical vinegar and salt mixtures to decrease pain at the site of the bite and sting.<sup>37,117,154,192</sup>

Large local reactions should be treated with oral corticosteroids, antihistamines, and analgesics. Secondary infections should be treated with antibiotics. It is reasonable for systemic reactions to be treated with subcutaneous or intravenous epinephrine.

## BUTTERFLIES, MOTHS, AND CATERPILLARS

Butterflies and moths are insects of the order Lepidoptera. Several moth and butterfly families have species whose caterpillars are clinically important, that is, they contain spines or urticating hairs that secrete a poison that is irritating to humans on contact. *Lepidopterism* is a general term that describes the systemic adverse effects such as generalized urticaria, headache, pharyngitis, conjunctivitis, nausea, vomiting, bronchospasm, wheezing, and dyspnea that occur when humans are exposed to moths and butterflies.<sup>164</sup> *Erucism* is the term used when a cutaneous dermatitis results from contact with urticating caterpillars, the larval forms of the insect order Lepidoptera (moths and butterflies).<sup>76</sup> Caterpillar species from about 12 families of moths and rarely butterflies worldwide can inflict serious human injuries, including urticarial dermatitis, allergic reactions, consumptive coagulopathy, acute kidney injury, intracerebral hemorrhage, arthritis, joint deformity, and even altered mental status, ataxia, and dysarthria.<sup>76,119</sup>

Caterpillar, which means *hairy cat* in Latin, is the larval stage for moths and butterflies. In the United States, several significant stinging caterpillars are of note. Often the puss caterpillar (*Megalopyge opercularis*) is considered one of the most important toxic caterpillars in the United States because of the frequency with which reactions are reported, especially in Texas.<sup>216</sup> Other names for the puss caterpillar are woolly/hairy worm, woolly slug, opossum bug, tree asp, Italian asp, and "el perrito" in Spanish.<sup>216</sup> The caterpillars look furry and are covered in silky tan to brownish hairs that hide short spines containing an urticarial toxin. The spines are yellowish with black tips, and the hairs vary in color, ranging from pale yellow and gray to brown.<sup>29</sup> Other significant stinging caterpillars in the United States are the flannel moth caterpillar (*Megalopyge crispata*), the Io moth (*Automeris io*), the saddleback caterpillar (*Sibine stimulata*), and the hickory tussock caterpillar (*Lophocampa caryae*).<sup>144</sup> In South America, especially Brazil, *Lonomia obliqua* caterpillars are notorious for causing severe pain and a hemorrhagic syndrome.<sup>48,65</sup> In Australia, several caterpillars are of medical importance: mistletoe brown tail moth (*Euproctis edwardsi*), processionary caterpillars (*Ochrogaster lunifer*), cup moths (*Doratifera* spp), and the white-stemmed gum moth (*Chelepteryx collesi*).<sup>13</sup> Pine processionary caterpillars (*Thaumetopoea pityocampa*) are the most important defoliator of pine forests in the Mediterranean and central European countries, with significant consequential economic and occupational repercussions for workers who frequent

these pine forests.<sup>231</sup> In Nigeria, the *Anaphe venata* caterpillar is an important resource for protein that can cause thiamine deficiency syndrome similar to dry beriberi.<sup>3,4</sup>

Finally, the dendrolimus caterpillars of China and the *Preolis semirufa* caterpillars in Brazil cause significant joint disease.

### Pathophysiology

The pathophysiology of dendrolimiasis is not understood, but the tegument-produced venom contains formaldehyde and several uncharacterized histamine analogs with a tropism for receptors in bone, joints, and cartilage and during the acute phase results from IgE-mediated allergy to foreign proteins, and the chronic bone and joint disease is thought to be autoimmune mediated.<sup>122</sup> The composition of the venom varies according to the different caterpillar species. Some toxins contain proteins that cause histamine release, such as thaumetopoein isolated from *T. pityocampa* or pine processionary caterpillar.<sup>231,232</sup> Another protein isolated from the *Lonomia achelous* caterpillar causes coagulopathy. It is called lonomin V and is a proteolytic enzyme, which is isolated in the hairs, spines, and hemolymph of the *L. achelous*.<sup>108</sup> Its mechanism of action is not fully known, but it activates coagulation factors X and II, and there is some evidence that collagen degradation is responsible for platelet inhibition.<sup>77,107,135</sup> The venom and hair structure of *Lagoa crispata*, which has often been confused with the southern Texas puss caterpillar, is characterized. *Lagoa crispata* larvae have verrucal ridges containing poisonous spines along its filiform hairs.<sup>144</sup> The venom is stored at the base of the hollow setae (spines) where the poison sac and nervous tissue are located. Upon contact with these spines, the toxin, which is a protein or a substance that conjugates with proteins, is released.<sup>84</sup> The varying differences of caterpillar venom and their clinical effects emphasize the importance of positive identification of caterpillars.

### Clinical Manifestations

The pathophysiologic effects of venomous caterpillar exposures are classified into 7 distinct clinical syndromes to guide clinicians in making earlier, more species-specific diagnoses to direct therapies, including (1) erucism, (2) lepidopterism, (3) dendrolimiasis, (4) ophthalmia nodosa, (5) consumptive coagulopathy with secondary fibrinolysis,<sup>76</sup> (6) seasonal ataxia, and (7) pararamose.<sup>119</sup> Erucism is the preferred term for caterpillar dermatitis caused by contact with caterpillar urticating hairs, spines, or toxic hemolymph. Lepidopterism is a systemic illness caused by a constellation of adverse effects resulting from direct or aerosol contact with caterpillar, cocoon, or moth urticating hairs, spines or body fluids and is characterized by generalized urticaria, headache, conjunctivitis, pharyngitis, nausea, vomiting, bronchospasm, wheezing, and, rarely, dyspnea. Dendrolimiasis is a chronic form of lepidopterism caused by direct contact with urticating hairs, spines, or hemolymph of living or dead central Asian pine-tree lappet moth caterpillars or their cocoons and is characterized by urticating maculopapular dermatitis, migratory inflammatory polyarthritis, migratory inflammatory polyarthralgia, chronic osteoarthritis, and, rarely, acute scleritis.<sup>122</sup> Ophthalmia nodosa is a chronic ocular condition characterized by initial conjunctivitis with subsequent panuveitis caused by corneal penetration and subsequent intraocular migration of urticating hairs from lymantriid caterpillars and moths and therapsid spiders (tarantulas).

The South American *Lonomia saturniid* moth caterpillars range from Venezuela to northern Argentina and pose a threat in Brazil because of the high fatality rates from venom-induced consumptive coagulopathy, intracerebral hemorrhage, and acute kidney injury, possibly due to a combination of venom nephrotoxicity and microcirculatory fibrin deposition.<sup>40</sup> A case reported from Brazil involved a patient who presented with persistent gingival bleeding, epistaxis, and ecchymoses to the upper extremities and abdomen 4 days after exposure. These manifestations persisted until day 8 postexposure, when the patient was treated with antivenom.<sup>199</sup> The hemorrhagic syndrome presents as a disseminating intravascular coagulopathy and as a secondary fibrinolysis with skin, mucosal, and visceral bleeding, acute kidney injury, and intracerebral hemorrhage.<sup>48,135</sup>

Seasonal ataxia is a syndrome of unsteady gait and dysarthria, which occurs after the ingestion of the caterpillar of *Anaphe venata*. This occurs in areas of Nigeria where the caterpillars are a source of protein.<sup>3,4</sup> Ingestion of the roasted larvae causes nausea and vomiting and progresses to dizziness, ataxia, and unsteady gait in more than 90% of victims. These findings may take weeks to months for resolution. Dysarthria and impaired consciousness are also reported. The pathogenesis is related to thiamine deficiency induced by thiaminases contained in the larvae.

Pararamose is similar to dendrolimiasis with pruritic or painful dermatitis associated with arthritis and joint deformity, arising from contact with the caterpillar of *Premolis semirufa*, which are found in the Brazilian Amazon rain forests. Rubber tree plantation workers are particularly at risk even when wearing protective gloves.<sup>62,74</sup>

The clinical effects of caterpillar exposure are generally separated into 2 types—stinging reaction and pruritic reaction—although overlap occurs. Stinging caterpillars, such as *M. opercularis*, envenomate by contact with their hollow spines containing venom. The reaction is characterized as a painful, burning sensation with local effects and, less commonly, systemic effects. The area becomes erythematous and swollen, and papules and vesicles may appear. A rash with a typical gridlike pattern develops within 2 to 3 hours of contact. Reported symptoms include nausea, vomiting, fever, headache, restlessness, tachycardia, hypotension, urticaria, seizures, and even radiating lymphadenitis and regional adenopathy.<sup>176</sup> Pruritic reactions occur upon exposure to the itchy caterpillars that have nonvenomous urticating hairs, which produce a mechanical irritation, allergic reaction, or a granulomatous reaction from the chronic presence of the hairs. Several species that cause allergic reactions are the white-stemmed moth (*C. collesi*), Douglas fir tussock moth (*Orgyria pseudotsugata*), and gypsy moth caterpillar (*Lymantria dispar*).<sup>164</sup> Caterpillar hairs can cause ophthalmic trauma, otherwise known as ophthalmia nodosa.<sup>213</sup> The range of ophthalmic pathology depends on the penetration factor and the effect of the released urticating toxins.<sup>46</sup> The ophthalmic spectrum is classified into 5 types.<sup>46</sup>

**Type 1:** Brief exposure time of 15 minutes. Symptoms of chemosis, inflammation, epiphora, and foreign body sensation are reported to last for weeks.

**Type 2:** Chronic mechanical keratoconjunctivitis (hairs in bulbar/palpebral conjunctivitis). Foreign body sensation is relieved by removal of hairs. Corneal abrasions are often present.

**Type 3:** Gray-yellow nodules or asymptomatic granulomas.

**Type 4:** Severe iritis with or without iritis nodules; hairs are in the anterior chamber and possible intralenticular foreign body.

**Type 5:** Vitreoretinal involvement. Hairs enter through the anterior chamber or iris lens or by transscleral migration. Causes vitritis, cystoid macular edema, papillitis, or endophthalmitis.

### Treatment

Management for most dermal caterpillar envenomations is entirely supportive and includes washing the area with soap and water; “no touch” drying of the sting site with a hair dryer; gentle stripping of the bite site with cellophane or adhesive duct tape; and application of ice packs with cooling enhanced by initial topical swabbing with isopropyl alcohol. Rings should be removed in anticipation for potential swelling of the extremity, and tetanus prophylaxis should be updated accordingly.<sup>76</sup>

Treatment of ophthalmic lesions depends upon the exposure classification and should be managed by an ophthalmologist. Most patients are classified as type 1 or 2. Irrigation with 0.9% sodium chloride solution should be followed by meticulous removal of setae, followed by topical steroids and antibiotics. Type 3 requires surgical excision of the nodules. Type 4 requires topical steroids with or without iridectomy for nodules or operative removal of setae. Type 5 requires local treatment with or without systemic steroids. Resistant cases require vitrectomy with removal of setae.

Opioids are recommended if minor analgesics do not provide relief. If muscle cramps develop, benzodiazepines are reasonable. One study recommended the use of 10 mL 10% calcium gluconate administered IV,

which provided pain relief and is therefore reasonable to use in this circumstance.<sup>157</sup> Topical corticosteroids are reasonable to decrease local inflammation. Antihistamines such as diphenhydramine (25–50 mg for adults and 1 mg/kg, maximum 50 mg, in children) are recommended to relieve pruritus and urticaria.<sup>157,176</sup> Nebulized  $\beta$ -agonists and epinephrine administered subcutaneously should be used for more severe respiratory symptoms and anaphylactoid/anaphylactic-type reactions. Dendrolimiasis treatment consists of mostly supportive care with early surgical intervention recommended to excise draining sinus tracts and infected cartilage and to prevent permanent bone and joint deformities.<sup>122</sup> For hemorrhagic syndrome resulting from exposure to *L. obliqua* caterpillar, besides restoration of clotting factors, platelet, and cryoprecipitate infusions, an antidote called the antilonomic serum (SALon) is available and is used for treatment of the hemorrhagic syndrome in Brazil.<sup>65</sup> It is important to involve an experienced hematologist for suspected *Lonomia* envenomation and very important to distinguish *Lonomia obliqua* from *Lonomia achelous* because the cryoprecipitate, purified fibrinogen, and antifibrinolytic drugs, such as aprotinin and  $\epsilon$ -aminocaproic acid, were used successfully in *Lonomia achelous* but exacerbated the hemorrhagic effects in *Lonomia obliqua* with fatal consequences.<sup>55,95</sup> Patients exposed to either species should neither receive whole blood nor fresh plasma, which aggravates the clinical effects. Treatment for the seasonal ataxia includes supportive care with the administration of thiamine 100 mg orally every 8 hours, which reversed symptoms within 48 hours without long-term sequelae in a double-blinded placebo-controlled trial.<sup>2</sup>

## BLISTER BEETLES

Blister beetles are plant-eating insects that exude the blistering irritant cantharidin as a presumed defense mechanism. They are found in the eastern United States, southern Europe, Africa, and Asia. Most are from the order Coleoptera, family Meloidae. *Epicauta vittata* is the most common of more than 200 blister beetles identified in the United States.<sup>134</sup> When the beetles sense danger, they exude cantharidin by filling their breathing tubes with air, closing their breathing pores, and building up body fluid pressure until fluid is pushed out through one or more leg joints.<sup>93</sup> Cantharidin is found throughout all 10 stages of life of the blister beetle.<sup>50</sup> Cantharidin is produced only by the male blister beetle and is stored until mating. In the wild, the female repeatedly acquires cantharidin as copulatory gifts from her mates. However, the female blister beetle loses most of her reserves as she matures.<sup>50</sup> Cantharidin, also known popularly as *Spanish fly*, takes its name from the Mediterranean beetle *Cantharis vesicatoria*. It has been ingested as a sexual stimulant for millennia. The aphrodisiac properties are related to the ability of cantharidin to cause vascular engorgement and inflammation of the genitourinary tract upon elimination, hence the reports of priapism and pelvic organ engorgement.<sup>229</sup> Cantharidin was once used for treatment of bladder and kidney infections, stones, stranguria (bladder spasm), and various venereal diseases.<sup>134</sup> In the last century, cantharidin was commonly used for treatment of pleurisy, pneumonia, arthritis, neuralgias, and various dermatitides. A topical 1% commercial preparation is used for removal of warts and molluscum contagiosum.<sup>61,206</sup> Cantharidin poisoning is reported by cutaneous exposure,<sup>36</sup> unintentional inoculation,<sup>179</sup> and inadvertent ingestion of the beetle itself.<sup>226</sup> A case was reported of a child being treated for molluscum contagiosum with cantharidin preparation that included podophyllin and salicylic acid, also called Canthacur PS or Canthacur Plus.<sup>206</sup> The child developed varicelliform vesicular dermatitis in the distribution of the application of petrolatum. It is thought that the petrolatum used by the parents to moisturize her skin spread the lipophilic cantharidin preparation to the nearby areas, causing the blistering reaction. Canthacur PS should not be used for molluscum contagiosum but is reserved for verrucae vulgaris on acral areas. Canthacur or Cantharone contains plain cantharidin and can be used for the treatment of molluscum contagiosum. Fewer than 30 cases of Spanish fly poisoning are reported since 1900.<sup>134</sup>

## Pathophysiology

Cantharidin is a natural, defensive, highly toxic terpenoid (lethal dose for humans 0.5 mg/kg) produced by blister beetles and shares a structural

similarity with the herbicide Endothall.<sup>146</sup> Endothall causes corrosive effects to the GI tract; cardiomyopathy and vascular permeability, which has resulted in shock. A single case report of lethal poisoning with 7 to 8 g of Endothall led to the death of healthy young boy from hemorrhage of the GI tract and lung, which is clinically similar to the cantharidin exposures. Although the mechanism of action has not been elucidated, one mechanism based on an in vitro study suggests that cantharidin inhibits the activity of protein phosphatases type 1 and 2A. This inhibition alters endothelial permeability by enhancing the phosphorylation state of endothelial regulatory proteins and results in elevated albumin flux and dysfunction of the barrier.<sup>140</sup> Enhanced permeability of albumin is thought to be responsible for the systemic effects of cantharidin that lead to diffuse injury of the vascular endothelium and resultant blistering, hemorrhage, and inflammation.

## Clinical Manifestations

The clinical effects are mostly attributed to the irritative effects on the exposed organ systems. The secretions of cantharidin from the beetle's leg joints cause an urticarial dermatitis that is manifested several hours later by burns, blisters, or vesicubullae.<sup>36</sup> Symptoms are often immediate or sometimes delayed over several hours. In addition to the local effects, cantharidin can be absorbed through the lipid bilayer of the epidermis and cause systemic toxicity, with diaphoresis, tachycardia, hematuria, and oliguria from extensive dermal exposure.<sup>229</sup> If the periorbital region is contaminated, edema and blistering can evolve. Ophthalmic findings from direct contact with the beetle or hand contamination include decreased vision, pain, lacrimation, corneal ulcerations, filamentary keratitis, and anterior uveitis.<sup>179</sup> Most human exposures involve inadvertent contact with the beetle or its secretions, resulting in dermatitis, keratoconjunctivitis, and periorbital edema secondary to hand–eye involvement, also called the *Nairobi eye*.<sup>179</sup>

When cantharidin is ingested, severe GI disturbances and hematuria occur. Initial patient complaints typically include burning of the oropharynx, dysphagia, abdominal cramping, vomiting, hematemesis followed by lower GI tract hematochezia, and tenesmus. An inadvertent blister beetle ingestion by a child who thought it was the edible *Eulepida mashona* or white grub resulted in hematuria and abdominal cramping.<sup>226</sup> Genitourinary effects include dysuria, urinary frequency, hematuria, proteinuria, and acute kidney injury impairment. Most symptoms resolved over several weeks. However, death from acute kidney injury with acute tubular necrosis is reported.<sup>229</sup>

## Diagnostic Testing

Cantharidin toxicosis is identified for equine and ruminant exposures by screening urine and gastric contents with high-performance liquid chromatography and gas chromatography–mass spectrometry.<sup>183,184</sup> This method is not used in clinical practice.

## Treatment

Treatment is largely supportive. Wound care and tetanus status should be assessed. For keratoconjunctivitis, an ophthalmologist should be consulted early in the clinical course and the patient should be treated with topical corticosteroids (prednisolone 0.125%), mydriatics (cyclopentolate 1%), and antibiotics (ciprofloxacin 0.3%).

## SUMMARY

- Health care providers should have an extensive knowledge regarding the identification of arthropods and their bites and stings to provide optimal care.
- Black widow: Latrodectism is a painful neurotoxic condition best known for causing intense muscle spasms associated with short-term autonomic and central nervous system dysfunction.
- Brown recluse: Loxoscelism is manifested by dermatonecrotic tissue loss, which is less often accompanied by systemic reactions such as hemolysis, coagulopathy, acute kidney injury, and death.
- Scorpions: Envenomation releases a neurotoxin that opens the sodium channels and causes local as well as systemic effects that activate the sympathetic and parasympathetic branches of the nervous system,

leading to intense pain, edema, erythema, as well as severe hypertension and tachy- or brady-dysrhythmias.

- Ticks: Ticks are vectors that are commonly known to transmit infectious diseases but in the setting of envenomations, one must remember tick toxicosis in the differential as a cause of progressive ascending flaccid paralysis that can be fatal if the tick is not removed.
- Caterpillars: Lepidopterism is another cause of common human envenomations including dermal and ophthalmic toxicity.

## ANTIVENOM: SPIDER

Michael A. Darracq and Richard F. Clark

**INTRODUCTION**

The terms “antivenom” and “antivenin” often are used interchangeably. Although the origin of the term “antivenom” is obvious, “venin” is French for venom and “antivenin” is traditionally used in certain parts of the world. Wyeth Pharmaceuticals, the maker of Crotaline and *Micrurus* antivenom, and Merck & Co, Inc, the maker of *Latrodectus* antivenom, adopted “antivenin” in the brand names for their products. Brand name recognition was largely responsible for the use of the term “antivenin” in place of “antivenom.” In 1981, the World Health Organization determined the preferred terms for the English language to be “venom” and “antivenom.”

**HISTORY**

Two of the most notable genera of spiders of medical importance in the United States are *Latrodectus* (*L. mactans*, *L. geometricus*, *L. variolus*, *L. hesperus*, and *L. bishopi* are native, whereas *L. geometricus* was introduced) and *Loxosceles*. Commercially available antivenom does not exist in the United States for treatment of *Loxosceles* envenomation. Currently, there is one commercially available *Latrodectus* antivenom in the United States. Black Widow Spider Antivenin (Merck & Co, Inc) (Merck BW-AV) has been available in the United States since its US Food and Drug Administration (FDA) approval in 1936.<sup>3</sup> The use of this antivenom in the treatment of *Latrodectus* envenomations remains controversial, as mortality from these bites is low in the United States,<sup>8,9,31,33</sup> and complications including death following antivenom administration are rarely reported.<sup>8,22,32</sup> Ongoing research and development of an F(ab')<sub>2</sub> antivenom may ameliorate concerns and limitations related to potential adverse events resulting from administration of the Merck antivenom and production shortages limiting availability.<sup>12</sup> As of June 2018, however, F(ab')<sub>2</sub> black widow antivenom has not been approved for use by the US Food and Drug Administration (FDA) but is in clinical trials under the trade name Analatro.

**PHARMACOLOGY****Chemistry, Preparation, and Mechanism of Action**

Antivenom for spiders is prepared in a similar manner as other antivenom products by first immunizing animals with nontoxic amounts of venom.<sup>5,26</sup> Monkeys, horses, goats, sheep, chicken, camels, and rabbits have been used historically to source antivenom.<sup>29</sup> The animals are placed on an inoculation schedule to allow gradual production of immunoglobulins, most importantly IgG. Sufficient antibody production usually occurs within 6 weeks. The species availability, financial considerations, and tradition rather than scientific modeling is typically responsible for animal choice for immune serum production. The majority of antivenom producers use horses, since they are relatively easy to maintain, and large volumes of serum can be obtained at one time without harming the animal. During antivenom production varying efforts are made to remove animal proteins such as albumin. Antivenoms target, bind, neutralize, and promote elimination or redistribution of toxins from body tissues. To date, no studies have compared immune sera of different animals for human compatibility or tolerance.

The antidotal fraction of an antivenom exists as either whole IgG, Fab, or F(ab')<sub>2</sub>. The IgG molecule is composed of 2 antigen-binding fragments (Fab fragments) that are fused together and attached to the larger complement binding fragment (Fc fragment). It is the larger Fc portion that is generally considered to be the most responsible for immune-mediated reactions. Digestion of the disulfide bonds of an IgG molecule by pepsin will cleave the

Fc fragment, allowing isolation of pure F(ab')<sub>2</sub> fragments (2 fused Fab fragments with some intact hinge region). By contrast, digestion with papain cleaves the molecule more distally such that a larger Fc portion is removed from 2 separate Fab fragments. Both Fab and F(ab')<sub>2</sub> molecules are isolated with affinity chromatography, and the highly antigenic Fc portion discarded. Although Fab and F(ab')<sub>2</sub> are more expensive to produce than their whole immunoglobulin counterparts, they are much less allergenic and therefore safer products.

Whole IgG antivenom is the easiest and least expensive to produce. It has a molecular weight of approximately 150 kDa, and is the largest of the 3 antivenom types. Because of its size, it is the least filterable at the glomerulus and has the smallest volume of distribution. Whole IgG has a longer elimination half-life than either Fab or F(ab')<sub>2</sub>.<sup>18</sup>

F(ab')<sub>2</sub> antivenom has an intermediate size (~100 kDa) and elimination half-life. Although it lowers the risk of anaphylaxis compared to whole IgG, the F(ab')<sub>2</sub> portion retains much of the allosteric configuration of the original IgG molecule that is lost when Fab are formed. This configuration theoretically allows for tighter binding to venom. The Fab antivenom is the smallest (~50 kDa) molecule in size and is eliminated by the kidneys. It has the largest volume of distribution and a greater ability to reach extravascular compartments. Arachnid venoms that affect the central nervous system have low molecular weights and large volumes of distribution. Thus Fab and F(ab')<sub>2</sub> based antivenoms are theoretically best suited for this function.<sup>18</sup>

Immunoglobulin-based antivenoms can be given by the intramuscular, intravenous, or subcutaneous route. Intravenous administration achieves rapid peak plasma concentrations, and the infusion can be stopped in the event of an allergic reaction.<sup>19</sup> Intramuscular and intraosseous injection has been used when intravenous access is unobtainable.<sup>20</sup>

**Pharmacokinetics and Pharmacodynamics**

Currently, there is no published pharmacokinetic or pharmacodynamic information available on Merck BW-AV in humans or animals. One study colleagues demonstrated Western blot binding of *L. hasselti* (redback spider) Antivenom (RBS-AV) to purified  $\alpha$ -latrotoxin and similar protein bands derived from multiple widow spiders (*L. mactans*, *L. hesperus*, *L. lugubris*, *L. tredecimguttatus*, and *L. hasselti*). When co-mixed with the venoms from these species prior to administration, RBS-AV prevented the development of a reproducible and rapid muscle contracture of an in vitro chicken nerve-muscle preparation. A dose-response relationship was observed with varying doses of RBS-AV administration.<sup>17</sup> This confirms a direct in vitro binding effect of RBS-AV against widow spider venoms.

Previous animal studies demonstrated that intramuscular administration of antivenom produced very low serum venom concentrations.<sup>36,37</sup> In these rabbit studies of intramuscular administration, F(ab')<sub>2</sub> and IgG had poor bioavailability (36%–42%) and delayed time to peak concentrations of 48 to 96 hours.

Pharmacokinetic and pharmacodynamic characteristics of equine-derived antivenoms differ between species studied. Equine-derived antivenom maximum concentrations were greater in cows than in horses, and steady-state distribution volumes were higher in cows than in horses in one study. Similar results were observed in rabbit models.<sup>38</sup> Pharmacokinetic and pharmacodynamic parameters observed in animal models should therefore be interpreted with caution with regard to behavior of antivenoms in humans.

Redback spider antivenom, available in Australia, has been administered intramuscularly to treat human envenomations, and clinical effectiveness equivalent to intravenous administration was reported.<sup>22</sup> Subsequent studies, however, demonstrated the absence of RBS-AV in circulating serum up to 5 hours following intramuscular administration. Serum concentrations of RBS-AV were detected within 30 minutes of administration following intravenous administration.<sup>25</sup> These results are consistent with animal studies demonstrating little if any effect on circulating venom when antivenoms are given intramuscularly. Additional studies on the pharmacokinetic and pharmacodynamic properties of RBS-AV, Merck Black Widow Antivenom, and F(ab')<sub>2</sub> based black widow antivenoms are needed.

### ROLE IN *LATRODECTUS* SPECIES (*L. BISHOPI*, *L. GEOMETRICUS*, *L. HESPERUS*, *L. INDISTINCTUS*, *L. MACTANS*, *L. VARIOLUS*)

Although black widow bites are associated with severe muscle pain, cramping, and autonomic disturbances, mortality remains low.<sup>7,8,31,34</sup> Symptomatic treatment with muscle relaxants and opioid analgesics is generally effective, although the duration of symptoms following severe envenomation may necessitate hospitalization for 1 to 2 days or more.

The use of Merck BW-AV appears to shorten the length of symptoms dramatically, allowing outpatient care in some cases.<sup>7,31,33,34,40</sup> Studies of reported *Latrodectus*-envenomated patients in Australia, however, demonstrated little clinical difference between *Latrodectus* antivenom and placebo.<sup>20,21</sup> In addition, anaphylaxis and other adverse events following the administration of *Latrodectus* antivenom are reported.<sup>7,20,21,31,32</sup>

Because of low mortality and the potential for adverse events following administration, some authors question the use of BW-AV.<sup>37</sup> We still believe *Latrodectus* antivenom is safe and effective when used appropriately, and recommended it in cases of severe envenomation where muscle cramping, hypertension, diaphoresis, nausea, vomiting, myocardial infarction, or respiratory difficulty are present and appropriate use of opioid analgesia and muscle relaxants are ineffective.<sup>7,9</sup>

*Latrodectus* antivenom is also reported to successfully treat priapism complicating severe envenomation.<sup>21</sup> Although the safety of antivenom is not clearly established in the developing fetus, pregnancy is a reasonable indication for *Latrodectus* antivenom administration, as the stress of severe pain and muscle cramps may have adverse fetal effects.<sup>4,39</sup>

Antivenoms for a number of *Latrodectus* spiders are available worldwide (Table A37-1). A shortage of Merck BW-AV prompted the finding that antivenom against *L. hasseltii* (RBS-AV) also neutralizes the venom of *L. mactans* in a mouse model.<sup>10</sup> Analatro, a polyvalent F(ab')<sub>2</sub>, is an equine-derived antivenom created for *L. mactans* in both Argentina and Mexico.

A randomized placebo-controlled multicenter trial of Analatro in the United States demonstrated similar overall reduction of pain between antivenom- and placebo-treated patients. Clinically significant reduction in pain, however, was more rapid with Analatro (30 minutes vs 90 minutes).<sup>12</sup>

In a review of 163 cases of presumed *L. hesperus* and *L. mactans* envenomations, Merck *Latrodectus* antivenom reduced the mean duration of symptoms from 22 to 9 hours. Symptoms usually subsided within 1 to 3 hours of antivenom administration. The hospital admission rate fell from 52% in those who were managed with opioids and muscle relaxants to 12% in those patients receiving antivenom.<sup>8</sup> A more recent review demonstrated immediate resolution of pain following BW-AV administration in suspected *L. mactans* envenomation.<sup>35</sup> Following administration of RBS-AV in redback spider envenomation, however, only 34% of recipients reported significant pain relief at 2 hours.<sup>23</sup>

### ROLE IN FUNNEL-WEB SPECIES (*ATRAX* AND *HADRONYCHE*)

A rabbit IgG-based funnel-web spider (*Atrax robustus* and others) antivenom is available in Australia. Since the introduction of the antivenom, no deaths have been reported.<sup>26</sup> Complete response following administration of antivenom was reported in 97% of envenomations in one series.<sup>25</sup>

### ROLE IN *LOXOSCELES* SPECIES (*L. RECLUSA*, *L. LAETA*, *L. RUFESCENS*, *L. ARIZONICA*, *L. UNICOLOR*)

Envenomation by the brown recluse spider *Loxosceles reclusa* is associated with low but significant morbidity, particularly in the midwest and southeast United States. Experimental anti-*Loxosceles* Fab blocked dermatonecrosis in a rabbit model, but only if provided within 24 to 48 hours of envenomation.<sup>16,37</sup> Although no commercially available antivenom exists in North America for treatment of *Loxosceles* envenomation, antivenom produced against South American *Loxosceles* spiders has cross-reactivity with North American species like *L. reclusa*.<sup>13</sup> The usual late presentation of patients with necrotic lesions from spider bites makes antivenom use for *Loxosceles* difficult to study. National laboratories in Brazil and Argentina produce antivenoms for *L. reclusa*, *L. boneti*, and *L. rufescens*.<sup>5,13</sup>

### ADVERSE EFFECTS AND SAFETY ISSUES

Despite the apparent efficacy of antivenom, the decision to give horse serum for a disease with limited mortality is serious. Death from bronchospasm and anaphylaxis is a rarely reported complication of whole IgG BW-AV (Merck) administration,<sup>8,23,34</sup> as is serum sickness.<sup>9</sup> Serum sickness is dose-dependent and is less likely when the typical dose of one to 2 vials are administered. A detailed review of one case of death following antivenom administration<sup>7</sup> demonstrates that the antivenom was inappropriately prepared (not diluted) and inappropriately administered (intravenous push rather than slow infusion) to a patient with multiple drug allergies, atopy, and asthma. Resuscitation was further complicated by the development of a pneumothorax. A second death<sup>34</sup> was reported in a 37-year-old man with history of asthma who received antivenom as an infusion and developed cardiac arrest as a complication of severe anaphylaxis. He died 40 hours after presentation.<sup>34</sup>

In Australia, antivenom to the redback spider (*L. hasseltii*, CSL Ltd) is made by immunizing horses for production of F(ab')<sub>2</sub>. Horse-derived F(ab')<sub>2</sub> has a lower reported incidence of allergic reactions, with early allergic reactions as infrequent as 0.5% to 0.8%. The incidence of serum sickness is reported at less than 5%.<sup>23,43,44</sup> Analatro, a similar F(ab')<sub>2</sub> product, is anticipated to be a safer antivenom than the currently available Merck whole IgG product. No serious adverse effects or deaths were observed in the previously described randomized controlled Analatro trial.<sup>12</sup>

A review of the US National Poison Data System (NPDS) demonstrated a 3.4% rate of adverse drug reactions (ADRs) following administration of the BW-AV.<sup>33</sup> This is consistent with previously reported rates of ADRs following BW-AV administration.<sup>9</sup> Directly attributing complications to administration of antivenom is difficult as these patients received multiple therapies, including opioids, benzodiazepines, and calcium salts preceding

antivenom administration, and NPDS does not attribute an ADE to a specific therapy. Similarly, the nature of these ADEs is not described in NPDS. However, it is noteworthy that no deaths occurred in 374 instances of use and only 5 patients received antihistamines, suggesting acute hypersensitivity reactions to the Merck BW-AV to be uncommon and that this antivenom is generally safe. Similarly, a review of 96 assessable instances of BW-AV administration over a 10-year period in a single state similarly demonstrated a low rate of adverse reactions. Four patients in the series had adverse effects ascribed to antivenom administration. These reactions were generally mild and included myalgias, fatigue, generalized paresthesias, flushing, and urticarial rash. There were no cases of dyspnea, angioedema, bronchospasm, hypotension, or death.<sup>35</sup> This low rate of severe adverse reactions and lack of death suggests that Merck BW-AV is a safe product when prepared and administered correctly to patients without underlying atopy, asthma, or drug allergies.

## PREGNANCY AND LACTATION

Black widow envenomations during pregnancy are relatively rare. In one study of 12,640 patients envenomated by a black widow spider, 97 (3%) were pregnant. When compared with nonpregnant women, no significant differences were observed in recommended or administered treatments including the use of antivenom.<sup>6</sup> There are 6 reported cases of *Loxosceles* envenomations in pregnant women. All were managed with supportive therapy including analgesics, antihistamines, and a short course of low-dose steroids. Pregnancy outcomes were favorable in all reported cases.<sup>2,15</sup> Merck BW-AV is Pregnancy Category C. It is not known whether antivenom is excreted in human milk.

## DOSING AND ADMINISTRATION

The starting recommended dose of the Merck antivenom is one vial reconstituted with 2.5 mL sterile water for injection and then diluted in 50 mL of saline for intravenous administration over 15 min. Although BW-AV can also be given intramuscularly, this route carries the disadvantage of slower, more erratic absorption, less control over the rate of administration, and the inability to stop the administration should an allergic reaction occur. In addition, recent studies suggest intramuscular injection of antivenom may not yield significant serum concentrations.<sup>27</sup> For these reasons, the intramuscular route is not routinely recommended.

The initial dose of antivenom in funnel-web spider envenomation is 2 vials in patients with any signs or symptoms of envenomation. Patients with acute respiratory distress syndrome or decreased consciousness should receive 4 vials.<sup>32</sup> The following protocol is recommended for severe cases:<sup>32</sup> 2 vials (each containing 100 mg of rabbit IgG) of antivenom are administered very slowly intravenously. The dose can be repeated in 15 minutes if no improvement occurs. The dose recommended for more severe cases. A rapid response is expected. Repeated administration of antivenom is recommended until symptoms are completely reversed.<sup>14</sup> *Atrax robustus* envenomations are reported to require multiple infusions of antivenom.<sup>14</sup> The recommended dosage for children is the same as for adults.

## FORMULATION AND ACQUISITION

Each vial of the Merck BW-AV contains 6,000 antivenom units standardized by biologic mouse assay. Because *Latrodectus* venoms are virtually identical by immunologic and electrophoretic mechanisms, antivenom created for *L. mactans* is presumed to be effective in other species of *Latrodectus* as well.<sup>30</sup>

*Latrodectus* antivenin is supplied as a white to gray crystalline powder in vials containing not less than 6,000 antivenin units with thimerosal 1:10,000 added as a preservative, along with a 2.5-mL vial of sterile diluent for reconstitution. The antivenin must be stored and shipped at 2°C to 8°C (36°F–46°F), but never frozen. The reconstituted antivenin color ranges from light straw to very dark iced tea, although color has no effect on potency.<sup>2</sup> A 1-mL vial of horse serum (1:10 dilution) for sensitivity testing is also included. We do not recommend utilization.

The Antivenom Index, maintained by the Association of Zoos and Aquariums (<https://www.aza.org/antivenom-index/>) and accessible by the nation's Poison Control Centers, might also serve as a resource.

## SUMMARY

- The decision to use spider antivenom must be individualized to the patient's clinical manifestations.
- Because mortality following black widow envenomation is low, antivenom is reserved for cases in which symptoms are severe or do not respond to other therapies, and after a frank discussion with the patient of possible adverse effects.
- Although a large body of literature suggests that Merck BW-AV is safe when properly prepared and administered to patients without asthma, adverse effects including severe anaphylaxis and death are reported.
- A new, purified F(ab')<sub>2</sub> BW-AV is in clinical development, but is currently unavailable.

## ANTIVENOM: SCORPION

Michael A. Darracq and Richard F. Clark

**INTRODUCTION**

*Centruroides exilicauda* (formerly known as *Centruroides sculpturatus*) is the only scorpion of medical importance in the United States. It is indigenous to the deserts of Arizona, but also can be found in Texas, New Mexico, California, and Nevada.<sup>10</sup> Occasionally, envenomations occur in nonindigenous areas of the country from “stowaway” scorpions in travelers’ luggage.<sup>34</sup>

**HISTORY**

Poison control centers in Arizona receive several thousand calls annually for scorpion stings. Although the incidence of morbidity with these envenomations is significant, no deaths associated with the toxic effects of scorpion venom have been reported in the United States for almost 50 years. Antivenom for the *Centruroides* spp was first produced in horses in Mexico in the 1930s.<sup>12</sup> In 1947, antivenom was produced from rabbits and cats immunized with *C. sculpturatus* and *C. gertschi*.<sup>31</sup> The Antivenom Production Laboratory at Arizona State University (APL-ASU) began producing antivenom to *C. sculpturatus* in goats in 1965. This antivenom was used for treatment of scorpion stings in Arizona until 2004, when production ceased and stockpiles expired. In June 2000, Silanes Laboratory received orphan drug status for a *C. scorpion* antivenom, an equine F(ab')<sub>2</sub> derived from *C. limpidus*, *C. noxius*, *C. suffusus*, and *C. meisei* (formerly known as *C. elegans*) manufactured by Instituto Bioclon of Mexico, and sold as Anascorp. In August 2011, Anascorp was approved by the US Food and Drug Administration (FDA) for the treatment of *C. exilicauda* envenomations.<sup>16</sup>

**PHARMACOLOGY**

Antivenom for scorpions is prepared in the same manner as other antivenom products (Antidotes in Depth: A37 and A39).

**Pharmacokinetics and Pharmacodynamics**

In a study of 8 healthy patients (6 males and 2 females, age 17–26 years) without prior scorpion envenomation, an intravenous bolus dose of 47.5 mg of Anascorp was administered. Serial blood samples were collected over 21 days. Measured pharmacokinetic parameters (mean ± standard deviation) included area under the curve (AUC), 706 ± 352 mcg/mL; clearance, 83.5 ± 38.4 mL/h; half-life, 159 ± 57 hours; and steady-state volume of distribution (V<sub>ss</sub>), 13.6 ± 5.4 L.<sup>35</sup>

**ROLE IN CENTRUROIDES SPECIES**

One vial of Anascorp antivenom contains sufficient F(ab')<sub>2</sub> to neutralize 150 mouse LD<sub>50</sub> of *Centruroides* venom.<sup>26</sup> Safety and efficacy are documented in both animals and humans.<sup>1,8–10</sup> In the FDA review and subsequent approval of Anascorp, 6 trials were submitted for evaluation. Only one study was prospective, randomized, double-blinded, and controlled. It demonstrated a clear benefit in reduction of signs and symptoms of scorpion envenomation by 4 hours post-administration (8/8 vs 1/7), reduction in quantity of sedative administered (mean midazolam dose of 0.1 mg/kg (0.0–0.2 mg/kg) in treated patients versus 4.6 mg/kg (0.1–16.7 mg/kg) in controls. It absence of free serum venom concentrations at one hour after administration (mean 0.0 in treated vs 2.65 ng/mL in controls).<sup>8</sup>

One retrospective trial using historical controls was included as representative of clinical outcomes in the absence of antivenom administration.

This trial demonstrated the need for exceedingly large dose of sedatives to treat the inability to walk and respiratory distress due to envenomation with a mean time to discharge of 12.6 hours without administration of scorpion antivenom.<sup>12</sup>

One large (n = 1,534), unpublished and open-label study was also included for review. The majority (1,204/1,534) of patients were children (0.7 months–18 years) and male (52.3%). In 1,396/1,425 patients, the mean time to resolution of clinically important signs of envenomation following Anascorp administration was 1.42 hours (0.2–20.5 hours). Children reportedly improved slightly faster than adults (1.28 ± 0.8 hours vs 1.91 ± 1.4 hours). Of the 1,534 patients included in the study, 95% had relief of systemic signs associated with *Centruroides* envenomation within 4 hours of Anascorp administration.<sup>9,15</sup>

Three additional open-label trials (AL-02/04-adult patients, AL-02/05-pediatric patients, and AL-02/06-pediatric patients) with the use of the Instituto Bioclon of Mexico product Alacramyn (Alacramyn is the Mexican equivalent of Anascorp) were reported by the study sponsors to demonstrate 100% resolution of symptoms by 4 hours following administration of antivenom.<sup>15</sup>

Because of the high cost of Anascorp (\$3,750), some hospitals have adopted guidelines advocating for single-vial initial dose rather than the FDA-approved 3-vial initial dose. A more recent retrospective cohort of grade III or IV pediatric *Centruroides* envenomations comparing treatment with supportive care including benzodiazepines and opioids for agitation and pain, FDA approved dosing, and one- to 2-vial initial dose demonstrated no significant difference in emergency department lengths of stay or outcomes between groups. Clinical presentation however appeared to influence treatment as patients receiving antivenom had a higher envenomation grade than those receiving supportive care alone, and the 3-vial initial dose group was younger and had more respiratory distress than those receiving one- to 2-vial initial dose.<sup>11</sup>

**ROLE IN LEIURUS SPECIES**

The *Leiurus quinquestriatus* scorpion is indigenous to Africa, Asia, and the Middle East, including Egypt, Israel, Jordan, Kuwait, Lebanon, Oman, Qatar, Saudi Arabia, Syria, and Turkey. Antivenom to *L. quinquestriatus* is currently made in France, Germany, Israel, Saudi Arabia, Egypt, Tunisia, and Turkey (Table A38–1).

In observational studies, an intravenous infusion of 5 to 20 mL of *Leiurus* antivenom was needed to control venom effects, and only patients given antivenom within the first several hours demonstrated significant benefit.<sup>2,21</sup> The rate of allergic reactions for the Turkish antiscorpion antivenom is reported to be 1.6% to 6.6%.<sup>21</sup> The recommended dose of the Israeli *L. quinquestriatus* antivenom is 5 to 15 mL for intravenous use, although several authors report lack of clinical efficacy of this particular antivenom.<sup>6,17,32</sup>

*Leiurus quinquestriatus* antivenom was successfully used to treat a 2-year-old boy with envenomation by *Androctonus crassicauda*. Symptoms resolved 2 hours after antivenom administration.<sup>30</sup>

**ROLE IN TITYUS SPECIES**

*Tityus* species of scorpions are endemic to South America, particularly Brazil. An F(ab')<sub>2</sub> antivenom for *Tityus serrulatus* is available from Fundação Ezequiel Dias (FUNED), in Belo Horizonte, Brazil. The usual dose of the antivenom is 20 mL as an intravenous infusion.<sup>14</sup>

In a series of 18 patients with *T. serrulatus* envenomation treated with antivenom, vomiting and local pain decreased within one hour, and cardio-respiratory manifestations disappeared within 6 to 24 hours in all patients except the 2 presenting with acute respiratory distress syndrome.<sup>14</sup> Sixteen patients recovered completely by 24 hours. The Instituto Buntantan in Brazil also produces Soro antiarachnidico and Soro antiscorpionico for treatment of *Tityus* spp.

### Role in *Androctonus* Species

Scorpion antivenom in South Africa is an equine-derived antivenom available from the South African Vaccine Producers, formerly South African Institute for Medical Research (SAIMR), Johannesburg, South Africa. Scorpi-FAV, produced by Aventis Pasteur, is produced for treatment of *Androctonus* spp, *Buthus occitanus*, and *L. quinquestriatus*.

*Buthus tamulus* monovalent red scorpion antivenom serum produced by Central Research Institute of India is an equine-derived lyophilized antivenom for the venom of *Mesobuthus tamulus*. The manufacturer recommends a dosage of one vial, although a dose of 5 vials significantly decreased mortality in one study.<sup>23,33</sup>

Prazosin has also been used in the treatment of children with *Buthus tamulus* envenomation in Southern India. The addition of monovalent scorpion antivenom reduced the duration of clinical symptoms (sweating, salivation, cool extremities, priapism, hypertension or hypotension, tachycardia), percentage of children deteriorating into more severe symptoms, and the mean dose of prazosin received when compared with prazosin treatment alone.<sup>4,28</sup>

In Pakistan, the treatment of scorpion stings was modified in 1991 to include the administration of 5 vials of antivenom. A retrospective case series of 950 patients treated with and without antivenom was compared to 968 cases treated after the 5 vial protocol was initiated. A statistically significant decrease in mortality was demonstrated. The last recorded death in Pakistan resulting from a scorpion sting occurred in 1991 in a patient who did not receive antivenom.<sup>33</sup>

*Parabuthus* spp antivenom from South African Vaccine Producers is an equine-derived antivenom to *Parabuthus* spp. In one study, antivenom was unavailable for a period of time allowing for a unique design of matched pair of patients. Patients who received antivenom had a significant decrease in hospital stay after receiving one (5-mL) vial. Pain, hypersalivation, fasciculations, tremor, and bladder distension responded best to antivenom, whereas dysphagia, ptosis, and local swelling were more resistant.<sup>7</sup>

The unavailability of specific antivenoms often necessitates symptomatic treatment or use of a comparable foreign antivenom. In a study of 72 moderate scorpion stings in Para, Brazil, 33% of patients did not receive treatment because of unavailability of the antivenom.<sup>29</sup>

### ADVERSE EFFECTS AND SAFETY ISSUES

Hypersensitivity reactions to Anascorp and other equine-derived antivenoms occasionally occur following administration. Adverse effects reported from cumulative clinical trial data revealed that 2.2% of patients experienced

severe adverse reactions (respiratory distress, aspiration, hypoxia, ataxia, pneumonia, and eye swelling) following Anascorp administration. However, these symptoms occurred in the setting of acute *Centruroides* envenomation, limiting the direct attribution of symptoms to antivenom administration alone. The most common adverse effects reported included vomiting (4.7%), pyrexia (4.1%), rash (2.7%), nausea (2.1%), and pruritus (2%).<sup>13</sup> No deaths were reported in clinical trials of Anascorp. The presence of cresol as an injectable excipient may increase localized reactions and generalized myalgias following administration. Patients with known equine protein allergies or previous exposure to Anascorp or other equine-derived antivenoms or antitoxins may also be at increased risk because of previous sensitization. No drug interaction studies have been conducted with Anascorp.

### PREGNANCY AND LACTATION

Anascorp is Pregnancy Category C. Animal reproduction studies have not been conducted, and it is unknown whether Anascorp causes fetal harm when administered to pregnant women. Reproductive capability postadministration similarly has not been assessed. Anascorp should only be administered in pregnant women if clearly needed for alleviation of symptoms and after other therapies have been utilized. It is unknown whether Anascorp is excreted in human breast milk.<sup>13</sup>

### DOSING AND ADMINISTRATION

Anascorp is the only FDA-approved treatment for the clinical signs and symptoms of *Centruroides* scorpion envenomation. These include, but are not limited to, loss of motor control, roving or abnormal eye movements, slurred speech, respiratory depression, and excessive oral secretions. Package insert dosing recommendations (FDA) are 3 vials administered intravenously over 10 minutes after reconstitution (5 mL sterile 0.9% sodium chloride solution/vial) and dilution to a total volume of 50 mL; thereafter administer one additional vial at a time at 30- to 60-minute intervals as needed for symptom control. Do not use if the solution is turbid.

A cost-effectiveness study of Anascorp demonstrated a mean cost \$10,708 (95% CI \$10,556–\$11,010) when antivenom was used as compared to a mean cost without scorpion antivenom of \$3,178 (95% CI \$1,627–\$5,184). The mean success rate was 99.87% (95% CI 99.64%–99.98%) with scorpion antivenom and 94.31% (95% CI 91.10%–96.61%) without scorpion antivenom. These data suggest a very high rate of success with antivenom but at a very high cost. The authors of this study conclude that at current cost, scorpion antivenom in the United States cannot be justified for use in most clinical situations and is not cost-effective.<sup>3</sup>

### FORMULATION AND ACQUISITION

Anascorp is supplied as a sterile lyophilized preparation in a single-use vial. When reconstituted, each vial contains not more than 24 mg per milliliter of protein, and not less than 150 mouse LD<sub>50</sub> neutralizing units. Anascorp should not be frozen, but stored at room temperature up to 25°C (77°F).<sup>15</sup>

The Antivenom Index, maintained by the Association of Zoos and Aquariums (<https://www.aza.org/antivenom-index/>) and accessible by the

nation's Poison Control Centers, may serve as a resource in the event of difficulty obtaining antivenom. The World Health Organization's World Directory of Poison Control Centres ([http://www.who.int/gho/phe/chemical\\_safety/poisons\\_centres/en/](http://www.who.int/gho/phe/chemical_safety/poisons_centres/en/)) might assist those outside of the United States to source more exotic antivenoms.

## SUMMARY

- The indications for antivenom administration following scorpion stings remain controversial, in large part because of the current cost of the product.
- The decision to use antivenom should be individualized to the patient, weighing the risk of giving an immune serum, the level of available supportive care, the risks and costs of supportive care alone, and the cost of obtaining or importing antivenom.
- Scorpion antivenom administration for some species may not improve outcome.
- The preferred route of administration of these products is intravenous. The current FDA approved dosing for Anascorp is 3 vials to initiate therapy, followed by additional doses to alleviate symptoms.

# MARINE ENVENOMATIONS

Eike Blohm and D. Eric Brush

Human contact with venomous marine creatures is common, with serious harm resulting from biological toxins or mechanical injury inflicted by the stinging apparatus. Envenomation occurs from both vertebrate and invertebrate animals. Venomous invertebrates include the phylum Cnidaria (jellyfish, anemones), Mollusca (snails, octopods), and Echinodermata (sea stars, sea urchins). Sea snakes and spiny fish are the common venomous vertebrates.

Our knowledge of the pathophysiology related to clinical syndromes in humans and the optimal therapies for human envenomation remain limited. Evidence for effective treatment is primarily derived from in vitro and in vivo animal research with few randomized controlled human trials. However, current research in toxinology coupled with clinical observations allows the development of cogent treatment guidelines for victims of marine envenomation.

## INVERTEBRATES

### Cnidaria

The phylum Cnidaria (formerly Coelenterata) originated in the Ediacaran period more than 750 million years ago and includes more than 9,000 species, of which approximately 100 are known to injure humans. Commonly referred to as jellyfish, they are the oldest lineage of venomous animals; however, their phylogenetic designations separate “true jellyfish” and other organisms into distinct classes (Table 116–1; Fig. 116–1A, B).

All species possess microscopic cnidae (the Greek *knide* means nettle), which are highly specialized organelles consisting of an encapsulated hollow barbed thread bathed in venom. Thousands of these stinging organelles, called nematocysts (or cnidocysts), are distributed along tentacles. A trigger mechanism called a cnidocil regulates nematocyst discharge. Pressure from contact with a victim’s skin, or chemical triggers such as osmotic change, stimulates discharge of the thread and toxin from its casing.<sup>140</sup> Although all Cnidaria feature cnidae, only those whose barbed thread can penetrate the human epidermis for intradermal venom delivery to inflict injury. Among these are members of the subphylum Cubozoa (sea wasp, Irukandji jellyfish), Hydrozoa (Portuguese man-of-war, bluebottle), Scyphozoa (sea nettle, mauve stinger), and a class of Anthozoa (anemones) (Fig. 116–2).

### Cubozoa

Members of Cubozoa are not true jellyfish. Animals of this subphylum have a cube-shaped bell with 4 corners, each supporting between 1 and 15 tentacles. Cubozoa species produce the greatest morbidity and mortality of all Cnidaria. The subphylum comprises 2 main families of toxicologic importance: Chirodropidae and Carybdeidae.

The Chirodropidae family is well known for the sea wasp (*Chironex fleckeri*, Greek *cheiro* means hand, Latin *nex* means death; therefore, “assassin’s hand”). When full grown, the bell of the sea wasp, a type of box jellyfish, measures 25 to 30 cm in diameter and 15 tentacles are attached at each “corner” of the bell. These tentacles extend up to 3 m in length.

The Carybdeidae family is most notable for the Irukandji jellyfish (*Carukia barnesi*).<sup>59</sup> Its small size, with a bell diameter of only 2.5 cm, limits detection in open waters. Along with the common kingslayer (*Malo kingi*), the Irukandji jellyfish is known to cause Irukandji syndrome in its victims.

### Hydrozoa

Members of the Hydrozoa class are also not true jellyfish. The order Siphonophorae (Physaliidae family) includes 2 unusual creatures of toxicologic concern: *Physalia physalis*, the Portuguese man-of-war, and its smaller counterpart, *Physalia utriculus*, the bluebottle. They are pelagic (floating)

colonial Hydrozoa, meaning one “jellyfish” is actually a colony of multiple specialized animals (zooids) in a formed mass. The easily recognizable pneumatophore (blue sail) that floats above the surface of the water is filled with up to 13% carbon monoxide, 15% to 20% oxygen, and nitrogen for the remaining partial pressure.<sup>164</sup> Tentacles of *P. physalis* reach lengths exceeding 30 m and contain more than 750,000 nematocysts in each of its numerous tentacles (up to 40). *Physalia utriculus* has only one tentacle that measures up to 15 m.

The Anthomedusae order includes the sessile *Millepora alcicornis* (fire coral) that exists as a fixed colony of hydroids. It appears much like true coral and has a white to yellow-green lime carbonate exoskeleton. Small nematocyst-containing tentacles protrude through minute surface gastropores. The overall structure ranges from 10 cm to 2 m.

**TABLE 116–1** Characteristics of Common Cnidaria

Latin Name	Common Name	Common Habitat (Coastal Waters)
<b>Cubozoa class</b>		
<i>Chironex fleckeri</i> <sup>a</sup>	Sea wasp	Tropical Pacific Ocean, Indian Ocean, Gulf of Oman
<i>Carukia barnesi</i> <sup>a</sup>	Irukandji jellyfish	North Australian
<i>Chiropsalmus</i> spp <sup>a</sup>	Sea wasp or fire medusa	North Australian, Philippines, Japan, Indian Ocean, Gulf of Mexico, Caribbean
<i>Chiropsalmus quadrigatus</i>	Box jellyfish	
<i>Chiropsalmus quadrumanus</i>	Box jellyfish	
<i>Carybdea alata</i>	Hawaiian box jellyfish	Hawaii
<i>Carybdea rastoni</i>	Jimble	Australia
<b>Hydrozoa class</b>		
<i>Physalia physalis</i> <sup>a</sup>	Portuguese man-of-war	Eastern US from Florida to North Carolina, Gulf of Mexico, Australia (rare reports)
<i>Physalia utriculus</i>	Bluebottle	Tropical Pacific Ocean, particularly Australia
<i>Millepora alcicornis</i>	Fire coral	Widespread in tropical waters, including Caribbean
<b>Scyphozoa class</b>		
<i>Chrysaora quinquecirrha</i>	Sea nettle	Chesapeake Bay, widely distributed in temperate and tropical waters
<i>Stomolophus meleagris</i>	Cabbage head or cannonball jellyfish	Gulf of Mexico, Caribbean
<i>Stomolophus nomura</i> <sup>a</sup>	Lion’s mane	Yellow Sea between China and South Korea
<i>Cyanea capillata</i>	Lion’s mane or hair jellyfish	Northwest US to Arctic Sea, Norway and Great Britain, Australia
<i>Pelagia noctiluca</i>	Mauve stinger or purple-striped jellyfish	Wide distribution in tropical zones
<i>Linuche unguiculata</i>	Thimble jellyfish	Florida, Mexico, and Caribbean
<b>Anthozoa<sup>b</sup> class</b>		
<i>Anemonia sulcata</i>	European stinging anemone	Eastern Atlantic, Mediterranean, Adriatic Sea
<i>Actinodendron plumosum</i>	Hell’s fire anemone	South Pacific
<i>Actinia equina</i>	Beadlet anemone	Great Britain, Ireland

<sup>a</sup>Well-documented human fatalities.

B

**FIGURE 116-1.** (A) North Atlantic Portuguese man-of-war *Physalia physalis* with multiple tentacles dangling in the water. The tentacles filled with venomous nematocysts extend several meters in length. (Reproduced with permission from Knoop KJ, Stack LB, Storrow AB, et al. *The Atlas of Emergency Medicine*, 3rd ed. New York, NY: McGraw-Hill Inc; 2010. Photo contributor: Adam Laverty.) (B) Linear eruption from contact with an unidentified jellyfish in the South Atlantic Ocean. (Used with permission from David Goldfarb.)

**FIGURE 116-2.** The structure and function of the nematocyst of the jellyfish (Cnidaria). The barbed thread rests inverted and spring-loaded in the nematocyst, which measures approximately 10–20  $\mu\text{m}$ . Upon mechanical or osmotic stimulation of the trigger mechanism (called the cnidocil), the hinged operculum places the barb in its upright position and the thread uncoils, propelling itself outward. Venom stored in the capsule flows through the thread into the victim's tissue.

### Scyphozoa

True jellyfish belong to the class Scyphozoa and are extremely diverse in size, shape, and color. Common varieties known to envenomate humans are *Cyanea capillata* (lion's mane or hair jelly), *Chrysaora quinquecirrha* (sea nettle), and *Pelagia noctiluca* (mauve stinger). The mauve stinger is easily recognized; it appears pink in daylight and phosphorescent at night. Larvae of *Linuche unguiculata* cause seabather's eruption (SBE).

### Anthozoa

The Anthozoa class of Cnidaria does not feature a medusa ("jellyfish") stage in its life cycle and is thus marked by sessility. Its diverse membership includes true corals, soft corals, and anemones. Only the anemones are of toxicologic importance. They are common inhabitants of reefs and tide pools and attach themselves to rock or coral. Armed with modified nematocysts known as *sporocysts* and *basitrichous isorhiza* located on their tentacles, they produce stings similar to those of organisms from other Cnidaria classes.

Cnidaria common to the United States include the Portuguese man-of-war and sea nettle. Other species are widely distributed throughout the tropical and temperate waters of the globe (Table 116-1). Locations with documented Cnidaria-related deaths include the United States (Florida, North Carolina, Texas), Australia, the Indo-Pacific region (Malaysia, Langkawi Islands, Philippines, Solomon Islands, Papua New Guinea), and the coast of China. Since 1884, approximately 70 deaths in Australia are attributed to *C. fleckeri*. An estimated 2 to 3 deaths per year occur in Malaysia from contact with unknown species. Approximately 20 to 40 deaths are reported yearly in the Philippines from unidentified species of the Chirodripidae family. Three deaths are well documented from *P. physalis* in the United States (Florida, North Carolina). One death from *Chiropsalmus quadrumanus* occurred along the coast of Texas. Eight fatalities in the Bohai waters of China (Yellow Sea) are reported from *Stomolophus nomurai*. Although Chirodripidae are found off the western coast of Africa, no fatalities in that region are documented.

### Cnidaria Dermatitis

#### Epidemiology

Stings from Cnidaria and subsequent dermal eruptions represent the overwhelming majority of marine envenomations. In Australia, approximately

10,000 stings per year are recorded from *Physalia* spp alone.<sup>55</sup> Most *Cnidaria* stings occur during the warmer months of the year. Stings occur with greatest frequency on hotter than average days with low winds, particularly during times of low precipitation. “Stinger nets” are used in high-risk areas of the Australian coastline. These nets often feature openings of 2 to 3 cm which prevent larger jellyfish from entering the protected area. Smaller jellyfish and severed tentacles continue to pose a threat. One study reported that 63% of stings requiring medical attention occurred within netted waters.<sup>91</sup> Along Australia’s northern coastline, 70% of stings resulted from the box jellyfish envenomation; the remaining 30% involved other *Cubozoa* such as *C. barnesi*.<sup>111</sup> Although this finding indicates a predominance of box jellyfish as the cause of stings, it also suggests that stings from box jellyfish are more severe and require medical attention with greater frequency than stings from other species of *Cnidaria*.

Related to changes in ocean pH and temperature as a result of climate change, the size of jellyfish blooms and the subsequent incidence of *Cnidaria* envenomation has increased. In addition, the geographical distribution of venomous jellyfish is expanding.<sup>76,78</sup>

### Pathophysiology

Dermal eruptions after *Cnidaria* envenomation occur due to both toxin and immune system mediated mechanisms. Toxins are subdivided into 4 types: Enzymes (Phospholipase A<sub>2</sub>, metalloproteases), pore-forming toxins, neurotoxins, and nonprotein bioactive components (serotonin, histamine). The exact composition varies by class; *Cubozoa* only produce enzymes and pore-forming toxins, whereas Anthozoa produce all toxin types and are the only class that produces neurotoxins. Enzymes and nonprotein bioactive compounds produce significant dermal pathology: phospholipase A<sub>2</sub> enzymatically cleaves glycerophospholipids into arachidonic acid and thus induces inflammation. Metalloproteases are proteolytic enzymes that break down extracellular matrix and prevent hemostasis. Tissue edema with necrosis and blister formation ensues. Intradermal injection of both serotonin and histamine causes vasodilation and pain.<sup>75</sup> *Chironex fleckeri* venom also possesses dermatonecrotic and hemolytic fractions, although hemolysis is not documented in humans.<sup>9</sup> Two myotoxins from *C. fleckeri* cause powerful sustained muscle contractions in isolated muscle fibers.<sup>42</sup>

An immune-mediated response to venom explains some sting-related symptoms. Elevated serum anti-sea nettle immunoglobulins IgM, IgG, and IgE persist for years in patients with exaggerated reactions to stings compared with controls.<sup>18</sup> A direct correlation between titers against *Chrysaora* and *Physalia* and severity of a visible skin reaction to envenomation strongly suggests an allergic component.<sup>129</sup> Elevated IgG titers were demonstrated in one death from *P. physalis*.<sup>139</sup> Postenvenomation syndromes results from an exaggerated, prolonged, or aberrant T-cell response.<sup>20,21</sup> Erythema nodosum following a sting from *P. physalis* lends further support to an immunologic component.<sup>3</sup>

### Clinical Manifestations

Most patients with stings are treated beachside and never require hospitalization. The vast majority of patients who seek medical care do so because of severe pain without evidence of systemic poisoning.<sup>38</sup> Envenomation by *C. fleckeri* inflicts the most severe pain and is frequently associated with systemic toxicity. Common symptoms include immediate severe pain, followed by an erythematous whiplike linear rash with a “frosted ladder” appearance. The pain often is excruciating and requires parenteral analgesia. Pain generally abates over several hours, although the rash typically persists for days. In a prospective series of *C. fleckeri* stings, 58% manifested delayed hypersensitivity reactions in the form of an itchy maculopapular rash at 7 to 14 days.<sup>111</sup> Most resolved spontaneously; some were treated with antihistamines and topical corticosteroids. Some patients experience flare-ups of an allergic dermatitis months to years after envenomation.<sup>96</sup>

*Millepora alcicornis* (fire coral) is a common cause of stings in southern United States and Caribbean waters. Although a member of the same phylogenetic class as *P. physalis*, it produces far less significant injuries. It is a

nuisance to divers who touch the coral and suffer moderate burning pain for hours. Untreated pain generally lessens within 90 minutes, with skin wheals flattening at 24 hours and resolving within one week. Hyperpigmentation persists for up to 8 weeks.<sup>14</sup> The feather hydroid is the most numerous of the *Hydrozoa* and produces only mild stings.<sup>100</sup>

Following stings from sea anemones, victims develop either immediate or delayed pain. Skin findings range from mild erythema and itching to ulceration. A review of 55 stings from *Anemonia sulcata* presenting to a hospital in Yugoslavia (Adriatic Sea) revealed that, in addition to the local skin findings, many patients suffered nausea, vomiting, muscle aches, and dizziness.<sup>97</sup>

### Diagnosis

Laboratory evaluation is warranted in patients suffering systemic toxicity following *Cnidaria* envenomation. Following severe stings from a variety of *Cnidaria*, urinalysis, hematocrit, and serum creatinine measurements serve to detect the presence of hemolysis and subsequent risk of kidney injury. Nonfatal elevation of hepatic enzyme concentrations following anemone sting also is reported.<sup>23</sup> Ocular exposure should be evaluated with slit lamp examination and fluorescein staining as corneal ulceration is a known complication.

Venom assays and serum antibody titers are not clinically useful.

### Management

Initial interventions after *Cnidaria* envenomation are directed toward stabilization of cardiopulmonary abnormalities in cases of severe envenomation. Secondary measures are directed toward the prevention of further nematocyst discharge, which could intensify pain and enhance toxicity. Many topical therapies are used for this purpose, including sea water, vinegar, a commercial solution known as Stingose, methylated spirits, ethanol, isopropyl alcohol, dilute ammonium hydroxide, urine, sodium bicarbonate, papain, shaving cream, and sand.

**Vinegar** is a common first-line treatment for topical application following *Cnidaria* stings. In vitro trials with *C. fleckeri* tentacles demonstrate complete irreversible inhibition of nematocyst discharge following a 30-second application.<sup>69</sup> Additional study findings include massive nematocyst discharge with application of urine or ethanol, and no effect on discharge with use of sodium bicarbonate. Follow-up in vivo experiments demonstrate that vinegar is effective for other *Cubozoa*, including Morbakka (large *Cubozoa* in Australia),<sup>46</sup> *Carybdea rastoni*,<sup>51</sup> and *C. barnesi*.<sup>50</sup> Although massive nematocyst discharge occurs when vinegar is applied to *C. capillata* tentacles in vitro, clinical exacerbation following this treatment is not reported in humans.<sup>47</sup> Massive discharge also occurs with *C. quinquecirrha*.<sup>53</sup> A smaller degree of discharge (30%) occurs with *P. physalis*,<sup>53</sup> whereas nematocysts of *P. utriculus* are unaffected by application of vinegar.<sup>69</sup> Identification of the offending *Cnidaria* is often only possible by microscopic evaluation of skin scrapings. Hence, therapy must be guided by geographic location. In the United States, where *P. physalis* and *C. quinquecirrha* are of greatest consequence, sea water is recommended to aid in tentacle removal given that vinegar enhances nematocyst discharge in those species. In the Indo-Pacific region, where *C. fleckeri* and *C. barnesi* are of greatest concern, vinegar application confers greater advantage. If local species prevalence is unknown, it is reasonable to attempt vinegar application to a small area of affected skin and assess its effects before large surface area application.

**Stingose** is an aqueous solution of 20% aluminum sulfate and 1.1% surfactant. Its purported mechanism of action is denaturing of proteins and long-chain polysaccharides via interactions with the Al<sup>3+</sup> ion, as well as osmotic removal of venom. A human volunteer trial involving stings from live tentacles of *C. fleckeri* demonstrated pain relief within 5 seconds of Stingose application.<sup>72</sup> Similar results were achieved following treatment of stings from *C. quinquecirrha*. A small randomized controlled trial found Stingose superior to salt water irrigation after *Physalia* envenomation.<sup>154</sup> A small volunteer study utilizing topical lidocaine reported successful treatment of stings via topical analgesia and reduced nematocyst discharge.<sup>12</sup>

**Ice packs** provided rapid, effective relief for patients with mild to moderate pain from *Cnidaria* stings in Australia. Patients with severe pain are less

likely to benefit from ice packs. Many *Cnidaria* venoms are heat labile and are neutralized at supraphysiologic temperatures.

**Hot water immersion (HWI)** at 45°C for 20 minutes provided pain relief to 87% of victims of bluebottle (*P. utriculus*) stings in a randomized controlled trial.<sup>94</sup> In-vitro data support thermal denaturing of *C. fleckeri* cardiotoxin. We continue to recommend HWI despite theoretical concern that it leads to local vasodilation and subsequent enhanced systemic distribution of venom.<sup>28</sup> No human randomized controlled trials exist to assess the efficacy of HWI in *C. fleckeri* envenomation.

**Pressure immobilization bandaging** is a technique that applies sufficient pressure to a wound to impede lymphatic drainage and prevent the entrance of venom into systemic circulation. Given the rapid onset of symptoms, the utility of a technique that impedes lymphatic drainage is unlikely to provide benefit. Although the technique would be used only after tentacle removal, some microscopic nematocysts remain adherent to the skin after visible tentacles are removed. In vitro data investigating the effect of pressure on discharged nematocysts demonstrate not only that discharged nematocysts still contain venom, but that applying pressure forces more venom down the hollow tube.<sup>114</sup> This finding is correlated clinically as patients can deteriorate following pressure immobilization bandaging.<sup>52</sup> Given the lack of evidence suggesting benefit, coupled with clear in vitro evidence of increased venom delivery with this technique, we recommend against the use of pressure immobilization bandaging for treatment of *Cnidaria* stings. Because studies have not assessed the risks and benefits of proximal tourniquet application, it cannot be recommended at this time.

## Cnidaria Cardiotoxicity

### Epidemiology

The majority of victims do not present to health care facilities following *Cnidaria* envenomation. Old reports suggesting a 15% to 20% fatality rate<sup>126</sup> following *C. fleckeri* envenomation likely represent a gross overestimation given the low number of documented fatalities in the context of the extraordinary number of yearly stings. A prospective study of stings from *Cubozoa* over one year in Australia revealed no dysrhythmias, pulmonary edema, or death.<sup>111</sup> No patient received antivenom, and analgesia was the only pharmacotherapy implemented. Hospital admission was not required for any victim. Although most victims suffer only local severe pain, serious systemic toxicity occurs occasionally, and may include vertigo, ataxia, paralysis, delirium, syncope, respiratory distress, cardiogenic pulmonary edema, hypotension, and dysrhythmias. In a series of 10 reported deaths from *C. fleckeri*, all occurred in children, suggesting vulnerability due to lower body mass and thinner dermis.<sup>38</sup>

### Pathophysiology

*Cnidaria* venoms contain a variety of components that induce cardiotoxicity. The cardiotoxin of *C. fleckeri* has not yet been fully identified, but is believed to be a pore-forming toxin of about 65 kDa.<sup>130</sup> This is supported by the nonspecific enhancement of cation conductance of isolated heart models exposed to *C. fleckeri* venom.<sup>108</sup> Other in vitro work confirms increased Na<sup>+</sup> permeability in cardiac tissue.<sup>61</sup> Cardiovascular collapse results from osmotic dysregulation of endothelial and cardiac tissues following pore formation. A rat model demonstrated hemolysis, but this is not observed in envenomated patients.<sup>75</sup> Anthozoa and Hydrozoa feature actinoporins: proteins that insert themselves into the victim's cell membrane and then oligomerize to form an ungated, non-selective ion channel. Cardiac effects in animals include negative inotropy, conduction delays, ventricular tachycardia, and coronary artery vasoconstriction.<sup>38,60</sup> However, experiments using the purest venom extracts without contamination from tentacle material demonstrate cardiovascular collapse without electrocardiographic changes.<sup>115</sup>

Cardiotoxicity also results from blockade of voltage-gated sodium and potassium channels. Venom from *Physalia* spp blocks neural impulses in isolated frog sciatic nerve<sup>82</sup> and produces ventricular ectopy, cardiovascular collapse, hyperkalemia, and hemolysis in dogs.<sup>70</sup> *Physalia* spp venom inhibits Ca<sup>2+</sup> entry into the sarcoplasmic reticulum.<sup>82</sup> Similar mechanisms

are proposed for *Chrysaora*, *Chiropsalmus*, and *Stomolophus*. *Chrysaora quinquecirrha* venom contains a 150-kDa polypeptide that induces atrioventricular block<sup>17</sup> and produces myocardial ischemia, hypertension, dysrhythmias, and nerve conduction block,<sup>19</sup> as well as hepatic and renal necrosis.<sup>107</sup>

### Clinical Manifestations

Fatality is documented to occur with only 4 m of tentacle markings.<sup>140</sup> Death is rapid, preventing many victims from reaching medical care, or even the shore.<sup>89</sup> Cardiac arrest and cardiogenic pulmonary edema develops in young, healthy patients without prior cardiopulmonary disease.<sup>95,161</sup> Survival is possible with immediate cardiopulmonary resuscitation (CPR).<sup>160</sup> *Chiropsalmus quadrumanus*, a close relative of the box jellyfish, induces symptoms that are similar to *C. fleckeri* stings, including cardiogenic pulmonary edema and death.<sup>11</sup>

### Diagnosis

*Cnidaria* cardiotoxicity should be suspected in all drowning victims with linear skin lesions. Onset of cardiovascular collapse occurs rapidly and is thus often confounded by saltwater aspiration and envenomation. Patients not in cardiac arrest present with hypotension and cardiac conduction abnormalities. An electrocardiogram is prudent to identify treatable dysrhythmias. Envenomation impairs coronary perfusion, and serial troponin assays are recommended.

### Management

Rescuer efforts should focus on immediate nematocyst inactivation, tentacle removal, and basic life support. Box jellyfish antivenom is available as an ovine whole IgG raised against the "milked" venom of *C. fleckeri*. Combining *C. fleckeri* venom with box jellyfish antivenom prior to injection into pigs prevents all toxicity.<sup>149</sup> An isolated chick muscle experiment demonstrates that box jellyfish antivenom prevents the neurotoxicity and myotoxicity from *C. fleckeri* following pretreatment.<sup>116</sup> In vitro data demonstrate that box jellyfish antivenom neutralizes the dermatonecrotic, hemolytic, and lethal fractions of venom from *Chiropsalmus* spp; however, the venom of *Physalia physalis* and *Chrysaora quinquecirrha* were not neutralized.<sup>10</sup> Other in vitro and in vivo data demonstrate incomplete neutralization of *Chiropsalmus* spp venom.<sup>10,116</sup> A murine experiment with "rescue" administration of antivenom failed to show increased rates of survival, but prolonged time until death. This raises the possibility antivenom is underdosed under current guidelines.<sup>41</sup>

Distance from medical care limits the ability to obtain antivenom in a timely fashion.<sup>38</sup> Although box jellyfish antivenom can be administered by paramedics via intramuscular (IM) injection,<sup>52</sup> poor IM absorption and incomplete venom neutralization with antivenoms, as well as delayed peak serum concentrations, limit the utility of this approach.<sup>123</sup> The amount of antivenom required to neutralize twice the lethal dose in humans is estimated at 12 vials.<sup>38</sup> The manufacturer recommends treating initially with one vial intravenously (IV) diluted 1:10 with saline or 3 undiluted vials (1.5–4 mL each) IM at 3 separate sites, if IV access is unavailable. Some authors who have treated multiple patients with antivenom suggest treating coma, dysrhythmia, or respiratory depression with one vial IV, titrating up to 3 vials with continuation of CPR in patients with refractory dysrhythmias until a total of 6 vials are administered.<sup>111</sup> Serious adverse events or delayed sequelae following the use of IV antivenom are uncommon, although allergic reactions are a consideration.<sup>142</sup> Although available in Australia since 1970, to this date no survival is attributable to the administration of antivenom, and there are multiple fatalities despite its use.<sup>38</sup> If available, antivenom administration is recommended but does not replace supportive care.

Verapamil was evaluated as a treatment for *C. fleckeri* stings based on evidence that Ca<sup>2+</sup> entry into cells represents an important mechanism of toxicity. One animal model demonstrated synergy with use of verapamil in combination with box jellyfish antivenom,<sup>22</sup> whereas another showed verapamil pretreatment as well as rescue prolonged survival.<sup>16</sup> This is in contrast to other models demonstrating that verapamil negates the benefits of antivenom<sup>117</sup> and increases mortality.<sup>149</sup> Verapamil administration to animals

with *Chrysaora quinquecirrha* envenomation demonstrated no benefit.<sup>107</sup> Interestingly, addition of magnesium to antivenom for treatment of *C. fleckeri* envenomation in rats prevented cardiovascular collapse in 100%, suggesting that magnesium has a role in the treatment of stings from this species.<sup>117</sup> Given that animal data are inconsistent with regard to verapamil and that hypotension often develops with severe envenomation, use of calcium channel blockers is not currently recommended for treatment of *C. fleckeri* stings.

Although successfully utilized for the treatment of pain associated with *C. fleckeri* stings, HWI is unlikely to demonstrate benefit in the treatment of cardiotoxicity. Immersion in hot water is impractical for the critically ill patient, and penetrance of heat is limited to superficial tissues and will not denature circulating cardiotoxins.

## Irukandji Syndrome

### Epidemiology

Stings from the Portuguese man-of-war (*Physalia physalis*) and the Irukandji jellyfish (*Carukia barnesi*) are associated with the development of Irukandji syndrome. However, an unidentified species produced 3 cases of an Irukandjilike syndrome in the Florida Keys, and 6 cases were reported off the coast of Hawaii.<sup>66,168</sup> This suggests a more diverse geographical distribution and possibly multiple responsible organisms.

### Pathophysiology

*Carukia barnesi*, the Irukandji jellyfish, likely induces its dramatic vasopressor effects via catecholamine release. In rats, the venom produces a pressor response that is blocked by  $\alpha_1$ -adrenergic antagonism.<sup>118</sup> The pressor response is not dose dependent; therefore, catecholamines in the venom are an unlikely cause. In vitro experiments suggest a  $\text{Na}^+$  channel modulator effect leading to massive catecholamine release.<sup>163</sup> Porcine studies with intravenous *C. barnesi* venom administration show a 4,000- and 1,000-fold increase in norepinephrine and epinephrine, respectively.<sup>163</sup> No electrocardiographic abnormalities occurred in envenomated rats.

### Clinical Manifestations

Irukandji syndrome is a severe form of envenomation following Cubozoa stings from *Carukia barnesi*.<sup>73</sup> Individuals afflicted often notice a mild sting while they are in the water; however, skin findings typically are absent. Severe systemic symptoms develop after a latent period of 5 to 40 minutes and mimic a catecholamine surge including tachycardia, hypertension, piloerection, hyperpnea, headache, pallor, restlessness, apprehension, sweating, and a sense of impending doom. A prominent feature is severe diffuse muscle spasms that come in waves and preferentially affect the back. Spasms are described as unbearable and frequently require parenteral analgesia. Symptoms generally abate over several hours but can last up to 2 days. Admission rates in patients presenting to medical care exceed 50%.<sup>91</sup> Hypertension is universal and is severe, with systolic blood pressures well over 200 mm Hg. Two fatalities are described involving severe hypertension (280/150 mm Hg and 230/90 mm Hg) resulting in intracranial hemorrhage.<sup>48,73</sup> Hypotension frequently follows, requiring vasopressor support. Cardiogenic pulmonary edema can develop within hours. Echocardiograms consistently reveal global ventricular dysfunction.<sup>92,98</sup> Restored cardiac function typically returns after several days.<sup>90</sup> A retrospective review of 116 cases of Irukandji presenting to Cairns Base Hospital identified elevated troponin I measurements in 22% of patients.<sup>73</sup> Electrocardiographic changes are described as nonspecific.

### Diagnosis

Irukandji syndrome is a clinical diagnosis based on the history of swimming in waters known to have Irukandji jellyfish and presentation compatible with hyperadrenergic state as described above. Complaint of headache or altered mental status should prompt cerebral imaging to assess for intracranial hemorrhage resulting from hypertensive crisis. Electrocardiogram, serial cardiac biomarkers, and echocardiography are recommended to screen for myocardial damage and Takotsubo (stress) cardiomyopathy.<sup>150</sup> Laboratory evaluation is recommended for rhabdomyolysis from severe muscle spasms and subsequent acute kidney injury (AKI).<sup>28</sup>

### Management

Vinegar irrigation, or HWI, prevents further envenomation as discussed above and is recommended early in the course of treatment. Further treatment for Irukandji syndrome should focus on analgesia and blood pressure control. Several modalities for control of severe hypertension are reasonable and include phentolamine, IV magnesium sulfate, and nitroglycerin.<sup>37,49</sup> Dosing guidelines and efficacy following magnesium infusion for this indication are not established, and a small randomized controlled trial failed to demonstrate benefit, although external factors forced early termination of the study.<sup>99</sup> Because hypotension occurs in late stages of toxicity, clinicians should only administer short-acting titratable antihypertensives such as esmolol, nitroprusside, or nicardipine for control of initial hypertension. Case reports of box jellyfish antivenom use for *Carukia barnesi* stings demonstrate no apparent benefit.<sup>44</sup> A single case report details near-complete resolution of symptoms after a single dose of clonidine.<sup>93</sup> Although central  $\alpha_2$ -agonism theoretically addresses the underlying pathophysiology, there is insufficient data to routinely recommend this therapy.

## Seabather's Eruption

### Epidemiology

Cases of Seabather's Eruption (SBE), a stinging rash evoked by contact with Cnidaria larvae, occur in clusters. Variation in intensity and frequency occurs from year to year as exemplified by a 25-year hiatus during which no cases were reported in Florida.<sup>151</sup> In 1992, more than 10,000 cases of SBE occurred in south Florida, with similar peaks in the 1940s and 1960s. Cases of SBE also are reported in Cuba, Mexico, Brazil, the Caribbean, and the coast of New York.

### Pathophysiology

Seabather's Eruption is the result of envenomation by the larvae of *Linuche unguiculata* and *Edwardsiella lineata*. The larvae appear as pin-sized (0.5 mm) brown to green-brown spheres in the upper 2 inches of the water and are typically unnoticed. Discharge of the immature nematocyst of the larvae requires significant mechanical stimulation (friction between bathing suit and skin) or osmotic changes (taking a fresh-water shower after exiting the water). The eruption displays a characteristic delay in onset of symptoms and is effectively treated with steroids, suggesting a primary immune-mediated process. This is further supported by histopathology revealing the presence of perivascular and interstitial infiltrates with lymphocytes, neutrophils, and eosinophils.<sup>165</sup>

### Clinical Manifestation

The pruritic papular eruption occurs mostly in areas covered by a bathing suit as a result of larvae trapped under the garments. Only 50% of people reported a stinging sensation while they were in the water, and 25% reported itching upon exiting the water.<sup>165</sup> The remainder of patients developed symptoms within 11 hours. Skin lesions develop within hours of itching and appear as discrete, closely spaced papules, with pustules, vesicles, and urticaria. Itching often is severe and prevents sleep. New lesions typically continue to develop over 72 hours. The average duration of symptoms is just under 2 weeks, and a small percentage of patients experience a recurrence of lesions several days later. Systemic symptoms such as chills, headache, nausea, vomiting, and malaise occur occasionally. Patients develop symptoms again when donning the same bathing suit unless it was decontaminated and washed with detergent.

### Diagnosis

The diagnosis of SBE is based on history and physical examination. A pruritic, papular, erythematous rash in high-friction areas (skin folds, swim suit) that occurred after recent immersion in ocean waters suggests SBE. Although embedded nematocyst threads are at times appreciated on skin biopsy, this is usually not required for diagnosis.

### Management

Although not rigorously evaluated for the treatment of SBE, topical application of vinegar is known to deactivate nematocysts of *Linuche unguiculata*.

Topical application of vinegar is thus reasonable. A case series of 14 patients used antihistamines and topical corticosteroids as treatment, with resolution of symptoms within 7 days.<sup>124</sup> This approach to symptomatic control is recommended. Bacterial superinfection due to excoriation occurs rarely and should be treated with antibiotic therapy.

## MOLLUSCA

The phylum Mollusca comprises Cephalopoda (octopus, squid, and cuttlefish) and Gastropoda (cone snails). Cephalopod species of toxicologic concern are limited to the blue-ringed octopus *Hapalochlaena maculosa* and the greater blue-ringed octopus *Hapalochlaena lunulata*. The blue-ringed and greater blue-ringed octopods are found in the Indo-Pacific region, primarily in Australian waters (Fig. 116–3). Of the 400 species of cone snails that belong to the genus *Conus*, 18 are implicated in human envenomations.

### Cephalopoda

#### Epidemiology

The blue-ringed octopus is a relatively small (12–20 cm) animal that lives camouflaged in crevices and rock piles around Australia, the Indo-Pacific region, and Japan. It normally displays a yellow-brown color, but flashes iridescent blue rings aposematically to warn and repel predators. The species is not aggressive and only bites humans when handled. A 1983 review of reported octopus envenomations uncovered a total of 14 cases, all of which occurred in Australia.<sup>156</sup> There were 2 deaths and 4 serious envenomations. Other reviews suggest that up to 7 deaths occurred prior to 1969, some outside Australia.<sup>40</sup>

#### Pathophysiology

Symbiotic bacteria in the posterior salivary glands of the blue-ringed octopus produce a toxin originally designated maculotoxin and later identified as tetrodotoxin (TTX).<sup>135</sup> The parrotlike beak of the octopus creates small punctures in human skin through which venom is introduced. Tetrodotoxin blocks Na<sup>+</sup> conductance in neurons, leading to flaccid paralysis. Subsequent respiratory insufficiency results in hypoxic cardiac arrest without evidence of primary cardiotoxicity. Hypotension ensues due to reduction of vascular smooth muscle tone rather than poor cardiac output. This is likely due to lack of sympathetic nerve impulses to arteriolar vasoconstrictor muscles.<sup>57</sup> The venom does not affect mentation. If the murine LD<sub>50</sub> of 9 mcg/kg translates to humans, an adult blue-ringed octopus carries enough TTX to kill 10 adults.<sup>162</sup> Venom also contains serotonin (5-HT), hyaluronidase, tyramine, histamine, tryptamine, octopine, taurine, acetylcholine, and dopamine.<sup>142</sup> Death occurs despite artificial respiration as a result of

profound hypotension and subsequent global ischemia. Poisoning also occurs when the blue-ringed octopus is consumed as TTX is also highly concentrated in its integument.

#### Clinical Manifestations

The blue-ringed octopus creates one or 2 puncture wounds with its chitinous jaws, inflicting only minor discomfort. A wheal typically develops with erythema, tenderness, and pruritus as a result of the histamine content of the venom. Tetrodotoxin exerts a curarelike effect characterized by paralysis without depressing mental status. Symptoms include perioral and intraoral paresthesias, diplopia, aphonia, dysphagia, ataxia, weakness, nausea, vomiting, flaccid muscle paralysis, respiratory failure, and death. Detailed case reports describe rapid onset of symptoms within minutes.<sup>27,156</sup>

Complete paralysis requiring intubation with findings of fixed and dilated pupils is followed within 24 to 48 hours by near-complete recovery of neuromuscular function. In one reported death, a young man placed the octopus on his shoulder. He subsequently noted a small puncture wound, developed dry mouth, dyspnea, inability to swallow, and became apneic. Asystole occurred 30 minutes after arrival at the hospital despite mechanical ventilation.<sup>58</sup> Another similar bite resulted in symptom onset at 10 minutes, followed by death at 90 minutes, despite bystander CPR.<sup>138</sup> With less severe envenomations, cerebellar signs arise without paralysis. Near-total paralysis with intact mentation resolving over 24 hours occurred in humans.<sup>141</sup>

#### Diagnostic Testing

Although not a widely available assay, TTX can be detected in the urine or serum using high-performance liquid chromatography with subsequent fluorescence detection.<sup>110</sup> This is unlikely to yield results prior to death or resolution of symptoms. In vitro exposure of human red blood cells to blue-ringed octopus venom shows the development of spherocytosis mirroring observations in victims of snake envenomation.<sup>56</sup> No case reports exist to corroborate this finding in vivo. Unless the diagnosis of TTX exposure is clear from patient or bystander reports, other conditions such as botulism and Guillain-Barré syndrome should be investigated.

#### Management

Tetrodotoxin from blue-ringed octopus envenomations produces two potentially lethal conditions: respiratory arrest and peripheral vasodilation with profound hypotension. Patients with compromised respiratory effort require basic airway management and ventilator support, with expectation of weaning within 24 to 48 hours of envenomation based on cases reported in the literature. Although no randomized controlled human trials exist regarding the best approach to hypotension, animal studies indicate that phenylephrine and norepinephrine successfully raises blood pressure to physiologic levels. Interestingly, epinephrine and dopamine lacked efficacy.<sup>57</sup> Based on extrapolation of animal data, norepinephrine or phenylephrine are the recommended therapy to treat vasoplegia. Intravascular volume expansion with crystalloids is reasonable although effectiveness as monotherapy is unlikely based on underlying pathophysiology. Additional measures include local wound care and tetanus prophylaxis. Antivenom is not commercially available.

### Gastropoda

#### Epidemiology

Cone snails predominantly inhabit the Indo-Pacific, including all parts of Australia, New Guinea, Solomon Islands, and the Philippines. Estimates of reported cone snail envenomations suggest only 16 human deaths have occurred worldwide. *Conus geographicus* (fish hunting cone) is the most common species implicated, and fatality is estimated in up to 25% of *C. geographicus* envenomations.<sup>43</sup> Mortality is difficult to assess because some patients do not present to health care facilities or die before eliciting a history of cone snail envenomation, or death is erroneously attributed to drowning. *Conus textile* also causes death in humans. Two deaths from *C. geographicus* occurred in Guam.<sup>88</sup>

**FIGURE 116–3.** The blue-ringed octopus, *Hapalochlaena maculosa*. (Used with permission from Dr. Roy Caldwell, Professor of Integrative Biology, University of California, Berkeley.)

## Pathophysiology

Cone snails have a hollow proboscis that contains a disposable radular tooth bathed in venom. Similar to a harpoon, the barbed tooth is fired from the proboscis to hunt or in defense. Human envenomations occur when the shells are handled. Firing of the eyelash-sized tooth is powerful enough to penetrate a 5-mm neoprene wetsuit.<sup>68</sup> The proboscis extends the length of its shell, thereby envenomation is possible regardless how the shell is held. Any *Conus* species contains approximately 100 peptides or *conotoxins* in its venom along with hyaluronidases, proteases, and lipases that aid in local tissue breakdown and diffusion of venom.<sup>155</sup> There is significant interspecies variation of venom composition depending on prey preference. Conotoxins are divided into 3 superfamilies (A, M, and O). The A-superfamily of conotoxins acts as competitive nicotinic acetylcholine receptor antagonists and voltage-gated potassium channel blockers. The M-superfamily contains non-competitive nicotinic acetylcholine receptor antagonists as well as voltage-gated sodium channel blockers. The O-superfamily blocks voltage-gated calcium, sodium, and potassium channels (Table 116–2).<sup>85,104,112,148</sup> Weakness and paralysis occur as a result of presynaptic voltage-gated calcium channel blockade with subsequent impaired acetylcholine release, as well as postsynaptic acetylcholine receptor blockade and inhibition of sodium-ion channels.<sup>43</sup>

Many of these peptides are used extensively in laboratory research for their ability to selectively target a variety of specific Ca<sup>2+</sup>-channel subtypes. Venom from *Conus imperialis* (worm hunter) contains a substantial amount of 5-HT, a component not found in any other *Conus* venom tested thus far.<sup>103</sup> This species also contains a vasopressinlike peptide.<sup>109</sup> The neuropeptide omega-conotoxin, isolated from *Conus magnus*, is valued for its antinociceptive properties that arise from blockade of the N-type voltage-sensitive Ca<sup>2+</sup> channel in spinal cord afferents.<sup>102</sup> The Food and Drug Administration approved ziconotide (Prialt, Elan Pharmaceuticals) in 2004 for intrathecal infusion in patients with severe chronic pain that require intrathecal therapy, and in whom other treatment modalities such as intrathecal morphine are not tolerated or ineffective. Frequent side effects such as dizziness, nausea, confusion, and memory impairment limit the broad application of this therapy.

## Clinical Manifestations

Cone snail envenomation results from careless handling of the animal or rummaging through sand. Cone snails are nocturnal feeders, so they present more of a hazard to night divers. Localized symptoms range from a slight sting to excruciating pain, tissue ischemia, cyanosis, and numbness. Systemic symptoms include weakness, diaphoresis, diplopia, blurred vision, aphonia, dysphagia, generalized muscle paralysis, respiratory failure, cardiovascular collapse, and coma. Systemic symptoms occur within 30 minutes of

envenomation; respiratory arrest occurs shortly thereafter.<sup>68</sup> Death is rapid and occurs within an hour.<sup>43</sup> Based on military medical records of more than 30 cases predating 1970, the mortality rate approaches 25%, with *Conus geographicus* causing the most deaths.<sup>88</sup> Other estimates suggest that, without medical care, mortality reaches 70%.<sup>167</sup> Given the rarity of severe human envenomations from cone snails, the manner of death, whether purely from respiratory insufficiency or direct cardiovascular toxicity, remains unknown.

## Diagnostic Testing

Diagnosis of conotoxin envenomation is challenging. Whereas most venomous marine animals leave a visible injury, hypodermal injection by the radula toothlike structure produces minimal tissue injury easily missed on physical examination. Surrounding discoloration and local edema provide clues of envenomation. Typical points of entry are the hands (during shell handling) or the waist area (if held in pocket).<sup>68</sup> Laboratory assays for conotoxin are not routinely available. Based on the ion-channel blocking properties of some venom components, patients are at risk of dysrhythmias, which are reported with administration of ziconotide.<sup>71</sup> Hence, an electrocardiogram should be obtained in combination monitoring by telemetry until the patient is asymptomatic.

## Management

Primary interventions include maintenance of airway, breathing, and circulation. The envenomation site should be irrigated and the patient's tetanus vaccination updated as appropriate. Some authors suggest HWI (113°–122°F, 45°–50°C) following cone snail stings for pain relief, but no data exist whether HWI enhances systemic distribution of conotoxins.<sup>88</sup> Antivenom is not available. Global flaccid paralysis requires short-term mechanical ventilation, but usually resolves within 24 hours.<sup>43</sup> Cardiac dysrhythmias require electrical cardioversion. Administration of antidysrhythmics that rely on sodium channel blockade for clinical effect could theoretically worsen the patient's dysrhythmia. Hypotension should be treated with intravenous fluids and norepinephrine as appropriate.

## Echinodermata, Annelida, and Porifera

The Echinodermata phylum includes sea stars, brittle stars, sea urchins, sand dollars, and sea cucumbers. Annelida are segmented worms that include the Polychaetae family of bristle worms. Sponges are classified in the Porifera phylum. One feature that all 3 phyla share is the passive envenomation of people who mistakenly handle or step on the animals. Most stings from these creatures are mild.

## Epidemiology

Echinoderms, annelids, and sponges are ubiquitous ocean inhabitants. The crown-of-thorns sea star (*Acanthaster planci*) is found in the warmest waters of Polynesia to the Red Sea and is a particularly venomous species because of its sharp spines that easily puncture human skin. Sea urchins inhabit all oceans of the world. They are nonaggressive, slow moving, bottom dwellers and human envenomation typically results from stepping on or handling the animal. The most venomous are species of *Diadema*, *Echinothrix*, and *Asthenosoma*. Bristle worms such as *Hermodice carunculata* typically inhabit tropical waters such as those of Florida and the Caribbean. However, some species thrive in the frigid waters of Antarctica. The fire sponge *Tedania ignis* is a brilliant yellow-orange sponge identified in large numbers off the coast of Hawaii and in the Florida Keys. Other common American sponges are *Neofibularia nolitangere* (poison-bun sponge or touch-me-not sponge) and *Microciona prolifera* (red sponge). *Neofibularia mordens* (Australian stinging sponge) is a common Southern Australian variety. In the Mediterranean, sponges are often colonized with sea anemones that inflict severe stings.<sup>14</sup>

## Pathophysiology

Sea urchins are covered in spines and pedicellariae. The pedicellariae are pincerlike appendages used for feeding, cleaning, and defense. They generally contain more venom than the spines and are more difficult to remove from wounds. Urchins laden with pedicellariae can evoke more severe

TABLE 116–2 *Conus* Peptide Targets

Peptide	Receptor Type	Mechanism
<i>Ligand-gated ion channels</i>		
Conantokins	NMDA	Inhibits conductance
α-Conotoxin	Nicotinic	Competitive antagonism
σ-Conotoxin	5-HT <sub>3</sub>	Noncompetitive antagonism
M1		Neuromuscular junction
M2		Neuronal receptors
<i>Voltage-gated ion channels</i>		
δ-Conotoxin		Delayed channel activation
κ-Conotoxin	K <sup>+</sup>	Channel blockade
μ-Conotoxin	Na <sup>+</sup>	Channel blockade
ω-Conotoxin	Ca <sup>2+</sup>	Channel blockade
<i>G-protein linked</i>		
Conopressin-G	Vasopressin receptor	Receptor agonism
Contulakin-G	Neurotensin receptor	Receptor agonism

stings than urchins with less pedicellariae. Venom contained within the spines consists of steroid glycosides, 5-HT, hemolysin, protease, acetylcholinelike substances, and bradykininlike substances. Some species harbor neurotoxins.

Sea stars are less noxious because they generally have short, blunt spiny projections. The crown-of-thorns is the exception with its longer, sharp spines containing toxic saponins (plancitoxin I and II) with hemolytic and anticoagulant effects as well as histaminelike substances. The venom is hepatotoxic by an elusive mechanism. Animal studies reveal inhibition of glutathione *S*-transferase by crown-of-thorns venom; theoretically this leads to organ damage from failure to detoxify reactive molecules.<sup>1</sup>

Sea cucumbers excrete holothurin, a sulfated triterpenoid oligoglycoside, from the anus (organs of Cuvier) as a defense. The toxin inhibits neural conduction in fish, leading to paralysis. Some sea cucumbers eat Cnidaria and subsequently secrete their venom.

Bristle worms have many parapodia that have the appearance, but not the function, of legs. Several bristles extend from each parapodium giving the family (Polychaeta) its name (*poly* means many, *chaetae* means bristles). The bristles penetrate human skin, leading to envenomation with an unknown substance.

Sponges have an elastic skeleton with spicules of silicon dioxide or calcium carbonate. They attach to the sea floor or coral beds. Toxins include halitoxin, odadaic acid, and subcritine, the nature of which is uncertain.<sup>15</sup> Dried sponges are nontoxic; however, on rewetting they produce toxicity even after several years.<sup>134,138</sup>

### Clinical Manifestations

Sea urchin envenomation presents as intense burning with local tissue reaction, including edema and erythema. Rarely, with multiple punctures, light-headedness, numbness, paralysis, bronchospasm, and hypotension occur, although this is not documented in the peer-reviewed medical literature.<sup>4</sup> Reports of death are not well substantiated. The Pacific urchin *Tripneustes* produces a neurotoxin with a predilection for cranial nerves.<sup>14</sup> Mild elevations of hepatic enzymes are reported in one patient with foot cellulitis from an urchin sting.<sup>166</sup> Retention of sea urchin spine fragments predisposes the patient to development of painful granulomata.<sup>67</sup> Spine penetration of a joint induced synovitis.<sup>125</sup>

Small cuts on the skin from handling sea stars allow venom to penetrate, leading to contact dermatitis. The crown-of-thorns sea star causes severe pain, nausea, vomiting, and muscular paralysis.<sup>100</sup> Massive hemolysis and hepatic necrosis were reported after a single-stinger envenomation.<sup>74</sup> Its spines are brittle with a tendency to splinter off once embedded in the victim's tissues.

Cutaneous, scleral, or corneal exposure to sea cucumbers triggers contact dermatitis, intense corneal inflammation, and even blindness. Bristle worms are shrouded with bristles that produce a reddened urticarial rash. Symptoms typically are mild and resolve over several hours to days.

Contact with the fire sponge, poison-bun sponge, or red-moss sponge causes erythema, papules, vesicles, and bullae that generally subside within 3 to 7 days. Some victims develop fever, chills, and muscle cramps. Skin desquamation occurs at 10 days to 2 months,<sup>4</sup> with chronic skin changes lasting several months.<sup>15</sup> Erythema multiforme and anaphylaxis are uncommon complications associated with *Neofibularia* spp exposure.<sup>14</sup> Contact with sponges that are colonized with Cnidaria leads to dermatitis with skin necrosis, referred to as *sponge diver's disease*.

### Diagnosis

Radiographic or ultrasonographic imaging of the affected body part is recommended to assess for the presence of remnant foreign bodies.<sup>131</sup> Elevated aminotransferase concentrations and hepatic necrosis are potential complications of crown-of-thorns envenomation, and plancitoxin I and II provoke hepatotoxicity in animal studies.<sup>74,87</sup> Phospholipase A<sub>2</sub> in the sea star's venom induces significant hemolysis *in vitro*.<sup>83</sup> Laboratory evaluation for these conditions is therefore reasonable.

### Management

The primary objective following envenomation from sea urchins and crown-of-thorns starfish is analgesia. Submersion of the affected extremity in hot water (105°–115°F; 40.6°–46.1°C) and administration of oral analgesics often is sufficient as several components of the venom are thermolabile.<sup>100</sup> The hemolytic component of crown-of-thorns venom retains 50% of its hemolytic activity despite incubation to 100°C for 30 minutes in laboratory testing.<sup>83</sup> Hence, HWI alleviates local symptoms yet fails to prevent systemic toxicity.

Spines frequently crumble with attempted extraction and often require surgical exploration of the tract for complete removal. Intraarticular spines necessitate surgical removal. Patients' pain and systemic symptoms persist for months if spines are not removed.<sup>131</sup> Tetanus immune status must be addressed. Antibiotic prophylaxis is recommended for patients with immunosuppressive risk factors such as diabetes or other comorbidities. Although most infections likely are secondary to human skin flora, marine flora such as *Mycobacterium marinum* and *Vibrio parahaemolyticus* are potential wound contaminants, and *M. marinum* is associated with the formation of granulomata after sea urchin envenomation.<sup>125</sup>
